As new scientific information becomes available through basic and clinical research, recommended treatments and drug therapies undergo changes. The author(s) and publisher have done everything possible to make this book accurate, up to date, and in accord with accepted standards at the time of publication. The authors, editors, and publisher are not responsible for errors or omissions or for consequences from application of the book, and make no warranty, expressed or implied, in regard to the contents of the book. Any practice described in this book should be applied by the reader in accordance with professional standards of care used in regard to the unique circumstances that may apply in each situation. The reader is advised always to check product information (package inserts) for changes and new information regarding dose and contraindications before administering any drug. Caution is especially urged when using new or infrequently ordered drugs.

To **our students**, who provide us with inspiration, motivation,
and the joy of being a part of their learning experience.

To **Garland**,

with love, for his continued support and encouragement
and many trips to the mailbox with manuscripts.

To my **daughter, son-in-law, and grandchildren** who bring me joy.

To my parents, who have always been supportive
and encouraging through both editions of this text.

LINDA WILLIAMS

To **Dave**, with love,

who still loves me after 25 years and two editions of this text.

To my children, **Dan and Libby**, the two greatest young adults in the universe.

To **my mom**, who taught me strength and integrity.

I regret she did not live to see this second edition.

And to **my dad**, whose pride in this project keeps
me motivated when I get tired of writing.

PAULA HOPPER

Preface

Welcome to the second edition of *Understanding Medical-Surgical Nursing!* We are thrilled with the enthusiastic feedback we received on the first edition, and we have worked to make this second edition even more student-friendly. To those of you who gave us valuable suggestions on the first edition, thank you. We have incorporated much of what you told us into this edition while maintaining our original vision for the book.

We initially embarked on the first edition because we were unsatisfied with the materials available for practical/vocational nursing students. There were texts with lots of information, but very little attempt was made to help students *understand why* they were doing what they were doing. We have once again worked hard to provide a text written at an understandable level, with features that help students understand, apply, and practice the challenging content required to function as a practical/vocational nurse.

As in the first edition, this book uses the nursing process to provide a unifying framework. Within this framework, emphasis is placed on understanding, critical thinking, and application. We believe that a student who learns to think critically will be better able to apply information to new situations. We hope both students and instructors find this new book more valuable than ever for learning and understanding medical-surgical nursing.

► FEATURES OF THE BOOK

One of the most exciting features of this edition is a new design and full-color contents. Naturally, all of the text has been updated to reflect current health care and nursing practice. And, based in part on user feedback, we have also made a number of helpful changes and added exciting new features:

- A new chapter on alternative and complementary therapies has been added.
- A full chapter on caring for patients with AIDS has been added.
- *Questions to Guide Your Reading* have replaced Chapter Objectives. In our experience, the standard objectives found in many textbooks have little meaning and provide little assistance to students who have much reading to do in minimal time. The literature suggests that comprehension increases when students read guiding questions before reading the text. So we have provided a series of questions that students should keep in mind as they read. These questions can be translated easily back into objectives by instructors who prefer this format.
- Special features written by actual patients, called *Patient Perspectives*, have been added. These essays, focused on each patient's experience with illness, help to make patients' thoughts and feelings more meaningful and personal for students. If you have stories you feel would make valuable additions to the book, please share them with us as we prepare the third edition.
- Web links have been added to the text to help students do further research on topics of interest. Every effort was made to use only major established web sites that are unlikely to change in the near future.
- One of our most popular features—Critical Thinking Exercises—have been expanded to help students practice and think about what they are learning. We also added math calculations and documentation practice to Critical Thinking Exercises where applicable. These exercises are provided throughout the book to foster critical thinking and are followed by questions that require more than simple recall of material.
- Answers for the Critical Thinking Exercises and Review Questions have been included. Research supports the importance of immediate feedback to reinforce correct learning, so we feel strongly that students should have access to correct answers while they are studying, without having to wait for their next instructor contact. Obviously there can be many answers to some of the critical thinking questions. We have provided sample answers to help stimulate students' thinking.

We have also kept our most popular features from the first edition:

- Pronunciation key for new words at the beginning of each chapter
- Review of anatomy and physiology at the beginning of each unit
- Information on the effects of aging on body systems
- Learning tips throughout the text
- Word-building footnotes to break down complex words
- Comprehensive glossary of new words
- Nursing care plans with geriatric considerations
- Common laboratory and diagnostic tests
- Brief pathophysiology for each disorder
- Boxed presentations of Cultural Considerations, Gerontological Issues, Home Health Hints, and Nutrition Notes. (Ethical dilemmas have been moved to the Instructor Guide because we believe this material is best learned during instructor-guided discussion.)
- Critical thinking exercises throughout the text
- Review questions at the end of each chapter

As in the previous edition, we have included many figures because we believe they enhance understanding and readability. Most of the artwork and photographs are original and specifically designed to support the text. Additional figures, tables and boxed materials are used to clarify complex material.

Using the Features of This Book

As you begin each chapter, carefully read the section labeled *Questions to Guide your Reading*. Then, when you are finished reading each chapter, go back and make sure you can answer each question.

You will also find a list of new words and their pronunciations at the beginning of each chapter. These words appear in bold at their first use in the text, indicating that they also appear in the glossary at the end of the book. By learning the meanings of these words as you encounter them, you will increase your understanding of the material.

You also will encounter other devices to increase your understanding and retention of the material, such as mnemonics, acrostics, and learning tips. You may want to develop your own memory techniques in addition to those provided. (If you think of a good one, send it to us and you may find it in the next edition!) Many of the learning tips have been developed and used in our own classrooms. We find them helpful in fostering understanding of complex concepts or as memory aids. However, we want to stress that memorization is not the primary focus of the text but rather a foundation for understanding and thinking about more complex information. Understanding and application will serve you far better than memorization when dealing with new situations.

Each chapter includes one or more case studies designed to help you apply material that has been presented. A series of questions related to the case study will help you integrate the material with what you already know. These questions emphasize critical thinking, which is based on a foundation of recall and understanding of material. To enhance your learning, try to answer the questions before looking up the answers at the end of the chapter.

Review questions appear at the end of each chapter. These are written in a multiple-choice format to help you prepare for the NCLEX-PN. Again, to assess your learning, try to answer the questions before looking up the answers at the back of the book.

A bibliography at the end of each unit provides sources for additional reading material. Web sites have been included in many chapters. We believe it is important for you to interact with current technology to expand your informational resources.

Appendices are included for easy reference. They cover the following:

- Nursing diagnoses
- Lab values
- Abbreviations
- Common prefixes and suffixes to assist in learning word building techniques

Supplemental Materials

A *Student Workbook* is available to provide the student additional contact and practice with the material. Each chapter includes vocabulary practice, objective exercises, a case study or other critical thinking practice and review questions written in NCLEX-PN format. Answers are provided so students can solidify their understanding and learning with immediate feedback. Rationales are provided for review question answers.

An *Instructor's Guide* provides materials for use in the classroom. Each chapter has a chapter outline with suggested classroom activities. Also included are student activities suitable for duplicating and using for individual practice or for collaborative learning activities. These activities help the student to interact with the material, understand it, and apply it. Many of the activities are based on real patient cases and have been used with our own practical nursing students. Feedback from students has helped to refine the exercises. We believe the use of collaborative learning has greatly enhanced our students' success in achieving their educational and licensure goals. Another benefit is the sense of community the students develop as a result of working in groups. A brief introduction and guidelines for using collaborative learning techniques is included.

An expanded computerized test bank, available to instructors who adopt the textbook, provides test questions that assist students to prepare for State Board Examinations. These questions have been prepared according to test item writing protocols. The questions are in multiple choice format, and test recall and application of material. Many of the test questions have been developed, used and refined by the authors in their own medical-surgical courses for practical nursing students. The new test bank program for the second edition is easier to use and allows instructors to choose and modify the questions that best suit their classroom needs.

Finally, new for this edition is a comprehensive PowerPoint program for classroom presentations. We have provided the basics; each unit presentation can be modified, reduced, or expanded by individual instructors to suit their needs.

► ACKNOWLEDGEMENTS

Many people helped us make this book a reality. First and foremost are our students, who provided us with the inspiration to undertake this project. We hope that they continue to find this text worth reading.

The F.A. Davis Company has been an exceptional publishing partner. We feel fortunate to have had their continued enthusiasm and confidence in our book. The staff at F.A. Davis has guided us through this project from its inception to publication to help us create a student-friendly book that truly promotes understanding of medical-surgical nursing.

F.A. Davis developmental editor Melanie Freely has been our guide, cheerleader and supporter. We appreciate all she has done to support our book. Lisa B. Deitch,

acquisitions editor, also helped shepherd the process, as did Bette Haitzsch and Bob Butler in Production. We thank them all for their assistance. Developmental editor Catherine Harold and her assistant Connie Warren helped us format the manuscript, meet deadlines and gave us helpful advice and guidance. They were a great mix of kind understanding and professionalism.

We thank the staff of Thomas Jefferson University Medical Center, in Philadelphia, and especially Ann Reynolds, for assisting us in the photo shoot originally done for the first edition. Thanks also to Nanine Hartzenbusch, our photographer, who provided a wonderful human touch to the photography.

Graphic World Publishing Services production editor Noelle Barrick did an outstanding job of coordinating the development of our manuscript into a book. Graphic World Illustration Studio's John Denk created the wonderful first edition artwork and updated it for the second edition.

Contributors from across the United States and Canada, including many well-known experts in their fields, brought expertise and diversity to the content. Their hard work is much appreciated. Reviewers from throughout the United States provided valuable insights that enhanced the quality of the text.

Many of our co-workers have contributed to this book and given us ongoing encouragement and validation of the worthiness of this project. Elizabeth Ackley, Marina-Martinez Kratz, Sharon Nowak, Kathy Walsh, Gail Ladwig, and Carroll Lutz were especially helpful in providing material, advice, and encouragement.

We wish to thank everyone who played a role, however large or small, in helping us to provide a tool to help students realize their dreams of becoming LPN/LVNs. We hope this book will help train nurses who can provide safe and expert care because they are able to think critically.

- subjective data (sub-**JEK**-tiv **DAY**-tuh)

QUESTIONS TO GUIDE YOUR READING

1. How is the nursing process defined?
2. What are the characteristics of each step of the nursing process?
3. What are three characteristics of critical thinking?
4. How is critical thinking of value in the nursing process?
5. What is the role of the licensed practical nurse/licensed vocational nurse in using the nursing process?
6. How would you prioritize patient care based on Maslow's hierarchy of human needs?
7. How does critical thinking enhance the implementation of the nursing process?

Excellence in the delivery of nursing care requires good thinking. Each day nurses make many decisions that affect the care of their patients. For those decisions to be effective, the thought processes behind them must be sound.

► CRITICAL THINKING

Nurses must learn to think critically. This means they must use their knowledge and skills to make the best decisions possible in patient care situations. Halpern¹ says that “**critical thinking** is the use of those cognitive (knowledge) skills or strategies that increase the probability of a desirable outcome.” Critical thinking is sometimes called directed thinking because it focuses on a goal. Other terms

used when talking about critical thinking include *reasoning, common sense, analysis, and inquiry*.

► PROBLEM SOLVING

Problem solving is one type of critical thinking. Nurses solve problems on a daily basis. However, a problem can be handled in a way that may or may not help the patient.

For instance, consider Mr. Frank, who is in pain and requests pain medication. You check the medication record and find that his analgesic medication is not due for another 40 minutes. You can choose to manage this problem in a variety of ways. One obvious approach is to return to Mr. Frank and tell him that it is not time for the pain medica-

tion and that he will have to wait. This may solve your problem (you can move on to the next patient), but it does not solve the problem in an acceptable way for Mr. Frank.

An alternative approach is to use a problem-solving method:

1. Gather **data**. When Mr. Frank requests pain medication, the first thing you do is obtain more data. A common way to assess pain is to use a pain rating scale in which the patient rates pain on a scale of 0 (no pain) to 10 (the greatest pain possible). Mr. Frank states that his pain is in his back and rates it as an 8 on the 10-point scale. His history includes compression fractures of his spine. You return to the medication record and find that he has no alternative pain medications ordered.
2. Identify the problem. Mr. Frank is in acute pain, and the current medication orders may not be sufficient to provide pain relief.
3. Decide what outcome (sometimes called a goal) is desirable. The outcome should be determined by you (the nurse) and the patient, working together. The patient is intimately involved in this situation and deserves to be consulted. In this case you talk to Mr. Frank and determine that he needs pain relief now; he cannot wait until the next scheduled dose of medication. He states that he is able to tolerate a pain rating of 3 or less on a 10-point scale.
4. Plan what to do. Formulate and evaluate some alternative solutions. For example, you can decide to tell Mr. Frank that he has to wait 40 minutes; however, this will not help him reach his desired outcome of pain control. Giving the medication early might relieve his pain, but this would not be following the physician's orders and may have harmful effects for Mr. Frank. You could decide to try some alternative pain control methods, such as relaxation, distraction, or imagery. These might be helpful, but with a pain rating of 8, he may also need medication to reach his goal. Another alternative is to report to the physician that Mr. Frank's pain is not controlled with the current pain control regimen. Once you have several alternatives, decide which ones you think will best help the patient. Then you can discuss those options with the registered nurse (RN) and together decide the best thing to do; in this case you might decide to have the RN contact the physician while you work with the patient on relaxation exercises. You might decide to ask Mr. Frank if he would like to listen to some of the music his wife brought in for him. You can also tell Mr. Frank that the physician is being contacted. This would assure Mr. Frank that his pain relief needs are being pursued.
5. Implement the plan of care. Suppose the RN enters the room and informs you and the patient that the physician has changed the analgesic orders. You obtain and administer the first dose of the new analgesic. The RN also informs Mr. Frank that the physician has ordered a consultation with the institution's pain clinic.
6. Evaluate the plan of care. Did the plan work? As you reassess Mr. Frank 30 minutes later, he rates his pain level at 2. You think back to the desired outcome, compare it with the current **assessment**, and determine that your **interventions** were successful.

Can you see how using the problem-solving process led to a better outcome than simply choosing the first obvious option? You were able to affect a positive change: assisting a patient in achieving pain relief.

► NURSING PROCESS

You have just used the **nursing process** to solve a real problem. The nursing process is an organizing framework that links the process of thinking with actions in nursing practice. The nursing process can be used to assess patient needs; formulate nursing diagnoses; and plan, implement, and evaluate care. As a nursing student, you will consciously use the nursing process with each patient problem. With experience, you will internalize the nursing process and use it without as much conscious effort.

Role of the Licensed Practical Nurse and Licensed Vocational Nurse

The licensed practical nurse (LPN) or licensed vocational nurse (LVN) carries out a specific role in the nursing process, as described in Table 1–1. The LPN/LVN collects data, assists in formulating nursing diagnoses, assists in determining outcomes and planning care to meet patient needs, implements patient care interventions, and assists in evaluating the effectiveness of nursing interventions in achieving the patient's outcomes. It is the role of the LPN/LVN to provide direct patient care. This gives the LPN/LVN an opportunity to develop a relationship with the patient that aids in collecting valuable data. The LPN/LVN and the RN work as a team to analyze data and develop, implement, and evaluate the plan of care (Fig. 1–1).

Data Collection

The first step in the nursing process is data collection. The LPN/LVN assists the RN in collecting data from a variety of sources. Data is divided into two types: **subjective data** and **objective data**.

TABLE 1–1 ROLE OF THE LPN/LVN IN THE NURSING PROCESS

Steps of the Process	Role of the LPN/LVN
Assessment	Assists in collecting data
Nursing Diagnosis	Assists in choosing appropriate nursing diagnoses
Plan of Care	Assists in developing outcomes and planning care to meet outcomes
Implementation	Carries out those portions of the plan of care that are within the LPN/LVN's scope of practice
Evaluation	Assists in evaluation and revision of the plan of care

Figure 1-1 An LPN and an RN collaborating on a nursing care plan.

Subjective Data

Information that is provided verbally by the patient is called subjective data. Symptoms are subjective data. Subjective data are often placed in quotes, such as “I have a headache” or “I feel out of breath.” You must listen carefully to the patient and understand that only the patient truly knows how he or she feels.

When collecting subjective data, first assess the chief complaint. Focus on the reason the patient is seeking health care. The question “What happened that made you decide to come to the hospital (clinic, office)?” can be helpful.

Once the patient has identified the main concern, further questioning can elicit more pertinent information. Use the letters of the “WHAT’S UP?” questioning format to remember questions to ask the patient (Table 1–2).

LEARNING TIPS

Practice assessing a symptom on a classmate. Ask the “WHAT’S UP?” questions.

Next, obtain a patient history. This is done by asking the patient and family questions about the patient’s past and present health problems, including specific questions about each body system, family health problems, and risk factors for health problems. The patient’s medical record may also be consulted for background history information.

In addition to assessment related to physiological functioning, ask the patient about personal habits that relate to health, such as exercise, diet, and the presence of stressors, per institutional assessment guidelines. Finally, assess the patient’s family role, support systems, and cultural and spiritual beliefs.

Objective Data

Objective data are pieces of factual information obtained through physical assessment and diagnostic tests and are observable or knowable through the five senses. Objective

TABLE 1-2 WHAT’S UP? GUIDE TO SYMPTOM ASSESSMENT

<p>W—Where is it? H—How does it feel? Describe the quality. A—Aggravating and alleviating factors. What makes it worse? What makes it better? T—Timing. When did it start? How long does it last? S—Severity. How bad is it? This can often be rated on a scale of 1 to 10. U—Useful other data. What other symptoms are present that might be related? P—Patient’s perception of the problem. The patient often has an idea about what the problem is, or the cause, but may not believe that his or her thoughts are worth sharing unless specifically asked.</p>

data are sometimes called *signs*. Examples of objective data include the following: respiratory rate 36, 3-cm red lesion, blood glucose 326 mg/dL, and patient moaning. Note that these are all observable or measurable by the nurse and do not require explanation by the patient.

Objective data are gathered through physical assessment. During the physical assessment, the nurse inspects, palpates, percusses, and auscultates (IPPA) to collect objective data. This is called the IPPA format. Special attention is given to areas that the patient has identified as potential problems.

INSPECTION. During the **inspection** phase of physical assessment, the nurse uses observation skills to systematically gather data that can be seen. This may include noting the patient’s respiratory effort, observing skin color, or measuring a wound. This phase continues throughout the assessment.

PALPATION. **Palpation** involves use of the fingers or hands to feel something. The nurse might palpate the abdomen for firmness or use the back of the hand to palpate for heat, such as palpating the forehead for fever. Physicians and advanced practice nurses also use deep palpation to assess abdominal organs.

PERCUSSION. **Percussion** is a technique used by physicians and advanced practice nurses to determine the consistency of underlying tissues. The examiner taps on the patient to elicit a sound. Generally, the middle finger of the nondominant hand is placed on the area to be percussed, and the middle finger of the dominant hand taps on the nondominant one (Fig. 1–2). This prevents patient discomfort. A dull sound is heard over a fluid-filled area, such as the liver or urinary bladder. A flat sound is heard over a solid area, such as muscle. Tympany is a drumlike sound heard over air, such as gas in the stomach. Resonance is a hollow sound heard over air-filled lung tissue. Although this technique generally is not used by LPN/LVNs, it is helpful to understand what it is when assisting another care provider performing percussion during a physical examination.

AUSCULTATION. **Auscultation** is usually done with a stethoscope. The chest is auscultated for heart sounds. Lung sounds are listened to anteriorly (chest) and posteriorly

Figure 1-2 Percussion.

Figure 1-3 Auscultation of posterior lung sounds. (From Anderson, MA: Nursing leadership, management, and professional practice for the LPN/LVN. FA Davis, Philadelphia, 1997, p 29, with permission.)

(back) for normal and adventitious lung sounds or (Fig. 1-3). The abdomen is auscultated for bowel sounds. Major vessels may be auscultated for turbulent blood flow by a physician or RN.

During physical assessment, the IPPA format is followed in the given order, except when assessing the abdomen. The order for the abdomen assessment is IAPP, because percussion and palpation of the abdomen can alter the auscultation findings.

Data collection related to each body system is covered in individual chapters throughout the book.

Documentation of Data

Once the data have been collected, they are documented in the patient's medical record. Identification of a significant problem is reported immediately to an RN or physician and

then documented. The recorded data should be accurate and concise. You should document exactly what was observed or stated by the patient, significant other, or health team members. Avoid interpreting the data and using words that have vague meanings in your documentation. For example, "nailbed color is pink" gives clearer information than "nailbed color is normal." "Capillary refill is 2 seconds" provides more precise data than "capillary refill is good." The statement "the wound looks better" is not meaningful unless the wound has been previously observed by the reader. Stating that "the wound is 1 by 2 inches, red, with no drainage or odor" provides data with which to compare the future status of the wound and determine whether it is responding to treatment. When documenting subjective data, direct quotations from the patient are desirable. Quotes accurately represent the patient's view and are least open to interpretation. Meaningful documentation promotes continuity of patient care.

LEARNING TIPS

Documenting exactly what is observed is more appropriate, easier, and less time consuming than seeking other words or ways to state observations. Nursing students and novices often search for elaborate phrases or words when simple, direct words are best. Stating exactly what is seen or heard usually provides the most clear and accurate information.

Nursing Diagnosis

Once data have been collected, the LPN/LVN assists the RN to compare the findings with what is considered "normal." Data are then grouped, or clustered, into sets of related information that identify problems.

According to the North American Nursing Diagnosis Association (NANDA), a **nursing diagnosis** is a clinical judgment about individual, family, or community response to actual or potential health problems or life processes.² Nursing diagnoses are standardized labels that make an identified problem understandable to all nurses. Nursing diagnoses are the foundation used to select interventions to achieve a desired outcome.

Nursing actions are either independent or collaborative. Independent nursing actions can be initiated by the nurse. Examples of independent nursing actions include teaching the patient deep breathing exercises, turning a patient every 2 hours, teaching about medications, and giving a back rub for comfort. Collaborative actions require a physician's order to perform them in response to both nursing and medical diagnoses. Examples of this are giving prescribed medications, applying antiembolism stockings, requesting a referral to physical therapy, and inserting a urinary catheter.

A diagnosis is considered "nursing" instead of "medical" if the interventions necessary to treat the problem are primarily independent nursing functions. Even with independent nursing functions, nurses often consult with physicians about plans of care. If, however, the physician directs

most of the care related to a particular health problem, it is a medical diagnosis, rather than a nursing diagnosis. For example, a patient with pneumonia (a medical diagnosis) has many needs that depend on physician orders, such as respiratory treatments and antibiotics. The nurse, however, can provide important assessment findings related to the health problem and provide nursing measures such as encouraging fluid intake, coughing, and deep breathing. When the physician and nurse work closely together on a patient problem, it is referred to as a collaborative problem.

One of the NANDA nursing diagnoses is acute pain. In Mr. Frank's example the pain was assessed as a health problem, and a plan of care was developed to manage the pain. The physician was contacted for analgesic orders, and independent nursing actions were used, including relaxation and distraction. These independent nursing actions did not require a physician's order. See the inside cover of this book for a complete list of nursing diagnoses recommended by NANDA.

CRITICAL THINKING

Nursing Diagnosis
Which of the following are NANDA nursing diagnoses? Which are medical diagnoses?

1. Impaired mobility
2. Ineffective coping
3. Herniated disk
4. Fractured femur
5. Diabetes
6. Impaired gas exchange
7. Appendicitis
8. Health-seeking behaviors

Answers at end of chapter.

A well-written nursing diagnosis helps guide development of a plan of care. The three parts to a diagnosis follow:

- Problem—the nursing diagnosis label from the NANDA list
- Etiology—the cause or related factor (often preceded by the words “related to”)
- Signs and symptoms—the subjective or objective data that are evidence that this is valid diagnosis (often preceded by the words “as evidenced by”)

Assessment of problem, etiology, and signs and symptoms is called the PES format. Look again at the case study of Mr. Frank. A diagnosis using this format might read as follows: “Acute pain related to muscle spasms and nerve compression as evidenced by patient pain rating of 8.” Note how the complete diagnosis gives you more helpful information than simply the label “pain.” This additional information helps determine an appropriate outcome to guide intervention selection.

Plan of Care

Once nursing diagnoses are identified, an individualized plan of care to help the patient meet his or her care needs is de-

signed. It is important to include the patient in the development of the plan of care. The patient must be in agreement with the plan for it to be successful in meeting the desired outcomes. The first step in planning care after diagnoses are selected is to prioritize the diagnoses and develop outcomes, or goals, for each. Actions that will help the patient meet the desired outcomes can then be determined.

LEARNING TIPS

If you are developing a plan of care for a complex patient and are not sure where to start, go back to the assessment phase. Often additional information can help you better understand the patient's needs and develop a plan of care that is individualized to the patient's specific problem areas.

Prioritizing Care

Once you know what problems need to be addressed, you must decide which problem or intervention must be taken care of first. You and the patient decide together which problems take priority. Maslow's hierarchy of human needs is one commonly used psychological theory that can be used as a basis for determining priorities (Fig. 1–4). According to Maslow, humans must meet their most basic needs (those at the bottom of the triangle) first. They can then move up the hierarchy to meet higher-level needs.

Physiological needs are the most basic. For example, a person who is short of breath can't attend to higher-level needs because the physiological need for oxygen is not being met. Once physiological needs are met, the patient can concentrate on meeting safety and security needs. Love, belonging, and self-esteem needs are next; self-actualization needs are the last to be met.

Throughout life, individuals move up and down Maslow's hierarchy in response to life events. If a need occurs on a level below the patient's current level, the patient will move down to the level of that need. Once the need is fulfilled, the person can move upward on the hierarchy again.

In a nursing plan of care the patient's most urgent problem is listed first. According to Maslow's hierarchy of human needs, this usually involves a physiological need such as oxygen or water, because these are life-sustaining needs. If several physiological needs are present, life-threatening

CRITICAL THINKING

Prioritizing Care
Based on Maslow's hierarchy of needs, list the following nursing diagnoses in order from highest (1) to lowest (5) priority. Give rationales for your decisions.

- ___ Deficient knowledge
- ___ Constipation
- ___ Disabled family coping
- ___ Anxiety
- ___ Ineffective airway clearance

Answers at end of chapter.

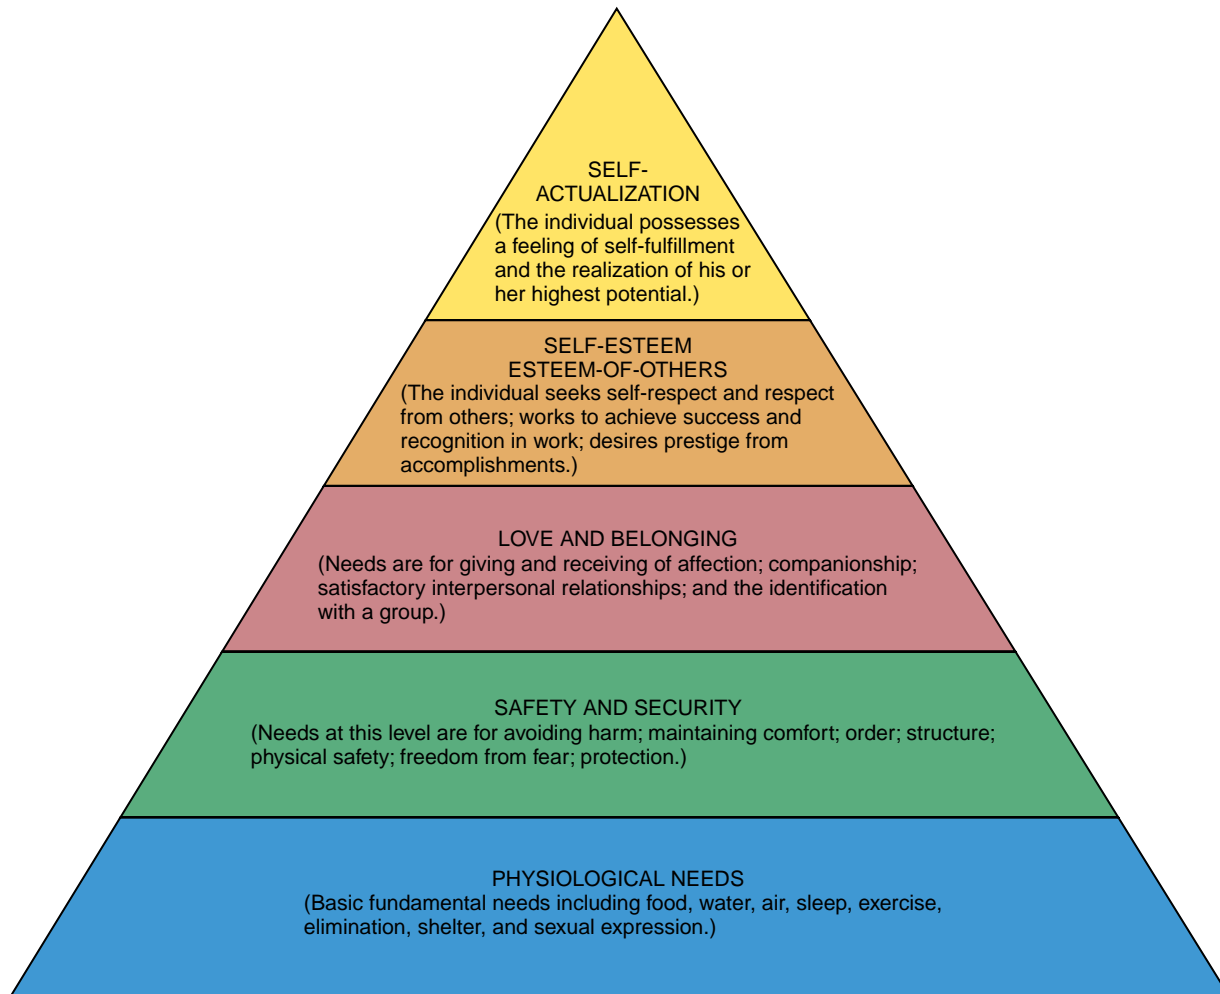

Figure 1-4 Maslow's hierarchy of human needs.

needs are ranked first, health-threatening needs are second, and health-promoting needs, although important, are last.

Once physiological needs are met, needs related to the next level of the hierarchy, safety and security, can be addressed. Remaining diagnoses are listed in order of urgency as they relate to the hierarchy. Needs can occur simultaneously on different levels and must be addressed in a holistic manner, with prioritization guiding the care provided.

Establishing Outcomes

An outcome is a statement that describes the patient's desired goal for a problem area. It should be measurable, be realistic for the patient, and have an appropriate time frame for achievement. *Measurable* means that the outcome can be observed, or is objective. It should not be vague or open to interpretation, with the use of subjective words such as *normal*, *large*, *small*, or *moderate*. Consider, for example, two outcomes:

- The patient's shortness of breath will improve.
- The patient will be less short of breath within 15 minutes as evidenced by patient rating the shortness of breath at less than 3 on a scale of 1 to 10, respiratory rate between 16 and 20, and relaxed appearance.

Although the first outcome seems appropriate, in reality it will be difficult to know when it has been met. There is nothing to objectively indicate when the problem has been resolved. The second outcome is objective. You can see that when the patient rates his or her shortness of breath less than 3, is breathing at a rate of 16 to 20, and appears relaxed, the desired outcome will have been met. The outcome is realistic, and the 15-minute time frame ensures that the patient's distress will be minimized. If the plan of care does not achieve the desired outcome in the given time frame, it should be evaluated and revised as needed.

When determining criteria for a measurable outcome, look at the signs and symptoms portion of the nursing diagnosis. The resolution or continuation of the signs and symptoms identified in the NANDA nursing diagnoses are evidence that nursing interventions were effective. If the desired outcome is not achieved, re-evaluation of the problem and interventions is needed. Look at another outcome example to see how criteria are used for measurement:

Nursing diagnosis—Ineffective airway clearance related to excess secretions as evidenced by coarse crackles and non-productive cough.

Outcome—Demonstrates clear lung sounds and productive cough within 8 hours.

Identifying Interventions

Interventions are the actions you take to help the patient meet the desired outcome. Therefore, interventions are considered goal directed. Any intervention that does not contribute to meeting the outcome should not be part of the plan of care.

One way to create a plan is to include interventions that can be categorized as “take, treat, and teach.” In the first intervention category, “take,” or identify, data that should be routinely collected related to the problem. Next, “treat” the problem by identifying deliberate actions to help reach the outcome. Last, identify what to “teach” the patient and family for the patient to learn to care for himself or herself.

Look again at the nursing diagnosis of impaired airway clearance. A plan of care for this problem using the take, treat, and teach method might look like the following:

- Take: Auscultate lung sounds every 4 hours and prn.
Assess respiratory rate every 4 hours and prn.
- Treat: Provide 2 L of fluids every 24 hours.
Offer expectorant as ordered.
Provide cool mist vaporizer in room.
- Teach: Teach the patient the importance of fluid intake.
Teach the patient to cough and deep breathe every 1 to 2 hours.

In addition to identifying interventions, it is important to understand how and why they will work. This is called identifying rationales. For example, assess lung sounds and respiratory rate every 4 hours because increased crackles and respiratory rate indicate retained secretions. Fluids are provided to help liquefy secretions and ease their removal. Sound rationale that is evidence (research) based should guide the selection of each nursing intervention.

Implementation

Once the plan of care has been identified, it must be communicated to the patient, family, and health team members and then implemented. One way a plan of care is communicated is by writing it as a nursing care plan. The nursing care plan is documented on the patient’s medical record and lets other nurses know the patient’s priority problems, the desired outcomes, and the plan for meeting the outcomes. In this way all nurses can provide consistent care for the patient.

When implementing the plan of care, the actions listed as interventions are performed. The patient’s response to each intervention is noted and documented. This documentation provides the basis for **evaluation** and revision of the plan of care.

Evaluation

The last step of the process is evaluation. Evaluation examines both outcomes and interventions. The nurse continuously evaluates the patient’s progress toward the desired outcomes and the effectiveness of each intervention. If the outcomes are not reached within the given time frame, or if the interventions are ineffective, the plan of care is revised. Any part of the plan of care can be revised, from the diagnosis or desired outcome to the interventions. Acute care institutions require review and updating of the plan of care every 24 hours.

► SUMMARY

Although the nursing process is presented in discrete steps in this chapter, in reality it is a continuous process. The nurse is constantly using critical thinking skills to assess, evaluate, and revise the plan of care to meet the patient’s changing needs.

In most chapters throughout this book, sample nursing care plans are provided. These are general guidelines for patient care. Any plan of care must be individualized based on a patient’s unique characteristics and needs.

Answers to CRITICAL THINKING

Nursing Diagnosis

1. Impaired mobility = nursing
2. Ineffective coping = nursing
3. Herniated disk = medical
4. Fractured femur = medical
5. Diabetes = medical
6. Impaired gas exchange = nursing
7. Appendicitis = medical
8. Health-seeking behaviors = nursing

Prioritizing Care

- 4 Deficient knowledge, safety and security need
- 2 Constipation, physiological need
- 5 Disabled family coping, love and belonging need
- 3 Anxiety, safety and security need
- 1 Ineffective airway clearance, physiological need

REVIEW QUESTIONS

1. Which of the following statements best defines the nursing process?
 - a. The process that nurses use to write nursing care plans
 - b. The process used by nurses to evaluate nursing care
 - c. A framework that links the process of thinking with nursing actions
 - d. A framework that promotes collaboration with other members of the health team
2. Which one of the following parts of the nursing process can be carried out by the LPN?
 - a. Implementation of interventions
 - b. Nursing diagnosis
 - c. Analysis of data
 - d. Evaluation of outcomes
3. Which of the following pieces of information is considered objective data?
 - a. Patient is short of breath.
 - b. Patient states, "I feel short of breath."
 - c. Patient's respiratory rate is 28.
 - d. Patient is feeling panicky.
4. An LPN is collecting data on a newly admitted patient. He has an ulcerated area on his left hip that is 2 inches in diameter and 1 inch deep, with yellow exudate. Which of the following statements best communicates findings in the patient's database?
 - a. Wound on left hip, 2 inches diameter, 1 inch deep, infected
 - b. Left hip wound is large, deep, and has yellow drainage
 - c. Pressure ulcer on left hip, yellow drainage
 - d. Wound on left hip 2 inches in diameter, 1 inch deep, yellow exudate
5. A 34-year-old mother of three children is admitted to a respiratory unit with pneumonia. Based on Maslow's hierarchy of needs, which of the following patient problems should the nurse address first?
 - a. Frontal headache from stress of hospital admission
 - b. Shortness of breath from newly diagnosed pneumonia
 - c. Anxiety related to concern about leaving children
 - d. Deficient knowledge about treatment plan
6. Which of the following is a nursing diagnosis?
 - a. Stroke
 - b. Renal failure
 - c. Fracture
 - d. Acute pain
7. You have just completed teaching a patient the importance of stopping smoking. Which of the following patient responses best evaluates patient teaching effectiveness?
 - a. "I have a brother who died of lung cancer. I know smoking is bad."
 - b. "I tried to quit 5 years ago, and I really would like to, but it is very hard."
 - c. "Thank you for the information. I will call the Smoke Stoppers organization today."
 - d. "I know you are right; I should stop smoking."

QUESTIONS TO GUIDE YOUR READING

1. Why are ethics important in health care?
2. What roles do values and rights have in making ethical decisions?
3. What is an example of a character trait and how does it relate to nursing?
4. What are the definitions of the four major principles in ethics and how would you apply one to an ethical dilemma?
5. What is one ethical theory and how would you apply it to an ethical dilemma?
6. What are the steps of the ethical decision-making model?
7. What are three legal concepts that relate to nursing practice?
8. How can you provide quality care and limit your liability?
9. How would you define malpractice insurance?

► ETHICS AND VALUES

One of the most exciting and challenging areas of nursing practice today is bioethics. Bioethics means the **ethical** principles and **values** of a particular culture or group that are applied to life. In the current practice of nursing, bioethics has come to be most closely associated with ethics in health care: life as affected by health, sickness, disease, or trauma. Ethics is the study of traditions, values, and beliefs as they relate to persons and their relationships with one another. Defining what is “good” and “bad,” what is “right” and “wrong,” and what values are used to make those judgments are all part of ethics. What *should* we do? and What *ought* we to do? are also ethical questions. We are responsible for knowing *why* we might take the intended action. Morals or **morality** are also related to ethics. Some individuals use the terms *ethics* and *morals* interchangeably; however, *morals* more specifically refers to our personal values, the standards set by our own conscience, and our personal choices of good and bad, right and wrong.

Values are ideals or concepts that give meaning to an individual’s life. Values are most commonly derived from societal norms, religion, and family traditions. They serve as a guide for making decisions and taking certain actions in everyday life. Values are not usually written down, but it can be helpful to make a list of your values and attempt to rank them by priority. Value conflicts often occur in everyday life and can force an individual to select a higher-priority value over a lower-priority value. For example, a nurse who values both her career and her family may be forced to decide between going to work or staying home with a sick child.

Values exist on many different levels. Individuals have personal values that govern their lives and actions. Many groups and organizations have values that may or may not be identical to personal values. When a person becomes a member of a group or organization, he or she agrees to accept the values of the group. Examples of groups include clubs, churches and religious organizations, and professions. The values of a profession are usually outlined in a **code of ethics**. Failure to adhere to a code of ethics of a profession may be an indication that the individual really does not want to belong to that group. Society as a whole has values. As a member of a society or country, an individual accepts the values of that culture.

Ethical issues surround us throughout our entire lifetime. Bioethical issues are particularly prevalent in our professional lives for several reasons. Health care has the potential to affect us at every milestone of human development. Life and death issues can be especially difficult for health care professionals, who may be faced with these issues every day. Today’s sophisticated technology and complex treatments, which continue to become more advanced, add another challenge. When sophisticated interventions are available, the ethical question is should we use them? Ethical issues are raised when the organization of health care delivery systems becomes more complex as mergers and alliances come and go. Despite the large percentage of our country’s wealth dedicated to health care, financial re-

sources are not unlimited. How those resources are divided can be troublesome, with the needs and desires of many different groups and organizations competing for a slice of the pie.

Although bioethical issues abound, not all issues are problems and not all ethical problems make headline news. Nurses are involved in some ethical decisions every day that may not become problems. A promise might be extended to return to the patient and assess whether or not the pain medication was effective. Patients might share information that they want to remain confidential. A family agrees to a do not resuscitate (DNR) order for their loved one when they believe there is no hope for recovery. A young man in the prime of life is given cardiopulmonary resuscitation (CPR) when he suddenly goes into respiratory failure on the day of his proposed discharge. These bioethical examples usually are not problems but, depending on the situation, can develop into ethical dilemmas.

An ethical dilemma is created when the required moral action is not clear or individuals in the situation do not agree on the proposed solution. Potential solutions may appear to be equally good or, worse, equally risky: A promise cannot be kept; information cannot remain confidential; DNR orders may not be acceptable for some individuals. Not every patient should be the recipient of CPR endeavors, even those who are very young. When patients are conscious, their choices are usually respected, but on occasion even that premise can be difficult to apply. Often groups of individuals must resolve a conflict that can occur if there is disagreement between physicians and families, nurses and physicians, or among family members.

A basic mastery of several elements will enhance your ability to perform competently when bioethical issues and decision making are the focus. Understanding the ethical component of your nursing role is a first step. Acquiring knowledge about relevant ethical material is also essential. An ethical decision-making process is a useful tool for examining ethical dilemmas. Together these elements provide a foundation from which you can begin to explore the meaning of bioethics in nursing practice today. For more information about bioethics, visit the America Journal of Bioethics Online at <http://www.ajobonline.com> and the National Institutes of Health at <http://www.nih.gov/sig/bioethics>.

Ethical Obligations and Nursing

As a nurse you are an invaluable member of the health care team. Members of the team contribute to patient care according to their educational preparation and assigned responsibilities. A common goal among all health team members is to provide holistic care to the patient, because the individual’s mind, body, and spirit are all affected by disease, illness, and trauma. Part of that holistic care encompasses your responsibility to practice ethically.

In addition to practicing within the **law**, nurses have ethical obligations related to the law. First, if the law is unethical or has serious limitations, a basic moral obligation of the nurse is to make an effort to change that law. Laws can

unfairly affect health care in relation to accessing health care, subsidizing health care, or allocating health care dollars. Laws can be unethical because they are enacted based on power, authority, and political influences rather than high moral standards. Laws are made to reflect common ethical beliefs (do not kill, do not steal). However, in a democratic society with a diverse population such as in the United States, there are serious questions about the degree to which society should enforce moral behavior through the law.

Nursing Code of Ethics

Some of the major ethical obligations of nursing practice are addressed within the nursing code of ethics. As a professional guide for ethical practice, the National Association for Practical Nurse Education and Service (NAPNES) developed a code of ethics for the licensed practical nurse/licensed vocational nurse (LPN/LVN). Like all codes of ethics, this code is an important document because it is a public statement of the basic ethical principles and standards for LPN/LVNs. A code should contain those basic ethical premises with which most members agree and for which the public can hold the professional morally accountable. A code does not dictate a particular action, nor is it a legal document, although the code should not be in conflict with the law. The code is not enforced by any organization, and no punishment exists if a nurse fails to adhere. A code must be interpreted because it usually contains broad statements, but it does serve as a general guideline for the most important professional ethical issues. From time to time codes are revised and updated. Although an early medical code, such as the Hippocratic oath from the fourth century B.C., contains good moral advice, the passage of time and the occurrence of notable events make it incomplete for medical practice today. Changes in society prompt us to examine the profession's ethical standards and update them appropriately.

Virtues

Particular ethical obligations can be summarized in the form of virtues. Each individual is endowed with specific character traits. As we grow and develop we acquire certain other character traits. Virtues are one kind of character trait most often associated with one's values and morality or conscience. Virtues are different from the skills that we acquire as nurses. Skills are used to implement various actions, something we do, whereas virtues define who we are. Examples of virtues include **fidelity**, **veracity**, integrity, compassion, discernment, trustworthiness, and respectfulness. These are all ideal traits, and although we may strive to act as virtuous persons, we may not always succeed. These are also the sort of traits that the profession encourages nurses to develop. For example, faithfulness and respect for patient beliefs are specifically included in the code. Virtues are related to roles and responsibilities and are therefore time dependent. For example, in the early decades of organized nursing in the United States, nurses occupied a handmaiden role relative to the physician. Obedience to the

physician was a virtue, but such obedience is no longer held as a virtue by nurses.

FIDELITY. Fidelity is the obligation to be faithful to commitments made to self and others. In health care, fidelity includes faithfulness or loyalty to agreements and responsibilities accepted as part of the practice of nursing. Fidelity is the main support for the concept of accountability, although conflicts in fidelity might arise because of obligations owed to different individuals or groups. For example, nurses have an obligation of fidelity to the patients they care for to provide the highest quality care possible, as well as an obligation of fidelity to their employing institution to follow its rules and policies. Nurses can have an ethical dilemma when a hospital's policy on staffing creates a situation that does not allow the nurses to provide the quality of care they feel is necessary.

Maintaining a patient's privacy and **confidentiality** is related to fidelity (Fig. 2-1). Privacy and confidentiality may or may not be explicit promises. For example, nurses are obligated to only discuss the patient under circumstances in which it is necessary to deliver high-quality health care. Care should be taken to hold change-of-shift reports and case conferences in settings where the discussion will remain private.

Confidentiality also includes the communication of information through the posting of unit census and various schedules for tests, procedures, or special examinations (operating room, physical therapy, radiology), storage and access of patient information through computers, and the transmission of patient information via fax machines, for

Figure 2-1 Maintaining privacy is a patient right and conveys caring to the patient.

example. Many individuals have legitimate access to the patient's chart in addition to direct caregivers: faculty members in the course of making student assignments, accrediting agencies, risk managers, quality assurance personnel, insurance companies, and researchers. Each is obligated to maintain patient confidentiality to the extent that concealing information does not compromise mandated reports (communicable diseases or gunshot wounds), releases already granted by the patient (such as when insurance coverage was obtained), or gathering data in the aggregate without identification of specific patients (research or institutional statistics).

VERACITY. Veracity is the virtue of truthfulness. It requires health care providers to tell the truth and not intentionally deceive or mislead patients. As with other rights and obligations, there are limitations to this virtue. The primary limitation occurs when telling patients the truth would seriously harm (principle of **nonmaleficence**) their ability to recover, or when the truth would produce greater illness. Another difficult situation is created in relation to diagnostic information. Although giving diagnostic information is the responsibility of the physician or registered nurse (RN), LPN/LVNs sometimes find themselves caught in situations in which they must deal with patients' questions. If LPN/LVNs feel uncomfortable about reinforcing physician or RN explanations about unpleasant information, they may avoid answering patients' questions directly by using half-truths or claiming ignorance. However, patients do have a right to know this information.

INTEGRITY. Integrity is the holistic, moral sense of self sustained over time. Each individual has a cluster of values, beliefs, and traditions that form the basis for moral decision making—in a sense, the conscience. This sense of self can be compromised when the nurse is requested to act in a manner that requires setting aside or acting against values, belief, or traditions. The nurse who believes in sanctity of life and that human life begins at conception will not be able to maintain integrity if required to participate in abortion procedures. At the same time, this nurse also has the responsibility not to accept a professional position where abortion will be an issue—the nurse cannot abandon a patient in need of nursing services. The nurse with integrity is faithful to professional responsibilities and obligations.

COMPASSION. Compassion or caring is a central virtue in nursing. Some label this **empathy** and connect it to the ability of a nurse to identify with a patient's suffering, pain, or disability. Patients are comforted by the compassionate nurse, and this emotion can assist in the healing process. A nurse without any emotion robs patients of the full potential for healing that is only possible when all parties are actively engaged in all aspects of the relationship. Compassion should not be so dominant that it clouds judgment and prevents effective and efficient provision of nursing services. Compassion needs to be tempered with rationality.

DISCERNMENT. Discernment has been described as practical wisdom or common sense. This is the ability to under-

stand, to have insight into the hidden, as well as the obvious, elements of a situation. A nurse who has discernment is one who is sensitive to the patient's actions and responses and does not necessarily accept what is seen at face value. Verbal and nonverbal communication, as well as concrete signs and symptoms, all contribute to the overall evaluation of the patient by the discerning nurse. This is sometimes translated as practical wisdom because this nurse has a depth of understanding of patients that leads to the selection of the appropriate action, which in turn is implemented in a caring manner.

TRUSTWORTHINESS. Trustworthiness is essential for patients to be able to rely on those professionals who care for them. Certain nurses may be preferred by patients because they convey a sense of confidence with the care they provide. In many situations, patients' lives are truly in the nurse's hands. With a trustworthy nurse, stress and anxiety over the illness are reduced and coping is improved. In fact it is the erosion of trust that is cited as a major factor in the escalating lawsuits that have been initiated against health professionals.

RESPECTFULNESS. Respectfulness is an attitude of a nurse toward the patient that indicates valuing that patient as a unique individual. All patients should be treated with dignity and their autonomy acknowledged. Nurses are obligated to make an effort to identify their own biases and prejudices and work to avoid stereotyping and "isms" in patient relationships—classism, sexism, racism, ageism, and ethnocentrism—as well as eliminate discrimination based on religion, sexual orientation, or disability. Attentiveness to bias and discrimination is not limited to private interactions, but nurses are also responsible for drawing attention to unacceptable statements or negative actions that reflect disrespect for race, religion, gender, class, age, culture, sexual orientation, or disability in any health care situation.

Rights

Rights represent at least two ways to think about what we are owed or what we deserve. First, some rights make claims about goods and services (right to clean water, right to food). These are positive rights, and because something needs to be provided, there is a responsibility for someone to furnish these items. Second, other rights can be determined to protect us (right to privacy, right to self-determination). These are negative rights preventing some action that would intrude on our lives or prevent us from acting as we choose.

Laws guarantee some rights. Others are moral rights based on values and ethical principles but are not enforceable by law. "Basic human rights" is a common phrase that we hear when discussing the condition of various people around the world, especially when those rights are compromised. The United Nations has a document, "The Universal Declaration of Human Rights," that serves to represent what all people should be provided with or protected from.

In health care, discussions of rights often include the concept of patients' rights. For many years, patients were

seen simply as passive recipients of whatever treatments or actions professionals determined necessary for their conditions. Now, professionals recognize patient autonomy and patients' active participation in health care. The American Hospital Association (AHA) first devised a patients' bill of rights in 1973, which formally began a recognition of what patients are entitled to but may not always receive. The revised bill includes statements on confidentiality, informed consent, and the right to refuse treatment. Many health care organizations followed with other more specific bills of rights, such as those developed by nursing homes and veterans' hospitals.

In bioethics many issues can be framed within a rights context. An important rights issue is whether people have a "right" to health care. Such a right is discussed at every level of society, from local governments that determine services they will provide in city clinics and public schools to the federal government, which periodically grapples with the debate on national health insurance. Another prominent dispute is the "right to die" with dignity, which arouses more interest as a larger segment of society reaches the later decades of life. The threat of the loss of autonomy and the possibility of being subjected to endless, painful technological interventions while dying helps fuel this concern. "Right to life" is another central concept in our society as groups organize politically to prevent abortions and overturn the *Roe v. Wade* decision of the Supreme Court. This right also extends to discussions of reproductive rights and the health care of pregnant women. These are but a few examples of rights issues and conflicts. Others can be identified as various areas in medical-surgical nursing are explored.

Building Blocks of Ethics

The discipline of ethics itself provides us with knowledge that can be applied to situations in health care. The professional's understanding of these basic concepts, presented here in the form of ethical principles and ethical theories, helps specifically target the ethical aspect of the problem. Principles and theories provide some insight into the ethical dimension. Knowledge about ethics cannot in itself solve the problem or dilemma. However, knowledge of ethics helps focus on the ethical aspect and aid in grounding ethical decision making in ethical rationale. Presenting a particular position relative to a situation or describing values, beliefs, and traditions using these common ethical terms helps clarify discussions and possibly prevents escalating arguments. Problems with communication, management of the unit, and legislation or the law can more easily be separated from the ethical dimension and resolved in their own problem-solving session.

Ethical Principles

The ethical principles that are widely used when examining bioethical dilemmas include autonomy, **beneficence**, non-maleficence, and justice. Given these ethical principles' prominence in the bioethical literature, a basic understanding of them is necessary.

AUTONOMY. Autonomy is the right of self-determination, independence, and freedom. *Autonomy* refers to patients' rights to make health care decisions for themselves, even if health care providers do not agree with those decisions. Preventing patients from making autonomous decisions or deciding for patients without regard for their preferences is **paternalism**. Autonomy also encompasses the professional's self-determination and freedom.

Autonomy, as with most rights, is not an absolute right, and under certain conditions, limitations can be imposed on autonomy. Generally these limitations occur when an individual's autonomy interferes with the rights, health, or well-being of others. For example, patients generally have an autonomous right to refuse any or all treatments. This autonomous right is guaranteed by federal legislation known as the Patient's Self-Determination Act. However, in the case of contagious diseases that affect society, such as tuberculosis (TB), an individual can be forced by the health care and legal systems to take medications to cure the disease. Individuals can also be quarantined to prevent the spread of disease.

BENEFICENCE. Beneficence views the primary goal of health care as doing good for patients. In general, the term good includes more than just technically competent care for patients. Good care requires a holistic approach to patients, including respect for their beliefs, feelings, and wishes, as well as those of their family and significant others. A problem sometimes encountered in implementing the principle of beneficence is in determining what exactly is good for another and who can best make the decision about this.

NONMALEFICENCE. Nonmaleficence is the requirement that health care providers do no harm to their patients, either intentionally or unintentionally. This is one of the oldest obligations in health care, dating back to the Hippocratic oath (fourth century B.C.). In a sense it is the opposite side of the coin of beneficence, and it is difficult to speak of one concept without mentioning the other. In current health care practice the principle of nonmaleficence is often violated in the short run to produce a greater good in the long-term treatment of the patient. For example, a patient may undergo a painful and debilitating or mutilating surgery to remove a cancerous growth, thereby avoiding death and prolonging life.

By extension, the principle of nonmaleficence also requires a nurse to protect from harm those who cannot protect themselves. This protection from harm includes groups such as children, the mentally incompetent, the unconscious, and those who are too weak or debilitated to protect themselves.

JUSTICE. Justice includes both fairness and equality. Concerns for justice encompass both material resources (**distributive justice**) and the fair treatment of individuals, groups, and communities (psychologically, socially, legally, politically). When the patient makes an appointment for 9 A.M. at the outpatient clinic and his or her neighbor makes a 10 A.M. appointment, each expects to be seen by

the primary care provider at the designated time unless some emergency prevails. Unequal treatment would result if a walk-in who has no pressing problem is seen by the provider in place of the 9 A.M. appointment, forcing each subsequent appointment to be delayed beyond the pre-arranged time. Distribution of material resources can be complex because it involves not only benefits (what we receive) but also burdens (what we may be taxed for but then do not receive). Burdens are not just monetary, but also include such factors as the unequal participation of individuals in medical research and the sacrifices family members make when caring for disabled individuals in the home.

One of the most serious limitations of these principles is the lack of any built-in priority when applying them to an ethical dilemma. Autonomy is not automatically prioritized over justice, or beneficence over nonmaleficence. However, these principles are helpful in categorizing various preferences and positions when examining a dilemma, and their categorizing can lead to a clarification of various disagreements among participants in the ethical discussion. Working with principles moves the discussion to a focus on ethics rather than a particular personal viewpoint or feeling. Such a strategy can also avoid a power struggle between participants who simply want to win the argument. An example of an ethical dilemma is the following scenario: A nurse attempts to support a patient's refusal of surgery, while the physician claims that the patient must have surgery or she will lose her leg. Realizing that the nurse is arguing the case from the perspective of autonomy, whereas the physician's desire to perform surgery is attributable to beneficence, moves the discussion to one based on conflicting principles rather than conflict between individuals. From this point of clarification, the discussion can focus on autonomy and beneficence and the rationale for the possible prioritizing of one principle over the other. This strategy does not resolve the dilemma, but it makes it less personal and forces participants to develop sound, ethical rationales for their solutions.

Ethical Theories

Another helpful device for examining ethical dilemmas is the use of various ethical theories. Ethical theories are concepts that are more complete than principles for analyzing ethical dilemmas. However, only a brief description is included here; a more in-depth understanding can be obtained from other resources, such as the Web links.

Two major theories used in bioethics are defined first, and then a subcategory of theories collectively known as feminist theories are introduced; finally, recognition of the relationship of theology or religion to bioethics completes this section.

UTILITARIANISM. In **utilitarian** theory the consequences or the outcomes of the dilemma are the most important elements to consider in decision making. Actions are morally preferred if they produce more happiness or greater benefits than unhappiness or burdens. The cost-benefit analysis is a very common approach used by institutions and organizations. A hospital that has the responsibility to care for hun-

dreds of patients is not as concerned with the individual patient who is caught in the bureaucracy of its functioning. This is not to say that all institutions operate on this theory at all times, but in general, rules, policies, and procedures are developed with the majority in mind. The sacrifice of the individual for the good of the majority is a significant criticism of this theory.

DEONTOLOGY. **Deontology** is a philosophical theory in which rules and guides for behavior and decisions regarding moral action are formed based on a search for the definition of duty. Ethical decisions are determined irrespective of the outcomes or consequences. For example, health professionals might operate by a rule that indicates that a moral person never lies. No matter how much the truth might hurt, the truth is told. Another rule might be to never use people as a means to an end. Translated this means that regardless of the benefits, individuals cannot be forced to participate in medical research studies to benefit others. An individual's right to voluntarily participate in research must be respected. Research does not have to benefit the individual participant as long as this is understood by the individual. However, the individual cannot be used simply to meet the investigator's needs. Acting morally only because one has a duty to do so, without any consideration of the outcome, is a serious limitation of this theory.

FEMINIST THEORIES. **Feminist** approaches focus on gender bias, discrimination, and prejudice in addition to the more serious actions of oppression and violence against women. These are important because of power differentials among the providers and recipients of health care, as well as the previous treatment of normal development, injury, illness, disease, and dying in women. Feminist theories are really a group of various approaches to ethical problems and decision making rather than one uniform approach. Feminists do use utilitarian and deontological theories, as well as various other approaches, to develop a systematic organization of ethical rules and principles. Some feminist theories focus on feminine attributes (emotional attachment, caring, prominence of relationships, and connection with people), emphasizing their importance in ethical decision making. In general, those who support this approach observe the devaluing of these attributes in society. Caring, as an example of one attribute, is important personally, but supporters recognize that caring is not systematically rewarded in our society.

Other theories are more politically oriented and concentrate their energies on developing approaches to ethical decision making that minimize the subordination and marginalization of women, whatever other principles they support. For example, in a liberal approach to ethical decision making, human beings have a political responsibility to organize and maintain society based on freedom and the various rights that we have. Rules protect our privacy. From a feminist perspective, the liberal approach focuses on making sure that women are included in the political processes when rules are made, helping to develop legislation, which serves to shape the communities in which we live. In health care a liberal feminist approach focuses on providing

women with educational and promotional opportunities for leadership positions in health care systems. In leadership positions, women have the power and authority to make the health care system more accommodating for women.

THEOLOGICAL PERSPECTIVES. Theological perspectives include the many religious traditions represented in our culture. Religious teachings are key concepts for ethical decision making for some individuals. In fact, for many individuals these teachings are the primary source of values and morals. Jehovah's Witness believers' rejection of blood transfusions is a common example of how religious beliefs affect health care decision making. This religious group has collected a large amount of information about blood substitutes and alternative therapies. Leaders of Jehovah's Witnesses are prepared to provide education for health professionals about their beliefs and acceptable interventions. In another area, a number of religious traditions oppose abortion, which affects both health professionals and patients. Euthanasia is an issue addressed by numerous organized religious groups, which in turn affects how patients make decisions regarding end-of-life issues. One of the difficulties with religious traditions is that it is not simply the official church teaching that is involved, but the individual member's interpretation of that teaching. Assessment of the importance of this dimension of the patient's life is important in the ethical analysis.

Ethical Decision Making

A variety of models and frameworks for ethical decision making are available. The steps listed in this section are a combination of several ideas that have been suggested. In its simplest form, ethical decision making is a problem-solving process. Similar to the nursing process, as discussed in the first chapter, the steps described in this section take the user through a set of strategies that assist in approaching a problem in an organized and systematic manner. Nurses applying these steps use critical thinking skills in order to be as logical and objective as possible. This is not to say that feelings and emotions are to be put aside. Bonding, love, commitment, and other sentiments define our human condition. However, a balanced perspective is the goal, which includes respecting these feelings without allowing them to overshadow the process and the outcome. Although making the final decision may not be easy, the user knows that once these steps have been completed, the situation has been thoroughly examined and all reasonable aspects explored before the decision was made.

Step 1: Gather and Verify the Information

Many kinds of information can contribute to an in-depth understanding of the situation, which provokes an ethical dilemma. Basically one needs to know who is involved, what is involved, and the context of the problem. Foremost is information about the patient, what the patient says when conscious and competent. Determining competency can sometimes be a challenging process. The chart is an obvious resource for clinical data, but so are the health professionals who are assigned to the patient, because not every

individual records all that is known about the patient. When appropriate, health care records from previous hospitalizations may be helpful, as well as charts from other institutions and agencies. External factors also need to be included, such as legal aspects, governing policies and procedures of the institution, and available resources. The amount of information gathered depends on the time frame and urgency of the decision.

Step 2: Clarify the Values of All the Participants

The values, beliefs, and traditions of all participants are important, especially the patient's, but more so when the patient is unconscious or incompetent and a group is attempting to reach a consensus based on some understanding of the patient. Advance directives or a living will prepared by the patient are often helpful as guides when the patient can no longer express personally held ethical beliefs. Determining the ethical orientation of all participants clarifies their perspectives and moves decision making to a more objective level. Decision makers must be especially aware of assumptions, stereotyping, biases, and prejudices related to socioeconomic status, ethnic identification, gender, religious preference, and other common characteristics of the participants.

Step 3: Identify the Ethical Dilemma and the Conflicts in Values

Separating the ethical aspects from the nonethical aspects facilitates the decision-making process. For example, a conflict can arise as a result of gaps in communication rather than a conflict of ethical principles. When the communication problem is solved, the dilemma is resolved, and as it turns out, there is no ethical dilemma. Sometimes both nonethical and ethical aspects need to be addressed in parallel fashion to reach a resolution of the situation. The importance of various ethical values for each participant should be explored.

Step 4: Examine Possible Actions and the Consequences of Each

There is no magic number of "possible actions," but it is easy to pose solutions at the extremes of possible actions. Take informing the patient as an example: The two obvious solutions are to tell and not to tell. But clinical practice is not that simple, and it is more useful to also pose solutions that are between the extremes. Suppose the issue is a critically injured patient who wants to know the condition of her spouse and child, who were also in the automobile accident. Her spouse was killed, and her child is in critical condition. At the moment her own status is unstable, and telling her might have a deleterious effect on her own health. Telling her is certainly an option, just one with certain limitations at the moment. Not saying anything in response to her question is a possibility but seems to show a lack of respect for her dignity as a person. What might be some possible actions in between those extremes? Is there some response that tells part of the information while

avoiding the worst part, her spouse's death? Even if the partial truths seem unacceptable at first glance, they ought to be added to the list of possible actions. Examination of a range of possible actions aids in identifying where the line is drawn for determining morally acceptable choices versus those not morally acceptable or for creating a list of each choice's risks and benefits.

Step 5: Determine the Ethical Foundation for Each Action

Each action should be based on selected ethical values, principles, or theories. Perhaps the code of ethics lends some support as ethical rationale. One strategy that is proposed on occasion, especially for an incompetent or unconscious patient, is an application of the standard of best interest. The best interest standard involves the determination of what action is in the best interest of the patient, given the information that is known about the patient and the situation. Family members together with health care providers usually make the best interest determination. Ideally this decision is made in an objective manner, setting aside any special interests of the family or health professionals. For example, it may be in the best interest of the patient to be discharged and go home so that recovery can be optimized in that setting. Family members themselves may have other goals that make placement in a long-term care facility better for them. Health professionals may be pressured by administrative personnel to simply arrange a discharge, regardless of where the patient might be discharged to or what might be best for the patient, because of utilization review and financial reimbursement considerations. Under the best interest standard, the optimal placement is in the home because it is best for the patient.

Step 6: Determine the Best Action with the Strongest Ethical Support

Each action is judged based on its risks, benefits, and supporting rationale. The actions are then ranked in order of their priority. Strong ethical support for the first priority is required, as well as a reasonable potential for the action to be implemented. For example, if placement in a nursing home after discharge from the acute care facility is ethically the best solution for a patient, but there is no room available in the potential facilities, that action must be set aside. If the preferred action fails, it is possible to move to choice number 2. The designation of these priorities does not necessarily mean that their supporting ethical rationale always results in the same ranking, nor does it mean that principles or theories are always in opposition to one another.

Utilitarians and deontologists may disagree about the important principles in decision making. However, it should not be assumed that different theorists cannot reach a mutually agreeable decision. Although their rationale for the decision may differ, the final solution each proposes can be identical. A case in point involves the relief of pain and suffering. The deontologist might argue that there is a duty among health professionals to provide pain medications and make patients comfortable. This action shows respect for

the dignity of the individual. A utilitarian might argue that pain and suffering should be relieved because doing so creates a positive outcome: the patient is more comfortable without pain. In an even broader context, the more pain and suffering that is relieved, the greater the number of patients who benefit. So both theorists support the same action, but for different reasons.

Even theorists, such as utilitarians, can disagree among themselves. A classic case involving confidentiality was solved based on utilitarian concepts, yet both the ruling vote and the dissenting vote were based on utilitarian principles.¹ The majority opinion of the court indicated that more good would be created by disregarding confidentiality obligations because overriding the patient's confidentiality would have saved the life of a third person who the patient threatened to murder. The minority opinion of the court stated that confidentiality should not be breached because it gave society the message that psychiatrists would not keep patient confessions secret and therefore would inhibit most individuals who have psychiatric problems from seeking professional help.

Step 7: Implement the Action

Needless to say, the selected action needs to be carried out. Responsibilities for the professionals and others in the situation can be assigned. Assigning a coordinator for the implementation of the action, especially if several individuals have responsibilities for portions of the action, enhances the potential for success, ensuring that someone will check on the process of implementation and that the action is evaluated.

Step 8: Evaluate the Outcome

We can learn from success and failure. Successful resolution of an ethical dilemma provides us with knowledge for the next ethical dilemma. Although no two dilemmas are exactly alike, selected features of a particular dilemma may parallel a subsequent situation and assist in solving the new dilemma. Failures also teach us a lesson. Retracing all the steps of the ethical decision-making process may provide insight and greater understanding of what steps of the process could have been better implemented. Evaluation is also important because the next time we confront a similar dilemma we may not have the luxury of examining the new dilemma in as much detail. Prior experience enables us to face new dilemmas more confidently and to determine the better action more quickly. One caution, however: It is very important to evaluate the outcome when decisions are made and the action taken within a limited time frame.

CRITICAL THINKING

Ethical Decisions

1. Identify a health care-related ethical dilemma you have encountered as a student. How did you solve the dilemma? What expert resources did you use?
2. Apply the ethical decision-making model to the ethical dilemma. How are your decision-making process and proposed actions different when using the model?

Summary

What lies ahead? We cannot predict exactly, but as a nurse you are sure to encounter ethical issues on a regular basis. Now that a selected knowledge base has been acquired, the next step is to practice decision making skills.

► LEGAL CONCEPTS

We are all members of a society. To promote harmony, safety, and productivity, members of society create rules. The rules of society can be informal or formal. An informal social rule, for example, is opening a door for someone. A criminal statute (law) is an example of a formal rule of society. Social rules or codes promote our social well-being. It would be unsafe to live in a community that existed without rules. All societies must require minimum standards of conduct for their members. Laws are the governmental mandates of a society that define individuals' duties to themselves, their neighbors, and the government. The failure to adhere to laws can result in punishment that may include imprisonment or monetary fines.

Regulation of Nursing Practice

Nursing is a licensed health care profession. Nurses must be licensed by their state to practice nursing. The rationale for state licensure is to improve the quality of health care services and to protect the public. As such, state governments have created licensing boards to establish the entry-level requirements for nurses. These licensing boards also establish regulations that define the scope of appropriate nursing practice for licensed nurses. These licensing regulations are found in state nursing practice laws and within regulations that are made by the licensing agency.

The state nursing practice laws and the attendant nursing regulations establish the parameters within which nurses must practice to obtain and maintain state license. These regulations are referred to as **administrative laws**. These considerations and mandates can be the basis for disciplinary actions by the licensing body. The failure to adhere to the regulatory mandates of the nursing licensing body can result in the loss of the privilege to practice nursing. Unprofessional conduct and conviction of a crime are examples of possible violations of nursing regulations.

Nursing Liability and the Law

Liability refers to the level of responsibility that society places on individuals for their actions. In recent years this responsibility has been interpreted to mean the financial responsibility owed to those who are injured by wrongful actions. Laws establish liability or responsibility for these wrongful actions. Following the law is a major part of the practice of nursing.

Administrative laws establish the licensing authority of the state to create, license, and regulate the practice of nursing. **Criminal law** regulates behaviors for citizens within this country. **Civil law** provides the rules by which individuals seek to protect their personal and property rights.

Criminal and Civil Law

All individuals, regardless of their occupations, are required to obey the criminal laws of the government. Criminal laws establish the rules of social behavior and define the punishment for the breaking of those rules, which can result in imprisonment or monetary fines.

Criminal law is different from civil law in the nature of remedies that are used for punishment. A crime is viewed as an action taken by an individual against society that the government will prosecute and punish. The breaking of a criminal law may result in criminal punishment and civil liability. For instance, an intoxicated driver may go to jail for a crime and also be held civilly liable for any personal injury that resulted. Examples of criminal acts are assault, battery, rape, murder, and larceny.

Civil laws dictate how disputes are settled among individuals and how liability is assigned for wrongful actions. For health care workers, civil liability is a constant concern. The potential for civil liability is demonstrated by an increased use of health care procedures such as diagnostic testing, which results in higher health care costs. Civil liability is a method by which a patient can seek financial recovery for injuries and losses caused by the wrongful action or lack of action by a health care worker.

A civil liability suit begins with the filing of a complaint with a court. A copy of the complaint must be given or served by the plaintiff to the defendant. A **summons**, which is a notice to defendants that they are being sued, is attached to the complaint. The complaint describes the claim being made by the plaintiff, and the summons instructs the defendant that the complaint must be answered within a specified period, usually 20 to 30 days. Nurses served with a summons relating to work should notify their employers. These important documents must be taken seriously. The nurse must make sure that the summons is answered. If the employer does not answer the summons, the nurse must seek legal counsel to answer the summons within the specified time. If the nurse fails to answer the summons and complaint, it may result in a default judgment, which is acknowledgment of liability.

Civil wrongs caused by the act or omission of a health care worker can be physical, emotional, and financial in nature. The person claiming a civil cause of action and injury is the plaintiff, and the person alleged to have caused the injury is the defendant. Lawsuits involving civil wrongs are called **torts**. The institution that employs the worker may also become liable for the acts or omissions of its employees. This theory of law is called **respondeat superior**. It is important for employees to understand that their work may result in civil liability for their employers.

Civil or tort liability for health care workers can be based on intentional actions, unintentional actions, and even the omission of action. **Malpractice** may be defined as a breach of the duty that arises out of the relationship that exists between the patient and the health care worker. This term includes liability that may arise from intentional torts and unintentional torts. Intentional torts are lawsuits wherein the

defendant is accused of intentionally causing injury to the plaintiff. Examples of intentional torts are assault, battery, defamation, false imprisonment, outrage, invasion of privacy, and wrongful disclosure of confidential information (Table 2-1).

Negligence

An unintentional tort is known as **negligence**. Negligence occurs when injury results from the failure of the wrongdoer to exercise care. This failure to follow due care in the protection of the person injured is referred to as a breach of duty. Professionals owe a higher duty of care to their patients. The failure of a health care professional to follow a prescribed duty of care is called malpractice. Professional negligence, therefore, is referred to as malpractice (Box 2-1). All professionals, including LPN/LVNs, are responsible for their own actions, whether they are intentional or negligent in nature. Although the employing agency is also responsible for the actions of its employees, employees always remain responsible for their own actions as well.

Limitation of Liability

All professions are concerned with the **limitation of liability**. This means that health care professionals can do some things to limit their individual and institutional liability. Some examples of liability limitations are ensuring patient rights, accurately documenting procedures, following institutional policies, acquiring individual malpractice or liability insurance, pursuing continuing education, and practicing in accordance with the current standards of the nursing profession. Several states have enacted tort reform legislation. Much of this legislation is directed at limiting liability for health care professionals and institutions. Examples of this reform legislation are limitations on the dollar amount allowable for a patient's damages, shortening the time in which a patient can file a lawsuit, and requiring stringent expert medical evaluation of a claim before a lawsuit can be filed.

BOX 2-1

Components Necessary for a Finding of Negligence

1. A duty of care owed to patients
2. A breach of duty to exercise care
3. Injury and damages occurring from this breach of duty

All patients are entitled to quality care and treatment with dignity and respect. To provide quality care and limit liability, understand and provide the rights your patient is entitled to and question directions that are controversial, given verbally, concern situations of high liability, or involve a discrepancy between the direction and standard policy. Rights are defined as something due an individual according to just claims, legal guarantees, or moral and ethical principles. **Welfare rights**, also called legal rights, are rights that are based on a legal entitlement to some good or benefit. These rights are guaranteed by laws such as the Bill of Rights and if violated can come under the powers of the legal system. For example, citizens of the United States have a right to equal access to employment regardless of race, sex, or religion. The American Hospital Association drafted a patients' bill of rights in 1973. The type of treatment and care a patient has the right to expect is outlined. Congress is currently involved with federal legislation related to a patients' bill of rights. Stay informed on the status of this legislation, which you will be expected to follow. Knocking before entering a patient's room and introducing oneself to the patient are examples of a patient's rights.

Documentation is a legal record of your actions. Document nursing actions based on orders given, as well as the name and title of the person who gave the verbal direction. Documentation must be clear, honest, and accurate. Always practice at a level that is generally accepted by the nursing profession. Failure to adhere to acceptable practice standards is cause for concern and can create potential liability for both you and the health care institution.

It is important to understand that some employers do not provide malpractice insurance for their nursing employees. Always ask an employer exactly who is covered under the employer's liability insurance. If nursing employees are covered, the employer's insurance will provide coverage from liability only as long as the employee follows the employer's work policies. For this reason, employer-provided liability insurance is not personal liability insurance. As a result, LPN/LVNs often carry personal liability insurance.

TABLE 2-1 INTENTIONAL TORTS

Assault	Unlawful conduct that places another in immediate fear of an unlawful touching or battery; real threat of bodily harm
Battery	Unlawful touching of another
Defamation	Wrongful injury to another's reputation or standing in a community; may be written (libel) or spoken (slander)
False Imprisonment	Unlawful restriction of a person's freedom
Outrage	Extreme and outrageous conduct by a defendant in the care of the client or the body of a deceased individual
Invasion of Privacy and Wrongful Disclosure of Confidential Information	Liability when a client's privacy is invaded physically or when records are released without authority

REVIEW QUESTIONS

1. As the nurse provides care to patients, it is important to have an understanding of ethics for which of the following reasons?
 - a. Health care resources are not limited.
 - b. Technological interventions are always helpful.
 - c. Health care systems are becoming more simplified.
 - d. Human development has the potential for health crisis at every stage.
2. The nurse is planning quality care for a patient without regard to race, ethnicity, and gender. Which of the following ethical obligations does this exhibit?
 - a. Fidelity
 - b. Integrity
 - c. Respectfulness
 - d. Compassion
3. The nurse is caring for a patient whose family requests that a feeding tube be inserted. The patient has an advance directive indicating that a feeding tube is not to be inserted. As the nurse and physician consider what is best for the patient in this ethical dilemma, which of the following principles is represented?
 - a. Autonomy
 - b. Beneficence
 - c. Nonmaleficence
 - d. Justice
4. The nurse has a question about how his nursing license is regulated. In which of the following documents will the nurse find this information?
 - a. An institutional policy
 - b. Nursing ethics code
 - c. State nursing practice laws
 - d. National nursing standards
5. In providing professional nursing care, the nurse understands that the law of negligence requires which of the following to create liability?
 - a. A crime
 - b. Assault
 - c. Ethical violations
 - d. A breach of duty

cultures (**KUL**-churs)
customs (**KUS**-tums)
ethnic (**ETH**-nick)
ethnocentrism (**ETH**-noh-**SEN**-trizm)
generalizations (**JEN**-er-al-i-**ZAY**-shuns)
stereotype (**STER**-ee-oh-**TIGHP**)
traditions (tra-**DISH**-uns)
values (**VAL**-use)
worldview (**WERLD**-vyoo)

QUESTIONS TO GUIDE YOUR READING

1. What are the meanings of the basic terms and concepts common to culture and ethnicity?
2. What are your own cultural characteristics, values, beliefs, and practices?
3. What are attributes of culturally diverse patients and their families and how do they influence nursing care?
4. What data should you collect from culturally diverse patients and their families?
5. How would you provide a holistic approach to patient care according to cultural characteristics and attributes?

Cultural diversity in the United States is increasing. As a result, **cultural** and **ethnic** differences between nurses and their patients are becoming more evident and must be recognized. Thus there is a need for nurses to become knowledgeable about **cultures** other than their own. This chapter provides you with the basics of culture and its impact on health promotion and wellness.

► CULTURE DEFINED

Culture refers to the socially transmitted behavior patterns, **beliefs**, **values**, **customs**, arts, and all other characteristics of people that guide their **worldview**. Cultural beliefs, val-

ues, customs, and **traditions** are primarily learned within the family on an unconscious level. They are also learned from the community in which one lives, in religious organizations, and in schools. All individuals and groups have the right to maintain their cultural practices as they deem appropriate. Because culture has powerful influences on a patient's interpretation of health and responses to nursing care, valuing diversity in nursing practice enhances the delivery and effectiveness of care (Fig. 3–1). As you accumulate knowledge about specific ethnic and cultural groups, you will be challenged to look at the differences and similarities across cultures.

Figure 3-1 The nurse must assess patients' special needs related to their cultural backgrounds.

The terms **cultural sensitivity**, **cultural awareness**, and **cultural competence** have different meanings. Cultural sensitivity is knowing politically correct language and not making statements that may be offensive to another person's cultural beliefs. Cultural awareness focuses on history and ancestry and emphasizes an appreciation for and attention to arts, music, crafts, celebrations, foods, and traditional clothing. Cultural competence includes the skills and knowledge required to provide nursing care and has at least four components. The first component is having an awareness of your own culture and not letting it have an undue influence on the patient. The second is having specific knowledge about the patient's culture. The third is accepting and respecting cultural differences. The fourth is adapting nursing care to the patient's culture.

Even though you may have knowledge about another culture, **ethnocentrism** can still pervade your attitudes and behavior. Ethnocentrism is the universal tendency for human beings to think that their ways of thinking, acting, and believing are the only right, proper, and natural ways. Ethnocentrism perpetrates an attitude that beliefs that differ greatly are strange or bizarre and therefore wrong. Ethnocentrism can be a major barrier to providing culturally competent care. Additionally, you must be careful not to **stereotype** a patient. A stereotype is an opinion or belief ascribed to an individual. For example, the statement "all Chinese people prefer traditional Chinese medicine" is a stereotype. This stereotype is not true. Although many Chinese people may prefer traditional Chinese medicine for some health conditions, not all Chinese people prefer traditional Chinese medicine. Some Chinese people prefer the Western medicine that is practiced in the United States.

However, one can still make **generalizations** about an ethnic individual without stereotyping. Whereas a general-

ization, or assumption, may be true for the group, it does not necessarily fit the individual. Therefore you must seek additional information to determine whether the generalization fits the individual. The challenge is to understand the patient's cultural perspective. If you have specific cultural knowledge, you can improve therapeutic interventions by becoming a co-participant with patients and their families. To do this, you must develop a personal, open style of communication and be receptive to learning from patients from cultures other than your own.

► CHARACTERISTICS OF DIVERSITY

Primary and secondary characteristics of diversity affect how people view their culture. The primary characteristics of diversity include nationality, race, skin color, gender, age, and religious affiliation. Secondary characteristics include socioeconomic status, education, occupation, military experience, political beliefs, length of time away from the country of origin, urban versus rural residence, marital status, parental status, physical characteristics, sexual orientation, and gender issues.

Cultural Groups in the United States

This chapter describes selected attributes of some of the cultural groups in the United States. These groups are European-Americans, Native-Americans, African Americans, Spanish/Hispanics/Latinos, Asian/Pacific Islander-Americans, Arab-Americans, and Appalachians.

Cultural Self-Assessment Exercise

- Identify your primary and secondary cultural characteristics. How do they affect your worldview?
- Share these views with others in your class.

Attributes presented for each group include communication styles, family organization, nutrition practices, death and dying issues, health care beliefs, and traditional health care practitioners. Traditional health care practitioners are those practitioners from the patient's native culture, such as shamans, herbalists, and other traditional healers. Racial and ethnic biologic variations, susceptibility to disease, and genetic diseases are covered elsewhere in this textbook. (See Ethical Consideration Box 3-1 and Gerontological Issues Box 3-2.)

► COMMUNICATION STYLES

Communication styles include verbal and nonverbal variations. Verbal communication includes spoken language, dialects, and voice volume. Dialects are variations in grammar, word meanings, and pronunciation of spoken language. Nonverbal communication includes the use and degree of eye contact, the perception of time, and physical closeness when talking with peers and perceived superiors.

In some societies, people are expected to maintain eye contact without staring, which denotes that they are listening and

ethnocentrism: ethnos=race + centr=center, self + ism=condition

BOX 3-1 ETHICAL CONSIDERATION

When dealing with patients from cultural backgrounds that are different from their own, nurses are sometimes faced with the possible risk of imposing their own values and standards in situations that they do not fully understand. The following is an example of that possible hazard.

A woman of Iranian cultural background delivered a still-born baby. After the delivery, she was transferred to the medical-surgical unit for postpartum care, a practice commonly followed when stillbirths occur. Sharon, an experienced licensed practical nurse (LPN), was assigned to care for the patient. While reading through her chart, Sharon noticed that the woman's husband refused to let his wife see the baby. The chart also contained a photograph of the dead baby, an ultrasound picture, and the footprints and handprints taken after the birth.

As expected, the woman appeared very depressed, and Sharon felt a great deal of sympathy for her. While caring for this woman, Sharon mentioned that there was a photograph and other mementos of the child and asked if she would like to see them. The woman's husband, who was visiting at the time, called Sharon out of the room and indicated his very strong displeasure that Sharon let his wife know about these pictures without first asking him. He expressed his desire to see the pictures but refused to let his wife see them. He also admonished Sharon to stop talking with his wife and emphasized the fact that Sharon had no understanding at all of their culture.

Sharon completed the shift without additional communication with the woman, who was discharged before Sharon returned the next day for her shift. Sharon was plagued by a feeling that she had made a major error in caring for this woman and had failed to meet the patient's emotional needs.

It is evident from this story that the American conception of the ideal marital relationship is not the same for other cultures, including this patient and her husband from Iran. It would be easy to judge the couple based on American values of individual independence and autonomy. Instead of judging, nurses need to assess the family's values, as well as their role expectations in that particular situation. Nurses should respect each patient's cultural origins and be sensitive to their cultural preferences. These values and preferences cannot be assumed, even when nurses can correctly identify the culture of the family. Cultural stereotyping is a possible mistake. The role of the woman in this Iranian family is different from that in the American culture; roles can also reflect the socioeconomic status and other characteristics of the patient or family. Connecting with the family's culture and strengths increases the nurse's ability to communicate with and help that family.

can be trusted. However, in other societies, as a sign of respect, people should not maintain eye contact with superiors such as teachers and those in positions of higher status.

The perception of time has two dimensions. The first dimension is related to clock versus social time. For example, some cultures have a flexible orientation to time and events, and appointments take place when the person arrives. An event scheduled for 2 P.M. may not begin until 2:30 or when a majority of the people arrive. For others, time is less flexible, and appointments and social events are expected to start at the agreed-on time. For many, social

BOX 3-2 GERONTOLOGICAL ISSUES**Aging, Ethnicity, Health, and Illness**

In the United States, ethnic minority elders have serious health and well-being issues. Compared with white or European-American elders, ethnic minority elders are more likely to:

- Live in poverty.
- Have a shorter life expectancy.
- Experience debilitating disease processes or functional disability at a higher rate and at an earlier age.
- Have difficulty accessing health care services.

Remember that older adults need to be assessed within their personal cultural context. Avoid generalizing cultural practices to individuals or families without first assessing whether this practice or belief is true for them. For example, it would be wrong to assume that an older Mexican-American woman who lives with her extended family will get the family's support for assistance with bathing and other activities of daily living. If an older Chinese woman uses herbs and folk treatments for common complaints, it does not mean that she will not use the services, treatments, or medications of Western medicine.

events may be flexible, whereas medical appointments and business engagements start on time.

The second dimension of time relates to whether the culture is predominantly concerned with the past, present, or future. Past-oriented individuals maintain traditions that were meaningful in the past and may worship ancestors. Present-oriented people accept the day as it comes, with little regard for the past; the future is unpredictable. Future-oriented people anticipate a bigger and better future and place a high value on change. However, some individuals balance all three views—they respect the past, enjoy living in the present, and plan for the future.

Nursing Assessment and Strategies

Ask the following questions:

- By what name do you prefer to be called?
- What language do you speak at home?

Cultural Self-Assessment Exercise

Whether we realize it or not, everyone has a cultural or ethnic background. This exercise is to help identify your personal beliefs and values, which are largely passed on to you through your family.

- How do you identify yourself in terms of racial, cultural, or ethnic background? From what country did your ancestors originate? Were your parents from the same or similar ethnic backgrounds?
- What stories do you remember that your parents, grandparents, or other relatives told about relocating in the United States? Do you know why they originally came to America?
- How do these stories compare with those of others from similar backgrounds?
- How do these stories compare with those of others from different backgrounds?

Remember, one's values and beliefs are not better than another's—they are just different.

- Are you normally on time for appointments?

Be sure to do the following:

- Take cues from the patient for voice volume.
- Be an active listener, and become comfortable with silence.
- Avoid appearing rushed.
- Be formal with greetings until told to do otherwise.
- Take greeting cues from the patient.
- Speak slowly and clearly. Do not speak loudly or with exaggerated mouthing.
- Explain why you are asking specific questions.
- Give reasons for treatments.
- Repeat questions if necessary.
- Provide written instructions in the patient's preferred language.
- Obtain an interpreter if necessary.

Cultural Self-Enrichment Exercise

- How many languages do you speak? Do you speak a dialect of your dominant language? Does it interfere with communication with your patients?
- Do you speak in a soft, medium, or loud tone of voice? Does this tone change in different situations? How close do you stand when you speak with close friends? Does this distance change when you converse with your teacher, your religious leader, or a politician?
- Identify characteristics from your worldview in terms of being present, past, and future oriented.
- By what name do you prefer to be called? Why? Does this change in different situations?

► FAMILY ORGANIZATION

Family organization includes the perceived head of the household, gender roles, and roles of the elderly and extended family members. The head of the household may be patriarchal (male dominated), matriarchal (female dominated), or egalitarian (shared equally between men and women). An awareness of the family dominance pattern is important for determining with which family member to speak when health care decisions have to be made.

In some cultures, specific roles are outlined for men and women. Men are expected to protect and provide for the family, manage finances, and deal with the outside world. Women are expected to maintain the home environment, including child care and household tasks. You must accept that not all societies share or even desire an egalitarian family structure.¹

Roles for the elderly and extended family vary among culturally diverse groups. In some cultures the elderly are seen as being wise, are deferred to for decision making, and are held in high esteem. Their children are expected to provide for them when they are no longer able to care for themselves. In other cultures, although the elderly may be loved by family members, they may not be given such high regard and may be cared for outside the home when self-care becomes a concern.

The extended family is very important in some groups, and a single household may include several generations living together out of desire rather than out of necessity. The extended family may include both blood-related and non-blood-related individuals who are provided with family status. For others, each generation lives separately and has its own living space.

Cultural Self-Enrichment Exercise

- Who is considered the head of the household in your family?
- Are there specified gender roles for family members?
- What are the roles of the elderly in your family?
- Do you identify with an extended family? Are they all blood relatives? What roles do they play?
- What kind of decisions do men make and what kind of decisions do women make?

Nursing Assessment and Strategies

Ask the following questions:

- Who makes the decisions in your household?
- Who takes care of money matters, does the cooking, or is responsible for child care?
- Who decides when it is time to see a health care provider?
- Who lives in your household? Are they all blood related?

Be sure to do the following:

- Observe the use of touch between family members.
- Allow family members to decide where they want to stand or sit for comfort.

► NUTRITION PRACTICES

Nutrition practices include the meaning of food to individuals, food choices and rituals, food taboos, and how food and food substances are used for health promotion and wellness. Cultural beliefs influence what people eat or avoid. Food offers security and acceptance; is necessary as a means of survival and relief from hunger; plays a significant role in socialization; has symbolic meaning for peaceful coexistence; is used to promote healing; denotes caring, closeness, and kinship; and may be used as an expression of love or anger.²

Culturally congruent dietary counseling, such as changing amounts and preparation practices and including ethnic food choices, can reduce health risks. Whenever possible, you should determine a patient's dietary practices during the intake interview. Culturally diverse patients may refuse to eat on a schedule of American mealtimes or eat American foods. Counseling about food group requirements, intake restrictions, and exercise that respects cultural behaviors is essential.

Most cultures have their own nutritional practices for health promotion and disease prevention. For many, a balance of different types of foods is important for maintaining health and preventing illness. Common folk practices recommend specific foods during illness and for prevention of illness or disease. Therefore a thorough history and assessment of dietary practices can be an important diagnostic tool to guide health promotion.

Cultural Self-Enrichment Exercise

- What is the meaning of food in your culture?
- Are there any dietary deficiencies or limitations in food for you?
- What cultural or ethnic foods do you prepare at home?
- When you eat out for lunch or dinner, what are your favorite ethnic foods? Which ethnic foods do you not like? Why?
- What are some of the dietary practices you engage in when you are ill?
- What kinds of foods do you eat to stay healthy?
- Are there any taboo or restricted foods in your culture or personal belief system?

Nursing Assessment and Strategies

Ask the following questions:

- What do you eat to stay healthy?
- What do you eat when you are ill?
- Are there certain foods that you do not eat? Why?
- Do certain foods cause you to become ill? What are they?
- Who prepares the food in your household?
- Who purchases the food in your household?

► DEATH AND DYING ISSUES

Death rituals of cultural groups are the least likely to change over time. To avoid cultural taboos, you must become knowledgeable about rituals surrounding death and bereavement. For some, the body should be buried whole. Therefore an amputated limb may be buried in a future grave site, and organ donation would probably not be acceptable. Cremation may be preferred for some, whereas for others it is taboo and burial is the preferred practice. Views on autopsy vary accordingly. Some cultural groups have elaborate ceremonies that last for days in commemoration of the dead. To some individuals these rituals appear to be a celebration, and in a sense they are—a celebration of the person's life rather than a mourning of the person's death.

The expression of grief in response to death varies within and among cultural and ethnic groups. For example, in some cultures, loved ones are expected to suffer the grief of death in silence, with little display of emotion. In other cultures, loved ones are expected to demonstrate an elaborate display of emotions to show that they cared for the individual. These variations in the grieving process may cause confusion if you perceive some individuals as overreacting and others as not caring. You must accept that there are culturally diverse behaviors associated with the grieving process. Bereavement support strategies include being physically present, encouraging reality orientation, openly acknowledging the family's right to grieve as they need to, assisting the family to express their feelings, encouraging interpersonal relationships, promoting interest in a new life, and making referrals to other staff and spiritual leaders as appropriate.

Nursing Assessment and Strategies

Ask the following questions:

- What are the usual burial practices in your family?
- Do you believe in autopsy?

Be sure to do the following:

- Observe expressions of grief. Support the family in their expression of grief.
- Observe for differences in the expression of grief among family members.
- Offer to obtain a religious counselor/spiritual leader if the family wishes.

Cultural Self-Enrichment Exercise

- What are the usual burial practices in your family?
- What is expected of family members and friends after a loved one dies?
- How is grief expressed in your family? Are there different expectations for men and women?
- Are any specific rituals associated with death?

► HEALTH CARE BELIEFS

The focus of health care includes prevention versus acute care practices and traditional, religious, and biomedical beliefs. Additionally, individual responsibility for health, self-medicating practices, views toward mental illness, and the patient's response to pain and the sick role are shaped by one's culture.

Most societies combine biomedical health care with traditional, folk, and religious practices, such as praying for good health and wearing amulets to ward off diseases and illnesses. The health care system abounds with individual and family folklore practices for curing or treating specific illnesses. Many times folk therapies are handed down from family members and may have their roots in religious beliefs. Examples of folk medicines include covering a boil with axle grease, wearing copper bracelets for arthritic pain, mixing wild turnip root and honey for a sore throat, and drinking herbal teas. As an adjunct to biomedical treatments, many people use complementary therapies, such as acupressure, acumassage, reflexology, and other traditional therapies specific to the cultural group.

Often folk practices are not harmful and should be incorporated into the patient's plan of care. However, some may conflict with prescription medications, intensify the treatment regimen, or cause an overdose. It is essential to inquire about the full range of therapies being used, such as food items, teas, herbal remedies, nonfood substances, over-the-counter medications, medications prescribed by others, and medications borrowed from others. If patients perceive that you do not accept their beliefs and practices, they may be less open to sharing information and less compliant with prescribed treatment.

Mental illness may be seen by many as being unimportant compared with physical illness. Mental illness is culture bound, and what may be perceived as a mental illness in one society may not be considered a mental illness in another society. Among some cultures, having a mental illness or an emotional difficulty is considered a disgrace and is taboo. As a result, the family is likely to keep the mentally

ill or handicapped person at home as long as possible.³ (See the Home Health Hints.)

HOME HEALTH HINTS

The effect of the patient's cultural beliefs and practices related to health care are more evident when care is provided in the home. The nurse must adapt care to the patient's environment, rather than the patient adapting to the nurse's hospital environment. The nurse is a guest in the patient's house.

Cultural responses to pain and the sick role vary among cultures. For example, some individuals are expected to openly express their pain. Others are expected to suffer their pain in silence. For some, the sick role is readily accepted, and any excuse is accepted for not fulfilling daily obligations. Others minimize their illness and make extended efforts to fulfill their obligations.

Cultural Self-Enrichment Exercise

- How do you define health for yourself?
- How do you define illness for yourself?
- Identify preventive health care practices that you use.
- When you see a health care provider for a minor illness, what do you expect the health care provider to do for you?
- Identify your self-medicating behaviors.
- What home remedies do you use when you are ill?
- What meaning does pain have to you? What measures do you use when you are in pain?
- What are your personal views toward autopsy, organ donation, organ transplantation, and receiving blood or blood products?

Nursing Assessment and Strategies

Ask the following questions:

- What do you usually do to maintain your health?
- What do you usually do when you are sick?
- What kind of home treatments do you use when you are sick?
- Who is the first person you see when you are sick?
- What do you do when you have pain?
- Do you wear charms or bracelets to ward off illness?
- Do you take herbs or drink special teas when you are sick? What are they?
- Do you practice special rituals or prayers to maintain your health?

► HEALTH CARE PRACTITIONERS

Health care practitioner choices are made based on the patient's perceived status and previous use of traditional, religious, and biomedical health care providers. In Western societies, educated health care providers are treated with great respect (Fig. 3–2). However, some people prefer traditional

Figure 3-2 Patients and health care workers may come from a variety of cultural backgrounds.

healers because they are known to the individual, family, and community.¹

Because some patients may be especially modest, you need to respect differences in gender relationships when providing care. Some people may be especially modest because of their religion, seeking out same-gender nurses and physicians for intimate care. Respect these patients' modesty by providing privacy and assigning a same-gender care provider when possible.

Cultural Self-Enrichment Exercise

- What complementary health care practitioners have you used? Were they successful?
- Identify complementary health care practitioners used by your friends. Were they successful?
- When you are ill and need to see a health care provider, do you prefer a same-gender provider? Why or why not?

Nursing Assessment and Strategies

Ask the following questions:

- What health care providers besides physicians and nurses do you see when you are ill?
- Do you object to male or female health care providers giving physical care to you?

Be sure to do the following:

- Observe for alternative care providers who may visit the patient in the health care facility.

► ETHNIC AND CULTURAL GROUPS

As of the 2000 census, the federal government has initiated new terminology for classifying people of diverse racial and ethnicity. The terminology used in this chapter reflects this new classification.

American Indians/Alaskan Natives

There are more than 400 American Indian/Alaskan Native tribes in the United States, totaling 0.9% of the population.⁴ Although there are similarities among Native-Americans, each tribe has its own unique perspective on health and illness. Many traditional American Indians/Alaskan Natives live on reservations; others live in urban areas and practice few of their traditions. Many American Indians/Alaskan Natives have a strong belief that illness is caused by an imbalance with nature and the universe.

Tribal identity is maintained through powwows, ceremonial events, and arts and crafts that are taught to children at a young age. Communicating with nature is important for maintaining life forces.¹ American Indians/Alaskan Natives are the original inhabitants of North America.

American Indians/Alaskan Natives are underrepresented in all the health professions. They are consistently identified as the most underrepresented minority group in institutions of higher learning.⁵ See Cultural Consideration Box 3–3 for cultural attributes of American Indians/Alaskan Natives.

BOX 3-3 CULTURAL CONSIDERATION

Cultural Group

Communication Styles

Family Organization

Nutrition

American Indians/
Alaskan Natives

Each tribe has its own language.
Many speak English, Spanish, or both.
Talking loudly may be considered rude.
Touch is not acceptable from strangers.
Pointing with a finger may be considered rude.
Direct eye contact may be considered rude, even with friends.
Appointments may not be kept.
Most are present oriented.

Most tribes are matriarchal, but some are egalitarian.
Gender roles are usually flexible.
Elderly persons are highly respected.
Family bonds are strong.
Extended family members are very important.

Herbs are used to cleanse the body of evil spirits and poison.
Nontraditional diets tend to be high in fat.
Diet commonly lacks fruits and vegetables on reservations.

European-Americans

Primary language is English.
Dialects vary by region of the country but are mutually understandable.
May also speak language of native country.
Loud voice tone is the norm.
Eye contact should be maintained without staring.
Value change, are future oriented, and emphasize accomplishments.
Punctual in social and business situations.
Many concerned with status.
Touch infrequently.

Goal is egalitarian family relationships, but some are nominally patriarchal or matriarchal.
Goal is gender role flexibility and equality.
Have impersonal relationships with outsiders.
Elderly persons are loved but may not be respected for wisdom or sought for advice.
Extended family not usually important on a daily basis.
Stress individualism over the group.

Diets tend to be high in fat and sodium.
The only group that uses the food pyramid.
Believe a balanced diet promotes a healthy body.
Eating and drinking may be social rituals.
Culture stresses thinness to be attractive.

African-Americans/
blacks

Primary language is English.
Many speak “black English” occasionally, depending on the situation.
Usually loud voice volume.
Punctuality is flexible.
Many are present oriented, believe there is little control over their destiny.
Place emphasis on nonverbal behaviors.
Direct eye contact may be interpreted as aggression.
Are comfortable with close personal space.
Touch frequently with friends, less so with strangers.

Usually matriarchal or egalitarian household.
Flexible gender roles.
Augmented families with non-blood relatives sharing space.
Group goals more important than individual goals.
Strong family ties.
Extended family assists in crisis.
Elderly persons respected, especially maternal grandmothers.
Church commonly plays a central role, and church members may be seen as family.

Diet commonly high in fat and sodium.
Many have lactose intolerance.
Food selections may vary according to socioeconomic class and rural versus urban residence.
Being overweight is seen as positive.
Food is a symbol of health and wealth.

BOX 3-3 CULTURAL CONSIDERATION

Cultural Group	Communication Styles	Family Organization	Nutrition
Spanish/Hispanics/ Latinos	<p>Primary language either English or Spanish.</p> <p>Numerous Spanish dialects, which are regionally specific and may not be mutually understandable.</p> <p>Present oriented, believe there is no control over destiny.</p> <p>Flexible with time and appointments.</p> <p>Some believe that direct eye contact can cause illness (“evil eye”).</p> <p>Touch with close same-gender friends but not with opposite-gender friends or strangers.</p>	<p>Patriarchal, matriarchal, or egalitarian households with women taking a more active role in health care decisions.</p> <p>Usually strict gender roles.</p> <p>Children are highly valued and taken everywhere, rarely left with babysitters.</p> <p>Elderly persons are highly respected.</p> <p>Extended family members, including godparents, are important.</p>	<p>Important for food to be served warm—not too hot or too cold.</p> <p>Many subscribe to the hot-and-cold theory, the concept that illness is caused when the body is exposed to an imbalance of hot and cold substances. Foods are classified as hot and cold, and their consumption must be balanced or illness will occur.</p> <p>Food choices vary by country of origin.</p> <p>Many adults have lactose intolerance.</p>
Asians	<p>Language specific to each country. Many dialects, with 55 in China alone.</p> <p>Loud talking is considered rude. Much communication is nonverbal.</p> <p>May be reluctant to maintain eye contact with elders or superiors.</p> <p>Touch acceptable only between members of the same gender.</p> <p>Present oriented.</p> <p>Flexible with social engagements, punctual in business appointments.</p> <p>“Yes” may not mean “I agree” or “I understand.” It may mean “I hear you.”</p> <p>Reluctant to disclose personal information.</p>	<p>Patriarchal households.</p> <p>Gender roles are well defined.</p> <p>Children are extremely important. Elderly persons are seen as wise and are respected.</p> <p>A child’s bad behavior is reflected on the entire family.</p> <p>Multigenerational and extended family important and may share the same living space.</p> <p>Responsibility of the family is to care for elderly, handicapped, and mentally ill at home.</p> <p>Group takes priority over the individual.</p>	<p>Foods are balanced between the yin and yang.</p> <p>Foods are used for health maintenance and treatment of illness.</p> <p>Diet is high in salt.</p> <p>Many have lactose intolerance.</p> <p>Food is a fundamental form of socialization.</p> <p>Food choices and preparation vary by specific country.</p>
Arab-Americans	<p>Primary language is Arabic. Most speak some English.</p> <p>Exaggerated, spirited, and loud voice is used.</p> <p>May be reluctant to disclose personal information.</p> <p>Maintain intense eye contact.</p> <p>Stand very close when talking.</p> <p>Touch only between the same gender.</p> <p>Flexible time schedules socially and for appointments.</p> <p>Present to future oriented according to socioeconomic status.</p>	<p>Patriarchal household.</p> <p>Well-defined gender roles.</p> <p>Very protective of children.</p> <p>Physical punishment is common.</p> <p>Loyalty to family over self.</p> <p>Elders are respected.</p> <p>Family obligated to care for elders.</p> <p>Extended family members important, freely offer advice.</p> <p>Extended family live in close proximity.</p>	<p>Food is a symbol of love, friendship, and generosity.</p> <p>Food preparation takes a long time; only fresh meats and vegetables are used when possible.</p> <p>Lunch is the main meal.</p> <p>Some do not eat pork or drink alcohol (Islam).</p> <p>Believe fasting cures disease.</p> <p>Believe in the hot-and-cold theory of foods.</p> <p>Many fast from sunrise to sunset during the holy month of Ramadan.</p>
Appalachians	<p>English language spoken with dialectal variations—“ing” endings become “in,” some plurals formed by adding “es” instead of “s” (e.g., “breastes”).</p> <p>Individualism and self-reliance idealized.</p> <p>May deny anger and tend to not complain.</p> <p>Direct eye contact from strangers may be perceived as aggression or hostility.</p> <p>Comfortable with silence.</p> <p>Relaxed, enjoying body rhythms instead of strong adherence to clock time.</p>	<p>Traditional home was patriarchal but is currently changing to egalitarian.</p> <p>Women are providers of emotional strength.</p> <p>Women and men marry earlier than in many other cultures.</p> <p>Have larger families than the rest of the white American groups.</p> <p>Most believe in physical punishment as a form of discipline.</p> <p>Elders are respected.</p> <p>Usually care for elderly persons in the home.</p>	<p>Wealth means having plenty of food.</p> <p>High-cholesterol organ meats are commonly used.</p> <p>Use lard for frying and baking.</p> <p>Diet frequently deficient in iron, calcium, and vitamin A.</p>

continued

BOX 3-3 CULTURAL CONSIDERATION—CONT'D**Cultural Group****Death and Dying Issues****Health Care Beliefs****Health Care Practitioners**

American Indians/
Alaskan Natives

Believe body should go into the after-life whole.
Some engage in a cleansing ceremony after touching a dead body.
Home has to be cleaned if person dies at home.
Taboo to talk directly about death or a grave diagnosis.
Openly express grief.
Tribal laws may dictate cremation versus burial.

Many practice acute care only.
Use herbs, corn, dances, and prayers to cure and balance life forces with nature.
Combine Western medicine with traditional practices.
Have a fear of witchcraft.
Inanimate objects are believed to ward off evil.
Theology and medicine are interwoven.
Promote harmony with nature.
Pain is something to be endured.
Sick role is not usually supported.

Traditional healers include shamans, singers, diviners, crystal gazers, hand tremblers.
Elderly may request same-gender direct care provider.

European-Americans

Autopsy and burial or cremation usually connected with religious practices or are individual decisions.
Have varied expression of grief.
Men are expected to be in more control of grief than women.

Believe humans can control nature.
Have strong belief and value in technology.
Practice primary acute care practices, but recent trend is moving toward prevention.
Value individual responsibility for health.
May use folk remedies or over-the-counter medicines before seeing a health care practitioner.
Use prayers and religious symbols for good health.
Have controlled expression of pain.
Need little encouragement for pain relief.
Sick role not well accepted except with a major illness.

Primarily use Western-educated health care providers.
Recent trend is to use complementary therapists, such as chiropractors, reflexologists, and acupuncture.
Most accept physical care from either gender.

African-Americans/
blacks

Death does not end connection between people.
Body is kept intact after death; prefer no autopsy.
Relatives may communicate with the dead person.
Offer eulogy at burial with religious songs.
Usually prefer burial, rarely cremation.
Express grief openly with emotional catharsis.

Believe diseases may be natural, caused by cold or bad air, food, or water.
Believe diseases may be unnatural, caused by voodoo, witchcraft, or a hex.
Believe serious illness may be sent from God.
May resist preventive care because illness is God's will.
Folk and herbal medicine prevalent.
Use prayers for prevention and health recovery.
Pain is seen as a sign of illness.
Sick role not seen as a burden.

A respected elderly female community member commonly sought for initial health care.
Use spiritualists who receive their gift from God.
Some seek care from voodoo priest or priestess.
May seek care from root doctor who uses herbs, oils, candles, and ointments.

Spanish/Hispanics/
Latinos

Burial is the usual practice, rarely cremation.
May resist autopsy; body should be buried whole.
May have elaborate ceremonial burial.
Women very expressive with grief; men are expected to maintain control of their grief.

Health beliefs strongly affected by religion.
Believe health and illness largely God's will.
May have shrines or statues in the home to pray for good health.
Frequently use over-the-counter medicines and medicines brought from home country.
Theory of hot and cold foods used for health maintenance and treatment of disease.

Santero in Cuba practices Santeria, a religion with animal sacrifice and worship of many gods.
Curandero uses herbs.
Espirituista uses prayers and amulets.
Sobador manipulates muscles and performs massage.
High degree of modesty, so may prefer same-gender provider for intimate care.

BOX 3-3 CULTURAL CONSIDERATION

Cultural Group	Death and Dying Issues	Health Care Beliefs	Health Care Practitioners
Spanish/Hispanics/ Latinos—cont'd		<p>Many are fearful and suspicious of hospitals.</p> <p>Expressive with pain.</p> <p>Easily enter the sick role.</p> <p>Primarily receive acute care with little prevention.</p> <p>Believe children and women are more susceptible to the evil eye.</p>	
Asians	<p>Autopsy not understood by many.</p> <p>Cremation acceptable, but burial is also common depending on the specific population.</p> <p>Extended grieving time (7 to 30 days) for the more traditional.</p> <p>Expression of grief is highly varied between men and women and among specific countries.</p>	<p>Good health is a gift from ancestors.</p> <p>Imbalances in the yin and yang cause illness.</p> <p>Believe blood is the source of life and is not replenished.</p> <p>Amulets are worn to ward off disease.</p> <p>Cleanliness is highly valued.</p> <p>Prayers are used for healing.</p> <p>Over-the-counter medicine use is common.</p> <p>Use of herbal teas and medicine is common.</p> <p>Commonly stoical with pain.</p> <p>Many delay seeking help until very ill.</p>	<p>Acupuncturist uses needle insertions at specific points to control pain.</p> <p>Practice acumassage: deep tissue and muscle massage.</p> <p>Moxibustion therapy uses heat instead of needles or massage.</p> <p>May practice coining, in which a heated coin is rubbed over body surfaces, causing dermabrasion.</p> <p>Cupping: involves heated cups applied over the body, which causes suction, leaving large ecchymotic areas when the cup is removed.</p>
Arab-Americans	<p>Believe death is God's will.</p> <p>At the time of death the bed should face the holy city of Mecca.</p> <p>Perform ritual washing of the body after death.</p> <p>No cremation or autopsy allowed.</p> <p>May weep with grief, but limited.</p>	<p>Primarily receive acute care with little prevention.</p> <p>Little responsibility for self-care.</p> <p>Pray five times each day for health.</p> <p>Combine prayers with meditation.</p> <p>Freely use over-the-counter medication.</p> <p>Illness is a punishment for sins.</p> <p>Considered rude and cruel to communicate a grave diagnosis.</p> <p>Organs may be purchased for transplantation.</p> <p>Will display overt expression of pain.</p> <p>Sick dependency role readily accepted.</p>	<p>Accept and prefer Western practitioners.</p> <p>May use cupping and phlebotomy.</p> <p>Primarily same-gender care only, especially among elderly persons.</p>
Appalachians	<p>Funerals are plain and an important social function.</p> <p>Family and friends remain at bedside when a death is expected.</p> <p>Deceased usually buried in his or her best clothes.</p> <p>Elaborate meals are served after the funeral.</p> <p>Funeral services are accompanied by singing.</p> <p>Clergy are good at helping family through the grieving process.</p>	<p>Injections preferred over pills.</p> <p>Prayer is a primary source of strength.</p> <p>Believe good health is largely a result of God's will.</p> <p>Biomedical care may be used as a last resort.</p> <p>Use many folk remedies, primarily passed on by "granny" practitioners who use poultices, herbs, and teas.</p> <p>Self-medicate first before seeking a biomedical practitioner.</p> <p>A major health concern is the state of the blood.</p>	<p>Physicians are commonly seen as outsiders.</p> <p>Family folk practitioners used as a primary source of health care.</p> <p>Nurses are highly respected in the culture.</p> <p>Practitioner must ask the patient what he or she thinks is the problem to be effective.</p>

European-Americans

European-American is the term used to describe people living in the United States whose heritage is from the countries of England, Scotland, Wales, Ireland, Norway, Switzerland, Sweden, the Netherlands, and other northern European countries. European-American groups include the white ethnic groups. Many of the descendants of these original European immigrants practice the unique attributes of the subcultures from which they originate. There is much diversity in the primary and secondary characteristics of diversity within this cultural group.

Many European-Americans maintain the value of individualism over group norms and are activity oriented. Most European-Americans practice Western medicine that uses high technology and emphasizes scientific discovery.¹ See Cultural Consideration Box 3–3 for common cultural attributes of European-Americans.

African-Americans/Blacks

African-Americans/blacks are the largest ethnic group in the United States and represent more than 100 racial strains.¹ They make up 12.3% of the population.⁴ Although African-Americans/blacks live in all 50 states, more than half live in the South. It is important to understand that not all people with black skin identify themselves as African-American. Many black-skinned people from the Caribbean prefer terms more specific to their identity, such as *Haitian*, *Jamaican*, or *West Indian*.

African-Americans/blacks have been called by many names. Their ancient African name is Nehesu or Nubian. During slavery days in America, they were called *Negro*, a Spanish-Portuguese word meaning “black.” After emancipation in 1863, they were called *colored*, a term adopted by the First Colored Men’s Convention in the United States in 1831. The United States Bureau of the Census adopted the word *Negro* in 1880. During the civil rights movements in the 1960s, the term *black* was used to signify a philosophy of life instead of color. In the 1970s these ethnic peoples referred to themselves as African-Americans because they were proud of both their African and American heritages. In 1988 the term *African-American* was widely adopted in the United States by individuals whose ancestry originated from Africa. These terms continue to cause confusion when people attempt to use the “politically correct” term for this group in the United States. Some individuals prefer terms more appropriate to their individual heritage instead of *African-American/black*. Additionally, titles such as the National Black Nurses Association and the National Association for the Advancement of Colored People still exist.¹

African-Americans/blacks are underrepresented in colleges and universities, managerial and administrative positions, and the health care professions. They are overrepresented in high-risk, hazardous occupations such as the steel and tire industries, construction industries, and high-pollution factories. See Cultural Consideration Box 3–3 for cultural attributes of African-Americans/blacks.

Spanish/Hispanics/Latinos

The term *Spanish/Hispanics/Latinos* is used to describe people whose cultural heritage has a strong Spanish influence. However, many people in this group prefer to identify themselves as Chicano or with terms that provide a country of origin, such as *Mexican*, *Peruvian*, *Puerto Rican*, and *Cuban*.¹ The largest Spanish/Hispanics/Latinos populations in the United States are Mexican-Americans (64%), Puerto Ricans (11%), Central Americans (7%), South Americans (7%), Cubans (4%), and Caribbean (3%). Hispanics also come from Venezuela, Colombia, Ecuador, Peru, Bolivia, Paraguay, Chile, Argentina, Uruguay, Dominican Republic, Guatemala, El Salvador, Costa Rica, Honduras, Nicaragua, and Panama. Thus there is much diversity in the Spanish/Hispanics/Latinos population in the United States.¹

Some Spanish/Hispanics/Latinos speak only Spanish, some speak only English, some speak both Spanish and English, and some speak neither Spanish nor English but rather an Indian dialect, depending on individual circumstances and the length of time spent in the United States. Spanish is the second most common spoken language in the United States.

Spanish/Hispanics/Latinos compose 12.5% of the U.S. population and live in all 50 states. More than 90% live in cities. Four out of every five Spanish/Hispanics/Latinos are born and raised in the United States.

The majority of Spanish/Hispanics/Latinos practice adaptations from the Roman Catholic religion. Their close relationship with God makes it acceptable for people to experience visions and dreams in which God or the saints speak directly to them. Thus health care providers must be careful not to attribute these culture-bound visions to hallucinations that indicate a need for psychiatric services.¹ See Cultural Consideration Box 3–3 for cultural attributes of Spanish/Hispanics/Latinos.

Asian-Americans

This large group, with more than 5,575,000 people, is far from homogeneous. The term *Asian*, as used in most references, includes 32 different groups. These groups include Asians, Pacific Islanders, Indochinese, and other Asian groups. Asians include people from Korea, Japan, and 54 ethnic groups from China. Pacific Islanders include Hawaiians, Polynesians, Filipinos, Malaysians, and Guamanians. Indochinese populations include Cambodian, Vietnamese, Hmong, and Laotian. Other Asian groups include Asian Indian, Pakistani, and Thai.

Although it is difficult to determine exact numbers of Asians from specific countries because of the method of keeping population statistics, they are a significant and fast-growing population in the United States. It is important for many Asian patients to “save face.” Individual shame is shared with the family and community. Most Asians see the nurse as an authority figure. Although known by different names, most Asian cultures practice the *yin* and *yang* balance of forces for illness prevention and maintaining

health. Yin is considered female and represents cold and weakness. Yang is considered male and represents strength and warmth. Foods and all forces are classified as yin or yang and must be balanced or illness occurs. Yin and yang forces are major components of traditional Chinese medicine, which includes acupressure, acumassage, cupping, and moxibustion.¹ See Cultural Consideration Box 3–3 for cultural attributes of Asian-Americans.

Arab-Americans

Arab-Americans are a large and diverse population, with more than 3,000,000 in the United States. Some common bonds include the Arabic language and the Islamic religion. Arab-Americans include people from Morocco, Algeria, Tunisia, Libya, Sudan, and Egypt and the western Asian countries of Lebanon, occupied Palestine, Syria, Jordan, Iraq, Iran, Kuwait, Bahrain, Qatar, United Arab Emirates, Saudi Arabia, Oman, and Yemen. Many early Arab immigrants were Christians from Lebanon and Syria.

Although many Arab-Americans favor professional occupations, many are underemployed, have their own businesses, and work in a variety of other occupations. Arab-Americans, whether born in the United States or in Arab countries, are more educated than the average American.^{1,6} They are more likely to be in managerial and professional specialty occupations than any other ethnic group in America.⁶ However, a significant number of Arab-Americans, primarily foreign born, are unemployed and live in poverty. See Cultural Consideration 3–3 for cultural attributes of Arab-Americans.

Appalachians

The term *Appalachian* is derived from the Apalache Indians, who inhabited what is today known as the Appalachian Mountain region. This chapter uses the term *Appalachian* to describe people born in this region and their descendants. Most Appalachians trace their heritage to Scotland, Wales, Ireland, England, or Germany. This large, mountainous region consists of part or all of the states of Georgia, Alabama, Mississippi, Virginia, West Virginia, North Carolina, South Carolina, Kentucky, Tennessee, Ohio, Maryland, Pennsylvania, and New York. Parts of Appalachia have insufficient roads, public transportation systems, and airports, creating a disparity in educational and health care facilities.

Appalachians are loyal, caring, family oriented, religious, hardy, independent, honest, patriotic, and resourceful. They value home, which is a connectedness to the land rather than a physical structure. Additional characteristics ascribed to Appalachians are avoidance of aggression and assertiveness, refusal to interfere with others' lives, avoidance of dominance over others, and avoidance of arguments and desire for agreement. They are private people who want to offend no one and may not easily trust outsiders.¹ See Cultural Consideration 3–3 for cultural attributes of Appalachians.

SUMMARY

Rarely do practicing nurses have the luxury to assess each patient comprehensively on a first encounter. The essentials for culturally competent interventions are obtained as needed. The patient database can be added to as time permits. Astute observations, an openness to diversity, and a willingness to learn from patients are requirements for effective cross-cultural competence in clinical practice. Through these avenues, you can provide culturally competent nursing care. Cultural competence is not a luxury; it is a necessity.

You can obtain additional information from the Transcultural Nursing Society at <http://www.tcns.org>, or go to <http://nursing.about.com> and click on "Transcultural."

CRITICAL THINKING

Mr. Bautista

Mustafa Bautista, age 62, and his wife, Mina, age 60, immigrated to the United States 3 years ago from Saudi Arabia. During a celebration of Ramadan, Mustafa collapsed and was taken to the nearest emergency room. He was admitted to the observation unit for diagnostic testing. He does not speak or understand English well, and when the nurse asks him a question, he stares at her, makes elaborate hand gesture, and speaks in a very loud voice. Mustafa is a devoted adherent of Islam, and his wife brings him the Koran, from which he reads several times each day.

Even though Mustafa is prescribed bedrest, he gets out of bed several times each day, kneels on a small carpet, and prays. He refuses to let the female nurses bathe him. Yesterday he refused his breakfast and lunch. Today he refused his dinner and insisted on keeping the tray at his bedside. At 8:00 P.M. he took the pork chops from his tray and placed them in the hall. Additionally, he refuses his oral medicines and insists on injections instead.

1. What nonverbal communication characteristics does this patient display that are common among people of Arabic descent?
2. Does his loud voice mean that he is angry?
3. What might you do when Mr. Bautista gets out of bed to pray?
4. Why do you think Mr. Bautista refused his breakfast and lunch?
5. Why did Mr. Bautista remove the pork chops from his tray and leave them in the hall?
6. What might you do to improve Mr. Bautista's nutrition while he is in the hospital?
7. What is Ramadan?
8. Why does Mr. Bautista insist on injections rather than oral medication?
9. What might you do to get Mr. Bautista to take oral medications rather than injections?

Answers at end of chapter.

REVIEW QUESTIONS

- The nurse is explaining the medication schedule to Mrs. Bing Bing, a 45-year-old Chinese woman with minimal English language skills. Which of the following will best help ensure compliance?
 - Provide written instructions in English.
 - Speak slowly and clearly, using the same phrase each time.
 - Speak loudly to make sure she understands you.
 - Speak slowly and exaggerate the words.
- A 12-year-old Mexican child needs an appendectomy. Who should sign the informed consent for the operation?
 - The mother
 - The father
 - Both parents
 - The parents decide
- Your 42-year-old male Islamic patient in a long-term care facility needs to have a urinary catheter inserted to obtain a specimen. Who is the best person to perform the procedure?
 - A female registered nurse
 - A male nurse
 - An orderly
 - The patient's wife
- A 22-year-old Osage American Indian woman is slow at giving responses and does not maintain eye contact with you when you are doing her intake interview. Which of the following interpretations of her behavior is most likely accurate?
 - Direct eye contact may be interpreted as rude in her culture.
 - She does not want to answer personal questions.
 - She does not understand you.
 - She does not want to talk with a nurse and prefers a physician.
- An 82-year-old African-American woman is in the coronary care unit to rule out a myocardial infarction. Several church members come to visit her on a daily basis. Which of the following actions by the nurse is correct?
 - Carefully explain to them that only family members are allowed to visit in the coronary care unit.
 - Allow two church members to visit and have them represent the entire group.
 - Set up a specific time during which several of them can visit for brief periods.
 - Report the situation to her physician.
- A 42-year-old Puerto Rican man has been admitted for reconstructive orthopedic surgery on his knee. His wife brings jars of special blends of spices that he wants to put on his food because the hospital food is too bland. He is on a general diet. What action should you take?
 - Allow him to use them.
 - Carefully explain that family cannot bring food items to the hospital.
 - Have the dietitian speak with the family.
 - Report the situation to the physician.

Answers to CRITICAL THINKING

Mr. Bautista

- Culture-bound communication patterns that Mr. Bautista displays include speaking in a loud voice, liberal use of hand gesturing, and maintaining intense eye contact.
- A loud voice does not necessarily mean that Mr. Bautista is angry.
- The nurse should instruct Mr. Bautista to call someone to help him get out of bed when he is ready to pray and when he is ready to return to bed. The danger of injuring himself while praying is minimal once he is out of bed and kneeling on his prayer rug.
- During Ramadan, Islamic people fast from sunup to sundown. Breakfast and lunch are served during daylight hours. Therefore Mr. Bautista refused his meals.
- Mr. Bautista removed the pork chops from his room because Islamic people do not eat pork.
- Because Islamic people fast from sunup until sundown during Ramadan, serve Mr. Bautista breakfast before sunup and hold his dinner until sundown. Provide snacks between dinner and breakfast as necessary.
- Ramadan is a holy month for adherents of Islam. It involves special religious observances.
- Many Arab-Americans prefer injections over oral medications because it is believed that injections are stronger than oral medicine. Additionally, fasting may include not taking medications.
- Administering medications after sundown may improve compliance. Explaining to Mr. Bautista that fasting is not required during times of illness may also improve compliance.

naturopathy (**NAY**-chur-**AH**-pa-thee)
osteopathic (**AHS**-tee-ah-**PATH**-ik)

QUESTIONS TO GUIDE YOUR READING

1. What is the difference between an alternative and complementary therapy?
2. What are some systems of health care that have contributed to the development of new therapies?
3. How can the different types of therapies be classified?
4. What are some safety issues in alternative and complementary therapies?
5. What is the role of the licensed practical nurse/registered nurse (LPN/LVN/RN) in assisting a patient with alternative and complementary therapies?

Health care in the twenty-first century requires that nurses recognize the shift of thinking toward the incorporation of alternative and complementary approaches to care. Nurses at all levels and in every area of practice are answering the call to use new methods to care for the ill and to enhance the health of those who are well.

Holistic nursing was a precursor to many of the now popular alternative and complementary therapies. It was introduced in the 1970s and has been growing ever since. Holistic nursing is simply defined as caring for the whole person—body, mind, and spirit—in an ever-changing environment.

▶ ALTERNATIVE OR COMPLEMENTARY: WHAT'S THE DIFFERENCE?

The words *alternative* and *complementary* are sometimes used interchangeably, but they are not the same. *Alternative* therapy, sometimes called “unconventional” therapy, refers to a therapy used instead of conventional or mainstream therapy. An example is using **acupuncture** instead of analgesics. *Complementary therapy* refers to a therapy used in addition

to a conventional therapy. For example, a nurse might use guided imagery, music, and relaxation techniques for pain control in addition to prescribed drug therapy.

A good all-around site for alternative and complementary medicine is <http://www.healthy.net>. To learn about holistic nursing and complementary therapies, visit <http://www.ahna.org>.

▶ INTRODUCTION OF NEW SYSTEMS INTO TRADITIONAL AMERICAN HEALTH CARE

There are many new and different philosophies within the scope of expanded medical and nursing practice. These systems reflect cultures and attitudes in healing that range from East to West and from ancient to modern.

In the United States the primary system of medicine is just called *medicine*, although some people refer to it as **allopathic** medicine. Upon closer look, you will find that a number of other schools of thought and philosophies are also being increasingly used. The most frequently seen new systems include **Ayurvedic**, Chinese, **chiropractic**,

acupuncture: acus—needle + punctura—puncture

allopathic: allos—other + pathic—disease or suffering
ayurvedic: ayu—life + veda—knowledge or science
chiropractic: cheir—hand + praktos—to do

naturopathic, American Indian, and **osteopathic** medicine. Each philosophical system can stand alone or, as in most instances in the United States, be used in combination with other systems. Most of these recently introduced systems use alternative and complementary therapies.

Allopathic/Western Medicine

The most common name for allopathic medicine is *Western medicine*. Other commonly used terms for Western medicine are *conventional medicine* and *mainstream medicine*. Many people have not heard the term *allopathic* because most doctors and nurses do not refer to themselves or their practice with this name. Practitioners of other systems of medicine more often use the term when referring to what most of us consider mainstream medicine. Allopathy is a method of treating disease with remedies that produce effects different from those caused by the disease itself. For example, when a patient has a bacterial infection, a Western medical practitioner prescribes an antibiotic to eliminate the invading pathogen.

Practitioners of Western medicine are medical doctors, nurses, and allied health personnel. This system of medicine uses scientific data to determine the validity of a diagnosis and the effectiveness of treatment. In other words, it is evidence-based medicine. This means that peer-reviewed medical literature is very important. In scientific investigations, results can be verified and reproduced through various types of studies and statistical analyses. Practitioners use a variety of therapies, including drugs, surgery, and radiation therapy. Western medicine practitioners have made most of the significant advances and developments in modern medicine.

For further information see the American Medical Association site at <http://www.ama-assn.org>.

Ayurvedic Medicine

Ayurveda is the ancient Hindu system of medicine, which originated in India. Its main goals are to maintain the health of healthy people and cure the illnesses of sick people. Ayurveda maintains that illness is the result of falling out of balance with nature. Diagnosis is based on three metabolic body types called *doshas*. An Ayurvedic doctor determines the dosha type as *vata*, *pitta*, or *kapha*. Treatment usually involves prescribing a diet, herbal remedies, breath work, physical exercise, yoga, meditation, massage, and a rejuvenation or detoxification program.

Ayurveda is rapidly becoming more popular in America. The books and videos of Deepak Chopra are an example of this increasingly popular system of therapy. An introduction to Ayurveda can be found at <http://www.ayurveda.org>.

Traditional Chinese Medicine

Traditional Chinese medicine is thousands of years old and involves such techniques and practices as acupuncture, acu-

pressure, herbs, massage, and qi gong. The diagnosis and treatment of disturbances of qi (pronounced “chee”)—or vital energy—is a distinctive characteristic of Chinese medicine.

Acupuncturists, one segment of traditional Chinese medicine practitioners, claim to be able to tell much about a patient’s state of health by checking pulses, looking at the color of the tongue, checking facial color, assessing voice and smell, and asking a variety of questions. To treat patients, acupuncturists insert one or more needles along the meridians (pathways) where qi flows (Fig. 4-1). Many acupuncturists also prescribe herbs.

Chiropractic Medicine

Daniel David Palmer founded chiropractic in 1895. Chiropractic holds that illness is a result of nerve dysfunction. The main treatment modality of chiropractors is manual adjustment and manipulation of the vertebral column and the extremities. They use direct hand contact and mechanical and electrical treatment methods to manipulate joints. The goal is to remove the interference with nerve function so the body can heal itself. Chiropractors do not perform surgery, nor do they prescribe drugs. See the American Chiropractic Association site at <http://www.amerchiro.org>.

Homeopathic Medicine

Homeopathy was developed by Samuel Hahnemann in Germany in the early nineteenth century. Homeopathy is based on Hahnemann’s principle that “like cures like”; in other words, that tiny doses of a substance that create the symptoms of disease in a healthy person will relieve those symptoms in a sick person.

Although there are schools and courses to train homeopaths, no diploma or certificate from any school or program is a license to practice homeopathy in the United States. Medical doctors and doctors of osteopathy are granted certificates of competency to practice homeopathy. Other health care practitioners may be allowed to use homeopathy within the scope of their state licenses.

See The National Center for Homeopathy site at <http://www.homeopathic.org>. This site has a research section with annotated listings from the medical literature discussing the value of homeopathy. In addition, there is a good review of licensing laws regarding homeopathy.

Naturopathic Medicine

Naturopathy primarily uses natural therapies such as nutrition, botanical medicine (herbs), hydrotherapy (water-based therapy), counseling, physical medicine, and homeopathy to treat disease, promote healing, and prevent illness. Naturopathic physicians have a doctor of naturopathy (ND) degree and can be licensed in 11 states. There are three schools of naturopathic medicine in the United

osteopathic: osteo—bone + pathy—disease

homeopathy: homeo—like + pathos—disease
naturopathy: naturo—nature + pathy—disease

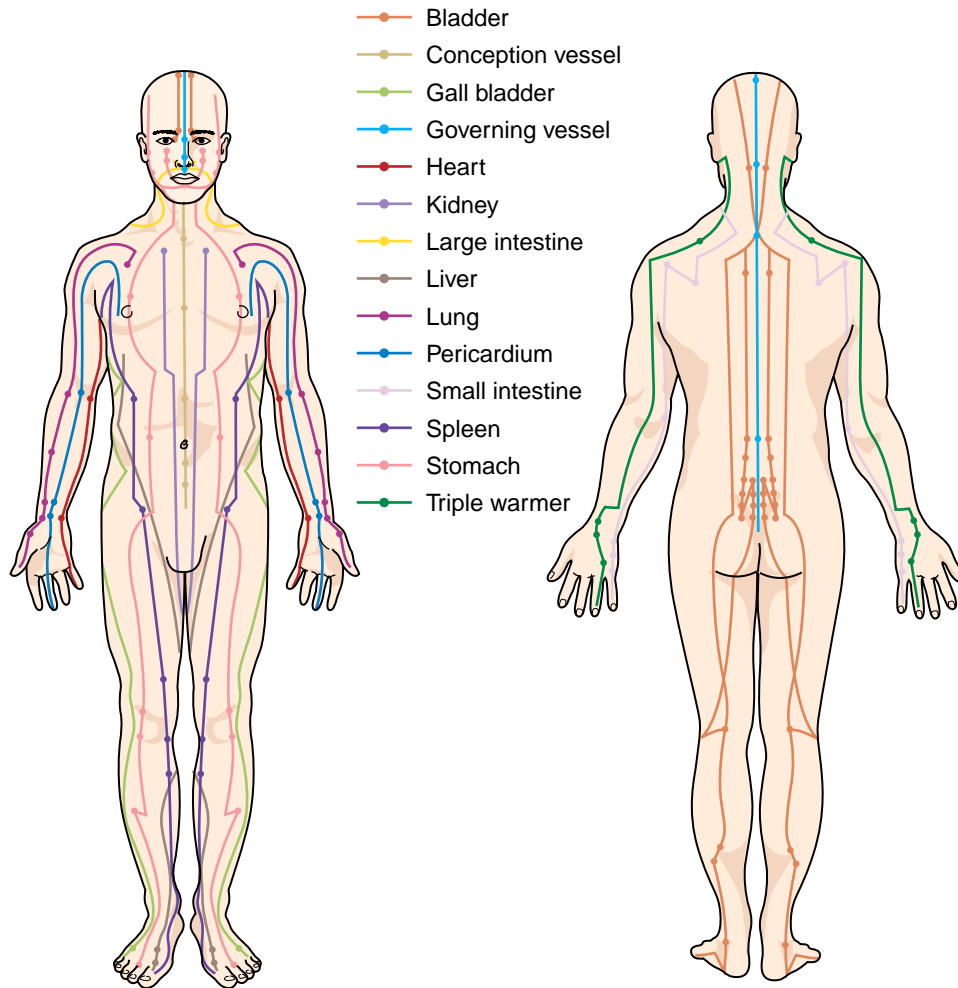

Figure 4-1 Qi meridians are used in the Chinese medicine techniques of acupressure and acupuncture.

States. For more information about naturopathy, visit <http://www.naturopathic.org>.

American Indian Medicine

American Indian medical practices vary from tribe to tribe. In general, American Indian medicine is a community-based system with rituals and practices such as the sweat lodge, herbal remedies, the medicine wheel, the sacred hoop, the “sing,” and shamanistic healing. For example, an ill person may be placed in a small, enclosed sweat lodge while singing or chanting is done outside the lodge. It is believed that toxic substances are drawn out in the sweat of the person inside the lodge. After the ceremony, the ill person may be placed on a cot outside and be prayed over. You can learn more about American Indian Medicine at the Association of American Indian Physicians’ site at <http://www.aaip.com>.

Osteopathic Medicine

Osteopathic medicine was founded in the United States in 1874 by Andrew Taylor Still, a frontier physician who was dissatisfied with the state of medicine at that time. This practice of medicine emphasizes the interrelationship of the body’s nerves, muscles, bones, and organs. The osteopathic

philosophy involves treating the whole person; recognizes the body’s ability to heal itself; and stresses the importance of diet, exercise, and fitness with a focus on prevention. For more information about osteopathy, visit the American Osteopathic Association site at <http://www.aoa-net.org>.

▶ ALTERNATIVE AND COMPLEMENTARY THERAPIES

See Table 4–1 for a summary of the most common alternative and complementary therapies. Discussion of all therapies is beyond the scope of this book. Therapies are listed to make you aware of others you might want to research.

Herb Use

Many people use herbs for healing. However, when doing so, the patient should only take herbs under the supervision of a health care provider. Herbs can aid in healing, but they also can harm. Some of the more common herbs are described in Table 4–2. Figure 4–2 shows echinacea, an herb commonly prepared for use as an immune system booster.

It is important to note that herbal remedies are not foods. They have potent medicinal effects and can interact with prescribed medications and even surgery. This can be

TABLE 4-1 CATEGORIES AND TYPES OF ALTERNATIVE AND COMPLEMENTARY THERAPIES	
Category of therapy	Types of individual therapies
Herbal medicine and nutritional supplements	Herbal medicine
	Nutrition and special diet therapies
	Nutritional supplements
Mind-body therapies	Art therapy
	Music/sound therapies
	Guided imagery
	Hypnosis and hypnotherapy
	Meditation and relaxation
Posture and mobility therapies	Movement therapies
	Tai chi and qi gong
	Yoga
Touch therapies and bodywork	Massage and related massage therapies
Energetic therapies	Acupressure
	Biofeedback
	Healing touch
	Magnet therapy
	Polarity therapy
	Reiki
	Spiritual healing
	Therapeutic touch
Miscellaneous therapies	Aquatherapy/hydrotherapy
	Aromatherapy
	Chanting
	Chelation therapy
	Colon therapy
	Kinesiology
	Light therapy
	Pet therapy

Figure 4-2 Echinacea is a commonly used herb for colds and flu.

problematic, both because herbs are readily available in health food stores and drugstores and because many patients do not tell their doctors about their herb use. Be sure to assess patients' use of herbs and supplements, and educate them about the need to inform primary care providers when using herbs.

Safety and Effectiveness of Alternative Therapies

Safety generally means that the benefits outweigh the risks of a treatment or therapy. If your patient is interested in using an alternative or complementary therapy, first counsel the patient to talk with the primary care provider. The patient also should ask the practitioner of the therapy about its safety and effectiveness. Patients should tell their primary care providers and alternative practitioners about all therapies they are receiving, because this information may used to consider the safety of their entire treatment plan.

The patient should be as informed as possible and continue gathering information even after a practitioner has been selected. You can find information about specific therapy or therapies in journal articles and books. See Box 4-1

BOX 4-1 Questions Patients Should Ask Before Starting an Alternative or Complementary Therapy

1. What will this therapy do for me?
2. What are the advantages of this therapy?
3. What are the disadvantages?
4. What are the side effects?
5. What risks are associated with this therapy?
6. How much will it cost?
7. How long will it take? How many treatments will be necessary?
8. How will it interact with my other therapies?
9. What research has been done on this therapy?

TABLE 4-2 COMMON HERBS AND THEIR INTENDED PROPERTIES AND USES	
Herb	Purported properties/uses
Aloe vera	Soothing agent, used for skin lesions; toxin absorber
Bee pollen	Increases energy, stamina, and strength
Capsaicin	For tenderness and pain of osteoarthritis, fibromyalgia, diabetic neuropathy, and shingles
Chamomile	For anxiety, stomach distress, and infant colic
Echinacea	Antiviral; used for colds, flu, and other infections
Feverfew	Antiinflammatory; used for migraine headaches and as an appetite stimulant; promotes menstruation, eliminates worms, suppresses fever
Ginger	For nausea and vomiting, hypertension, and high cholesterol
Ginkgo	May improve memory and help cognitive function in Alzheimer's disease
Kava	For anxiety, insomnia, low energy, muscle tension
St. John's wort	For mild to moderate depression; viral infections, including human immunodeficiency virus (HIV); and herpes

for questions patients should ask when considering alternative therapies.

► ROLE OF THE LPN/LVN

Patients may ask you about the use of an alternative or a complementary therapy. Because the safety and effectiveness of many therapies is still unknown, advising patients presents a challenge. The following steps may help you to help your patient. You can advise patients to do the following:

1. Take a close look at the background, qualifications, and competence of the proposed practitioner. Check credentials with a state or local regulatory agency with authority over the area of practice they seek. Are they licensed or certified? By whom?
2. Visit the practitioner's office, clinic, or hospital. Evaluate the conditions of the setting.
3. Talk with others who have used this practitioner.
4. Consider the costs. Are the treatments covered by insurance, or is it direct pay?
5. Discuss use of an alternative or complementary therapy with their primary care provider.

You can help direct your patient's questions and concerns to the primary care provider. See Home Health Hints for tips.

HOME HEALTH HINTS

- When taking a health history, ask the patient or caregiver about the use of complementary or alternative therapies, because these may influence the effect or side effects of some prescription medications.
- Be mindful of the importance of complementary and alternative therapies to the patient's health care belief system.
- Consider the alternative practitioner as part of the patient's health care team.

► NURSING APPLICATIONS

Familiarization Strategies

There are ways to gain confidence with alternative and complementary therapies:

1. Begin by trying one or two of these therapies yourself. Start by choosing a basic therapy such as massage, music, or guided imagery. Follow the guidelines listed in Box 4–1 to make sure it is a safe strategy. Not only will you encounter the benefits firsthand, but you will also come away with a better understanding of what patients experience.
2. Ask your patients if they use any alternative or complementary therapies and what their responses to them are. Try to eliminate any preconceived notions you might have. Your patients will feel more comfortable mentioning them to you if they feel you understand the treatment and why they decided to use it.
3. If you decide to become involved, get adequate instruction in the therapies before you administer them. Many

universities and agencies offer continuing education courses on these therapies, and some nursing schools incorporate alternative and complementary therapies in their skills courses.

If you wish to incorporate alternative and complementary therapies into your practice, be sure to check your state's nurse practice act for any regulations. Discuss them with the patient and his or her primary care provider before using them. If you work for a hospital or other health care institution, also check institutional policy.

As the public understands more about alternative and complementary therapies, you can expect to see even greater demand for these treatments. Nurses have been in the forefront of developing the holistic philosophy that has now become an accepted standard of care.

Relaxation Therapies

Progressive Muscle Relaxation

Progressive muscle relaxation is a simple technique that anyone can learn. It is the process of alternately tensing and relaxing muscle groups. The purpose of the technique is to help the participant identify subtle levels of mental and physical tension that accompany mental and emotional stress. When our conscious awareness of the tensions increases, we can learn to relax and thus reduce the effects of stress and tension. The idea is to become aware of the ability to fine-tune the relaxation response.

LEARNING TIPS

Try using progressive muscle relaxation the next time you are anxious during a nursing exam.

Guided Imagery

Guided imagery is another example of a complementary therapy that many nurses use. Guided imagery involves using mental images to promote physical healing or changes in attitudes or behavior. Practitioners may lead patients through visualization exercises or offer instruction in using imagery as a self-help tool. Guided imagery is often used to alleviate stress and to treat stress-related conditions such as insomnia and high blood pressure. People with cancer, acquired immunodeficiency syndrome (AIDS), chronic fatigue syndrome, and other disorders can use specific images to boost the immune system. Guided imagery is often an

CRITICAL THINKING

Mr. Jones

Scenario: Mr. Jones asks you whether he should stop his chemotherapy and try magnet therapy for his prostate cancer. How do you respond?

Answers at end of chapter.

added layer of therapy for someone who has learned the progressive relaxation skill discussed previously.

A common guided imagery technique begins with a general relaxation process. For those new to the process, it is good to begin with the progressive muscle relaxation as cited above. Box 4–2 gives an example of guided imagery. Guided imagery works best when all the senses are used. This exercise is very basic but gives an idea of how the technique works. When used for healing, many more steps are involved. For additional information read journal articles, books, and Internet sites. It is important to note that with this and any of the alternative and complementary therapies, one must have some training and skill before using the technique with patients. One of a number of good sites on guided imagery is <http://www.healthy.net/agi>.

LEARNING TIPS

Another test-taking tip: When you are stumped on a test question, close your eyes and imagine yourself asking the question of your favorite instructor. Imagine what his or her answer would be.

Biofeedback

Biofeedback might be considered the third tier of learning of progressive relaxation. It is a technique used especially for stress-related conditions such as asthma, migraines, insomnia, and high blood pressure. Biofeedback is a way of monitoring and controlling tiny metabolic changes in one's body with the aid of sensitive machines.

SUMMARY

The use of alternative and complementary therapies is growing in the United States. Nurses must be aware of their use and ask about them in their patient assessments. Nurses who have additional training in specific therapies can use many of them when caring for patients. When patients use complementary therapies, nurses should view it as an attempt to increase potential benefit and not as a sign of distress or dissatisfaction.

BOX 4–2 Guided Imagery

Assist your patient to progress through the following steps:

- Assume a comfortable position in a quiet environment.
- Close your eyes and keep them closed until the exercise is completed.
- Breathe in and out deeply to the count of four, repeating this step four times.
- When relaxed, think of a favorite peaceful place and prepare to take an imaginary journey there.
- Picture what this place looks like and how comfortable you feel being there.
- Listen to all the sounds; feel the gentle, clean air; and smell the pleasant aromas.
- Continue to breathe deeply, and appreciate the feeling of being in this special place.
- Feel the sense of deep relaxation and peace of this place.
- As you continue to breathe deeply, slowly and gently bring your consciousness back to the setting in this room.
- Slowly and gently open your eyes, stretch, and think about how relaxed you feel.

Answers to CRITICAL THINKING

Mr. Jones

As with all medical treatments, it is important to support the established therapy the physician has prescribed. Therefore a good response might be the following:

“Mr. Jones, chemotherapy is an established medical treatment for your condition. There is a lot of evidence for its effectiveness in the medical literature. If you want to supplement your therapy, there may be some other treatments you can add. I suggest that you discuss your feelings about seeking some additional treatments with your doctor.”

REVIEW QUESTIONS

1. Which of the following statements best defines a complementary therapy?
 - a. An alternative treatment that is used in place of a conventional treatment
 - b. A treatment that is often dangerous and should be avoided
 - c. A treatment that can be used in addition to a conventional treatment
 - d. A treatment that is used after conventional treatments have failed
2. Which of the following therapies is most likely to use research-based interventions?
 - a. Naturopathy
 - b. Osteopathy
 - c. Allopathy
 - d. Homeopathy
3. Mr. Flynn is admitted for heart failure. He has been taking a ginger supplement in addition to his prescribed medications at home. What is the best response by the nurse when he shares this information during the admission interview?
 - a. “Nonprescription supplements can interact with prescription medications. You should not take it any longer.”

- b. "Ginger can be effective for hypertension. Be sure to monitor your blood pressure while you are taking it."
 - c. "Ginger is a safe supplement because it is a food. It should not interact with your medications."
 - d. "You should check with your physician to make sure the ginger doesn't interact with your other medications before you continue to take it."
4. According to recent research, biofeedback-assisted relaxation training may be used to promote healing of foot ulcers by:
- a. increasing peripheral perfusion.
 - b. eliminating bacteria in the wounds.
 - c. enhancing growth of new tissue.
 - d. reducing wound drainage.
5. Which of the following statements best describes the most important role of the LPN in alternative and complementary therapies?
- a. The LPN should become familiar with and practice at least one alternative or complementary therapy.
 - b. The LPN should become adept at collecting and reporting data related to patients' use of alternative and complementary therapies.
 - c. The LPN should discourage use of alternative and complementary therapies because they can interact negatively with conventional therapies.
 - d. The LPN does not need to become involved in alternative and complementary therapies.

 (**SEM**-ee-**PER**-mee-uh-bull)
 transcellular (trans-**SELL**-yoo-lar)

The body undergoes continuous dynamic change. The proper amount of fluid is needed to support these changes and to transport building and waste materials. Approximately 60 percent of a young adult's body weight is water. Elderly people are less than 50 percent water, and infants are between 70 percent and 80 percent water. Women have less body water because they have more fat than men. Fat cells do not contain water.

In addition to water, body fluids also contain solid substances that dissolve, called solutes. Some solutes are **electrolytes** and some are nonelectrolytes. Electrolytes are chemicals that can conduct electricity when dissolved in water. Examples of electrolytes are sodium, potassium, calcium, magnesium, acids, and bases; these are discussed later in this chapter. Nonelectrolytes do not conduct electricity. Examples are glucose and urea.

► FLUID BALANCE

Fluids are located both inside the cells (**intracellular** fluid [ICF]) and outside the cells (**extracellular** fluid [ECF]). As seen in Figure 5-1, ECF can be further divided into three types: **interstitial** fluid, **intravascular** fluid, and **transcellular** fluid.

Interstitial fluid is the water that surrounds the body's cells and includes lymph. Fluids and electrolytes move between the interstitial fluid and the intravascular fluid, which is the plasma of the blood. Transcellular fluids are those in specific compartments of the body, such as cerebrospinal fluid, digestive juices, and synovial fluid in joints.

Figure 5-1 Normal distribution of total body water.

electrolyte: electro—electricity + lyte—dissolve
intracellular: intra—within + cellular—cell
extracellular: extra—outside of + cellular—cell
interstitial: inter—between + stitial—tissue
intravascular: intra—within + vascular—blood vessel
transcellular: trans—across + cellular—cell

Control of Fluid Balance

The primary control of water in the body is through pressure sensors in the vascular system, which stimulate or inhibit the release of **antidiuretic** hormone (ADH) from the pituitary gland. A diuretic is a substance that causes the kidneys to excrete more fluid. ADH works in just the opposite way. ADH causes the kidneys to retain fluid. If fluid pressures within the vascular system decrease because there is less fluid, more ADH is released. If fluid pressures increase, less ADH is released and the kidneys eliminate more fluid.

Movement of Fluids and Electrolytes in the Body

Fluids and electrolytes move in the body by active and passive transport systems. Active transport depends on the presence of adequate cellular adenosine triphosphate for energy. The most common example of active transport is the sodium-potassium pump. This pump, located in the cell membrane, causes sodium to move out of the cell and potassium to move into the cell when needed.

In passive transport, no energy is expended specifically to move the substances. General body movements aid passive transport. The three passive transport systems are **diffusion**, **filtration**, and **osmosis**.

Diffusion is a process in which the substance moves from an area of higher concentration to an area of lower concentration. If you pour cream into a cup of coffee, the movement of the molecules causes the cream to eventually be dispersed throughout the beverage. If you stir the coffee, this process occurs at a faster rate. Body movement assists passive transport, like stirring the coffee. It causes the diffusion to occur at a faster rate.

Filtration is the movement of both water and smaller molecules through a **semipermeable** membrane. The semipermeable membrane works like a screen that keeps the larger substances on one side and only permits the smaller molecules to filter to the other side of the membrane. Filtration is promoted by **hydrostatic** pressure differences between areas.

Hydrostatic pressure is the force that water exerts, sometimes called water pushing pressure. In the body, filtration is important for the movement of water, nutrients, and waste products in the capillaries. The capillaries serve as semipermeable membranes allowing water and smaller substances to move from the vascular system to the interstitial fluid, but larger molecules and red blood cells are kept inside the capillary walls.

antidiuretic: anti—against + diuretic—urination

diffusion: diffuse—spread, scattered

filtration: filter—strain through

osmosis: osmo—impulse + osis—condition

semipermeable: semi—half or part of + permeable—passing through

hydrostatic: hydro—water + static—standing

Osmosis is the movement of water from an area of lower substance concentration to an area of higher concentration. The substances exert an osmotic pressure, sometimes called water pulling pressure. The term *osmolarity* refers to the concentration of the substances in body fluids. The normal osmolarity of the blood is between 270 and 300 milliosmoles per liter (mOsm/L).

Another term for osmolarity is *tonicity*. Fluids or solutions can be classified as **isotonic**, **hypotonic**, or **hypertonic**. A fluid that has the same osmolarity as the blood is called isotonic. For example, a 0.9 percent saline solution (normal saline) is isotonic to the blood and is often used as a solution for intravenous (IV) therapy. A solution that has a lower osmolarity than blood is called hypotonic. When a hypotonic solution is given to a patient, the water leaves the blood and other ECF areas and enters the cells. Hypertonic solutions exert greater osmotic pressure than blood. When a hypertonic solution is given to a patient, water leaves the cells and enters the bloodstream and other ECF spaces.

Fluid Gains and Fluid Losses

Water is very important to the body for cellular metabolism, blood volume, body temperature regulation, and solute transport. Although people can survive without food for several weeks, they can survive only a few days without water.

Water is gained and lost from the body every day. In addition to liquid intake, some fluid is obtained from solid foods. When too much fluid is lost, the brain's thirst mechanism tells the individual that more fluid intake is needed. Older adults are more prone to fluid deficits because they have a diminished thirst reflex and their kidneys do not function as effectively. An adult loses as much as 2500 mL of sensible and insensible fluid each day. Sensible losses are those of which the person is aware, such as urination. Insensible losses may occur without the person recognizing the loss. Perspiration and water lost through respiration and feces are examples of insensible losses.

▶ FLUID IMBALANCES

Fluid imbalances are common in any clinical setting. Elderly people are at the highest risk for life-threatening complications that can result from either fluid deficit, more commonly called **dehydration**, or fluid overload. Infants are at risk for fluid deficit because they take in and excrete a large proportion of their total body water each day.

Dehydration

Although there are several types of dehydration, only the most common type is discussed in this chapter. Dehydration occurs when there is not enough fluid in the body, especially in the blood (intravascular area).

isotonic: iso—equal + tonic—strength
hypotonic: hypo—less than + tonic—strength
hypertonic: hyper—more than + tonic—strength
dehydration: de—down + hydration—water

Pathophysiology and Etiology

The most common form of dehydration results from loss of fluid from the body, resulting in decreased blood volume. This decrease is referred to as **hypovolemia**. Hypovolemia occurs when the patient is hemorrhaging or when fluids from other parts of the body are lost. For example, severe vomiting and diarrhea, severely draining wounds, and profuse diaphoresis (sweating) can cause dehydration.

Hypovolemia may also occur when fluid from the intravascular space moves into the interstitial fluid space. This process is called third spacing. Examples of conditions in which third spacing is common include burns, liver cirrhosis, and extensive trauma. Box 5-1 lists the common causes of dehydration.

As described earlier in this chapter, the body initially attempts to compensate for fluid loss by a number of mechanisms. If the cause of dehydration is not resolved or the patient is not able to replace the fluid, a state of dehydration occurs.

Prevention

You can help prevent dehydration by identifying patients who have the highest risk for developing this condition. High-risk patients include the elderly, infants, children, and any patient who has one of the conditions listed in Box 5-1.

Adequate hydration is another important intervention to help prevent dehydration. You should encourage patients to drink adequate fluids. If the patient is unable to take enough fluid by mouth, check with the physician for an order for IV therapy to replace fluid in the body.

Signs and Symptoms

Thirst is the initial symptom experienced by otherwise healthy adults in response to hypovolemia. As the percentage of water in the blood goes down, the percentage of other

BOX 5-1 Common Causes of Dehydration

- Long-term nothing by mouth (NPO) status
- Hemorrhage
- Profuse diaphoresis (sweating)
- Diuretic therapy
- Diarrhea

- Gastrointestinal suction
- Draining fistulas
- Draining abscesses
- Severely draining wounds
- Systemic infection
- Fever
- Frequent enemas
- Ileostomy
- Cecostomy
- Diabetes insipidus

hypovolemia: hypo—less than + vol—volume + emia—blood

substances goes up, resulting in the thirst response. As the blood volume decreases, the heart pumps the remaining blood faster but not as powerfully, resulting in a rapid, weak pulse and a low blood pressure. The body pulls water into the vascular system from other areas, resulting in decreased tear formation, dry skin, and dry mucous membranes.

The individual with dehydration has poor skin turgor. Turgor is poor if the skin is pinched and a small “tent” remains (called *tenting*). Temperature increases because the body is less able to cool itself through perspiration. Temperature may not appear elevated in an elderly person because an elder’s normal body temperature is often several degrees lower than a younger person’s. Urine output decreases and the urine becomes more concentrated as water is conserved. Dehydration should be considered in any adult with a urine output of less than 30 mL per hour. The urine may appear darker because it is less diluted. The patient becomes constipated as the intestines absorb more water from the feces. A major method of evaluating dehydration is weight loss. A pint of water weighs approximately 1 pound. Symptoms of dehydration in the elderly may be atypical (Gerontological Issues 5–2).

BOX 5-2 GERONTOLOGICAL ISSUES

As a person ages, total body water decreases from 60 percent to 50 percent of total body weight. The age-related decrease in total body water is secondary to an increase in body fat and decreased thirst sensation. These factors increase the risk of developing dehydration.

Manifestations of dehydration in an older adult are different from typical manifestations in a younger person. Atypical manifestations include altered mental status, light-headedness, and syncope. These occur because a patient with hypovolemia has an inadequate blood supply, and therefore oxygen supply, to the brain.

Complications

If dehydration is not treated, lack of sufficient blood volume causes organ function to decrease and eventually fail. The brain, kidneys, and heart must be adequately supplied with blood (perfused) to function properly. The body protects these organs by decreasing blood flow to other areas. When these organs no longer receive their minimum requirements, death results.

Diagnostic Tests

The patient with dehydration usually has an elevated blood urea nitrogen (BUN) level and elevated hematocrit. Both values are increased because there is less water in proportion to the solid substances being measured. The specific gravity of the urine also increases as the kidneys attempt to conserve water, resulting in a more concentrated urine.

Medical Treatment

The goals of medical treatment are to replace fluids and resolve the cause of dehydration. In a patient with moderate or severe dehydration, IV therapy is used. Isotonic fluids

that have the same osmolarity as blood are typically administered.

Nursing Process

You can play a major role in identifying patients who are dehydrated.

ASSESSMENT. Assess the patient for signs and symptoms of dehydration. All the classic signs and symptoms may not be present.

When assessing an elderly patient for skin turgor (*tenting*), assess the skin over the forehead or sternum. The skin over these areas usually retains elasticity and is therefore a more reliable indicator of skin turgor.

Weight is the most reliable indicator of fluid loss or gain. A loss of 1 to 2 pounds or more per day suggests water loss rather than fat loss. The patient in the hospital setting should be weighed every day. The patient in the nursing home or home setting should be weighed three times a week if the patient is at risk for fluid imbalance. The nursing staff should weigh the patient before breakfast using the same scale each time.

NURSING DIAGNOSES. The primary nursing diagnoses for the patient with dehydration include the following:

- Deficient fluid volume related to fluid loss or inadequate fluid intake
- Decreased cardiac output related to insufficient blood volume
- Impaired oral mucous membrane related to inadequate oral secretions
- Ineffective (cerebral) tissue perfusion related to insufficient blood volume
- Constipation related to decreased body fluids

PLANNING. The health care team works together to restore fluids in the patient. The expected outcome is that the patient will be adequately hydrated and not experience further episodes of dehydration.

IMPLEMENTATION. Patients can become dehydrated in any setting. For the patient who is mildly dehydrated, interventions can be implemented in the home or nursing home setting. For moderate or severe dehydration, the patient may require hospitalization to treat the underlying cause and replace fluid losses. Make sure the patient does not receive too much fluid replacement, which could cause fluid overload, discussed in the next section of this chapter. Fluid intake and output (I&O) should be carefully measured and monitored (Cultural Consideration 5–3).

BOX 5-3 CULTURAL CONSIDERATION

Muslims who celebrate Ramadan fast for 1 month from sunup to sundown. Although the ill are not required to fast, the pious may still insist on doing so. Fasting may include not taking fluids and medications during daylight hours. Therefore the nurse may need to alter times for medication administration, including intramuscular medication. Special precautions may need to be taken to prevent dehydration in Muslim patients.

EVALUATION. As part of evaluation, determine whether the patient has been adequately rehydrated, using the assessment techniques described earlier.

Patient Education

The patient, family, and significant others need to be taught the importance of reporting early signs and symptoms of dehydration to a physician or other health care provider. At home or in the nursing home, infections often cause fever and sepsis, a serious condition in which the infection invades the bloodstream. The body attempts to decrease the temperature through perspiration. The patient becomes dehydrated as a result and can become increasingly ill.

CRITICAL THINKING

Mrs. Levitt

Mrs. Levitt is a 92-year-old widow who has been in a nursing home for 4 years. Today she complains that her urine smells bad and that her heart feels like it is beating faster than usual. You suspect that she is becoming dehydrated. You check her urine and find that it is a dark amber color and that it smells strong. Her heart rate is 98, blood pressure 126/74, respiratory rate 20, and temperature 99.2.

1. What other data should you collect, and what results do you expect?
2. Which interventions should you provide at this time?
3. How should you document your findings?

Answers at end of chapter.

Fluid Overload

Fluid overload, sometimes called overhydration, is a condition in which a patient has too much fluid in the body. Most of the problems related to fluid overload result from too much fluid in the bloodstream or from dilution of electrolytes and red blood cells.

Pathophysiology and Etiology

The most common result of fluid overload is **hypervolemia**, in which there is excess fluid in the intravascular space. Healthy adult kidneys can compensate for mild to moderate hypervolemia. The kidneys increase urinary output to rid the body of the extra fluid.

The causes of fluid overload are related to excessive intake of fluids or inadequate excretion of fluids. Conditions that can cause excessive fluid intake are poorly controlled IV therapy, excessive irrigation of wounds or body cavities, and excessive ingestion of water. Conditions that can result in inadequate excretion of fluid include renal failure, heart failure, and syndrome of inappropriate antidiuretic hormone. These conditions are discussed elsewhere in this book.

Prevention

One of the best ways to prevent fluid overload is to avoid excessive fluid intake. For example, you should monitor the patient receiving IV therapy for signs and symptoms of fluid overload. In at-risk patients an electronic infusion pump or a quantity-limiting device, such as a burette, should be used to control the rate of infusion.

Also monitor the amount of fluid used for irrigations. For example, when a patient's stomach is being irrigated (gastric lavage), be sure an excess amount of fluid is not absorbed.

Signs and Symptoms

The vital sign changes seen in the patient with fluid overload are the opposite of those found in patients with dehydration. The blood pressure is elevated, pulse is bounding, and respirations are increased and shallow. The neck veins may become distended, and pitting **edema** in the feet and legs may be present. The skin is pale and cool. The kidneys increase urine output, and the urine appears diluted, almost like water. The patient rapidly gains weight. In severe fluid overload the patient develops moist crackles in the lungs, dyspnea, and ascites (excess peritoneal fluid).

Complications

Acute fluid overload typically results in congestive heart failure. As the fluid builds up in the heart, the heart is not able to properly function as a pump. The fluid then backs up into the lungs, causing a condition known as pulmonary edema. Other major organs of the body cannot receive adequate oxygen, and organ failure can lead to death.

Diagnostic Tests

In the patient experiencing fluid overload, the BUN and hematocrit levels tend to decrease from hemodilution. The plasma content of the blood is proportionately increased when compared with the solid substances. The specific gravity of the urine also diminishes as the urinary output increases.

Medical Treatment

Once the patient's breathing has been supported, the goal of treatment is to rid the body of excessive fluid and resolve the underlying cause of the overload. Drug therapy and diet therapy are commonly used to decrease fluid retention.

POSITIONING. To facilitate ease in breathing, the head of the patient's bed should be in semi-Fowler's or high Fowler's position. These positions allow greater lung expansion and thus aid respiratory effort. Once the patient has been properly positioned, oxygen therapy may be necessary (Fig. 5-2).

OXYGEN THERAPY. Oxygen therapy is typically used to ensure adequate perfusion of major organs and to minimize dyspnea. If the patient has a history of chronic obstructive

hypervolemia: hyper—more than + vol—volume + emia—blood

edema: swelling

Figure 5-2 Patient in high Fowler's position with oxygen.

pulmonary disease, such as emphysema or chronic bronchitis, do not administer more than 2 L per minute of oxygen. At higher oxygen doses the patient may lose the stimulus to breathe and may suffer respiratory arrest.

DRUG THERAPY. Diuretics are frequently administered to rapidly rid the body of excess water. A diuretic is a drug that increases elimination by the kidneys. The drug of choice for fluid overload when the patient has adequately functioning kidneys is usually furosemide (Lasix). Furosemide is a loop (high-ceiling) diuretic that causes the kidneys to excrete sodium and water. Sodium (Na^+) and water tend to move together in the body. Potassium (K^+), another electrolyte, is also lost, which can lead to a potassium deficit, discussed later in this chapter.

Furosemide may be given by the oral, intramuscular, or IV route. The oral route is used most commonly for mild fluid overload. IV furosemide is administered by a registered nurse (RN) or physician for severe overload. The patient should begin diuresis within 30 minutes after receiving IV furosemide. If not, another dose is given.

DIET THERAPY. Mild to moderate fluid restriction may be necessary, as well as a sodium-restricted diet. In collaboration with the dietitian, a physician prescribes the specific restriction necessary, usually a 1 to 2 g Na^+ restriction for severe overload. Different diuretics result in differing electrolyte elimination. Specific diet therapy depends on the medications the patient is receiving and the patient's underlying medical problems.

Nursing Process

The nurse plays a pivotal role in the care of a patient with fluid overload. Prompt action is needed to prevent life-threatening complications.

ASSESSMENT. Observe a patient who is at high risk for fluid overload and monitor fluid I&O carefully. If the pa-

tient is drinking adequate amounts of fluid (1500 mL per day or more) but is voiding in small amounts, the fluid is being retained by the body.

Assess for edema, which is fluid that accumulates in the interstitial tissues. If the edema is pitting, a finger pressed against the skin over a bony area such as the tibia leaves a temporary indentation. For patients in bed, check the sacrum for edema. For patients in the sitting position, check the feet and legs.

As mentioned earlier, weight is the most reliable indicator of fluid gain. A gain of 1 to 2 pounds or more per day indicates fluid retention, even though other signs and symptoms may not be present.

NURSING DIAGNOSES. Common nursing diagnoses for a patient with fluid overload are as follows:

- Excess fluid volume related to excessive fluid intake or inadequate excretion of body fluid
- Decreased cardiac output related to excess work on the heart from fluid retention
- Ineffective tissue perfusion related to dependent edema
- Risk for impaired gas exchange related to fluid in the lungs

PLANNING. The expected outcome for the patient is that fluid balance is achieved and that the patient does not experience life-threatening cardiac or pulmonary failure.

IMPLEMENTATION. The patient at risk for fluid overload may be in the hospital, nursing home, or private home. Severe overload requires hospitalization, possibly to a critical care unit, and placement on a ventilator if the patient has severe pulmonary edema. Mild or moderate overload may be treated outside the hospital, but the patient must follow the treatment plan carefully to avoid worsening the condition.

If the patient is placed on a fluid restriction, you can work with the RN to determine how it should be implemented. For example, if a patient is on a 1000 mL per day fluid restriction, you might plan for 150 mL with each meal, 450 mL to be given to the patient to use as he or she likes during the day and 100 mL to be used during the night. Be sure to include the patient in your planning, and remember to reserve enough fluid for swallowing pills. Post a sign in the patient's room so other caregivers know how much fluid the patient can have.

EVALUATION. During treatment, evaluate whether the expected outcomes are achieved. Many patients must remain on drug and diet therapy after hospital discharge to prevent the problem from recurring.

Patient Education

In collaboration with the dietitian, the patient, family, or other caregiver should be instructed about the fluid and sodium restrictions to prevent further problems (Nutrition Notes Box 5-4). High-sodium foods to avoid are listed in Box 5-5.

Teaching caregivers about diuretic therapy is essential to prevent electrolyte imbalances. If a potassium-losing diuretic is prescribed, teach which foods are high in potas-

BOX 5-4

Nutrition Notes

Reducing Sodium Intake

Many foods, such as dairy products, grain products, and some vegetables, are naturally high in sodium, but the major sources of sodium in the diet are salted and processed foods, including baked goods and condiments. For example, compare the sodium content of cheddar and American cheese and of fresh and cured pork in Box 5-2. Drinking water may contain significant amounts of sodium, particularly if it is a softened or mineral water. Because of the numerous “hidden” sources of sodium, a dietitian’s services are often necessary.

Specific definitions for reduced sodium food products have been adopted. Note that serving size is an important variable. The amount of daily intake of sodium recommended for adults is 2400 mg.

- Salt or sodium free: <5 mg sodium per serving
- Very low sodium: <35 mg sodium per serving (per 100 g if main dish)
- Low sodium: <140 mg sodium per serving (per 100 g if main dish)

sium, such as oranges and other citrus fruits, melons, bananas, and potatoes. The patient’s serum potassium level needs to be periodically monitored by a physician or home care nurse. If it becomes too low, an oral potassium supplement is needed.

The family or other caregiver also needs to be taught common signs and symptoms of fluid overload that should be reported to a physician or other health care provider. Of special importance is weight gain. The patient should be weighed at least three times a week in the home or nursing home if he or she is at high risk for fluid overload.

CRITICAL THINKING

Mr. Peters

Mr. Peters is a 32-year-old man with a congenital heart problem. He has been recovering from congestive heart failure and fluid overload. Today his blood pressure is higher than usual and his pulse is bounding. He is having trouble breathing and presses the call light for your assistance.

1. What should you do first when you assess Mr. Peters’s condition?
2. What questions should you ask him?
3. What other assessments should you perform?

Answers at end of chapter.

ELECTROLYTE BALANCE

Natural minerals in food become electrolytes or ions in the body through digestion and metabolism. Electrolytes are usually measured in milliequivalents per liter (mEq/L) or in milligrams per deciliter (mg/dL).

Electrolytes are one of two types: **cations**, which carry a positive electrical charge, and **anions**, which carry a negative electrical charge. Although there are many electrolytes in the body, this chapter discusses the most important ones, including sodium (Na⁺), potassium (K⁺), calcium (Ca²⁺), and magnesium (Mg²⁺). These electrolytes are maintained in different concentrations inside the cell and outside the cell because of pumps in the cell wall (Fig. 5-3).

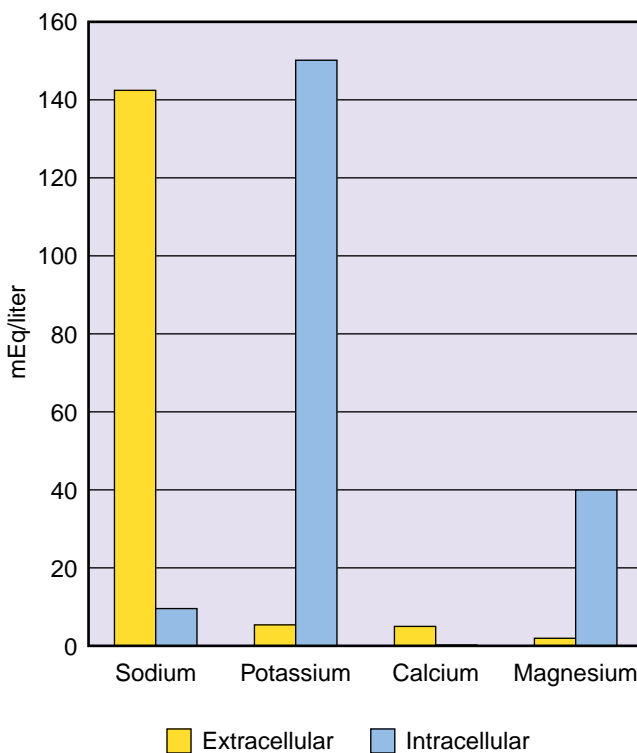

Figure 5-3 Extracellular and intracellular electrolytes.

cation: cat—descending + ion—carrying
anion: an—without + ion—carrying

▶ ELECTROLYTE IMBALANCES

The two types of electrolyte imbalances are deficit and excess. In general, if a patient experiences a deficit of an electrolyte, the electrolyte is replaced either orally or intravenously. If the patient experiences an excess of the electrolyte, treatment focuses on getting rid of the excess, often by the kidneys. The underlying cause of the imbalance must also be treated.

The most important aspect of nursing care is preventing and assessing electrolyte imbalances. High-risk patients should be identified and monitored carefully. Serum electrolytes are measured on a regular basis. As a general rule, patients should be checked for electrolyte imbalance when there is a change in their mental state (either increased irritability or decreased responsiveness) or when their muscles start cramping. Patient education is another important nursing role for patients with electrolyte imbalances.

Sodium Imbalances

The normal level of serum sodium is 135 to 145 mEq/L. Because sodium is the major cation in the blood, it helps maintain serum osmolarity. Therefore sodium imbalances are often associated with fluid imbalances, described earlier in this chapter. Sodium is also important for cell function, especially in the central nervous system. The two sodium imbalances are **hyponatremia** (sodium deficit) and **hypernatremia** (sodium excess).

Hyponatremia

Hyponatremia occurs when the serum sodium level is less than 135 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Many conditions can lead to either an actual or a relative decrease in sodium. In an actual decrease the patient has inadequate intake of sodium or excessive sodium loss from the body. As the percentage of sodium in the ECFs decreases, water is pulled by osmotic pressure into the cells. In a relative decrease the sodium is not lost from the body but leaves the intravascular space and moves into the interstitial tissues (third spacing). Another cause of a relative decrease occurs when the plasma volume increases (fluid overload), causing a dilutional effect. The percentage of sodium compared with the fluid is diminished.

PREVENTION. Additional sodium is commonly administered to patients at high risk for hyponatremia (Box 5–6), usually by the IV route. Individuals who have high fevers or who engage in strenuous exercise or physical labor, especially in the heat, need to replace both sodium and water. Hyponatremia is especially dangerous for the elderly patient.

SIGNS AND SYMPTOMS. Unfortunately, the signs and symptoms of hyponatremia are vague and depend somewhat

hyponatremia: hypo—less than + natr—sodium + emia—blood

hypernatremia: hyper—more than + natr—sodium + emia—blood

BOX 5–6 Patients at High Risk for Hyponatremia

Nothing by mouth (NPO)
Excessive diaphoresis (sweating)
Diuretics
Gastrointestinal suction
Syndrome of inappropriate antidiuretic hormone
Excessive ingestion of hypotonic fluids
Freshwater near-drowning
Decreased aldosterone

on whether a fluid imbalance accompanies the hyponatremia. The patient with sodium and fluid deficits has signs and symptoms of dehydration (discussed earlier). The patient with a sodium deficit and fluid overload has signs and symptoms associated with fluid overload.

In addition, the patient experiences mental status changes, including disorientation, confusion, and personality changes, caused by cerebral edema (fluid around the brain). Weakness, nausea, vomiting, and diarrhea may also occur.

COMPLICATIONS. In severe hyponatremia, respiratory arrest or coma can lead to death. The patient who also has fluid overload may develop pulmonary edema, another life-threatening complication.

DIAGNOSTIC TESTS. The primary diagnostic test is to obtain the serum sodium level, which is lower than the normal value when hyponatremia is present. The serum osmolarity also decreases in patients with hyponatremia. Other laboratory tests may be affected if the patient experiences an accompanying fluid imbalance. Serum chloride (Cl^-), an anion, is often depleted when sodium decreases because these two electrolytes commonly combine as NaCl (salt in solution, or saline).

MEDICAL TREATMENT. Medical treatment focuses on resolving the underlying cause of hyponatremia and replacing the lost sodium. The physician orders IV saline for patients who have hyponatremia without fluid overload. The saline solution given may be isotonic (0.9 percent) or hypertonic (3 percent), depending on the severity of the problem.

For patients who have a fluid overload, a fluid restriction is often ordered. Diuretics that rid the body of fluid but do not cause sodium loss may also be needed. For patients with cerebral edema, steroids may be prescribed to reduce **intracranial** swelling. I&O are strictly monitored, and the patient is weighed daily.

Hypernatremia

Hypernatremia occurs when the serum sodium level is above 145 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Serum sodium increase may be an actual increase or a relative increase. In an

intracranial: intra—within + cranial—cranium (skull)

actual increase the patient receives too much sodium or is unable to excrete sodium, as seen in renal failure. In a relative increase the amount of sodium does not change but the amount of fluid in the intravascular space decreases. The percentage of sodium (solid) is increased in relationship to the amount of plasma (water).

In mild hypernatremia, most excitable tissues, such as muscle and neurons of the brain, become more stimulated. The patient becomes irritable and has tremors. In severe cases, these tissues fail to respond.

PREVENTION. Prevention of hypernatremia is not as simple as prevention of hyponatremia. Most patients have a sodium excess as a result of an acute or chronic illness. Patients with a potential for electrolyte imbalance must always have their IV fluids carefully regulated.

SIGNS AND SYMPTOMS. Thirst is usually one of the first symptoms to appear. If you eat salty foods, such as potato chips, the amount of sodium in the body increases and you become thirsty. Other signs and symptoms of hypernatremia are vague and nonspecific until severe excess is present. Like the patient with a sodium deficit, the patient experiencing sodium excess has mental status changes, such as agitation, confusion, and personality changes. Seizures may also occur.

At first, muscle twitches and unusual contractions may be present. Later, skeletal muscle weakness occurs that can lead to respiratory failure. If fluid deficit or fluid overload accompanies the hypernatremic state, the patient also has signs and symptoms associated with these imbalances.

COMPLICATIONS. The patient experiencing severe hypernatremia may become comatose or have respiratory arrest as skeletal muscles weaken.

DIAGNOSTIC TEST. The most reliable diagnostic test is the serum sodium level, which indicates an increase above the normal level. Serum osmolarity may also increase. If the patient has a fluid imbalance, other laboratory values, such as BUN, hematocrit, and urine specific gravity, are affected (see earlier discussion).

MEDICAL TREATMENT. If a fluid imbalance accompanies hypernatremia, it is treated first. For example, fluid replacement without sodium in a patient with dehydration should correct a relative sodium excess. If the kidneys are not excreting adequate amounts of sodium, diuretics may help if the kidneys are functional. If the kidneys are not functioning properly, dialysis may be ordered. I&O and daily weights are strictly monitored.

The cause of hypernatremia is also treated in an attempt to prevent further episodes of this imbalance. For some patients, a sodium-restricted diet is prescribed.

Potassium Imbalances

Potassium is the most common electrolyte in the ICF compartment. Therefore only a small amount, 3.5 to 5 mEq/L, is found in the bloodstream. Minimal changes in this laboratory value cause major changes in the body.

Potassium is especially important for cardiac muscle, skeletal muscle, and smooth muscle function. As the serum potassium level falls, the body attempts to compensate by moving potassium from the cells into the bloodstream.

The two potassium imbalances are **hypokalemia** (potassium deficit) and **hyperkalemia** (potassium excess). Hypokalemia is the most commonly occurring imbalance.

Hypokalemia

Hypokalemia occurs when the serum potassium level falls below 3.5 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Most cases of hypokalemia result from inadequate intake of potassium or excessive loss of potassium through the kidneys. Hypokalemia most often occurs as a result of medications. Potassium-losing diuretics (e.g., furosemide [Lasix]), digitalis preparations (e.g., digoxin [Lanoxin]), and corticosteroids (e.g., prednisone [Deltasone]) are examples of drugs that cause increased excretion of potassium from the body. Potassium may also be lost through the gastrointestinal (GI) tract, which is rich in potassium and other electrolytes. Severe vomiting, diarrhea, and prolonged GI suction cause hypokalemia. Major surgery and hemorrhage can also lead to potassium deficit.

PREVENTION. Most patients having major surgery receive potassium supplements in their IV fluids to prevent hypokalemia. For patients receiving drugs known to cause hypokalemia, foods high in potassium may prevent a deficit (Box 5–7). Patients receiving digitalis must be closely monitored because hypokalemia can enhance the action of digitalis and cause digitalis toxicity.

SIGNS AND SYMPTOMS. Many body systems are affected by a potassium imbalance. Muscle cramping occurs with either a deficit or an excess of potassium. Vital signs change because the respiratory and cardiovascular systems need potassium to function properly. Skeletal muscle activity diminishes, resulting in shallow, ineffective respirations. The pulse is typically weak, irregular, and thready because the heart muscle is depleted of potassium. A major danger is an irregular heartbeat (**dysrhythmia**), which can lead to a cardiac arrest. Orthostatic (postural) hypotension may also be present.

The nervous system is usually affected as well. The patient experiences changes in mental status, followed by lethargy. The motility of the GI system is slowed, causing nausea, vomiting, abdominal distention, and constipation. Vomiting may further increase potassium loss.

COMPLICATIONS. If not corrected, hypokalemia can result in death from dysrhythmia, respiratory failure and arrest, or

hypokalemia: hypo—less than + kal—potassium + emia—blood

hyperkalemia: hyper—more than + kalpotassium + emia—blood

dysrhythmia: dys—bad or disordered + rhythmia—measured motion

coma. The patient must be treated promptly before these complications occur.

DIAGNOSTIC TESTS. The primary laboratory test is to obtain a serum potassium level. The patient's electrocardiogram (ECG) may show cardiac dysrhythmias associated with potassium deficit. In addition to a decrease in serum potassium level, the patient may have an acid-base imbalance known as metabolic **alkalosis**, which commonly accompanies hypokalemia. In metabolic alkalosis, the serum potential of hydrogen (pH) of the blood increases (above 7.45) so that the blood is more alkaline than usual. Acid-base imbalances are discussed later in this chapter.

alkalosis: alka—alkaline + losis—condition

MEDICAL TREATMENT. The goal of treatment is to replace potassium in the body and resolve the underlying cause of the imbalance. For mild to moderate hypokalemia, oral potassium supplements are given.

For severe hypokalemia, IV potassium supplements are given. Because the kidneys eliminate excess potassium, physicians frequently add potassium to the IV fluids only after the patient has voided. Potassium is a potentially dangerous drug, especially when administered intravenously. In too high a concentration, it causes cardiac arrest. For this reason, most health care facilities do not permit concentrated potassium in patient care areas. The IV container should be changed to one premixed with the proper potassium concentration instead of adding concentrated potassium to the existing container. Potassium is *never* given by IV push. The patient's laboratory values must be monitored carefully to prevent giving too much potassium.

Teach the patient about the side effects of oral potassium and precautions associated with potassium administration. Box 5–8 summarizes the precautions you need to be aware of when giving oral potassium supplements.

Hyperkalemia

Hyperkalemia is a condition in which the serum potassium level exceeds 5 mEq/L. It is rare in a person with healthy kidneys.

PATHOPHYSIOLOGY AND ETIOLOGY. Hyperkalemia may result from an actual increase in the amount of total body potassium or from the movement of intracellular potassium

BOX 5–8 Education Tips for Patients Receiving Oral Potassium Supplements

- Do not substitute one potassium supplement for another.
- Dilute powders and liquids in juice or other desired liquid to improve taste and to prevent gastrointestinal irritation. Follow manufacturer's recommendations for the amount of fluid to use for dilution, most commonly 4 oz per 20 mEq of potassium.
- Do not drink diluted solutions until mixed thoroughly.
- Do not crush potassium tablets, such as Slow-K or K-tab tablets. Read manufacturer's directions regarding which tablets can be crushed.
- Administer slow-release tablets with 8 oz of water to help them dissolve.
- Do not take potassium supplements if taking potassium-sparing diuretics such as spironolactone or triamterene.
- Do not use salt substitutes containing potassium unless prescribed by the physician.
- Take potassium supplements with meals.
- Report adverse effects, such as nausea, vomiting, diarrhea, and abdominal cramping, to the physician.
- Have frequent laboratory testing for potassium levels as recommended by the physician.

Source: Adapted from Lee, CA, Barrett, CA, and Ignatavicius, DD: *Fluids and Electrolytes: A Practical Approach*, ed 4. FA Davis, Philadelphia, 1996.

into the blood. Overuse of potassium-based salt substitutes or excessive intake of oral or IV potassium supplements can cause hyperkalemia. Use of potassium-sparing diuretics (e.g., spironolactone [Aldactone]) may also contribute to hyperkalemia. Patients with renal failure are at risk for hyperkalemia because the kidneys cannot excrete potassium.

Movement of potassium from the cells into the blood and other ECF is common in massive tissue trauma and metabolic **acidosis**. Metabolic acidosis is an acid-base imbalance commonly seen in patients with uncontrolled diabetes mellitus. Acid-base imbalances are discussed later in this chapter.

PREVENTION. For patients receiving potassium supplements, hyperkalemia can be prevented by monitoring serum electrolyte values and the patient's signs and symptoms.

SIGNS AND SYMPTOMS. Most cases of hyperkalemia occur in patients who are hospitalized or those undergoing medical treatment for a chronic condition. The classic manifestations are muscle twitches and cramps, later followed by profound muscular weakness; increased GI motility (diarrhea); slow, irregular heart rate; and decreased blood pressure.

COMPLICATIONS. Cardiac dysrhythmias and respiratory failure can occur in severe hyperkalemia, causing death.

DIAGNOSTIC TESTS. In addition to an elevated serum potassium level, an irregular ECG is associated with hyperkalemia. If the patient also has metabolic acidosis, the serum pH falls below 7.35.

MEDICAL TREATMENT. For mild, chronic hyperkalemia, dietary limitation of potassium-rich foods may be helpful. Potassium supplements are discontinued, and potassium-losing diuretics are given to patients with healthy kidneys. For patients with renal problems, a cation exchange resin, such as sodium polystyrene sulfonate (Kayexalate), is administered either orally or rectally. This drug releases sodium and absorbs potassium for excretion through the feces and out of the body.

In cases in which cellular potassium has moved into the bloodstream, administration of glucose and insulin can facilitate the movement of potassium back into the cells. During treatment of moderate to severe hyperkalemia, the patient should be in the hospital on a cardiac monitor.

Calcium Imbalances

Calcium is a mineral that is primarily stored in bones and teeth. A small amount is found in ECF. The normal value for serum calcium is 9 to 11 mg/dL, or 4.5 to 5.5 mEq/L. Minimal changes in serum calcium levels can have major negative effects in the body.

Calcium is needed for the proper function of excitable tissues, especially cardiac muscle. It is also needed for adequate blood clotting. The two calcium imbalances are **hypocalcemia** and **hypercalcemia**.

Hypocalcemia

Hypocalcemia occurs when the serum calcium falls below 9 mg/dL or 4.5 mEq/L.

PATHOPHYSIOLOGY AND ETIOLOGY. Although calcium deficit can be acute or chronic, most patients develop hypocalcemia slowly as a result of chronic disease or poor intake. The woman who is postmenopausal is most at risk for hypocalcemia. As a woman ages, calcium intake typically declines. The parathyroid glands recognize this decrease and stimulate bone to release some of its stored calcium into the blood for replacement. The result is a condition known as **osteoporosis**, in which bones become porous and brittle and fracture easily. The woman who is postmenopausal has a decreased level of estrogens, hormones that help prevent bone loss in the younger woman. Immobility or decreased mobility also contributes to bone loss in many patients. The patients at highest risk for osteoporosis are thin, petite, Caucasian women.

Hypocalcemia can also result from inadequate absorption of calcium from the intestines, as seen in patients with Crohn's disease, a chronic inflammatory bowel disease. An insufficient intake of vitamin D prevents calcium absorption as well. Conditions that interfere with the production of parathyroid hormone, such as partial or complete surgical removal of the thyroid or parathyroids, can also cause hypocalcemia.

Finally, patients with hyperphosphatemia (usually those with renal failure) often experience hypocalcemia. Calcium and phosphate have an inverse relationship. When one of these electrolytes increases, the other decreases, and vice versa.

PREVENTION. In the United States the typical daily calcium intake is less than 550 mg. The adequate intake (AI) of calcium for adults ages 19 to 50 is 1000 mg; the AI for adults over age 50 is 1200 mg.

Hypocalcemia can be prevented in premenopausal and postmenopausal women by consuming calcium-rich foods and by taking calcium supplements. These supplements can be purchased over the counter in any pharmacy or large food store. An inexpensive source of calcium for patients who do not require vitamin D supplementation is calcium carbonate (Tums), which provides 240 mg of elemental calcium in each tablet.

acidosis: acid—acidic + osis—condition

hypocalcemia: hypo—less than + calc—calcium + emia—blood

hypercalcemia: hyper—more than + calc + calcium + emia—blood

osteoporosis: osteo—bone + porosis—porous

Vitamin D supplementation may be required in addition to calcium for homebound or institutionalized patients who have no exposure to the sun. The ultraviolet light causes the skin to manufacture vitamin D.

SIGNS AND SYMPTOMS. Chronic hypocalcemia is usually not diagnosed until the patient breaks a bone, usually a hip. Acute hypocalcemia, which can occur after surgery or in patients with acute pancreatitis, has several signs and symptoms. These include increased and irregular heart rate, mental status changes, hyperactive deep tendon reflexes, and increased GI motility, including diarrhea and abdominal cramping. Two classic signs that can be used to assess for hypocalcemia are Trousseau's sign and Chvostek's sign.

To test for Trousseau's sign, inflate a blood pressure cuff around the patient's upper arm for 1 to 4 minutes. In a patient with hypocalcemia the hand and fingers become spastic and go into palmar flexion (Fig. 5-4). A positive Chvostek's sign test also indicates calcium deficit. To test for this sign, tap the face just below and in front of the ear. Facial twitching on that side of the face indicates a positive test (Fig. 5-5).

COMPLICATIONS. In severe hypocalcemia, seizures, respiratory failure, or cardiac failure can occur and lead to death if not aggressively treated. The patient may have a sudden laryngospasm that will stop air from entering the patient's lungs.

DIAGNOSTIC TESTS. The patient with hypocalcemia has a lowered serum calcium and an abnormal ECG. The parathyroid hormone level may be increased because it stimulates bone to release more calcium into the blood.

MEDICAL TREATMENT. In addition to treating the cause of hypocalcemia, calcium is replaced. For mild or chronic hypocalcemia, oral calcium supplements with or without vitamin D are given. Calcium supplements should be administered 1 to 2 hours after meals to increase intestinal absorption.

For patients with acute or severe hypocalcemia, IV calcium gluconate or calcium chloride is given. When a pa-

Figure 5-4 Trousseau's sign.

Figure 5-5 Chvostek's sign.

tient has had thyroid or parathyroid surgery, this medication must be readily available for emergency use.

For patients with hyperphosphatemia, usually those with renal failure, aluminum hydroxide is used to bind the excess phosphate for elimination via the GI tract. As the phosphate decreases, the serum calcium begins to increase closer to normal levels.

Diet therapy is an important part of treatment. Teach the patient, family, or other caregiver which foods are high in calcium (Table 5-1). Many foods today are fortified with calcium. Vitamin D foods are also encouraged, especially milk and other dairy products.

Hypercalcemia

Hypercalcemia occurs when the serum calcium is above 11 mg/dL or 5.5 mEq/L.

TABLE 5-1 QUANTITIES OF FOOD CONTAINING CALCIUM EQUAL TO 1 CUP OF MILK, IN ORDER OF ENERGY CONTENT

Food	Amount	Kilocalories
Skim milk	1 c	86
Grated Parmesan cheese	4.3 tbs	99
Plain low-fat yogurt	0.7 c	101
Swiss cheese	1.1 oz	118
2% milk	1 c	121
Whole milk	1 c	150
Cheddar cheese	1.5 oz	171
Processed American cheese	1.7 oz	180
Low-fat yogurt with fruit	0.9 c	199
Blue cheese	2 oz	200
Vanilla milkshake	0.9 c	273
2% low-fat cottage cheese	2 c	410
Hard ice cream, vanilla	1.7 c	459
Soft ice cream	1.3 c	479

CRITICAL THINKING

Mrs. Wright

Mrs. Wright is a 77-year-old petite Caucasian woman who lives alone at home. She is on a fixed income and rarely eats calcium-rich foods. She recently fell and broke her hip. After surgery she returned home under the care of a home health agency.

1. What made the patient at high risk for a fracture?
2. What would you expect her serum calcium level to have been before the fall?
3. What patient teaching related to diet and calcium supplements should the home health care nurse include during his or her home visits?

Answers at end of chapter.

PATHOPHYSIOLOGY AND ETIOLOGY. Chronic hypercalcemia can result from excessive intake of calcium or vitamin D, renal failure, hyperparathyroidism, cancers, and overuse or prolonged use of thiazide diuretics, such as hydrochlorothiazide (HydroDiuril). Acute hypercalcemia can occur as an emergency in patients with invasive or metastatic cancers.

PREVENTION. Although many causes of increased calcium cannot be prevented, a person receiving calcium supplements should be monitored carefully. Some women believe that if 2 or 3 tablets a day is helpful, consuming twice that much will help even more. The result can be serum calcium excess. Educating the public about the proper amount of calcium needed each day and the danger of too much calcium is very important.

SIGNS AND SYMPTOMS. Patients who have mild hypercalcemia or a slowly progressing calcium increase may have no obvious signs and symptoms. However, acute hypercalcemia is associated with increased heart rate and blood pressure, skeletal muscle weakness, and decreased GI motility. The patient also has a decreased blood clotting capability.

COMPLICATIONS. In some cases the patient may experience renal or urinary calculi (stones) resulting from the buildup of calcium. In more severe cases of acute hypercalcemia, the patient may experience respiratory failure caused by profound muscle weakness or heart failure caused by dysrhythmias.

MEDICAL TREATMENT. Patients with severe hypercalcemia should be hospitalized and placed on a cardiac monitor. Unless contraindicated by other conditions, the primary treatment is to give large amounts of fluids and promote diuresis. Saline infusions are the most useful solutions to promote renal excretion of calcium.

The physician also discontinues thiazide diuretics if the patient was receiving them and prescribes diuretics that promote calcium excretion, such as furosemide (Lasix). Other drugs that bind with calcium to lower calcium levels may also be used, such as plicamycin (Mithramycin, Mithracin) and D-penicillamine (Cuprimine).

If hypercalcemia is so severe that cardiac problems are present, hemodialysis, peritoneal dialysis, or ultrafiltration

may be necessary to cleanse the blood of excess calcium. (See Chapter 35 for discussion of these procedures.)

Magnesium Imbalances

Magnesium and calcium work together for the proper functioning of excitable cells, such as cardiac muscle and nerve cells. Therefore an imbalance of magnesium is usually accompanied by an imbalance of calcium.

The normal value for serum magnesium is 1.5 to 2.5 mEq/L. The magnesium imbalances are called **hypomagnesemia** and **hypermagnesemia**.

Hypomagnesemia

Hypomagnesemia occurs when the serum magnesium level falls below 1.5 mEq/L. It results from either a decreased intake or an excessive loss of magnesium. Causes of inadequate intake include malnutrition and starvation diets. Patients with severe diarrhea and Crohn's disease are unable to absorb magnesium in the intestines.

One of the major causes of hypomagnesemia is alcoholism, which causes both a decreased intake and an increased renal excretion of magnesium. Certain drugs, such as loop (high-ceiling) and osmotic diuretics, aminoglycosides (e.g., gentamicin), and some anticancer agents (e.g., cisplatin), can increase renal excretion of magnesium.

The signs and symptoms of hypomagnesemia are similar to those for hypocalcemia, including positive Trousseau's and Chvostek's signs, described earlier in this chapter.

The goal of management is to treat the underlying cause and replace magnesium in the body. Magnesium sulfate is administered intravenously. If the serum calcium is also low, calcium replacement is prescribed. The patient is placed on a cardiac monitor because of magnesium's effect on the heart. Life-threatening dysrhythmias can lead to cardiac failure and arrest.

Hypermagnesemia

Hypermagnesemia results when the serum magnesium level increases above 2.5 mEq/L. The most common cause of hypermagnesemia is increased intake coupled with decreased renal excretion caused by renal failure.

Signs and symptoms are usually not apparent until the serum level is greater than 4 mEq/L. Then the signs and symptoms include bradycardia and other dysrhythmias, hypotension, lethargy or drowsiness, and skeletal muscle weakness. If not treated, the patient experiences coma, respiratory failure, or cardiac failure.

When kidneys are functioning properly, loop diuretics such as furosemide (Lasix) and IV fluids can help increase magnesium excretion. For patients with renal failure, dialysis may be the only option.

hypomagnesemia: hypo—less than + magnes—magnesium + emia—blood

hypermagnesemia: hyper—more than + magnes—magnesium + emia—blood

► ACID-BASE BALANCE

The cells of the body function best when the body fluids and electrolytes are within a very narrow range. Hydrogen (H^+) is another ion that must stay within its normal limits. The amount of hydrogen determines whether a fluid is an acid or base.

An acid is a substance that releases a hydrogen ion. The stronger the acid, the more hydrogen ions are released. A common acid in the body is hydrochloric acid (HCl), which is found in the stomach. A base is a substance that binds hydrogen. A common base in the body is bicarbonate (HCO_3). *Alkali* is another word for base.

Sources of Acids and Bases

Acids and bases are formed in the body as part of normal metabolic processes. Acids are formed as end products of glucose, fat, and protein metabolism. These are called fixed acids because they do not change once they are formed. A weak acid, carbonic acid, can be formed when the carbon dioxide resulting from cellular metabolism combines with water. This acid can again change to bicarbonate (a base) and hydrogen and therefore is not a fixed acid.

The ECF maintains a delicate balance between acids and bases. The strength of the acids and bases can be measured by pH. The pH of a solution can vary from 0 to 14, with 7 being neutral, 0 to 6.99 being acid, and 7.01 to 14 being base, also called alkaline. The normal serum pH is 7.35 to 7.45, or slightly alkaline. It must remain in an extremely narrow range to sustain life. A pH lower than 6.9 or higher than 7.8 is usually fatal.

Control of Acid-Base Balance

As discussed in the sections on fluid and electrolyte balance, the body has several ways in which it tries to compensate for changes in the serum pH. Three major mechanisms are used: cellular buffers, the lungs, and the kidneys.

Cellular buffers are the first to attempt a return of the pH to its normal range. Examples of cellular buffers are proteins, hemoglobin, bicarbonate, and phosphates. These buffers act as a type of sponge to “soak up” extra hydrogen ions if there are too many (too acidic) or release hydrogen ions if there are not enough (too alkaline).

The lungs are the second line of defense to restore normal pH. When the blood is too acidic (pH is decreased), the lungs “blow off” additional carbon dioxide through rapid, deep breathing. This reduces the amount of carbon dioxide available to make carbonic acid in the body. If the blood is too alkaline (pH is increased), the lungs try to conserve carbon dioxide through shallow respirations.

The kidneys are the slowest to respond to changes in serum pH, taking as long as 24 to 48 hours to assist with compensation. The kidneys help in a number of ways, including regulating the amount of bicarbonate (base) that is kept in the body. If the serum pH lowers and becomes too acidic, the kidneys reabsorb additional bicarbonate rather than excreting it so that it can help neutralize the acid. If

the serum pH increases and becomes too alkaline, the kidneys excrete additional bicarbonate to get rid of the extra base. The kidneys also buffer pH by forming acids and ammonium (a base).

Acidosis or alkalosis that is corrected for by the body is referred to as compensated. The pH is returned to normal or near normal, but the PCO_2 and HCO_3 are abnormal.

► ACID-BASE IMBALANCES

Most acid-base imbalances are caused by a number of acute and chronic illnesses or conditions. The primary treatment for each of the imbalances is to manage the underlying cause, which corrects the imbalance. The role of the nurse is to identify patients at risk and monitor laboratory test values for significant changes.

The laboratory tests that are used are called arterial blood gases (ABGs). As the name implies, the blood sample that is analyzed must be from an artery, rather than a vein. The femoral, brachial, and radial arteries are most often used to obtain the sample. Table 5–2 lists these major tests and normal values.

The two broad types of acid-base imbalance are acidosis and alkalosis. Each of these types can occur suddenly, which is called an acute imbalance, or develop over a long period, referred to as a chronic imbalance.

When the serum pH falls below 7.35, the patient has acidosis because the blood becomes more acidic than normal. Too much acid in the body or too little base causes acidosis. Acidosis can be divided into two types: respiratory and metabolic. Respiratory acidosis is caused by problems occurring in the respiratory system. Metabolic acidosis is the result of problems in the rest of the body.

When the serum pH increases above 7.45, the patient has alkalosis because the blood becomes more alkaline or basic. Alkalosis is caused by too little acid in the body or too much base. It can also be divided into two types: respiratory alkalosis and metabolic alkalosis.

Respiratory Acidosis

As the name indicates, the primary cause of this type of acidosis is respiratory problems. Carbon dioxide is not adequately “blown off” during expiration, causing a buildup of carbon dioxide in the blood. As mentioned earlier, carbon dioxide mixes with water to create a weak acid in the body, thus increasing the acidity of the blood.

Acute respiratory acidosis is caused by hypoventilation, usually as a result of an acute flare up of chronic respiratory disease, drugs, or neurological problems that depress breathing. Patients with chronic respiratory disease may have chronic respiratory acidosis.

The signs and symptoms of respiratory acidosis involve the central nervous system and the musculoskeletal system. As carbon dioxide increases, mental status is altered, progressing from confusion and lethargy to stupor and coma if not treated. The lungs are not able to get rid of excess carbon dioxide. Instead respirations become more depressed and shallow as muscle weakness worsens.

TABLE 5-2 ARTERIAL BLOOD GAS VALUES AND CHANGES IN ACID-BASE IMBALANCES

	pH	Pco ₂	Hco ₃
Normal Values	7.35–7.45	32–45 mm Hg	20–26 mEq/L
Respiratory acidosis	Decreased	Increased	Normal
Respiratory acidosis with compensation	Nearly normal	Increased	Increased
Respiratory alkalosis	Increased	Decreased	Normal
Respiratory alkalosis with compensation	Nearly normal	Decreased	Decreased
Metabolic acidosis	Decreased	Normal	Decreased
Metabolic acidosis with compensation	Nearly normal	Decreased	Decreased
Metabolic alkalosis	Increased	Normal	Increased
Metabolic alkalosis with compensation	Nearly normal	Increased	Increased

The treatment of respiratory acidosis is aggressive management of the underlying respiratory problem, discussed in the respiratory unit of this text.

Metabolic Acidosis

Metabolic acidosis can result from too much acid in the body (usually fixed acids) or too little bicarbonate in the body. Uncontrolled diabetes mellitus and end-stage renal failure are the two most common causes of metabolic acidosis resulting from increased fixed acids.

The GI tract is rich in bicarbonate. Patients experiencing severe diarrhea or prolonged nasointestinal suction are at high risk for metabolic acidosis as a result of bicarbonate (base) loss. As seen in Table 5-2, the serum pH decreases and the bicarbonate level decreases. As mentioned earlier in the discussion on hyperkalemia, serum potassium tends to increase in the presence of metabolic acidosis. Excess hydrogen in the ECF moves into the cells in exchange for potassium, which leaves the cells and enters the blood. In a sense, this is a way of compensating for the acidotic state.

The signs and symptoms are similar to those associated with respiratory acidosis, with the exception of the respiratory pattern. To help compensate for the acidotic state, the lungs get rid of extra carbon dioxide through Kussmaul's respirations. Kussmaul's respirations are deep and rapid and can occur only in patients with healthy lungs.

The treatment for the patient with metabolic acidosis is management of the underlying disease or condition. Information about disease management, such as diabetes, is found elsewhere in this book.

Respiratory Alkalosis

Respiratory alkalosis is probably the least common acid-base imbalance. It occurs when there is excessive loss of carbon dioxide through **hyperventilation**. Patients may hyperventilate when they are severely anxious or fearful. Patients who hyperventilate have rapid shallow respirations, are light-headed, and may become confused. The heart rate increases and the pulse becomes weak and thready. The serum pH is increased and the PaCO₂ is very low. Mechanical ventilation can also cause respiratory alkalosis, and it can occur as a result of being at high altitudes.

Respiratory alkalosis is treated by having patients rebreathe their own carbon dioxide with the use of either a rebreathing mask or a plain paper bag. The underlying cause must also be treated.

Metabolic Alkalosis

Metabolic alkalosis results from excessive ingestion of bicarbonate or other bases into the body or loss of acids from the body. Overuse or abuse of antacids or baking soda (sodium bicarbonate) can lead to metabolic alkalosis. Because the stomach contains hydrochloric acid, prolonged vomiting or nasogastric suction can cause loss of acid and also lead to metabolic alkalosis.

The serum pH is increased, as is bicarbonate. As discussed under potassium imbalances, the serum potassium decreases. Hydrogen from the ICF moves into the blood in exchange for potassium, which moves from the blood into the cells. This is one way that the body works to keep an acid-base balance. Hypocalcemia may also accompany hypokalemia.

The signs and symptoms of metabolic alkalosis are related to hypokalemia and hypocalcemia rather than the alkalotic state, itself. Treatment involves identifying the underlying cause and managing it as quickly as possible.

hyperventilation: hyper—more than + ventilation—air

REVIEW QUESTIONS

- Mrs. Rodriguez is a 93-year-old patient with diarrhea and dehydration. She has been admitted to the hospital from an extended care facility. Which of the following symptoms of dehydration do you expect to see?
 - Pale-colored urine, bradycardia
 - Disorientation, poor skin turgor
 - Decreased hematocrit, hypothermia
 - Lung congestion, abdominal discomfort
- Which of the following is the most reliable way to monitor Mrs. Rodriguez's fluid status?
 - I&O
 - Skin turgor
 - Daily weights
 - Lung sounds
- When caring for a patient with fluid overload, which of the following interventions will help relieve respiratory distress?
 - Elevate the head of the bed.
 - Encourage the patient to cough and deep breathe.
 - Increase fluids to promote urine output.
 - Perform percussion and postural drainage.
- Mr. Janes is being treated for hypokalemia. When evaluating his response to potassium replacement therapy, which of the following changes in his assessment should you observe for?
 - Improving visual acuity
 - Worsening constipation
 - Decreasing serum glucose
 - Increasing muscle strength
- Which of the following organ systems is most at risk for life-threatening complications when a patient has hyperkalemia?
 - Cardiovascular
 - Renal
 - Nervous
 - Musculoskeletal
- Which of the following adaptive responses occurs when a patient is in metabolic acidosis?
 - Respiratory depression
 - Kussmaul's respirations
 - Increased urine output
 - Highly concentrated urine

Answers to CRITICAL THINKING

Mrs. Levitt

- Check her weight and compare it with her previous weights. Dehydration is associated with weight loss. Monitor mental status for disorientation. Check skin turgor for tenting. Continue to monitor vital signs.
- Encourage increased fluid intake; notify the RN or physician if Mrs. Levitt is unable to take in additional fluids or if the fluids do not normalize assessment findings.
- S: "My urine smells bad, and my heart is beating fast."
O: Pt's urine is dark amber and strong smelling. VS P 98, BP 126/74, RR 20, T 99.2. Fluids encouraged. RN notified.

Mr. Peters

- Raise the head of the bed to assist breathing.
- Questions to ask might include the following: When did your symptoms begin? Have you had these symptoms before? (If the patient is too dyspneic to answer, do not ask many questions.)

- Check breath sounds for crackles, observe for dependent edema and ascites, observe for distended neck veins, assess skin for color and temperature, check weight and compare with previous weight, and monitor I&O.

Mrs. Wright

- The patient is at high risk for osteoporosis, and thus fracture, because she is an elderly, petite, Caucasian woman.
- Her serum calcium levels should have been lower than normal.
- Teach her about consuming foods high in calcium, teach her about the need to be compliant with taking her calcium supplements, and teach her to take them 1 to 2 hours after meals for best absorption by the body.

QUESTIONS TO GUIDE YOUR READING

1. What is the definition of intravenous therapy?
2. How is the practice of intravenous therapy regulated?
3. What are the indications for intravenous therapy?
4. What are the preferred sites for intravenous therapy?
5. What factors influence the condition, size, and long-term use of veins?
6. What steps are used for insertion of an intravenous catheter?
7. How will you know if your nursing interventions to prevent complications of intravenous therapy are effective?
8. How will you calculate a drip rate for a patient receiving a parenteral solution?
9. What is the difference between isotonic, hypertonic, and hypotonic solutions?
10. How would you explain the basic differences between central venous access devices: percutaneous catheters, peripherally inserted central catheters, tunneled catheters, and implanted ports?

Intravenous (IV) therapy is the administration of fluids or medication via a needle or catheter (**cannula**) directly into the bloodstream. The practice of IV therapy is governed by state nurse practice acts as statutory laws. Some states now include IV therapy within the licensed practical nurse (LPN) and licensed vocational nurse (LVN) roles. The practice acts define the parameters within which individuals are qualified and licensed to practice nursing in

a particular state and serve to codify the nursing obligation to act in the best interest of society.

Various specialty organizations, such as the Infusion Nurses Society (INS), the Centers for Disease Control and Prevention (CDC), the Occupational Safety and Health Administration, and the American Society for Parenteral and Enteral Nutrition (ASPEN), set forth guidelines for standards of practice for infusion therapy.

See <http://www.ins1.org/> for more information about the INS. See <http://www.cdc.gov/niosh/2000-108.html> for information on preventing needlestick injuries. See <http://www.clinnutr.org> for information on ASPEN. See <http://www.oshasafety.com> for information about workplace safety.

intravenous: intra—within + venous—vein
cannula: tube or sheath

► INDICATIONS FOR INTRAVENOUS THERAPY

Patients receive a variety of substances via IV therapy, including fluids, electrolytes, nutrients, blood products, and medications. Patients can receive life-sustaining fluids, electrolytes, and nutrition when they are unable to eat or drink adequate amounts. The IV route also allows rapid delivery of medication in an emergency. Many medications are faster acting and more effective when given via the IV route. Other medications can be administered continuously to maintain a therapeutic blood level. Patients with anemia or blood loss receive lifesaving IV transfusions. Patients who are unable to eat for an extended period can have their nutritional needs met with total parenteral nutrition (TPN).

When a patient needs intermittent rather than continuous IV therapy, access to the venous system can be provided by a locking device whereby an IV catheter is inserted and capped with a port or cap that is resealable. (See the intermittent infusion section later in this chapter.) This is to provide access to the bloodstream for intermittent or emergency medications.

► INTRAVENOUS ACCESS

Intravenous therapy can be administered into the systemic circulation via the peripheral or central veins. Peripheral veins lie beneath the epidermis, dermis, and subcutaneous tissue of the skin. They usually provide easy access to the venous system. Central veins are located close to the heart. Special catheters that end in a large vessel near the heart are called central lines. This chapter primarily discusses peripheral catheters. The definitions of the various central venous access devices are discussed briefly at the end of the chapter.

► ADMINISTERING PERIPHERAL INTRAVENOUS THERAPY

Starting a Peripheral Line

The Phillips 15-step approach to starting a peripheral line offers an organized and thorough method, as described in Table 6-1. Remember to always check your institution's policy before performing any procedure.

Check Physician's Order

A physician's order is necessary to initiate IV therapy. According to the INS, a prescriber's verbal order written by a nurse in the medical record in a hospital setting should be signed by the prescriber within an appropriate time. The order should include solution, volume, rate, and route. If medication is ordered, the order should also include the medication, dosage, and frequency.

Wash Hands

Before beginning the procedure, wash your hands for 15 to 20 seconds. Wear gloves when inserting the needle and any time you have a risk of exposure to body fluid.

TABLE 6-1 PHILLIPS 15-STEP METHOD FOR STARTING A PERIPHERAL LINE

Phase	Step
Precannulation (preparation)	1. Check physician's order.
	2. Wash your hands for 15 to 20 seconds.
	3. Prepare the equipment.
	4. Assess the patient.
	5. Select the site and dilate the vein.
Cannulation (venipuncture)	6. Select the needle (catheter).
	7. Put on gloves.
	8. Prepare the site.
	9. Enter the vein using the direct or indirect method.
	10. Stabilize the catheter with tape, and apply a dressing.
Postcannulation (cleanup)	11. Label the site, tubing, and bag.
	12. Properly dispose of used equipment.
	13. Educate the patient.
	14. Calculate the drip rate, if applicable.
	15. Document the procedure.

Source: Phillips, L: Manual of IV therapeutics (3rd ed.). FA Davis, Philadelphia, 2001.

Gather Equipment

Obtain the following equipment and inspect it for integrity:

- Clean gloves
- Prepping solution (70 percent isopropyl alcohol, povidone-iodine, tincture of iodine 2 percent, or chlorhexidine)
- Sterile 2-inch by 2-inch gauze pads
- ½-inch or 1-inch tape
- Disposable latex tourniquet
- Cannulas (over-the-needle sizes 18, 20, 22, and 24 are the most common)
- Appropriate administration set
- IV solution (inspected for puncture holes, visible contamination, and expiration date)
- PRN device (locking device) if the catheter is maintained as a saline lock
- IV pole if needed

Some institutions have IV start kits that contain a tourniquet, gloves, alcohol, bandages, and prepping solution.

Once the solution is verified and inspected for integrity, the administration set is spiked to puncture the solution bag or bottle, taking care to keep the spike and the bag opening sterile. The administration set is then primed with the IV solution ordered by the physician.

Assess and Prepare Patient

Several factors should be considered before venipuncture. The type of solution, condition of vein, duration of therapy, cannula size needed, patient age, patient activity, presence of disease or previous surgery, presence of a dialysis shunt or graft, medications being taken by the patient (such as anticoagulants), and allergies must be assessed before a venipuncture. Provide privacy for the procedure, explain

the procedure to the patient, and evaluate the patient's knowledge of the procedure by talking with the patient before assessing the upper arms for suitable venipuncture sites.

Select Site and Dilate Vein

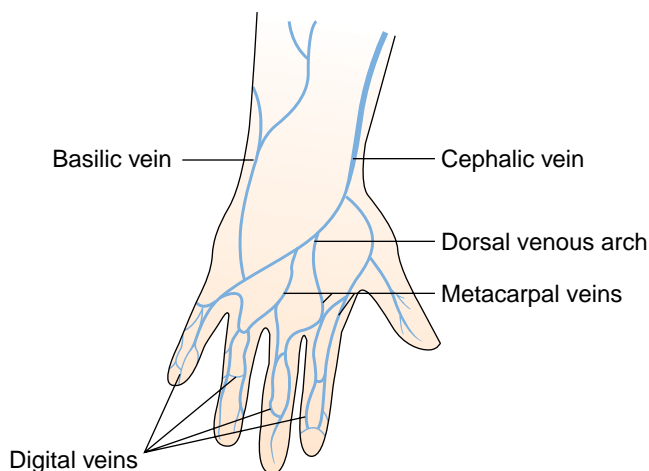

Proper vein selection is important to accommodate the prescribed therapy and to minimize potential complications (Box 6-1). Avoid use of an arm on the side where the patient has had a mastectomy, has a dialysis access site, or is scheduled for a surgical procedure. The patient's condition and diagnosis, age, vein condition, size, location, and type and duration of therapy should be considered before initiation of intravenous therapy (Box 6-2). The vein should be able to accommodate the gauge and length of catheter used.

Hand veins are used first if long-term intravenous therapy is expected (Cultural Consideration 6-3). This allows each successive venipuncture to be made proximal to the site of the previous one, which eliminates the passage of irritating fluids through a previously injured vein and dis-

courages leakage through old puncture sites. Hand veins can be used successfully for most hydrating solutions, but they are best avoided when irritating solutions of potassium or antibiotics are anticipated.

Vein size must also be considered. Small veins do not tolerate large volumes of fluid, high infusion rates, or irritating solutions. Large veins should be used for these purposes. Figure 6-1 shows peripheral veins that may be used for IV therapy.

If veins are constricted, venipuncture is more difficult. Fever, anxiety, and cold temperatures can cause veins to constrict. Smoking before the insertion of an IV line also causes veins to constrict.

BOX 6-1 Considerations for Vein Selection

- Age of patient
- Availability of sites
- Size of catheter to be used
- Purpose of infusion therapy
- Osmolarity of solution to be infused
- Volume, rate, and length of infusion
- Degree of mobility desired

BOX 6-2 General Considerations When Initiating Intravenous Therapy

1. Use veins in the upper part of the body.
2. When multiple sticks are anticipated, make the first venipuncture distally and work proximal with subsequent punctures.
3. If therapy will be prescribed for longer than 3 weeks, a long-term access device should be considered.
4. Avoid using venipunctures in affected arms of patients with radical mastectomies or a dialysis access site.
5. If possible, avoid taking a blood pressure on the arm receiving an infusion because the cuff interferes with blood flow and forces blood back into the needle. This may cause a clot or cause the vein or catheter to rupture.
6. No more than two attempts should be made at venipuncture before getting help.
7. Immobilizers should not be placed on or above an infusion site.

BOX 6-3 CULTURAL CONSIDERATION

Among the Vietnamese, the head is considered sacred. Thus the practice of starting IV lines in the scalp may cause a Vietnamese patient significant anxiety. If the patient must have an IV line in the scalp, carefully explain the necessity for it.

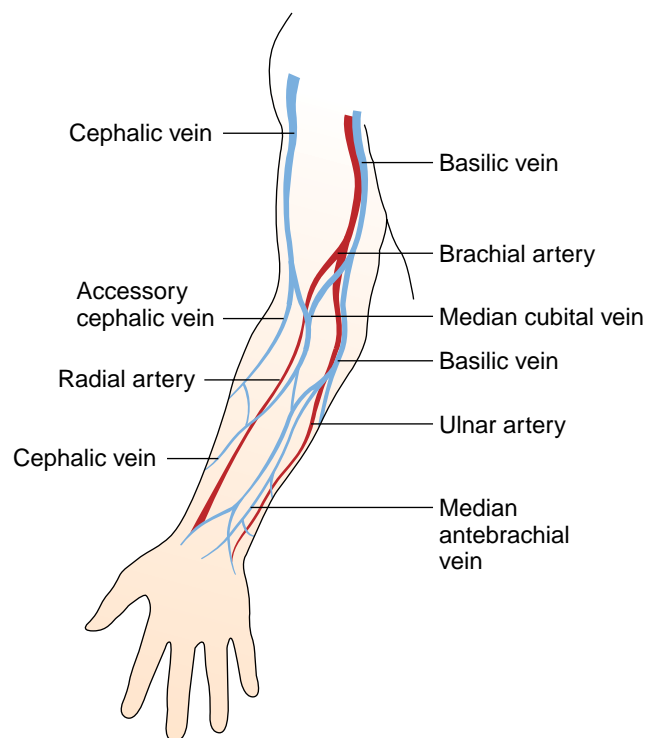

Figure 6-1 Peripheral veins used for IV therapy. (Modified from Phillips, L: Manual of IV therapeutics [3rd ed.]. FA Davis, Philadelphia, 2001.)

DILATE VEIN. A tourniquet helps to dilate and stabilize the vein, easing venipuncture and threading of the catheter. Place the tourniquet 6 to 8 inches above the insertion site. If the tourniquet is too close to the insertion site, it will create too much pressure and cause the vein to burst. The tourniquet should be tight enough to impede venous flow while maintaining arterial flow. A tourniquet should be at least 1 inch wide and should not be left on for more than 3 minutes to prevent impaired blood flow to the extremity.

Occasionally, additional techniques are necessary to distend the vein. Placing the arm in a dependent position or placing a warm towel over the site for several minutes before applying the tourniquet help to dilate a vein. The whole extremity must be warmed to improve blood flow to the area. Opening and closing the fist pumps blood to the extremity and increases blood flow to help dilate the vein. A blood pressure cuff inflated to 30 mm Hg is an appropriate method for vein dilation, especially with fragile veins in the elderly.

Choose the Cannula

Needles have been largely replaced with flexible plastic catheters, or cannulas, that are inserted over a needle (Fig. 6–2). The needle (or stylet) is removed after the catheter is in place. These are available in a variety of sizes (gauges) and lengths. For patient comfort, choose the smallest-gauge catheter that will work for the intended purpose. Use smaller-gauge needles (20 to 24 gauge) for fluids and slow infusion rates. Use larger needles (18 gauge) for rapid fluid administration and viscous solutions such as blood. Also consider vein size when choosing a catheter gauge. Refer to institution policy and equipment stock for specific recommendations. Keep in mind that the INS recommends that short peripheral catheters be removed every 72 hours and immediately upon suspected contamination.

Gloves

The CDC recommends following standard precautions whenever exposure to blood or body fluids is likely. Wearing latex or vinyl gloves provides basic protection from blood and body fluids.

Prepare the Site

Clean the peripheral insertion site with an antimicrobial solution before cannula placement. If the skin is dirty, it should be washed with soap and water before application of the antimicrobial solution. If the patient has excess hair, it can be clipped with scissors. Be sure to follow institution policy when choosing a solution. Most institutions use an alcohol- or iodine-based product. Avoid using alcohol after an iodine preparation because alcohol negates the effect of iodine.

Apply the solution in a circular motion, starting at the intended site and working outward to clean an area 2 to 3 inches in diameter. If alcohol is used, it should be applied with friction for at least 30 seconds or until the final applicator is visually clean. Blotting of excess solution at the insertion site is not recommended. Allow the solution to air dry completely.

Insert the Cannula

Venipuncture can be performed using a direct (one-step) or indirect (two-step) method. The direct method is appropriate for small-gauge needles, fragile hand veins, or rolling veins. The indirect method can be used for all venipunctures.

Hold the catheter with the bevel (slanted opening) of the needle facing up. With the tourniquet in place, enter the vein using either the direct or indirect approach. When using the direct entry approach, hold the needle at a 30- to 45-degree angle directly above the vein and then penetrate the skin and vein in one motion (Fig. 6–3). When using some newer catheters, the angle of insertion is minimal.

The indirect approach may help decrease vein collapse. To use it, hold the needle at a 30- to 45-degree angle over the skin next to (not over) the vein. Once the skin is punctured, lower the needle angle and locate and puncture the vein. Depending on the type of device used, a small flash of blood may be seen in the tubing or at the hub of the catheter when the needle is in the vein. The angle of the

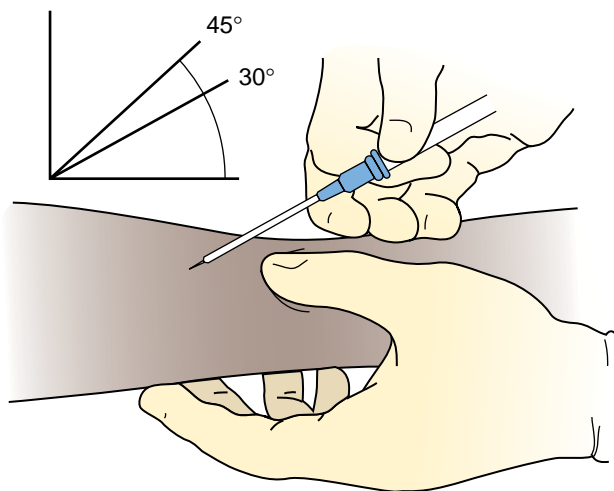

Figure 6-3 Insert the needle of choice bevel up at a 30- to 45-degree angle, depending on the vein location and catheter.

needle is then lowered so that it is parallel with the skin as it is threaded into the lumen of the vein. If a catheter-over-needle device is used, the needle is advanced one-fourth inch and then the catheter is advanced for its remaining length as the metal needle (stylet) is withdrawn.

The tourniquet is then released, and the IV solution or injection cap is connected to the hub of the catheter. Blood may ooze from the hub at this time. If an injection cap is being used, the catheter is flushed with 0.9 percent sodium chloride solution to check for patency. A smooth, easy flush and no signs of infiltration indicate that the catheter is patent and that the prescribed solution can be administered.

LEARNING TIPS

Use traction (a downward pulling motion to make the skin taut below the puncture site) before venipuncture to stabilize the skin and prevent the vein from rolling during venipuncture (Fig. 6-4).

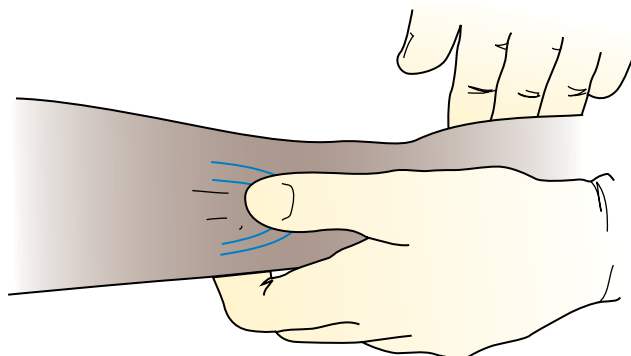

Figure 6-4 Pull skin below the intended puncture site using a downward motion to stabilize the skin and prevent the vein from rolling.

Stabilize the Cannula and Dress the Site

A common problem in IV therapy is dislodgement of the cannula. Secure taping keeps the catheter in place and stable, thus preventing complications caused by damage to the intima of the vein. There are several different techniques for taping a cannula securely, including the U, H, and chevron methods (Fig. 6-5). Take care to apply tape in a manner that does not constrict blood flow to the extremity.

A transparent, semipermeable membrane dressing allows the nurse to stabilize the cannula and monitor the venipuncture site for redness or swelling and provides an occlusive dressing for the site. Another acceptable method of dressing management is the use of sterile 2-inch by 2-inch gauze over the venipuncture site and a piece of 1-inch tape over the gauze. Band-Aids are not acceptable dressings over catheters.

Arm boards are not used routinely. However, if a confused patient places the IV site in danger, the extremity can be immobilized as a last resort; this requires a physician's order.

Label the Site

The IV setup should be labeled in three areas: the insertion site, the tubing, and the solution container. Once the venipuncture procedure is completed, label the setup with the date, time, catheter type and size, and your initials.

Use for Winged Set Use for Winged Set Use for Winged Set

Place over the wings to stabilize wings and hub. | <ol style="list-style-type: none"> 1. Cover the venipuncture with transparent dressing or 2 x 2 gauze dressing. 2. Cut a long 5- to 6-in strip of 1/2-in tape. Place one strip of tape, sticky side under hub, parallel with the dressing. 3. Cross the end of the tape over the opposite side of the needle so that the tape sticks to the patient's skin. 4. Apply a piece of 1-in tape across the wings of the chevron. Loop the tubing and secure it with another piece of 1-in tape. |
|---|---|---|

*For all methods, include on the last piece of tape the date, time of insertion, size of gauge, length of needle or catheter, and your initials.

Figure 6-5 Taping techniques for IV access devices. (From Phillips, L: Manual of IV therapeutics [3rd ed.]. FA Davis, Philadelphia, 2001.)

Dispose of Equipment

All needles and blood-contaminated equipment should be disposed of according to institution policy in a tamper-proof, nonpermeable container.

Educate Patient

Patients have the right to receive information on all aspects of their care in a manner they can understand. They also have the right to accept or refuse treatment.

Calculate Drip Rate

All IV infusions should be monitored frequently for accurate flow rates and complications associated with infusion therapy. (See the section on calculating drip rates later in this chapter.)

Document

Documentation is noted in the medical record according to institution policy. All IV solutions are also documented on the medication administration record in the medical record. Document the following:

- Date and time of insertion
- Manufacturer's brand name and style of device
- Gauge and length of the device
- Location of the accessed vein
- Solution infusing and rate of flow
- Method of infusion (gravity or pump)
- Number of attempts needed for a successful IV start
- Patient's specific comments related to the procedure
- Signature

CRITICAL THINKING

Insertion of a Peripheral Line

A patient is admitted with a diagnosis of symptomatic anemia and has an atrioventricular (AV) shunt in the left arm. An IV line is ordered for administration of two units of packed red blood cells. What must be taken into consideration when assessing the patient for an appropriate venipuncture site?

Answers at end of chapter.

▶ TYPES OF INFUSIONS

Continuous

In a continuous infusion, the physician orders the infusion in milliliters to be delivered over a specific amount of time. The infusion is kept running constantly until discontinued by the physician. An IV controller or roller clamp allows the solution to infuse at a constant rate.

Intermittent Infusion

Intermittent IV lines are “capped off” with an injection port and used only periodically. Thus intermittent IV therapy is administered at prescribed intervals. Patency must be ensured before an intermittent site is used to inject a drug

or solution. Check for backflow of blood in the syringe before injection.

Sites that are capped with an injection cap are called saline or heparin locks. A diluted solution of heparin, an anticoagulant, may be used to flush the needle after each use and every 8 hours or according to institution policy. However, many institutions are changing this practice and specifying saline solution for flushes, which is believed to be safer and less costly. In *2000 Standards of Practice*,² the INS recommends the use of saline (0.9 percent sodium chloride) solution for maintaining peripheral locking devices, whereas heparin is recommended for central venous access devices. Check your institution's policy and guidelines.

LEARNING TIPS

Always check for catheter patency before injecting any substance into the circulatory system.

Regular flushing ensures cannula patency. Flushing also prevents the mixing of incompatible medications and solutions. Positive pressure must be maintained in the lumen of the catheter during the administration of the flush solution to prevent a backflow of blood into the cannula lumen. This is accomplished by continuing to slowly inject the saline or heparin solution even as the needle is withdrawn from the cap. Intermittent cannulas should be flushed after administration of IV medication, blood sampling, and conversion from continuous to intermittent IV therapy.

If resistance is met while a cannula is being flushed, a clot may be occluding the cannula. Do not exert pressure in an attempt to restore patency because doing so may dislodge the clot into the vascular system or rupture the catheter.

Some medications that are given intermittently are not compatible with heparin and therefore are given by the sodium chloride administration (of drug) sodium chloride heparin (SASH) method:

1. Flush with **S**aline solution.
2. Administer the medication.
3. Flush with **S**aline solution.
4. Flush with **H**eparin solution.

Bolus

A **bolus** drug (sometimes called an IV push [IVP] drug) is injected slowly via a syringe into the IV site or tubing port. It provides a rapid effect because it is delivered directly into the patient's bloodstream. Bolus drugs can be dangerous if they are given incorrectly, and a drug reference should always be checked to determine the safe amount of time over which the drug can be injected. IV push drugs are administered by registered nurses (RNs) and are not within the

bolus: mass or lump

scope of practice of the LPN/LVN. However, you should be aware of the drugs being given and should observe the patient for desired or adverse effects.

► METHODS OF INFUSION

Gravity Drip

Gravity is often used to drip a solution into a vein (Fig. 6–6). The solution is positioned about 3 feet above the infusion site. If it is positioned too high above the patient, the infusion may run too fast. Positioned too low, it may run too slowly. Flow is controlled with a roller, screw, or slide clamp. A mechanical flow device can be added to achieve accurate delivery of fluid with minimal deviation.

Calculating Drip Rates

When using a gravity set, the nurse must calculate the drops required per minute to deliver fluid at the ordered rate. Commercial parenteral administration sets vary in the number of drops delivering 1 mL. Sets typically deliver 10, 15, 20, or 60 drops per mL of fluid. For example, to deliver 100 mL per hour using a set with 10 drop factor tubing, a flow rate of 17 drops per minute is necessary. To administer the same amount using a set with 15 drop factor tubing, a flow rate of 25 drops per minute is necessary. Check the manufacturer's instructions on the administration set to determine how many drops per milliliter (drop factor) are delivered by the set. Sets delivering 60 drops per milliliter are

called minidrip or microdrip sets and are used for solutions that need to be infused slowly.

To determine drops per minute of an IV solution, the nurse needs to know the amount of fluid to be given in a specified time interval and the drop factor of the administration set to be used. The formula for determining drops per minute is as follows:

$$\frac{\text{mL per hour} \times \text{drops per mL (drop factor)}}{60 \text{ (minutes per hour)}} = \text{drops per minute}$$

Sample Problem: A physician orders 1000 mL of 5 percent dextrose in water to be infused at 125 mL per hour. You have on hand an administration set that delivers 10 drops per 1 mL.

Formula:

$$\frac{125 \text{ mL} \times (\text{drop factor})}{60} = \text{drops per minute}$$

$$\text{Step 1: } \frac{125 \times 10}{60} = \text{drops per minute}$$

$$\text{Step 2: } \frac{125}{6} = 21 \text{ drops per minute}$$

Factors Affecting Flow Rates

CHANGE IN CATHETER POSITION. A change in the catheter's position may push the bevel either against the wall of the vein, which will decrease the flow rate, or away from the wall of the vein, which may increase the flow rate. Careful taping and avoidance of joint flexion above the site minimizes this problem.

HEIGHT OF THE SOLUTION. Because infusions flow by gravity, a change in the height of the infusion bottle or a change in the level of the bed can increase or decrease the flow rate. The flow rate increases as the distance between the solution and the patient increases. A patient may alter the flow rate greatly simply by standing up. The ideal height for a solution is 3 feet above the level of the heart.

PATENCY OF THE CATHETER. A small clot or fibrin sheath may occlude the needle lumen and decrease or stop the flow rate. Clot formation can result from irritation, increased venous pressure, or backup of blood into the line. Avoid use of a blood pressure cuff on the affected extremity because of the resulting transient increase in venous pressure. A regular flush schedule helps maintain patency.

Electronic Control Devices

Electronic pumps and controllers regulate the rate of infusion (Fig. 6–7). Controllers measure the amount of solution delivered and depend on gravity to deliver the infusion. Pumps use positive pressure to deliver the solution. Pumps are often used for central lines to help overcome the high pressure of the central circulation.

Pumps and controllers are used for the infusion of precise volumes of solution. Institution policy often dictates use of controllers for infusion of potent medications, such as heparin, concentrated morphine, and chemotherapy solutions,

Figure 6-6 Gravity drip setup with piggyback infusion.

Figure 6-7 Infusion pump: LIFECARE 5000. (Courtesy Abbott Laboratories Hospital Products Division, North Chicago, Ill.)

and for very fast or slow rates. Some electronic infusion devices are portable and are designed to be worn on the body. These are called ambulatory infusion devices. It is important to know the type of pump being used and its manufacturer's guidelines.

Filters

It is recommended by the Infusion Nursing Standards of Practice that filters be used routinely for the delivery of IV therapy. Filters fit onto the IV tubing between the solution and the insertion site and remove contaminants from the IV fluid. A 0.22-micron filter removes bacteria and fungi from IV fluids. Check institution policy and manufacturers' guidelines for use of filters.

► TYPES OF FLUIDS

Fluids and electrolytes administered intravenously pass directly into the plasma space of the extracellular fluid compartment. They are then absorbed based on the characteristics of the fluid and the hydration status of the patient. The most commonly infused fluids are dextrose and sodium solutions. These are called crystalloid solutions.

Dextrose Solutions

Dextrose in water is available in many concentrations and provides carbohydrates in a readily usable form. Solutions of 2.5 percent, 5 percent, and 10 percent dextrose in water are used for peripheral infusions. Concentrations of 20 percent and above must be given into a large vein and are infused via a central line. These high concentrations can be used for treating hypoglycemia or in combination with TPN because they supply a large number of calories.

Sodium Chloride Solutions

Sodium chloride solutions are available in concentrations of 0.25 percent, 0.33 percent, 0.45 percent, 0.9 percent (normal saline solution), 3 percent, and 5 percent. Combination dextrose and sodium chloride solutions, such as 5 percent dextrose with 0.45 percent sodium chloride (often referred to as "D5 and a half"), are commonly used.

Electrolyte Solutions

Electrolyte solutions are used to replace lost fluids and electrolytes. Lactated Ringer's solution is an example of a pre-mixed electrolyte solution. Potassium is an electrolyte that is commonly added to a solution to replace deficits. Potassium is limited to 10 to 20 mEq per hour and is never administered as an IV bolus because of the risk of cardiac complications.

Tonicity of IV Solutions

Intravenous fluids may be classified as **isotonic**, **hypotonic**, or **hypertonic**. (See Chapter 5 to review these concepts.) Isotonic fluids have the same concentration of solutes to water as body fluids. Hypertonic solutions have more solutes (i.e., are more concentrated) than body fluids. Hypotonic solutions have fewer solutes (i.e., are less concentrated) than body fluids. Water moves from areas of lesser concentration to areas of greater concentration. Therefore hypotonic solutions send water into areas of greater concentration (cells), and hypertonic solutions pull water from the more highly concentrated cells.

Isotonic Solutions

Normal saline (0.9 percent sodium chloride) solution is an isotonic solution that has the same tonicity as body fluid. When administered to a patient requiring water, it neither enters cells nor pulls water from cells; it therefore expands the extracellular fluid volume. A solution of 5 percent dextrose in water (D5W) is also isotonic when infused, but the dextrose is quickly metabolized, making the solution hypotonic.

Hypotonic Solutions

Hypotonic fluids are used when fluid is needed to enter the cells, as in the patient with cellular dehydration. They are also used as fluid maintenance therapy. An example of a hypotonic solution is 0.45 percent sodium chloride solution.

Hypertonic Solutions

Examples of hypertonic solutions include 5 percent dextrose in 0.45 percent sodium chloride, 5 percent dextrose in 0.9 percent sodium chloride, and 5 percent dextrose in lactated Ringer's solution. Hypertonic solutions are used to ex-

isotonic: iso—equal + tonic—tension or tone
hypotonic: hypo—deficient + tonic—tension or tone
hypertonic: hyper—excessive + tonic—tension or tone

pand the plasma volume, as in the hypovolemic patient. They are also used to replace electrolytes.

► NURSING PROCESS FOR THE PATIENT RECEIVING IV THERAPY

Assessment

A patient receiving IV therapy is assessed routinely. IV therapy is a medical intervention, and the nurse is responsible primarily for appropriate monitoring, documenting, and reporting related to the therapeutic goals. Some institution policies require assessment as often as every hour. Assessment should be systematic and thorough. It begins with observation and evaluation of the patient for signs of fluid imbalance. This is especially important when caring for an older patient (Gerontological Issues Box 6-4). Daily weighing and measuring of intake and output help determine whether the patient is retaining too much fluid. Skin turgor, mucous membrane moisture, vital signs, and level of consciousness also indicate hydration status. New onset of fine crackles in the lungs can indicate fluid retention. Table 6-2

BOX 6-4 GERONTOLOGICAL ISSUES

Care of the Patient with Intravenous Therapy

When an older patient is receiving fluids intravenously, the nurse must regularly assess the patient for potential fluid volume excess. Symptoms of fluid volume excess include:

- elevated blood pressure.
- full bounding pulse.
- shallow but rapid respirations.
- jugular-venous distention.
- increased urine output.
- lung sounds—moist crackles related to pulmonary edema.

If these signs are present:

- immediately turn down IV to a minimum drip rate (1 mL per minute); do not discontinue or shut IV off because the physician may want to administer IV diuretics.
- Position the patient to maximize lung expansion.
- Check peripheral oxygen perfusion with an oximeter.
- Start emergency oxygen per mask or nasal cannula if indicated.
- Closely monitor patient's vital signs, level of consciousness, and oxygen perfusion along with fluid output.
- Assist the physician or RN with IV push administration of diuretic medication such as furosemide if ordered.

extravasation: extra—outside + vas—vessel + tion—condition

TABLE 6-2 COMPLICATIONS OF INTRAVENOUS THERAPY

Local Complications	Symptoms	Prevention	Treatment
Phlebitis (inflammation of vein)	Pain and erythema at insertion site	Anchor cannula well. Avoid insertion near joint. Dilute medication. Use large veins. Use an in-line filter.	Remove cannula. Restart in new site.
Infiltration (solution leaks out of the vein into tissues)	Insertion site puffy and cool	Monitor patency of intravenous line. Check for blood return if unsure.	Stop the infusion. Apply warm compresses. Elevate extremity. Restart in new site.
Extravasation—infiltration of a vesicant (drug that causes tissue necrosis)	Redness, edema, exudate at site	Strict aseptic technique during insertion and site care. Inspect fluid before hanging.	Discontinue infusion. Replace in new site.
Infection	Serious local tissue necrosis or death of the surrounding tissue; pain	Check that IV line is patent with blood return before and during vesicant drug infusion.	Stop infusion immediately. Follow institution policy. Many have extravasation kits. Pharmacist can provide information related to specific drug.
Pain (can occur with some medications even if IV is patent)	Complaint of discomfort at or above infusion site	Check manufacturer recommendations for specific drugs.	Obtain physician order to slow infusion, dilute medication, or add lidocaine.
Systemic Complications	Symptoms	Prevention	Treatment
Circulatory overload (fluid administered too fast or too much)	Dyspnea, new-onset crackles, bounding pulse, intake greater than output	Monitor flow rate, lung sounds, and intake and output. Use controller in elderly patients.	Raise head of bed. Reduce flow rate and contact physician.
Infection (septicemia)	Fever, chills, thready pulse, tachycardia	Follow strict aseptic technique at all times. Inspect all fluids and equipment before infusion.	Discontinue infusion. Be prepared to send catheter and tubing to laboratory for culture. Culture IV site if ordered by physician.
Pulmonary embolism (clot or particle in pulmonary artery)	Shortness of breath, feeling of panic, chest pain, bloody sputum	Never irrigate a plugged cannula. Inspect all fluids for particles.	Notify physician for emergency treatment. Administer IV anticoagulants per order.

TABLE 6-2 COMPLICATIONS OF INTRAVENOUS THERAPY — CONT'D

Systemic Complications	Symptoms	Prevention	Treatment
Air embolism (air in bloodstream)	Cyanosis; hypotension; weak, rapid pulse; loss of consciousness	Inspect tubing for cracks, poor connections, other places where air could enter. Highest risk in central lines.	Clamp tubing. Administer oxygen. Place patient on left side with head down to allow air to rise into the right atrium and be excreted via pulmonary circulation.
Speed shock (shock symptoms from infusing drug too rapidly)	Syncope, flushing, headache, chest pain, hypotension, respiratory distress, cardiac arrest	Check drug manufacturer recommendations for proper dilution and rate of administration. Use IV controllers.	Discontinue infusion. Contact physician or pharmacist for treatment for specific drug.
Incompatibility (two drugs do not dissolve together)	Symptoms of embolism	Check drug reference or pharmacist before mixing medications or infusing via same IV tubing. If a precipitate is noted in tubing, do not infuse.	Notify physician and pharmacist for drug-specific remedy.

lists other symptoms of complications, along with prevention and treatment strategies.

Inspection of the site for redness or swelling and evaluation of the integrity of the dressing should be documented. Inspect the tubing to ensure tight connections and the absence of kinks or defects. Inspect the solution container and compare it with the physician's order for type, amount, and rate. Report complications to the RN or physician.

Nursing Diagnosis, Planning, and Implementation

All patients receiving IV therapy have a risk for complications. Monitor each patient carefully for the onset of complications, and report them promptly to the RN. Patients also may experience some anxiety related to IV therapy. Patient education may help alleviate anxiety. The RN is responsible for explaining the actions of and rationale for therapy.

Evaluation

The RN is responsible for evaluation and thus monitors the patient for evidence that the goals of therapy are being met and that complications are avoided. The LPN/LVN collects data that contribute to the evaluation. For example, if antibiotic therapy is administered, monitor the patient's temperature and other signs that the infection is resolving. If IV therapy is ordered to correct dehydration, monitor skin turgor, vital signs, and other appropriate signs of improved fluid balance. Document all findings and report them to the RN.

CRITICAL THINKING

Blood in IV Tubing

You have walked into the room of a patient whose IV has blood backed up in the tubing. When you open the clamp to increase the flow, nothing happens. What should you do?

Answer at end of chapter.

► COMPLICATIONS OF IV THERAPY

See Table 6-2 for complications, their prevention, and treatment. Any complication or unusual incident should be reported to the physician, and an incident report should be prepared according to institution policy. This applies to the hospital and the home situation.

CRITICAL THINKING

Complications of IV Therapy

A patient is receiving 5 percent dextrose in water at 83 mL per hour. One hour after the infusion starts, the patient complains of pain at the site. The site is cool to the touch and swollen, and the infusion rate is sluggish.

1. What might be happening?
2. How do you further assess the patient?
3. What action do you take?
4. How should you document your findings?

Answers at end of chapter.

► ALTERNATIVE ACCESS ROUTES

The role of the LPN/LVN in central venous access in most states is limited to assisting the RN with assessments. It is important for you to be able to recognize the different central venous access devices.

Central Venous Catheters

Central venous catheters terminate in the superior vena cava near the heart (Fig. 6-8). They are used when peripheral sites are inadequate or when large amounts of fluid or irritating medication must be given. Central catheter devices include a percutaneous catheter, peripherally inserted central catheter (PICC), tunneled catheter, and implanted port. These devices can have one, two, or three lumens in the catheter or one or more port chambers. Each lumen exits the site in a separate line, called a tail. Multilumen

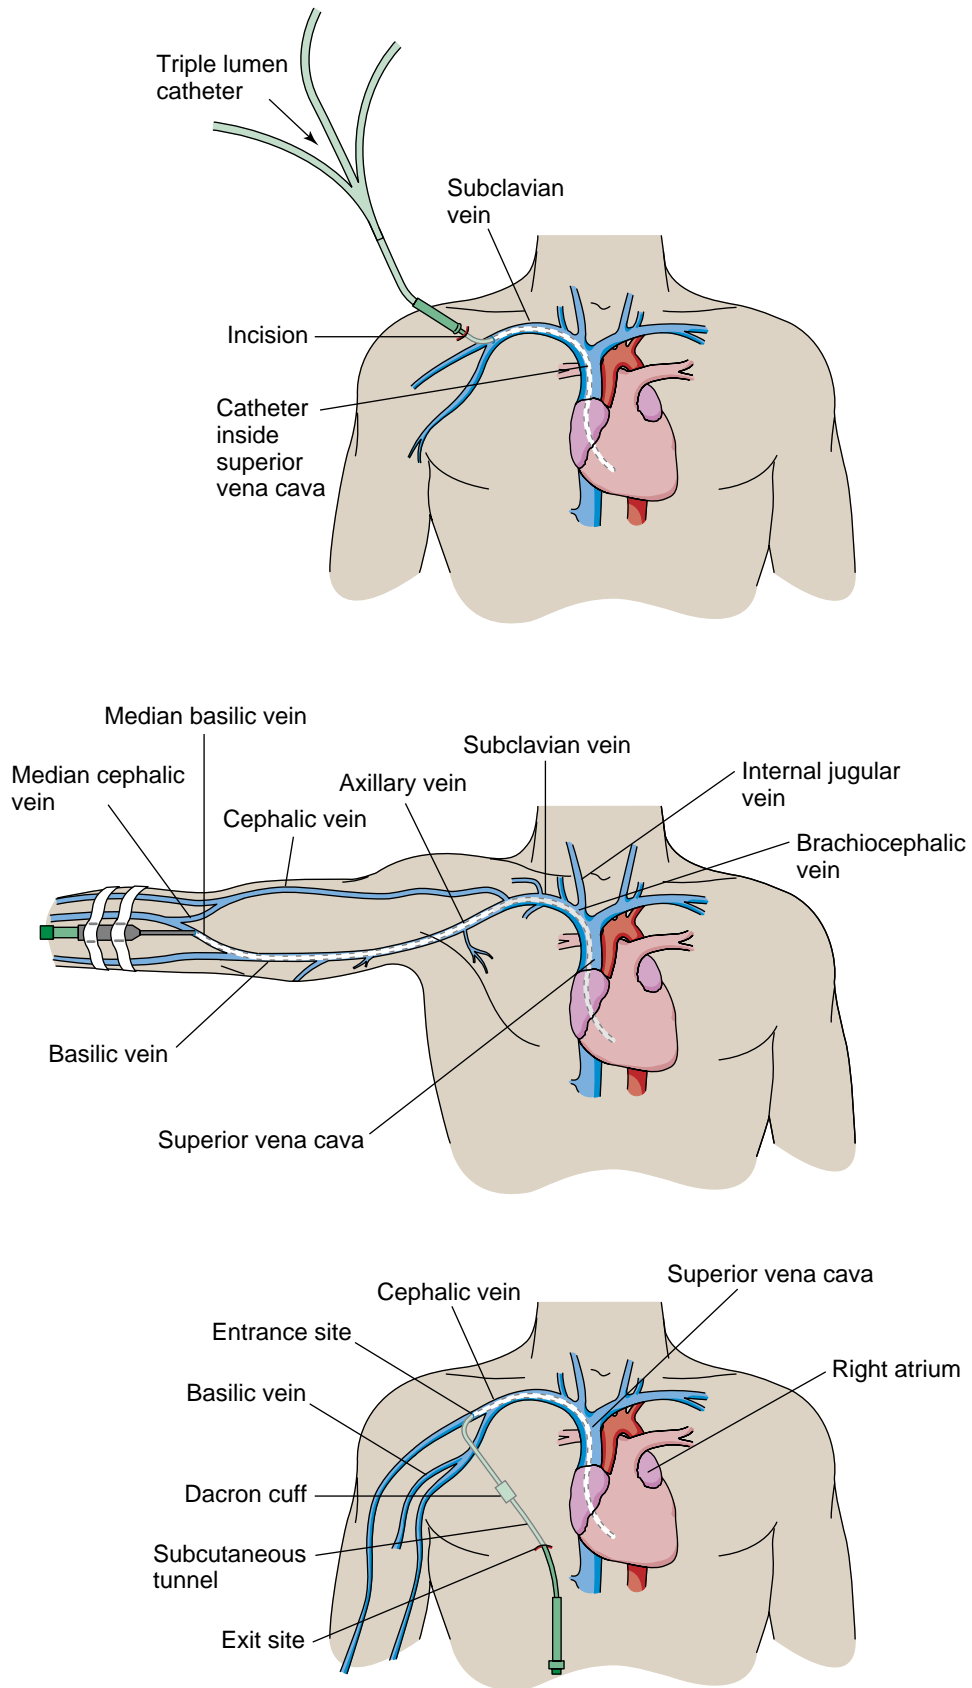

Figure 6-8 Central lines. (A) Triple-lumen subclavian catheter. (B) PICC line. (C) Tunneled catheter. (B and C modified from Phillips, L. Manual of IV therapeutics [3rd ed.]. FA Davis, Philadelphia, 2001, pp 529, 549.)

catheters allow for the administration of incompatible solutions at the same time.

Percutaneous Catheter

A percutaneous catheter is inserted by a physician into the jugular or subclavian vein. After insertion, correct placement is determined by x-ray before the catheter is used. These short-term central venous catheters may remain in place up to several weeks, but usual placement time is 7 days. These catheters are inserted at the bedside and are cost effective for short-term central venous access in the acute care setting.

Peripherally Inserted Central Catheter

A PICC line is a long catheter that is inserted in the arm and that terminates in the central circulation. This device is used when therapy will last more than 2 weeks or the medication is too caustic for peripheral administration. Specially trained RNs insert PICC lines. They can be left in place for long periods, minimizing the trauma of frequent IV insertions. Consult with a physician if long-term therapy is anticipated.

It is important to follow the manufacturer's recommended guidelines for flushing the catheter and to be aware of your institution's policy. An RN removes the PICC or midline catheter when therapy is terminated. An LPN/LVN may assist the RN with this procedure if the state nursing practice act permits.

Ports

A port is a reservoir that is surgically implanted into a pocket created under the skin, usually in the upper chest. An attached catheter is tunneled under the skin into a central vein. An advantage of a port is that, when not in use, it can be flushed and left unused for long periods. Because the port is under the skin, the patient can swim and shower without risk of contaminating the site.

Ports come in a variety of sizes and styles and are now being used in many areas of the body. Ports can be used to administer chemotherapeutic agents and antibiotics that are toxic to tissues and are suitable for long-term therapy. Ports should be accessed only by specially trained RNs. Most ports require the use of special noncoring needles that are specifically designed for this purpose. Regular needles can cut a "core" in the septum, which can travel through the catheter and cause an embolism.

Nursing Management of Central Access Devices

Central lines have sterile, occlusive dressings to protect the site. Sterile gloves and mask should be worn during the dressing change. Whenever tubing is disconnected for changing, the patient is instructed to perform Valsalva's maneuver if able. This maneuver increases thoracic pressure and prevents air from entering the central line. Institution policy directs specific dressing and tubing change procedures.

► NUTRITION SUPPORT

Total parenteral nutrition is complete IV nutrition that is administered to patients who are unable to take adequate nutrients via the enteral route (mouth or tube feeding). TPN may be used to promote wound healing or to help the patient achieve optimal weight before surgery, or it may be used to avoid malnutrition from chronic disease or after surgery. Patients with ulcerative colitis, trauma, or cancer cachexia are candidates for TPN. Every effort should be made to return a patient on TPN to oral or tube feedings as soon as possible (Nutrition Notes Box 6–5).

BOX 6-5

Nutrition Notes

Attending to Patients Receiving Total Parenteral Nutrition

Serious metabolic complications of total parenteral nutrition can occur quickly. Rapid shifts in potassium, magnesium, phosphorus, and glucose among the fluid compartments of the body can become life-threatening. Glucose in excess of the body's need can produce carbon dioxide retention, hyperlipoproteinemia, and fatty deposits in the liver. Therefore administration of TPN requires careful monitoring. The goal is to provide sufficient nutrients but not excessive amounts that create physiological stress.

To avoid complications, TPN infusions are started slowly at low concentrations. Adjustments are made cautiously, changing one component (amount, concentration, or rate) at a time and observing the patient's reaction.

In a patient whose only nutrition is obtained from TPN, the gastrointestinal cells will atrophy. Therefore the patient must be weaned from parenteral feeding while oral or tube feedings are slowly introduced. As gastrointestinal intake increases, TPN is decreased. Sometimes, when circumstances permit, gastrointestinal function can be maintained throughout TPN administration by giving the patient a liquid or light diet along with TPN.

TPN provides and maintains the essential nutrients required by the body. Solutions contain carbohydrates, amino acids, lipid emulsions, electrolytes, trace elements, and vitamins in varied amounts according to the patient's needs. Parenteral nutrition requires filtration and an electronic infusion device for administration. In the home setting an ambulatory infusion device is used to allow the patient more mobility.

Initial assessment includes the patient's height, daily weight, nutritional status, and current laboratory values. Because of the high glucose concentration of TPN, the patient is at risk for infection and blood glucose disturbances. Insulin therapy may be necessary during TPN administration. Ongoing assessments include blood glucose levels according to institution policy and monitoring for signs and symptoms of infection, hyperglycemia, and hypoglycemia. When TPN therapy is begun, the rate is increased gradually to the prescribed rate to help prevent hyperglycemia. When it ends, the rate is gradually decreased to prevent hypoglycemia.

When nutritional solutions contain final concentrations exceeding 10 percent dextrose or 5 percent protein, they must be administered via a central catheter. When final concentrations are 10 percent dextrose or lower or 5 percent protein, they may be administered through a peripheral vein. Peripheral therapy is a short-term intervention because it does not provide adequate nutrition over an extended period.

It is essential that the entire health care team be involved in TPN therapy because TPN is total replacement for food. The pharmacist, dietitian, physician, and nurse communicate in a team conference to discuss the assessment, plan, and outcome criteria. Many institutions have nutrition teams that assess the appropriateness of TPN for individual patients.

► HOME INTRAVENOUS THERAPY

As health care costs continue to escalate, patients are using more alternatives to hospitalization. Subacute care, skilled nursing care in nursing homes, and home health care are growing. Home IV therapy allows many patients the benefit of early discharge and the ability to accomplish health care in the privacy and comfort of their own homes. Some home health agencies employ nurses to instruct patients and their families in the administration of home IV therapy (see Home Health Hints).

HOME HEALTH HINTS

If IV therapy is to be continued after hospital discharge, assist the RN in teaching the patient and family or caregiver the skills to oversee the IV therapy. A home care nurse will continue teaching after discharge.

In addition to basic IV care, teach the caregiver the effects and side effects of the medications and signs and symptoms that should be reported to the nurse or doctor.

Instruct the home care patient to refrain from smoking for at least 30 minutes before IV insertion to prevent vasoconstriction and ensure successful venipuncture.

Home IV antibiotic therapy is becoming the method of choice in the long-term treatment of a number of infections, including bacterial endocarditis, osteomyelitis, and septic arthritis. Other patients with chronic diseases choose to receive TPN at home. The health team can assess patients and their families for their ability to manage home IV therapy.

REVIEW QUESTIONS

- Which of the following is the best resource for the nurse who has a question about implementation of IV therapy at a specific institution?
 - An experienced nurse
 - Institution policy
 - The physician
 - INS standards
- Which of the following sites is the best choice for initiating a peripheral IV catheter?
 - In the antecubital fossa
 - In a lower extremity
 - In the hand or forearm
 - Distal to previous insertion sites
- Which of the following techniques helps dilate a vein for IV catheter insertion?
 - Apply a cool compress.
 - Elevate the extremity.
 - Apply a tourniquet 6 to 8 inches above the insertion site.
 - Teach the patient a relaxation technique.
- Which of the following is the drop factor for minib drip tubing?
 - 10
 - 15
 - 30
 - 60
- The patient is to receive 1000 mL of 5 percent dextrose in water at 75 mL per hour. The tubing has a drop factor of 10. The nurse adjusts the drip rate to how many drops per minute?
 - 13
 - 19
 - 25
 - 75
- A client receiving IV therapy via a central line develops hypotension, cyanosis, and tachycardia. You note a crack in the tubing. Which of the following actions should you take first?
 - Have the RN call the physician.
 - Clamp the tubing and administer oxygen.
 - Raise the head of the bed.
 - Slow the infusion and lay the patient flat.

Answers to CRITICAL THINKING

Insertion of a Peripheral Line

Consider the following when assessing the patient for an appropriate venipuncture site:

- An 18-gauge catheter should be used for blood administration whenever possible.
- The catheter should not be inserted in the arm that has the shunt.
- The catheter should be placed in the forearm. Hand veins are too small to accommodate the delivery of blood.

Blood in IV Tubing

Your patient's IV line is clotted. If it has been so for a long time, it will not be salvageable. Do not flush it because doing so can dislodge the clot into the circulation. Discontinue the IV and insert a new catheter.

Complications of IV Therapy

- The IV fluid may be leaking at the insertion site and flowing into the subcutaneous tissue, a problem known as extravasation.
- Consider whether the pain could be caused by the buildup of fluid under the skin.
- Compare the insertion site with the opposite limb. If the IV solution has infiltrated, stop the infusion, discontinue the cannula, and restart the needle in a new site.
- "Patient complains of pain at IV site in right arm; area is cool to touch and edematous in 45 cm area around site. Flow rate sluggish. Infusion discontinued; IV restarted in left arm with 22-gauge catheter. Infusing well with no signs of infiltration."

QUESTIONS TO GUIDE YOUR READING

1. What types of organisms cause infectious disease?
2. How can you interrupt the routes of transmission of infectious disease?
3. How can you assist the body's defense mechanisms to fight infectious disease?
4. What are the signs and symptoms of a localized versus a generalized infection?
5. How would you apply the principles of medical and surgical asepsis?
6. How will you use standard precautions to protect yourself from infection?
7. What nursing care will you provide for a patient with an infectious disease?
8. How will you know if your nursing care has been effective?

The authors acknowledge the contribution to this chapter by Betty Ackley.

► THE INFECTIOUS PROCESS

Events in the chain of infection are shown in Figure 7-1. To prevent an infection, the chain must be broken. If infection occurs, treatment focuses on breaking the chain of infection to prevent the spread of infection to others (Cultural Consideration Box 7-1).

A **pathogen** is able to cause disease. When pathogenic microbes are present in the body without causing symptomatic infection, it is referred to as **colonization**. When an infection occurs without producing symptoms, it is known as a subclinical infection. Identification of a subclinical infection is made from an increased antibody level for the mi-

BOX 7-1 CULTURAL CONSIDERATION

One concern when caring for refugees, migrant workers, and immigrants is treating infectious conditions that jeopardize both the patient and the resident population. Some immigrants may suffer from malaria; dengue fever; gastrointestinal parasites; tuberculosis; hepatitis A, B, or C; and other infectious diseases. The hepatitis B virus is hyperendemic in Vietnam, Cambodia, and Laos. Most people are infected during childhood and then bring it with them when they emigrate to the United States. Standard precautions are a must when working with any patient.

Among the Native Americans, infectious health problems include the plague, tick fever, and the Muerto Canyon *Hantavirus*. Many of these illnesses are due to the reservation's rodent population, which includes prairie dogs and deer mice.

Some Appalachians live in rural areas that lack electricity, plumbing, and running water, putting them at increased risk of infection. Teach all patients to thoroughly wash their hands after toileting and coming in contact with raw food or contaminated water.

The drug isoniazid (INH), used in the treatment of tuberculosis, may be metabolized differently by some ethnic and racial groups. Half of European-Americans and a smaller percentage of Asian persons are slow eliminators of INH. These individuals may have high blood concentrations of this medicine, leading to harmful reactions. Carefully monitor these patients for reactions to INH.

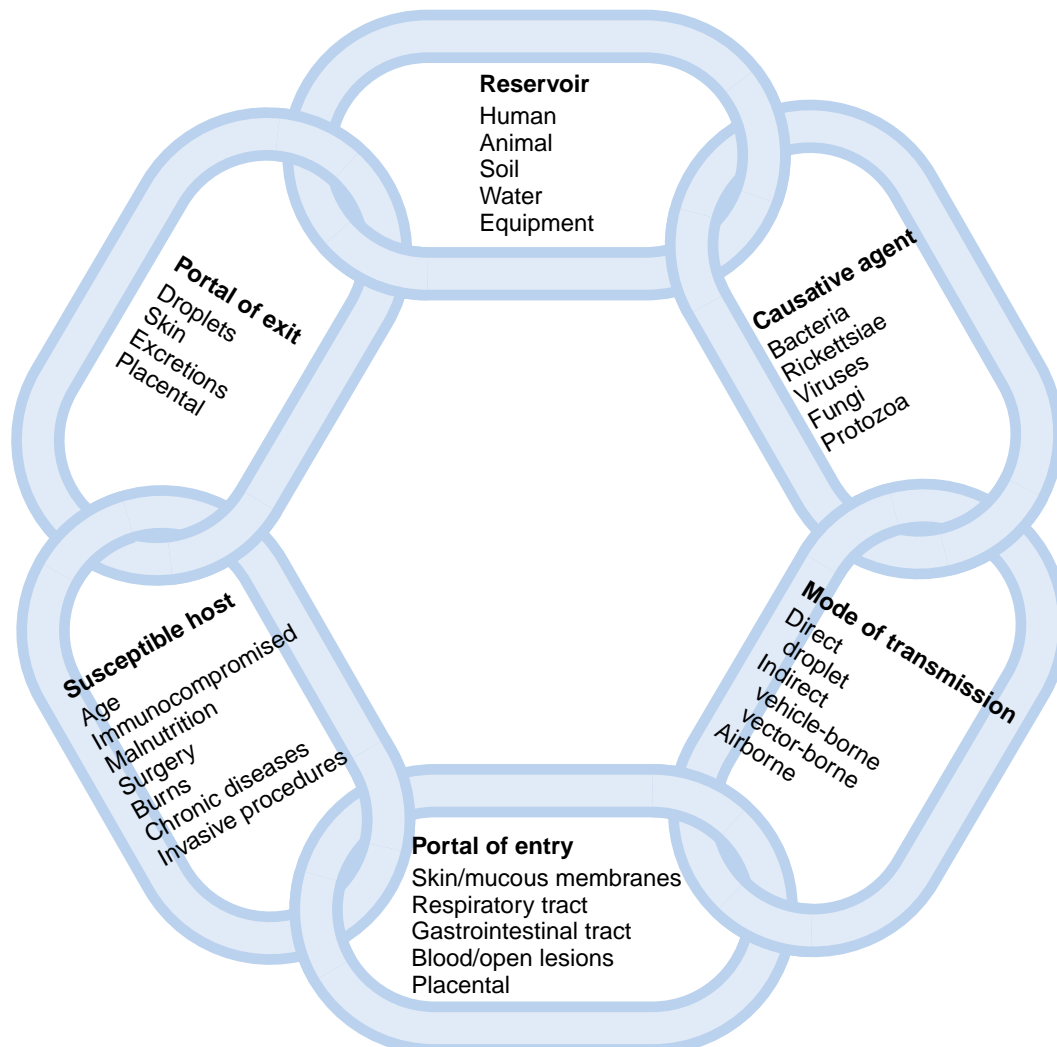

Figure 7-1 Chain of events in the infectious process.

probe. An infection results in apparent signs and symptoms and injury to the **host**.

Reservoir

A **reservoir** is the place in the environment where infectious agents live, multiply, and reproduce so they can be transmitted to a susceptible host. A reservoir can be animate, such as people, insects, animals, and plants, or inanimate, such as water, soil, or medical devices.

Causative Agents

Microorganisms that cause infection include **bacteria**, **viruses**, **fungi**, **protozoa**, helminths, and a newly discovered agent called a prion (Table 7–1). Microbes that occur naturally in or on a particular body part are known as normal **flora**. They are usually harmless, or nonpathogenic, because they do not normally produce disease in a healthy person. Normal flora are helpful to the human host. For example, intestinal flora (bacterial) assist in vitamin K production, a necessary nutrient for normal blood clotting. However, if

these bacteria get into another area of the body, such as the blood, they may produce disease and are then referred to as pathogens.

Bacteria

Bacteria are single-celled organisms that usually reproduce by simple cellular division. Bacteria may depend on a host or may live and reproduce outside a host. Most bacteria produce cell walls that are susceptible to antibiotics. However, bacteria can mutate to survive.

Bacteria are named according to their shape (spherical [coccus], rod [bacillus], and spiral [spirillum]) and classified according to their staining properties (Gram’s method, acid-fast staining). Bacteria respond to stains in one of three ways: gram-positive bacteria stain purple; gram-negative bacteria lose purple stain when exposed to alcohol but stain red with a second dye; and acid-fast bacteria keep purple stain when an acid is applied.

Bacterial growth depends on oxygen, nutrition, light, temperature, and humidity. **Aerobic** bacteria, such as those found on the skin, need oxygen to live. **Anaerobic** bacteria, such as bacteria in the gastrointestinal tract, live without oxygen. Most bacteria that inhabit humans grow best at body temperature, 98.6° F (37° C).

protozoa: proto–first + zoon–animal

TABLE 7-1 COMMON INFECTIONS	
Microorganism	Type or Site of Infection
Gram-Positive Bacteria	
Staphylococcus aureus	Pneumonia, cellulitis, peritonitis, and toxic shock
Staphylococcus epidermidis	Postoperative bone/joints, IV line–related phlebitis
Staphylococcus pneumoniae	Pneumonia, meningitis, otitis media, sinusitis, septicemia
Gram-Negative Bacteria	
Escherichia coli	Urinary tract, pyelonephritis, septicemia, and gastroenteritis
Klebsiella pneumoniae	Pneumonia and wounds
Legionella pneumophila	Pneumonia
Neisseria gonorrhoeae	Gonorrhea
Pseudomonas aeruginosa	Wounds, urinary tract, pneumonia, and IV lines
Salmonella enteritidis	Gastroenteritis, food poisoning
Viruses	
Herpes virus group	Cold sores/fever blisters, genital herpes
Epstein-Barr	Infectious mononucleosis
Varicella zoster	Skin (chickenpox and shingles)
Hepatitis (A, B, C, D, E)	Liver
Human immunodeficiency virus	Acquired immunodeficiency syndrome
Influenza (A, B, C)	Bronchiolitis, pneumonia
Rubella	German measles
Rubeola	Measles
Protozoa	
Giardia lamblia	Gastroenteritis
Trichomonas vaginalis	Trichomoniasis
Dientamoeba fragilis	Diarrhea, fever
Entamoeba histolytica	Amebic dysentery
Toxoplasma gondii	Toxoplasmosis
Plasmodium falciparum	Malaria
Fungi	
Candida albicans	Nailbed, thrush, vaginitis
Histoplasma capsulatum	Pneumonia

Rod-shaped bacteria form spores that are thick walled and hard to kill. Spores remain in a resting state until favorable conditions exist that allow the organism to resume normal function. Prolonged exposure to high temperature destroys spores on surgical equipment. Bleach is used in patient rooms to kill spores from *Clostridium difficile* (C. diff).

RICKETTSIAE. Rickettsiae are a type of bacteria that must be inside living cells to reproduce. Rickettsiae **vectors** (living organisms that transmit disease) are infected fleas, ticks, mites, and lice that bite humans. Several diseases are caused by **rickettsia**. Rocky Mountain spotted fever, caused by *Rickettsia rickettsii*, whose reservoirs (the places in nature where the organism usually lives and multiplies without causing disease) are rodents and dogs, is transmitted to humans by tick bite.

Viruses

Viruses are organisms smaller than bacteria that depend on host cells to live and reproduce (see Table 7-1). Invaded host cells make more virus material. The new virus particles are then released either by destroying the host cell or by forming small buds that break away to infect other cells.

When a virus enters a cell, it may immediately trigger disease or remain **dormant** (inactive) for years without causing illness. An example of this is *Human herpesvirus 3* (varicella zoster virus), which can cause disease quickly (chickenpox) or remain dormant for years, eventually erupting in the disease called shingles. Antibiotics are not effective against viruses. Newer antiviral drugs are used to decrease symptoms caused by viruses and to decrease the viral load (the number of virus cells in the patient's blood).

Fungi

Fungi are a group of organisms that includes yeasts, molds, and mushrooms and can produce highly resistant spores (see Table 7-1). Because fungi do not contain chlorophyll, they must obtain food from living organisms or dead organic matter. Normal flora of the mouth, skin, vagina, and intestinal tract include many fungi. Most fungi are not pathogenic, and serious fungal infections are rare. Antifungal medications treat fungal infections.

Protozoa

Protozoa are single-celled parasitic organisms with flexible membranes that live in the soil and obtain nourishment from dead or decaying organic material (see Table 7-1). Protozoa infect humans through fecal-oral contamination or through ingestion of food or water contaminated with cysts or spores, through host-to-host contact, or by the bite of a mosquito or other insect that has previously bitten an infected person.

Helminths

Helminths are wormlike parasitic animals: roundworms, flatworms, tapeworms, pinworms, hookworms, and flukes. Disease transmission occurs through skin penetration of larva or ingestion of helminth eggs. Trichinellosis (caused by the roundworm *Trichinella spiralis*) is a disease caused by eating raw or undercooked meat of pigs or wild animals that contain *Trichinella* larvae.

Prions

Prions are recently identified organisms or agents thought to be unique proteins with long incubation periods. How they reproduce is unknown. Research will shed light on these unusual organisms or protein particles, which are thought to cause mad cow disease and the human dementia Jakob-Creutzfeldt syndrome.

Mode of Transmission

Once the causative agent exits the reservoir, a means of transfer to a susceptible host is needed. Transmission methods for microorganisms include direct contact, indirect contact, and through the air.

Direct Contact

Direct transmission occurs through touching, biting, kissing, sexual contact, or droplet spray into the eyes or mucous membranes while sneezing, coughing, spitting, singing, or talking. Droplet spread is usually limited to 3 feet or less. Illnesses spread by direct transmission may include influenza, impetigo, scabies, conjunctivitis, pediculosis, herpes, *C. difficile*, and all sexually transmitted diseases, including human immunodeficiency virus (HIV). Protect yourself and your patients from direct transmission with hand washing, aseptic technique, gloves, surgical masks, goggles, gowns, and booties.

Indirect Contact

Indirect transmission is either vehicle-borne or vector-borne. Vehicle-borne transmission is the spread of an infectious organism by contact with a contaminated object, such as a toy, soiled bedding, dressings from a wound, surgical instruments, water, food, and biologic products such as blood, serum, plasma, tissues, and organs. Vehicle-borne illnesses include conjunctivitis, trichinellosis, HIV, and hepatitis A, B, C, D, and E. Vehicle transmission can be avoided through proper hand washing, excellent cleaning of the patient environment, and provision of clean water and food supplies. Vector-borne transmission is the spread of infectious organisms through a living source other than humans, such as an insect, flea, mouse, or rat. Diseases spread through vectors include malaria, plague, and Lyme disease. Vector transmission can be reduced with insect repellents, avoidance of infested areas, and rodent control.

Airborne

Airborne transmission is different from droplet transmission (see Direct Contact earlier) because the particles floating in the air are much smaller, remain suspended in the air for a long time, and may travel large distances. Airborne organisms can be inhaled or deposited on the mucus membrane of a susceptible host. Measles, chickenpox, and tuberculosis are transmitted by airborne transmission. Airborne transmission is prevented with the use of high-efficiency particulate air (HEPA) respirators (also known as a tuberculosis [TB] mask). HEPA respirators filter the tiniest particles from the air, unlike surgical masks, which can allow such particles to pass into the respiratory system of a host. Insti-

tutions provide individual fit testing and training for HEPA respirator use for each health care worker.

LEARNING TIPS

If you provide care for patients with suspected or confirmed diseases that are spread through airborne transmission, such as TB, be sure you have your own fit-tested HEPA mask to wear. Do not use other masks because they do not provide adequate protection. If you cannot obtain your own fit-tested mask, you should not enter the patient's room.

Multiple Modes of Transmission

Many diseases have multiple modes of transmission requiring a variety of protective techniques. For example, chickenpox is transmitted by direct contact, indirect contact, and airborne transmission. It is no wonder 80 percent to 90 percent of susceptible persons exposed develop the disease. Understanding the modes of transmission of a particular disease allows you to use the appropriate means of protection without using unnecessary supplies that increase costs.

Portal of Entry

To produce disease, organisms must gain entry into a susceptible host. Routes of entry into a susceptible host include the respiratory tract, skin (usually nonintact), mucous membranes, gastrointestinal tract, genitourinary tract, and placenta. Once the organism enters the host, it may lead to disease, depending on the condition of the host and many other factors, such as the **virulence** of the organism.

Susceptible Host

The body has many defense mechanisms to prevent infection, such as intact skin and mucous membranes, and a functioning immune system. A breakdown in these defenses increases the possibility of infection. Factors that increase susceptibility to infection are very young age, old age, malnourishment, immunocompromise, chronic disease, stress, and invasive procedures (Gerontological Issues Box 7–2).

BOX 7-2 GERONTOLOGICAL ISSUES

Infection and Older Patients

Often an older patient may not have typical symptoms of an infection. For example, a serious bacterial infection may cause no elevation in temperature. In fact, a fever is not a common complaint or sign of infection for an older adult.

This difference among elderly patients may cause significant delay in providing appropriate treatment and care. Be alert for the following in the elderly patient, which may indicate an infection:

- Behavioral change, such as pacing or irritability.
- Masking of the symptoms of infection by a chronic disease. For example, the inflammation and pain of degenerative joint disease may make it difficult for a patient to recognize an infection in an affected joint.

Portal of Exit

The portal of exit is the route by which the infectious agent leaves the host, who has become a reservoir for infection: respiratory tract, skin, mucous membranes, gastrointestinal tract, genitourinary tract, blood, open lesions, or placenta.

▶ THE HUMAN BODY'S DEFENSE MECHANISMS

Skin and Mucous Membranes

Intact skin and mucous membranes are the body's first line of defense against infection. Oral mucous membranes have many layers, making it difficult for organisms to enter the body. The skin has acidic (pH <7.0) properties that render some organisms unable to produce disease. For example, many bacteria prefer an alkaline (pH >7.0) environment for reproduction. There is also an abundance of normal flora that impairs the growth of pathogens both on the skin and in the gastrointestinal (GI) tract.

Mucociliary Membranes

Cilia are hairlike structures lining upper respiratory tract mucous membranes that protect the lungs. Cilia trap mucus, pus, dust, and foreign particles to prevent them from entering the lungs. Then the cilia push the trapped particles up to the pharynx with wavelike movements for expectoration.

Gastric Juices

Gastric juices inside the stomach are very acidic (pH 1.0 to 5.0). This acidic environment destroys most organisms that enter the stomach.

Immunoglobulins

Immunoglobulins are proteins found in serum and body fluids that may act as **antibodies** to destroy invading organisms and prevent the development of infectious disease. Antibodies are proteins that are produced by B-lymphocytes when foreign **antigens** of invading cells are detected. Antigens are markers on the surface of cells that identify cells as being the body's own cells (autoantigens) or as being foreign cells (foreign antigens). Antibodies combine with specific foreign antigens on the surface of the invading organisms, such as bacteria or viruses, to control or destroy them. Antigens are neutralized or destroyed by antibodies in several ways. Antibodies can initiate destruction of the antigen, neutralize toxins released by bacteria, promote antigen clumping with the antibody, or prevent the antigen from adhering to host cells.

Leukocytes and Macrophages

Leukocytes (white blood cells) are the primary cells that protect against infection and tissue damage. There are five types of leukocytes: neutrophils, which are phagocytic cells

antigen: anti—against + gennan—to produce

focusing on bacteria and small particles; monocytes, which become macrophages and are mainly phagocytic on tissue debris and large particles; lymphocytes, whose functions include antigen recognition and antibody production; basophils, which respond to inflammation from injury; and eosinophils, which destroy parasites and respond in allergic reactions.

After recognizing a foreign antigen, neutrophils and macrophages engulf and digest it, a process known as **phagocytosis**. The macrophages move the antigen fragments to their surface to be recognized by T lymphocytes to further stimulate action of the immune system. Phagocytes ingest and destroy bacteria, damaged or dead cells, cellular debris, and foreign substances.

Lysozymes

Lysozymes are bactericidal enzymes present in white blood cells and most body fluids, such as tears, saliva, and sweat. These enzymes dissolve the walls of bacteria, destroying them.

Interferon

If an invading organism is a virus, white blood cells and fibroblasts release interferon (a group of antiviral proteins). Interferon aids in the destruction of infected cells and inhibits production of the virus within infected cells. Tumor cell growth may also be inhibited by interferon.

Inflammatory Response

The inflammatory response occurs as a result of any bodily injury. This response can be caused by pathogens, trauma, or other events causing injury to tissues. Infection may or may not be present.

Vascular Response

The first step of the inflammatory process is local vasodilation, which increases blood flow to the injured area. Increased blood flow creates redness and heat at the injury. Pathogenic organisms can trigger the first step of the inflammatory process.

Inflammatory Exudate

Next, increased permeability of the blood vessels allows plasma to move out of the capillaries and into the tissues. Swelling occurs resulting in pain from pressure on nearby nerve endings.

Phagocytosis and Purulent Exudate

The final step of the inflammatory process is the destruction of pathogenic organisms and their toxins by leukocytes. During this process, a purulent exudate (pus) may form that contains protein, cellular debris, and dead leukocytes.

Immune System

The immune system is the body's final line of defense against infection. Immune cells and lymphoid tissue work with the body's other defense mechanisms. Immune cells include lymphocytes (T cells, B cells, and natural killer cells), which have protective functions related to specific antigens. Macrophages assist T and B lymphocytes.

The lymphoid organs are the thymus, which is vital to the development of the immune system, and the bone marrow, which produces leukocytes. Other lymphoid structures include the spleen, tonsils, intestinal lymphoid tissue, and lymph nodes, where immune cells grow and whose filtering of foreign materials prevents them from entering the bloodstream. The spleen destroys old or damaged red blood cells and contains large amounts of lymphocytes.

The immune system is a finely tuned network that functions together to protect the body from invasion by pathogenic organisms. When this network breaks down, infectious disease can result.

► INFECTIOUS DISEASE

General Clinical Manifestations of Infections

Localized Infection

Localized infection is caused by an increase of microbes in one area that triggers the inflammatory response. Manifestations of a local infection include pain, redness, swelling, and warmth at the site. Pain is most severe when the infection occurs in closed cavities. Redness and swelling are seen when surface structures are involved. Warmth may be felt at the site. Temperature may rise.

Generalized Infection

Generalized infections occur when there is systemic or whole body involvement. Symptoms of generalized infection may include headache, malaise, muscle aches, fever, and anorexia. As the infection progresses, there can be an increase in fever, elevated white blood cell count, decreased blood pressure, mental confusion, tachycardia, and shock. **Sepsis** is the term used for an infection that has spread to the bloodstream.

Laboratory Assessment

Several methods are used to identify pathogens. One method is performing a microscopic examination, such as Gram's method of staining. Another method is culture examination, in which the organism is grown on a laboratory plate and identified within 24 to 48 hours. A sensitivity examination is then done, which exposes the organism to many antibiotics to determine which the pathogen is sensitive to and which it is resistant to for treatment.

A serum antibody test measures reaction to a certain antigen. A positive result on this test does not always mean an active infection is present. It can simply mean there has been an exposure to the antigen, so it is not as accurate as a culture.

A complete blood cell count with differential (CBC with diff) is usually obtained when an infectious disease is suspected. The five different types of leukocytes and their levels are identified. Elevations in specific leukocytes occur based on the type and severity of the pathogen.

Erythrocyte sedimentation rate (ESR, sed rate) is an early screening test for inflammation but not a definitive test for infection. During the inflammatory process, red blood cells become heavier and during the test settle to the bottom of a tube. The ESR measures in millimeters per hour the speed at which the red blood cells settle in the tube. The faster the settling, the greater the inflammation.

Other tests such as x-rays, computed tomography (CT), and magnetic resonance imagery (MRI) are helpful in identifying abscesses (walled-off infections). Skin tests diagnose infections, such as the Mantoux test (commonly called a PPD), which screens for tuberculosis. (See Chapter 28.)

Immunity

Immunity is the ability of the body to protect itself from disease. (See Chapter 52.) There are several types of immunity:

- Natural immunity occurs in species and prevents one species from contracting illnesses found in another species.
- Innate immunity is genetic, hereditary immunity a person is born with.
- Acquired immunity is obtained either actively or passively through exposure to an organism, from a vaccine, or from an injection of immunoglobulins (antibodies) or is passed from mother to baby.

Mononucleosis

Infectious mononucleosis (referred to as mono or the kissing disease) is an infection that is usually caused by the Epstein-Barr virus (a herpes virus). Mononucleosis is a contagious disease that anyone may develop. However, it is mainly diagnosed in young adults. Most adults have been exposed to the virus and have antibodies to it but never develop the disease. The virus remains in the body for a lifetime but rarely causes another infection.

Mononucleosis is primarily spread through person-to-person contact, mainly through saliva. Sharing utensils, food, or beverages can transmit the disease. Coughing or sneezing of small droplets of infected saliva or mucus into the air allows the virus to be inhaled by others.

The incubation period for mononucleosis is 4 to 8 weeks after exposure. Symptoms during the first 3 days include extreme fatigue, loss of appetite, and chills. Then a severe sore throat, headache, high fever, reddened throat and tonsils with a white coating, generalized lymphadenopathy (enlarged lymph nodes in two different sites other than inguinal nodes), or diarrhea occur. The spleen enlarges 50% of the time. Occasionally a rash develops similar to the measles.

Signs and symptoms, as well as diagnostic tests, confirm mononucleosis. Lymphocyte levels are elevated. The monospot and heterophile antibody tests confirm mononucleosis.

Usually no specific treatment is needed. The illness runs its course as other viral illnesses do. Antiviral drugs are not effective. Symptoms are treated as needed with supportive care. Fatigue may last for months. Rest is important. If the spleen is enlarged, contact sports, lifting, and straining are avoided to prevent trauma and rupture. Mild inflammation of the liver or hepatitis may occur, but no treatment is usually required. Other complications are rare.

► INFECTION CONTROL IN THE COMMUNITY

Many levels of organizations work closely together to control communicable diseases. The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) teach standards to prevent and control diseases and monitor disease outbreaks. Local health departments teach how to prevent and control the spread of disease. The community health nurse collects health data, sets up immunization programs within the community, and educates the public about health and illness.

Community immunization programs have helped reduce infectious diseases. Although requirements vary from state to state, most elementary schools require some proof of childhood immunization. Many colleges also require proof of immunization to help control the outbreak of diseases such as measles. Vaccination has played a major role in preventing many infectious diseases and controlling the spread of existing disease outbreaks. In addition, educating the public about the importance of hand washing, immunization, clean water, safe food handling techniques, and safer sex precautions in preventing the spread of disease cannot be overemphasized.

Both the hospital and home health care nurse have a responsibility to provide infection control teaching for the patient and family. Such techniques may include use of disposable dishes and utensils and disposable gloves or proper disposal of contaminated items. Techniques used should be specific to the interruption of the transmission of the particular disease.

► BIOTERRORISM

Preparing for a bioterrorism attack is difficult. The Global Outbreak Alert and Response Network monitors for global outbreaks of infectious diseases. Staying informed and understanding how to respond if an emergency or disaster occurs is the best way to be prepared. Participating in your agency's disaster drills can increase your confidence if a disaster occurs. Infectious agents that might be used in a biologic attack include anthrax, botulism, plague, and smallpox.

For more information on public health emergency preparedness and response and facts about bioterrorism agents, visit www.bt.cdc.gov. For more information on infectious diseases, visit www.cdc.gov/ncidod/eid. For the Federal Emergency Management Agency, visit www.fema.gov.

Anthrax

Anthrax, a bacterial disease caused by *Bacillus anthracis*, is found around the world. Anthrax occurs in animals (such as

goats, sheep, cattle, deer, horses). Anthrax spores are found in the environment and can survive for many years in water and soil. Exposure to infected animals and animal products (such as infected wool, hides, body fluids, feces, or bone meal) can result in infection. Anthrax is not transmitted person to person, so isolation is not needed.

There are three kinds of anthrax: skin anthrax (most common), occurring when a spore enters the skin through a cut or an abrasion; inhalation anthrax, resulting from inhalation of airborne anthrax spores; and gastrointestinal tract anthrax, acquired from eating infected meat. All forms of anthrax can be fatal if not treated promptly.

Symptoms of skin anthrax occur 1 to 7 days after contact. The affected skin itches with papular and vesicular lesions, edema, ulceration, and sloughing of the skin. Inhalation anthrax exposure results in flulike symptoms after 48 hours, followed 2 to 4 days later by severe respiratory distress and shock; there is a high **mortality** rate within 24 hours of onset of respiratory distress and shock.

Standard precautions are used during patient care for all forms of anthrax. Vaccines for anthrax are available and given to people primarily in high-risk situations. To treat anthrax, antibiotic therapy is beneficial if given before or just after onset of illness. Penicillin, ciprofloxacin, and doxycycline are effective antibiotics. Antibiotic therapy is also given as prophylaxis for exposure to anthrax spores. Chlorine destroys spores. Boiling contaminated articles in water for 30 minutes destroys anthrax.

► INFECTION CONTROL IN HEALTH CARE AGENCIES

If on admission to a hospital or health care agency a patient already has an infection, it is referred to as a community-acquired infection. An infection that develops as a result of the stay in the hospital or health care agency is called a **nosocomial infection**. The host's condition plays a major role in whether or not an infection is acquired. Patients in the hospital are commonly debilitated, malnourished, or immunocompromised. Multiple antibiotic therapy also increases susceptibility to other types of infection and promotes the resistance of pathogens to antibiotics. Therefore the risk of developing a nosocomial infection is very high. Some areas within an institution tend to have an increased number of nosocomial infections, such as intensive care, neonatal, dialysis, oncology, and burn units. Patients in these areas tend to undergo more invasive procedures and are debilitated, increasing susceptibility to infection.

Several pathogens are commonly responsible for causing nosocomial infections:

- *Escherichia coli* is the most common pathogen causing nosocomial urinary tract infections. *E. coli* normally lives in the healthy intestinal tract of humans. *E. coli* can be spread by the patient, by the unwashed hands of a health care worker, or through contaminated food and water.
- *Staphylococcus aureus* (commonly known as staph) is the most common pathogen causing nosocomial surgical wound infections and nosocomial septicemia. Staph usu-

ally lives in the nose and on the skin of healthy people. (Some highly pathogenic strains of staph are also emerging in the world.)

- *Pseudomonas aeruginosa* is the most common pathogen in nosocomial pneumonia. It is found in soil, around water, and in the health care setting around sinks, water, irrigating solutions, and nebulizers on respiratory equipment.

The single most effective way to prevent and control the spread of infection is by effective hand washing. Most organisms in the institutional setting are transmitted via the hands of health care workers. Hands *must* be washed before and after every patient contact to prevent the direct transmission of organisms (Fig. 7–2). Patients may also transmit organisms with inadequate hand washing. Teach patients the importance of hand washing after handling their own secretions. The use of gloves decreases the transmission of organisms, but CDC guidelines also require hand washing before and after glove use.

Asepsis

The concept of **asepsis** (freedom from organisms) is important for all health care workers who have direct or indirect patient contact. For hospitalized patients, the most common sites for infectious diseases are the genitourinary tract, respiratory tract, bloodstream, and surgical wounds. Be aware of patients at risk of developing these infections and protect them with aseptic techniques.

Medical Asepsis

Medical asepsis is commonly referred to as clean technique. The goal is to reduce the number of pathogens or prevent

Figure 7-2 Frequent hand washing by health care workers helps reduce the spread of microorganisms.

CRITICAL THINKING

Mrs. Sampson

Mrs. Sampson has neutropenia from chemotherapy treatments.

1. Why is hand washing the most important intervention you can do to help prevent infection for Mrs. Sampson?
2. What would be a priority nursing diagnosis for Mrs. Sampson?
3. What type of isolation could be beneficial to Mrs. Sampson?

Answers at end of chapter.

LEARNING TIPS

Proper hand washing requires wetting the hands, soaping, and lathering, with at least 10 seconds of rubbing your hands together under running water with fingertips pointed downward. Interlace your fingers to cleanse between them, rub your nails against your palms to clean under the nails, and then rinse your hands with fingertips pointed downward. Dry your hands with clean paper towels. Use the paper towel to turn off the faucet. Apply lotion to your hands to prevent drying and possible cracking or open areas in which infection could develop.

the transmission of pathogens from one person to another. Frequent, proper hand washing is one of the best ways to achieve this goal. Gowns, gloves, masks, and protective eyewear or rooms with special ventilation may also be helpful (Fig. 7-3). Disinfectants and precautions as defined by the CDC are also crucial tools. Techniques used should be appropriate to interrupt the spread of the known pathogen. As part of medical asepsis you should keep your own body and clothing clean to prevent spread of infection to patients, yourself, and your family (Box 7-3).

Surgical Asepsis

Surgical asepsis (sterile technique) refers to an item or area that is free of all microorganisms and spores. Surgical asepsis is used in surgery and to sterilize equipment. Articles can be subjected to intense heat or chemical disinfectants to destroy all organisms. The use of pressurized steam sterilizers, called autoclaves, kills even the most powerful organisms.

CRITICAL THINKING

Which of the following patients is at greatest risk for infection and why?

1. Mr. Ashland, age 55, is hospitalized for a hernia repair. He is overweight and has adult-onset diabetes.
2. Mrs. Burrows, age 72, is hospitalized for a broken hip. She is thin, frail, has dementia, and has undergone placement of a urinary catheter.
3. Jackson Dent, age 2, is hospitalized for minor surgery. Jackson is thin and small for his age.

Answers at end of chapter.

Figure 7-3 Gloves, gowns, masks, goggles, and face shields help prevent the spread of infection to health care workers and patients.

BOX 7-3 Guidelines to Prevent Spread of Infection to the Patient, Self, and Family

- Bathe daily and wear a clean uniform/clothing every day.
- Keep your fingernails short, piano playing length, and do not wear acrylic nails. Both long nails and acrylic nails have been associated with spread of infection to patients and can be colonized with harmful bacteria. Multiple studies have demonstrated that long fingernails and artificial nails harbor bacteria and have caused infections for patients that sometimes have resulted in death.
- Avoid wearing rings and bracelets that harbor organisms.
- Cleanse your stethoscope at least daily and in between patient use with alcohol. VRE bacteria have been cultured from stethoscopes in a hospital setting.
- Wash your hands between each patient contact. Hand washing is recognized as the single most important action to take to prevent spread of infection. If you are unable to use soap and water, use a nondrying alcohol hand gel, which has shown to be effective in cleansing hands and preventing drying of the skin.
- Follow prescribed isolation precautions for your protection, as well as that of the patient.
- Remove your uniform and bathe/shower when you come home from work. This will decrease the spread of antibiotic-resistant bacteria to your home and your family. Keep your nursing shoes clean and put away from the rest of the family.

Some equipment cannot be exposed to moist heat, so gas sterilizers are used instead. Once these articles are sterilized, they are dated, packaged, and sealed. Once a package is opened or outdated, it is no longer considered sterile. Sterile technique is rarely required in the home care setting.

Infection Prevention Guidelines

The CDC guidelines for infection control and isolation precautions are used in hospitals and health care agencies. Health care agencies use these guidelines to establish their own policies. CDC and agency guidelines are continuously updated and should be followed for your protection, as well as your patients'. Current CDC guidelines for isolation precautions in hospitals include two tiers of precautions:

standard precautions and transmission-based precautions (Table 7–2).

Standard Precautions

Standard precautions require you to assume that all patients are infectious regardless of their diagnosis. Standard precautions combine reducing the spread of blood-borne pathogens found in blood and body fluids with body substance isolation to decrease transmission of moist body substance pathogens. Standard precautions apply to blood, secretions, excretions, open skin, mucous membranes, and all body fluids, excluding sweat. All patients with draining wounds or secretions of body fluids are considered infectious until an infection is confirmed or ruled out. Using gloves,

TABLE 7–2 STANDARD PRECAUTIONS AND TRANSMISSION-BASED PRECAUTIONS

Standard Precautions

Use standard precautions for all patient care. Combine standard precautions with transmission-based precautions as needed based on the patient's illness.

Hand washing	Wash hands with nonmicrobial soap unless specially contraindicated before and after using gloves, between patients, and between procedures on same patient.
Gloves	Wear gloves before contact with any body fluids or substances.
Mask, eye protection, face shield	Use protective equipment for patient care if splashes or sprays of blood or body fluids are likely.
Gown	Wear gown to protect skin/prevent soiling of clothing for patient care if splashes or sprays of blood or body fluids are likely.
Occupational health and blood-borne pathogens	Dispose of sharps properly; do not recap needles.
Patient care equipment	Clean reusable equipment before reuse. Discard single-use items properly.
Linen	Handle linen to avoid clothing contamination.
Patient placement	Use private room for infectious patients.

Transmission-based Precautions

Airborne Precautions

Examples: measles, tuberculosis, varicella (chickenpox, shingles)	
Patient placement	Provide private room with regulated air flow. Keep door closed.
Respiratory protection	Do not enter room if susceptible to measles or chickenpox unless no immune caregivers available. If susceptible, wear fit-tested N95 or HEPA respirator.
Patient transport	Limit patient transport to essential purposes. Place surgical mask on patient.

Droplet Precautions

Examples: diphtheria (pharyngeal), <i>Haemophilus influenzae</i> (epiglottitis, meningitis, pneumonia, sepsis), influenza, mumps, mycoplasma pneumonia, <i>Neisseria meningitidis</i> (meningitis, pneumonia, sepsis), pertussis, pneumonic plague, rubella, streptococcal pharyngitis, pneumonia	
Patient placement	Provide private room or separation of at least 3 feet between the infected patient and other patients.
Mask	Wear mask for patient care if within 3 feet of patient.
Patient transport	Limit patient transport to essential purposes. Place surgical mask on patient.

Contact Precautions

Examples: cellulitis, <i>Clostridium difficile</i> , skin infections (diphtheria, herpes simplex virus, impetigo, pediculosis, scabies), viral/hemorrhagic conjunctivitis, viral hemorrhagic infections (Ebola, Lassa, or Marburg), herpes zoster	
Patient placement	Provide private room or place with patient with same infection and no other infection.
Hand washing, gloves, gown	Protect self and others from contaminated items.
Patient transport	Limit patient transport.
Patient care equipment	Dedicate the use of noncritical patient care equipment to a single patient.

Data from Public Health Service, US Department of Health and Human Services, Centers for Disease Control and Prevention, Atlanta, Georgia; and Garner JS, Hospital Infection Control Practices Advisory Committee: Guideline for isolation precautions in hospitals. *Infect Control Hosp Epidemiol* 17:53, 1996; and *Am J Infect Control* 24:24, 1996.

gowns, masks, goggles, face shields, and, most important, hand washing helps prevent the spread of infection to health care workers and other patients.

Transmission-based Precautions

Transmission-based precautions are used for patients with specific communicable diseases that can be transmitted to others. Transmission-based precautions are used with standard precautions to control the spread of infection.

Prevention of Respiratory Tract Infections

Nosocomial pneumonia has been linked with the highest infection mortality rate in hospitalized patients. Patients who are at highest risk for pneumonia are those with endotracheal, nasotracheal, or tracheostomy tubes because these invasive tubes bypass the normal defenses of the upper respiratory tract. To prevent infection in these patients in the agency setting, care of respiratory tubes usually requires sterile technique. If patients are on ventilators or receiving respiratory treatments, the tubing and equipment are usually changed every 48 hours. Protecting debilitated patients or those with an ineffective cough from aspirating also helps prevent pneumonia.

Prevention of Genitourinary Tract Infections

The most common hospital-acquired infection is a urinary tract infection. Patients with urinary catheters are at the greatest risk. The urinary tract is normally a sterile tract, but insertion of a catheter into the bladder may allow organisms to enter. Institutional policy on appropriate use of urinary catheters differs, and you should follow the policy of your particular institution. Appropriate uses of catheters include use in patients with urinary obstructions and neurogenic bladder conditions and in those in shock.

LEARNING TIPS

Catheters should be used only when necessary because of the **morbidity** and mortality associated with infections that develop from them.

Indwelling urinary catheters should be removed as soon as possible. For patients requiring long-term use of urinary catheters, intermittent catheterization is preferred because it has been shown to significantly reduce the risk of infection. Using strict aseptic technique while inserting and caring for the catheter in the health care agency is imperative. The catheter tubing must be securely anchored to the patient's leg, according to agency protocol, so it does not move in and out of the urethra. Movement can encourage organisms to enter the urinary tract.

The closed urinary drainage system seal should never be opened. If intermittent irrigation is ordered, sterile technique must be used to protect both ends from contamination. The drainage bag should be positioned so that it is never higher than the level of the bladder to prevent backflow of urine into the bladder, which could contaminate the sterile urinary tract. If an indwelling urinary catheter and drainage system is used long term, the catheter and the entire system should be changed regularly using sterile technique. Standards in home care differ from institutional care because patients are generally at lower risk of infection within their own environment.

All long-term indwelling urinary catheters are considered colonized, but only a few will cause infection in the patient. Remember that the most crucial point at which bacteria may enter the patient is during the insertion of the catheter, so excellent technique is required. Another point to remember is that the urinary tract is highly vascular (many blood vessels close to the surface), so that an infection in this tract can easily result in bacteremia (bacteria in the blood), which can then progress to septicemia (infection in the blood), a potentially life-threatening condition.

CRITICAL THINKING

Mr. Carson

While working in an extended care facility you see Mrs. Brandt's nursing assistant wheeling Mr. Carson to activities. He has a long-term urinary catheter. The urine bag is hung on the arm of the wheelchair with a cloth partially covering it. What is your responsibility in this situation?

Answers at end of chapter.

Prevention of Surgical Wound Infections

The initial dressing for surgical wounds is applied in the operating room using sterile aseptic technique. Postoperative orders indicate when to change the dressing. Sterile technique should be used. The wound is monitored with every dressing change for signs of infection.

Protection from Septicemia (Sepsis)

Septicemia (commonly called blood poisoning) is a blood infection with a variety of causes, including infection in another body site, invasive catheters and solutions (central lines, arterial lines, pulmonary artery catheters, urinary catheters). Insertion and care of these catheters require sterile technique and careful observation for infection signs. All solutions should be examined for expiration date, signs of contamination, cloudiness, particles, or discoloration before use. Indications of sepsis such as fever, tachypnea, tachycardia, hypotension, and elevated white blood cell count should be reported promptly to the physician for immediate treatment. Blood cultures may be ordered. Antibiotics are used to treat sepsis. A new intra-

venous (IV) drug, drotrecogin alfa (activated) (Xigris), is available to treat severe sepsis when death is likely. Drotrecogin alfa (activated) is given for 96 hours. It is associated with a risk of bleeding. Drotrecogin alfa (activated) has reduced mortality in patients that may be due to anti-inflammatory effects.

▶ ANTIBIOTIC-RESISTANT INFECTIONS

Antibiotic-resistant infections are on the rise and are creating significant treatment problems. These infections result in increased health care costs, morbidity (death), and mortality (illness). Preventive measures to reduce the occurrence of antibiotic-resistant infections, include avoiding the use of antibiotics in animal feed, teaching patients to take all prescribed medications exactly as ordered, and avoiding the use of antibiotics for viral infections (common cold or flu). Newer American College of Physicians/American Society of Internal Medicine guidelines suggest that most upper respiratory infections do not require antibiotic treatment. For healthy adults with the symptoms of bronchitis, sinusitis, pharyngitis, and other upper respiratory infections, it is suggested to use over-the-counter cold symptom remedies and saltwater gargles. Two infections that are on the rise include methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci (VRE). For more information on antibiotic resistance, visit the World Health Organization at www.who.int/emc/amr.html.

LEARNING TIPS

Antibiotics are not effective against viral infections such as colds or the flu. People need to be educated that antibiotics do not work on viral infections. The misuse of antibiotics is creating antibiotic-resistant “superbugs.” People should not ask health care providers for antibiotics to treat viral infections. Use of antibacterial products such as antibacterial soaps may also contribute to the superbug problem. You play a vital role in educating people of this growing problem.

MRSA

A serious antibiotic-resistant infection is caused by methicillin-resistant *S. aureus* (commonly called MRSA). MRSA is difficult to treat and has a high mortality rate. MRSA affects mainly the elderly and the chronically ill. Vancomycin hydrochloride, a potent and expensive antibiotic, can be used intravenously to treat MRSA. Fear exists that the bacteria will further mutate to become resistant to all currently available antibiotics. A few isolated cases of this have been documented worldwide. The risk that these resistant organisms will spread is real, which will return us to the preantibiotic days when *S. aureus* was a killer.

VRE

Vancomycin-resistant enterococci infections are common. Although enterococci are normal flora in the GI and female

genital tracts, VRE are a new pathogenic strain. VRE are transmitted via direct or indirect contact. Patients at risk for VRE infections include those with indwelling urinary or central venous catheters, the immunocompromised or critically ill, those receiving multiple antibiotics or vancomycin therapy, surgical patients, and those with extended hospital stays. Preventive VRE measures focus on proper hand washing, education of health care workers, aggressive infection-control methods and restricting use of vancomycin. Patients with VRE should be isolated, and current CDC and institutional isolation policies should be strictly followed (Fig. 7-4). Treatment is difficult, involving combination antibiotic therapy, but VRE may also be resistant to other antibiotics.

New drugs have been developed for treating antibiotic-resistant infections. Quinupristin/dalfopristin (Synercid) is an intravenous drug for VRE treatment. When using quinupristin/dalfopristin, the IV line can only be flushed before and after with 5 percent dextrose in water (D5W), not 0.9 percent normal saline or heparin. Linezolid (Zyvox) can treat both VRE and MRSA and should ideally only be used for these serious infections, so that resistance does not develop to it. Research is ongoing to develop more antibiotics for resistant organisms, but antibiotic-resistant bacteria remain a very serious threat to the health of the world population.

▶ TREATMENT OF INFECTIOUS DISEASES

Treatment is begun once an infectious organism and the affected body system are identified. Many factors play a part in determining the drug to be used. The type of organism is very important in selecting an appropriate medication.

- Antibiotics treat bacterial infections, not viruses, fungi, helminthes, or prions.
- Antiviral medications treat viral infections, but their use is aimed at symptom control rather than cure.
- Antifungal drugs are available for fungal infections, but cure may require their extended use.

The drug of choice must be able to destroy (or control) the pathogen while preserving the patient’s healthy cells (Relevant Research Box 7-4). Cost-effectiveness is another concern when selecting a medication. Newer antibiotics can be very expensive and therefore are not available to everyone.

Numerous antibiotics are available on the market today to treat bacterial infections. When giving an antibiotic, several things must be considered. First, consider any allergies the patient may have to a particular group or class of antibiotics. Patients may have allergies to one antibiotic group that prevents the use of chemically similar drugs. Therefore all allergies should be reported to the prescribing health care provider.

The patient’s kidney and liver function should be known. Many antibiotics are metabolized by the liver and excreted by the kidneys. Diseases of these organs may require a lower dose. Antibiotic levels fluctuate greatly de-

Antibiotic-Resistant Organism Precautions

Visitors: Report to the Nurses' Station before entering the room.

1. **Private Room** required.
2. **Gloves** must be worn by all hospital personnel entering the room.
3. **Wash Hands** on entering and leaving the room.
4. **Gowns:** required **IF** contamination of clothing is likely.
5. **Decontaminate All Equipment** used in the room before removal from the room.

Figure 7-4 Antibiotic-resistant organism precautions for Vancomycin resistant enterococci (VRE).

RELEVANT RESEARCH BOX 7-4

Use of Probiotics to Prevent Infection

Probiotics are live microorganisms that interact with the human flora, improving the intestinal microbial balance with normal bacterial flora. An example of a probiotic is yogurt that contains live cultures. Probiotics can also be taken as a capsule, but there is only preliminary research to demonstrate what bacteria is helpful for different conditions.

Some probiotics have shown the ability to prevent the diarrhea associated with antibiotic use, including decreasing the incidence of *Clostridium difficile*.¹ Clinically significant benefit has been shown in the use of probiotics to treat acute infectious diarrhea in children.² Some studies have shown the benefit of probiotics to prevent and treat vaginal infections, and also prevent urinary tract infections.^{2,3} Research is ongoing to prove that probiotics may be useful to control inflammatory diseases and some allergies and to stimulate the immune system, which may reduce the incidence of respiratory infections.⁴ It should be noted that the severely immunosuppressed patient should avoid use of probiotics because they contain live bacteria. Probiotics is a new and exciting area of research in infection control.

1. Elmer, GW: Probiotics: "Living drugs." *Am J Health Sys Pharm* 58:12, 2001.
2. Szajewska, H, and Mrukowicz, JZ: Probiotics in the treatment and prevention of acute infectious diarrhea in infants and children: a systematic review of published randomized, double-blind, placebo-controlled trials. *J Pediatr Gastroenterol Nutr* 33:4, 2001.
3. Reid, G, and Bruce A: Selection of Lactobacillus strains for urogenital probiotic applications. *J Infect Dis* (suppl)183:1, 2001.

pending on organ function, age, sex, health, and many other factors. Antibiotic peak (highest blood level) and trough levels (lowest blood level) need to be monitored to prevent toxicity and damage to major organs. Site of infection is another factor that determines the choice of antibi-

otic. Possible routes of administration include oral, parenteral, intravenous, or instillation into a body cavity.

Antibiotics can be classified as either bactericidal or bacteriostatic (Table 7-3). Bactericidal agents kill bacteria, whereas bacteriostatic agents inhibit or retard bacterial growth, leaving the final destruction of the bacteria up to the infected host's immune system. Bacteriostatic agents therefore may be less helpful for the patient who is immunocompromised.

General Principles

Consult drug references for further information on anti-infective medications. You are responsible for administering medications correctly and for teaching the patient the importance of taking these medications properly. Certain nursing and patient teaching responsibilities relate to *all* anti-infective medications. These general principles include the following.

Nursing Responsibilities

- All patient allergies are noted, especially any documented allergy to the specific drug ordered or cross-allergies to the drug ordered, and the primary provider is notified before treatment is started.
- Monitor and report any side effects or signs of allergic response, especially anaphylactic reactions.
- Observe and report any signs of superinfection (one that occurs as a result of antibiotic use). For example, thrush may develop as antibiotics disrupt the normal flora of the GI tract.

Patient Education

- Stress to the patient and family the need to take *all* the medication exactly as prescribed. Explain that stopping treatment when the patient feels better results in potential relapse with more resistant organisms.
- Explain what signs and symptoms to watch for (allergic and nonallergic side effects) and what to do about them, especially when to call the primary provider.

TABLE 7-3 DRUGS FOR TREATING INFECTIOUS DISEASE

Type and Examples	Nursing Considerations	Patient Teaching
Bactericidal Antibiotics		
Penicillins amoxicillin (Amoxil), ticarcillin (Ticar), penicillin G, ampicillin (Omnipen)	<ul style="list-style-type: none"> • Most widely used antibiotic. • Most effective against gram-positive organisms. • Monitor patient for allergic reaction (rash, hives, itching) or anaphylactic shock (fever, chills, trouble breathing, lower blood pressure, tight throat). Keep epinephrine available. • If signs of allergic reaction occur, stop parenteral drug and notify primary care provider immediately. • Watch for superinfection. 	<ul style="list-style-type: none"> • Review signs of allergic reactions. • Tell patient and family to stop drug and call primary provider if they occur. • Tell patient to notify primary care provider if white patches appear in mouth or vagina becomes irritated.
Cephalosporins cephalthin (Keflin), cefazolin (Ancef), cefaclor (Ceclor), ceftriaxone (Rocephin)	<ul style="list-style-type: none"> • First-generation drugs are most effective against gram-positive organisms. • Second- and third-generation are more effective against gram-negative organisms. • Patient with penicillin allergy may have cross-allergy to cephalosporins. • Common side effects include GI disturbance, phlebitis, pain at injection site, rash, and hives. • Less common but serious side effects include kidney and liver damage and superinfection. • Monitor blood urea nitrogen, creatinine, lactic dehydrogenase, aspartate aminotransferase, and alanine aminotransferase to detect kidney or liver damage. 	<ul style="list-style-type: none"> • Tell patient to take drug on an empty stomach, 1 hour before or 2 hours after meals, to increase absorption. • Tell patient to take drug at specified intervals over 24-hour period.
Aminoglycosides amikacin (Amikin), gentamicin (Garamycin), tobramycin (Nebcin)	<ul style="list-style-type: none"> • Used to treat gram-negative organisms. • Usually given parenterally because they are not absorbed well in GI tract. • Monitor peak and trough levels to keep drug in therapeutic range. • Assess patient's kidney function. • Check for ototoxicity (ringing in ears, deafness). • Don't mix or infuse with any other drug. 	<ul style="list-style-type: none"> • Tell patient to report signs of allergy, tinnitus, vertigo, or hearing loss. • Tell patient to obtain daily weights because weight gain may indicate kidney problems.
Fluoroquinolones ciprofloxacin (Cipro), levofloxacin (Levaquin), norfloxacin (Noroxin), ofloxacin (Floxin), trovafloxacin (Trovan)	<ul style="list-style-type: none"> • Used to treat a variety of infections, such as bronchitis, bone and joint infection, pneumonia, tuberculosis, sexually transmitted disease, and urinary tract infection. • Give drug on an empty stomach. • Do not give with antacids that contain aluminum, calcium, or magnesium. • Monitor liver function and report signs of dysfunction (fatal hepatitis may occur). 	<ul style="list-style-type: none"> • Tell patient to take with a full glass of water; encourage fluids. • Tell patient to report side effects: swelling of face/throat; trouble swallowing; shortness of breath; itching; hives; pain in shoulder, hands, or heel tendons. • Explain that drug may cause drowsiness and increase sensitivity to light. Advise sun protection.
Bacteriostatic Antibiotics		
Tetracyclines tetracycline HCl, doxycycline (Vibramycin), minocycline HCl (Minocin)	<ul style="list-style-type: none"> • Treat most gram-positive and gram-negative organisms. • Tetracycline HCl comes only in oral form. The others are usually given IV because intramuscular route leads to poor absorption. • Give 1 hour before or 2 hours after meals. • Do not give with milk, milk products, or antacids because they impair absorption. • GI disturbances are the most common side effect. • Tetracyclines increase anticoagulant activity. Monitor prothrombin time, international normalized ratio, partial prothrombin time as ordered. 	<ul style="list-style-type: none"> • Suggest eating crackers and juice (but not a full meal) to reduce GI upset. • Tell patient to avoid prolonged sun exposure during therapy.
Erythromycin E-Mycin, E.E.S., Erythrocin	<ul style="list-style-type: none"> • A broad-spectrum antibiotic effective against many gram-negative and gram-positive organisms. • Give on an empty stomach 1 hour before or 2 hours after meals. • Give with a full glass of water (not with acidic fruit juices, such as orange juice or grapefruit juice). • When giving drug IV, administer slowly to decrease vein irritation. 	<ul style="list-style-type: none"> • Urge patient to take drug around the clock and complete entire course of treatment. • Explain that gastric distress is common but not a reason to stop the drug. • Suggest that patient contact primary care provider if side effects are intolerable.

TABLE 7-3 DRUGS FOR TREATING INFECTIOUS DISEASE — CONT'D

Type and Examples	Nursing Considerations	Patient Teaching
Bacteriostatic Antibiotics		
Sulfonamides sulfamethoxazole (Gantanol), sulfasalazine (Azulfidine), sulfisoxazole (Gantrisin), trimethoprim-sulfamethoxazole (Bactrim, Septra)	<ul style="list-style-type: none"> • Effective against most gram-positive and many gram-negative organisms. • Commonly used with urinary tract infections, <i>Pneumocystis carinii</i> pneumonia, and otitis media. • Common side effects include rash, pruritus, nausea, vomiting, phlebitis, signs of bleeding. • IV drug should be given over 1 hour. • Monitor intake and output. • Fluid intake should be at least 1500 mL daily. • Bleeding time may increase, so use caution with anticoagulants. • Phenytoin (Dilantin) toxicity may be increased. • The risk of hypoglycemia may be increased. 	<ul style="list-style-type: none"> • Instruct patient to take drug on an empty stomach 1 hour before or 2 hours after meals. • Tell patient to take with a full glass of water; encourage fluids. • Advise against prolonged exposure to the sun. • Tell patient to stop drug and call primary care provider if signs of allergic reaction or bleeding occur.
Antifungal Agents		
Amphotericin B	<ul style="list-style-type: none"> • Interferes with the cell wall structure of the fungus, causing it to die. • Given parenterally and reserved for life-threatening fungal infections. Monitor patient during first hour of infusion for febrile reaction. • Monitor injection site often because drug is very irritating to tissues. • Report side effects: nausea, vomiting, diarrhea. • Monitor intake and output, blood urea nitrogen (BUN), and creatinine levels for signs of kidney damage. • Obtain daily weight because fluid retention follows kidney damage. • Encourage 2000 to 3000 mL of fluid daily to help flush drug through kidneys. 	<ul style="list-style-type: none"> • Explain the purpose of treatment and need for long-term IV therapy. • Instruct patient and family on side effects and possible discomfort at IV site.
Fluconazole (Diflucan)	<ul style="list-style-type: none"> • Used to treat candidal and urinary tract infections, as well as cryptococcal meningitis. • Can be given either parenterally or orally. • Cultures are obtained before giving drug. • Monitor BUN and creatinine. Use cautiously if patient has renal impairment. • Monitor liver function. • Monitor side effects: hepatotoxicity, nausea, vomiting, diarrhea, abdominal discomfort. 	<ul style="list-style-type: none"> • Tell patient to take drug at same time each day and not to double a dose if one is missed. • Teach patient and family to notify the primary provider at the first sign of yellow skin, dark urine, or pale stools (signs of liver damage).

CRITICAL THINKING

Mr. Cheevers

Mr. Cheevers is admitted to the hospital for IV antibiotic therapy. He states that he has no allergies. One hour after the infusion begins you happen to meet the nursing assistant coming down the hall with a blanket. He casually says, "Mr. Cheevers is very cold. I'm bringing him a blanket." It is a warm mid-June day. What is your responsibility in this situation?

Answers at end of chapter.

► NURSING PROCESS

Assessment

It is important to recognize the earliest signs and symptoms of infection. Early detection can help provide early treatment to prevent major complications and reduce costs.

Signs of Respiratory Tract Infections

Patients with respiratory tract infections may have a cough, a congested or runny nose, a sore throat, chest congestion, or chest pain. The throat may be reddened, or there may be white patches in the back of the throat. Lung sounds can include crackles, rhonchi, or wheezing. Ask patients if they have a productive cough and the amount, frequency, and color of the sputum. A sputum culture is obtained to identify the presence of pathogenic organisms for appropriate treatment.

Signs of Gastrointestinal Tract Infections

The symptoms of GI tract infections may include nausea, vomiting, diarrhea, cramping, and anorexia. Patients may have frequent episodes of emesis and diarrhea and need to be monitored for signs of dehydration resulting from the loss of fluid. Stool cultures may be ordered.

Signs of Genitourinary Tract Infection

Symptoms of a urinary tract infection can include voiding urgency, frequency, burning, flank pain, change in color of urine, foul odor, or discharge. Monitor frequency, amount, color, and odor of the urine. Urinalysis and urine cultures are ordered to detect organisms. Collect urine cultures using sterile (via catheter) or clean (via clean catch) technique. Urinary tract infections need to be treated because those left untreated can lead to serious kidney problems.

Nursing Diagnosis

Nursing diagnoses for a patient with an infection may include the following:

- Risk for infection related to external factors
- Pain related to the infectious process
- Imbalanced nutrition: less than body requirements related to problems eating or digesting food
- Ineffective protection related to suppressed immune function
- Deficient knowledge related to disease process and treatment

Planning

The patient's goals are to remain free of infection symptoms, have pain relieved, consume adequate nourishment, remain free of infection, and verbalize knowledge of disorder and therapy.

Implementation

It is important to follow agency policy and procedures for infection control. Understanding how infections are contracted and spread help control infectious disease. Ensuring that the appropriate medication is given on time and understanding how to care for patients with infections can help the patient recover quickly. All members of the health care team must be aware of the patient's infection and their role in helping the patient recover. Providing emotional support to the patient is also important (see Patient Perspective Box 7-5).

Patients, families, and all members of the health care team must be aware of the events that cause infections and understand treatment plans for infections. Patients who are prone to infection because of immunosuppression should take special precautions to prevent infection (Box 7-6). Education should be directed toward prevention of infectious diseases. Teaching patients how to participate in their care and having them assist in the development of their plan of care promote compliance with treatment. Patients' understanding of how infections occur helps them in controlling their risk for developing an infection.

BOX 7-5 Patient Perspective

Emotions of Chronic Infection

Edie

It was back! I wasn't sure I could deal with it one more time. I've been hospitalized four times with this same infection (cellulitis) in my leg. It feels like I've lost my life. I can't count on being able to do anything and go anywhere because the infection just keeps coming back.

My left leg is now all swollen, reddened, discolored, and very painful. I can tell when I'm infected by more than the pain in the leg. I feel weak, kind of spacey, and once I passed out. I'm so sick of going into the emergency room—waiting forever to get admitted, all the IV starts and blood draws. With these infections, I've had a PICC [peripherally inserted central catheter] line twice. I've been sent home on IV antibiotics, sometimes for weeks at a time. I've learned how to hang my own IV antibiotics; in fact, I've learned much more than I ever wanted to.

My cellulitis is associated with chronic lymphedema, causing swelling in my legs. I'm working hard to keep the swelling down, so that the infection doesn't reoccur. Wish me luck and keep giving me psychosocial support during your nursing care. I'm not sure how I will be able to deal with this much longer.

BOX 7-6 Teaching Points to Prevent Infection in the Elderly, Debilitated, or Immunocompromised Patient

- Wash your hands frequently, using proper technique.
- Avoid crowds or anyone with an infection.
- Stay well nourished because food helps keep the immune system healthy.
- Have a flu shot yearly and a pneumonia shot as recommended by your primary care provider.
- Wash raw fruits and vegetables thoroughly, cook food thoroughly, and store food safely to prevent food poisoning. (NOTE: with severe immunocompromise, raw foods, soft cheeses, and yogurt may be contraindicated.)
- If your immune system is depressed, notify your primary care provider about any elevated temperature, even in the absence of other symptoms. People with depressed immune function cannot mount the usual immune response to infection, and a low-grade fever may be the only sign of infection.

Evaluation

Patient outcomes are met if the patient:

- has laboratory data within normal limits, indicating infection is controlled and no symptoms of infection are present.
- reports pain is relieved.
- maintains ideal body weight for height and weight and eats a balanced diet.
- remains free of infection.
- describes therapy and carries out treatment.

REVIEW QUESTIONS

- Which of the following nursing actions should the nurse include in the plan of care to help maintain the body's first line of defense against infection?
 - Help the patient cough and deep breathe.
 - Give an antibiotic as ordered.
 - Apply lotion to clean skin.
 - Help the patient void.
- Which of the following is the most important nursing action for the nurse to use to prevent a hospital-acquired urinary tract infection in a patient with an indwelling urinary catheter?
 - Ensure an adequate intake of IV and oral fluids.
 - Use clean technique for catheter insertion.
 - Position drainage bag higher than bladder level.
 - Maintain a closed urinary drainage system.
- The nurse is to give a newly ordered antibiotic to a patient with a wound infection. Which of the following should the nurse do first?
 - Check all patient allergies.
 - Check the patient's temperature.
 - Change dressing and note wound appearance.
 - Give antibiotic at meal time.
- Which of the following is the most important technique for the nurse to use during patient care to prevent infection transmission?
 - Wear gloves
 - Wear gown
 - Wash hands
 - Wear mask
- Which of the following statements suggests that the patient understands the general principles of appropriate antibiotic use?
 - "I'll take this until I feel better."
 - "I have some pills from the last time that I had this infection that I will take."
 - "I'll take all of this as it says on the label."
 - "I take only half a pill to reduce the cost."

Answers to CRITICAL THINKING

Mrs. Sampson

- Hand washing reduces the microorganisms on the nurse's hands to help reduce their transmission from patient to patient. This helps prevent exposure to pathogens and infection.
- Risk for infection.
- Reverse isolation, the goal of which is to protect the patient from exposure to organisms rather than to protect others from exposure to the patient.

Who Is at Greatest Risk of Infection?

- Mr. Ashland has two risk factors: chronic disease and probably stress.
- Mrs. Burrows has many risk factors, including old age, debilitated condition, probable malnourishment, probable stress, and an invasive procedure. This patient is at greatest risk.
- Jackson has four risk factors: his young age, probable stress, possible malnourishment, and an invasive procedure.

Mr. Carson

- Ask the nursing assistant about the Foley bag placed above the patient's bladder. Explain that the bag should always stay below the level of the bladder both for proper drainage and for infection control.
- Assist the nursing assistant in repositioning the bag properly.
- Let Mr. Carson's primary nurse know about the potential back-flow of urine so that he can be assessed in the next few days for signs of a bladder infection.

Mr. Cheevers

Mr. Cheevers may be experiencing a sign of allergic reaction to the medication. The fact that he has no history of allergy is no guarantee that he is not experiencing one now. He needs to be evaluated immediately, and if allergy is suspected, the IV should be stopped and the primary provider notified. Epinephrine should be on hand if the patient develops an anaphylactic response. The primary nurse needs to be alerted to the situation in the event that it worsens. Later the nursing assistant can be instructed about the signs of allergic response.

QUESTIONS TO GUIDE YOUR READING

1. What is the definition of shock?
 2. How would you explain the pathophysiology of shock?
 3. What are the etiologies, signs, and symptoms of the four categories of shock?
 4. What is the current medical treatment for shock?
 5. Which data should you collect when caring for patients with shock?
 6. What nursing care should you provide for patients with shock?
 7. How will you know if your nursing interventions have been effective?
- thrombi (**THROM**-bye)
 toxemia (tock-**SEE**-me-ah)
 trauma (**TRAW**-mah)
 Trendelenburg (tren-**DELL**-en-berg)
 urticaria (**UR**-ti-**CARE**-ee-ah)

A patient in shock is in a state of circulatory collapse that results in organ damage and death without immediate treatment. Massive bleeding, overwhelming infection, severe allergic reactions, and cardiac failure are examples of conditions that may lead to shock. No matter what its source, shock is a medical emergency that requires rapid, comprehensive nursing assessment and intervention in collaboration with the health care team.

The commonly used definition of shock is “inadequate tissue **perfusion**,” in which there is insufficient delivery of oxygen and nutrients to the body’s tissues and inadequate removal of waste products from the tissues. All body systems are affected by reduced oxygen supplies. The resulting injury to the body can be treated in the early stages of shock, but if shock is prolonged, it leads to irreversible cell damage and death. By the time the blood pressure drops, cellular and tissue damage have already occurred. Therefore it is important to identify patients at risk for shock and carefully assess them for early symptoms.

▶ PATHOPHYSIOLOGY OF SHOCK

Tissue perfusion and blood pressure are maintained in the body by three mechanisms: adequate blood volume, an effective cardiac pump, and effective blood vessels. The body is able to compensate for failure of one of these mechanisms by making a change in one or both of the other two. Shock occurs when compensatory mechanisms fail and inadequate tissue perfusion occurs. Common causes include inadequate **cardiac output** caused by heart failure, a sudden loss of blood volume resulting from hemorrhage, or a sudden decrease in peripheral vascular resistance caused by **anaphylaxis**, **sepsis**, and neurological alterations.

Metabolic and Hemodynamic Changes in Shock

When blood pressure falls, the body responds by activating the sympathetic nervous system (SNS). The SNS secretes **epinephrine** and **norepinephrine** to increase cardiac output by causing the heart to beat faster and stronger. Blood is shunted away from the skin, kidneys, and intestines to preserve blood flow to the brain, liver, and heart. Epinephrine, cortisol, and glucagon raise blood glucose levels to supply cells with fuel. Stimulation of the renin-angiotensin-aldosterone system (RAAS) from decreased cardiac output causes vasoconstriction and retention of sodium and water to decrease further fluid loss. Respiratory rate increases to deliver more oxygen to the tissues. Together these compensatory responses produce the classic signs and symptoms of the initial phase of shock: **tachycardia**, **tachypnea**, **oliguria**, restlessness, anxiety, and cool, clammy skin with pallor. If oxygen delivery remains inadequate, signs and symptoms of moderate and irreversible shock phases are seen (Table 8–1).

anaphylaxis: an—without + phylaxis—protection
tachycardia: tachy—fast + cardia—heart condition
tachypnea: tachy—fast + pnea—breathing
oliguria: olig—few + uria—urine condition

LEARNING TIPS

Tachycardia is a compensatory mechanism that is usually the first sign of shock. When a patient develops sustained tachycardia, it is a signal that the patient’s condition is changing. Be aware that elderly patients cannot tolerate tachycardia very long because their ability to adapt to stress is reduced.

Consider the cause of the tachycardia. For example, a surgical patient who develops tachycardia may be hemorrhaging and should be assessed for bleeding. Be aware that with internal hemorrhaging there may not be any visible signs of bleeding. Changes in vital signs may be the only evidence.

Provide prompt intervention, such as applying direct pressure to an area of hemorrhage, and implement the physician’s orders immediately.

Inadequate tissue blood flow causes an important change in cellular metabolism. When cells are deprived of oxygen, they shift to **anaerobic** metabolism to continue to receive nutrition and energy. As you may recall, anaerobic metabolism is an inefficient form of metabolism that can supply the energy needs of the cell for a few minutes only. After that, the body’s metabolic rate and temperature begin to fall as a result of reduced energy production. Anaerobic metabolism results in the production of **lactic acid** as an unwanted byproduct. Unless the lactic acid can be circulated to the liver and thus removed from the bloodstream, the blood will become increasingly acidic. **Acidosis**, which is a fall in blood pH below 7.35, is one of the classic signs of shock.

CRITICAL THINKING

Anaerobic Metabolism

Why is anaerobic metabolism necessary and helpful if it produces the complication of metabolic acidosis?

Answer at end of chapter.

Effect on Organs and Organ Systems

Prolonged shock causes extensive damage to the organs and organ systems (Table 8–2). Inadequate blood flow results in tissue **ischemia** and injury. Because blood is shunted away from the kidneys early in shock to save fluid and provide oxygen to vital organs, the kidneys commonly are injured first. The kidneys can tolerate reduced blood flow for about 1 hour before sustaining permanent damage. Cells in the kidneys die when there is a lack of oxygen and nutrients. If there is widespread damage to the kidneys, complete renal failure is likely. Renal failure resulting from inadequate blood flow to the kidneys can be prevented and treated by replacing lost fluids.

Several organs of the gastrointestinal system may be injured early in shock. Inadequate circulation to the intestines may result in injury of the mucosa and may even cause paralytic ileus. **Toxemia** may result when the body absorbs

anaerobic: an—without + aerobic—presence of oxygen
acidosis: acid—sour + osis—condition

TABLE 8-1 SIGNS AND SYMPTOMS OF SHOCK PHASES

Signs and Symptoms	Phases		
	Mild/Compensating	Moderate/Progressive	Severe/Irreversible
Heart Rate	Tachycardia	Tachycardia	Slowing
Pulses	Bounding	Weaker, thready	Absent
Blood Pressure			
Systolic	Normal	Below 90 mm Hg In hypertensive 25% below baseline	Below 60 mm Hg
Diastolic	Normal	Decreased	Decreasing to 0
Respirations	Elevated	Tachypnea	Slowing
Depth	Deep	Shallow	Irregular, shallow
Temperature	Varies	Decreased May elevate in septic shock	Decreasing
Level of consciousness	Anxious, restless, irritable, alert, oriented	Confused, lethargy	Unconscious, comatose
Skin and Mucous Membranes	Cool, clammy, pale	Cold, moist, clammy, pale	Cyanosis, mottled cold, clammy
Urine Output	Normal	Decreasing to less than 20 mL/h	15 mL/h decreasing to anuria
Bowel Sounds	Normal	Decreasing	Absent

TABLE 8-2 EFFECT OF SHOCK ON ORGANS AND ORGAN SYSTEMS

Lungs	Acute respiratory failure Acute respiratory distress syndrome
Renal	Renal failure
Heart	Dysrhythmias, myocardial ischemia, and myocardial depression
Liver	Abnormal clotting; decreased production of plasma proteins; elevated serum levels of ammonia, bilirubin, and liver enzymes
Immune System	Depletion of defense components
Gastrointestinal System	Mucosal injury, paralytic ileus, pancreatitis, absorption of endotoxins and bacteria
Central Nervous System	Ischemic damage, necrosis, brain death

into the circulation normally occurring bacteria and endotoxins from inside the bowel. The liver may be injured both by ischemia and by toxins created by the shock state as blood is circulated through it for cleansing. Signs and symptoms of liver injury include decreased production of plasma proteins; abnormal clotting, because clotting factor production by the liver is impaired; and elevated serum levels of ammonia, bilirubin, and liver enzymes.

The immune system is also affected by shock. Many of the body's defenses become depleted from shock, leaving the body vulnerable to infection. Also, if the liver has been damaged, it is unable to assist the immune system in providing defense.

The body attempts to preserve blood supply to the heart and brain because these are vital organs that require a continuous supply of oxygen. Shock places extra demands on the heart itself, creating a situation in which the heart is in extra need of oxygen at a time when oxygen supplies are already low. When the **myocardium** receives inadequate oxygenation, cardiac output decreases and shock worsens. The pumping ability of the heart can be further depressed by acidosis, toxins released into the blood from ischemic tissues,

or ischemia-induced **dysrhythmias**. If the brain is deprived of circulation for more than 4 minutes, brain cells die from a lack of oxygen and glucose. Lengthy shock may result in brain death.

► COMPLICATIONS FROM SHOCK

Acute respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), and multisystem organ failure are three especially grave conditions that may follow a prolonged episode of shock. Patients with ARDS usually develop respiratory failure despite high levels of supplemental oxygen and mechanical ventilation. DIC results from ischemic damage to the endothelial lining of blood vessels. The formation of multiple tiny **thrombi**, microscopic debris, and depletion of tissue clotting factors cause abnormal bleeding and additional tissue damage. DIC itself may cause shock and death. Multisystem organ failure is a major cause of death following shock. It usually begins with respiratory failure, followed by failure of the kidneys, heart, liver, and finally cerebral and gastrointestinal function.

LEARNING TIPS

To understand what *disseminated intravascular coagulation* means, define each of the words and then put the definitions together.

Disseminated = scattered or widespread
Intravascular: intra = inside + vascular = vessels
Coagulation = clotting

These definitions put together tell you that DIC is scattered, widespread clotting inside the vessels.

At first, hemorrhage does not seem reasonable in light of a clotting problem, but if you think about what is occurring, it does make sense. When many clots form throughout the body in response to stressors, few clotting factors remain available to form the clots needed to prevent hemorrhage. As a result, hemorrhage is a risk in DIC.

dysrhythmia: dys—difficult or abnormal + rhythmia—rhythm

► CLASSIFICATION OF SHOCK

The different forms of shock are classified by their cardiovascular characteristics. The four shock categories are: (1) **hypovolemic** shock caused by a decrease in the circulating blood volume, (2) **cardiogenic** shock caused by cardiac failure, (3) **extracardiac** obstructive shock caused by a blockage of blood flow in the cardiovascular circuit outside the heart, and (4) **distributive** shock caused by excessive dilation of the venules and arterioles (Table 8–3). Most cases of clinical shock show only some components of each of these categories. However, this classification system is helpful in understanding shock. The hallmark characteristic, which all forms of shock exhibit, is a decrease in blood pressure. The blood pressure usually falls below the level required to provide an adequate supply of blood to the tissues.

Hypovolemic Shock

Any severe loss of body fluid may lead to hypovolemic shock. Hypovolemic shock can be caused by dehydration; internal or external hemorrhage; fluid loss from burns, vomiting, or diarrhea; or loss of intravascular fluid into the interstitium as a result of sepsis or **trauma**. Clinical signs and symptoms include pale, cool, clammy skin; tachycardia; tachypnea; flat, nondistended peripheral veins; decreased jugular vein circumference; decreased urine output; and altered mental status. With a 10 percent loss of blood volume,

tachycardia is the only obvious sign. At 20 to 25 percent blood loss, tachycardia and mild to moderate **hypotension** are present. With a loss of 40 percent or greater, all clinical signs and symptoms of shock are present.

Cardiogenic Shock

Cardiogenic shock results when the heart fails as a pump. It occurs in 5 to 10 percent of patients with acute myocardial infarction (AMI). In most cases, approximately 40 percent of the myocardium must be lost to produce cardiogenic shock. Patients with cardiogenic shock have signs and symptoms similar to hypovolemic shock, except that they may display distended jugular and peripheral veins, as well as other symptoms of heart failure, such as pulmonary edema. Other causes of cardiogenic shock include rupture of heart valves, acute **myocarditis**, end-stage heart disease, severe dysrhythmias, or traumatic injury to the heart.

Obstructive Shock

Extracardiac obstructive shock occurs when there is a blockage of blood flow in the cardiovascular circuit outside the heart. Several conditions may cause obstructive shock. **Pericardial tamponade**, which is the filling of the pericardial sac with blood, compresses the heart and limits its filling capacity. **Tension pneumothorax** compresses the heart from an abnormal collection of air in the pleural space and

TABLE 8–3 CATEGORIES OF SHOCK

Category	Causes	Signs and Symptoms
<i>Hypovolemic Shock</i>	Any severe loss of body fluid; dehydration, internal or external hemorrhage, fluid loss from burns or from vomiting or diarrhea, or loss of intravascular fluid into the interstitium.	Tachycardia, tachypnea, hypotension, cyanosis, oliguria, flat nondistended peripheral veins, decreased jugular veins, and altered mental status.
<i>Cardiogenic Shock</i>	Myocardial infarction, myocarditis, end-stage cardiomyopathy, severe dysrhythmias, valvular disease, severe electrolyte imbalance, and drug overdoses.	Dysrhythmias, labored respirations, hypotension, cyanosis, oliguria, altered mental status, possibly distended jugular and peripheral veins, and symptoms of congestive heart failure.
<i>Obstructive Shock</i>	Any block to the cardiovascular flow. Pericardial tamponade, tension pneumothorax, intrathoracic tumors, massive pulmonary emboli, and large systemic emboli.	Tachycardia, tachypnea, hypotension, cyanosis, oliguria, and altered mental status; jugular veins may be distended.
<i>Distributive Shock</i>	Any condition causing massive vasodilation of the peripheral circulation. Subcategories include anaphylactic, septic, and neurogenic shock.	See subcategories below.
Anaphylactic shock	Insect stings, antibiotics, anesthetics, contrast dye and blood products are typical allergens.	Tachycardia, tachypnea, hypotension, cyanosis, oliguria, and altered mental status. May also have urticaria, laryngeal edema, and severe bronchospasm. If conscious, may be extremely apprehensive and complain of a metallic taste.
Septic shock	Massive release of chemical mediators and endotoxins causes loss of vascular autoregulatory control and loss of fluid into the interstitium. Bacteria, especially gram-negative strains, protozoans, and viruses.	Early or warm phase: blood pressure, urine output, and neck veins may be normal. Skin warm and flushed with full veins. Fever usually present, although temperature may be subnormal. Late phase: tachycardia, tachypnea, hypotension, oliguria, flat jugular and peripheral veins, and cool clammy skin. Normal or subnormal temperature.
Neurogenic shock	Dysfunction or injury to the nervous system. Spinal cord injury, general anesthesia, fever, metabolic disturbances, and brain injuries.	Early phase: hypotension and altered mental status, bradycardia, and skin that is warm and dry. Late phase: tachycardia, tachypnea, and cool clammy skin.

interferes with normal cardiac functioning. **Acute pulmonary hypertension**, a sudden abnormally elevated pressure in the pulmonary artery, increases resistance for blood flowing out the right side of the heart. All these conditions decrease cardiac output, which can lead to shock. Tumors or large emboli may also cause shock. Signs and symptoms of obstructive shock are similar to those of hypovolemic shock, except that jugular veins are usually distended.

Distributive Shock

Distributive shock occurs when peripheral vascular resistance is lost because of massive vasodilation of the peripheral circulation. Distributive shock includes anaphylactic, septic, and **neurogenic** shock.

Anaphylactic Shock

Anaphylactic shock occurs when the body has an extreme hypersensitivity reaction. It occurs most commonly from insect stings, antibiotics (especially penicillins), anesthetics, contrast dye, and blood products. The signs and symptoms are similar to those seen in hypovolemic shock. Additionally, patients may have symptoms specific to allergic reactions, including **urticaria**, wheezing, **laryngeal edema**, and severe **bronchospasm**. If conscious, patients may be extremely apprehensive and short of breath, and they may complain of a metallic taste.

Septic Shock

Septic shock is caused by systemic infection and inflammation. Extensive release of chemical mediators and endotoxins causes dilation of blood vessels and loss of fluid into the interstitial space. Most cases of sepsis are caused by gram-negative bacteria, although other bacteria and viruses may be the cause. Septic shock is the leading cause of death

among critical care patients. Predisposing conditions include trauma, diabetes mellitus, corticosteroid therapy, immunocompromise (e.g., as seen in patients with human immunodeficiency virus [HIV] and in those undergoing chemotherapy treatment for cancer), and an indwelling Foley catheter.

During the early, or warm, phase of septic shock (which may be referred to as “pink” shock), blood pressure, urine output, and neck vein size may be normal, but the skin is warm and flushed. Fever is present in the majority of patients, although some may have a subnormal temperature. Untreated, septic shock progresses to a second phase with signs and symptoms similar to hypovolemic shock: hypotension, oliguria, tachycardia, tachypnea, flat jugular and peripheral veins, and cold, clammy skin. Body temperature may be normal or subnormal.

Neurogenic Shock

Neurogenic shock occurs when dysfunction or injury to the nervous system causes extensive dilation of peripheral blood vessels. It is a rarer form of shock, occurring most commonly as a result of injury to the spinal cord (referred to as spinal shock). Other causes include general anesthesia, fever, metabolic disturbances, and brain contusions and concussions. Signs and symptoms include hypotension and altered mental status and, during the early phases, bradycardia and warm, dry skin. As shock progresses, however, tachycardia and cool, clammy skin develop.

► MEDICAL-SURGICAL MANAGEMENT OF SHOCK

Because of the emergency nature of shock, life-threatening symptoms must be treated immediately (Table 8–4). The exact nature of the shock must be assessed while interven-

TABLE 8–4 MEDICAL-SURGICAL MANAGEMENT OF SHOCK

<i>Respiratory support</i>	Oxygen (nasal cannula, face mask, non-rebreather mask, assisted ventilations with bag-valve-mask, ventilator) SPO ₂ > 90% Venous lactic acid < 2.2 mmol/L
<i>Cardiovascular support</i>	Vasopressor medication (dopamine) if fluid resuscitation not effective Revascularization of heart in cardiogenic shock via angioplasty with or without stent or fibrinolytic therapy (alteplase) Antidysrhythmics Positive inotropes
<i>Adequate circulatory volume</i>	1–3 L IV fluids Crystalloid fluids: normal saline (0.9% sodium chloride) or lactated Ringer’s solution 3 mL crystalloid solution for every 1 mL fluid lost Blood or blood products Urine output > 30 mL/h Hemoglobin > 10 g/dL
<i>Control of bleeding</i>	Pressure dressings Surgical intervention
<i>Treatment of life-threatening injuries</i>	Surgical interventions Medications
<i>Determination and treatment of causes of shock</i>	Septic shock: antibiotics Cardiogenic shock: morphine, diuretics, nitrates Anaphylactic shock: epinephrine, diphenhydramine (Benadryl), methylprednisolone (Solu-Medrol), aminophylline

TABLE 8-5 ASSESSMENT OF THE PATIENT IN SHOCK

Signs and Symptoms	Tachycardia, tachypnea, hypotension, oliguria, cyanosis, and altered mental status
Laboratory Tests	Complete blood count, serum osmolarity, blood chemistries, prothrombin time, partial thromboplastin time, blood typing and crossmatch, serum lactate, arterial blood gases, cardiac isoenzymes, urinalysis
Imaging	Chest x-ray, spinal films, computed tomography, echocardiogram
Monitoring	Electrocardiogram, arterial pressure monitor, central venous pressure monitor, pulmonary artery catheter, gastric pH

tions such as ventilatory and circulatory support are being implemented (Table 8-5). The order of interventions and testing is guided by the stability of the patient. Intervention priorities are as follows:

1. Airway and respiratory support
2. Cardiovascular support
3. Maintenance of circulatory volume
4. Control of bleeding if present
5. Assessment of neurological status
6. Treatment of life-threatening injuries
7. Determination and treatment of the cause of shock

► NURSING PROCESS

Assessment

Assessment of the patient in shock must be carried out quickly and should always start with the ABCDs: airway, breathing, circulation, and disability.

Airway is assessed for patency and opened as necessary. A compromised airway must be treated immediately with the head-tilt/chin-lift method, an oral or nasal airway, or endotracheal intubation.

Breathing is assessed for rate, depth, and symmetry of chest movement. The patient is observed for use of accessory muscles. Lung sounds are auscultated. Crackles may be found in the patient with cardiogenic shock or in the patient who has received too much intravenous (IV) fluid.

Circulation is assessed with blood pressure. A narrowing pulse pressure may be present before a drop in systolic pressure and indicates a decrease in cardiac stroke volume and peripheral vasoconstriction. Peripheral pulses are palpated. Tachycardia is the first sign of shock. The pulse is assessed for quality; commonly it is weak and thready in a patient with shock. As shock progresses, the peripheral pulses become bradycardic or absent. The radial pulse is present if the patient's systolic blood pressure is below 80 mm Hg. A capillary refill greater than 2 seconds indicates inadequate circulation. Capillary refill has been found to be an unreliable indicator of shock in adults, especially elderly people. Other observations regarding circulation include

distended neck veins, which may be collapsed or full; skin that may be cool, pale, and diaphoretic; presence of **cyanosis**; mucous membranes that may be pale and dry; and thirst. Rapidly scan the entire body for evidence of bleeding or other injuries. Palpate the abdomen for signs of internal bleeding, such as a tender, distended, boardlike abdomen.

Disability is assessed by determining the patient's level of consciousness (LOC).

LEARNING TIPS

To assess level of consciousness, determine if the patient is alert by asking his or her name, the date, and the location. If the patient can answer all three questions, he or she is "alert and oriented \times 3 (person, place, time)." You can also use these indicators:

- A: alert
- V: responds to verbal commands
- P: responds to painful stimuli
- U: unresponsive

All four limbs are assessed for circulation, sensation, and mobility. Bilateral responses are compared for equality. **Circulation** is assessed by palpating pulses for presence and quality. **Sensation** is determined by touching the patient's hands and feet and asking what the patient feels and if there is any numbness or tingling. **Mobility** (motor ability) is assessed by having the patient move all four limbs and wiggle the fingers and toes. Have the patient push with his or her feet against your hands and squeeze two of your fingers to assess strength.

A "head-to-toe" approach can follow the primary ABCD assessment. The presence, severity, and location of pain or nausea and vomiting are assessed. Bowel sounds are auscultated to determine whether they are normal, absent, hyperactive, or hypoactive. When an indwelling urinary catheter has been placed, the color of the urine and the rate of urine output are noted. Body temperature should be noted.

CRITICAL THINKING

Classic Signs of Shock

What is the cause and compensatory purpose of each of the classic signs of shock: tachycardia, tachypnea, oliguria, pallor, and cool, clammy skin?

Answer at end of chapter.

CRITICAL THINKING

Beta Blockers

You are assessing a patient admitted with sepsis. The patient has been taking a beta blocker. You are assessing the patient for septic shock. What sign of shock will not be present in a patient taking a beta blocker?

Answer at end of chapter.

Nursing Diagnosis

The major nursing diagnoses for shock include but are not limited to the following:

- Ineffective tissue perfusion (renal, cerebral, cardiopulmonary, gastrointestinal, peripheral) related to hypovolemia or inadequate cardiac output or mechanical reduction of venous and/or arterial blood flow
- Fear related to severity of condition and unknown outcome
- Deficient knowledge related to unfamiliar condition

See Nursing Care Plan 8–1 for the Patient in Shock.

Planning

The patient's goals are to (1) demonstrate adequate tissue perfusion, (2) verbalize reduced fear, and (3) understand the condition and its treatment.

Nursing Interventions

The cardiovascular status of patients in shock must be carefully monitored based on their stability. IV fluids, medica-

tions, and oxygen are given as ordered. The **Trendelenburg** position is avoided, but a modified Trendelenburg position (raising legs only) may be used to increase venous return to the heart except in patients with cardiogenic shock. If there is no neck or spinal trauma, the patient is placed supine with the trunk horizontal and the legs elevated 20 to 45 degrees, knees straight. The modified Trendelenburg position prevents gravity from stimulating cardiac reflexes, compressing coronary arteries, and causing the abdominal organs to press against the diaphragm. In cardiogenic shock, any position that could increase blood flow to the compromised heart could be fatal and therefore is avoided.

Reducing patient fear is important in controlling shock and preventing complications. The patient should be allowed to express fears and ask questions. Family members should be allowed to provide support to the patient.

The patient and family are included in education sessions. Simple explanations of what has occurred and what is happening can be followed by more complete explanations as the patient's condition improves. Interventions should include explanation of all diagnostic and treatment procedures, rationales, and outcome goals.

BOX 8-1 NURSING CARE PLAN FOR THE PATIENT IN SHOCK

Ineffective tissue perfusion (renal, cerebral, cardiopulmonary, gastrointestinal, peripheral) related to hypovolemia or inadequate cardiac output or inadequate vascular tone

PATIENT OUTCOME

Patient demonstrates adequate tissue perfusion

EVALUATION OF OUTCOME

Is patient's skin warm/dry, peripheral pulses present/strong? Are vital signs within patient's normal range? Are lung sounds normal, intake/output balanced, edema absent, pain/discomfort absent? Is patient alert/oriented?

INTERVENTION	RATIONALE	EVALUATION
Monitor vital signs.	Changes in vital signs, which indicate change in condition, can be detected early and treated promptly.	Is heart rate between 60 and 100 beats per minute? Is heart rhythm regular? Are peripheral pulses strong? Is systolic blood pressure (BP) > 100 mm Hg? Is patient alert and oriented × 3? Is SPO ₂ > 90%? Is skin pink? Are respirations between 12 and 20?
Maintain airway and provide oxygenation.	Ensures adequate oxygenation and tissue perfusion.	Is urinary output > 30 mL/h? Are mucous membranes moist? Is skin turgor < 3 seconds? Is edema noted? Is skin breakdown noted?
Monitor intake and output. Provide adequate fluid intake.	Provides adequate cardiac output to perfuse tissues. Assesses renal function. Urine output is an indicator of renal function.	Is patient resting comfortably without anxiety? Is body temperature within normal limits?
Position patient appropriately (head elevated for patients with shortness of breath, increased intracranial pressure). Provide quiet, restful environment. Maintain body temperature with warmed IV fluids, room temperature, blankets. Assess for pain and provide pain relief measures.	Proper positioning promotes circulation and helps prevent skin breakdown. Conserves energy and lowers tissue oxygen demands. Recovery is aided by normal body temperature. Pain increases tissue demands for blood and oxygen.	Is patient pain free?
Change positions slowly.	Age-related losses of cardiovascular reflexes can result in hypotension.	Is systolic BP > 100 mm Hg?

GERIATRIC

CRITICAL THINKING**Modified Trendelenburg Position**

Why would the use of modified Trendelenburg positioning be life threatening in a patient in cardiogenic shock?

Answer at end of chapter.

Evaluation

The ultimate goal of nursing care for the patient in shock is to restore normal tissue perfusion quickly enough to ensure recovery without complications. Short-term goals may include the following:

1. Reduce blood and fluid loss
2. Maintain adequate cardiac output
3. Restore adequate circulating volume
4. Reduce fear
5. Maintain optimal body temperature
6. Maintain normal baseline LOC

Once these goals are met, discharge planning for home care or rehabilitation can begin based on the patient's individualized needs.

CRITICAL THINKING**Mr. Hall**

Mr. Hall, who is 55 years old, has suffered an acute myocardial infarction. He is complaining of chest pain (rated 10 out of 10 on the pain rating scale) and difficulty breathing. His SpO_2 is 89 percent. Crackles are heard on auscultation of breath sounds. The electrocardiogram shows an irregular and rapid heartbeat. He is restless and apprehensive.

1. Name three nursing priorities for Mr. Hall's care.
2. What type of IV fluid and rate is appropriate for Mr. Hall?
3. What signs and symptoms indicate Mr. Hall is in cardiogenic shock?

Answers at end of chapter.

CRITICAL THINKING**Mrs. Neal**

Mrs. Neal, who is 45 years old, came to the emergency room in severe hypovolemic shock after sustaining several bleeding wounds in an automobile accident. Her shock is resolving after receiving several transfusions and surgical repair of her injuries. She has just been admitted to the surgical unit for postoperative care.

1. What postoperative nursing assessments should be performed first?
2. Mrs. Neal's family is very alarmed by her condition. What interventions can you provide to decrease their anxiety?
3. What postoperative complications may develop in Mrs. Neal?
4. What documentation is appropriate for Mrs. Neal?

Answers at end of chapter.

REVIEW QUESTIONS

1. Which of the following mechanisms does the body use to compensate for shock?
 - a. Peripheral nervous system depression
 - b. Central nervous system depression
 - c. Sympathetic nervous system stimulation
 - d. Parasympathetic nervous system stimulation
2. Which of the following findings is seen specifically with anaphylactic shock?
 - a. Tachycardia
 - b. Hypotension
 - c. Laryngeal edema
 - d. Oliguria
3. Which of the following conditions causes the decreased level of consciousness commonly found in patients experiencing shock?
 - a. Severe pain
 - b. Endotoxins
 - c. Cerebral hypoxia
 - d. Cerebral edema
4. Which of the following nursing diagnoses is most appropriate to include in the plan of care for a patient experiencing shock?
 - a. Fatigue
 - b. Ineffective tissue perfusion
 - c. Ineffective health maintenance
 - d. Hopelessness
5. You enter a patient's room and find the patient lying in a pool of blood from a leg incision that has opened. The patient is restless and confused. You call for help and take vital signs. Which of the following treatments for shock should be started first?
 - a. IV fluids
 - b. Oxygen
 - c. Vasopressor medications
 - d. Antibiotics

Answers to CRITICAL THINKING

Anaerobic Metabolism

Anaerobic metabolism is the source of nutrition and energy for the cell that prevents cellular death when oxygen is not available. It is a short-term compensatory mechanism to save the cell until oxygen becomes available again.

Classic Signs of Shock

Tachycardia is caused by decreased cardiac output and reduced tissue oxygenation. Its purpose is to increase cardiac output and oxygen delivery by causing more heartbeats to pump out blood from the heart.

Tachypnea is caused by decreased tissue oxygenation. Its purpose is to increase respirations so more oxygen is available for delivery to tissues.

Oliguria is caused by a reduced blood flow to the kidneys. Its purpose as a compensatory mechanism is to conserve as much fluid as possible to help maintain a normal blood pressure.

Pallor is caused by reduced blood volume or flow. When pallor results from compensation, it is due to peripheral vasoconstriction that occurs to shunt blood volume to the vital organs.

Cool, clammy skin is the result of decreased blood flow to the skin and the release of moisture (sweat) from the skin. The sympathetic nervous system causes these compensatory mechanisms; peripheral vasoconstriction shunts blood to the vital organs, and sweating cools the body in anticipation of the fight or flight response, which generates body heat when it occurred.

Beta Blockers

Tachycardia will not be present. Beta blockers block the response of the sympathetic nervous system, which is activated in shock.

Modified Trendelenburg Position

The modified Trendelenburg position increases venous blood return to the heart, which is helpful in improving cardiac output in shock. In cardiogenic shock, any position that increases blood flow to the

compromised heart increases the heart's workload. This could overwhelm or flood the heart so that it is unable to keep up with the blood volume returning to it. The result could be death.

Mr. Hall

1. Nursing priorities for Mr. Hall include relief of chest pain and anxiety, stabilization of cardiac rhythm and vital signs, and adequate tissue oxygenation.
2. Because Mr. Hall has crackles, which indicate fluid in the lungs, he should not be given IV fluids. He should have an IV access to give IV medications as needed. He already has too much fluid for his heart to handle, and giving him IV fluids could be life threatening.
3. Signs of cardiogenic shock include decreased blood pressure; increased heart and respiratory rates; cyanosis; decreased urine output; cool, pale skin; and decreased mental status.

Mrs. Neal

1. Assessment of respiratory status and cardiovascular status, inspection of surgical wounds for bleeding, assessment of mental status, and need for pain relief should be performed first.
2. Explain the cause of shock and all interventions, rationales, and desired outcomes. Keep the environment calm, provide for privacy, and answer all questions in a matter-of-fact and reassuring manner. Allow Mrs. Neal's family to visit.
3. Unrelieved pain, bleeding, infection, and respiratory complications are possible.
4. Airway: rate, depth, regularity of respirations; breath sounds, SPO₂. Vital signs: cardiac rhythm, quality of pulses, skin color, blood pressure, body temperature. Urine output: oral and IV intake, fluid balance. Pain: measures to relieve pain and evaluation of those measures. Dressings: any bleeding. Bowel sounds.

QUESTIONS TO GUIDE YOUR READING

1. How is pain defined?
2. What are the common myths and barriers to the effective management of pain?
3. What are the differences between addiction, physical dependence, and tolerance?
4. What is current knowledge of the basic physiology of the pain response?
5. What are characteristics that help to define acute, chronic nonmalignant, and cancer pain?
6. What are the primary components of a pain assessment?
7. How is the World Health Organization analgesic ladder used for the treatment of pain?
8. What are the three categories of analgesics and their uses?
9. What are commonly used pain treatment modalities and when are they used?
10. How are nondrug pain management techniques utilized?
11. How does ethical decision making play a role in the care of the patient in pain?

▶ THE PAIN PUZZLE

Pain is the most common reason patients seek medical advice. However, despite the widespread nature of the problem, pain is often untreated or undertreated. The care of patients with pain is challenging and requires a systematic approach to assessment and treatment.

Decisions about pain management require careful assessment of the patient's condition and attention to the ethical principles that influence patient care. Providing information and giving the patient choices help maintain autonomy. When patients are not involved in the process of choosing their own pain management options, they cannot be autonomous. Just as risks, benefits, and alternatives to surgery and anesthesia are discussed with the patient, so should pain management options be discussed in the process of obtaining informed consent. Nurses often worry about overmedicating patients, thinking that they are “doing good” (beneficence) or “doing no harm” (nonmaleficence) by withholding medication from a patient they do not believe is in pain (Ethical Consideration Box 9–1). It is important to learn as much as you can about pain and pain management, so you can effectively advocate for your patients, assist with patient education, and provide appropriate resources.

The Joint Commission for Accreditation of Healthcare Organizations (JCAHO) published pain management standards in 2000 and began assessing the management of pain in hospitals based on these standards in January 2001. These standards have added to the importance of pain management. They address assessment and appropriate pharmacological management of pain, as well as patient and family teaching, postoperative pain, management of side effects, discharge planning, and continuous quality improvement. These guidelines can be found at the JCAHO Web site.

For more information on pain management, visit the following Web sites. For some sites, you may need to type “pain” in the search window.

<http://www.iasp-pain.org>

http://www.jcaho.org/standards_frm.html

<http://www.who.org>

Cultural differences must be considered when planning care for the patient in pain. People from various cultures have different ways of expressing pain (Cultural Consideration Box 9–2). Some may be dramatic and emotional; others tend to be stoic and quiet. Knowledge of widely accepted information about different ethnic and cultural groups can be useful in understanding a patient's experience and what care might be considered acceptable. It is important, however, to assess a patient's pain care needs individually and not make assumptions based on culture or ethnicity alone.

Because of the importance of controlling health care costs, the entire health team must provide care in the most cost-effective manner possible while continuing to provide the best quality of care. Effective pain management can help reach those goals by enhancing comfort, minimizing

BOX 9-1 ETHICAL CONSIDERATION

Case Study—Controlling Pain

A client was admitted to the medical unit 2 days after his 83rd birthday with a diagnosis of metastatic cancer of the pancreas. He had several full-course treatments of chemotherapy and radiation during the previous year with only temporary remissions of the disease. His condition deteriorated rapidly during the previous month, and his family was no longer able to care for him at home. The patient's physician expected him to die within a few weeks, if not sooner, and admitted him to the hospital primarily for pain control. On admission, the physician ordered morphine sulfate (MS) 5 mg IV to be given every 2 hours around the clock.

Although this seemed like a relatively large dose of a strong narcotic medication to be given this frequently, the patient tolerated the treatment for the first 36 hours, and reported a significant reduction in his pain. On the third morning after his admission, he was difficult to arouse for his morning vital signs and breakfast. When his nurse, Kathy P., finally did manage to awaken the patient, he was confused, and his blood pressure was 82/50 with shallow respirations at 10/min. He still complained of severe generalized pain and asked for “more of that medication that helped so much the day before.”

Kathy did not give the patient his scheduled 0800 dose of MS. She phoned the physician and reported her assessment of the patient, expressing her belief that continuing the medication at the previously prescribed dose and frequency would be fatal to this patient. The physician, who had been up most of the night with an emergency patient, stated sarcastically, “. . . and your patient has such a productive life to look forward to—give the #& medication like I ordered it! And don't call me any more about this—I'll be in after lunch!” and slammed down the phone.

What should Kathy do? What are her ethical obligations in this particular case? How should the nurse weigh the risks and benefits of providing adequate pain medication given the possible side effects of hastening the patient's death? If the nurse has a moral objection to carrying out a physician's order, what options are available to that nurse? Use the ethical decision-making model to resolve this ethical dilemma. What information can assist in solving the problem if the material about virtues is applied to this situation? Would it make a difference if the nurse thought the patient should receive the pain medication and the patient refused on the basis of stoicism or from a religious perspective in which suffering is seen as a way to grow spiritually?

side effects of **opioids** and complications related to inadequate pain control, and reducing the lengths of hospital stays.

It is not possible to record a patient's pain on a machine or measure it with a blood or urine sample. It is difficult to objectively gauge the effect of a nursing intervention on pain, whether the intervention is medication or nondrug therapy. Pain and its treatment can be likened to a difficult puzzle that requires many pieces to solve.

In this chapter the many challenges of pain assessment and treatment are discussed. Some of the tools needed to effectively deal with these challenges are presented. Common myths and barriers that continue to affect nursing practice are clarified.

BOX 9-2 CULTURAL CONSIDERATION

The pain experience may differ between and among ethnocultural individuals. Remember that individuals within groups vary, and not all fit the general descriptions and previous experience with pain. (See Chapter 3.)

Culture	Expression and Meaning of Pain	Patient Preferences	Assessment	Interventions
Native-American	Frequently do not request pain medicine and are undertreated. May not realize that they can ask for pain medicine. Many believe pain is something that must be endured. May describe pain in general terms such as "not feeling good." The word for pain varies according to the tribal language.	Many prefer traditional herbal medicines. May complain to family member or visitor, who relays message to caregiver.	Frequently ask patient and family members or visitors if patient has pain. Observe for non-verbal clues of pain.	Explain that the control of pain can promote healing. Offer pain medicine as needed. Allow adequate time for response; silence is valued. Maintain a calm, relaxing environment. Incorporate traditional practices for pain relief if not harmful.
European-American	Strong sense of stoicism, especially men. Fear of being dependent may decrease use of pain medicine. Many have fear of addiction. May continue to work and carry out daily activities and minimize pain.	Prefer relaxation and distractions as means of pain control.	Observe for non-verbal signs of pain. Use visual analog or numerical pain scales to assess severity of pain.	Encourage use of pain medicine as needed. Incorporate distraction and relaxation techniques.
African-American	Usually openly and publicly display pain, but this is highly variable. Many, especially the elderly, fear that medication may be addictive. Pain is seen as a sign of illness or disease. Many believe that suffering and pain are inevitable and should be endured.	May focus on spirituality and religious beliefs to endure pain. Prayers and the laying on of hands are thought to relieve pain if the client has enough faith.	Observe for verbal and nonverbal expressions of pain. Use of pain scales is helpful.	Offer pain medication as needed. Allow meditation and prayer along with pain medication. Support patient's spiritual practices.
Hispanic-American	Puerto Ricans tend to be expressive of pain and discomfort. Moaning, groaning, and crying are culturally accepted ways of dealing with and reducing pain. Mexicans may bear pain stoically because it is "God's will." Many feel that pain and suffering are a consequence of immoral behavior. For men, expressing pain shows weakness and a possible loss of a respect. The Spanish word for pain is <i>dolar</i> .	Prefer oral or intravenous medication for pain. Heat, herbal teas, and prayer are used to manage pain.	Visual analog and numerical scales may be helpful. Observe and compare verbal and nonverbal behaviors indicating pain.	Do not censor verbal expression of pain. Incorporate traditional practices as permitted. For individuals who are stoical with pain, encourage pain medicine frequently. Explain that pain control can hasten healing.
Asian-American	Chinese and Koreans tend to be stoical, although there is a wide variation, and describe pain in terms of diverse body symptoms instead of locally. Filipinos may view pain as a part of living an honorable life. Some view this as an opportunity to reach a fuller life and to atone for past transgressions. Frequently stoic and tolerate pain to a high degree. Some moan as an expression of pain.	Prefer oral or intravenous pain medications. Like warm compresses. For Koreans, intramuscular injections may be seen as an invasion of privacy. Vietnamese maintain self-control as a means of pain relief.	Observe for non-verbal signs of pain. Vietnamese may not understand numerical scale of rating pain. Observing facial expression may be a good indicator of pain.	Incorporate traditional healing methods as much as possible. Offer and encourage pain medicines to promote healing.

BOX 9-2 CULTURAL CONSIDERATION—CONT'D

Culture	Expression and Meaning of Pain	Patient Preferences	Assessment	Interventions
Asian-American— cont'd	For the Japanese, bearing pain is a virtue and a matter of family honor. Some, especially older individuals, may fear addiction. For Vietnamese, enduring pain is an indication of strong character. Family may be very attentive and request pain medication for the patient.	Vietnamese maintain self-control as a means of pain relief.		
Arab-American	See pain as something to be controlled. May express pain openly to family with elaborate verbal expressions, less so with caregivers. Expect prompt interventions for pain control. Tend to describe pain as diffuse rather than locally. May use terms such as fire, hot, and cold.	Intramuscular or intravenous usually preferred over oral medications.	Compare verbal and nonverbal characteristics of pain to determine degree of pain.	Engage family to help with distraction and relaxation techniques. Administer medication promptly.
Appalachian	Pain is something to be endured, and many respond stoically, especially men. May continue activities until pain forces cessation of work.	Some may place a knife or axe under the bed or mattress to “cut pain.”	Observe for verbal and nonverbal signs of pain. Many do not like visual analog or numerical pain scales.	Offer pain medication frequently. Encourage relaxation techniques and distraction. Talking about the pain may have pain-relieving results.

► DEFINITIONS OF PAIN

According to Margo McCaffery, a well-known consultant in the care of patients with pain, “Pain is whatever the experiencing person says it is, existing whenever the experiencing person says it does.”¹ This is a reminder to nurses to accept the patient’s report of pain.

In 1979 pain was defined by the International Association for the Study of Pain (IASP) as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.² This definition indicates that pain is complex and has not only a physical component but an emotional one as well.

What is pain, and why does it exist? Pain is a protective mechanism or a warning. Pain in the presence of injury may help to prevent further injury. Consider the patient who experiences a fracture and holds it still to prevent further damage or a child who touches a hot stove and pulls his or her hand away before a serious burn occurs.

Why is untreated or undertreated pain a bad thing? Basic complications can occur when pain is experienced. The body produces a stress response in the presence of pain during which harmful substances are released from injured tissue. Reactions include breakdown of tissue, increased metabolic rate, impaired immune function, and negative emotions. In addition, pain prevents the patient from participating in self-care activities such as walking, deep breathing, and coughing. Consider the patient who has had chest surgery and then has to cough and deep breathe. It

hurts! So the patient tries not to cough, turn, or even move. Retained pulmonary secretions and pneumonia can develop. If the patient does not move around, return of bowel function is delayed and an ileus can result. When pain is well controlled, patients are able to do what they need to do to get well and go home from the hospital or continue with recovery activities.

Suffering often accompanies pain, but not all pain has the element of suffering. Suffering can exist without pain and pain without suffering. Suffering represents a threat to one’s self-image or life. According to the latest cancer pain guidelines from the Agency for Health Care Policy and Research (now called the Agency for Health Care Research and Quality), suffering is defined as the state of severe distress associated with events that threaten the intactness of the person.³ Pain can be a constant reminder for patients with cancer that they have a life-threatening illness. Suffering can often be relieved if patients believe that their pain can be relieved.

► MYTHS AND BARRIERS TO EFFECTIVE PAIN MANAGEMENT

Treatment of patients in pain is influenced by a number of factors, including the way the nurse was treated when in pain as a child. Why aren’t patients believed when they report pain? Why do nurses and other health care team members often insist that patients behave a certain way before they are believed? Common myths about pain may impair

the nurse's ability to be objective about pain and create barriers to effective treatment. Because there is no objective measure for pain, nurses may rely on what is comfortable rather than what has been proven to be effective.

Myth: A person who is laughing and talking is not in pain.

Fact: A person in pain is likely to use laughing and talking as a form of distraction. This can be very effective in the management of pain, especially when used in conjunction with appropriate drug therapies.

Myth: If morphine is given too early to the patient with cancer pain, it will not work when the patient really needs it, toward the end, when the pain is worse.

Fact: Morphine is an opioid **agonist**. Opioid doses can be escalated (titrated upward) indefinitely as needed as the patient's pain increases. There is no **ceiling effect**, or maximum effective dose. Side effects such as sedation or clinically significant respiratory depression may temporarily limit the dose or the rate at which the dose can be increased.

Myth: Respiratory depression is common in patients receiving opioid pain medications.

Fact: Respiratory depression is uncommon in patients receiving opioid pain medications. If patients are monitored carefully when they are at risk, such as with the first dose of an opioid or when a dose is increased, respiratory depression is preventable. A patient's respiratory status and level of sedation (LOS) should be routinely monitored using an LOS scale.

Myth: Pain medication is more effective when given by injection.

Fact: Intramuscular (IM) injections are not recommended because they are painful, have unreliable absorption from the muscle, and have a lag time to peak effect and rapid falloff compared with oral administration. Oral administration is the first choice if possible; the intravenous (IV) route has the most rapid onset of action and is the preferred route for postoperative administration.

Myth: Teenagers are more likely to become addicted than older patients.

Fact: **Addiction** to opioids is very uncommon in all age groups when taken for pain by patients without a prior drug abuse history.

CRITICAL THINKING

Smithers and Barnett

Mrs. Smithers had an abdominal hysterectomy and is sitting up in bed the morning after surgery, putting on her makeup. On morning rounds she is smiling but reports that her pain is at 6 on a scale of 0 to 10. Mr. Barnett has just been transferred from the surgical intensive care unit the day after surgery for multiple injuries. He is moaning and reports his pain at 6 on a scale of 0 to 10. Which of these patients is really having as much pain as they say they are? How can you make that judgment?

Answers at end of chapter.

MORE DEFINITIONS

Nurses often express concern about patients who require large amounts of pain medication or know exactly when their next dose of pain medication is due. Nurses may say that such patients are addicted or that they are “clock watchers,” but do we really know what that means? Patients are expected to be informed about their medications and involved in their care, but when they know when their medications are due, we may become suspicious. In truth, if a patient is watching the clock, the most likely reason is because he or she is in pain. The most common reason that patients ask for more pain medicine is because they have increased pain. It is important to understand the differences between addiction, **physical dependence**, and **tolerance**. When talking with patients and teaching them about their medications, it is important to help them understand these differences as well. It is something many patients worry about.

Tolerance simply means that it takes a larger dose to provide the same level of pain relief. Physical dependence is a physiological phenomenon that most people experience after a few weeks of continuous opioid use. If an opioid is abruptly discontinued after a few weeks of use, the patient may experience a withdrawal syndrome, exhibiting symptoms such as sweating, tearing, runny nose, restlessness, irritability, tremors, dilated pupils, sleeplessness, nausea, vomiting, and diarrhea. These symptoms can be prevented by slowly weaning a patient from an opioid, rather than stopping it suddenly.

Psychological dependence is another term for addiction and is defined as a pattern of compulsive drug use characterized by a continued craving for an opioid and the need to use the opioid for effects other than pain relief. **Pseudo-addiction** has been described in patients who are prescribed opioid doses that are too low or spaced too far apart to relieve their pain, and certain behavioral characteristics resembling psychological dependence, such as drug-seeking behaviors, have developed. Educating patients and families about these concerns helps alleviate their fears and increases their satisfaction with the pain relief measures that are employed.

MECHANISMS OF PAIN TRANSMISSION

Many theories of how pain is transmitted are in the literature. The specificity theory, developed by Descartes in 1644, proposed that body trauma sends a message directly to the brain, causing a sort of “bell” to ring, prompting a response from the brain. In 1965 Melzack and Wall proposed the gate control theory, which describes the dorsal horn of the spinal cord as a gate, allowing impulses to go through when there is a pain stimulus and closing the gate when those impulses are inhibited. The gate control theory stimulated massive research on the physiology of pain.

pseudoaddiction: pseudo—false + addiction—psychological dependence

Much more is known about the transmission of pain today. **Endorphins** are endogenous (naturally occurring) chemicals that act like opioids to inhibit pain impulses in the spinal cord and brain. Unfortunately they degrade too quickly to be considered effective **analgesics**. Endorphins are the chemicals that stimulate the long-distance runner’s “high.” **Enkephalins** are one type of endorphin.

Pain is transmitted through the dorsal horn of the spinal cord and other points in the central nervous system to higher centers of the brain with the influence of chemicals known as neurotransmitters, which are released during pain or trauma. These chemicals include **serotonin, prostaglandins**, and others. Many treatments and analgesics are designed, based on known principles, to inhibit the release of these chemicals at different points along the pain pathway.

Mechanisms of pain transmission are **nociceptive** and **neuropathic**. *Nociception* refers to the body’s reaction to noxious stimuli, such as tissue damage, with the release of pain-producing substances. Nociceptive pain in the visceral organs may be referred to other parts of the body. See Figure 9–1 for sites of referred pain. Neuropathic pain is pain associated with injury to either the peripheral or central nervous system. Unlike nociceptive pain, neuropathic pain is not usually localized, and it may spread to involve other areas along the nerve pathway.

► **TYPES OF PAIN**

Pain is often categorized according to whether it is acute, cancer related, or chronic nonmalignant. Acute pain is described as pain that follows injury to the body and subsides

when healing takes place. It may be associated with objective physical signs such as increased heart rate and elevated blood pressure. Examples of acute pain include pain related to fractures, burns, or other trauma. Cancer pain may be acute, chronic, or intermittent and often has a definable cause such as tumor invasion or neuropathy caused by the cancer treatment. Chronic nonmalignant pain persists beyond the time when healing usually takes place. Examples include low back pain, arthritic pain, and phantom limb pain. Chronic nonmalignant pain may have nociceptive, as well as neuropathic, components and may require a variety of medications and nondrug treatments. Because of the body’s ability to adapt, patients with chronic nonmalignant pain or chronic cancer pain may not appear to be in pain. The physiological responses that accompany acute pain, such as elevated heart rate and blood pressure, cannot be sustained without harm to the body, so the body adapts and the vital signs return to normal.

► **OPTIONS FOR TREATMENT OF PAIN**

Analgesics

Medications that relieve pain are called analgesics. Analgesics are the biggest pieces of the pain management puzzle. There are three main categories of analgesics: opioids, nonopioids, and **adjuvants**. Opioids are classified by their ability to bind to opioid receptors in the brain and spinal cord, as well as other areas of the body, inhibiting the perception of pain. Nonopioids include nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen (Tylenol). Adjuvants include classes of drugs that were originally developed for a different purpose but have been found to have pain-relieving properties in certain painful conditions.

nociceptive: noci—pain + ceptive—reception
neuropathic: neuro—nerves + pathy—disease, suffering

Figure 9-1 Sites of referred pain.

Nonopioids

Nonopioids are generally the first class of drugs used for treatment of pain. They can be useful for acute and chronic pain from a variety of causes, such as surgery, trauma, arthritis, and cancer. These medications are limited in their use because they have a ceiling effect to analgesia. A ceiling effect indicates that there is a dose beyond which there is no improvement in the **analgesic** effect and there may be an increase in side effects. When used in combination with opioids, care must be taken to ensure that the dose of the nonopioid drug does not exceed the maximum safe dose for a 24-hour period. For example, if a patient receiving two aspirin with codeine tablets every 4 hours continues to experience pain, the dose cannot be increased because of the potential toxic effects of the aspirin (Table 9–1). Nonopioids do not produce tolerance or physical or psychological dependence. They do have antipyretic (fever-reducing) effects. This class of drugs works primarily at the site of injury, or peripherally, rather than in the central nervous system like opioids do. NSAIDs block the synthesis of prostaglandin, one of many chemicals necessary for pain transmission. In general it is helpful to include a nonopioid in any analgesic regimen, even if the pain is severe enough to require the addition of an opioid.

Opioids

Opioids are added to nonopioids for pain that cannot be managed effectively by nonopioids alone. Opioids are classified as full agonists, partial agonists, or mixed agonists and **antagonists**. Full agonists have a complete response at the

BOX 9–3 Common Side Effects of Opioids

Sedation
 Respiratory depression*
 Constipation
 Nausea, vomiting
 Itching
 Constricted pupils*

*These effects are not common, but they alert the nurse to possible overdose.

opioid receptor site; the partial agonist has a lesser response. The mixed agonist and antagonist activates one type of opioid receptor while blocking another.

Opioids alone have no ceiling effect to analgesia. Doses can safely be increased to treat increasing pain if the patient’s respiratory status and level of sedation are stable. See Box 9–3 for side effects of opioids. Controlled-release opioids such as oxycodone (Oxycontin) and morphine (MS Contin) are effective for prolonged periods.

Controlled- or time-release medication should never be crushed, but always taken whole. Whenever a controlled-release preparation is used, it is important to have an immediate-release medication available for **breakthrough** pain, such as oral morphine solution (OMS) or other immediate-release opioid.

Morphine is the drug of choice for the treatment of moderate to severe pain. It is the drug used as a standard against which all other analgesics are compared. (See Table 9–2 for **equianalgesic** doses of medications.) Morphine is long acting (4 to 5 hours) and available in many forms, making it convenient, as well as affordable, for the patient. It has a slower onset than the other opioid agonists.

Hydromorphone (Dilaudid) is commonly used for moderate to severe pain as well. It is shorter acting than morphine and has a somewhat faster onset. It is a good option for pain management in most patients.

Meperidine (Demerol), also an opioid agonist, should be reserved for healthy patients requiring opioids for a short period or for those who have unusual reactions or allergic responses to other opioids. When broken down in the body,

equianalgesic: equi—equal + analgesic—relieving pain

Drug	Side Effects
NSAIDs (including aspirin)	Gastrointestinal (GI) irritation and bleeding Inhibition of platelet aggregation, increasing risk of GI bleeding Renal insufficiency in some patients, especially the elderly Patients with asthma at risk for hypersensitive reactions
Acetaminophen	Necrosis of the liver with overdose

Drug	Parenteral (IM/IV/SQ)	Oral Dose	Conversion Factor (Parenteral to PO)
Morphine	10 mg	30 mg	3
Codeine	130 mg	200 mg NR	1.5
Hydromorphone (Dilaudid)	1.5 mg	7.5 mg	5
Methadone (Dolophine)	10 mg	20 mg	2
Meperidine (Demerol)	75 mg	300 mg NR	4

Source: Adapted from McCaffery, M: Pain: Assessment and Use of Analgesics (conference handouts). Fall 1996. NR—not recommended at that dose.

it produces a toxic metabolite called normeperidine. Normeperidine is a cerebral irritant that can cause side effects ranging from dysphoria and irritable mood to seizures. It has a long half-life even in healthy patients, so patients with impaired renal function are at increased risk. Meperidine use should be avoided in patients over the age of 65, in those with impaired renal function, and in those receiving monoamine oxidase inhibitor (MAOI) antidepressants. Additionally, the effective dose of oral meperidine is three to four times the parenteral dose, a toxic dose that is not recommended.

Fentanyl (Sublimaze, Duragesic) can be administered parenterally, intraspinally, or by **transdermal** patch (Duragesic patch). Fentanyl is commonly used intravenously with anesthesia for surgery and also for relief of postoperative pain via the epidural route. Administration can also be effective via IV **patient-controlled analgesia** (discussed later in this chapter) for postoperative pain management, but other drugs may be preferred. IV fentanyl is very short acting and must be administered frequently. The fentanyl patch is useful for the patient with stable cancer pain and requires dosing only every 3 days.

Methadone (Dolophine) is a potent analgesic that has a longer duration of action than morphine. It has a very long half-life and accumulates in the body with continued dosing. Dosing intervals should be lengthened after pain relief has been achieved. Methadone is well absorbed from the gastrointestinal tract and is very effective when given orally at doses similar to the parenteral dose. Methadone is also used in drug treatment programs during detoxification from heroin and other opioids. Patients on methadone maintenance can present a unique challenge when admitted to the hospital. It is important to continue the maintenance dose even if other pain medications are given after surgery or trauma.

LEARNING TIPS

It is important to monitor a patient's level of sedation and respiratory status whenever administering opioids. Increased sedation, decreased respiratory effort, and constricted pupils can be signs of opioid overdose. Careful monitoring and **titration** of opioids can prevent opioid-induced respiratory depression.

Opioid Antagonists

Naloxone (Narcan) is a pure opioid antagonist that counteracts, or antagonizes, the effect of opioids. It is often used in the emergency department setting for treatment of opioid overdose. Caution must be used when naloxone is given to the patient receiving opioids for the treatment of pain. If too much naloxone is given too fast, it can reverse not only the respiratory depression and sedation but the analgesia as well.

transdermal: trans—across + dermal—the skin

CRITICAL THINKING

Mrs. Shepard

Mrs. Shepard is 92 years old and has undergone an open cholecystectomy. Her continuous epidural infusion of analgesic has been discontinued. The physician has ordered oral hydrocodone with acetaminophen (Vicodin) every 3 to 4 hours as required for pain. This is her second postoperative day, and she refuses to get out of bed because her pain is 7 on a scale of 0 to 10.

The medication record shows that Mrs. Shepard has not received any pain medication since the continuous epidural infusion was stopped 3 hours ago.

1. Why is Mrs. Shepard in so much pain?
2. What complications can occur as a result of her pain?
3. Each Vicodin tablet contains 500 mg of acetaminophen. The maximum daily dose of acetaminophen is 4 g. If she takes one Vicodin every 3 hours, is her dose safe?
4. What can be done to relieve her pain and better prevent it in the future?

Answers at end of chapter.

Antagonists are generally shorter acting than the opioid that is being used. If the antagonist is given because of respiratory depression, the dose may need to be repeated because its effect may wear off before that of the opioid.

Some analgesics are classified as combined agonist and antagonist. These drugs bind with some opioid receptors and block others. The most commonly used agonist-antagonist drugs are butorphanol (Stadol) and nalbuphine (Nubain).

How does this information translate into nursing practice? Consider, for example, a patient who is taking sustained-release morphine every 12 hours to control metastatic bone pain and is experiencing breakthrough pain between doses. You observe that butorphanol has been ordered for pain by another doctor and administer it. The butorphanol will antagonize, or counteract, the effects of the morphine, and the patient may develop acute pain. It is important to be informed about the actions of all drugs that are administered and to be aware of possible drug interactions that may interfere with patient care.

Agonist-antagonist drugs are also used sometimes to counteract opioid side effects. Nalbuphine (Nubain) can be used to treat itching and nausea that may accompany the administration of opioids. A smaller dose can be given so that the analgesia is not reversed completely along with the reversal of the side effect.

Analgesic Adjuvants

Adjuvants are classes of medications that may potentiate the effects of opioids or nonopioids, have analgesic activity themselves, or counteract unwanted effects of other analgesics. Adjuvants are especially important when treating pain that does not respond well to traditional analgesics alone.

Steroids can be used to treat a variety of pain conditions, including acute and chronic cancer-related pain. They may be used as part of actual cancer treatment because of their

toxicity to some cancer cells, or they may reduce pain by decreasing inflammation and the resultant compression of healthy tissues. Their use is standard emergency practice in the treatment of suspected spinal cord compression. Patients with pain caused by malignant lesions pressing on nerves such as the brachial or lumbosacral plexus may receive large doses of steroids.

Benzodiazepines such as midazolam (Versed) or diazepam (Valium) are effective for the treatment of anxiety or muscle spasms associated with pain. These drugs do not provide pain relief except in the treatment of muscle spasms. Benzodiazepines may cause sedation, which limits the amount of opioid that may be given safely.

Tricyclic antidepressants such as amitriptyline, imipramine, desipramine, and doxepin have been shown to relieve pain related to neuropathy and other painful nerve-related conditions. These medications must be taken for a time before they are fully effective, and patients must be instructed about this so that they do not stop taking the medication after a few days. Additional benefits of this class of medications may include mood elevation and improved ability to sleep.

Anticonvulsants such as phenytoin (Dilantin) and carbamazepine (Tegretol) are often used to relieve the sharp or cutting pain caused by peripheral nerve syndromes. Again, these medications must be taken regularly before full benefit is realized.

Amphetamines such as methylphenidate hydrochloride (Ritalin) may be used to counteract the sedating effects of opioids in some patients.

OTHER INTERVENTIONS. Other pain treatments include the use of radiation therapy or antineoplastic chemotherapy to help shrink tumors that are causing pain for a patient with cancer. Chemotherapy is also used for treating pain associated with connective tissue disorders such as rheumatoid arthritis or systemic lupus erythematosus. Bowel regimens, laxatives, enemas, or antigas medication to decrease abdominal fullness may be considered pain management if it is the primary source of discomfort for the patient. In patients with osteoporosis, drugs that result in calcium uptake by the bones can aid in relief of pain. These may include hormonal agents and medications that decrease calcium resorption from bone, such as etidronate (Didronel).

The IV administration of strontium-89 chloride (Metastron) by a qualified physician helps ease the bone pain of some patients with metastatic bone cancer. It is most effective for patients who have hormone-related cancers, such as cancer of the breast or prostate.

Lidocaine/prilocaine (EMLA, a eutectic mixture of local anesthetics) cream is a topical local anesthetic that decreases pain associated with procedures such as venipunctures and lumbar punctures. It is most effective if left in place for 1 hour before the procedure and covered with a semipermeable membrane dressing such as Tegaderm or Opsite before the needle stick.

PLACEBOS. Use of placebos involves the administration of an inactive substitute such as normal saline in place of a real

medication. In the past, placebos were sometimes given in an attempt to determine whether a patient's pain was "real." Placebos are also given in drug studies (clinical trials) to compare a new drug with an inactive substance. The use of placebos is not justified in the treatment of pain. Placebos should only be used if the patient has agreed to be a part of a research study and has consented to the possibility that he or she may receive a placebo. The use of placebos is a denial of the patient's report of pain. If a placebo is ordered for a patient, discuss your concerns with the physician and nurse supervisor.

Routes for Medication Administration

ORAL. Medication administration by the oral (PO) route is preferred whenever possible. It is convenient, flexible, and inexpensive and provides consistent blood levels when given around the clock (ATC).

RECTAL. When the patient is not able to take medications by the oral route, rectal administration is an alternative. Many medications may be given by the rectal route. Often oral preparations (tablets or capsules) can be administered rectally, as well as intrastromally, intravaginally, or buccally.

INHALATION. Butorphanol (Stadol) can be administered via the nasal route and is sometimes used for treatment of migraine headaches. It is an agonist-antagonist, and caution must be used if the patient is also taking opioids, as discussed earlier. The use of aerosolized morphine is now being used successfully in some patients with diseased lungs.

TRANSDERMAL. Fentanyl patches are used in the treatment of chronic pain and are dosed in micrograms (mcg) per hour. It may seem easy enough to apply a patch, but there are some special considerations when using this route.

- There is about a 12-hour delay until an effective level is reached, and the patient may require an immediate-release form of pain medication until that time.
- The patches may not be as effective in patients who smoke.
- Absorption may be reduced if the patch is placed in an area with little or no fatty tissue.
- Absorption may be increased in patients with body temperatures of 101°F or greater. Increased or erratic absorption may require patches to be replaced more frequently.
- When applying the patch, use caution to prevent touching the membrane covering the medication to prevent exposure. If contact occurs, rinse with plain water.
- Patches should not be used with other sustained-release analgesics.
- Multiple patches may be used.
- When the patch is discontinued, the residual medication in the skin continues to be absorbed for about 17 hours. During this time the patient must be monitored for pain control and overdose if another pain medication has been administered.
- Caution should be exercised when disposing of the patch because active drug remains even after 72 hours.

INTRAMUSCULAR. The IM route is appropriate only if the medication cannot be delivered by another route. IM injections are painful and inconvenient and absorption is unpredictable. IM injections are never recommended for treatment of chronic pain.

INTRAVENOUS. The IV route is the preferred route of opioid administration for postoperative pain and when the patient is unable to tolerate oral medications. IV infusions of opioids are preferred over intermittent doses of IM or subcutaneous medication for chronic cancer pain. Continuous infusion of an opioid provides a steady blood level, which tends to give the most effective analgesia with the fewest side effects. Routes other than IV require lag time for absorption of the drug into the circulation. Self-administration of an opioid by the patient is called patient-controlled analgesia (PCA). PCA is most commonly administered intravenously, although it can be administered orally or via epidural. This chapter focuses on IV PCA.

IV PCA is a safe method for postoperative pain management that many patients prefer over intermittent injections. A special pump is programmed to administer the prescribed dose of opioid by pushing a patient-controlled button. A lockout interval is also programmed into the pump, which regulates the frequency with which the patient can receive a dose of medication to protect against overdose. A typical dose of morphine is 1 mg, with a lockout interval of 5 to 10 minutes. All PCA pumps can also deliver a continuous, or basal, infusion in addition to the patient-controlled dose. One advantage of the basal infusion is that the patient can have intervals of uninterrupted sleep. Basal infusions should be used cautiously in patients who are newly receiving opioids. An hourly limit is also prescribed by the physician and programmed into the pump, which keeps track of the number of doses a patient uses (doses actually received by the patient) and the number of attempts made (times the button was pushed). This helps you know how much medication the patient is using and if the use of the pump is understood. If the patient has a record of many attempts and very few injections, the patient may not be waiting the full interval between doses. This occurs because the patient is in severe pain and cannot wait or because he or she does not understand the instructions. Patient education should include information about the medication that is being administered, safety features and the use of the pump, potential side effects, and what to report to the nurse. Refer to institutional policy for safe PCA administration guidelines. It is important that patients, families, and caregivers understand that no one should push the button except the patient. This modality is safe if it is patient controlled and appropriately monitored. Family members can help by reminding their loved one to use the PCA if they think the person is in pain.

SUBCUTANEOUS. If IV access is problematic, the subcutaneous route can be used as an alternative for opioid therapy in patients with chronic cancer pain. A needle is placed into the subcutaneous tissue and a small volume of a high

concentration of opioid can be infused for effective pain management.

INTRASPINAL. The intraspinal (epidural or subarachnoid) route is an appropriate pain relief modality for some patients. Patients with traumatic injuries, including rib fractures or orthopedic injuries of the pelvis and lower extremities, and patients undergoing chest, abdominal, or lower extremity orthopedic surgical procedures may benefit from the epidural route of opioid administration. Advantages to the intraspinal route of administration include the ability to provide superior pain relief while administering overall lower doses of opioid. There is less systemic effect of the opioid because it is administered close to the site of the nerves serving the area of injury or surgical incision and not into the systemic circulation. Intraspinal opioids can be safely administered in a variety of hospital and home care settings if protocols for the care and monitoring of the patient are in place and enforced.

Nondrug Therapies

Nondrug treatments are usually classified as cognitive-behavioral interventions or physical agents. The goals of these two groups of treatments are different. Cognitive-behavioral interventions can help patients understand and cope with pain and take an active part in its assessment and control. The goals of physical agents may include providing comfort, correcting physical dysfunction, altering physiological response, and reducing fear that might be associated with immobility.

Cognitive-Behavioral Interventions

Included in this group are interventions such as educational information, relaxation exercises, guided imagery, distraction (e.g., music, television), and biofeedback. These treatments require extra time for detailed instruction and demonstration.

Providing patients with educational information about what to expect and how patients can participate in their own care has been shown to decrease patients' reports of postoperative pain and analgesic use. Relaxation can be accomplished through a variety of methods. The patient may prefer a relaxation exercise with a script that can be practiced and used the same way each time or simply the use of a favorite piece of music that will allow a state of muscle relaxation and freedom from anxiety. Guided imagery uses the patient's imagination to take the patient away from the pain to a favorite place, such as a beach in Tahiti. The success of guided imagery does not mean that the pain is in any way imaginary. The use of distraction is something that many of us do without thinking about it. We focus our attention on something other than the pain. Patients watch a favorite television program or laugh with visitors when they are in pain. When the program is over or the visitors leave, the patient may notice the pain again and ask for a dose of pain medication.

Biofeedback is commonly used in behavioral chronic pain programs to show patients how to teach their bodies to

respond to different signals. Biofeedback has been very useful in patients with migraine headaches. When patients experience the aura that many migraine sufferers get before the headache, they begin the exercise that relaxes them and prevents the migraine.

Physical Agents

Physical agents may contribute directly to the patient’s comfort. Applications of heat or cold, massage, exercise and immobilization, and transcutaneous electrical nerve stimulation (TENS) are commonly used physical agents.

The application of heat to sore muscles and joints is effective for pain relief. Heat works to increase circulation, induce muscle relaxation, and decrease inflammation when applied to a painful area. Heat can be applied using dry or moist packs or wraps or in a bath or whirlpool. Heat is contraindicated in conditions that would be worsened by its use, such as in an area of trauma, because of the possibility of increased swelling caused by vasodilation. To prevent burns, heat should not be applied over areas of decreased sensation.

Cold can reduce swelling, bleeding, and pain when used to treat to a new injury. Cold can be applied by a variety of methods, such as cold wraps and cold packs, as well as localized ice massage. Patients often choose heat over cold if they have the choice. Cold is better tolerated over a small area. Alternating heat and cold therapies is most effective if not contraindicated.

Massage and exercise are used to stretch and regain muscle and tendon length and probably work by relaxing the muscles. Massage pressure can be superficial or deep. It is important that massage is acceptable and not offensive to the patient. Immobilization is used following a variety of orthopedic procedures, as well as fractures and other injuries worsened by movement.

Physical agents are readily available, are inexpensive, and require little preparation or instruction. It is important to use nondrug treatments to enhance appropriate drug treatments, not as a substitute.

NURSING PROCESS

Assessment

Accurate assessment of pain is essential to effective treatment. Without appropriate assessment, it is not possible to intervene in a way that meets the patient’s needs. The American Pain Society recommends that nurses consider pain the “fifth vital sign.”⁴ That way it will be routinely assessed whenever other vital signs are assessed. The WHAT’S UP? format found in Chapter 1 can assist you in performing a complete and effective assessment (Table 9–3). Following are some additional key points for assessing pain and putting together more pieces of the pain puzzle.

Believe the Patient

Pain is what the patient says it is, not what the nurse or physician thinks it should be. When a member of the health

TABLE 9-3 WHAT’S UP? FORMAT FOR ASSESSMENT OF PAIN

W—Where is the pain? Be specific. Use drawing of body if necessary.
 H—How does the pain feel? Is it shooting, burning, dull, sharp?
 A—Aggravating and alleviating factors. What makes the pain better? Worse?
 T—Timing. When did the pain start? Is it intermittent? Continuous?
 S—Severity. How bad is the pain on a 0 to 10 (0 to 5; faces scale)
 U—Useful other data. Are you experiencing any other symptoms associated with the pain or pain treatment? Itching, nausea, sedation, constipation?
 P—Perception. What is the patient’s perception of what caused the pain?

care team distrusts the patient’s report of pain, the patient can usually sense that he or she is not believed. The patient may compensate by either underreporting pain or, less commonly, anxiously overreporting.

Take a Pain History

Information is obtained from the patient about the pain that he or she is experiencing. Allowing and encouraging the patient to describe the pain in his or her own words helps establish a trust relationship between you and the patient and also helps discover the effects the pain is having on the patient’s lifestyle. Is the pain keeping the patient from eating, sleeping, or participating in work or family activities? The patient’s emotional and spiritual distress and coping abilities should be assessed to individualize the interventions to the patient’s needs. The patient can tell you how he or she has coped with pain previously and what treatment measures have been effective in the past.

A variety of tools are available to assist in accurate and complete pain assessment. You should become familiar with the tool used in your setting and use it consistently. It is of utmost importance that all health care personnel caring for the patient use the same pain rating scale, whether it is a numerical scale (e.g., 0 to 5 or 0 to 10), a visual analog scale (a 10-cm line on which the level is marked and then measured from the beginning of the line to indicate the amount of pain), or the Wong-Baker faces scale (Figs. 9–2 and 9–3). Whichever scale is used, it must be one that has been validated with research. Some scales are cute and interesting

Figure 9-2 Pain scale.

but may not be accurate or even useful. The best tools are simple and easy to use. Longer questionnaires require more time and may cause distress for the patient in acute pain but may be helpful when doing a complete pain history (Fig. 9–4). A scale should also be used to monitor the patient’s level of sedation following opioid administration (Fig. 9–5). Any unexpected decrease in the patient’s level of sedation should be reported promptly to the registered nurse (RN) or physician.

It is important to use the patient’s own descriptions and words when taking the pain history, such as *aching*, *knifelike*, or *throbbing*. This is also true when the patient is experiencing neuropathic pain. Neuropathic pain is often difficult to define. Terms commonly used to describe neuropathic pain include *burning*, *shocklike*, and *tingling*.

Do a Complete Physical Assessment

A good physical assessment is necessary to determine the effect of the pain and pain treatments on the body. It helps identify all the pain sites and helps you to prioritize the seemingly overwhelming task of helping the patient achieve acceptable pain management and good quality of life. As discussed previously, the patient with acute pain may exhibit signs such as grimacing and moaning or elevated pulse and blood pressure, but these signs cannot be relied on to “prove” that the patient is in pain. The only reliable source of pain assessment is the patient’s self-report (Gerontological Issues Box 9–4).

Planning and Implementation

Establish a pain control goal during the planning phase. The patient must be asked to determine an acceptable level of pain if complete freedom from pain is not possible. It is also important to identify the patient’s activity goals. After

BOX 9-4 GERONTOLOGICAL ISSUES

The older patient may have different manifestations of pain than a younger patient. Older patients who are confused may be unable to tell the nurse that they are feeling pain. The nurse should consider incidents of restlessness and confusion as possible signs of pain. Pulling at dressings, tugging at IV sites, and trying to climb over the side rails to get out of bed can also be symptoms of discomfort.

The nurse can anticipate pain and provide relief measures to prevent severe pain. Pain medications and basic comfort care can be administered routinely if pain is likely. Naggling aching in hands and feet is often noted as a reason for decreased activity, inability to sleep, and altered functional ability. A hand or foot massage using lotion and gentle massage strokes is often a very relaxing comfort measure.

CRITICAL THINKING

Mr. Sebastian

Mr. Sebastian is a 75-year-old gentleman who has been diagnosed with lung cancer and is anxious about leaving the hospital to return home following a thoracotomy. The nursing assessment reveals the need for home health care for dressing changes and teaching about the medications he will need at home. While in the hospital, Mr. Sebastian has required 5 mg morphine IV every 4 hours around the clock.

What discharge instructions must be given to Mr. Sebastian and his wife before sending him home? How might his pain be managed at home to prevent unnecessary readmissions to the hospital?

Answers at end of chapter.

surgery, goals may include the ability to ambulate and sleep without pain. For patients with chronic pain, the goals may be different. For example, if a patient with terminal cancer wants to be able to attend her granddaughter’s wedding, you can assist the patient in reaching that goal. She can be

taught to reserve energy that day for the activity that is most important to her. Instructing her in optimal timing of her pain medication will also assist her in reaching a good comfort level for the activity.

Some additional principles to consider during the planning phase follow.

Allow the Patient As Much Control As Possible

Pain can bring forth feelings of helplessness and hopelessness. Giving patients pain management options allows them to maintain some control. It is also the nurse’s responsibility to teach patients about the goals of pain management and why it is an important part of care. If patients understand that the health care provider’s goals and theirs are the same, they are likely to cooperate with and contribute to the pain management plan.

Pain Affects the Whole Family

It is important to include the whole family in the plan. Understanding family dynamics helps the nurse in implementing an effective pain management plan. Cultural influences are important to consider when planning pain treatment (see Chapter 3). It is difficult for family members to see loved ones in pain. Including them in the planning helps them feel that they may be helping to make the patient more comfortable. (See Home Health Hints.)

HOME HEALTH HINTS

- Emotional or spiritual distress and fear related to dependence on family caregivers may alter the patient’s perception or report of pain.
- Several alternative measures are easily taught to patients and caregivers in the home. For example, ice can be made in paper cups and used for a cold massage of a painful area.
- Repositioning can alleviate some aches, and soothing music can serve as a distraction from the pain.

Pain is Exhausting

Pain may keep the patient from sleeping. This cycle of sleeplessness and pain must be interrupted to help the patient. The need for adequate rest must not be ignored. This is more often an ongoing problem for the patient with chronic nonmalignant pain or chronic cancer pain, and it is perhaps more difficult to manage. The patient must get at least 4 to 6 hours of uninterrupted sleep to be relaxed enough to break the cycle. Controlled-release opioid pain

medications may help maintain pain relief, allowing the patient to sleep. If controlled-release medications are not used, it may be necessary to wake a patient to administer pain medication so that the pain does not get out of control. The addition of a sedative may be necessary to allow the patient to sleep.

A Team Approach to Pain Management

A plan must be developed using an interdisciplinary approach, including the patient and family, the nurse, and the physician. Others, such as the occupational and physical therapist, chaplain, social worker, and pharmacist, should be included as appropriate. Communication is the important link allowing this team to be effective in creating a plan that works for the patient. Plans must be individualized to meet the special needs of each patient and vary greatly depending on the type of pain the patient is experiencing.

In 1990 the World Health Organization (WHO) developed the WHO analgesic ladder, which involves choosing among three levels of treatments based on intensity of pain (Fig. 9-6). The ladder, which helps direct the interventions required when using medications to treat pain, was developed for the treatment of cancer pain but can be used when treating other types of pain as well.

When experiencing mild pain (level I on the WHO ladder), the patient can usually sleep, perform activities of daily living, and even work. The first level of the ladder addresses the use of nonopioid analgesics. When pain is unre-

Figure 9-6 World Health Organization three-step analgesic ladder.

lieved by maximum ATC dosing, the treatment moves up the ladder to level II (mild to moderate pain) and adds an opioid analgesic. The patient with mild to moderate pain may not be able to sleep or may have trouble working and staying focused. If pain increases beyond that which is controlled by the level II analgesics, it is time to move on to level III. At this level the pain is moderate to severe and is affecting the quality of the patient's life, and he or she may not be able to perform activities of daily living. At level III an adjuvant analgesic may be added.

Analgesics should be given on an ATC basis to prevent breakthrough pain, especially for cancer and chronic benign pain. For patients experiencing surgical or traumatic pain, analgesics should be given ATC until the pain decreases to a level that allows medications to be given as required (prn). When using the WHO ladder it is important to keep in mind that it may not be necessary to start at level I if the patient is having severe pain. Analgesics from level III on the WHO ladder may be the starting point for some patients.

CRITICAL THINKING

Mrs. Zales

Mrs. Zales, a 32-year-old woman, was admitted for a hysterectomy after being treated for painful endometriosis for 12 months. After her surgery she had a PCA pump with hydromorphone, which was effective in relieving her pain. Forty-eight hours after surgery the surgeon discontinued the PCA pump and ordered oral hydrocodone with acetaminophen (Lortab). It was ineffective, so an order for hydromorphone, 2 to 4 mg orally every 3 to 4 hours as needed, was added. The nurses gave only one dose of the hydromorphone, then, thinking that her pain should be lessening, switched Mrs. Zales back to the hydrocodone with acetaminophen. By the next morning she was in severe pain, and the on-call physician ordered IM meperidine and promethazine (Phenergan). Mrs. Zales's discharge was delayed until her pain could be controlled.

What do you think happened? How could the delayed discharge have been avoided?

Answers at end of chapter.

Patient Education

Patients must be informed about the medications they are taking for pain management so they can take an active role in their care. Patients informed about the goals of pain management are more likely to report unrelieved pain so that they can receive prompt and effective treatment. Goals include a satisfactory comfort level with minimal side effects and complications of pain and its treatment, as well as a reduced period of recovery.

It is important to provide the patient with information about the drug's common side effects, the frequency of the dose and its duration of action, and potential drug-drug and food-drug interactions if indicated. Education must be presented at a level that the patient can understand. Informed patients use their medications more effectively and safely.

CRITICAL THINKING

Ms. Jackson

Ms. Jackson had abdominal surgery 2 days ago. She has been receiving morphine via IV PCA at an average of 2.5 mg per hour for the last 6 hours. She rates her pain at 3 on a scale of 0 to 10. She is to be discharged today. Her physician has ordered codeine 30 mg with acetaminophen (Tylenol with codeine No. 3), 1 or 2 tablets every 4 hours as needed for pain at home.

Will Ms. Jackson be comfortable at home? Why or why not?

Answers at end of chapter.

LEARNING TIPS

Many medication interventions are available for the treatment of pain. Whenever possible, administer analgesics by the mouth, by the WHO ladder, and by the clock.

Evaluation

The final phase of the nursing process is evaluation. Once the plan of care has been implemented, evaluate whether the patient's goals have been met. Evaluation is an ongoing process that continues as the plan of care is carried out to be sure that pain management is effective and that changes are made as needs are identified. Has the patient's identified goal for an acceptable level of pain been met? How well were the pain treatments tolerated? Were there any adverse effects to the medications that were given? Were the side effects managed appropriately? Poorly managed side effects can be as problematic as poorly managed pain. For example, when nausea has been identified as something that is always a problem for the patient after surgery, it is imperative to include in the plan how it will be addressed. Was monitoring appropriate at each point in the pain management plan for the prevention of uncontrolled pain and clinically significant respiratory depression? Was the patient able to participate in activities that he or she identified as important? The plan should be continuously updated based on the evaluation. (See Nursing Care Plan 9–5 for the Patient in Pain.)

BOX 9-5 NURSING CARE PLAN FOR THE PATIENT IN PAIN**PATIENT OUTCOME**

Pain is at a level that is acceptable to the patient. Patient is able to participate in activities that are important to him or her.

EVALUATION OF OUTCOME

Is pain at a level that is acceptable to the patient? Is the patient able to participate in activities that he or she has identified as important?

INTERVENTION

Assess pain based on patient report. Use the WHAT'S UP format.

Teach the patient to use a pain rating scale. Use the same scale consistently.

Determine with patient what is an acceptable pain level.

Assess whether pain is acute, chronic, or both.

Assess need for and offer emotional and spiritual support for the experience of pain and suffering.

Give analgesics before pain becomes severe. For moderate to severe pain, give analgesic ATC.

Assess for pain relief approximately 1 hour after administration of oral analgesics, or 30 minutes after IV analgesics.

Observe for anticipated side effects of pain medication.

If opioids are being used, assess for respiratory depression and reduced level of consciousness at regular intervals.

Institute measures to prevent constipation: 8 to 10 glasses of fluid daily (unless contraindicated), fiber in meals, fiber or bulk laxatives, exercise as tolerated.

Teach patient alternative pain relief interventions, such as relaxation and distraction, to be used with medication.

Assess whether patient is taking pain medications appropriately, and if not, assess reasons. Instruct in how to manage pain interventions.

RATIONALE

Patient's pain is defined as what the patient says it is, when the patient says it is occurring.

A rating scale is the most reliable method for assessing pain severity.

Only the patient can decide what pain level is tolerable.

Acute and chronic pain may present differently and may require different interventions. Pain, as well as disease processes, can be accompanied by feelings of powerlessness and distress.

Severe pain is more difficult to relieve.

If pain is not relieved, additional measures will be needed.

Many pain medications cause nausea and constipation. The nausea usually subsides after several days, but the constipation does not.

High doses or sudden increases in dose of an opioid can result in respiratory depression and reduced level of consciousness.

Opioids cause constipation.

Alternative interventions can help the patient feel in control and may help reduce the perception of pain.

Pain medications must be taken appropriately to be effective.

EVALUATION

Does the patient verbalize his or her pain? Does the patient use verbal or nonverbal messages that imply trust in nurse's belief of pain report?

Does the patient understand the use of the scale and use it to report pain?

Is the patient's pain at an acceptable level?

Has acute versus chronic pain been identified? Are treatments appropriate?

Does the patient appear emotional, angry, or withdrawn? Does the patient have difficulty making decisions? Is the patient-nurse relationship therapeutic?

Is analgesic schedule effective?

Does patient report acceptable level of relief?

Are side effects occurring? Can they be managed? Does medication regimen need to be adjusted?

Is the patient's respiratory rate greater than 8 per minute or above the parameter ordered by the physician? Is the patient alert and oriented?

Are the patient's bowels moving according to his or her usual pattern?

Does the patient use alternative interventions effectively?

Is the patient able to manage the pain control regimen? Are adjustments necessary?

REVIEW QUESTIONS

1. Mr. White is walking up and down the hall and visiting with other patients. He is laughing and joking. He approaches the nurse's station, asks for his pain shot, and reports that his pain is 6 on a scale of 0 to 10. Based on McCaffery's definition of pain, which of the following assumptions by the nurse is most likely correct?
 - a. Mr. White is not really in pain but just wants his medication.
 - b. Mr. White is having pain at a level of 6 on a scale of 0 to 10.
 - c. Mr. White is in minimal pain and should receive a pill instead of a shot.
 - d. Mr. White is in pain but does not need his pain medication yet.
2. Ms. Williams has incisional pain following total hip replacement surgery. Which of the following types of pain is she experiencing?
 - a. Nociceptive
 - b. Neuropathic
 - c. Chronic
3. Which of the following methods is the most reliable way to assess a patient's pain?
 - a. Obtain a pain history from the patient.
 - b. Observe the patient for signs of pain.
 - c. Ask the patient to rate his or her pain using a valid assessment scale.
 - d. Ask a family member to rate the patient's pain.
4. Jim is hospitalized following a motor vehicle accident. He has multiple orthopedic injuries and is in acute pain. He has an order for morphine 6 mg IV every 2 to 3 hours as needed. Assuming his respiratory rate and level of sedation are acceptable and his pain is controlled, which of the following analgesic schedules will be most effective for relieving his pain?
 - a. Offer the analgesic every 2 to 3 hours.
 - b. Tell him to put on his light when he feels pain, and give the drug immediately when he requests it.
 - c. Give the IV analgesic every 2 to 3 hours ATC.
 - d. Alternate the IV analgesic with an oral analgesic.
5. Mrs. Edwards has terminal cancer and has been requiring 5 mg of IV morphine every 1 to 2 hours to control her pain, yet she is laughing and enjoying her visitors. Which of the following explanations of her behavior is most likely correct?
 - a. Denial of pain is common in patients with cancer.
 - b. Mrs. Edwards's cancer is improving.
 - c. Mrs. Edwards is hiding her pain when visitors are present.
 - d. Distraction can be an effective treatment for pain when used with appropriate drug treatments.
6. Mr. Lawrence is an 88-year-old gentleman admitted with a broken hip after a fall. He has an order for meperidine 50 to 75 mg IM q4–6h prn pain. As his nurse, which of the following actions should you take?
 - a. Give the meperidine every 4 hours ATC.
 - b. Offer the meperidine every 6 hours because you know that his liver and kidney function may be diminished.
 - c. Administer an NSAID with the meperidine for added pain relief.
 - d. Talk to the RN or physician about getting an order for a different analgesic.

Answers to CRITICAL THINKING

Smithers and Barnett

It is important to accept both patients' pain reports. Assessment should be based on what the patient says rather than what is observed. Each patient copes with his or her pain in a unique way, and the nurse cannot judge whether one is in more pain than the other.

Mrs. Shepard

1. Pain medication is most effective when given on a routine schedule around the clock to avoid breakthrough pain. Mrs. Shepard's epidural infusion should continue to relieve her pain for a time, up to several hours after it is discontinued, depending on the medication used. The oral medication is most effective when given at the time the epidural is stopped so that it is taking effect as the epidural effects wear off.
2. Pain prevents patients from moving freely. Postoperative complications such as retained pulmonary secretions and ileus can occur when patients are immobile. Effective pain management can help prevent these complications.
3. If she takes a dose every 3 hours, then she will receive 8 doses in 24 hours; $500 \text{ mg} \times 8 = 4000 \text{ mg}$ or 4 g, which is the maximum safe dose. Recall that elderly patients metabolize and excrete medications more slowly than younger patients. If she will need the hydrocodone/acetaminophen more than a few days, it would be wise to consult with the physician about giving the opioid and acetaminophen separately.
4. Mrs. Shepard should be instructed what her role will be when her pain management regimen is altered. Does she have to ask for the pain medication or will it just be brought to her? Patient and family education is vital to success in management of a patient's pain.

Mr. Sebastian

Home instruction regarding ATC administration of pain medication is indicated. MS Contin, a long-acting form of morphine, may be an option for Mr. Sebastian, along with an immediate-release

preparation for breakthrough pain. Also, information about what to do and who to contact if pain becomes unmanageable is necessary to help prevent readmissions to the hospital.

Mrs. Zales

Mrs. Zales was probably tolerant to opioids because of her need for medication for chronic pain over the last year. For this reason, she needed more medication than a nontolerant patient who does not usually use opioids. Also, the belief that promethazine and other phenothiazines potentiate opioids is a myth. They do cause increased levels of sedation and may limit the amount of opioid that can be given safely. IM injections are not recommended because they are painful, absorption is not predictable, and there is a delay between injection and relief. Nurses often base the treatment of a patient's pain on what they usually do or what they think should be effective rather than on sound pain management practices and principles. A more rational approach to Mrs. Zales would have been regular pain assessment with ATC treatment until pain began to subside. If her pain level had been better controlled, she might have been discharged on oral analgesics without the delay.

Ms. Jackson

Using an equianalgesic conversion, we can determine whether Ms. Jackson is likely to have good pain relief based on her requirement with the PCA. Her current pain level of 3 shows that the morphine has been effective. Remember that the pump keeps a history of what the patient uses, which is the best indicator of what the patient needs. Ms. Jackson has used 15 mg of morphine during the past 6 hours. An equianalgesic dose of Tylenol with codeine No. 3 would be almost 200 mg of codeine, but only 30 to 60 mg has been ordered. In addition, if Ms. Jackson takes enough Tylenol with codeine No. 3 to get 200 mg of codeine, she will receive a dangerous dose of both the codeine and the acetaminophen. The physician needs to be contacted for different analgesic orders.

QUESTIONS TO GUIDE YOUR READING

1. What are the normal structure and functions of the cell?
2. What changes occur in the cell when it becomes malignant?
3. Which medications are commonly used as chemotherapy agents?
4. What are the special nursing needs of the patient receiving chemotherapy or radiation therapy?
5. Which data should you collect when caring for a patient with cancer?
6. What are nursing interventions for common oncological emergencies?
7. How will you know if your nursing interventions have been effective?
8. What is the role of hospice in providing care for patients with advanced cancer?

▶ REVIEW OF NORMAL ANATOMY AND PHYSIOLOGY OF CELLS

Cells are the smallest living structural and functional subunits of the body. Although human cells vary in size, shape, and certain metabolic activities, they have many characteristics in common.

Cell Structure

Human cells have a cell membrane, cytoplasm, cell organelles, and, with the exception of mature red blood cells, a nucleus. In the mature red blood cell the nucleus has been lost. Each cell structure has a specific and vital function. The cell membrane forms the outer boundary of the cell and is made up of protein, phospholipids, and cholesterol. Proteins serve three different purposes: (1) Some are pores or enzymes to permit transport of materials, (2) some are receptor sites for hormones to trigger a cell's activity, and (3) some are antigens to identify the cell as belonging in the body.

A cell membrane is selectively permeable, meaning that not all substances pass through. The lipids permit the diffusion of lipid-soluble materials into or out of the cell. Materials may enter or leave a cell in one of several ways. These transport mechanisms (with examples of their importance in the body) are summarized in Table 10–1.

Cytoplasm and Cell Organelles

Cytoplasm is a watery solution of minerals, gases, and organic molecules that is found between the cell membrane

and the nucleus. Chemical reactions (such as the synthesis of adenosine triphosphate [ATP]) take place in the cytoplasm. Cell organelles are subcellular structures with specific functions, which are summarized in Table 10–2 and shown in Figure 10–1. Many cell organelles are found in the cytoplasm.

Nucleus

The nucleus of a cell is surrounded by a double-layered nuclear membrane with many pores. Inside the nucleus are one or more nucleoli and the chromosomes of the cell.

A nucleolus is a small sphere made of deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and protein. The nucleoli form a type of RNA called ribosomal RNA, which is part of the cell organelle called the ribosome and is involved in protein synthesis.

The nucleus is the control center of the cell because it contains the chromosomes. The 46 chromosomes of a human cell are made of DNA and protein. DNA is the genetic code for the characteristics and activities of the cell. Specific regions of DNA are called genes; a gene is the code for one protein. Not all the genes in any cell are active, only those relative few needed for the proteins to carry out their specific functions. These proteins may be structural, such as the collagen of connective tissue, or functional, such as the hemoglobin of red blood cells. Important functional proteins are the enzymes that catalyze the specific reactions characteristic of each type of cell.

TABLE 10–1 CELLULAR TRANSPORT MECHANISMS

Mechanism	Definition	Example in the Body
<i>Diffusion</i>	Movement of molecules from an area of greater concentration to an area of lesser concentration	Exchange of gases in the lungs or body tissues
<i>Osmosis</i>	The diffusion of water	Absorption of water by the intestines or kidneys
<i>Facilitated Diffusion</i>	Carrier enzymes move molecules across cell membranes	Intake of glucose by most cells
<i>Active Transport</i>	The use of ATP to move molecules from an area of lesser concentration to an area of greater concentration	Absorption of glucose and amino acids by the small intestine
<i>Filtration</i>	Movement of water and dissolved materials from an area of higher pressure to an area of lower pressure (blood pressure)	Formation of tissue fluid; the first step in the formation of urine
<i>Phagocytosis</i>	A moving cell engulfs something	White blood cells engulf bacteria
<i>Pinocytosis</i>	A stationary cell engulfs something	Cells of the kidney tubules reabsorb small proteins

TABLE 10–2 FUNCTIONS OF CELL ORGANELLES

Organelle	Function(s)
<i>Endoplasmic Reticulum</i>	Passageway for transport of materials within the cell Synthesis of lipids
<i>Ribosomes</i>	Site of protein synthesis
<i>Golgi Apparatus</i>	Synthesis of carbohydrates Packaging of materials for secretion from the cell
<i>Mitochondria</i>	Site of aerobic cell respiration, synthesis of ATP
<i>Lysosomes</i>	Contain enzymes to digest ingested material or damaged tissue
<i>Centrioles</i>	Organize the spindle fibers during cell division
<i>Cilia</i>	Sweep materials across the cell surface, as in the respiratory passages
<i>Flagellum</i>	Enables a sperm cell to move

Figure 10-1 Schematic diagram of a typical human cell. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed 3. FA Davis, Philadelphia, 1999.)

Genetic Code and Protein Synthesis

The genetic code of DNA is the code for the amino acid sequences needed to synthesize a cell's proteins. This process is shown in Figure 10-2 and may be described simply as follows. A complementary copy of the DNA's gene is made by a molecule called messenger RNA (mRNA). The mRNA then moves to the cytoplasm of the cell and attaches to the ribosomes. Transfer RNA (tRNA) molecules bring the necessary amino acids to the proper places on the mRNA molecule, and enzymes of the ribosomes catalyze the formation of peptide bonds to link the amino acids into a finished protein.

As with any complex process, mistakes are possible. Should there be a mistake in the DNA code, the process of protein synthesis may go on anyway, but the resulting protein will not function normally; this is the basis for genetic diseases. DNA mistakes acquired during life are called mu-

tations. A mutation is any change in the DNA code. Ultraviolet rays or exposure to certain chemicals may cause structural changes in the DNA code. These changes may kill the affected cells or may irreversibly alter their function. Such altered cells may become **malignant**, unable to function normally but very active; this is the basis of some forms of **cancer**.

Mitosis

Mitosis is the process by which a cell reproduces itself. One cell, after its 46 chromosomes have duplicated themselves, divides into two cells, each with membrane, cytoplasm, and organelles from the original cell and a complete set of chromosomes. Mitosis is necessary for the growth of the body and the replacement of dead or damaged cells. Some cells are capable of mitosis and others are

Figure 10-2 Schematic diagram of the process of protein synthesis. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed 3. FA Davis, Philadelphia, 1999.)

not. Cells of the epidermis of the skin undergo mitosis continuously to replace the superficial cells that are constantly worn off the skin surface. The same is true of cells that line the stomach and intestines. Cells in the red bone marrow also divide frequently; red blood cells have a fixed life span (about 120 days) and must be replaced. Some cells seem to be capable of only a limited number of divisions, and when that limit has been reached, the cells die and are not replaced.

Other cells do not undergo mitosis to any great extent after birth. Nerve cells (neurons) are unable to divide, and

muscle cells have very limited mitotic capability. When such cells are lost through injury or disease, the loss of their function in the individual is usually permanent.

Cell Cycle

The cell cycle involves a series of changes through which a cell progresses, starting from the time it develops until it reproduces itself. The duration of the cell's life, the time it takes for mitosis to occur, the growth ratio (percentage of cycling cells), the frequency of cell loss, and the doubling

time (time for a **tumor** to double its size) are important concepts related to tumor growth and treatment strategies.

Cells can occupy three functions in the cell cycle: cells that are actively dividing, cells that leave the cycle after a certain point and die, and cells that temporarily leave the cycle and remain inactive until reentry into the cycle. Inactive cells continue to synthesize RNA and protein (Fig. 10-3).

Cells and Tissues

A tissue is a group of cells with similar structure and functions. The four groups of human tissues are epithelial, connective, muscle, and nerve.

Epithelial tissues form coverings and linings throughout the body. Often the cells are capable of mitosis, and damage to the tissue may be repaired. The healing of a cut to the skin is a typical example.

There are many types of connective tissues with varied functions. For example, blood is a connective tissue involved in the transportation of materials throughout the body. Fibrous connective tissue, made mostly of the protein collagen, forms strong membranes such as those around muscles, attaching structures such as ligaments and tendons and the dermis of the skin. Bone and cartilage are supporting connective tissues. Adipose tissue, another form of connective tissue, stores fat as potential energy. Many kinds of connective tissue cells are capable of mitosis.

There are three kinds of muscle tissue: skeletal muscle, smooth muscle, and cardiac muscle. Skeletal muscle tissue makes up the voluntary muscles attached to the skeleton. Smooth muscle is found in viscera such as the stomach and intestines; the walls of arteries and veins; the walls of the bronchial tubes; and, in women, the uterus. Cardiac muscle forms the walls of the chambers of the heart. As mentioned, the cells of muscle tissue have little ability to reproduce themselves.

Nerve tissue is made of neurons and supporting cells; in the central nervous system these supporting cells are called neuroglia. Although mature nerve cells are not capable of mitosis, many neuroglia are capable of mitosis. It is the neuroglia, not neurons, that usually form the tumors that develop in the central nervous system.

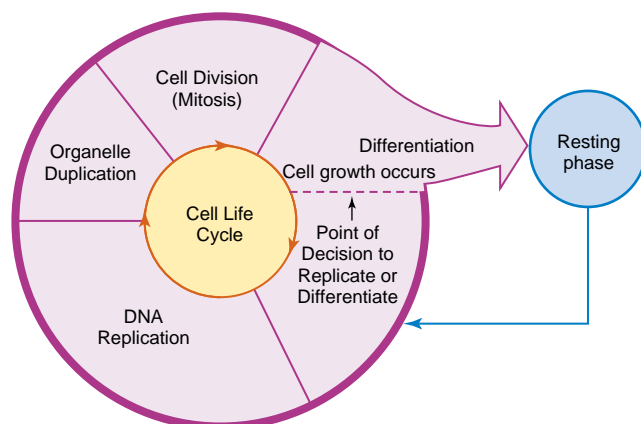

Figure 10-3 Cell cycle.

► INTRODUCTION TO CANCER CONCEPTS

Oncology is the branch of medicine dealing with tumors. Oncology nursing is also called cancer nursing; it is an important component of medical-surgical nursing care. A list of cancer resources is provided in Box 10-1. Cancer is second only to heart disease in mortality rates in the United States. The American Cancer Society reports that an estimated 10 million Americans alive today have a history of cancer.

Early accounts of cancer date back to the seventeenth century B.C. Documentation of the benefits of early cancer detection and its impact on treatment exist from the beginning of the nineteenth century. Today microscopic technology and genetic engineering provide physicians with a better understanding of tumor growth and cell activity and a means for early cancer detection and intervention.

► BENIGN TUMORS

Normal cells that reproduce abnormally result in **neoplasms**, or tumors. *Neoplasm* is a term that combines the Greek word *neo*, meaning “new,” and *plasia*, meaning “growth,” to suggest new tissue growth. A neoplasm is an enlargement of tissue and the formation of an abnormal mass. A neoplasm develops as cells multiply. Not all neoplasms contain cancer cells; however, a neoplastic cell is responsible for producing a tumor and shows a lively growing cell. New neoplastic growth is very difficult to detect until it contains about 500 cells and is approximately 1 cm.

A **benign** tumor is defined as a cluster of cells that is not normal to the body but is noncancerous. Benign tumors grow more slowly and have cells that are the same as the original tissue. An organ containing a benign tumor usually continues to function normally, whereas an organ affected with a cancerous tumor eventually ceases to function. *Malignant*, a term often used as a synonym for cancer, is defined as a growth that resists treatment. A comparison of benign and malignant tumors is found in Table 10-3.

oncology: onco—mass + logy—word, reason

neoplasm: neo—new + plasm—form

TABLE 10-3 BENIGN AND MALIGNANT TUMORS

	Benign	Malignant
<i>Growth Rate</i>	Typically slow expansion	Often rapid with cell numbers doubling normal cell growth; malignant cells infiltrate surrounding tissue
<i>Cell Features</i>	Typical of the tissue of origin	Atypical in varying degrees of the tissue or origin; altered cell membrane; contains tumor-specific antigens
<i>Tissue Damage</i>	Minor	Often causes necrosis and ulceration of tissue
<i>Metastasis</i>	Not seen; remains localized at origin site	Often spreads to form tumors in other parts of the body
<i>Recurrence after Treatment</i>	Seldom recurrence after surgical removal	Recurrence can be seen after surgical removal and following radiation and chemotherapy
<i>Related Terminology</i>	Hyperplasia, polyp, and benign neoplasia	Cancer, malignancy, and malignant neoplasia
<i>Prognosis</i>	Not injurious unless location causes pressure or obstruction to vital organs	Death if uncontrolled

► CANCER

Cancer is a group of cells that grows out of control, taking over the function of the affected organ. Cancer cells are described as poorly constructed, loosely formed, and without organization. A simplistic definition is “confused cell.”

LEARNING TIPS

Cancer is not contagious.

Pathophysiology

Cancer is not one disease, but many diseases with different causes, manifestations, treatments, and prognoses. It is a disease of more than 100 different types, caused by mutation of cellular genes. Cancer takes on the characteristics of the cell it mutates and then takes on characteristics of the mutation. Growth-regulating signals in the cell’s surrounding environment are ignored as the abnormal cell growth increases. Normal cells are limited to about 50 to 60 divisions before they die. Cancer cells do not have a division limit and are considered immortal.

The progression from a normal cell to a malignant cell follows a pattern of mutation, defective division and abnormal growth cycles, and defective cell communication. Cell mutation occurs when a sudden change affects the chromosomes, causing the new cell to differ from the parent. The malignant cell enzymes destroy the glue-like substance found between normal cells, which disrupts the transfer of information used for normal cell structure.

LEARNING TIPS

An individual’s cancer risk is viewed as the balance between exposure and susceptibility to **carcinogens**.

Cancer Classification

Cancers are identified by the tissue affected, speed of cell growth, cell appearance, and location. Neoplasms occurring in the epithelial cells are called carcinomas. Carcinoma is

the most common type of cancer and includes cells of the skin, gastrointestinal system, and lungs (Figs. 10-4 and 10-5). Cancer cells affecting connective tissue, including fat, the sheath that contains nerves, cartilage, muscle, and bone, are called sarcomas. *Leukemia* is the term used to describe the abnormal growth of white blood cells. Cancers involving cells of the lymphatic system, lymph nodes, and spleen are called lymphomas (Table 10-4).

carcinogen: karkinos—cancer, crab + genesis—birth

Figure 10-4 Adenocarcinoma of the caecum. (Photo courtesy Dinesh Patel, MD. Medical Oncology, Internal Medicine, Zanesville, Ohio.)

Figure 10-5 Lung cancer. (Photo courtesy Dinesh Patel, MD. Medical Oncology, Internal Medicine, Zanesville, Ohio.)

TABLE 10-4 TUMOR DESCRIPTION

Tumor Type	Character	Origin
Fibroma	Benign	Connective tissue
Lipoma	Benign	Fat tissue
Carcinoma	Cancerous	Tissue of the skin, glands, and digestive, urinary, and respiratory tract linings
Sarcoma	Cancerous	Connective tissue, including bone and muscle
Leukemia	Cancerous	Blood, plasma cells, and bone marrow
Lymphoma	Cancerous	Lymph tissue
Melanoma	Cancerous	Skin cells

Spread of Cancer

Neoplastic cells that remain in one area are considered localized, or **in situ**, cancers. These tumors may be difficult to visualize on clinical examination and are detected through microscopic cell examination. In situ tumors are often removed surgically and require no further treatment. **Metastasis** is the term used to describe the spread of the tumor from the primary site into separate and distinct areas.

Metastasis is the stage at which cancer cells acquire invasive behavior characteristics and cause the surrounding tissue to change (Fig. 10-6). Metastasis occurs primarily because cancer cells break away more easily than normal cells and can survive for a time independently from other cells. There are three steps in the formation of a metastasis. Cancer cells are able to (1) invade blood or lymph vessels, (2) move by mechanical means, and (3) lodge and grow in a new location.

Metastatic tumors carry with them the cell characteristics of the original or primary tumor site. As a result, surgeons are able to determine the original tumor site based on metastatic cell characteristics. For example, lung tissue found in the brain suggests a primary lung tumor with metastasis to brain tissue. Common sites of metastasis are the lungs, liver, bones, and brain.

in situ: in—in + situ—position

metastasis: meta—beyond + stasis—stand

Figure 10-6 Invasive metastasis to skin area following mastectomy for breast cancer. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, Ohio.)

Incidence of Cancer

Cancer affects all age groups, although the incidence is higher in people ages 60 to 69. The second highest age group is ages 70 to 79. Men have a higher incidence of cancer than women. Cancer in people over age 60 is thought to occur from a combination of exposure to carcinogens and weakening of the body's immune system.

Some cancers, such as Wilms' tumor of the kidney and acute lymphocytic leukemia, occur more commonly in young people. The cause of tumors in young people is not well understood, but genetic predisposition tends to be a major factor.

The most common type of cancer in adults is skin cancer; it is also considered to be the most preventable. Exposure to ultraviolet radiation (sunlight) increases the risk of skin cancer. Wearing protective clothing and sunscreen can greatly reduce the risk of skin cancer.

Lung cancer is responsible for the highest mortality rate in both men and women and also is commonly preventable. Cigarette smoking is the main cause, along with air pollution and exposure to chemical agents.

Men have a high incidence of prostate cancer between ages 60 and 79. Cancer of the colon and rectum has been linked to the consumption of high-fat, low-fiber diets and ranks as the third highest cancer in men (Fig. 10-7).

The highest incidence of cancer in women is in the lungs, and the second highest is in the breast. Women with a family history of breast cancer have a greater risk than those with no family history. Commercial testing for the oncogene linked with breast cancer is available and marketed for high-risk women, especially those in the Ashkenazi Jewish population. Genetic testing is done through genetic counseling programs, and the cost ranges from \$700 to \$2400, depending on the geographic region.

Mortality Rates

Cancer survival rates have improved over the past 30 years. The American Cancer Society reports a gain in patient survival rates from 33 percent in the 1960s to 40 percent currently. A 5-year period is used to monitor cancer patients' progress following diagnosis and treatment. Survival statistics are based on persons living 5 years in remission.

For more information about cancer incidence and mortality data, visit the National Cancer Institute Web site at <http://www.nci.nih.gov> or <http://www.seer.ims.nci.nih.gov>,

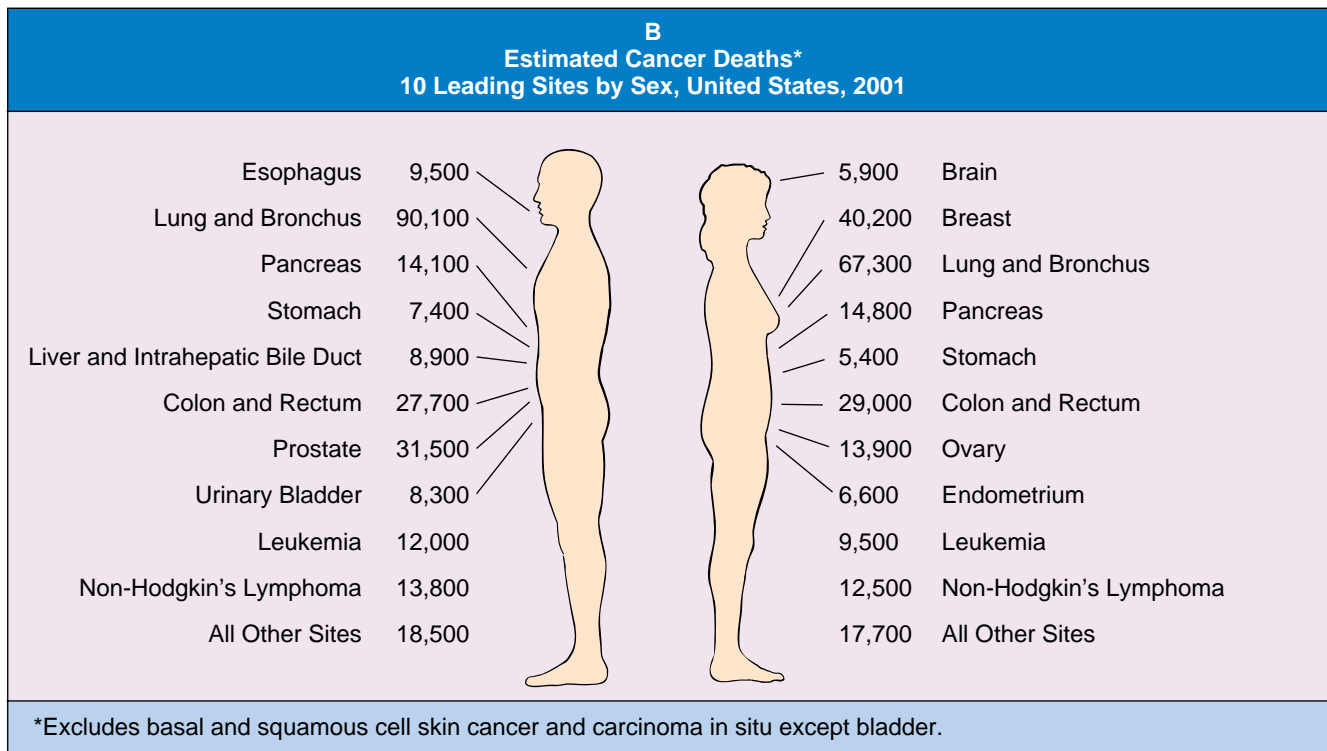

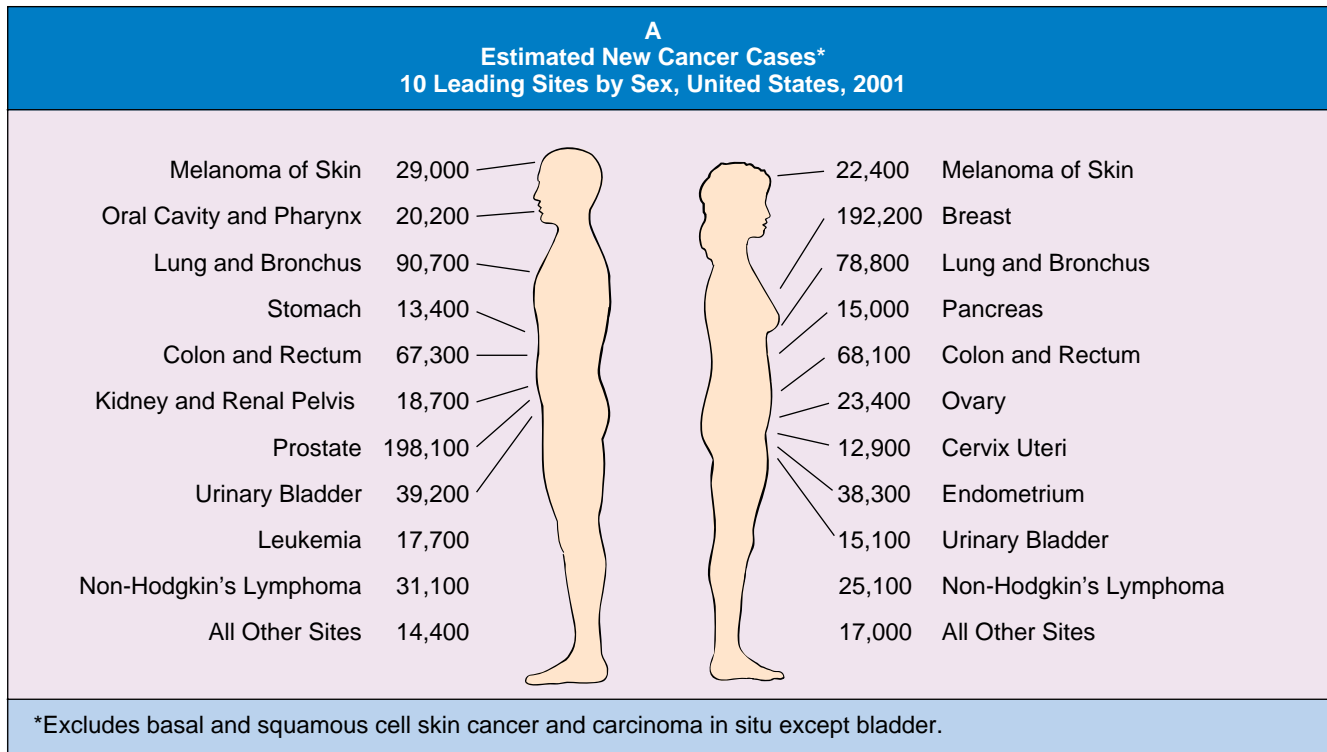

Figure 10-7 (A) Estimated new cancer cases, 10 leading sites by sex, United States, 2001. (B) Estimated cancer deaths, 10 leading sites by sex, United States, 2001. (Modified from Cancer Facts and Figures, American Cancer Society, 2001.)

or visit the National Coalition for Cancer Survivorship Web site at <http://www.cansearch.org>.

Etiology

Cancer cell growth and reproduction involves a two-step process. The first step in cancer growth is called initiation.

Initiation causes an alteration in the genetic structure of the cell (DNA). Cell alteration is associated with exposure to a carcinogen. The cellular change primes the cell to become cancerous.

Promotion is the second type of cancer cell growth. It occurs after repeated exposure to carcinogens causes initi-

ated cells to mutate. During the promotion step, a tumor forms from mutated cell reproduction.

A healthy immune system can often destroy cancer cells before they replicate and become a tumor. It is important to remember that any substance that weakens or alters the immune system puts the individual at risk for cell mutation. Medical researchers support the theory that cancer is a symptom of a weakened immune system.

Risk Factors

Increased risk of cancer is linked to several environmental factors. An evaluation of cancer begins with assessment of well-known risk factors such as specific viruses; exposure to radiation, chemicals, and irritants; genetics; diet; and general immunity. Certain racial and ethnic groups also are at higher risk for some types of cancer (Cultural Consideration Box 10–2).

BOX 10-2 CULTURAL CONSIDERATION

Many racial and ethnic groups in the United States have high rates of cancer. Although risk factors for the development of specific cancers are similar, barriers to prevention and nursing strategies to reduce risk factors vary among ethnicities.

Foreign-born and first-generation white men from Norway, Sweden, and Germany have an increased risk of stomach cancer. This suggests an interrelation among ethnic, geographic, and dietary risk factors as the cause of this high incidence of stomach cancer. Assessing for this data among these populations may assist in the diagnostic process.

Recent Eastern European immigrants may be at risk for thyroid cancer and leukemia because of the current industrial pollution and radiation exposure from the Chernobyl nuclear disaster in 1986. Some contamination occurred in Estonia, Latvia, Lithuania, and Poland. This may constitute a health hazard and may affect both recent immigrants and visitors to these countries. It is essential that health care providers carefully screen individuals for these cancers.

The Appalachian region has the highest rate of cervical cancer in the United States. Thus the nurse needs to encourage Appalachian women to have gynecological examinations on a yearly basis, and be flexible with appointments.

Cancer sites among African-Americans include the prostate, breast, lung, colon, rectum, cervix, pancreas, and esophagus. Because African-Americans are overrepresented in the working class, they experience increased exposure to hazardous occupations. For example, African-American men are at a higher risk for developing cancer related to their high representation in the steel and tire industries and in factories manufacturing chemicals and pesticides. They have the highest overall cancer rate, the highest overall mortality rate, and their 5-year survival rate is 30% lower than that of European-Americans. In general, African-Americans report later for treatment than European-Americans. Colon tumors are deeper within African-Americans, making detection on digital examination more difficult. Poverty, a diet high in fat and low in fiber, and lower levels of thiamine, riboflavin, vitamins A and C, and iron may increase cancer risk among African-Americans. Additionally, cigarette smoking, inner city living with pollution, obesity, and alcohol consumption increase African-Americans' risk for developing cancer.

Lack of medical care access acts as a barrier to prevention among African-Americans. Survival, not prevention, is the priority for some. Additional barriers include a lack of cancer risk teaching and detection in some African-American communities, lack of health insurance, and little stigma attached to alcohol consumption, and smoking. Strong family ties encourage seeking health care from family members before professionals.

Primary strategies for cancer prevention and increasing survival among African-Americans include using African-American professionals as speakers in community activities, using church-based information dissemination, providing forums in African-American

communities, and addressing smoking advertisements in African-American communities. Additional strategies include involving granny healers and ministers, changing food preparation practices and amounts rather than changing cultural food habits, involving extended family members in educational campaigns, and using African-American sports leaders in media campaigns.

Hispanic populations in the United States have an increased incidence for some types of cancer. Cervical cancer is increased among Central and South American women. Pancreatic, liver, and gallbladder cancer is increased among Mexican-Americans. Many Mexican-Americans are less aware of the early warning signs of cancer; many are more fearful of getting cancer than the general public; and many work in mining, factories using chemicals, and farming using pesticides.

Barriers to preventive health care among many Hispanics include high poverty rates, low educational rates, a preference for health care providers who understand Spanish, a preference for health care information presented in Spanish, a delay in seeking treatments for symptoms, and using lay healers as a first choice in health care. Additionally, many have a fear of surgical intervention with a body cavity left open to air and have decreased access to health care. For some, an undocumented immigration status creates a fear of reprisal.

Nursing approaches effective among Hispanics include educating lay healers regarding cancer prevention and early warning signs of cancer, using bilingual health care providers, using Hispanic health care providers whenever available, using respected Hispanic community leaders in educational programs, presenting videos in Spanish using Hispanic actors, educating the entire family because of close family networks, and connecting with Hispanic community churches, restaurants, and stores. Additionally, the nurse can use the 1-800-4-CANCER telephone number for Spanish translation and counseling, become involved with Hispanic community movements, and provide information in community and regional Hispanic newspapers and community publications.

Cervical, liver, lung, stomach, multiple myeloma, esophageal, pancreatic, and nasopharyngeal cancer are higher among Chinese-Americans. Chinese-American women have a 20% higher rate of pancreatic cancer. High rates of stomach and liver cancer in Korea predispose recent immigrants to these conditions. Thus the nurse needs to assess and teach newer immigrants regarding these types of cancer.

High rates of stomach, breast, colon, and rectal cancer common among Japanese people may be related to the high sodium content of the Japanese diet, a genetic predisposition, consumption of salted fish and contaminated grain, hepatitis B, smoking, vitamin A deficiency, low vitamin C intake, chronic esophagitis, and pulmonary sequelae of cigarette smoking. Barriers to prevention include the following: prevention models are not native to their culture; there may be a lack of trust in Western medicine; they have decreased access

BOX 10-2 CULTURAL CONSIDERATION—CONT'D

to health care; some are unable to speak the English language; and for some, an undocumented immigration status creates a fear of reprisal.

Nursing approaches to improve cancer risk prevention among Asians and Pacific Islanders include education about prevention versus acute care practice, educating native healers, involvement in community with respected native leaders, videos and literature in native language, and incorporating native healing practices such as traditional Chinese medicine.

Native-American populations have an increased risk for skin, pancreatic, gallbladder, liver, and prostate cancer. Risk factors for the development of cancer include obesity, a diet high in fat, high rates of alcohol consumption, and high rates of smoking. Barriers to preven-

tion include a lack of Native-American health care providers, health care providers' unfamiliarity with Native-American cultures, lack of financial resources, and a lack of integration of Native-American healing resources into prevention practices. Nursing approaches to decrease cancer risk prevention among Native-American populations include the following: incorporate prevention into Native-American healing practices; educate Native-American lay healers regarding cancer prevention practices; work with tribal community leaders; respect modesty, gender roles, and tribal customs; work with the Indian Health Service and Bureau of Indian Affairs; encourage traditional customs of physical fitness and exercise; and encourage dietary portion control and healthy food preparation practices instead of changing cultural food habits.

VIRUSES. Certain viruses, such as the **oncoviruses** (RNA-type viruses), are linked to cancer in humans. Retrovirus is an enzyme produced by RNA tumor viruses and is found in human leukemia cells.

The Epstein-Barr virus (EBV), which causes infectious mononucleosis, is also associated with Burkitt's lymphoma. Herpes simplex virus II has been associated with cervical and penile cancers. Papillomavirus associated with genital warts is considered one cause of cervical cancer in women. Chronic hepatitis B is linked with liver cancer.

RADIATION. There is an increased incidence of cancer in persons exposed to prolonged or large amounts of radiation. Ionizing radiation involving x-rays; alpha, beta, and gamma rays; and ultraviolet rays such as sunlight play a major role in promoting leukemia and skin cancers, primarily melanomas.

Persons exposed to radioactive materials in large doses, such as a radiation leak or an atomic bomb, are at risk for leukemia, breast, bone, lung, and thyroid cancer. Controlled **radiation therapy** is used to treat cancer patients by destroying rapidly dividing cancer cells. Radiation can also damage normal cells. The decision to use radiation is made after careful evaluation of the tumor's location and vulnerability to other treatments.

CHEMICALS. Chemicals are present in air, water, soil, food, drugs, and tobacco smoke. Chemical carcinogens are implicated as triggering mechanisms in malignant tumor development. Length of exposure time and degree of exposure intensity to chemical carcinogens are associated with risk for cancer development.

Smoking accounts for 87 percent of lung cancer worldwide. Chemical agents, as in tobacco, are more toxic when used with alcohol. Alcohol and tobacco are the most frequent causes of cancers of the mouth and throat. Chemicals used in manufacturing, such as vinyl chloride, are associated with liver cancer.

IRRITANTS. Chronic irritation or inflammation caused by irritants such as snuff or pipe smoke often cause cancer in

local areas. Nevi (moles) that are chronically irritated by clothing, especially clothing contaminated by chemical residue, may become malignant. Asbestos found in temperature and sound insulation has been proven to cause a particularly virulent type of lung cancer.

GENETICS. Genetics plays a large part in cancer formation. Certain breast cancers are linked to a specific gene mutation. Skin and colon cancers have a genetic tendency. People with Down syndrome (a chromosomal abnormality) have a higher risk of developing acute leukemia.

DIET. Diet is a large factor in both cause and prevention of malignancies. People who eat high-fat, low-fiber diets are more prone to develop colon cancers. Diets high in fiber reduce the risk of colon cancer. High-fat diets are linked to breast cancer in women and prostate cancer in men. Consumption of large amounts of pickled, smoked, and char-broiled foods has been linked with esophageal and stomach cancers. A diet low in vitamins A, C, and E is associated with cancers of the lungs, esophagus, mouth, larynx, cervix, and breast.

HORMONES. Hormonal agents that disturb the balance of the body may also promote cancer. Long-term use of the female hormone estrogen is associated with cancer of the breast, uterus, ovaries, cervix, and vagina. It has been found that children born of mothers who took diethylstilbestrol (DES) during pregnancy have an increased incidence of reproductive cancers. DES is a synthetic hormone with estrogen-like properties used in the past to prevent miscarriage.

Tumors of the breast and uterus are tested for estrogen or progesterone influence. If a breast tumor is malignant, the tumor is tested and treatment varies depending on whether it is positive for estrogen or progesterone dependence.

IMMUNE FACTORS. A healthy immune system destroys mutant cells quickly on formation. An individual with altered immunity is more susceptible to cancer formation when exposed to small amounts of carcinogens compared with someone with a healthy immune system. Immune system suppression allows malignant cells to develop in large numbers.

Altered immunity is noted in persons with chronic illness and stress. An increased risk of cancer follows a traumatic, stressful period in life, such as the loss of a mate or a job. Failure to decrease stress productively contributes to a higher incidence of chronic illnesses. Thus a cycle of stress, illness, and increased cancer risk develops. Individuals with acquired immunodeficiency syndrome (AIDS) have a compromised immune system and an increased risk for certain cancers. A decline in the immune system is also noted as the body ages. A weaker immune system contributes to chronic illnesses and cancers associated with the elderly population.

Detection and Prevention

Nurses play an important role in preventing and detecting cancer. They help educate patients about risk factors, self-examination, and cancer screening programs (Nutrition Notes Box 10–3). Early diagnosis and treatment provide time to stop the progression of cancer.

BOX 10-3

Nutrition Notes

Reducing Cancer Risk

Encourage patient to consume these foods:

- Fruits and vegetables, especially those rich in vitamin C or carotene
- Cruciferous vegetables (cabbage, broccoli, brussels sprouts)
- Whole grains

Encourage patient to limit these foods:

- Excessive meat, especially when smoked, salted, char-broiled, or cooked at high temperature
- Excessive fat (more than 30% of daily calories)
- Excessive calories
- Alcohol

An annual physical examination helps medical personnel detect the seven warning signals of cancer promoted by the American Cancer Society. The warning signals can be remembered with the mnemonic CAUTION:

- Change in bowel or bladder habits
- A sore that fails to heal
- Unusual bleeding or discharge
- Thickening or lump in breast or other tissue
- Indigestion or swallowing difficulties
- Obvious change in wart or mole
- Nagging cough or hoarseness

Monthly breast self-examination is recommended after puberty for both men and women, and monthly self-testicular examination is recommended for men. (See Chapter 39 for information on how to do self-examinations.) Mammography (a specific x-ray of breast tissue used to detect a mass too small for palpation) is recommended once between ages 35 and 39 to provide a baseline and then annually after age 40. Routine pelvic examination and Papanicolaou testing (Pap smear) are recommended annually

after age 18 to screen for cervical cancer. Cytological examination of cervical cells increases the chance of diagnosing cervical cancer in situ.

Promotion of healthy lifestyles, including proper diet and exercise, helps strengthen the immune system and reduce cancer risks. The American Cancer Society promotes smoking cessation campaigns and supports the effort by stating that smoking is the most preventable cause of death from lung cancer. Secondhand smoke contributes to an increased risk of lung cancer in nonsmokers as well.

The American Cancer Society recommends one of the following five options to screen for colorectal cancer, beginning at age 50:

1. An annual stool test for blood
2. A flexible sigmoidoscopy every 5 years
3. A yearly stool test for blood and flexible sigmoidoscopy every 5 years
4. A double-contrast barium enema every 5 years
5. A colonoscopy every 10 years

Option 3 is preferred. Screening should begin earlier and take place more frequently in high-risk people.

Detection of prostate cancer is significant for men beginning around age 50. Digital rectal examination and prostate-specific antigen (PSA) blood testing is recommended annually for men older than 50 who have a life expectancy of at least 10 years and for younger men who are at higher risk. See Gerontological Issues Box 10–4 for specific screening recommendations for older adults.

BOX 10-4

GERONTOLOGICAL ISSUES

Screening Guidelines

Cancer is more common in older adults. Therefore screening for early detection is important. Use the following American Cancer Society guidelines for patients over age 65.

Colorectal cancer:

- Sigmoidoscopy every 3 to 5 years
- Fecal occult blood test yearly
- Digital rectal exam yearly

Breast cancer:

- Breast self-exam monthly
- Breast clinical exam yearly
- Mammogram yearly

Prostate cancer:

- Prostate exam (digital rectal exam) yearly
- Prostatic surface antigen yearly

Currently, much attention is directed toward genetic testing and identification of persons at risk for cancer. Genetic testing technology poses both legal and ethical questions concerning confidentiality and insurance cost issues. The cooperation of family members is important because genetic testing is done after a family member has been diagnosed with cancer. Family members may experience a variety of emotions surrounding the increased risk for themselves and their guilt over the role they may have played in increasing the risk for their children.

Preventive cancer vaccines are being developed for cancers associated with specific viruses. At present, most cancer vaccines are therapeutic rather than prophylactic and are used to stimulate the patient's immune system to destroy cancer cells. Vaccine therapy for malignant melanoma is being tested.

Diagnosis of Cancer

A diagnosis of cancer can be a very frightening experience (see Patient Perspective Box 10–5). Often people try to mask symptoms because they are so frightened of the disease. Exploring patient attitudes and perceptions about the disease helps you construct an effective teaching plan. A careful and thorough assessment of the patient's present and past medical and surgical history and pertinent family history are obtained. A complete physical examination provides both objective and subjective data. The most conclu-

sive information about the health of tissue is acquired by examining cell activity through biopsy.

Biopsy

Accurate identification of a cancer can only be done by **biopsy** (the surgical removal of tissue cells). Microscopic examination of a piece of suspected tissue or aspirated body fluid can confirm the presence of mutant cells. A biopsy is commonly done in a physician's office or outpatient surgery department.

Incisional biopsy is an invasive procedure that involves the surgical removal of a small amount of tissue for inspection. Tissue can also be removed during endoscopic procedures (insertion of a tube to observe the inside of a hollow organ or cavity), such as a lung biopsy done during bronchoscopy. Excisional biopsy is used to remove an entire tissue mass. Needle aspiration biopsy involves insertion of a needle into tissue for fluid or tissue aspiration (Fig. 10–8).

BOX 10–5

Patient Perspective

Robyn

I am a 43-year-old woman with three children and in the prime of my life, at least I thought. That was before I was diagnosed with cancer in my left breast. I was breast-feeding at the time I felt the lump and, although I went for a biopsy, I felt sure the lump resulted from a blocked milk duct or fibroid cyst. But, unbelievably, the biopsy came back positive for cancer. My whole life flipped upside down. I was devastated.

I was scheduled for surgery within a week, and my emotions were in complete turmoil. I felt nauseated all the time, vomited almost every morning, and had diarrhea daily. My stomach felt like it had a pot of bees inside. I never cried so much in my life. Thinking about all the tests, the surgery, and the untold ways my life could be affected made me a nervous wreck. Finally, I got down on my knees and turned this whole crisis over to God. I couldn't handle it anymore, so I asked God to give me peace, and I placed all my trust and faith in Him. It worked, and I was finally able to get control and face this thing head on.

As I went for further testing, the nurses and technicians I met were all very helpful and informative. Some actually broke down with me because they had endured this same disease. We would hold each other and then exchange phone numbers just to "talk" if I needed it. It was very encouraging to know these women had made it through, and I could too.

The surgery went smoothly, and I was released the next day. There wasn't much discomfort, and I felt good physically. The nerve was removed and a scar runs from the center of my chest down under my armpit. I was able to return to work in 3 weeks. The doctor gave me a prescription for a prosthesis as soon as the drains were removed and I began healing. We went to a specialty place to be fitted, and, although the prosthesis was nothing like the real thing, I looked normal and it helped to build my confidence.

The impact on my family was one of complete bewilderment because I had no family history of this type of cancer. Everyone tried to help with positive sentiments like we caught it early, breast cancer has a high cure rate, periodic followup can keep you cancer free, and so on. My husband and children supported and comforted me. I tried to focus on them because I want to be there for them when they graduate, get married, etc. My mother and sister helped get me to all my appointments and filled my prescriptions.

Chemo was advised as a follow-up treatment, and I was scheduled for four rounds, one every 3 weeks. This was undoubtedly the worst thing I have ever endured. Not even giving birth can compare to the way chemo makes you feel. I had a very bad experience the first round and was extremely sick and unable to eat for 5 days. I wondered why I didn't just die from the cancer because I felt that this was killing me. Before the second round, I told the doctor how violently ill I'd been and she adjusted the dosages of some of the drugs. Still, I was very groggy; although I didn't vomit, I still wasn't feeling myself. For the third round, they changed a medication and I withstood the side effects a lot better—although I was still nauseated, light-headed, fatigued, and unable to focus, eat, or taste anything. At times it was hard just to put one foot in front of the other. They prepared me for the loss of my hair, but you really don't know how hard that is until it starts coming out in globs. Not just the loss, but then you have such a long time to wait for it to grow back. When the chemo is over, it's hard to look back and feel the way you did then, but when you look in the mirror and your hair is still gone, it's a hard reminder.

All through being diagnosed and dealing with breast cancer I have felt a tremendous outpouring of love and caring, not only from my immediate family but also from my church family. I was never so well taken care of. All the hugs, cards, calls, food, and flowers brought to the house encouraged me tremendously. It makes it a little easier to cope when you know you have so many people who care and are concerned enough to take time out of their daily lives to give you support.

I'm lucky because my sister is an RN and prepared me for many of the side effects and difficulties. She also was there to help ask questions and get information from other survivors that kept me in a positive frame of mind. I know that without her help and God's grace and peace, my recovery would not have been so easy. Looking back I can't really feel all those terrible emotions and symptoms, but I still am afraid of the unknown. It is not easy when it is you and not someone else this happens to.

Now that I'm through the worst part of this, I take positive steps every day to enjoy the little things in life. I feel that the more you keep involved in everyday activities and become educated in the disease and its treatments, the easier it is to deal with. I am taking a drug called Tamoxifen now and will be for 5 years. Two of the side effects are hot flashes and sweats. If this is all I have to deal with, however, praise God. My prognosis is very good, and I am expecting a complete cure because I am a survivor.

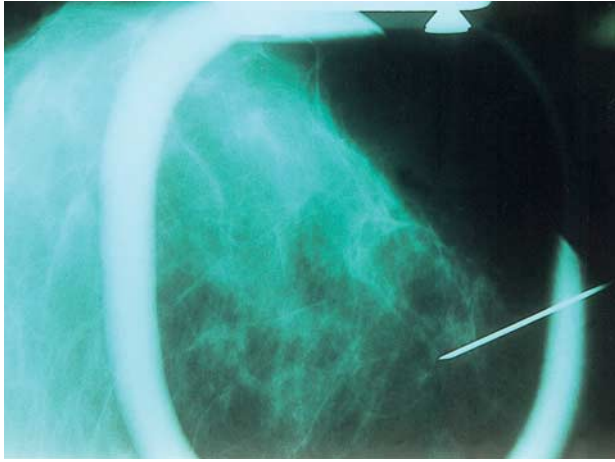

Figure 10-8 Fine needle breast biopsy. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, Ohio.)

This procedure is considered less invasive than incisional or excisional biopsy. Transcutaneous aspiration involves the insertion of a fine needle into tissue such as breast, prostate, or salivary gland and is used for diagnosing metastatic cancers. Frozen section biopsy provides immediate evaluation of the tissue sample during a surgical procedure. By freezing the tissue sample for microscopic examination, a quick analysis is possible, which helps direct additional surgical intervention. Frozen section biopsy is useful in the diagnosis and surgical intervention of breast cancer.

Stereotactic biopsy is a safe and efficient procedure for evaluating lesions in the brain and breast. The procedure is done by a specially trained radiologist. The biopsy site must be firmly immobilized. The lesion is scanned for location, and a small incision is made for easy insertion of a small fiberoptic instrument (Fig. 10-9). Stereotactic biopsy of the brain involves a local anesthetic because a small hole in the skull is made. Breast stereotactic biopsy uses pressure exerted by a mammogram machine to secure the breast; anesthesia may not be necessary.

Laboratory Tests

Blood, serum, and urine tests are important in establishing baseline values and general health status. Laboratory values are used with other assessment findings. An elevated white blood cell (WBC) count is expected if the patient has evidence of infection; however, an increase in WBCs without infection raises suspicion of leukemia. Fifty percent of patients with liver cancer have increased levels of bilirubin, alkaline phosphatase, and glutamic-oxaloacetic transaminase.

Bone marrow aspiration is done to learn the number, size, and shape of red and white blood cells and platelets. Bone marrow aspiration is a major tool for diagnosis of leukemia. (See Chapter 23 for a description of this test and related nursing care.)

Tumor markers, also called biochemical markers, are proteins, antigens, genes, hormones, and enzymes produced and secreted by tumor cells. Tumor markers help confirm a diagnosis of cancer, detect cancer origin, monitor the effect

Figure 10-9 Stereotactic biopsy of a brain lesion. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, Ohio.)

of cancer therapy, and determine cancer remission. Tumor markers include the following:

- Prostatic acid phosphatase (PAP)—high levels noted in prostate cancer
- PSA—elevated levels associated with prostate cancer
- Cancer antigen (CA) 15-3—elevated levels noted in breast cancer; useful in monitoring patient response to therapy for metastatic breast cancer
- CA 125—increased levels in ovarian, cervical, liver, and pancreas cancers
- CA 19-9—used to diagnose and evaluate pancreatic and hepatobiliary cancer; levels elevated in cancer
- Carcinoembryonic antigen (CEA)—increased levels suggest tumor activity

Cytological Study

Cytology is the study of the formation, structure, and function of cells. Cytological diagnosis of cancer is obtained primarily through Pap smears of cells shed from a mucous membrane (e.g., cervical or oral smear). Test results are based on the degree of cell abnormality. Normal results reflect no cellular changes. Slight cellular changes are considered normal, with a possible link to abnormal cells seen in infection. Severe cellular changes reflect a higher probability of precancerous or cancerous cellular activity. Infection causes cellular changes and contributes to an increase in abnormal cells detected.

Radiological Procedures

X-ray examination is a valuable diagnostic tool in detecting cancer of the bones and hollow organs. Routine chest x-ray examination is one diagnostic test used in detecting lung cancer. Mammography is a reliable and noninvasive low-radiation x-ray procedure for detecting breast masses. Breast tissue is compressed to allow better visualization of the soft tissue. You must alert patients that soft tissue compression

causes a degree of discomfort, but the compression is necessary to obtain an accurate picture. The discomfort is brief (Figs. 10–10 and 10–11).

Contrast media x-ray studies are used to detect abnormalities of bone and the gastrointestinal and urinary systems. Contrast media can be given by various methods. Barium is given orally for visualization of the esophagus and stomach or rectally for visualization of the colon (e.g., a barium enema). Intravenous injection of contrast media is used for lung and brain scans.

Computed tomography (CT) provides a three-dimensional, cross-sectional, computerized picture of the body. CT scans are important in the diagnosis and staging of malignancies and can detect minor variations in tissue thickness. The use of a contrast medium enhances the accuracy of an abdominal CT scan. CT scans are also used to improve the accuracy of inserting a fine needle for biopsy.

Nuclear Imaging Procedures

Nuclear medicine imaging involves camera imaging of organs or tissues containing radioactive media. Radioactive compounds are given intravenously or by ingestion. These studies are highly sensitive and can detect sites of abnormal cell growth months before changes are seen on an x-ray.

Positron emission tomography (PET) scanning provides information about cellular biochemical and metabolic activity. Patients are given biochemical compounds, and im-

Figure 10-10 Mammogram procedure. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, Ohio.)

Figure 10-11 Mammogram. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, Ohio.)

ages are made of the tissue through gamma-camera tomography. PET scans have been useful in brain imaging.

Ultrasound Procedures

Ultrasonography uses high-frequency sound waves to provide images of deep soft-tissue structures in the body. The procedure is noninvasive and does not use x-rays. Echoes from high-frequency sound waves outline tissue density and masses. This technology helps detect tumors of the pelvis and breast. Ultrasound may also be used to distinguish between benign and malignant breast tumors.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) creates sectional images of the body. MRI can be done with or without contrast dye and does not use radiation. The patient is placed in a cylinder-shaped magnetic field. The magnetic field aligns the nuclei of body cells in one direction. The magnetized cells are then excited by radiofrequency pulses. Images are made as cell nuclei change their alignment. MRI is valuable in the detection, localization, and staging of malignant tumors in the central nervous system, spine, head, and musculoskeletal system. MRI cannot be used in patients with pacemakers, implanted pumps, surgical clips, metal knees or hips, or tattooed eyeliner.

Endoscopic Procedures

An endoscopic examination allows the direct visualization of a body cavity or opening. The procedure involves the insertion of a flexible endoscope containing fiberoptic glass bundles that transmit light and can produce an image. Endoscopy enables the surgeon to biopsy abnormal tissue and is used to detect lesions of the throat, esophagus, stomach, colon, and lungs.

Oral endoscopic procedures require patient preparation to reduce the risk of aspirating stomach secretions. The patient is given nothing to eat or drink before and immediately after the examination. A local anesthetic is used during the examination to anesthetize the throat. Following the procedure, oral food and fluids are withheld until the

gag reflex returns, to prevent aspiration. The gag reflex is assessed by placing a tongue blade on the back of the tongue or by using a cotton-tipped swab at the back of the throat to stimulate the gag reflex after the procedure.

Staging and Grading

Tumor staging is used to determine the stage of solid-tumor masses, providing valuable information about the potential success of treatment plans. Tumor staging is important in the development of an international system that can compare statistics among cancer centers. The most common system used for staging tumors is called tumor, node, metastasis (TNM).

This staging system classifies solid tumors by size and tissue involvement. TNM stages are T0 (no tumor), Tis (tumor in situ), and T1 through T4 (progressive increase in tumor size or involvement). Extent of lymph node involvement ranges from N0, no nodes, to N4, a large amount of lymph node involvement. Metastasis is described as M0, no metastasis, to M1, metastasis to some area (Table 10–5).

There is also a rating or grading system to define the cell types of tumors. Tumors are classified according to the percentage of cells that are differentiated (mature). If the tissue of a neoplastic tumor closely resembles normal tissue, it is called well differentiated. A poorly differentiated tumor is a malignant neoplasm that contains some normal cells, but most of the cells are abnormal. The better defined or differentiated the tumor, the easier it is to treat.

Treatment for Cancer

There are three main types of treatment for cancer: surgery, radiation therapy, and **chemotherapy**. To find out more about cancer treatment options, go to the American Cancer Society Web site at <http://www.cancer.org>.

chemotherapy: chemo—chemistry + therapy—treatment

TABLE 10-5 TUMOR, NODE, METASTASIS CLASSIFICATION, STAGING, AND TISSUE INVOLVEMENT

Classification	Staging	Tissue Involvement
Primary tumor (T)		
T _{is}	Stage I	Tumor in situ, indicates no invasion of other tissues
T ₁ , T ₂ , T ₃ , T ₄	Stage II	Ranges indicate progressive increase in tumor size with local metastasis
Regional lymph node involvement (N)		
N ₀	No nodes	
N ₁ , N ₂ , N ₃	Stage III	Metastasis to regional lymph nodes
Metastasis (M)		
M ₀		No metastasis
M ₁	Stage IV	Distant metastasis

Surgery

Surgery can be used to cure cancer when it is possible to remove the entire tumor. Skin cancers and well-defined tumors without metastasis can be removed without any additional intervention.

Prophylactic surgery is used to remove moles or lesions that have the potential to become malignant. Colon polyps are often removed to prevent malignancies from developing, especially if the polyps are considered premalignant. An extreme example of prophylactic surgery is a woman who elects to have a mastectomy (surgical removal of the breast) because of a high incidence of breast cancer in her family.

Surgery may also be done for **palliation** (symptom control). Surgical removal of tissue to reduce the size of the tumor mass is helpful, especially if the tumor is compressing nerves or blocking the passage of body fluids. The goals of palliative surgery are less discomfort and an improved quality of life.

Reconstructive surgery can be done for cosmetic enhancement or for return of function of a body part. Facial reconstruction is important for a patient's self-image after removal of head or neck tumors. Women can elect to have breast implants after mastectomy.

Surgical intervention for cancer treatment is typically not an emergency intervention, which allows patients and medical personnel time for planning. Autologous blood donation (blood donated by the patient before surgery) has become popular and reduces the risk of exposure to blood-borne infections. The American Red Cross and many hospitals have programs specifically designed for autologous blood donation and accept donations from 30 days to 72 hours before surgery.

You can play a major role in reducing the patient's fears about postoperative pain. Patient-controlled analgesia (PCA) provides patients with some control over their pain. Therapies such as deep relaxation, imagery, and hypnosis can be used with traditional pain control measures.

It is important to encourage patients to express and discuss their fears. Patients with a limited understanding of cancer may fear that tissues will not heal postoperatively. Provide information about wound care, including dressing changes and drainage tubes, to increase the patient's knowledge base and sense of control. Visual aids concerning tumor site and surgical procedures are valuable teaching tools.

Patients who are undernourished are poor surgical candidates and require intervention such as enteral or parenteral nutrition before and after surgery. Patients with cancer are also at increased risk for postoperative deep vein thrombosis (DVT). Preoperative teaching includes the importance of leg movement, early ambulation, wearing antiembolism stockings, and recognizing symptoms of DVT, such as a cramping sensation in the calf muscle and pain when the foot is dorsiflexed.

Radiation

Radiation is used commonly in the treatment of cancer for control or palliation, and it can be curative if the disease is

localized. The decision to use radiation is commonly based on cancer site and size. Radiation destroys cancer cells by affecting cell structure and the cell environment. It is used in fractionated (divided) doses to prevent destructive side effects; however, side effects can occur in the area being treated because of damage to normal cells.

The size of a large tumor can be decreased with radiation before surgery, making surgical intervention more effective and less dangerous. Palliative radiation is used to reduce the size of a large cancerous lesion and consequently reduce pressure and pain. Radioisotopes inserted into cancerous tissue during surgery help destroy the cancerous cells without removing the organ.

NURSING CARE OF THE PATIENT RECEIVING RADIATION TREATMENT. Symptoms of tissue reaction to radiation treatment can be expected about 10 to 14 days after the start of the treatment program and continue up to 2 weeks after treatment is completed. Typical reactions and appropriate nursing interventions include the following:

- Fatigue. Encourage the patient to nap frequently and prioritize activities. Reassure the patient that the feeling will go away when the treatments are completed.
- Nausea, vomiting, and **anorexia**. Encourage the patient to take prescribed medication for nausea and vomiting. Anorexia can be eased by giving small amounts of high-carbohydrate, high-protein foods and avoiding foods high in fiber.
- **Mucositis** (inflammation of the mucous membranes, especially of the mouth and throat). Encourage the patient to avoid irritants such as smoking, alcohol, acidic food or drinks, extremely hot or cold foods and drinks, and commercial mouthwash. Advise the patient to perform mouth care before meals and every 3 to 4 hours. A neutral mouthwash is appropriate and can be made by using 1 ounce of diphenhydramine hydrochloride (Benadryl) elixir diluted in 1 quart of water or normal saline solution. Agents that coat the mouth, such as Maalox, are sometimes used. Lidocaine hydrochloride 2 percent viscous has an anesthetic effect on the mouth and throat.
- **Xerostomia** (dry mouth). Encourage frequent mouth care. Saliva substitute is available over the counter and is helpful, especially at night when patients complain of a choking sensation from extreme dryness.
- Skin reactions. These vary from mild redness to raw moist lesions similar to a second-degree burn. Skin surfaces that are especially warm and moist, such as the groin, perineum, and axillae, have poor tolerance to radiation. Prophylactic skin care includes keeping skin dry; keeping it free from irritants, such as powder, lotions, deodorants, and restrictive clothing; and protecting it against exposure to direct sunlight.
- Bone marrow depression. This reaction occurs with both radiation and chemotherapy. Weekly blood cell counts are

done to detect low levels of WBCs, red blood cells, and platelets. Transfusions of whole blood, platelets, or other blood components may be necessary.

SAFETY CONSIDERATIONS. Radiation may be administered externally or internally. External radiation is given by a trained medical specialist in a designated area in the hospital or clinic. Internal radiation is administered to patients admitted to a health care facility.

Safety guidelines must be followed when caring for a patient with radioactive materials implanted into tissue or body cavities or administered orally or intravenously. Nursing responsibilities include knowledge about the following:

1. Radiation source being used
2. Method of administration
3. Start of treatment
4. Length of treatment
5. Prescribed nursing precautions

Personnel involved with radiation therapy must recognize the three primary factors in radiation protection: time, distance, and shielding. These three factors depend on the type of radiation used. *Time* involves the time spent administering care, *distance* involves the amount of space between the radioisotope and the nurse, and *shielding* involves the use of a barrier such as a lead apron.

You must work efficiently when caring for patients who are receiving radioisotopes that are releasing gamma rays. Your exposure to radiation is proportionate to the time spent and the distance from the radiation source. For example, you will receive less exposure standing at the foot of the bed of a patient with radioisotopes inserted into the head than if you stand at the head of the bed (Fig. 10–12). Time and distance are used to protect the nurse, visitors, and other personnel.

It is important to teach the patient and family members the reason nursing care focuses on providing only essential care. Speedy nursing encounters and visitor restrictions are better accepted and less likely to promote feelings of isolation when patients understand the reasons behind them.

Drainage from the site of a radioactive colloid injection is considered radioactive, and the physician must be informed immediately. Dressings contaminated with radioactive seepage must be removed with long-handled forceps. Radioactive materials must never be touched with unprotected hands; shielding is required to prevent exposure to radiation. Contamination from radioisotope applicators or interstitial implants cannot occur when the capsule is intact; contamination occurs when the capsule is broken.

LEARNING TIPS

Remember to use the principles of time, distance, and shielding to protect yourself from radiation exposure.

anorexia: an—not + orexis—appetite
mucositis: muco—mucous (membrane) + itis—inflammation
xerostomia: xero—dry + stoma—mouth

Figure 10-12 Radiation distancing. Nurse B receives less radiation than Nurse A, and Nurse C receives less radiation than Nurse B.

Chemotherapy

Chemotherapy is chemical therapy that uses **cytotoxic** drugs to treat cancer. Cytotoxic drugs can be used for cure, control, or palliation of cancerous tumors and are described according to how they affect cell activity. For example, alkylating agents bind with DNA to stop the production of RNA; antimetabolites substitute for nutrients or enzymes in the cell life cycle; mitotic inhibitors interfere with cell division; antibiotics inhibit DNA and RNA synthesis; and hormonal agents alter the hormonal structure of the body. Chemotherapy is usually more effective when multiple drugs are given in multiple doses. Examples of specific drugs and their adverse effects are provided in Table 10-6.

The effects of chemotherapy are systemic unless used topically for skin lesions. Chemotherapy is used preoperatively to shrink tumors and postoperatively to treat residual tumors. Factors influencing the effectiveness of chemotherapy are tumor type, available chemotherapeutic drugs, and genetics.

ROUTES OF ADMINISTRATION. Drugs may be given via oral, intramuscular, intravenous, or topical routes. The dosage of medication is regulated by the size of the individual and the toxicities of the drug. The administration of intravenous chemotherapeutic drugs requires specialized training and knowledge of antineoplastic drugs.

Vesicant drugs are given only by the intravenous route. These drugs cause blistering of tissue that eventually leads to necrosis if they infiltrate, or leak out of the blood vessel, into soft tissue (Fig. 10-13). Skin grafts may be necessary if tissue damage is extensive.

Central Lines. Central lines are intravenous catheters that terminate in the superior vena cava near the right atrium of the heart. This is a large vessel that allows for dilution of vesicant drugs and reduces the risk of infiltration. Central lines may be external, with the distal end of the catheter exiting the skin, or internal, with the distal catheter ending in an implanted port. See Chapter 6 for additional information on central lines.

SIDE EFFECTS OF CHEMOTHERAPY. Toxicities in patients receiving chemotherapy vary according to the medications given; however, some general side effects are commonly associated with chemotherapy drugs. Fast-growing epithelial cells, such as those of the hair, blood, skin, and gastrointestinal tract, are generally affected by both chemotherapy and radiation.

Bone Marrow. Chemotherapy is toxic to the bone marrow, where the blood cells are produced. Patients may develop low white blood cell counts (**leukopenia**), increasing their susceptibility to infection and sepsis. A reduction in

cytotoxic: cyt—cell + toxic—poison

vesicant: vesicate—to blister

leukopenia: leuko—white cells + penia—lack

TABLE 10-6 CHEMOTHERAPY MEDICATIONS

Medication	Classification	Method of Administration	Common Adverse Effects
Bleomycin	Antibiotic	IM or IV	Fever and chills, cough, shortness of breath; in severe cases, pulmonary fibrosis.
Busulfan	Alkylating	PO	Unusual bleeding or bruising, diarrhea, fatigue, nausea, vomiting
Carboplatin (Paraplatin)	Alkylating	IV	Abdominal pain, nausea and vomiting, electrolyte imbalances
Carmustine (BCNU)	Alkylating	IV	Fever and chills, nausea and vomiting
Cisplatin	Alkylating	IV	Difficulty hearing, fever and chills, ringing in ears, nausea and vomiting.
Cyclophosphamide (Cytoxan)	Alkylating	IV or PO	Nausea and vomiting, blood in the urine, loss of hair
Cytarabine (Cytosar)	Antimetabolic	IV	Fever and chills, unusual bleeding or bruising, sore throat, tiredness, nausea and vomiting
Dactinomycin (Cosmegen)	Antibiotic (vesicant)	IV	Loss of hair, nausea and vomiting, tiredness
Daunorubicin	Antibiotic (vesicant)	IV	Red urine, nausea and vomiting, loss of hair
Docetaxel (Taxotere)	Toxoid	IV	Fatigue, edema, nausea and vomiting, stomatitis, anemia, thrombocytopenia, myalgia, hair loss
Doxorubicin (Adriamycin)	Antibiotic (vesicant)	IV	Red urine, nausea and vomiting, loss of hair, cardiac damage
Estramustine (Emcyt)	Alkylating	PO	Nausea, vomiting, anorexia, estrogenic, edema, breast tenderness or enlargement
Etoposide (VP-16)	Alkylating (mild vesicant)	IV	Nausea and vomiting, loss of hair, numbness and tingling in fingers and toes
Floxuridine (FUDR)	Antimetabolic	IV	Diarrhea, nausea and vomiting, loss of appetite, sores in mouth
Fludarabine (Fludara)	Antimetabolic	IV	Bone marrow depression, nausea, vomiting, diarrhea, neurotoxicity
Fluorouracil (5-FU)	Antimetabolic	IV	Diarrhea, loss of appetite, loss of hair, nausea and vomiting
Gemcitabine (Gemzar)	Nucleoside analogue	IV	Dyspnea, edema, nausea, vomiting, diarrhea, stomatitis, hematuria, hair loss, bone marrow suppression
Hydroxyurea (Hydrea)	Antimetabolic	PO	Fever and chills, sore throat, drowsiness, diarrhea, nausea and vomiting
Ifosfamide (Ifex)	Alkylating	IV	CNS toxicity, nausea, vomiting, cystitis, hair loss
Irinotecan (Camptosar)	Enzyme inhibitor	IV	Dizziness, headache, insomnia, dyspnea, edema, nausea, vomiting, constipation, stomatitis, hair loss, bone marrow suppression, weight loss
Melphalan (Alkeran)	Alkylating	PO	Nausea and vomiting
Methotrexate	Antimetabolite	PO, IV, intrathecal	Blood in urine, sun sensitivity, diarrhea, sores in mouth, jaundice, nausea and vomiting
Mitomycin-C (Mutamycin)	Antibiotic (vesicant)	IV	Blood in urine, nausea and vomiting, loss of appetite
Mitotane (Lysodren)	Miscellaneous	PO	Dizziness, drowsiness, GI distress
Mitoxantrone (Novantrone)	Antibiotic	IV	Headache, dyspnea, diarrhea, nausea, vomiting, stomatitis, hair loss, fever, bone marrow suppression
Paclitaxel (Taxol)	Miscellaneous	IV	Nausea, vomiting, muscle aches, cardiac toxicities
Procarbazine	Alkylating	PO	MAO inhibitor, drowsiness, nausea and vomiting
Rituximab (Rituxan)	Miscellaneous	IV	Nausea, vomiting, bone marrow suppression, bronchospasm
Streptozocin (Zanosar)	Antibiotic	IV	Anxiety, chills, nausea and vomiting
Tamoxifen (Nolvadex)	Hormone	PO	Hot flashes, weight gain, nausea, bone pain
Topotecan (Hycamtin)	Enzyme inhibitor	IV	Headache, dyspnea, nausea, vomiting, diarrhea, hair loss, bone marrow suppression
Vinblastine (Velban)	Vinca alkaloid	IV	Muscle pain, nausea and vomiting, loss of hair
Vincristine (Oncovin)	Vinca alkaloid	IV	Constipation, difficulty walking, tingling in fingers and toes
Vinorelbine (Navelbine)	Vinca alkaloid (vesicant)	IV	Fatigue, constipation, nausea, hair loss, bone marrow suppression, neurotoxicity

CNS = Central nervous system; GI = gastrointestinal; IM = intramuscular; IV = intravenous; MAO = monoamine oxidase inhibitor.

Figure 10-13 Necrosis of skin tissue resulting from administration of a vesicant chemotherapy drug. (Photo courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, Ohio.)

platelets (**thrombocytopenia**) increases the risk of bruising and bleeding and can require platelet transfusions. Increased risk of **anemia** occurs with the reduction of red blood cells and may require blood transfusions.

Gastrointestinal Tract. The gastrointestinal tract is susceptible to the toxicity of chemotherapy drugs. Patients often become nauseated and vomit or experience diarrhea. **Stomatitis** is a common complaint and is discussed under side effects of radiation. These side effects can be controlled with medication.

Hair. **Alopecia** (hair loss) is common with many chemotherapy drugs. This is a temporary condition, and growth of the new hair usually starts when the chemotherapy medication is stopped. Alopecia involves the entire body and includes eyebrows, eyelashes, and axillary and pubic hair. Hair regrowth may be of different color or texture than the original hair. It is not uncommon for individuals who originally had straight hair to regrow curly hair.

Reproductive System. The effects of chemotherapy or radiation can cause temporary or permanent alterations of the reproductive system. Occasionally, patients are rendered sterile because of the treatment. Issues concerning fertility should be discussed with the patient before treatment. Measures such as freezing ova and the use of sperm banks provide options for the patient and his or her partner.

Neurological System. Drugs may affect the neurological system. An adverse reaction to vincristine is neurotoxicity,

which may result in tingling or numbness in the extremities and in severe cases may cause footdrop from muscle weakness.

Less common complications include renal toxicities, such as pain and burning on urination, and hematuria. Doxorubicin (Adriamycin) has been associated with permanent heart damage, and bleomycin can cause pulmonary fibrosis.

Severe toxic side effects can be controlled by carefully limiting the amount of medication given and constantly monitoring the patient for complications.

New Treatments Being Researched

Laetrile is a medication made from the pits of peaches or apricots. The main ingredient of this medication is cyanide. The drug is given with very strict dietary guidelines, and conditions are very difficult for the patient to manage.

Hyperthermia has been used with radiation and chemotherapy. It has been beneficial in some types of cancer but is seldom used except in investigational studies.

Biologic response modifiers (such as interferons) are drugs used to stimulate the immune system. These drugs are used commonly for specific types of cancer and have produced some beneficial results. They are also being used in many investigational studies.

► NURSING PROCESS FOR THE PATIENT WITH CANCER

Assessment

Patients are assessed for many different problems associated with cancer and its treatment (Nursing Care Plan Box 10–6). Assessment of patient knowledge concerning the disease, treatment, and expected outcomes helps you provide adequate information about patient rights and responsibilities. See Box 10–7 for the cancer survivor's bill of rights.

Assess home safety management and coping skills of the patient and family. Determine patient and caregiver strengths and weaknesses related to therapeutic care.

Assess for side effects of chemotherapy or radiation, as described earlier. Infection and septicemia can occur quickly, especially when the patient's white blood cell count is low. Monitor body temperature frequently to detect infection. Examine the patient daily for signs of inflammation or purulent drainage at potential infection sites, such as old aspirate sites, old and new venipuncture sites, mouth and rectal mucosa, perineal area, axilla, incisions, earlobes if ears are pierced, under breasts, and between toes. Monitor the patient for signs of respiratory infection, such as a sore throat, cough, shortness of breath, and purulent sputum. Signs of urinary infection include burning, pain, urgency, frequency, and presence of blood or pus in the urine.

Bleeding can occur when the platelet count is low. Report bleeding gums, easy bruising, tarry stools, and bloody urine to the physician immediately.

Monitor the patient's weight, and note complaints of nausea, vomiting, and diarrhea related to either the disease or treatment. Patients with cancer are at risk for dehydration and wasting syndrome. Pain may also keep the patient from eating.

thrombocytopenia: thrombo—clot + cyte—cell + penia—lack

anemia: an—not + emia—blood

stomatitis: stoma—mouth + itis—inflammation

BOX 10-6 NURSING CARE PLAN FOR THE PATIENT WITH CANCER**Risk for ineffective coping related to the diagnosis and treatment of cancer as evidenced by behaviors such as denial, isolation, anxiety, and depression****OUTCOMES**

Patient will cope effectively as evidenced by identifying stressors related to illness and treatment; communicating needs, concerns, and fears; and use of appropriate resources to support coping.

EVALUATION OF OUTCOMES

Is patient able to identify stressors and communicate concerns? Does patient have and appropriately use support systems?

INTERVENTIONS

Assess effective coping mechanisms used in the past and currently available to the patient.

Use active listening skills to encourage the patient to express feelings and fears.

Assess the meaning of quality of life to the patient.

Assess for suicide risks.

Explore outlets that promote feelings of personal achievement.

Promote the use of humor.

RATIONALE

Coping mechanisms that worked in the past may be helpful again, and the nurse can support appropriate choices.

The patient must identify fears to be able to cope effectively with them.

Once identified, the nurse can assist the patient to achieve quality-of-life goals.

A patient who feels hopeless may be at risk for suicide.

Personal achievement promotes self-esteem.

Humor can be distracting and therapeutic.

EVALUATION

Is the patient able to identify and draw on past coping mechanisms?

Does the patient identify fears and concerns?

Is the patient able to identify the meaning of quality of life? Are there ways the nurse can assist the patient to reach quality-of-life goals? Is the patient at risk? Are suicide precautions necessary?

Does the patient have creative outlets that promote feelings of achievement? Can the nurse assist in implementing these activities? Does the patient use humor? Does it provide temporary distraction from concerns?

Pain related to tissue injury from tumor invasion or surgical intervention**OUTCOME**

Patient will be pain free as evidenced by patient statement of comfort on pain scale.

EVALUATION OF OUTCOME

Does patient state pain is controlled?

INTERVENTIONS

Ask patient to rate pain on a scale from 0 to 10 (0 = absence of pain; 10 = worst pain).

Educate patient on use of patient-controlled analgesic (PCA).

Monitor pain relief every 2 to 4 hours.

Explain and encourage use of relaxation techniques and other complementary techniques.

RATIONALE

A complete pain assessment should be done before and after any interventions for pain.

PCA allows the patient to be in control of own pain relief.

Alternative medications may be necessary for breakthrough pain.

Relaxation techniques can reduce pain intensity by reducing skeletal muscle tension.

EVALUATION

Does patient use pain assessment scale effectively? Is patient in pain?

Does PCA keep patient pain free and able to participate in desired activities? Is PCA or epidural analgesic effective?

Does patient use relaxation techniques effectively?

The patient's pain may be slight to severe, with both physical and emotional components. Pain assessment includes location, onset, intensity, pattern, duration, mental state, and known relief measures. This may be accomplished with the WHAT'S UP? format presented in Table 1-2. Assessment of intensity is best done by using a pain scale, such as a 0 to 10 scale with 0 indicating no pain and 10 indicating the worst pain imaginable. The patient's perceptions about pain management and the impact of pain on performance of activities of daily living are also assessed.

LEARNING TIPS

When assessing patients with possible side effects of chemotherapy and radiation, use the mnemonic BITES:

B—Bleeding suggests low platelet count.

I—Infection suggests low WBC count and a risk for septicemia.

T—Tiredness suggests anemia.

E—Emesis places the patient at risk for altered nutrition and fluid and electrolyte imbalance.

S—Skin changes may be evidence of radiation reaction or skin breakdown.

- Risk for infection related to diminished immunity and bone marrow suppression as a result of chemotherapy or radiation
- Risk for injury related to bleeding tendencies associated with chemotherapy and radiation
- Nutrition, imbalanced: less than body requirements related to anorexia, nausea, or vomiting associated with disease, pain, and treatment
- Deficient self-care related to weakness and fatigue
- Anticipatory grieving related to potential disease outcome
- Caregiver role strain related to patient care and anticipated outcome
- Social isolation related to changing relationships
- Ineffective sexuality pattern related to change in body functions
- Disturbed body image related to surgical procedures such as an ostomy or loss of hair associated with chemotherapy.

Planning and Implementation

Short- and long-term goals must be set and mutually agreed upon by the nurse and the patient. You must advocate for active patient participation in the manner that the patient requires. Short-term goals are centered around control of pain and side effects of therapy. Long-term goals are determined by the patient's lifestyle, quality of life, and outcome of therapy.

Pain

Pain intervention involves a multidimensional nursing approach. Cancer pain is associated with (1) surgical interventions, postoperative recovery, and painful medical or nursing procedures; (2) pressure from a large tumor mass on nerves and blood vessels; (3) psychological depression and anxiety about mortality; and (4) cultural views and perceptions concerning the cancer process.

Pain affects quality of life for the patient with cancer. Chronic pain places the patient at risk for depression, hopelessness, delirium, loss of control, exhaustion, and suicide. Patients need reassurance that measures will be taken to control their pain and that they will not become addicted to pain medication (Ethical Consideration Box 10–8).

Obstacles to effective pain management include a lack of understanding about pain, inadequate pain assessment, ineffective treatment with analgesics, and fears of addiction, sedation, and respiratory depression.

Cancer pain is treated first with analgesics. The goal is effective prevention of pain, rather than treatment of pain once it occurs. Use of medications for pain is discussed in Chapter 9.

Procedures such as administration of anesthetics or nerve blocks are used for intractable pain. Nursing responsibilities associated with these procedures include teaching the patient why and how the procedure will be done, potential complications, and expected benefits from the procedure.

Noninvasive therapies may be used in addition to pain medication to increase the patient's control over the pain.

Nursing Diagnosis

Individual diagnoses must be determined based on specific patient assessment. Possible nursing diagnoses include the following:

- Chronic pain related to disease process and cancer treatment

BOX 10-8 ETHICAL CONSIDERATION**Pain Medications for the Patient with Cancer**

Ms. Parker, LPN, returned to work on the oncology unit after a 2-week vacation. During report, she could hear moans of pain emanating from the room of Mr. Stipe, a 32-year-old male suffering from metastatic bone cancer. She had liked Mr. Stipe when he was admitted for diagnosis and initial treatment several months ago, and now he was back to die. The metastatic growths in his spine were causing intolerable pain, while the metastatic growths in his liver were threatening death.

The goal the oncology team had established for Mr. Stipe was to keep him as pain free as possible, and correspondingly large doses of morphine sulfate had been ordered both by continuous drip and PCA pump boosters. In reviewing Mr. Stipe's chart for the last shift, Ms. Parker noted that he had received 800 mg by drip with 20 mg boosters every hour. She became very concerned that this much morphine would cause respiratory depression and arrest.

The head nurse verified the dose with Ms. Parker and also explained that Mr. Stipe had a very high tolerance to the medication due to his severe pain and long-term use of the medication for pain control. When Mr. Stipe screamed in pain again, the head nurse instructed Ms. Parker to give another 20 mg booster. "Our goal is to keep him comfortable," she said, "and the only way to do that is to give him his medication." Ms. Parker agreed that the pain must be relieved, but she felt very uncomfortable giving more medication on top of the medication he had already been given. What if he went into respiratory arrest after the next dose of medication? Would Ms. Parker be responsible for his death? What effect does the patient's dying status have on the ethical obligation to provide pain medication? What should a nurse do when the treatment ordered for the patient has the potential to compromise personal values and conscience?

These may include (1) cutaneous stimulation, which eliminates or decreases pain by using massage and vibration, heat and cold, and menthol application; (2) distraction, such as music therapy or coping statements; (3) relaxation through deep breathing exercises and humor therapy; (4) imagery; and (5) comfort measures, such as good body positioning, a comfortable mattress and pillows, and so on.

Risk for Infection

Leukopenia occurs when the WBC count is decreased to 2000 (normal range is 5000 to 10,000/mm³), increasing the patient's risk for infection. Patients with leukopenia must be protected against sources of infection, such as people with transmissible illnesses; bird, cat, or dog feces; stagnant water in flower vases, denture cups, irrigating containers, respiratory equipment, or soap dishes; and fruit peelings.

Report signs and symptoms of infection to a physician immediately. Antibiotics and analgesics are administered as ordered. The patient is advised to avoid intercourse while the WBC count is low to prevent secondary infection.

Risk for Injury Related to Bleeding

Thrombocytopenia increases the risk for bleeding or hemorrhage. The normal platelet level is 150,000 to

300,000/mm³. Potential for bleeding exists when the platelet count is 50,000; risk for spontaneous bleeding occurs when the count is less than 20,000. Bleeding precautions are necessary when the platelet count falls below 50,000.

Bleeding precautions include monitoring platelet counts daily and observing for signs of bleeding such as bruising, petechiae, bleeding gums, tarry stools, and black emesis. Intramuscular and subcutaneous injections are avoided to prevent bleeding into the injection site. Safety measures are instituted to prevent cuts, bruises, and falls. The patient is advised to use an electric razor, avoid blowing the nose, and avoid intercourse to prevent bleeding for the duration of the thrombocytopenia.

Imbalanced Nutrition

Patients are instructed about the importance of maintaining proper nutrition. Nutrition Notes Box 10-9 presents criteria for determining whether a patient needs nutritional support. Consult with a dietitian and physician for dietary supplements and medications used to control nausea, vomiting, and diarrhea. Keep the environment free of odors that might induce nausea, such as strong disinfectants, perfumes, deodorizers, and body wastes. Monitor intake and output every 8 hours, and weigh the patient daily.

BOX 10-9**Nutrition Notes****Assessing the Need for Nutritional Support**

Any two of the following findings indicate a need for nutritional support:

- Weight loss of 10% or more of body weight
- Serum albumin less than 3.4 g/dL
- Serum transferrin less than 190 mg/dL

Source: *Daly, HM, and Shinkwin, M: Nutrition and the cancer patient. In Holleb, AI, Fink, DJ, and Murphy, GP (eds): American Cancer Society Textbook of Clinical Oncology. American Cancer Society, Atlanta, 1991.*

Room-temperature foods or cold foods and clear liquids may help reduce vomiting. Sour foods such as hard candy, lemon, and pickles might be helpful. Music or relaxation exercises may help distract the patient from the nausea. Adding nutmeg to foods may help slow down motility of the gastrointestinal tract. Provide mouth care before meals to make eating more pleasant. Small, high-calorie meals are better tolerated than large meals. Administer pain medication before meals to help reduce the impact of pain on the appetite. Instruct the patient to avoid fluids with meals to prevent premature feelings of fullness and to avoid exercise before meals to prevent fatigue. See Nutrition Notes Box 10-10 for additional nutrition interventions.

Self-Care Deficit

Psychosocial issues related to cancer are as varied as the persons afflicted with the disease. You can help the patient ex-

BOX 10-10

Nutrition Notes

Treating Problems Related to Nutrition

Try these ideas if a cancer patient has early satiety or anorexia, a bitter or metallic taste, local oral effects, nausea and vomiting, diarrhea, or an altered immune response.

Early Satiety and Anorexia

- Select nutrient-dense foods. For example, fortify puddings and milkshakes with dry skim milk powder.
- Encourage appropriate exercise.
- Present food attractively.
- Remove covers from food containers away from the bedside if strong odors annoy the patient.
- Offer small, frequent meals.
- Provide home-cooked food.
- If meals are rejected, offer 1 oz of a complete nutritional supplement every hour.

Bitter or Metallic Taste

- Cook in glass containers in a microwave oven.
- Serve food cold or at room temperature.
- See if the patient prefers eggs, fish, poultry, and dairy products to beef and pork.
- Experiment with sauces and seasonings. Sweet sauces and marinades may improve the palatability of meats.

Local Oral Effects

- Ulcerations—Offer soft, mild foods; cream sauces, gravies, and dressings for lubrication; cold foods for numbing; and soda straws for liquids. Topical vitamin E oil may be effective for chemotherapy-induced lesions. Avoid hot items, salty or spicy foods, and acidic juices. If an anesthetic mouthwash is prescribed, caution the patient to chew carefully to avoid biting the lips, tongue, or cheeks.
- Dry mouth—Offer frequent sips of water or an artificial saliva. Lubricate with gravies, butter, margarine, milk, cream, or bouillon. Sugarless hard candy, chewing gum, or popsicles may stimulate saliva production.

- Dysphagia—Teach the patient to make swallowing a conscious act (inhale, swallow, exhale) and to experiment with head position. Offer foods with a smooth, even consistency. Thick liquids are easier to swallow than thin. Encourage dunking breads in a beverage to soften.

Nausea and Vomiting

- Administer antiemetics on a regular prophylactic schedule.
- Suggest dry crackers.
- Offer liquids between meals to reduce stomach volume and low-fat meals to facilitate stomach emptying.
- Instruct the patient to chew thoroughly, eat slowly, and rest afterward.
- Arrange unconventional meal schedule to take advantage times when patient feels better.
- Avoid serving favorite foods when the patient is nauseous to avoid an association between those foods and vomiting.

Diarrhea

- Suggest a low-residue diet. (Citrolean and Enlive are clear liquid complete nutritional supplements.)
- Try a lactose-free diet for temporary lactose intolerance.
- Propose pectin-containing foods (apples, strawberries, citrus fruits) to absorb water in the bowel.
- Recommend active cultures of yogurt to repopulate intestine.

Altered Immune Response

- Restrict fresh fruits and vegetables that cannot be peeled or adequately disinfected.
- Consider avoiding yogurt to prevent translocation of the bacteria to the bloodstream.

plore perceptions about quality of life. Help the patient rank quality-of-life issues based on an understanding of the disease process, treatment, and specific limitations. Culture and age affect cancer perceptions (e.g., in a culture in which life expectancy is short, possible death from cancer in the later years is not a significant threat).

It is helpful for patients with cancer to anticipate a time when they will no longer be able to care for their own needs. You can assist patients to determine resources that can be called on at that time. If patients live with family members, the family can be instructed in how to assist in daily care. Home health nurses and hospice care can also be invaluable.

Anticipatory Grieving

To many people, cancer is synonymous with death. Although some cancers are very aggressive and death occurs quickly after diagnosis, many cancers are controllable and allow years of living after diagnosis and treatment. Make sure that the patient has received accurate information about the prognosis, but never give false hope. Use thera-

peutic communication techniques to help the patient talk about an anticipated death. Encourage family members to spend time with the patient. Contact the patient's minister or clergy if the patient agrees.

Risk for Caregiver Role Strain

The emotional issues of the disease can be devastating for patients, family members, and other support persons. Income is lost and lifestyles are changed when the disease affects wage-earning members of the family. When a patient's caregiver works outside the home, the stress of dual responsibility takes its toll. Family growth needs are often replaced with meeting basic survival needs such as providing food, clothing, and shelter. This can create many guilt feelings for both the patient and family. You can help by providing information about local community resources.

Role changes are sometimes needed and may be difficult for family members to make. If the dominant person is the patient, the less dominant partner may have to assume new responsibilities that contribute to stress. Your ability to actively listen to family members' concerns is important.

Social Isolation

Isolation can be either self-imposed or imposed by friends and family as terminal illness issues are confronted. It can be very frustrating to see a loved one decline with cancer; often people say they are “afraid of saying or doing the wrong thing” so they “just stay away.” Patients may engage in self-blame, and their anger may lead to depression and further isolation. It is important to recognize signs of depression and suicidal tendencies.

Ineffective Sexuality Patterns

Maintaining healthy sexuality is important to all patients, including those with cancer. Individual sexual attitudes and practices vary, making it difficult to define what is “normal.” Normal can be best described as what the patient and partner consider pleasurable.

A decline in sexual desire is not uncommon during cancer treatment. Anxiety about sexual intercourse includes fears concerning contracting cancer from the patient and fears that sexual intercourse will make the cancer worse.

It is important to stress that cancer is not contagious. It cannot be passed from person to person, even through contact as close as kissing, intercourse, or oral and genital sex. Sexual activity is usually safe during and after cancer treatment. Patients who are advised to abstain from sexual intercourse because of low blood counts are temporarily at risk for secondary infections and bleeding until blood counts return to normal. They do not put their partners at risk. Closeness and intimacy are often desired even if sexual intercourse is not.

Pain is the most common problem for both male and female patients during intercourse. Pain is associated with pelvic surgery, radiation therapy, or treatment that affects hormone levels, and pain can prevent the male patient from achieving an erection. Most obstacles can be overcome if the couple are open and honest about their feelings. Be prepared to address sexuality issues in a timely fashion.

Disturbed Body Image

The loss of any body part can be traumatic to a person’s self-image. You can provide information about plastic surgery and prosthetics and help the patient through the grieving process related to the loss.

Cancer treatment is costly, and financial aid may be needed. Provide information about community assistance programs or services. Social service personnel are available in most health care facilities.

Evaluation

If interventions have been effective, the patient can describe known facts about the disease and the prescribed treatment plan. The patient verbalizes relief or a reduction in pain intensity. Pain management should provide the patient with periods of rest and an ability to appropriately focus on living. The patient or family demonstrates knowledge of risk factors associated with bleeding and infection. The patient remains infection free and maintains intact

skin as evidenced by an absence of reddened or ulcerated areas. The patient has no signs of bleeding or anemia. The patient maintains optimal nutritional status, as reflected by caloric intake adequate to meet body requirements, balanced intake and output, absence of nausea and vomiting, and good skin turgor. The patient feels free to share feelings about his or her disease and coping abilities and achieves or maintains control of his or her body.

 **CRITICAL THINKING**

Mrs. Jones
Mrs. Jones is admitted to your unit following a simple mastectomy for breast cancer. The tumor was staged as a T2, N0, M0. Estrogen and progesterone receptors were negative. A bone scan was negative for metastasis. She is scheduled for four chemotherapy treatments, 3 weeks apart. The medications prescribed are high doses of doxorubicin and cyclophosphamide (Cytoxan). A central line is inserted for chemotherapy.

1. What does the staging of Mrs. Jones’s tumor mean?
2. What major side effects of her medications should you observe for?
3. Why was a central line inserted?
4. What nursing diagnoses are appropriate for Mrs. Jones?

Answers at end of chapter.

▶ HOSPICE CARE OF THE PATIENT WITH CANCER

Patients who are considered terminal and have a life expectancy of 6 months or less are eligible for hospice care, which provides humanistic care for dying people and their families. The dying person is provided care in a home or homelike setting that promotes comfort and quality of life until death. Hospice care is offered as an inpatient or outpatient service (see Home Health Hints).

HOME HEALTH HINTS

- The home health or hospice nurse helps manage cancer pain in the home. Intramuscular dosing of pain medication should be avoided because of pain associated with injections and the burden this places on the caregiver. Oral or intravenous analgesics are preferred. For moderate to severe pain, medication dosing should be around-the-clock with prn doses for breakthrough pain. The nurse should anticipate constipation from opioid administration and treat prophylactically.
- Home health nurses are in key positions for making timely referrals for hospice care. Eligible clients are those who have a life expectancy of 6 months or less, have a desire for supportive care rather than continued treatments, and have a friend or relative who is willing to coordinate the care.

Inpatient services are used for symptom control and respite care for the family. Family and pets are allowed to stay with the patient. Hospice care deals with the family in crisis and continues after the patient dies, with follow-up counseling, listening, nurturing, and referral.

Outpatient care is given in the home with family members providing the primary care. Support care is given by the hospice staff. Medications and supplies are furnished by the hospice service. At home, the patient can enjoy loved ones, pets, plants, music, and other personal possessions for as long as possible.

▶ ONCOLOGICAL EMERGENCIES

Superior Vena Cava Syndrome

Superior vena cava syndrome occurs in patients with lung cancer when the tumor or enlarged lymph nodes block the circulation in the vena cava. This results in edema of the head and neck and may lead to seizures. Radiation therapy can be used to shrink the tumor and allow for circulation to resume naturally.

Spinal Cord Compression

Spinal cord compression may develop in patients with bone metastasis when the bones collapse. This is a very painful problem and requires pain management while radiation is given to relieve the symptoms. Patients may develop some motor loss when this occurs. Often a myelogram or bone scan is used for diagnosis.

Hypercalcemia

Hypercalcemia occurs when the serum calcium level exceeds 11 mg/dL. In patients with cancer, hypercalcemia is associated with the release of calcium into the blood from bone deterioration. It is common in patients with bone metastasis, especially metastasis from breast cancer. It can be treated with intravenous medication to lower the calcium levels.

Pericardial Effusion/Cardiac Tamponade

Pericardial effusion, or cardiac tamponade, is a condition usually caused by direct invasion of the cancer, causing the pericardial sac to fill with fluid. Treatment involves draining the fluid from the heart sac by pericardiocentesis and using sclerosing agents to keep the pericardial sac from refilling with fluid.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) involves an abnormal activation of the clot formation and fibrin mechanisms of the blood, resulting in the consumption of coagulation factors and platelets. Patients with DIC are at high risk for thrombus formation, infarctions, and bleeding. Treatment includes fresh frozen plasma and cryoprecipitates with heparin.

- 
- Which of the following is the hereditary material of cells?
 - Protein in the ribosomes
 - DNA in the chromosomes
 - RNA in the nucleus
 - Ribosomes in the cytoplasm
 - Mr. Michaels, age 56, has been recently diagnosed with prostate cancer. He asks you, "How do malignant tumors differ from benign tumors?" Which of the following is the most accurate statement?
 - Malignant tumors invade surrounding cells.
 - Malignant tumors are encapsulated.
 - Malignant tumors remain localized.
 - Malignant tumors always require surgical intervention.
 - A patient asks the meaning of alopecia. Which of the following is the most appropriate response?
 - Itching of skin
 - Frequent bowel movements
 - Blood vessel constriction
 - Hair loss
 - Why is the cell cycle important in chemotherapy?
 - Dividing cells tend to be more vulnerable to chemotherapy.
 - Chemotherapeutic agents act on only the last phase of the cell cycle.
 - Chemotherapeutic agents are unable to destroy all cancer cells.
 - Most normal cells are not affected by chemotherapeutic agents.
 - Mr. West is receiving radiation therapy and notes that the skin over the treated area is slightly reddened. What is the best care for this area?
 - Applying moist normal saline compresses
 - Lubricating the skin with water-soluble lubricant
 - Keeping the skin clean and protected from the sun
 - Applying a heat lamp to the area two times a day
 - Mr. Waist, age 70, admitted for diagnostic tests to confirm cancer of the colon, is restless and uncomfortable. He states that he will need a pain pill soon. Which of the following nursing actions is best before administering pain medication?
 - Assess the patient's anxiety level.
 - Assess the patient's understanding of the side effects of pain medication.
 - Determine the patient's pain tolerance.
 - Assess the success of past pain management measures.

Answers to CRITICAL THINKING**Mrs. Jones**

1. Mrs. Jones's tumor is beginning to invade surrounding tissue. There is no lymph node involvement and no metastasis.
2. Doxorubicin is commonly associated with red urine. Cyclophosphamide can cause blood in the urine. Both medications can cause nausea, vomiting, and alopecia. Both are vesicants.
3. Because the drugs are vesicants, it is important to inject them into a large vein.
4. Many diagnoses are appropriate, including acute pain related to surgical incision, disturbed body image related to alopecia and loss of a breast, imbalanced nutrition related to nausea and vomiting, risk for injury related to medication side effects, and deficient knowledge about cancer treatment and management of side effects.

QUESTIONS TO GUIDE YOUR READING

1. How would you describe the three phases of perioperative nursing?
2. What is your role in each perioperative phase?
3. What are six factors influencing surgical outcomes?
4. What is the purpose of preoperative patient data collection?
5. How would you enhance learning for the elderly preoperative patient?
6. What are some nursing interventions for common postoperative patient needs?
7. How will you know if your nursing interventions have been effective?
8. What are signs and symptoms of common postoperative complications?
9. What are the criteria for ambulatory discharge?
10. How would you help reinforce patient discharge instructions?
11. What is the postoperative role of the home health nurse?

Surgery is the use of instruments during an operation to treat injuries, diseases, and deformities. Physicians perform surgical procedures, including **surgeons**, family practice physicians, or other physicians trained to do certain surgical procedures. Surgery is performed in clinics, physicians' offices, ambulatory surgical centers, and hospitals. Laser and scope technology continues to lead to new procedures that offer less risk, less invasion, faster recovery,

and reduced hospitalization or ambulatory surgery. Today surgery is a safe, effective treatment option because of medications such as antibiotics and anesthetics that allow a quicker recovery.

► SURGERY CATEGORIES

Surgical procedures are named according to the involved body organ, part, or location and are given a suffix that describes what is done during the procedure (Table 11–1). The urgency levels to have a successful outcome for the patient determine the scheduling time frame for a surgery (Table 11–2). The various indications for surgery are listed in Table 11–2.

The author acknowledges the contributions to this chapter by Linda Nabozny and Deanna Casler.

TABLE 11-1 SURGICAL PROCEDURE SUFFIXES

Suffix	Meaning	Word-Building Examples
-ectomy	Removal by cutting	crani (skull) + ectomy = craniectomy appen (appendix) + ectomy = appendectomy
-orrhaphy	Suture of or repair	colo (colon) + orrhaphy = colorrhaphy herni (hernia) + orrhaphy = herniorrhaphy
-oscopy	Looking into	colon (intestine) + oscopy = colonoscopy gastr (stomach) + oscopy = gastroscopy
-ostomy	Formation of a permanent artificial opening	ureter + ostomy = ureterostomy colo (colon) + ostomy = colostomy
-otomy	Incision or cutting into	oust (bone) + otomy = osteotomy thoro (thorax) + otomy = thoracotomy
-plasty	Formation or repair	oto (ear) + plasty = otoplasty mamm (breast) + plasty = mammoplasty

TABLE 11-2 SURGERY CATEGORIES

Urgency Level		
Type	Definition	Examples
Emergent	Immediate surgery needed to save life or limb.	Ruptured aortic aneurysm or appendix, traumatic limb amputation, loss of extremity pulse from emboli
Urgent	Surgery needed within 24–30 hours.	Fracture repair, infected gallbladder
Elective	Planned/scheduled, with no time requirements	Joint replacement, hernia repair, skin lesion removal
Indications		
Aesthetic	Requested by patient for improvement	Blepharoplasty, breast augmentation
Diagnostic	To obtain tissue samples, make an incision, or use a scope to make a diagnosis	Biopsy
Exploratory	Confirmation or measurement of extent of condition	Exploratory laparotomy
Preventive	Removal of tissue before it causes a problem	Mole or polyp removal
Curative	Removal of diseased or abnormal tissue	Inflamed appendix, tumor, benign cyst
Reconstructive	Correction of defects of body parts	Scar repair, total knee replacement
Palliative	Alleviation of symptoms without curing disease	Rhizotomy (cuts nerve root to relieve pain), partial tumor removal to relieve pain or pressure, gastrostomy tube for swallowing problem

► PERIOPERATIVE PHASES

There are three phases in the surgical process: **preoperative**, **intraoperative**, and **postoperative**. They are referred to collectively as **perioperative**, which is the time surrounding and during surgery. Each of the perioperative surgical phases has a defined time frame in which specific events related to surgery occur (Table 11-3). Throughout each phase, nurses interact closely with the patient, physician, and other members of the health care team.

TABLE 11-3 PERIOPERATIVE SURGICAL PHASES

Perioperative	All three phases surrounding and during surgery
Preoperative	Begins with decision for surgery and ends with transfer to the operating room
Intraoperative	Begins with transfer to operating room and ends with admission to postanesthesia care unit (PACU)
Postoperative	Begins with admission to PACU and continues until recovery is complete

► PREOPERATIVE PHASE

Your primary roles in the preoperative phase are to:

- assist in data collection for developing the patient’s plan of care.
- reinforce explanations and instructions given to the patient and family by the physician and registered nurse.
- provide emotional and psychological support for patients and their families.

Studies show that a patient’s family experiences anxiety during the surgical procedure even if the patient’s surgery is elective and of short duration. You can make a major contribution by reducing the family’s anxiety. If families are less anxious, they are more helpful in assisting patients as they recover.

Other health team members assist in preparing the patient for surgery. The physician obtains a medical history, performs a physical examination, and orders diagnostic testing. Registered nurses perform a baseline preoperative assessment, provide explanations and instructions, offer patients and families emotional and psychological support to ease anxiety, develop a plan of care, and then verify the pa-

tient's name, surgical site, allergies, and related information when the patient arrives in the surgical waiting area.

Factors Influencing Surgical Outcomes

When preparing a patient for surgery and developing a nursing care plan, the goal is to identify and implement actions that reduce surgical risk factors. Preoperative care focuses on helping the patient achieve the best possible surgical outcome by being in the healthiest possible condition for surgery.

Emotional Responses

The word *surgery* causes a common emotional reaction in patients and their families. You need to be aware of these reactions to assist the patient in coping with them. If any of the patient's fears are extreme, such as a fear of dying or not waking after surgery, the physician should be informed.

Surgical patients may experience various fears related to **anesthesia**: possible brain damage; feeling sensation during surgery; feeling loss of control; a fear of not waking up. The patient should discuss these concerns with the **anesthesiologist**. Listening to music or using guided imagery before surgery may help reduce patients' anxiety and calm them.

A concern of being in pain is normal among surgical patients. Patients are informed about pain control methods. During the operation, the anesthesia provider uses medications to control pain. Analgesics are given for pain relief after surgery. Complementary techniques can also be used to help reduce pain, such as guided imagery or focused breathing.

Changes in body image may be a great fear for some patients. The thought of disfigurement, mutilation, bleeding, or having a scar causes great anxiety for some patients.

Age

Surgery can be a positive experience that promotes quality of life for many elderly patients. For healthy older patients, age alone does not mean that they are a greater surgical risk. Complications can occur, however, related to previous health status, immobilization occurring from surgery, normal aging changes reducing the effectiveness of deep breathing and coughing, and the effects of administered medications (Gerontological Issues Box 11–1). Older patients may require a longer time to recover from anesthetic agents because of aging changes in drug metabolism and elimination. To reduce complications the elderly patient's health problems need to be controlled before surgery.

BOX 11-1 GERONTOLOGICAL ISSUES

Surgical Considerations for the Older Adult

Older adults usually have limited physiological reserve, resulting in decreased ability to compensate for changes that occur during surgery. There is increased risk for hemorrhage, anemia, fluid/electrolyte imbalance, and infection. Increased risk for complications is secondary to age-related loss of blood vessel elasticity and decreased cardiac, respiratory, and renal reserves. Nursing interventions should be aimed at these age-related changes before, during, and after the surgical procedure to help reduce complications.

Preoperatively:

- Reassure the patient and family.
- Pad bony prominences to protect against pressure ulcers and muscle and bone discomfort.
- Teach what to expect before, during, and after surgery, diet changes, description and length of surgical procedure, activities in the recovery room, pain management, coughing and deep breathing exercises, procedures, and treatments (e.g., dressings, catheters).
- Ensure preoperative screening: blood work, radiographic studies, nutritional assessments, pulmonary function tests, electrocardiogram.

Intraoperatively:

- Assess patient for hypothermia (cool temperature in operating room, medications that slow metabolism).
- Assess patient for hypoxia (older adult may exhibit restlessness).
- Assess patient for hemorrhage.
- Assess patient's output (urine, drainage, bleeding, vomitus).

Postoperatively:

Pain Control—Provide adequate pain relief so required postoperative activities, such as deep breathing, coughing, position changes, and exercise, can be performed more effectively.

Respiratory Function—Reduce respiratory complications by encouraging deep breathing and coughing:

- Do deep breathing and coughing after pain medication has begun to take effect because this will increase the older patient's ability to take deeper breaths. Assess the patient carefully when giving narcotic analgesics because they may cause respiratory depression.
- Use a pillow and instruct the patient to hold it firmly over abdominal or chest incisions to support the incision. Taking a deep breath increases chest expansion, as well as abdominal pressure, which may pull or stretch an incision.
- Elderly patients perform deep breathing and coughing exercises better if the nurse performs the exercises with them. For example, say the following:
“Let's take a deep breath in through the nose, hold it and count to three, then slowly blow it out completely through the mouth. When you blow the air out, shape your lips like they are going to whistle. Great, let's do it again.”

Mobility—Encourage mobility through the following nursing actions and observations:

- Use pillows to support the patient's body alignment; assist the patient to ambulate as soon as possible after surgery; and regularly help the patient with passive or active range-of-motion exercises, along with flexion and extension exercises, for legs and feet.
- Deep vein thrombosis is a risk related to venous pooling in the lower extremities. This risk is increased with postoperative inactivity.
- If patients lay in one position too long, pressure ulcers can develop. When tissues are compressed between bones and the bed surface, blood supply is reduced to the tissue and cells begin to die. This results in painful open wounds.

BOX 11-1 GERONTOLOGICAL ISSUES—CONT'D

Bowel Function—Assess bowel sounds. It is common for patients to feel bloated after surgery. Increasing activity, such as walking—not just sitting in a chair—stimulates peristaltic action of the bowel. This helps expel flatus and reduce discomfort.

Urinary Function—Be aware of the following aspects of urinary function:

- It is common for individuals to have difficulty emptying their bladder after surgery. Patients who are sleeping but restless should be evaluated for bladder distention. It is often difficult to void on a bed pan or in a urinal in a supine position.
- Older men with an enlarged prostate may have even greater difficulty voiding if they have received medications that have urinary retention side effects.
- Assisting patients to sit or stand to use urinals, use a bedside commode, or ambulate to the bathroom promotes

bladder emptying and helps avoid the use of urinary catheters.

- Measure urine output that is voided or from a catheter. Note the color and odor of the urine. The elderly are prone to dehydration, and this provides an indication of their hydration status for intervention.

Delirium—Perform the following nursing actions to minimize delirium:

- Monitor level of consciousness routinely. Provide a calm environment and orient the patient to their environment. Restraints should not be used because they can worsen delirium.
- Recognize that urinary catheter presence can contribute to delirium, so methods to avoid the need for a catheter should be tried.

Hydration and Nutrition

A normal fluid and electrolyte balance decreases complications. Patients should be well nourished to adequately heal and recover from surgery. Higher levels of protein (tissue repair and healing), vitamin C (collagen formation), and zinc (tissue growth, skin integrity, and cell-mediated immunity) are required. Obese or underweight patients may not heal as well and may have complications. Obese patients have more respiratory problems and wound healing difficulties, such as delayed healing and wound dehiscence (opening of the incision). Emaciated individuals may have more infections and delayed wound healing because they lack the nutrients needed for tissue healing. Identifying patients at risk and providing preoperative intervention reduce the risks of surgery for these patients (Nutrition Notes Box 11–2).

Smoking and Alcohol

The use of tobacco and alcohol increases the surgical patient's risks. Smoking thickens and increases the amount of lung secretions and reduces the action of cilia that remove the secretions. Patients should be encouraged to avoid smoking for 24 hours before surgery. A patient who smokes and has a chronic lung disorder should be encouraged to stop smoking 3 to 4 weeks before surgery. Cessation of smoking allows an increase in the action of the lungs' defense mechanisms and makes more hemoglobin available to carry oxygen during surgery.

Long-term alcohol use may cause nutritional deficiencies and liver damage, which can create bleeding problems, fluid volume imbalances, and drug metabolism alterations. In addition, alcohol interacts with medications and should be avoided before surgery.

Diseases

Chronic disorders may increase the patient's surgical risk unless they are well controlled. A preoperative assessment and clearance for surgery by the patient's physician may be needed. For diabetics, the stress of surgery can alter blood

BOX 11-2*Nutrition Notes*

Screening and Nourishing the Preoperative Patient

In a recent study, preoperative protein energy malnutrition was identified in 38% of patients undergoing abdominal surgery for benign conditions. Of these malnourished patients, 75% developed postoperative complications, compared with 22% of well-nourished patients. Mild to severe malnutrition affected 39% of patients undergoing gastrointestinal or orthopedic surgical procedures, but only about two-thirds of them received nutritional support in another study. History of a gain or loss of 10 pounds within the past 6 months should trigger a nutritional assessment; however, just 59% of the patients in this study even had a weight recorded on their chart.

Before elective surgery, the patient may have time to correct some nutritional deficiencies. Many patients are instructed to lose weight to reduce the risk of surgery. If they are anemic, an iron preparation can be administered. At least 2 to 3 weeks are required for objective evidence of the effectiveness of nutritional therapy. In patients identified as high risk, 7 days of preoperative total parenteral nutrition (TPN) produced a sixfold reduction in major sepsis. Before surgery on the gastrointestinal tract, a low-residue diet may be given for 2 to 3 days to minimize the feces in the bowel.

Many botanical products sold in the United States over the counter as nutritional supplements profoundly affect body systems during surgery. So many people are taking botanical products that the American Society of Anesthesiologists issued a warning to consumers of herbal medicine to stop taking the products 2 to 3 weeks before scheduled surgery. Possible interactions cited were an unintended deepening of anesthesia and problems with bleeding and blood pressure. In addition to inquiring about weight loss, the preoperative assessment should include questions about herbal or traditional medicines. Many patients do not regard these products as medicines or are reluctant to tell their doctors that they are using them. For more information about the American Society of Anesthesiologists' warning, visit the public education section of www.asahq.org.

glucose levels. Patients with chronic lung disorders may have pulmonary complications from anesthesia. To prepare patients with lung disorders for surgery, teach them to deep breathe and cough and to use an incentive spirometer (Fig. 11–1).

Figure 11-1 An incentive spirometer aids lung expansion.

Preoperative Patient Assessment

Nonemergent surgical patients are assessed before admission to a surgical facility or hospital in the preadmission testing (PAT) department. PAT nurses and anesthesia department members obtain a health history, identify risk factors, begin patient and family teaching, and make necessary referrals to social work, support groups, and educational programs, such as a total joint education program for patients undergoing a total joint replacement. Laboratory tests, electrocardiograms (ECGs), chest x-rays, and other diagnostic testing are done based on the patient's needs. A urine or serum pregnancy test as appropriate for female patients may be done to prevent fetal exposure to anesthetics. Health information and

diagnostic testing results are reviewed. Interventions are ordered for abnormalities. Then preoperative, intraoperative, and postoperative care is planned.

Federal law dictates that patients must be asked before surgery if they have a signed advance directive. An advance directive (e.g., health care durable power of attorney or living will) indicates a person's wishes for medical care if they become unable to speak for themselves. A copy of the advance directive is entered into the medical record. If there is no advance directive, written information on advance directives is provided. A health care power of attorney allows patients to place someone of their own choosing, such as a relative or friend, in control of their medical decisions if they are unable to make them. A living will instructs the physician when to provide, withhold, or withdraw treatment that prolongs life and specifies types of treatment the patient wishes, such as comfort care only.

Preoperative Patient Admission

Upon admission for surgery, subjective and objective patient data are collected (Table 11-4). It is important for the patient to have access to their contact lenses, glasses, or hearing aids whenever explanations or instructions are given to ensure effective communication. During the interview, the patient's emotional reaction to surgery is noted. If the patient is anxious, you should explore the cause of the anxiety and allow the patient to express any concerns. Past experiences of patients or their significant others can impact the surgical experience.

Subjective Data

During data collection, it is important to ask the patient if there have been any personal or family problems with anesthesia. A rare hereditary muscle disease known as malignant hyperthermia can predispose the patient to a serious

TABLE 11-4 NURSING ASSESSMENT OF THE PREOPERATIVE PATIENT

Subjective Data: Health History Questions

- Demographic information:** Name, age, marital status, occupation, roles?
- History of condition for which surgery is scheduled:** Why are you having surgery?
- Medical history:** Any allergies, acute or chronic conditions, current medications, pain, or prior hospitalizations?
- Surgical history:** Any reactions or problems with anesthesia? Previous surgeries?
- Tobacco use:** How much do you smoke? Pack-year history (number of packs per day 3 number of years)?
- Alcohol use:** How often do you drink alcohol? How much?
- Coping techniques:** How do you usually cope with stressful situations? Support systems?
- Family history:** Hereditary conditions—diabetes, cardiovascular, anesthesia problems?
- Female patients:** Date of last menses and obstetrical information?

Objective Data: Body System Review

- Vital signs, oxygen saturation
- Height and weight
- Emotional status:** calm, anxious, tearful, affect
- Neurological:** ability to follow instructions
- Skin:** color, warmth, bruises, lesions, turgor, dryness, mucous membranes
- Respiratory:** infection: cough; breath sounds; chronic obstructive pulmonary disease; respiratory rate, pattern, and effort; barrel chest
- Cardiovascular:** angina, myocardial infarction, heart failure, hypertension, valvular heart disease, mitral valve prolapse, heart rate and rhythm, peripheral pulses, edema, jugular vein distention
- Gastrointestinal:** bowel sounds, date of last bowel movement, abdominal distention
- Musculoskeletal:** deformities, weakness, decreased range of motion, crepitation, gait, artificial limbs, prostheses

life-threatening reaction to certain anesthetic agents (discussed later). Prior surgeries are recorded.

Medications

All medications (herbs and over-the-counter, prescription, and recreational drugs) that the patient is taking must be reviewed. Alterations in drug dosages and routes of administration may be required. You should ensure that the patient clearly understands all medication instructions. For example, patients taking an anticoagulant such as warfarin (Coumadin) may be told by their physician to decrease or stop it several days before surgery to avoid bleeding problems during surgery. Many herbs can interfere with medications used during surgery or increase bleeding times. Patients may be instructed to stop certain herbs several days or weeks before surgery.

Diabetic patients on insulin are usually given instructions by the physician to either hold their insulin or take half of their normal dose of insulin the day of surgery. On the day of surgery, blood glucose monitoring is done every 4 hours to ensure that blood glucose levels are maintained within a desired range.

Patients on chronic oral steroid therapy cannot abruptly stop their medication if they are told to take nothing by mouth (NPO) before or after surgery. Serious complications, including circulatory collapse, can develop if steroids are stopped abruptly. The physician should order a patient's steroid therapy to be given by a parenteral route if the patient is NPO, so that it is not interrupted. You should ensure that the therapy is ordered and continued for the patient by an alternate route.

Patients should be asked about the use of drugs such as cocaine, marijuana, or opioids because these drugs can interact with anesthesia or other medications. To obtain accurate information, patients should be told of this potential interaction. Information and questions should be stated in a nonjudgmental manner. For example, you should ask, "How much alcohol do you drink daily or weekly?" instead of "Do you drink alcohol?" The first statement assumes that people drink alcohol. This allows the patient who does not drink to indicate none and the patient who does to state an amount rather than having to say yes and then give an amount with further questioning. More accurate responses are given because this approach is viewed more positively by the patient who consumes alcohol. Another example would be to ask the patient, "What roles do drugs or alcohol play in your life?"

Objective Data

A physical assessment of body systems is performed. This information can highlight risk factors for surgery, determine the type of anesthesia to be used, and assist in planning interventions to reduce risk factors. A cough, cold, or fever is reported to the physician because surgery may be delayed until the patient recovers from an acute infection. Dentures, bridges, capped teeth, and loose teeth are documented because they can become dislodged during intuba-

tion (insertion of endotracheal breathing tube) for general anesthesia, causing complications.

SKIN ASSESSMENT. The skin is observed for color, bruises, and open areas. Palpation of the skin is done to check turgor, warmth, and dryness. Mucous membranes are inspected for color and moistness, especially for elderly patients, who are at greater risk for hydration problems.

SENSORY ASSESSMENT. The patient's ability to see and hear are assessed. Assistive devices (e.g., contact lenses, glasses, or hearing aids) are documented. Patients must have access to these devices whenever explanations or instructions are given for effective communication.

NERVOUS SYSTEM ASSESSMENT. Assessing a patient's ability to understand and follow directions is important because preoperative instructions such as being NPO after a specified time are given. Instructions must be followed to avoid delaying surgery. If cognitive impairments are found, the physician is informed. A family member may need to be included in teaching sessions to assist the patient with following instructions.

RESPIRATORY ASSESSMENT. Respiratory rate and pattern and breathing effort are noted. Oxygen saturation is obtained using an electronic oximeter attached to the finger, nose, or ear that measures the oxygen saturation of the blood flowing past the sensor. The thorax is inspected for use of accessory muscles. A barrel chest (increase in anteroposterior diameter of the chest that looks like the shape of a barrel) is noted. Patients who develop barrel chests usually have chronic obstructive lung disease and may be at greater risk for lung problems. Breath sounds are auscultated, and abnormalities are documented and reported to the physician. Pulmonary function tests or arterial blood gas measurements are done based on the patient's history of lung disease and assessment findings, such as shortness of breath, inability to tolerate activity without dyspnea (feeling out of breath and laboring to breathe), or abnormal breath sounds such as crackles or wheezes.

LEARNING TIPS

Crackles are produced by air flowing over secretions or the snapping open of collapsed airways. They sound like the crackling of Velcro being opened and can be fine (soft, short, high-pitched) or coarse (loud, long, low-pitched). Wheezes are a continuous musical sound caused by airway narrowing.

CARDIOVASCULAR ASSESSMENT. Apical heart rate and rhythm are auscultated. Pulses are palpated for presence and quality. Edema or jugular vein distention is documented.

MUSCULOSKELETAL ASSESSMENT. The patient's joint range of motion, muscular strength, gait, and mobility are observed. The presence of deficits, artificial limbs, prosthe-

ses, or pain is documented. Joints are inspected and palpated for warmth, redness, swelling, or crepitation (grating with movement). Positioning in surgery may be affected by any abnormal findings.

ABDOMINAL ASSESSMENT. The abdomen is inspected for distention and firmness. Bowel sounds are auscultated. Ostomies are noted.

DIAGNOSTIC TESTING. Patient preoperative diagnostic testing is based on the patient’s age, medical history, and assessment findings. Institutional protocols for patients of specified age ranges or with certain conditions may guide testing (Table 11–5). Abnormal findings are reported to the physician.

Nursing Process for Preoperative Patients
Nursing Assessment

The nursing assessment findings are used to plan care for the surgical patient. (See Table 11–4.)

Nursing Diagnosis

Common preoperative nursing diagnoses can include the following:

- Anxiety related to potential change in body image, hospitalization, pain, loss of control, and uncertainties surrounding surgery
- Fear related to expectation of pain and surgical risk factors
- Deficient knowledge related to lack of prior experience with surgical routines and procedures.

Planning

The patient’s goals are to have decreased anxiety, reduced fear, and increased knowledge of surgical routines and procedures.

Nursing Interventions

ANXIETY OR FEAR. Anxiety is a feeling of apprehension or uneasiness resulting from the uncertainties and risks associated with surgery. Fear, a feeling of dread from a source known to the patient, is an extreme reaction to surgery. Anxiety and fear can be reduced by informing patients about procedures and surgical routines. Patients should be allowed to express their concerns. If the patient expresses extreme anxiety or fear, inform the physician because complications or even death could result. When fear is excessive, the physician may reschedule the surgery until the patient is better able to cope.

DEFICIENT KNOWLEDGE. Deficient knowledge occurs from a lack of information and experience with surgery. Providing information to patients decreases their anxiety, promotes informed choice, and increases self-care abilities. Teaching is caring in action and empowers patients to be a participant in their care. Teaching can be done in preadmission testing, by telephone for outpatient surgery, and upon admission.

Teaching sessions include the patient, family members, or others assisting the patient through the surgical experience. Patient anxiety levels should be considered in planning teaching sessions because learning can be affected by high anxiety levels. Knowledge deficiencies should be identified by both you and the patient so that he or she is motivated to learn. Use a variety of teaching methods (discussion, written materials and instructions, models, and videos) to allow for different learning styles and to reinforce learning. Individualize explanations so the patient is given enough information without being overwhelmed. Gerontological Issues Box 11–3 describes methods to provide a positive learning experience for the elderly patient by adapting

TABLE 11-5 PREOPERATIVE DIAGNOSTIC TESTS	
Diagnostic Test	Purpose
Chest x-ray	Detect pulmonary and cardiac abnormalities
Oxygen saturation	Obtain baseline level and detect abnormality
Serum Tests	
Arterial blood gases	Obtain baseline levels and detect pH and oxygenation abnormalities
Bleeding time	Detect prolonged bleeding problem
Blood urea nitrogen	Detect kidney problem
Creatinine	Detect kidney problem
Complete blood cell count	Detect anemia, infection, clotting problem
Electrolytes	Detect potassium, sodium, chloride imbalances
Fasting blood glucose	Detect abnormalities, monitor diabetes control
Pregnancy	Detect early, unknown pregnancy
Partial thromboplastin time	Detect clotting problem
Prothrombin time, INR	Detect clotting problem, monitor warfarin therapy
Type and cross-match	Identify blood type to match blood for possible transfusion
Urine Tests	
Pregnancy	Detect early, unknown pregnancy
Urinalysis	Detect infection, abnormalities

INR = International normalized ratio.

BOX 11-3 GERONTOLOGICAL ISSUES**Considerations for Elderly Patient Teaching Session****Environmental considerations:**

- Comfortable: anxiety free, quiet, appropriate temperature
- Correctly lit: small, intense, nonglare, soft white light (not fluorescent)
- Private: no distractions, no background noise

Presentation considerations:

- Assess readiness to learn.
- Assess comfort and safety needs.
- Use past experience and relate to new learning.
- Base learning on assessment data and current knowledge base.
- Use preferred learning style, using understandable words.
- Use legible audiovisual materials: large print, black print on white nonglare paper.
- If using colors, remember that elders see red, orange, and yellow best; blue, violet, and green are difficult for elders to see.
- Perform ongoing assessment of energy level of patient.
- Answer questions as they occur.

Presenter considerations:

- Have positive attitude and belief in self-care promotion for elderly.
- Earn trust by being viewed as credible, positive role model.
- Maintain professional appearance.
- Use knowledge of aging changes in presentation:
 - Speak slowly in low tone.
 - Sit near patient for best visibility.
 - Ensure that prostheses are in place: glasses, hearing aids.
- Allow patient increased response time and use memory aids.
- Use touch appropriately to convey caring.
- Teach most important information first.
- Present one idea at a time.
- Provide instruction using multiple senses (vision and hearing).
- Emphasize concrete versus abstract information.
- Provide repetition.
- Ask for feedback to ensure comprehension.
- Provide feedback and positive reinforcement.

to aging changes that may affect learning. All teaching and levels of patient understanding is documented.

PREOPERATIVE ROUTINES. Preoperative teaching provides information about common surgical preparation procedures and routines:

- Date and time of admission and surgery
- Admission procedures: arrive about 2 hours before surgery to allow preparation time
- Length of stay, items to bring and wear
- Recovery
- Family information: where to wait during surgery and who communicates patient's status to them
- Discharge criteria: after outpatient surgery, a responsible adult must take the patient home

Preoperative Instructions. To reduce the risk of aspiration when anesthesia is started, as well as postoperative nausea and vomiting, the anesthesiologist orders fluid and food restrictions. The patient is told when to stop fluid and food intake (NPO), usually after midnight the night before surgery. If surgery is scheduled for the afternoon, clear liquids in the early morning may be allowed by the anesthesiologist. Patients may brush their teeth or rinse their mouth if no water is swallowed. Cancellation of surgery may result if the patient has not been NPO as ordered.

Any medications the patient is to take the morning of surgery, with an ounce of water, are explained. Special preparations, such as an enema, are also described. For abdominal or intestinal surgery, enemas are ordered to empty the bowel in order to reduce fecal contamination preoperatively and straining or distention postoperatively.

Instructions for postoperative care are given before surgery so the patient is alert when being taught and has time to learn. Patients should be told that active participation in postoperative care aids in their recovery. Teach patients how to report their pain level using a pain rating scale (such as a 0 [none] to 10 [severe] rating scale, a color-based rating scale, or a scale using pictures of faces showing varying degrees of frowning or smiling that indicate a certain pain level) so that prompt pain relief can be provided (see Chapter 9). Pain relief methods are described, such as analgesic injections, an epidural catheter, or patient-controlled analgesia (PCA). Anticipated dressings, tubes, casts, or special equipment, such as a continuous passive motion machine for total knee replacement, are also described. If needed, crutches are fitted to the patient, and their proper use is explained and demonstrated.

Postoperative exercises are taught to decrease complications. They include deep breathing and coughing, use of incentive spirometry, leg exercises, turning, and how to get out of bed. After an exercise is taught, the patient should perform a return demonstration so understanding and ability to perform the exercise correctly can be evaluated.

Deep breathing helps prevent the development of **atelectasis** (collapse of the lung caused by hypoventilation or mucus obstruction preventing some alveoli from opening and being fully ventilated) by expanding and ventilating the lungs. The patient is taught to sit up, exhale fully, take in a deep breath through the nose, hold the breath and count to three, and then exhale completely through the mouth. The patient is told to repeat this hourly while awake, in sets of five, for 24 to 48 hours postoperatively.

Incentive spirometry may also be ordered postoperatively to prevent atelectasis by increasing lung volume, alveoli expansion, and venous return. (See Fig. 11-1.) Any patient can benefit from incentive spirometry, especially the elderly and those at increased risk for developing lung complications. The spirometer stays at the patient's bedside for hourly use while awake. Offer the spirometer to the patient

atelectasis: ateles—imperfect + ektasis—expansion

each hour to ensure that it is used. Teach patients to do the following:

- Sit upright, at 45 degrees minimum, if possible.
- Take two normal breaths. Place mouthpiece of spirometer in mouth.
- Inhale until target, designated by spirometer light or rising ball, is reached, and hold breath for 3 to 5 seconds.
- Exhale completely.
- Perform 10 sets of breaths each hour.

Coughing moves secretions to prevent pneumonia. Teach patients how to cough effectively (Table 11–6). Give pain medication before coughing and offer reassurance that coughing should not harm the incision. Several sets of coughing are performed, if not contraindicated by the patient's condition (such as hernia repair or head injury), every 1 to 2 hours while the patient is awake.

Leg exercises, if not contraindicated, improve circulation and help prevent complications related to stasis of blood, such as emboli formation. Patients are told to lie down, raise the leg, bend it at the knee, flex the foot, extend the leg, and lower it to the bed. Each leg is exercised in sets of five. Foot circles are also done every hour while awake. Teach the patient to raise a leg slightly off the bed with toes pointed. Draw a circle in the air with the great toe, rotating to the right four times, then to the left. Repeat this five times and then do the same with the other foot.

Patients are taught that turning from side to side in bed is aided by bending the leg that is to be on top and placing a pillow between the legs to support the top leg. They are told, unless contraindicated, to use the bed rail to pull themselves over to the side. They are encouraged to deep breathe while turning instead of holding their breath to promote comfort.

To reduce the strain on the incision and to make it easier for patients to get out of bed, patients are instructed to turn to their side, without pillows between their knees. Then they should place their hands flat against the bed and

push up while swinging their legs out of bed and into a sitting position. Patients should be told to sit for a few minutes after changing position to avoid dizziness and falling. They should also deep breathe while sitting up to promote lung expansion.

Evaluation

The goal of decreased anxiety is achieved if the patient states and demonstrates that anxiety is relieved. If the patient is able to learn during teaching sessions, anxiety is not a barrier to learning.

The goal for relieved fear is accomplished if the patient verbalizes fears or states that fear is decreased or gone.

The goal for correcting deficient knowledge is reached if the patient states understanding of the information presented and accurately performs return demonstrations.

Preoperative Consent

Before performing surgery, it is the physician's responsibility to obtain voluntary, written, informed consent from the patient. The consent gives legal permission for the surgery and has two purposes. It protects the patient from unauthorized procedures, and it protects the physician, anesthesiologist, hospital, and hospital employees from claims of performing unauthorized procedures. A consent is needed for all invasive procedures, anesthesia, blood administration, and radiation or cobalt therapy.

Informed consent involves three elements. (1) The physician must tell the patient in understandable terms about the diagnosis, the proposed treatment and who will perform it, the likely outcome, possible risks and complications of treatment, alternative treatments, and the prognosis without treatment. If the patient has questions before signing the consent, the physician must be contacted to provide further explanation to the patient. It is not within the nurse's scope of practice to provide this information. (2) The consent must be signed before analgesics or sedatives are given because patients must demonstrate that they are informed and understand the surgery. (3) Consent must be given voluntarily. No persuasion or threats can be used to influence the patient. The patient can withdraw consent at any time, even after the consent form has been signed.

It is often your role to obtain and witness the patient's or authorized person's signature on the consent form. You should ensure that the person signing the consent form understands its meaning and that it is being signed voluntarily. If the patient is unable to read, the entire consent must be read to the patient before it is signed. Patients are unable to give consent if they are unconscious, are mentally incompetent, are minors, or have received analgesics or drugs that alter central nervous system function within time frames specified by agency policy. Consent can be obtained in any of these cases from parents, next of kin, or legal guardians.

In a medical emergency, the patient may not be able to give consent. In this case the next of kin or legal guardian may give telephone consent, or a court order can be

TABLE 11–6 TEACHING PATIENTS
COUGHING TECHNIQUES

Procedure	Rationale
Have patient sit up and forward.	Promotes lung expansion and ability to generate forceful cough
Show patient how to splint incision with hands, pillow, or blanket.	Reduces incision pressure so it does not feel as if incision is opening
Have patient inhale and exhale deeply three times through mouth.	Helps expand lungs
Take in deep breath and cough out the breath forcefully with three short coughs using diaphragmatic muscles. Take in quick deep breath through mouth, cough deeply, and deep breathe.	Generates forceful cough and expands lungs to help move secretions

obtained. If time does not permit this, the physician documents the need for treatment in the chart as necessary to save the patient’s life or avoid serious harm, according to state law and institutional policy.

LEARNING TIPS

Witnessing a Consent

As the patient’s advocate you should ensure, before the consent is signed, that the patient is informed about the surgery and has no further questions for the physician.

If the patient does have questions, the consent should not be signed and the physician should be contacted to answer the patient’s questions.

Your signature as a witness on a consent form indicates that you observed the informed patient or patient’s authorized representative voluntarily sign the consent form. It does not mean that you informed the patient about the surgical procedure; that is the responsibility of the physician.

Preparation for Surgery Preoperative Checklist

A preoperative checklist is completed and signed by the nurse (per agency policy) before the patient is transported from the unit to surgery (Fig. 11–2). The checklist provides guidance for preoperative preparation of the patient:

- An identification band is placed on the patient. A hospital gown is given to the patient to wear. Underwear is removed, depending on the type of surgery.
- Vital signs are taken and recorded as baseline information and to assess patient status.

- Makeup, nail polish, and one artificial nail (if applicable) are removed to allow assessment of natural color and pulse oximetry for oxygenation status during surgery.
- Removal of hair pins, wigs, and jewelry prevents loss or injury. Rings are taped in place if the patient does not want to take them off, unless the ring is on the operative side (arm or chest surgery), in case edema occurs.
- Dentures, contact lenses, and prostheses are removed to prevent injury. Some patients are concerned about body image and do not want family members to see them without dentures or makeup. Remove dentures after the family goes to the waiting room and insert them before the family sees the patient postoperatively.
- Glasses and hearing aids go with patients to surgery if they are unable to communicate without them. Label them with the patient’s name and document where they go.
- All orders, diagnostic test results, consents, and history and physical (required on the chart) are reviewed for completion and documented on the checklist.
- Patient valuables are recorded and given to a family member or locked up per institutional policy by the nurse.
- Antiembolism devices are applied if ordered.
- Patients are asked to void before sedating preoperative medications are given, unless a urinary catheter is present, to prevent injury to the bladder during surgery.

Preoperative Medications

The final preparation before surgery is giving preoperative medications (Table 11–7). The medications may be given alone or in combination to achieve desired effects. Preoperative medications may be ordered at a specific time, usually 1 hour before, or on call to surgery (surgery calls you to instruct you that it is time to give the drugs). All medications

TABLE 11-7 PREOPERATIVE MEDICATIONS

Category	Medication	Purpose
Narcotics	morphine sulfate meperidine (Demerol) fentanyl (Sublimaze)	Analgesia Enhancement of postoperative pain relief
Antianxiety and sedative hypnotics	diazepam (Valium) hydroxyzine hydrochloride (Vistaril) lorazepam (Ativan) midazolam (Versed) phenobarbital sodium (Luminal sodium)	Sedation Anxiety reduction
Anticholinergic	atropine sulfate glycopyrrolate (Robinul) scopolamine hydrobromide	Secretion reduction
Antiemetic	droperidol (Inapsine) ondansetron (Zofran) metoclopramide (Reglan) promethazine hydrochloride (Phenergan)	Control nausea and vomiting; may be effective into the postoperative period
Histamine (H ₂) antagonist	cimetidine (Tagamet) famotidine (Pepcid) ranitidine (Zantac)	Reduction of acidic gastric secretions in case aspiration occurs either silently or with vomiting
Alkalinizing agent	Sodium citrate and citric acid (Bicitra)	Prevention of an asthmalike attack, pneumonitis, pulmonary edema, or severe hypoxia
Antibiotic	cefazolin (Ancef) cefoxitin (Cefotan) ampicillin (Omnipen)	Prevention of postoperative infection

TABLE 11–8 POSTOPERATIVE PATIENT HOSPITAL ROOM PREPARATION

After patient transfer to surgery, the nurse should prepare the patient's room for the patient's postoperative care needs to be ready for the patient's return from the postanesthesia care unit.

Preparation	Rationale
Bed	
Bed linens should be clean and are changed if used before surgery by patient.	Reduces contamination of surgical wound
Place disposable, absorbent, waterproof pads on bottom sheet if drainage is expected.	Protects linen from wetness and soiling so a patient in pain does not have to be disturbed for linen change.
Apply lift sheet on bed of patient needing assistance with repositioning.	Makes lifting and turning easier for patient and nurse.
Have extra blankets available.	Patient may be cold or have a low temperature.
Fanfold top cover to end of bed or to side of bed away from patient transfer side.	Bed ready to receive patient on transfer from cart to bed. Allows covers to be easily pulled up over patient.
Obtain extra pillows as needed for positioning, elevating extremities, splinting during coughing.	Pillows help maintain position when patient is turned, elevate operative extremities for comfort and swelling reduction, or splint an incision during coughing.
Equipment	
Obtain IV pole.	Surgical patients have IV infusions postoperatively.
Have emesis basin at bedside.	Nausea or vomiting may occur, especially after movement during transfer.
Have tissues and washcloths in room.	Promotes comfort: washing face or a cool cloth on forehead.
Have urinal or bedpan available in room.	Patients may be unable to get out of bed for first voiding.
Prepare suction setup for tracheostomy, nasogastric tube, or drains as ordered.	Suction may be ordered related to surgical procedures: Sterile suction: tracheostomy Nasogastric tube: thoracic, abdominal, gastrointestinal surgery T-tube: cholecystectomy
Have oxygen set up as needed.	After tracheostomy, patients wear humidified oxygen mask.
Obtain special equipment as indicated by the surgical procedure.	Institutional policy and physician orders may require specialized equipment. Examples: Jaw surgery: suction, wire cutters, tracheostomy tray Tracheostomy: suction, extra tracheostomy set, tracheostomy care supplies Transurethral resection of prostate: irrigation supplies.
Have vital sign equipment available.	Promotes ability to promptly obtain vital signs.
Documentation Forms	
Obtain agency postoperative documentation forms and place in room	Promotes timely and accurate documentation of patient data.

IV = Intravenous.

administered are documented. The bed rails are raised for safety and the patient is instructed not to get up alone after medications are given.

Transfer to Surgery

When the surgery department is ready, the patient is taken to the surgical holding area on a stretcher. The patient's chart, inhaler medications for those with asthma, and glasses or hearing aids for those who need them to communicate also go to the surgical holding area. The patient can be accompanied by family members.

During surgery, the family waits in the surgical waiting area, which is a communication center where the family is kept informed regarding the patient's status. The physician calls the family there when surgery is over. Families may be given beepers so that they can walk outside or to other areas of the hospital and still be reached.

After Transfer

After the patient goes to surgery, prepare the patient's room and necessary equipment so it is ready for the patient's return (Table 11–8).

▶ INTRAOPERATIVE PHASE

When the patient is transferred to the operating table, the next phase of the perioperative period, the intraoperative phase, begins. Surgery may take place in a hospital operating room (OR) or freestanding ambulatory or outpatient surgical centers. Additionally, surgery is performed in physician's offices, cardiac catheterization laboratories, radiology centers, emergency rooms, and specialized units that perform endoscopy procedures.

Gloves are worn as part of the surgical sterile field by the OR team. The OR team members must perform a sterile surgical hand scrub to reduce the amount of microorganisms

on their hands and arms. An antimicrobial soap scrub is used to reduce the chances of microorganism contamination. Jewelry (e.g., watches, rings, bracelets) is also removed. Fingernails are kept short and clean. Artificial nails and colored nail polish are not permitted. Artificial nails can harbor microorganisms and colored nail polish prevents seeing if nails are clean.

The OR is designed to enhance **aseptic** technique. Clean and contaminated areas are separated. Special ventilation systems control dust and prevent air from flowing into the OR from hallways. The temperature and humidity in the room are controlled to discourage bacterial growth. Everyone entering the OR wears surgical scrubs, shoe covers, caps, masks, and goggles to protect the patient from infection and themselves from blood-borne pathogens. Traffic in and out of the OR is limited. Strong disinfectants are used to clean the OR after each surgical case, and instruments are sterilized.

Before the patient arrives in surgery, a nursing plan of care is developed from preadmission assessment data. The OR is prepared based on the plan of care (Nursing Care Plan Box 11-4). Attention is given to safety needs of the patient. Special needs are addressed, such as a tall patient's need for longer table length or an elderly patient's positioning needs resulting from osteoporosis. A surgical case cart containing sterile instruments required for the patient's case is prepared ahead of time. Items such as needles and sponges are counted before surgery and again before closure of the incision to account for all of them and ensure that none have been left in the patient. To ensure safety, electrical equipment is checked for proper functioning.

Health Care Team Member Roles

The licensed practical nurse/licensed vocational nurse's (LPN/LVN's) major role in this phase is as a scrub nurse who assists the physician during the surgery. Scrub nurses scrub their hands and arms and dress in sterile garb. They maintain the sterile instrument field and hand the sterile surgical instruments to the physician. The scrub nurse creates a sterile field and removes the sterile instruments from the cart.

Other health care team members involved in this phase may include the following:

- Physician (medical doctor [MD], doctor of osteopathy [DO], oral surgeon, or podiatrist)
- Surgical (first) assistant: assists the physician and is either another physician, a specially trained registered nurse, or a physician's assistant

- Anesthesiologist: physician who specializes in anesthesia and supervises certified registered nurse anesthetists in the operating room
- Certified registered nurse anesthetist (CRNA): registered nurse trained and certified in the administration of anesthesia, usually at the master's degree level
- Registered nurse (RN): circulates in OR; roles include being patient's advocate, planning care, protecting patient safety, monitoring patient positioning, checking vital signs and making patient assessment, reducing patient's anxiety, monitoring sterility during surgery, preparing skin before incision, managing equipment such as by making sponge counts, documenting the procedure, and aiding health team communications
- Surgical (second assistant) technician: assists physician, such as scrub nurse (may be an RN, LPN/LVN, or surgical technologist)

Patient Arrival in Surgery

The nurse greets the patient; verifies the patient's name, age, allergies, surgeon performing the surgery, consent, surgical procedure (especially right or left when applicable), and medical history; answers questions; and alleviates anxiety. The patient is introduced to the anesthesiologist and CRNA, who also verify patient information and explain the type of anesthesia that is to be used. All surgical patients have intravenous (IV) fluids started, and the patient may receive prophylactic antibiotics.

As a patient enters the OR, he or she should be told what to expect:

- "The room may feel cool, but you can request extra blankets."
- "There is a lot of equipment in the room, including a table and large, bright overhead lights."
- "Several health care team members will introduce themselves to you."
- "Your physician will greet you."

The patient is assisted onto the operating table, and a safety strap is carefully applied. Monitoring equipment is applied and readings recorded. Then the anesthesia provider begins anesthesia. When the anesthesia provider gives permission, the patient is carefully positioned to prevent pressure points that could cause tissue or nerve damage. Any necessary tubes that are not already in place, such as a nasogastric tube or urinary catheter, are inserted by the RN.

BOX 11-4 NURSING CARE PLAN FOR INTRAOPERATIVE NURSING DIAGNOSES AND OUTCOMES

- Risk for perioperative-positioning injury related to positioning, chemicals, electrical equipment, and effect of being anesthetized
Free from injury
- Risk for impaired skin integrity related to chemicals, positioning, and immobility
Skin integrity is maintained
- Risk for deficient fluid volume related to NPO status and blood loss
Maintains blood pressure, pulse, and urine output within normal limits
- Risk for infection related to incision and invasive procedures
Is free of symptoms of infection
- Pain related to positioning, incision, and surgical procedure
Reports pain is relieved to satisfactory level

Patient allergies are checked. Then a skin prepping solution that the patient is not allergic to, such as povidone iodine, is used to cleanse the skin. A large area surrounding the operative site is scrubbed to allow for extension of the incision. The scrub is completed in a circular motion from inside to outer edge. If an allergic reaction to the solution occurs, it can cause skin redness and blistering wherever the solution was used. After the skin is scrubbed, a sterile drape is applied with the incisional area left exposed.

Anesthesia

Anesthesia is used for surgery to prevent pain and allow the procedure to be done safely. The type of anesthesia and the anesthetic agents are ordered by the anesthesia provider with input from the patient and physician (Cultural Consideration Box 11-5).

BOX 11-5 CULTURAL CONSIDERATION

Care of the Patient Having Surgery

Chinese people show a greater increase in heart rate in response to atropine than Caucasian persons. Thus the nurse needs to carefully monitor the pulse after atropine is given as a preoperative medication. Additionally, Chinese people are more sensitive to the sedative effects of diazepam (Valium) and require lower doses. Thus the nurse needs to carefully monitor the Chinese patient for untoward effects of diazepam (Valium).

There are two types of anesthesia: general and local (regional). General anesthesia (GA) causes the patient to lose sensation, consciousness, and reflexes. GA acts directly on the central nervous system. Local anesthesia results in the loss of sensation to a region of the body without the loss of consciousness. Local anesthesia works by blocking the nerve impulses along the nerve where it is injected.

General Anesthesia

General anesthesia is commonly given by an IV or inhalation route. GA is chosen when patients are very anxious or do not want local anesthesia, when the surgical procedure will take a long time and there is a need for muscle relaxation, or when the patient is unable to cooperate, as in head injury, muscle disorders, or impaired cognitive function.

INTRAVENOUS AGENTS. To begin most general anesthesia, the patient is induced (i.e., anesthesia is caused) with a short-acting IV agent that provides a rapid, smooth **induction** (the period from when anesthetic is first given until full anesthesia is reached). Because these agents last only a few minutes, they are used along with inhalation agents, which maintain anesthesia during surgery. After induction, the patient is intubated with an endotracheal (ET) tube to provide mechanical ventilation and anesthesia (Fig. 11-3).

INHALATION AGENTS. Maintenance of anesthesia is accomplished by using inhalation agents. These agents are de-

Figure 11-3 Endotracheal tube with cuff inflated.

livered, controlled, and excreted through mechanical ventilation. Inhalation agents and the ET tube can be irritating to the respiratory tract. Complications that can occur from their use include laryngospasm (sudden violent contraction of the vocal cords), laryngeal edema, irritated throat, or injury to the vocal cords. When the tube is removed, the nurse should closely monitor the patient and be prepared to provide respiratory support and assist with reintubation if complications arise.

ADJUNCT AGENTS. An **adjunct** agent is a medication used along with the primary anesthetic agents. These medications can include narcotics to control pain, muscle relaxers to avoid movement of muscles during surgery, antiemetics to control nausea or vomiting, and sedatives to supplement anesthesia.

Malignant Hyperthermia

Malignant hyperthermia (MH) is a rare hereditary muscle disease that can be triggered by some types of general anesthesia agents. Obtaining a history of anesthesia problems in the patient or family members can help detect the potential for development of this condition so that precautions can be taken. A muscle biopsy can also diagnose this problem. Patients with this condition can undergo surgery safely with careful planning and choice of anesthetic agents by the anesthesia provider.

With MH there is increased metabolism in muscles, which produces a very high fever and muscle rigidity, as well as tachycardia, tachypnea, hypertension, dysrhythmias, hyperkalemia, metabolic and respiratory acidosis, and cyanosis. MH is life threatening, so immediate treatment is required or death results. Surgery is stopped and anesthesia discontinued immediately. Oxygen at 100% is given. The patient must be cooled with ice and infusions of iced solutions. Dantrolene sodium (Dantrium), a muscle relaxant that relieves the muscle spasms, is the most effective medication for treating malignant hyperthermia. Dantrolene sodium is kept readily available in the OR and administered according to

the treatment protocol of the Malignant Hyperthermia Association of the United States. For more information about malignant hyperthermia, visit www.mhaus.org.

Local (Regional) Anesthesia

Local anesthesia is selected when the patient is not anxious, can tolerate the local agent, and is not required by the surgical procedure to be unconscious or relaxed. It is a good choice for some outpatient procedures or when the patient has not been NPO. The anesthesia provider, or sometimes the physician, administers local anesthesia.

Local anesthetic agents may include bupivacaine hydrochloride (Marcaine), lidocaine (Xylocaine), and dibucaine (Nupercainal). Topical administration places the agent directly on the surgical area. Local infiltration is achieved by injecting the medication into the tissue where the incision is to be made. A regional block is done by injecting the local agent along a nerve that carries impulses in the region where anesthesia is desired. There are several types of regional blocks. A nerve block is the injection of a nerve at a specific point. A Bier block is done by placing a tourniquet on an extremity to remove the blood and then injecting the local agent into the extremity. A field block is a series of injections surrounding the surgical area. A spinal or epidural block is injection of a local agent into an area around the spinal nerves.

SPINAL AND EPIDURAL BLOCKS. Injection of a local agent into the subarachnoid space produces spinal block (Fig. 11-4). Epidural block occurs when the local agent is injected

Figure 11-4 Injection of spinal anesthesia. (A) Epidural anesthesia. (B) Epidural catheter. (C) Spinal anesthesia.

into the epidural space. Spinal and epidural blocks are used mainly for lower extremity and lower abdominal surgery. Both motor and sensory function is blocked. The patient must be carefully monitored for complications. Hypotension results from sympathetic blockade causing vasodilation, which reduces venous return to the heart and therefore reduces cardiac output. Respiratory depression results if the block travels too far upward. As the block wears off, patients feel as if their legs are very heavy and numb. This is normal, and reassurance should be offered to the patient that this type of feeling does not last after the block wears off.

Complications. A postdural puncture headache may occur in 10 to 40 percent of patients caused by leakage of cerebrospinal fluid (CSF) from the needle hole in the dura that does not close when the needle is withdrawn. The use of a small-gauge spinal needle (less than 25 gauge) helps prevent headaches. Photophobia or double vision may also be present. Postanesthesia orders usually include methods to help reduce the pain of a headache, including positioning the patient flat and forcing fluids.

If a spinal headache develops, it may be severe and can last for weeks. Lying flat and prone (on abdomen) may help relieve the pain of the headache. Adequate fluid intake and analgesics may be ordered, and steroids may be helpful. If the headache continues, a blood patch treatment can be used to stop the CSF leakage. This treatment can be done by the anesthesiologist at the bedside or in the postanesthesia care unit (PACU). To create a blood patch, approximately 10 mL of the patient's own blood is injected into the epidural space at the previous puncture site. The injected blood forms a clot that "patches" the dura hole to prevent further CSF leakage. Pain relief should occur quickly if the patch is successful. Blood patch treatment can be repeated.

Adjunct Anesthesia Techniques

Several techniques may be used with anesthesia to improve the outcome of surgery. Cryoanesthesia uses cooling or freezing in a localized area to block pain impulses. Acupuncture produces loss of sensation. Controlled hypotension decreases blood loss by lowering the blood pressure.

Conscious Sedation

Conscious sedation is purposeful, minimal sedation that does not cause the complete loss of consciousness during selected medical, dental, or diagnostic procedures. IV medications such as sedatives, hypnotics, and opioids are given to produce conscious sedation. Selection of patients who are eligible for conscious sedation is based on the procedure, the patient's general health, patient preference, and physician preference. Examples of short procedures for which conscious sedation is used are dental procedures, endoscopy, cardiac catheterization, cardioversion, and closed fracture reduction. During conscious sedation, patients are comfortable, respond purposefully, and maintain their own patent airway. Medications are ordered by the physician and usually administration by a specially trained registered nurse, as defined by agency and state scope of nursing practice.

LEARNING TIPS

In comparison with general anesthesia, conscious sedation:

- is less invasive.
- requires less medication.
- causes less depression of the cardiovascular and respiratory systems.
- allows the patient to more quickly return to a wakeful state.

A signed surgical consent is obtained. Then an IV for medications and fluids is inserted before the procedure. Patient monitoring is done every 5 minutes to check vital signs, electrocardiogram, and oxygen saturation. Changes are reported to the physician. Oxygen may be given by nasal cannula or mask. Emergency equipment (e.g., airway suction, defibrillator, drugs) is on standby, according to advanced cardiac life support (ACLS) protocols.

After the procedure, the patient awakens easily and quickly. The patient is monitored every 15 to 30 minutes for response to the procedure and the drugs, until the patient is fully awake and stable. The patient is ready for discharge when vital signs return to baseline and are stable, oral fluids are retained, he or she has voided (if applicable), and written and oral discharge teaching is given to both the patient and the responsible adult to whom the patient is being discharged. The responsible adult and the patient must sign the instructions. Instructions include the following: an adult must drive the patient home and provide a safe environment; the patient must not and will not drive or operate heavy machinery or sign legal documents for 24 hours.

Transfer from Surgery

When surgery is completed and anesthesia stopped, the patient is stabilized for transfer. After local anesthesia, the patient may return directly to a nursing unit. After general and spinal anesthesia, the patient goes to the PACU or in some cases the intensive care unit (ICU).

Patient safety, which is always a priority, is an important concern at this time. The patient is never left alone. Ensuring a patent airway and preventing falls and injury from uncontrolled movements are priorities. The anesthesia provider and OR nurses transfer the patient to the PACU and monitor the patient until the PACU nurse is able to receive the report and assume care of the patient. This begins the final patient perioperative phase, the postoperative period.

▶ POSTOPERATIVE PHASE

The postoperative phase begins when the patient is admitted to the PACU or a nursing unit and ends with the patient's postoperative evaluation in the physician's office. The family is updated on the patient's status by the physician as the patient is admitted to the PACU.

Admission to the Postanesthesia Care Unit

The goal of the postanesthesia nurse is to promote recovery from anesthesia. The nurse's role in the PACU begins by re-

ceiving a patient report from the OR nurse and anesthesia provider. When the patient is admitted to the PACU, an admission assessment is done. The priority areas of patient assessment are the following:

- Respiratory status and patency of airway
- Vital signs
- Level of consciousness
- Surgical site incision/dressing
- Pain level

Oxygen by nasal cannula or mask is given if the patient has had general anesthesia, or as ordered. Some patients who are still intubated may require mechanical ventilation. Continuous monitoring is done on all patients for ECG, pulse oximetry, and blood pressure measurements. The surgical site incision or dressing is assessed. Drainage and **hematoma** formation are documented and reported. Urinary catheter, drains, and nasogastric tubes are checked for function and patency as applicable.

The patient's body temperature is measured on admission, and then blankets heated in blanket warmers are applied. If the patient's temperature is below normal, a warming blanket that can be set to a desired temperature is applied. Body temperature may be decreased as a result of a cool OR environment, anesthesia, cool IV solutions, and incisional openings, which allow heat loss. Patient recovery is aided by avoiding a decrease in body temperature during surgery. Using forced warm air before surgery to warm the patient, rather than warm blankets, has been shown to maintain body temperature best upon arrival in PACU. Be aware that the elderly are at increased risk of **hypothermia**. Temperature is measured again before PACU discharge because a normal body temperature is usually one of the discharge criteria.

Shivering may occur from anesthesia or as a result of being cold. It is important to control shivering because it increases oxygen consumption 400 to 500 percent. Meperidine (Demerol) is effective in relieving shivering when anesthesia is the cause. If the patient is cold, raising the body temperature is helpful to decrease shivering.

PACU nursing responsibilities are listed in Box 11–6. Vital signs and assessment are done at least every 15 min-

BOX 11–6 Postanesthesia Care Unit Nursing Responsibilities

- Airway maintenance
- Vital signs
- Respiratory assessment
- Neurological assessment
- Surgical site status
- General assessment
- Patient safety
- Monitoring anesthetic effects
- Pain relief
- Assessing PACU discharge readiness

hematoma: heimatós—blood + oma—tumor

utes, IV fluid infusion is maintained, and IV analgesics are given for pain as needed. Antiemetics are administered for nausea or vomiting. Deep breathing and coughing, if not contraindicated by the surgical procedure, are encouraged. Coughing increases pressure, which could cause harm to some surgical areas. Surgical procedures that prohibit coughing include hernia repair; eye, ear, intracranial, and plastic surgery; and jaw surgery. If the patient is no longer NPO, ice chips or sips of water may be offered when the patient is fully awake to promote comfort for a dry mouth. If ordered, postoperative therapies such as patient-controlled analgesia, which allows patients to administer their own pain medication (see Chapter 9), or continuous passive motion machines for joint replacement surgeries are begun in the PACU.

Nursing Process for Postoperative Patients in PACU

Many postoperative complications may occur in the PACU or later in the postoperative phase. The cause of these complications may be the surgical procedure, anesthesia, blood and fluid loss, immobility, unrelieved pain, or other diseases the patient may have. Nursing care focuses on preventing, detecting, and caring for these complications.

Respiratory Function

ASSESSMENT. Normal respiratory function can be altered in the immediate postoperative period by airway obstruction, hypoventilation, secretions, laryngospasm, or decreased swallowing and cough reflexes. Respiratory function assessment includes respiratory rate, depth, ease, and pattern. Breath sounds, chest symmetry, accessory muscle use, and sputum are also observed.

NURSING DIAGNOSIS. Respiratory-related nursing diagnoses for the PACU include the following:

- Ineffective airway clearance related to obstruction, anesthesia medications, and secretions
- Ineffective breathing pattern related to anesthesia medications and pain
- Risk for aspiration related to depressed cough and gag reflexes and reduced level of consciousness

PLANNING. The patient's goals are to have a patent airway at all times, breathe comfortably and maintain normal arterial blood gases, and have clear lung sounds.

NURSING INTERVENTIONS. The priority nursing responsibility in the PACU is to ensure that patients maintain a patent airway. Airway obstruction is usually caused from relaxed muscles allowing the tongue to block the pharynx in the patient who has a decreased level of consciousness. It may be necessary to manually open a patient's airway to prevent obstruction if the patient has snoring respirations and has not completely emerged from anesthesia. The jaw-thrust method is used to open the airway.

Patients are positioned on their side, unless contraindicated, to protect the airway until they are awake. Then

when they are awake, elevating the head in a supine position assists respiration.

Suction equipment is always readily available to clear secretions or emesis. Aspiration is a risk because of the effects of anesthesia, which depresses cough and gag reflexes and reduces level of consciousness. As a result, secretions may accumulate and not be effectively controlled.

Oxygen therapy is started on all general anesthesia patients. Hypoventilation can be an effect of anesthesia medications or analgesics, decreased level of consciousness, or an incision in the thorax causing painful respirations.

Deep breathing is encouraged to expand the lungs. Pain is controlled with carefully administered analgesics to promote deep breathing but avoid respiratory depression. Respiratory depression is reported to the anesthesiologist for prompt treatment.

EVALUATION. The goal for ineffective airway clearance and aspiration is achieved if the patient's airway remains patent and lung sounds remain clear.

The goal for ineffective breathing pattern is met if the patient's respiratory rate is within normal limits, no dyspnea is reported, and arterial blood gases are within normal limits.

Cardiovascular Function

ASSESSMENT. Alterations in cardiovascular function can include hypotension, dysrhythmias, and hypertension. Hypotension can be the result of blood and fluid volume loss or cardiac abnormalities. Shock can result from significant blood and fluid volume loss (see Chapter 8). Dysrhythmias may occur from hypoxia, altered potassium levels, hypothermia, pain, stress, or cardiac disease. New-onset hypertension can develop from pain, a full bladder, or respiratory distress. Cardiovascular function assessment includes heart rate, blood pressure, ECG, and skin temperature, color, and moistness. Vital signs are compared with baseline readings to determine if they are normal. Tachycardia, hypotension, pale skin color, cool, clammy skin, and decreased urine output indicate hypovolemic shock, which requires prompt treatment. Abnormal findings are promptly reported to the physician for intervention.

LEARNING TIPS

Tachycardia: An Early Warning Sign

Tachycardia is a compensatory mechanism designed to provide adequate delivery of oxygen in times of altered function. It is usually the earliest warning sign that an abnormality is occurring. It should be a red flag to assess the patient and ask yourself what this particular patient is likely to be experiencing that is compromising oxygenation, allowing you to begin prompt treatment.

Patient Condition	Possible Causes of Compromised Oxygenation
Postoperative patient	Hemorrhage, respiratory depression, pain
Myocardial infarction patient	Cardiogenic shock, pain
Respiratory patient	Respiratory distress
Trauma patient	Hemorrhage, severe pain

NURSING DIAGNOSIS. The PACU cardiovascular-related nursing diagnoses include the following:

- Deficient fluid volume related to blood and fluid loss or NPO status
- Decreased cardiac output related to volume loss, medication effects, or cardiac disease

PLANNING. The patient's goals are to maintain blood pressure, pulse, and urine output within normal limits; and to maintain blood pressure, pulse, and rhythm within normal limits.

NURSING INTERVENTIONS

- Dressings and incisions are checked for color and amount of drainage.
- IV fluids are maintained at the ordered rate to replace lost fluids but avoid fluid overload.
- Intake and output are monitored to detect imbalances.
- Providing pain relief, warming the patient, and preventing bladder distention help prevent hypertension.

EVALUATION. The goal for deficient fluid volume is met if vital signs and urine output are within normal limits.

The goal for decreased cardiac output is achieved if vital signs and rhythm are within normal limits.

Neurological Function

Until its effects wear off, anesthesia can alter neurological function. Patients may arrive in the PACU either awake, arousable, or sleeping. If patients are sleeping, they should become more alert during their stay in the PACU. As emergence from anesthesia occurs, patients may become wild or agitated for a short period. This is referred to as emergence delirium. Amnesia effects can be caused by anesthesia. Movement, sensations, and perceptions may also be altered by anesthesia. Movement is the first function to return after spinal anesthesia.

For geriatric patients, it is important to review their history to understand if they have any cognitive or neurological deficits. Confused patients may be agitated or frightened when they awaken. It is helpful to know how caregivers normally communicate with the patient. You should understand that the patient may not be able to report pain or follow commands. If possible, it may be helpful to have a familiar relative or caregiver with the patient in the PACU to calm them and help them communicate. You should watch for nonverbal pain cues such as moaning, grimacing, rubbing an area, and restlessness. If patients have limited movements or sensations before surgery, you should know this to obtain an accurate assessment of anesthesia effects.

ASSESSMENT. A neurological assessment includes level of consciousness; orientation to person, place, and time; pupil size and reaction to light; and motor and sensory function.

NURSING DIAGNOSIS. The PACU neurological-related nursing diagnoses include the following:

- Risk for injury related to anesthesia effects causing decreased level of consciousness, sensation, and movement.

- Disturbed sensory perception related to decreased level of consciousness, amnesiac effects of anesthesia, or spinal anesthesia.

PLANNING. The patient's goals are to maintain safety and be free from injury.

NURSING INTERVENTIONS

- All patient data are verified until patients are awake and can communicate.
- Patients' safety is maintained until they are fully awake or movement and sensation return following spinal anesthesia. Side rails are kept up. Extremities are positioned in proper alignment and protected from injury until sensation and movement return.
- Tubes, dressings, and IVs are secured and monitored.
- As patients wake up, orientation explanations are provided and repeated until amnesiac anesthesia effects are no longer present. Examples of explanations include the following: "Mr. Smith, surgery is over; you are in the recovery room." "Your family is waiting for you and knows you are in the recovery room." "The doctor spoke with your family about how you are doing."

EVALUATION. The goals for risk for injury and disturbed sensory perception are met if the patient remains free from injury.

Pain

ASSESSMENT. If patients are awake, they are asked to rate the presence of pain using a scale, such as 0 to 10, a pain scale using color, or pictures that rate pain. The location and character of the pain are documented. When patients are not fully awake, vital signs and nonverbal indications of pain should be monitored. Nonverbal indications of pain can include abnormal vital signs, restlessness, moaning, grimacing, rubbing, or pulling at specific areas or equipment.

PLANNING. The patient's goal for pain is to report that pain is relieved at a satisfactory level.

NURSING INTERVENTIONS

- Patient pain is monitored and promptly relieved. IV narcotic analgesics are used for their rapid onset. If PCA is ordered, it is started in PACU. Pain can result from the surgical procedure, movement, deep breathing, anxiety, or a full bladder. Positioning during surgery and the presence of devices such as nasogastric tubes, catheters, IVs, or ET tubes can also be a source of pain.
- Repositioning the patient, providing warmth, and emptying a full bladder may alleviate pain.
- Playing music in the PACU, such as nature sounds or Mozart, dimming the lights, and reducing noise can reduce pain.

EVALUATION. After pain medication is given, patients are asked to rate their pain level. The goal for pain is met if they report a decreased level of pain that is satisfactory to them. For example, the patient reports pain of 10 on a scale of 0 to 10. You medicate the patient, and 30 minutes later the patient rates pain as 2 on a scale of 0 to 10.

Discharge from the Postanesthesia Care Unit

The length of stay in the PACU if the patient remains stable is normally 1 hour. A postanesthesia recovery scale is used to score the patient's readiness to be discharged. The scale rates categories such as respiration, oxygen saturation, level of consciousness, activity, and circulation. The anesthesiologist orders the patient to be transferred to a nursing unit or discharged home when discharge criteria are met (Table 11-9). The patient may be transferred to the ICU if frequent monitoring is needed.

Transfer to Nursing Unit

The PACU nurse gives a report of the patient's condition to the unit nurse when the patient is transferred to the nursing unit. The patient is moved into bed on the nursing unit with assistance to prevent dislodging IVs, tubes, drains, or dressings. After patients are placed in bed, the following safety interventions are performed:

- The bed is placed in its lowest position, with the side rails raised.
- The nurse's call button is placed within easy patient reach and answered promptly.
- Patients are instructed that they should be assisted with ambulation when they get up.

When patients get up postoperatively, especially for the first time, they may be weak or dizzy. One or two health care workers should assist the patient and allow the patient to dangle before standing (Fig. 11-5). These precautions can help prevent falls.

Nursing Process for Postoperative Patients

A complete patient assessment is performed after transfer to the nursing unit. Respiratory status, vital signs (including temperature), level of consciousness, surgical site, dressings, and pain assessment are especially noted. IV site and patency are assessed. The IV solution and infusion rate are verified and monitored. Nasogastric tubes are hooked to suction or clamped as ordered. Drains and catheters are positioned to promote proper functioning.

TABLE 11-9 DISCHARGE CRITERIA FOR POSTANESTHESIA CARE UNIT OR AMBULATORY SURGERY

Vital signs stable
Patient awake or at baseline level of consciousness
Drainage or bleeding not excessive
Respiratory function not depressed
Oxygen saturation above 90%
Additional Criteria for Ambulatory Surgery
No nausea or vomiting
No IV narcotics within last 30 minutes
Voided if required by surgical procedure or ordered
Is ambulatory or has baseline mobility
Understands discharge instructions
Provides means of contact for follow-up telephone assessment
Released to responsible adult

Figure 11-5 Patient dangling.

After patients are discharged from the PACU, your role is to provide interventions to promote recovery. These interventions may include monitoring for complications, providing postoperative care, educating patients and their significant others, making necessary referrals, and providing home health care (Nursing Care Plan Box 11-7 for the Postoperative Patient). The patient is watched for possible problems such as respiratory depression, hemorrhage, and shock. This is especially important during the first 24 hours postoperatively.

Respiratory Function

ASSESSMENT. The patient's respiratory status is assessed and monitored to ensure that a patent airway is maintained. Chest symmetry is noted. If the patient's airway is compromised, immediate action is taken to support the airway and the physician is notified. Breath sounds are auscultated for adequate air exchange and absence of abnormal sounds in all lobes. The patient's cough is assessed if it is not contraindicated by the type of surgery, such as hernia repair or eye, ear, intracranial, jaw, or plastic surgery.

NURSING DIAGNOSES. Postoperative respiratory-related nursing diagnoses include the following:

- Ineffective airway clearance related to ineffective cough and secretion retention
- Ineffective breathing pattern related to analgesic medications and pain

PLANNING. The patient's goals are to have a patent airway and clear breath sounds and normal arterial blood gases. Factors that may inhibit this goal should be identified and discussed with the patient.

NURSING INTERVENTIONS

- Regular monitoring of the patient's respiratory rate, depth, and effort; cough strength; and breath sounds should be done. Postoperative patients are at risk for developing atelectasis and pneumonia. They may have a weak cough as

BOX 11-7 NURSING CARE PLAN FOR THE POSTOPERATIVE PATIENT

Ineffective airway clearance related to ineffective cough and secretion retention

PATIENT OUTCOMES

Patient maintains a patent airway at all times. Breath sounds remain clear.

EVALUATION OF OUTCOMES

Is patient able to clear own secretions? Are breath sounds clear?

INTERVENTION

Monitor breath sounds.

Encourage deep breathing and coughing and use of incentive spirometer hourly while awake.
Ensure patient pain is relieved before activity.
Encourage movement by turning every 2 hours and ambulating as able.

RATIONALE

Abnormal breath sounds such as crackles or wheezes can indicate retained secretions.
Lung expansion helps prevent atelectasis and keeps lungs clear of secretions.

Movement can cause or increase pain.

Movement promotes lung expansion and movement of secretions.

EVALUATION

Are breath sounds clear?

Does patient perform breathing and coughing and use incentive spirometer?

Does patient state pain is controlled before activity?
Is patient moving?

Acute pain related to surgery, nausea, and vomiting

PATIENT OUTCOMES

Patient reports pain management relieves pain satisfactorily and describes pain management plan.

EVALUATION OF OUTCOMES

Does patient report satisfactory pain relief? Is patient able to describe pain management plan?

INTERVENTION

Assess pain using grating scale such as 0 to 10.
Provide analgesics prn.
Provide antiemetics prn.

Position patient comfortably.

RATIONALE

Self-report is the most reliable indicator of pain.
Analgesics relieve pain.
Antiemetics relieve nausea and vomiting.

Incisions, drains, tubing, equipment, and bed rest can cause discomfort, which positioning can relieve.

EVALUATION

Does patient report pain using scale?

Is patient's pain less after medication?
Is patient's nausea and vomiting less after medication?
Does patient report positioning is comfortable?

GERIATRIC

When assessing pain speak clearly and slowly so elderly patient can hear.
Assess elderly patients' pain level regularly, observing nonverbal pain cues (restlessness, grimacing, moaning), especially for those cognitively impaired.

If elderly patient does not hear or misunderstands, pain may not be reported accurately to ensure appropriate intervention provided.
The pain of elderly patients is often underreported and undertreated, especially if cognitively impaired, and noting nonverbal cues can aid in pain treatment.

Does patient hear and report pain and relief accurately using pain scale?

Are nonverbal cues present in elderly patients, especially those cognitively impaired?

Risk for infection related to inadequate primary defenses from surgical wound

PATIENT OUTCOMES

Patient remains free from infection.

EVALUATION OF OUTCOMES

Does patient remain free from infection?

INTERVENTION

Observe incision for signs and symptoms of infection.
Monitor drainage and maintain drains.

Maintain sterile technique for dressing changes.

RATIONALE

Redness, warmth, fever, and swelling indicate infection.
Drains remove fluid from the surgical site to prevent infection development.

Sterile technique reduces infection development.

EVALUATION

Are signs and symptoms of infection present?

Are drainage amount and color normal for procedure?
Are drains functioning?
Is incision free of signs and symptoms of infection?

a result of being drowsy from anesthesia or analgesics. If fine crackles are heard in the lung bases, the patient should be encouraged to deep breathe or cough. Afterward you should listen again to see if the crackles have cleared.

- Preoperative teaching of deep breathing and coughing is reinforced and encouraged every hour while the patient is awake. Deep breathing and coughing, especially through the first postoperative day, help prevent atelectasis and keep lungs clear of secretions. If secretions are retained, mucus plugs can develop and block bronchioles, causing alveoli to collapse. Infection can develop from the stasis of mucus, resulting in pneumonia.
- An incentive spirometer also helps prevent atelectasis by encouraging patients to inspire a deep breath, which opens their airways. After the patient is taught to use the incentive spirometer, it is placed within the patient's reach and encouragement to use it is given frequently.
- Pain should be controlled so the patient does not guard against deep respirations or coughing. An incision near the diaphragm makes deep breathing or coughing painful, so patients avoid deep breathing or coughing.
- Turning the patient at least every 2 hours helps expand the lungs and moves secretions. Bedrest results in decreased movement of secretions, so ambulating the patient as soon as possible also aids in keeping the airway clear.

EVALUATION. If the patient's breath sounds are clear and arterial blood gases remain normal, the goals are met. The patient's ability and willingness to deep breathe or cough and use an incentive spirometer every hour while awake are important in achieving the goal.

Circulatory Function

ASSESSMENT. The primary concern in monitoring the patient's circulatory status is the detection and prevention of hemorrhage, shock, and thrombophlebitis. Vital signs and skin temperature, color, and moistness are observed and compared with baseline data. The incision or dressing is checked for drainage or hematoma formation. Drainage may leak down the patient's side and pool underneath the patient. While wearing gloves, you should feel underneath the patient or turn the patient to check for bleeding. Any signs of hemorrhage or shock are promptly reported to the physician.

Institutional policy is followed for frequency of patient monitoring. A typical protocol for monitoring vital signs and oxygen saturation is every 15 minutes for 4 hours, then every 30 minutes for 2 hours, hourly for 4 hours, and then every 4 hours if stable.

The lower extremities of surgical patients are observed. Tenderness or pain in the calf may be the first indication of a deep vein thrombosis. Leg swelling, warmth, and redness, as well as fever, may also be present. Bilateral calf and thigh measurement is done daily if thrombophlebitis is suspected or diagnosed. Peripheral pulses and capillary refill are also checked.

NURSING DIAGNOSIS. Postoperative cardiovascular-related nursing diagnoses include the following:

- Deficient fluid volume related to blood and fluid loss or NPO status
- Ineffective tissue perfusion: peripheral or pulmonary related to interruption of blood flow

PLANNING. The patient's goals are to maintain blood pressure and pulse within normal limits and maintain normal tissue perfusion.

NURSING INTERVENTIONS. Vital signs are monitored and abnormal trends noted. Dressings, incisions, drains, and tubes are checked for color and amount of drainage. Bright red drainage or excessive drainage amounts are reported immediately to the physician. Intake and output are monitored to detect imbalances. IV fluids are maintained at the ordered rate.

Slower blood flow during surgery, dehydration, leg straps, and positioning may contribute to venous injury or thrombosis development. Preventive interventions to decrease the development of thrombophlebitis and pulmonary embolism should be used (see Chapter 17). Leg exercises that were taught preoperatively are encouraged hourly while the patient is awake. Early postoperative ambulation is a major preventive technique for thrombosis. Patients' pain should be controlled to facilitate their ability to participate in early ambulation. Knee-length or thigh-length antiembolism elastic stockings or intermittent pneumatic compression may be ordered. (See Fig. 15–15.) Low-dose heparin, low-molecular-weight heparin (enoxaparin [Lovenox]), warfarin, and plasma expanders such as dextran 40 and dextran 70 reduce clot formation. It is important to avoid pressure under the knee from pillows, rolled blankets, or prolonged bending of the knee. Leg elevation is helpful in preventing venous stasis.

EVALUATION. The goal for deficient fluid volume is met if vital signs and urine output are within normal limits.

The goal for ineffective tissue perfusion is met if tissue blood flow remains normal.

Postoperative Pain

It is common for patients to experience pain after surgery, although each patient's pain experience varies. In addition to incisional pain, painful muscle spasms can occur. Nausea and vomiting, ambulation, coughing, deep breathing, and anxiety can cause discomfort and increase postoperative pain. Unrelieved pain has negative physiological effects. It also impairs deep breathing and coughing and hinders early ambulation, which may increase complications, length of hospital stay, and health care costs. Nurses should understand that providing pain relief not only reduces suffering, it also has positive benefits for a quicker recovery. It is important for nurses to stay informed of advances in pain management and ensure that they make pain relief a priority in providing patient care. (See Chapter 9.)

ASSESSMENT. Nurses must be proactive and diligent in their provision of pain relief. Studies show that commonly used intramuscular (IM) pain medication orders may not provide adequate pain relief in many patients and can result in the patient's waiting for periods of up to 20 minutes for requested

pain injections. Anticipating postoperative patients' pain by regularly monitoring their pain level instead of waiting until it is the time for the next dose of pain medication is essential to provide quality nursing care for pain relief.

Elderly patients, including the very oldest, experience postoperative pain. Pain is not a normal part of aging. Careful assessment of elderly patients' unique aging changes, chronic diseases, and pain relief needs is required to appropriately treat their pain. Cognitively impaired adults are at risk for undertreatment of their postoperative pain. Pain relief needs remain even when patient communication is impaired. You must ensure that you assess and treat pain for these patients.

If patients are not fully awake on transfer, vital signs and nonverbal indications of pain should be monitored. Nonverbal indicators of pain include abnormal vital signs (usually elevated blood pressure, although hypotension can occur in some patients), restlessness, moaning, grimacing, and rubbing or pulling at specific body areas or equipment. Patients who are awake are asked the location of the pain, to rate the presence of pain and describe the pain quality, such as sharp, aching, throbbing, or burning, which you should document.

NURSING DIAGNOSIS. Postoperative pain-related nursing diagnoses include pain related to tissue damage from surgery, muscle spasms, nausea, or vomiting.

PLANNING. The patient's goal for pain is to report pain relief at a satisfactory level. Patients should be involved in setting the goal for the level of pain relief that is satisfactory to them using the pain rating scale.

NURSING INTERVENTIONS

Patients are monitored for pain and provided prompt interventions for relief. If analgesics are used IV initially, such as in the PACU, and then ordered as IM injections on the unit, you should know the length of action of the IV analgesic. IV analgesics usually have a shorter duration than IMs. You should consult the physician or pharmacist for appropriate timing intervals for IV to IM doses of analgesics.

LEARNING TIPS

- For their first dose of an IM analgesic, patients in pain should not have to wait the ordered time interval of the IM dose after an intravenous analgesic dose (i.e., 3 hours if the IM order is morphine 10 mg IM q3h prn). Having to wait when the IV analgesic is no longer effective can cause needless pain.
- PCA may be started in the PACU. The patient's ability to use PCA, the patient's response to the medication, and the relief obtained from it are monitored. If PCA is not effective or if side effects occur, the physician should be notified.
- Comfortable positioning, warming the patient, and relieving a patient's full bladder can also alleviate pain. Attention to environmental factors such as bright overhead lighting, excessive noise or visitors, and extreme room temperatures also helps promote comfort.
- Antiemetics should be given as ordered to relieve the discomfort of nausea and vomiting. If vomiting occurs, patients should be turned onto one side to aid emesis removal and prevent aspiration. A nasogastric tube may be ordered to help control vomiting.

EVALUATION. Thirty minutes after pain medication is given, patients are asked to rate their pain level. If patients are sleeping at this time, you should allow them to sleep. When they awaken, you can ask them to rate their pain level. The goal for pain is met when patients report a decreased level of pain, as compared with their previous level of pain, that is satisfactory to them. If the patient does not report satisfactory pain relief, the physician should be promptly notified of the inadequate pain relief.

CRITICAL THINKING

Mrs. Wood

Mrs. Wood, following a hysterectomy, returns to the unit from the PACU. Mrs. Wood's postoperative vital signs and assessment findings are normal. You ask Mrs. Wood her pain level, noting that she moans occasionally, moves her legs, and pulls at her covers near her abdominal incision. She is drowsy but says it hurts. In the PACU, she received 10 mg of morphine IV 55 minutes ago. Morphine 5 to 10 mg IM is ordered every 3 hours as needed.

1. What nonverbal pain cues does Mrs. Wood display?
2. How should you document Mrs. Wood's pain?
3. What action should you take to relieve Mrs. Wood's pain?
4. When should you next monitor Mrs. Wood's pain level?
5. If Mrs. Wood indicates that her pain is unrelieved after 30 minutes, what action should you take?
6. You are to give Mrs. Wood morphine 8 mg IM now. You have available morphine 10 mg/mL. How many milliliters will you give?

Answers at end of chapter.

Urinary Function

ASSESSMENT. The patient's urinary status is monitored to ensure that normal function is maintained because urinary retention can occur after anesthesia. For outpatient surgery, patients may be required to void before being discharged. If the patient has a urinary catheter, the amount, color, and consistency of the urine are noted. Otherwise, monitor the patient's first postoperative voiding to prevent bladder distention. Patients should void within 8 hours of their last voiding. For patients having urinary or gynecologic procedures, the patient may need to void within 4 to 6 hours to prevent increased pressure on the surgical site. Catheterization may be necessary if the patient is unable to void.

If patients report the inability to void, the bladder is palpated for distention. You should be aware that restlessness can be caused by discomfort from a full bladder. A distended bladder requires intervention to empty it. Efforts are made to promote voiding before inserting a urinary catheter because of the risk of infection.

The amount, color, and consistency of the patient's urine is noted. The body's stress response to the surgical experience stimulates the sympathetic nervous system ("fight or flight" response), which saves fluid by reducing urine output. Therefore initially urine output may be reduced and concentrated. Then it should gradually increase, becoming less concentrated and lighter in color.

NURSING DIAGNOSIS. Postoperative urinary-related nursing diagnoses include the following:

- Impaired urinary elimination related to surgery, pain, anesthesia, altered positioning
- Urinary retention related to surgery, pain, anesthesia, altered positioning

PLANNING. The patient’s goals are to completely and regularly empty the bladder and to remain free from pain during voiding.

NURSING INTERVENTIONS

- Output is measured and recorded on most postoperative patients, especially those undergoing major procedures or urological surgery, elderly patients, and those with an IV or urinary catheter.
- If the patient’s urinary output from the catheter is less than 30 mL in 1 hour, it is reported to the physician.
- Patients who void small, frequent amounts (30 to 50 mL every 20 to 30 minutes) or dribble may have retention overflow and may not be emptying their bladder. This is not normal and may require catheterization to empty the bladder and prevent complications.
- To promote voiding, patients should be assisted to the bathroom or bedside commode, and men should be allowed to stand or sit to void if possible. If bedpans are used, they should be warmed to prevent reflexive sphincter tightening.
- If the patient is unable to void, techniques to promote voiding should be used before catheterization. Running water, pouring warm water over a female patient’s perineum, or drinking a hot beverage may stimulate voiding. The patient is given privacy to void after safety is ensured. Having patients place their feet solidly on the floor relaxes the pelvic muscles to aid voiding.
- If the patient is uncomfortable, has a distended bladder, or has not voided within the specified time frame, the physician is notified. After other measures have been unsuccessful, an order to catheterize the patient, either with a straight or an indwelling catheter, is usually received.

EVALUATION. The goal for impaired urinary elimination is met if the patient is able to void completely and regularly.

The goal for urinary retention is met if the patient is able to void without pain or complications.

Surgical Wound Care

ASSESSMENT. A wound is a break in the skin. An incision is a wound made by a physician with a sharp instrument such as a scalpel. A puncture wound has a small opening and may be made with a scalpel to insert a tube or drain. Incisions are closed with sutures or staples, or surgical glue, which is painless and produces less scarring, is rapidly applied (Fig. 11–6). Wound healing occurs in phases (Table 11–10). As the wound heals, sutures or staples are removed in 7 to 10 days, and Steri-Strips may be applied to continue supporting the wound as it heals.

When a wound occurs, it disrupts the integrity of the skin, giving bacteria an entry point into the body. Wounds can be clean or dirty. Clean wounds are surgical wounds that are not infected. Contaminated wounds include accidental wounds or surgical incisions exposed to gastrointestinal (GI) contents or unsterile conditions. Infected wounds and dirty wounds contain microorganisms from trauma, ruptured organs, or infection. Necrotic and infected tissue is removed before infected wounds are closed. This is known as **debridement**.

NURSING DIAGNOSIS. Postoperative skin-related nursing diagnoses include the following:

- Impaired skin integrity related to surgical incision
- Risk for infection related to inadequate primary defenses from surgical wound

Figure 11-6 A stapled incision. (A) Note wound edges not approximated at arrows. (B) Arrows indicate puncture sites where drains were inserted.

TABLE 11-10 WOUND HEALING			
Wound Healing Processes			
First intention	Wound edges well approximated, little tissue loss		
Second intention	Large tissue loss, granulation tissue fills in area over time		
Third intention	Granulation tissue fills in area with scar formation		
Wound Healing Phases			
Phase	Time Frame	Wound Healing	Patient Effect
Phase I	Incision to second postoperative day	Inflammatory response	Fever, malaise
Phase II	Third to fourteenth postoperative day	Granulation tissue forms	Feeling better
Phase III	Third to sixth postoperative week	Collagen deposited	Raised scar formed
Phase IV	Months to 1 year	Collagen deposited	Flat, thin scar

PLANNING. The patient's goals are to regain skin integrity and to remain free from infection. The patient should know the signs and symptoms indicating infection that should be reported to the physician.

NURSING INTERVENTIONS

Drains. Drains are inserted into wounds during surgery to prevent accumulation of blood, lymph, or necrotic tissue in wounds that can lead to infection or delayed healing. Drains may work by gravity or suction. Penrose drains are open, soft, flat, rubberlike drains that carry drainage out of the wound. Moderate **serosanguineous** drainage is expected from a Penrose drain and may require frequent dressing changes. Examples of drains that use suction to gently enhance drainage include the Jackson-Pratt, Hemovac, and Mini-Snyder Hemovac (Fig. 11–7). These drains are closed systems that may require periodic emptying and reapplication of the suction by compressing the drain. Output is recorded when the drainage is emptied. The amount of drainage expected varies with the type of surgery. Specialized drainage systems allow the autotransfusion of bloody drainage back to the patient to maintain hemoglobin levels without the risks associated with blood transfusions, such as transfusion reactions or transmission of infections.

Surgical wound drainage initially is sanguineous (red) and changes to serosanguineous (pink) and then serous (pale yellow) after a few hours to days. Drainage that is bright red, remains sanguineous after a few hours, or is profuse should be promptly reported to the physician because the patient may be hemorrhaging.

Dressings. Dressings are applied to surgical wounds for several reasons. They protect the wound, absorb drainage, prevent contamination from body fluids, provide comfort, and apply pressure to reduce swelling or bleeding as in a pressure dressing. The initial dressing is applied in surgery and then is usually removed by the physician approximately 24 hours postoperatively. If drainage appears on the initial dressing,

you will usually reinforce it with another dressing, according to physician orders or institution policy, and document the color, amount, and consistency of the drainage.

After the initial dressing is removed, if the wound is dry and the edges intact (approximated), the physician may not order the dressing to be replaced. This allows easy observation of the wound and avoidance of applying tape to the skin. Draining wounds are dressed with several layers that are changed as needed. The Centers for Disease Control and Prevention's standard precautions are used when changing dressings. When the old dressing is removed, it should be done carefully to prevent dislodging of tubes or drains. The condition of the wound is documented with each dressing change. It is normal for the incision to be puffy and red from the inflammatory response. The surrounding skin should be the patient's normal color and temperature. Sterile technique is used to reapply the new dressing. Correct tape application over the dressing is done by gently laying the tape over the dressing and applying even pressure on each side of the wound. Pressure should not be applied on top of the wound by pulling on the tape from one side of the wound to the other side.

EVALUATION. The goal for impaired skin integrity is met if the patient's wound heals and skin integrity is regained without complications.

The goal for risk for infections is achieved if the patient remains free from signs and symptoms of infection.

WOUND COMPLICATIONS. Wound problems can include hematoma, infection, dehiscence, and **evisceration**. A hematoma occurs from bleeding in the wound and into the tissue around the wound. A clot forms from the bleeding. If the clot is large with swelling, the clot may need to be removed by the physician.

Infected wounds may be warm, reddened, and tender and have **purulent** (pus) drainage. The drainage may have a foul odor. A fever and elevated white blood cell (WBC) count

serosanguineous: sero—whey + sanguineous—bloody

evisceration: e—out + viscera—body organs

Figure 11-7 Surgical drains. (A) Hemovac. (B) Mini-Snyder Hemovac. (C) T drain. (D) Flat drains. (E) Hemovac autotransfusion system. (From Zimmer Patient Care Products, Dover, Ohio, with permission.)

Figure 11-8 (A) Wound dehiscence. (B) Wound evisceration.

may be present. Antibiotics are used to treat the infection. Careful use of sterile technique for incisional care can help prevent infection.

Dehiscence and evisceration are serious wound complications (Fig. 11-8). Wound dehiscence is the sudden bursting open of a wound's edges, which may be preceded by an increase in serosanguineous drainage. Evisceration is the viscera spilling out of the abdomen. Dehiscence and evisceration often occur with abdominal incisions in patients who are malnourished, obese, elderly, or who have poor wound healing. Supporting the wound during coughing and other activities that pull on the incision or applying an abdominal binder on patients who are at risk help prevent dehiscence and evisceration. When evisceration occurs, the patient may have pain and vomiting and may report that "something let loose" or "gave way."

If dehiscence or evisceration occurs, place the patient in low Fowler's position with flexed knees. Cover the wound with sterile dressings or towels moistened with warm sterile normal saline. Notify the physician immediately of this surgical emergency. Apply gentle pressure over the wound and keep the patient still and calm. Monitor vital signs for evidence of shock (e.g., tachycardia, tachypnea, dyspnea, hypotension). IV fluids are infused as ordered. Prepare the patient for immediate surgery to close the wound.

For dehiscenced surgical incisions that resist healing, a newer device, vacuum-assisted closure (VAC), is available to aid in healing the incision. The device can be used on other types of wounds. Wound closure is aided by application of local negative pressure to wound edges by VAC.

Gastrointestinal Function

Nutritional intake and bowel functioning can be affected by surgery and anesthesia. Application of NPO status and un-

dergoing bowel preparation often occur preoperatively. Postoperatively, intestinal handling during surgery, the need to rest the GI tract following a procedure, immobility, lack of peristalsis, and complications such as nausea and vomiting, paralytic ileus (from peristalsis stopping), constipation, or obstruction can interfere with normal GI function.

ASSESSMENT. Postoperatively, bowel sounds are auscultated every 4 hours. If no bowel sounds are heard initially, you should listen for 5 minutes in each quadrant before documenting that they are absent. Normally, 5 to 30 bowel sounds are heard per minute. Bowel sounds can be absent, hypoactive, normal, or hyperactive. The abdomen is checked to see if it is soft or firm and flat or distended. When the patient begins passing flatus or stool, document it. Any abnormal findings are reported to the physician.

After abdominal surgery, peristalsis and bowel sounds usually stop for 24 to 72 hours. Flatus is usually absent for 24 to 72 hours postoperatively. Patients do not have bowel movements until peristalsis returns. The patient is kept NPO until flatus and bowel sounds return or as ordered by the physician. A nasogastric or gastrointestinal tube may be inserted and attached to suction to remove secretions and flatus until peristalsis returns. The patient's abdominal girth is measured if distention occurs. Drainage from the decompression tube is observed for amount, color, and consistency. Intake and output are measured. Removal of gastric secretions can cause electrolyte imbalances. Signs and symptoms of electrolyte imbalance can include new-onset confusion or weakness, which should be reported.

NURSING DIAGNOSIS. Postoperative gastrointestinal-related nursing diagnoses include the following:

- Imbalanced nutrition: less than body requirements related to NPO, pain, nausea
- Constipation related to decreased peristalsis, immobility, altered diet, narcotic side effect
- Impaired oral mucous membranes related to NPO status

PLANNING. The patient's goals are to resume normal dietary intake and maintain weight within normal limits; to return to normal bowel elimination patterns and report freedom from gas pains and constipation; and to maintain intact, moist mucous membranes.

NURSING INTERVENTIONS. Your primary focus is to help restore normal GI functioning. When normal GI function is achieved, dietary intake can be resumed. Until the patient can resume a normal dietary intake, as determined by the surgical procedure, IV fluids, total parenteral nutrition, or enteral feedings may be required (Nutrition Notes Box 11-8).

EVALUATION. The goal for imbalanced nutrition: less than body requirements is met if patients are able to maintain their baseline weight and resume a normal dietary intake.

The goal for constipation is met if patients are free from discomfort and establish a regular bowel elimination pattern.

The goal for impaired oral mucous membranes is met if patients maintain intact, moist mucous membranes.

BOX 11-8

Nutrition Notes

Nourishing the Postoperative Patient

After surgery, intravenous 5% glucose in water is commonly prescribed. Two liters of this solution contain only 340 calories, insufficient to meet the patient's energy needs but enough to prevent ketosis from breakdown of adipose tissue. Previously well-nourished adults generally have nutrient reserves for 3 to 4 days of semistarvation. To prevent excessive muscle protein from being used for energy, adequate nourishment should be delivered to the patient within 3 days. Complete nutrition is available in clear liquid formulations such as Citrotein and Enlive.

To avoid abdominal distention, oral feedings are delayed until peristalsis returns, as evidenced by the patient's passing flatus or the health care worker's auscultating bowel sounds. Patients usually progress from clear liquids to a regular diet as soon as possible. If "diet as tolerated" is prescribed, the patient should be asked what sounds good. Sometimes a full dinner tray when the patient doesn't feel well "turns off" the appetite. After gastrointestinal surgery, oral food and fluids are deferred longer than with other surgeries to allow healing. When particular amounts are prescribed, those limits should be strictly implemented to preserve the suture lines. One other precaution is often taken after surgery on the mouth and throat: After tonsillectomy, for example, no red liquids are given so that bleeding can be seen and vomitus is not mistaken for blood.

Specific nutrients necessary for healing are as follows:

- Vitamin C for collagen formation
- Vitamin K for blood clotting
- Zinc for tissue growth, skin integrity, and cell-mediated immunity
- Protein for controlling fluid balance and edema and for manufacturing antibodies and white blood cells, as well as for building scar tissue

Mobility

ASSESSMENT. It is important for the patient to move as much as possible to prevent complications and promote healing. Pain, incisions, tubes, drains, dressings, and other equipment may make movement difficult. You should determine the patient's ability to move in bed, to get out of bed, and to walk. Pain levels that may interfere with movement are assessed. The patient's tolerance to activity is observed. Understanding of how to perform exercises is noted.

NURSING DIAGNOSIS. Postoperative mobility-related nursing diagnoses include the following:

- Impaired physical mobility related to surgery, decreased strength, and movement restriction
- Activity intolerance related to immobility and weakness

PLANNING. The patient's goals are to resume normal physical activity and to demonstrate increased activity tolerance.

NURSING INTERVENTIONS. The patient is assisted with positioning in bed. Pillows can be used to support the body

LEARNING TIPS

The primary purpose of most IV fluids is to provide hydration. Most IV solutions do not provide enough nutrients or calories to prevent malnutrition. A 1000-mL IV solution containing 5% dextrose provides only about 170 calories. This does not meet an adult's daily caloric needs, especially if healing is occurring. You should ensure that early consideration of other nutritional methods is made to meet the patient's dietary needs.

- If nausea and vomiting occur, antiemetics may be given.
- Early ambulation, exercise, and diet promote restoration of GI functioning. The patient should be encouraged to be as active as possible. If gas pains occur, techniques to relieve the pain, as tolerated, include ambulation, having the patient lie prone, and pulling the knees up to the chest.
- If the patient is NPO, oral care is provided frequently. Good oral hygiene helps promote appetite. A dry mouth is uncomfortable and can cause increased bacterial accumulation and mucous membrane breakdown. Products such as dry mouth toothpaste, moisturizing gel, or mouthwash can be used to promote good oral hygiene and decrease dryness. If the patient is allowed occasional ice chips, they can be made from normal saline to prevent depletion of electrolytes. Alcohol-containing mouthwashes increase dryness and should be avoided. Lemon glycerin swabs may also increase dryness.
- If a paralytic ileus develops, abdominal distention, absent bowel sounds, and pain may result. If severe peristalsis occurs, nausea and vomiting result. As ordered, a nasogastric tube can be used to decompress the GI tract until peristalsis returns.
- When the patient is able to resume oral intake, food is introduced gradually to tolerance. Water and clear liquids are usually started first. Then the diet is advanced to soft and finally solid foods.

in good alignment. The patient should be turned at least every 2 hours. Positioning should be alternated from supine to side to side. Patients should move themselves as much as possible for several reasons. Movement increases circulation and promotes lung expansion to prevent complications. Also, patients know where it hurts and are less likely to increase their pain when moving.

Encouraging exercises in bed is important, especially if ambulation is not possible. Exercises should be done hourly while awake to promote normal functioning and prevent complications.

Deep breathing, range of motion of all joints, and isometric exercises of the abdominal, gluteal, and leg muscles should be performed by the patient. Passive joint range of motion is done by the nurse if the patient is unable to do active range of motion.

As patients are assisted to sit up, the head of the bed is raised slowly to allow the circulatory system to adjust to the position change. If patients report dizziness or feeling faint, the head of the bed is lowered. Vital signs and skin color are noted. Patients should rest about 1 hour, as tolerated, before sitting up again. Once patients tolerate a sitting position, they can be dangled on the side of the bed in preparation for ambulation.

If dangling is tolerated, patients can be ambulated. Before getting up, patients should pedal their feet to “wake up” the muscles controlling the arteries. To rise, they should keep their eyes forward and move slowly until they feel adjusted to being up. Usually the patient ambulates a short distance the first time and increases the distance as tolerated. One or two health care workers should assist the patient and use a gait (walking) belt for safety. Walkers with wheels and seats may also be used for support and for resting if the patient becomes dizzy or tired. If patients feel faint or dizzy or their vital signs change, they should be assisted back to bed. A wheelchair may be needed to transport them safely back to their room.

EVALUATION. The goal for impaired physical mobility is met if patients are able to increase ambulation and resume normal activities.

The goal for activity intolerance is met if patients are able to increase activity to desired level and maintain vital signs within normal limits.

Postoperative Patient Discharge

Discharge planning begins in preadmission testing and continues after admission to ensure that the patient is ready for a timely discharge. When the patient meets discharge criteria, the physician discharges the patient from either the ambulatory setting or the hospital.

Ambulatory Surgery

DISCHARGE CRITERIA. Generally the patient can be considered a candidate for discharge 1 hour after surgery if discharge criteria are met (see Table 11–9). Discharge criteria include stable vital signs, no bleeding, no nausea or vomiting, and controlled pain that is not severe. Depending on the type of surgical procedure, such as urological, gynecologic, or hernia surgery, the patient may be required to void before discharge. The patient should be able to sit up without dizziness before discharge. When patients meet discharge criteria and are discharged by the physician, they are released to a responsible adult. They are not permitted to drive themselves home because of the effects of anesthesia and medications they have received.

DISCHARGE INSTRUCTIONS. Patients and their families are given written discharge instructions before discharge. Elderly patients should have a caregiver participate in the discharge instruction session to understand what observations to make and what to do if complications develop. The instruction form is signed by the patient or an authorized representative to indicate understanding. Prescriptions and a copy of the instructions, to provide a reference for later, are sent with the patient. The patient is encouraged to rest for 24 to 48 hours. The patient is to avoid operating machinery, driving, drinking alcoholic beverages, and making major decisions for 24 hours because the effects of undergoing surgery can alter energy levels and thinking ability. The physician orders any fluid, dietary, activity, or work restrictions.

Patients are taught wound care, medication information (including side effects), and signs and symptoms of complications to report to the physician. Phone numbers for the physician, surgical facility, and emergency care are provided. Patients are informed of the date for their follow-up visit to the physician and told to call and make an appointment. They are also told that a nurse will call the next day to check on their progress and answer any questions.

Inpatient Surgery

DISCHARGE CRITERIA. The physician determines the patient’s readiness for discharge from the hospital. Postoperative lengths of stay vary based on the surgical procedure and the patient’s individual needs. Before discharge, a complete assessment of the patient is performed and documented.

DISCHARGE INSTRUCTIONS. Patients and their families are given prescriptions and a copy of written instructions that are signed by the patient to indicate understanding before discharge. All necessary teaching is completed before discharge. If more teaching or reinforcement is needed, a referral to a home health nurse can be requested.

The physician orders any fluid, dietary, activity, or work restrictions. Patients are taught wound care, medication information (including side effects), and signs and symptoms of complications to report to the physician. Patients are informed of the date for their follow-up visit to the physician.

Home Health Care

The role of the home health nurse is to assist the patient in the recovery process (Home Health Hints).

A referral to the home health nurse is made when the patient requires the following:

- Continued assistance with skilled nursing interventions, such as wound care, IV medications, or ostomy care
- Additional teaching to be able to perform self-care, such as diabetic teaching for a patient with newly diagnosed diabetes or ostomy care
- Assessment of the recovery process
- Assistance needed because of weakness, lack of social support, or development of complications; care provided in the home is adapted to the patient’s resources and environment to facilitate compliance

Home health care workers can include assistants who help with activities of daily living and household chores, LPNs/LVNs who provide basic nursing care, and registered nurses who perform patient assessments, teaching, and complex nursing care. The frequency of visits is determined by the patient’s needs. The RN can contact the physician from the patient’s phone for orders for abnormal findings.

REVIEW QUESTIONS

- Which of the following is a LPN/LVN patient care role in the preoperative phase?
 - Assisting in data collection
 - Explaining the surgical procedure
 - Obtaining preoperative orders
 - Providing informed consent
- When teaching the elderly preoperative patient, which of the following is a teaching strategy that improves learning?
 - Sit near a window with bright sunlight
 - Use large black-on-white printed materials
 - Sit beside patient
 - Use blue and green materials
- Which of the following related to the patient providing consent for surgery is within the LPN/LVN's scope of practice?
 - Obtaining informed consent
 - Providing informed consent
 - Answering surgical procedure questions
 - Requesting patient questions be referred to physician
- The nurse is assessing a postoperative patient. Which of the following findings would the nurse correctly evaluate as being the earliest indicator of hemorrhage or shock that should be reported to the physician?
 - Tachycardia
 - Polyuria
 - Nausea
 - Fever
- Which one of the following would the nurse evaluate as indicating that the patient's diet can be resumed as ordered?
 - Absence of flatus
 - Bowel sounds every 8 seconds
 - Excessive thirst
 - Absent bowel sounds
- Which of the following interventions should the nurse include in the plan of care to help prevent atelectasis in a postoperative patient?
 - Coughing and deep breathing
 - Holding breath while moving
 - Restricting fluids
 - Leg exercises
- Which of the following is one criterion the nurse uses to evaluate patient readiness for discharge from ambulatory surgery?
 - Ability to drive an automobile
 - Ability to ambulate 50 feet
 - Being pain free
 - Absence of nausea or vomiting

QUESTIONS TO GUIDE YOUR READING

1. What are common signs and symptoms of shock?
2. How would you describe hypovolemic, distributive, and cardiogenic shock?
3. What are the components of the primary survey?
4. How would you prioritize interventions for a multisystem trauma victim?
5. What is the difference between a partial-thickness and full-thickness burn?
6. What are the symptoms of inhalation injury?
7. What are the stages of hypothermia and hyperthermia?
8. What are priorities of care for poison overdose?
9. What is your role in crisis situations and psychiatric emergencies?

The ability to recognize an emergent condition, prioritize, and provide quick assessments and interventions is essential in nursing. In emergent situations, initial assessment and intervention is guided by the ABCs of the primary survey. The primary survey of the patient's airway, breathing, and circulation allows recognition, prioritization, and treatment of life-threatening situations. The secondary survey, a rapid head-to-toe assessment, identifies additional serious injuries throughout the body. This chapter presents components of the primary and secondary surveys followed by specific emergent conditions with application of the nursing process.

► PRIMARY SURVEY

To recognize life-threatening conditions and determine priorities of care, an initial assessment of the patient's airway, breathing, and circulation is conducted. This process is known as the primary survey. The components of the primary survey are listed in Table 12-1.

A = Airway

The airway is the most important component of the primary survey. The airway is opened using the chin lift or jaw thrust maneuver (Fig. 12-1). It is essential to maintain alignment of the cervical spine if there is any possibility of a cervical spine injury. The neck should not be hyperextended, flexed, or rotated until spinal injury is ruled out because any movement may worsen an existing cervical spine injury. The airway is inspected for obstruction, including loose teeth, foreign objects, bleeding, and vomitus. Next, any visible airway obstructions are removed using a finger sweep or suction if available.

Airway adjuncts, such as nasopharyngeal or oropharyngeal airways, may be used to keep the airway open. When additional airway support and mechanical ventilation are required, advanced airway adjuncts, such as endotracheal intubation or cricothyroidotomy, may be performed by specially trained emergency personnel or physicians.

B = Breathing

After the patency of the airway is ensured, the patient is assessed for spontaneous breathing and respiratory rate and depth. If the patient is not breathing, interventions are conducted before proceeding. The patient may be ventilated with a mouth-to-face mask or a bag-valve-face mask. Endotracheal intubation is the preferred method of maintaining an airway in an unconscious patient because it ensures air-

Figure 12-1 (A) Chin lift maneuver is used to open the airway. (B) Jaw thrust maneuver is used to open the airway if the patient may have a head or neck injury.

way patency and protects the lungs from aspiration. (See Chapter 26.) The nurse observes whether the patient's chest rises and falls spontaneously and auscultates for breath sounds bilaterally.

C = Circulation and Consciousness

The carotid pulse is palpated for quality and rate. The skin is inspected for color and temperature. External bleeding is controlled by external pressure and elevation when possible. Any life-threatening conditions that may compromise circulation are assessed and interventions provided before proceeding. Other conditions that may compromise circulation include internal bleeding, **shock** resulting from hemorrhage, or major burns. Large-gauge intravenous (IV) cannulas (16 gauge or 18 gauge) are initiated for fluid resuscitation. If the patient does not have a pulse, cardiopulmonary resuscitation must be initiated. If a pulse can be palpated, vital signs are taken and recorded.

After assessment of airway, breathing, and circulation, a brief neurological assessment is conducted to determine the level of consciousness, which may range from alert and talking to unresponsive. If the patient is unresponsive, a painful stimulus is applied, such as rubbing the sternum, pressing a pen against the base of the nail, or applying periorbital

TABLE 12-1 COMPONENTS OF THE PRIMARY SURVEY

A	Airway
B	Breathing
C	Circulation and consciousness

pressure. The patient is observed for any response to the pain, and the response is recorded.

▶ SECONDARY SURVEY

For victims of severe trauma, a secondary survey is conducted. Major body areas that may sustain serious injury, such as the head, spine, chest, abdomen, and musculoskeletal system, are quickly examined to detect additional injuries. To adequately perform a head-to-toe assessment, the patient's clothing is removed. Each major body area is inspected and palpated for deformity, bruising, open wounds, bleeding, and pain. The chest is palpated for subcutaneous emphysema, a crackling feeling in the skin caused by air escaping from the lungs into the soft tissue. The chest is auscultated for equal breath sounds and heart sounds. The abdomen is inspected for open wounds, bruising, and distention, and then auscultated for bowel sounds. Tenderness and rigidity of the abdomen are noted and reported. Next the extremities are inspected and palpated for injury, deformity, peripheral pulses, temperature, and capillary refill. Movement and sensation in the fingers and toes are noted. If the patient is conscious and lucid, a history is taken. Details of the accident or illness and information regarding the patient's medical history are obtained if possible.

LEARNING TIPS

Subcutaneous emphysema feels similar to the sensation of squeezing a bubble in the bubble wrap used for packaging.

▶ SHOCK

Shock is a condition of acute peripheral circulatory failure, causing inadequate and progressively failing tissue perfusion that results in cell death if not treated. During the initial phases of shock, compensatory adjustments allow the body to adapt to the circulatory changes. Eventually, however, these compensatory mechanisms fail and cellular perfusion decreases, causing cell death. There are four types of shock: hypovolemic, **cardiogenic**, obstructive, and **distributive**. (See Chapter 8.)

Nursing Process for Shock

Assessment

When assessing a patient at risk for shock, be aware of the signs and symptoms common to all types of shock (Box 12–1). It is important to note the patient's initial level of consciousness and monitor the patient for any subsequent changes. A progressive decline in level of consciousness indicates an urgent need for intervention. Pulses indicate the strength of the heart's contractions. Because a pulse is an immediate indicator of the patient's condition, it should be taken frequently during any emergency condition. Changes in blood pressure may also indicate changes in blood vol-

BOX 12-1 Common Signs and Symptoms of Shock

- Restlessness and anxiety
- Weak, rapid, thready pulse
- Cold and clammy skin
- Pale skin color
- Shallow, rapid, labored breathing
- Gradually and steadily falling blood pressure
- Alteration in consciousness in severe shock state
- Thirst

ume. Blood pressure changes can occur rapidly but usually not as swiftly as pulse changes.

Skin temperature and color changes may be seen with shock. Severe blood loss activates the “fight-or-flight” response in the sympathetic nervous system, which causes the skin to become cool and clammy. This occurs when peripheral blood vessels constrict to shunt blood to vital organs. Skin color depends on the presence of circulating blood in the vessels of the skin. Pale, white, or ashen skin indicates insufficient circulation. In patients with deeply pigmented skin, color changes may be apparent in the nailbeds, conjunctiva of the eye, or mucous membranes of the mouth.

Capillary refill is checked on nailbeds to evaluate arterial circulation to an extremity. The nailbed is compressed to produce blanching (lighter color change), released, and the seconds counted until color returns to the blanched area. Normally, nail color should return within 3 seconds after the pressure is released. Patients in shock may have delayed or absent capillary refill.

LEARNING TIPS

Gently squeeze your own nailbed. Do you see the color change? Count the seconds until the color returns. That is your capillary refill time.

Nursing Diagnosis

Examples of applicable nursing diagnoses include the following:

- Decreased cardiac output related to hypovolemia
- Ineffective tissue perfusion: cerebral, related to hypovolemia

Planning

The patient's goals are to maintain vital signs and level of consciousness within normal limits.

Interventions

Patients who have signs or symptoms of shock must be treated immediately. Ongoing data collection helps to iden-

BOX 12-2 Guiding Principles for Treating Shock

- Maintain an open airway and give oxygen as ordered.
- Control external bleeding by direct pressure.
- Keep the patient supine if possible.
- Accurately record vital signs.
- Give IV fluids as ordered.
- Give the patient nothing to eat or drink until surgery is ruled out.

tify the probable cause of shock so that appropriate treatment can be given.

Guiding principles for treating patients in shock are listed in Box 12-2. External bleeding is controlled by applying direct pressure to stop the flow of blood and allow normal coagulation to occur. If bleeding continues after a dressing is in place, additional manual pressure may be indicated. If additional dressings are needed, they are applied over the initial dressing. Elevation of a bleeding extremity helps stop venous bleeding and should be combined with direct pressure. When direct pressure and elevation do not control hemorrhage, pressure-point control should be attempted (Fig. 12-2). The chosen artery for pressure-point control must be proximal to the injury site and must overlies a bony structure.

Vital signs are continually taken, recorded, and reported to the physician if changes occur. The legs may be elevated to heart level to promote venous return to the heart (contraindicated in cardiogenic shock). A blanket can be used to help keep the patient from getting cold; however, the patient also should not be allowed to overheat because this causes peripheral blood vessels to dilate, which draws blood away from vital organs. IV fluids are administered to increase circulating volume.

Figure 12-2 Arterial pressure points to control bleeding.

Tourniquets are used only as a last resort to control bleeding. If a tourniquet is required, a blood pressure cuff, inflated proximal to the bleeding point, is used. Material that is narrow or cuts into the skin should never be used. Tourniquets should not be placed below the knee or elbow or covered with a bandage. Neurovascular damage to the underlying tissues can result from an improperly applied tourniquet.

Evaluation

Criteria indicating a positive outcome for the treatment of shock include a rising blood pressure; a strong pulse; warm, dry skin; and a calmer patient. If signs of shock persist, the physician must be notified. Persistent shock can lead to irreversible shock and death.

Irreversible shock occurs when attempts fail to increase cardiac output and tissue perfusion to vital organs. The body's compensatory mechanisms are no longer helpful, and medical interventions to alleviate shock are unsuccessful. Severely decreased cardiac output and acidosis with multisystem organ failure leads to cardiac arrest and death.

▶ ANAPHYLAXIS

Anaphylaxis is a severe allergic hypersensitivity reaction. The reaction may occur suddenly after initial contact with an allergen or after any subsequent exposure. Signs and symptoms result from a massive release of chemical mediators from mast cells and basophils throughout the body. Chemical mediators lead to vasodilation and capillary leaking that results in hypotension and possible vascular collapse. Signs and symptoms of an allergic reaction are listed in Box 12-3.

Pathophysiology

Anaphylactic shock is a form of distributive shock. There is no loss of blood, but there is excessive vasodilation. Bronchi constrict, and air movement into the lungs becomes increasingly difficult. Increased fluid and mucus are secreted into the bronchial passages. Fluid in the air passages and constricted bronchi cause wheezing. The body is rapidly deprived of needed oxygen by this respiratory system reaction. Signs of severe anaphylaxis include hypotension, decreased level of consciousness, and respiratory distress.

BOX 12-3 Signs and Symptoms of an Allergic Reaction

- Generalized itching and burning
- Urticaria (hives)
- Swelling about the lips and tongue
- Dyspnea
- Bronchospasm and wheezing
- Chest tightness and cough
- Anxiety
- Hypotension

with stridor and cyanosis. One of the increasing causes of anaphylactic shock is latex allergy reaction. This type of allergy is on the rise among health care workers as a result of exposure to health care products such as gloves that are made of latex. Using latex-free products limits exposure and reduces the risk of developing this type of allergy.

Nursing Process for Anaphylaxis

Nursing Diagnosis

Examples of applicable nursing diagnoses include the following:

- Ineffective breathing patterns related to airway constriction
- Decreased cardiac output related to vasodilation

Planning

The patient's goals are to maintain vital signs and level of consciousness within normal limits.

Interventions

When anaphylaxis occurs, airway compromise is an immediate threat to life and must be treated quickly. The patient is given oxygen for respiratory distress. Epinephrine, the drug of choice for treating anaphylaxis, is used to decrease edema, dilate bronchial smooth muscle, and increase blood pressure by vasoconstriction. The standard adult dose of epinephrine is 0.2 mg to 0.5 mg of a 1:1000 solution given subcutaneously. Injections can be repeated every 10 to 15 minutes until the desired effect is achieved or significant side effects occur. Antihistamines are used to control the allergic rash and pruritus. Steroids are given in gradually tapered doses to prevent return of symptoms.

Evaluation

When treatment is effective, the patient should show an immediate reversal of shock symptoms. Breathing is easy, and blood pressure and pulse return to the normal range. Breath sounds become clear, and hives and pruritus subside.

► MAJOR TRAUMA

Major trauma is the fifth leading cause of death in the United States. It mainly affects persons under age 36. Young men have the highest overall incidence of traumatic injury. Victims of major trauma may receive injury to an isolated vital organ or to multiple body systems. To recognize life-threatening conditions and determine priorities of care, a primary survey followed by a secondary survey is conducted to detect additional serious injuries.

Mechanism of Injury

When assessing a victim of major trauma, it is important to determine the mechanism of injury whereby energy is transferred from the environment to the person (Gerontological Issues Box 12-4). Injuries resulting from the transfer of mechanical energy are either penetrating or blunt. Penetrating, or open, injuries may be caused by any sharp object, such as broken glass or a knife, or by projectiles traveling at high speed, such as bullets or fragments from an explosion.

BOX 12-4 GERONTOLOGICAL ISSUES

Injuries and Older Adults

Older adults are at a high risk for falls that put them at risk for bruises, abrasions, cuts, and fractures. Nurses who initially assess older adults with injuries requiring treatment must ask questions and perform assessments that would identify if the patient is a victim of abuse or neglect.

Injuries Caused by Falls versus Battery or Assault

Any unexplained bruises, burns, abrasions, cuts, fractures, evidence of old injuries or bruises, burns, and cuts that are in different stages of healing suggest abuse. The pattern of an injury can also suggest abuse—for example, cigarette burns in areas covered with clothing; bruises or friction burns in a ring around the neck, ankles, or wrists; welts, burns, or bruises in the outline of a hand or belt buckle; multiple similar injuries in an area, such as whip marks across the buttocks or back of the legs; defensive injury pattern of bruising; and trauma to the hands and forearms.

Injuries related to falls have a predictable injury pattern related to the history and report of the fall. When an older adult falls there is bruising of the hands and knees caused when the person attempts to break the fall. Additional bruising or injuries to the front of the body, arms, and head could be caused by hitting furniture or other items during the fall. Skin tears on the arms are common with a fall. Often, a friend or family member sees the older adult starting to fall and tries to steady the person by grabbing the area, tearing the skin. Ask questions to be sure that the report of the fall incident is consistent with the presenting injuries.

Any form of abuse or suspicion of abuse must be reported to the state agency that investigates reports of suspected abuse. It is not the nurse's responsibility to prove that there has been abuse or neglect, only to report incidents or cases of possible abuse.

In blunt, or closed, injuries the skin surface is intact. The injury from blunt trauma usually extends beyond the point of impact to surrounding and underlying structures, such as a broken rib that results from a blow to the chest.

The mechanism of injury from firearms is related to the energy created and dissipated by the bullet into the surrounding tissues. Damage caused by a gunshot wound and the trajectory of the bullet depends on the projectile mass, the type of tissue struck, the striking velocity, and the range. Entrance wounds are round or oval and may be surrounded by an **abrasion** rim. Powder burns are visible if the firearm was discharged at close range. Exit wounds are usually larger than entrance wounds and commonly produce a starburst or stellate wound. Documentation of these wounds should include a clear description of their appearance but should not include the words *entry* or *exit*. Patients with gunshot wounds near the level of the diaphragm should be evaluated for both abdominal and thoracic injuries.

Surface Trauma

Surface trauma is an injury that does not break the skin (closed wound) or an open wound in which the skin surface is broken. Types of closed wounds include contusions (bruises-

ing) and hematomas (collection of blood under the skin). Types of open wounds include abrasions, **lacerations**, avulsions, **amputations**, and punctures.

Abrasions are a scratching of the epidermal and dermal layers of the skin. They bleed very little but can be extremely painful because of inflamed nerve endings. Dirt may be ground into abrasions and can pose an infection threat when large areas of skin are involved.

Lacerations are open wounds resulting from snagging or tearing of tissue. Skin tissue may be partly or completely torn away. Lacerations can cause significant bleeding if blood vessels or arteries are involved.

Avulsions involve a full-thickness skin loss in which wound edges cannot be approximated. This type of injury is often seen in machine operators or in lawn mower and power tool accidents.

An amputation is a partial or complete severing of a body part. In cases of complete amputation the arteries usually spasm and retract into the tissue, resulting in less bleeding than does a partial amputation, in which the lacerated arteries continue to bleed.

Puncture wounds result from sharp, narrow objects such as knives, nails, or high-velocity bullets. They can often be deceptive because the entrance wound may be small with little or no bleeding. It is difficult to estimate the extent of damage to underlying organs as a result. Puncture wounds usually do not bleed profusely unless they are located in the chest or abdomen.

Nursing Process for Surface Trauma

NURSING DIAGNOSIS. Examples of applicable nursing diagnoses include the following:

- Acute pain related to tissue trauma
- Impaired skin integrity related to trauma
- Risk for infection related to tissue trauma

PLANNING. The patient's goals are to maintain vital signs within normal limits, remain free of infection, restore skin integrity, and be pain free.

INTERVENTIONS. The management of closed wounds includes application of ice, elevation, and immobilization of the affected part to decrease swelling and relieve pain. Deformity, pain, and inability of the patient to voluntarily move the affected part may indicate an underlying fracture. The management of open wounds includes application of direct pressure to control bleeding. Open wounds are irrigated with sterile saline solution to thoroughly remove dirt and debris and clean exposed tissue to prevent infection. Injuries that could potentially cause shock are identified and treated accordingly.

Open wounds are treated with a **tetanus** immunization if it has been more than 5 years since one was last given. Tetanus is a disease caused by the bacillus *Clostridium tetani*, which enters the body through an open wound. Tetanus causes seizures, muscle spasms, stiffness of the jaw, coma, and death. Tetanus vaccinations should begin at 2 months of age and be followed by a series of pediatric immunizations

until age 15. Thereafter, booster vaccinations are recommended every 10 years in the absence of an open wound.

If the patient has sustained an amputation, bleeding is controlled with direct pressure and elevation. A tourniquet is applied only as a last resort. If a tourniquet is necessary, it should be made of wide material such as a blood pressure cuff, which is less damaging to nerves and blood vessels. A dressing is applied to the amputated extremity, referred to as the stump. The stump is covered with sterile saline-moistened gauze followed by dry gauze, which is held in place with an elastic bandage for pressure. Amputated parts are taken to the hospital with the patient for possible reattachment. At the hospital, the amputated part is rinsed with saline solution, wrapped in sterile gauze, and placed in a sealed plastic bag, which is then placed in slushy ice water.

For a patient with an injury caused by an impaled object, it is imperative that the object not be removed unless it is obstructing the airway. Removing an impaled object may cause additional trauma. Impaled objects are never cut off, broken off, or shortened unless transportation to the emergency department is otherwise impossible. A bulky dressing is applied around the object to stabilize it and reduce motion.

EVALUATION. When treatment is effective for surface trauma, the patient reports a satisfactory pain level and the patient's wound heals without infection.

Head Trauma

Sharp blows to the head can cause shifting of intracranial contents and lead to brain tissue contusion. The pathophysiology of head trauma can be divided into two phases. The first phase is the initial injury that occurs at the time of the accident and cannot be reversed. The second phase involves intracerebral bleeding and edema from the initial injury, which causes increased intracranial pressure (ICP). Management of head trauma is directed at the second phase and involves decreasing ICP. Early and late signs and symptoms of increased ICP are listed in Box 12-5.

BOX 12-5 Signs and Symptoms of Increased Intracranial Pressure

Early Signs and Symptoms of Increased ICP

- Headache
- Nausea and vomiting
- Amnesia
- Altered level of consciousness
- Changes in speech
- Drowsiness

Late Signs and Symptoms of Increased ICP

- Dilated nonreactive pupils
- Unresponsiveness
- Abnormal posturing
- Widening pulse pressure
- Decreased pulse rate
- Changes in respiratory pattern

Nursing Process for Head Trauma

ASSESSMENT. The mechanism of injury is determined to identify the extent of injury. Loss of consciousness immediately after the injury indicates that a concussion has occurred. The Glasgow Coma Scale (GCS) is used to rate a patient's level of consciousness (Fig. 12-3). The highest score is 15, indicating that the patient is alert and only needs observation. Scores lower than 13 may indicate the need for immediate treatment. Morbidity and mortality are highest for patients with GCS scores of 8 or lower. Pupil size and reaction are monitored and recorded. Dilated or nonreactive pupils indicate increased ICP and a need for immediate intervention.

NURSING DIAGNOSIS. An example of an applicable nursing diagnosis includes the following:

- Ineffective tissue perfusion: cerebral, related to cerebral edema

PLANNING. The patient's goal is to remain alert and oriented.

INTERVENTIONS. Oxygen is administered to the patient who has sustained head trauma. If the patient has an altered level of consciousness or deteriorating respiratory effort, endotracheal intubation is performed. Oxygen delivery and ventilation improve cerebral tissue oxygenation and perfusion. The head of the patient's bed is elevated 15 to 30 degrees, if possible, to reduce ICP. The patient's head position should remain at midline to ensure unobstructed venous

GLASGOW COMA SCALE	
Areas of Response	Points
Eye Opening	
Eyes open spontaneously	4
Eyes open in response to voice	3
Eyes open in response to pain	2
No eye opening response	1

Moderate Head Injury	9–12
Minor Head Injury	13–15

Figure 12-3 The Glasgow Coma Scale is used to determine level of consciousness.

drainage. Intravenous access is established to maintain hemodynamic stability and access for medications. Mannitol IV, an osmotic diuretic, may be ordered to decrease cerebral edema. If the patient is agitated, calming the patient is important because agitation increases ICP.

EVALUATION. Criteria for evaluating a positive outcome in the treatment of head trauma include a GCS of 14 to 15. The goal is met if the patient is alert, oriented, and able to follow verbal commands; vital signs are within normal limits; and pupils are equal in size, shape, and reactivity to light.

Spinal Trauma

Spinal cord injury most often results from motor vehicle crashes, sports injuries, falls, and assaults, with most cases occurring in men ages 16 to 30. The cervical spine is especially vulnerable to traumatic injury. Patients who have sustained severe multiple injuries should be suspected of having a spinal cord injury, especially when they have signs of head trauma. All trauma patients should be treated as though they have a spinal cord injury until proven otherwise. Stabilization of the neck and back with a cervical collar and backboard is essential until spinal cord injury is ruled out (Fig. 12-4).

Nursing Process for Spine Trauma

ASSESSMENT. Spinal nerves are located in the spinal cord and transmit motor and sensory impulses to the body. The higher a traumatic lesion is on the spinal column, the more extensive will be the loss of muscle and sensory function. The patient's muscle functions correlate with the level of spinal injury (Table 12-2). A spinal cord injury at the level of C5 or above interferes with diaphragmatic function and affects respiratory effort, which must be carefully assessed. The patient's level of muscle control and ability to feel each extremity is noted and recorded.

NURSING DIAGNOSIS. Examples of applicable nursing diagnoses include the following:

- Ineffective breathing pattern related to neck injury
- Ineffective airway clearance related to neck injury
- Impaired mobility related to neck injury

PLANNING. Goals for the patient are to maintain arterial blood gases within normal limits and maintain or increase mobility.

INTERVENTIONS. During initial treatment of a patient with head or neck trauma, it is imperative that the neck remain immobilized. A cervical collar and backboard must be in place. If the cervical spinal cord has been traumatized, the effectiveness of breathing may be altered. If signs of respiratory distress are present, the patency of the airway should be maintained using the jaw thrust or chin lift maneuver, along with suction and airway adjuncts as needed. Oxygen is administered to improve tissue oxygenation. Advanced adjunct airway equipment, including an endotracheal tube, must be readily available.

Figure 12-4 Immobilization of a patient suspected of having a spinal cord injury using a backboard and cervical collar.

TABLE 12-2 CORRELATING SPINAL INJURY WITH IMPAIRMENT OF MOTOR FUNCTION

Injury Level	Impairment
S3–S5 or above	Patient unable to tighten anus
L4–L5 or above	Patient unable to flex foot and extend toes
L2–L4 or above	Patient unable to extend and flex legs
C5–C7 or above	Patient unable to extend and flex arms

EVALUATION. Outcome criteria for effectively treating cervical spine trauma include maintaining a regular rate, rhythm, and pattern of breathing; maintaining clear lung sounds by protecting the airway from aspiration; and maintaining intactness of mobility by keeping the spine immobile until injury is ruled out.

Chest Trauma

Chest trauma can damage the heart and lungs and cause life-threatening injuries, including pericardial tamponade, hemothorax, tension pneumothorax, and **flail chest**. Potentially life-threatening injuries include pulmonary and myocardial contusion, aortic and tracheobronchial disruption, and diaphragmatic rupture.

Chest trauma can result in laceration of lung tissue and cause a change in the negative intrapleural pressure. Air or blood leaking into the intrapleural space collapses the lung, resulting in a hemothorax and ineffective ventilation. In a tension pneumothorax, air is trapped in the pleural space during exhalation, resulting in increased pressure on the unaffected lung. The heart, great vessels, and trachea shift toward the unaffected side of the chest. As a result, blood flow to and from the heart is greatly reduced, causing a decrease in cardiac output. An uncorrected tension pneumothorax is fatal.

Chest trauma can also injure the heart and great vessels and reduce the amount of circulating blood volume. The heart may be bruised (myocardial contusion) or may sustain

direct trauma. **Cardiac tamponade** occurs when blood accumulates in the pericardial sac and increases pressure around the heart. The increased pericardial pressure prevents the heart chambers from filling and contracting effectively. A patient with cardiac tamponade exhibits hypotension, tachycardia, and neck vein distention and requires immediate intervention to reduce the pressure in the pericardial sac and restore normal filling and contraction of the heart chambers.

Nursing Process for Chest Trauma

ASSESSMENT. Patients with major chest injuries can have dramatic symptoms. They may exhibit classic signs of shock with cyanosis, dyspnea, and restlessness. The patient's breathing pattern and effectiveness of respirations are assessed. The rise and fall of the chest is observed, as well as symmetrical chest movement. Any bruising on the chest or upper abdomen is noted. Seat belts and restraint systems can cause significant bruising in high-impact crashes.

NURSING DIAGNOSIS. Examples of applicable nursing diagnoses include the following:

- Ineffective breathing pattern related to unstable chest wall segment or lung collapse
- Deficient fluid volume related to hemorrhage
- Decreased cardiac output related to compression of heart and great vessels

PLANNING. Goals for the patient are to maintain arterial blood gases and vital signs within normal limits.

INTERVENTIONS. Patients with major chest injuries require immediate treatment. Supplemental oxygen is administered to promote tissue oxygenation. A chest tube may be inserted by the physician to relieve a pneumothorax or a hemothorax. IV fluids are initiated with 18- or 16-gauge cannulas. The patient's vital signs and oxygen saturation are continuously monitored to detect signs of shock. Respiratory status is observed to detect ineffective ventilation.

Patients with unstable vital signs need immediate surgical intervention in the operating room. Patients with stable vital signs undergo radiographic studies to determine the extent of cardiac or pulmonary injury.

EVALUATION. Outcome criteria for evaluating the achievement of goals for a patient with chest trauma include maintenance of a patent airway and effective breathing pattern. Respirations are of normal rate and depth with equal chest expansion and no dyspnea or cyanosis. Vital signs and oxygen saturation are within normal limits. Jugular vein distention is absent, and the trachea is midline. Urinary output is 30 to 50 mL/hour. Capillary refill is less than 3 seconds, and skin is warm and dry.

Abdominal Trauma

The organs of the abdomen are vulnerable to injury because there is limited bony protection. Injury to organs such as the spleen and liver, which have a rich blood supply, can result in rapid loss of blood volume and **hypovolemic shock**. If the urinary bladder ruptures, urine leaks into the abdomen and blood may be detected at the urinary meatus or perineum. Penetrating trauma can cause lacerations to abdominal organs, resulting in rapid blood loss and hypovolemic shock.

Nursing Process for Abdominal Trauma

ASSESSMENT. Vital signs are taken to detect tachycardia and hypotension from shock. The shape of the abdomen is observed to detect distention from intra-abdominal hemorrhage. Skin color, bruising, open wounds, and penetrating trauma are noted. The abdomen is auscultated for bowel sounds. The perineum is inspected for blood from the urethra.

NURSING DIAGNOSIS. Examples of applicable nursing diagnoses include the following:

- Deficient fluid volume related to abdominal organ injury
- Impaired urinary elimination related to urethral or renal trauma

PLANNING. Goals for the patient are to maintain vital signs and urinary output within normal limits.

INTERVENTIONS. Abdominal organs may be injured as a result of severe blunt or penetrating trauma. If hypotension is present, intra-abdominal hemorrhage may exist. IV fluids are administered via 16- or 18-gauge cannulas to restore circulating volume. A peritoneal lavage may be performed to detect intra-abdominal hemorrhage. An indwelling urinary catheter may be ordered unless blood is present at the urethra. A nasogastric tube may be inserted to decompress the stomach. Open abdominal wounds are covered with a sterile dressing. If abdominal organs are exposed, they are covered with sterile saline-soaked dressings to prevent tissue necrosis.

EVALUATION. Expected outcome criteria for patients with abdominal trauma include effective circulating volume as evidenced by vital signs within normal limits. Skin or mu-

cous membrane color is pink, and skin is warm and dry. Urine output is 30 to 50 mL/hour with no hematuria.

Orthopedic Trauma

Fractured bones can result in blood loss, compromised circulation, infection, and immobility. Unstable pelvic fractures can cause injury to the genitourinary system or disrupt the veins in the pelvis. Fractures of large bones such as the femur and tibia can cause significant blood loss. For example, a fractured femur can cause up to 1500 mL of blood loss and fractured tibia or humerus can cause up to 750 mL of blood loss. Joint dislocations can cause neurovascular compromise by applying pressure to the nerves and blood vessels. Delayed fracture reduction (realignment or setting) can cause **avascular necrosis**, which leads to death of the affected tissue and bone.

Nursing Process for Orthopedic Trauma

ASSESSMENT. Vital signs and pain level are assessed to detect abnormalities. A respiratory assessment is done to detect a pulmonary embolism as a result of a long bone fracture. The injured extremity is inspected, and skin color and capillary refill are noted. Skin integrity, protruding bone, or deformity are noted. Pulses distal to the injury are palpated to assess circulation to the area. Motor function and sensation are assessed to determine the extent of nerve injury.

NURSING DIAGNOSIS. Examples of applicable nursing diagnoses include the following:

- Acute pain related to trauma
- Deficient fluid volume related to hemorrhage
- Impaired physical mobility related to bone injury

PLANNING. Goals for the patient are to maintain vital signs within normal limits, be pain free, and maintain motor and sensory function at baseline level.

INTERVENTIONS. The extremity is splinted and immobilized if there is severe pain or deformity. Splinting promotes comfort and prevents further damage to surrounding tissue by preventing movement of broken bone ends. The joints above and below the affected area are immobilized using a folded towel or a pillow until the patient is evaluated by a physician. Because the extremity may swell after injury, all jewelry is removed before applying a splint. Skin color, temperature, distal pulses, capillary refill, movement, and sensation of the extremity are re-evaluated after splint application. The extremity is elevated and ice applied to reduce edema and relieve pain. Deformed extremities from fractures or dislocations are splinted in the position they are found unless the distal circulation is severely compromised. A patient with a deformed extremity and an absent distal pulse requires immediate medical intervention by a physician to realign the bones. Bleeding from an injured extremity may be severe enough to cause hypovolemic shock. Patients should be monitored for signs of shock and treated accordingly.

LEARNING TIPS

If an extremity is fractured, splint it as it lies to prevent further damage. If the distal circulation is severely compromised, the patient needs immediate medical intervention.

EVALUATION. Outcome criteria for patients with orthopedic trauma include the following:

- Effective circulating volume as evidenced by strong and palpable pulses, normal blood pressure, normal skin color, skin that is warm and dry, and capillary refill that is less than 3 seconds
- Pain controlled to a satisfactory level
- Normal motor function and sensation in the extremity

► BURNS

Burn injuries are acutely painful events that may be dramatic in appearance. Nursing care depends on the extent and depth of the burn injury and the presence of any associated factors such as smoke inhalation, blunt trauma, or fractures. The skin protects the body by preventing bacterial or viral invasion, enhancing temperature regulation, and conserving body fluids and electrolytes. These functions are impaired with a burn injury and can lead to multisystem alterations. The more extensive the burn injury, the greater the potential for complications and mortality. The patient's age may contribute to the risk of mortality as well. Infants under age 2 and elderly patients over age 60 have the highest mortality rates from major burns.

Types of Burns

Burns can be thermal, chemical, or electrical. The most common are thermal burns, caused by steam, scalds, fire injuries, contact with hot substances, or excessive exposure to the sun or radiation. Chemical burns are caused by acids or alkalis. Alkali burns are usually more serious than acid burns because alkalis penetrate deeper and burn longer. The concentration of the chemical agent and the duration of exposure determine the extent and depth of damage. Electrical burns can be caused by low-voltage (alternating) current or high-voltage (alternating or direct) current.

Burn Pathophysiology

Three factors influence the extent of the burn injury: the intensity of the energy source, the duration of exposure to the energy source, and the conductance of the tissue exposed. Increased intensity with increased exposure causes greater tissue damage. Initially there is decreased blood flow to the local burn area, followed by vasodilation and increased **capillary permeability**, which causes fluid and electrolytes to leak from cells into the interstitial space. Fluid can also be lost directly through the burn wound. These responses cause intravascular fluid loss and can place the patient at risk for hypovolemic shock.

Burn Classification

Burns are classified as either major or minor depending on the depth of the burn, the percentage of body surface area burned, the age of the patient, medical history, and the part of the body burned.

Burn depth is described as either partial thickness or full thickness, based on the appearance of the wound (Fig. 12-5). Partial-thickness burns can be either superficial or deep. Superficial **partial-thickness burns** primarily involve the epidermis of the skin. These wounds appear red and cause severe local pain. Common examples of this type of burn include sunburns and minor steam burns. This type of burn typically heals in 2 to 7 days.

Deep partial-thickness burns involve the entire epidermal layer and part of the dermis. These burns appear red or mottled and are more painful. The epidermis is blistered or broken (Fig. 12-6). Deep partial-thickness burns can be-

Figure 12-5 Partial- and full-thickness burns and structures affected.

Figure 12-6 A blistered partial-thickness thermal burn.

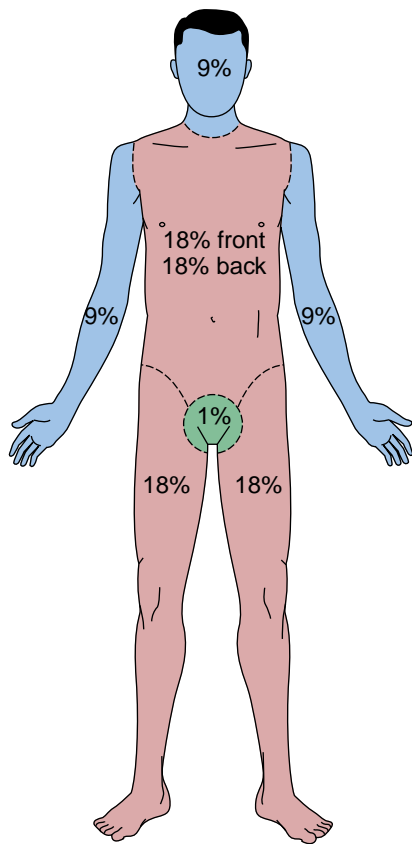

Figure 12-7 The rule of nines is used to estimate the amount of body surface burned using areas approximating 9 percent and multiples of 9 percent.

come full-thickness injuries if they become infected or if there is further trauma to the site.

Full-thickness burns involve all the layers of the skin and the subcutaneous tissue. The burn appears pale white or charred, red or brown, and leathery. Nerve endings have been destroyed, so the severely burned area may be painless; however, the surrounding areas may be very painful and sensitive to air.

The percent of total body surface area (TBSA) burned can be estimated using the **rule of nines**, which divides the body surface into areas equal to 9 percent or a multiple of 9 percent (Fig. 12-7). Deep partial-thickness burns of the face, neck, hands, feet, and genitalia are considered severe even though they do not involve a large percentage of the TBSA. Superficial partial-thickness burns are not included in the estimates of TBSA because the skin does not lose its functioning ability.

Chemical Burns

Chemical burns differ from thermal burns in that the burning process continues until the agent is inactivated, neutralized, or diluted with water. The degree of damage caused by a chemical depends on its concentration and quantity, its mechanism of action, and the duration of contact. Most chemical burns are caused by strong acids or alkalis that get on the skin or clothing. The fumes of strong chemicals can cause pulmonary burns.

To stop the burning process of most chemical burns, all saturated clothing must be removed and the burn copiously irrigated with water. The stream of water should be gentle to avoid further injury to the burned skin. Strong alkalis may cause more severe burns than strong acids because they penetrate more deeply into the tissues. Dry chemicals such as lime must be brushed off before flushing with water because they may be activated by contact with water and cause more damage to the skin.

Eyes involved in chemical burns can be seriously damaged. Eyes should be immediately flushed under running water for at least 5 minutes for an acid burn and 10 to 20 minutes for an alkali burn. Immediately after flushing the eye, the patient should be taken for evaluation and treatment of the injury.

Electrical Burns

Electrical burns frequently are much more serious than they appear. As the electrical current passes through the body, it damages the inner tissues, leaving little evidence of a burn on the skin surface. The type and voltage, resistance, path of transmission through the body, and duration of contact determine the amount of damage sustained. From the point of entry, an electrical current follows the path of least resistance, causing one or more tracks of damage. Energy from a high-voltage electrical current may disrupt the normal electrical rhythm of the heart, causing cardiac arrest. The electrical current also may cause violent muscle contractions, resulting in fractures or dislocations.

Lightning contains massive amounts of energy (up to 50 million volts) and can reach temperatures in excess of 50,000° F. Injuries that result from lightning include cardiac arrest, neurological injuries, blunt trauma, and superficial burns. Surface burns from lightning have a spidery, feathery, branching appearance.

Patients with minor electrical burns may have lost consciousness briefly and are often confused. The skin protects the body by preventing bacterial or viral invasion, enhancing temperature regulation, and conserving body fluids and electrolytes. These functions are impaired with a burn injury and can cause multisystem physiological alterations.

Moderately injured persons show more obvious altered mentation and may be combative or comatose. The more extensive the burn injury, the greater the potential for complications and mortality.

Nursing Process for Burns

Assessment

The assessment of the burn patient begins with the ABCs of the primary survey (Nursing Care Plan Box 12-6). The history should include the mechanism and time of the injury and a description of the surrounding environment, including the presence of noxious chemicals and inhalation of smoke in an enclosed space. The greatest threat to life in a patient with a major burn injury is smoke or heat inhalation, which causes edema in the respiratory passages. Continuous assessment of respiratory status is essential when

BOX 12-6 NURSING CARE PLAN FOR THE PATIENT WITH BURNS**▶ Ineffective airway clearance related to edema from burn injury****OUTCOME**

Patient has patent airway.

EVALUATION OF OUTCOME

Is respiratory rate within normal limits? Is pulse oximetry reading above 90 percent? Can the patient talk without a hoarse voice?

INTERVENTION

Assess for burns to the face, singed nasal hair, or soot around the mouth and nose.

Elevate the head of bed 30 degrees.

RATIONALE

Burns to the face swell rapidly and can compromise the airway. Evidence of soot and singed nasal hair can be a sign of smoke inhalation and pulmonary injury.

Elevation can minimize edema by dependent gravity.

EVALUATION

Is respiratory rate between 10 and 20?
Is pulse oximetry reading above 90 percent?

Can patient talk without a hoarse voice?

▶ Deficient fluid volume related to fluid loss secondary to increased capillary permeability**OUTCOME**

Maintains normal vital signs and has urine output of more than 30 mL/hour.

EVALUATION OF OUTCOME

Are blood pressure, pulse, and respiratory rate within normal limits? Is urinary output 30 mL/hour?

INTERVENTION

Monitor vital signs and report abnormalities.

Give intravenous fluids as ordered.

RATIONALE

Changes in heart rate and blood pressure can be readily detected.

Fluid volume is replaced by infusing intravenous fluids.

EVALUATION

Is pulse rate less than 120?
Is blood pressure within normal limits?
Is patient's urinary output 30 mL/hr?

▶ Acute pain related to major burn**OUTCOME**

Patient states pain is at satisfactory level.

EVALUATION OF OUTCOME

Does patient state pain is relieved?

INTERVENTION

Administer narcotics as ordered.

Keep burned areas covered with sterile dressings.

RATIONALE

Burns cause damage or exposure of the nerve endings.

Air movement over exposed nerve endings increases pain.

EVALUATION

Does patient state pain is relieved?

Does patient report comfort?

▶ Risk for infection related to altered skin integrity**OUTCOME**

Patient remains free from signs of infection.

EVALUATION OF OUTCOME

Does the patient have a normal temperature? Is the white blood cell (WBC) count less than 10,000? Is the burn wound absent of purulent drainage?

INTERVENTION

Wash hands frequently. Wear sterile gloves, gown, and mask when providing care.
Maintain sterile dressings.

Monitor patient's temperature and WBC results.

RATIONALE

Patient's first line of defense (the skin) can no longer provide protection from bacterial or viral invasion.

Abnormal findings are detected and can be reported to physician.

EVALUATION

Are signs of infection present: fever, purulent wound drainage, elevated WBCs?

Is WBC count less than 10,000? Is patient's core temperature normal?

you observe burns or soot on the face, singed nasal hairs, a hoarse voice, or restlessness.

Nursing Diagnosis

Examples of applicable nursing diagnoses include the following:

- Deficient fluid volume related to increased capillary permeability
- Pain related to major burn
- Risk for infection related to impaired skin integrity

Planning

The patient's goals are to maintain vital signs and oxygen saturation within normal limits, have pain relieved, remain free of infection, and restore skin integrity.

Interventions

The first responsibility when caring for a burn victim is to stop any further burning. The victim is removed from the burning area. If clothing is on fire, the victim is placed on the ground and rolled in a blanket. All jewelry is removed as soon as possible because swelling begins soon after injury. The burned area is covered with a dry sterile dressing or clean linen. If the TBSA affected appears to be less than 10%, cool saline-moistened sterile dressings may be applied within the first 10 minutes to help relieve pain and reduce the heat content of the tissue. Generally, wet dressings should not be used if the TBSA is greater than 10 percent because they provide a pathway for infection and cause hypothermia. Blisters provide a protective covering to underlying tissue and should not be ruptured. Cold packs and ice are never placed over the burn area because they can cause further thermal tissue damage.

LEARNING TIPS

Over-the-counter ointments, lotions, butter, and antiseptics are never used on a major burn because they may promote infection, retain heat, and cause more pain.

Burns of the face may swell rapidly and can compromise the airway. Facial and respiratory burns should be suspected if nasal hair, eyebrows, eyelashes, or scalp hair are singed, if soot is on the face or neck, or if the patient has a hoarse voice or is coughing. Facial burns are treated by elevating the head of the bed to 30 degrees to minimize edema. Oxygen is administered to the patient with potential pulmonary injury. Equipment for endotracheal intubation should be readily available. Because large fluid losses occur in burn injuries, an IV infusion with large-bore cannulas should be started. The patient's weight and the extent of the burn determine fluid resuscitation needs.

The patient is kept warm because when skin is lost, a burn victim cannot maintain body heat. IV narcotics are

administered for pain. Partial-thickness burns that involve a small area are cleaned with sterile saline solution, covered with a 1/8-inch layer of an anti-infective cream such as silver sulfadiazine (Silvadene, Flamazine), and covered with bulky, fluffed dressings. Major full-thickness wounds are covered with dry, sterile dressings or linen. Patients with major burns are transferred to a specialized burn unit.

Evaluation

When treatment is effective for deficient fluid volume, vital signs remain normal. The goal for pain is met if the patient reports satisfactory relief. The goal for impaired skin integrity and risk for infection is met if the patient's wounds heal without infection.

CRITICAL THINKING

Mr. Smith
Mr. Smith is a 28-year-old man who was welding close to a natural gas line. The flame of the welder caused the gas line to explode, throwing Mr. Smith 50 feet. He landed on his back. He is brought to the emergency department by the rescue squad. Mr. Smith is awake, alert, and oriented. He has soot around his mouth and nose. He sustained deep partial-thickness burns to his neck, upper chest, and both forearms. He is complaining of pain from his burns and also thoracic back and hip pain. His pulse rate is 100. His blood pressure is 160/90. His respiratory rate is 20.

1. What is the first priority of care for Mr. Smith?
2. Is Mr. Smith at risk for respiratory burns? Why?
3. Are Mr. Smith's vital signs within normal limits?
4. Would wet or dry dressings be preferable for his large areas of deep partial-thickness burns?
5. Mr. Smith is wearing a neck chain and a wedding ring. Should they be removed immediately, or should you wait until Mr. Smith's wife arrives to take them? Why?
6. Mr. Smith continues to complain of hip and back pain. In reviewing his mechanism of injury, what other injuries could Mr. Smith have?

Answers at end of chapter.

▶ HYPOTHERMIA

Normally the body maintains its temperature in a narrow range on either side of 98.6° F (37° C) to allow chemical reactions to work most efficiently. Body heat escapes to the environment through conduction, convection, radiation, and evaporation. Heat loss is inversely proportional to body size and body fat. Fat insulates because it has less blood flow and consequently has less ability to vasodilate and lose heat.

Nursing Process for Hypothermia *Assessment of Stages of Hypothermia*

Hypothermia occurs when the core body temperature falls below 95° F (35° C). As the core temperature falls below 95° F, the body is less able to regulate its temperature and generate body heat, causing progressive loss of body heat to occur.

In cases of mild hypothermia (core temperature between 90° F [32° C] and 95° F [35° C]) the patient is usually alert,

shivering, and may appear clumsy, apathetic, or irritable (Table 12–3). Hypoglycemia can occur because glucose and glycogen stores are depleted by long-term shivering. Respiratory rate, heart rate, and cardiac output decrease.

More severe hypothermia occurs between 85° F and 90° F (29° C and 32° C). Shivering stops and muscle activity decreases. Initially, fine muscle coordination ceases. Then, as core body temperature continues to drop, all muscle activity stops and the muscles become rigid. The patient becomes lethargic and less interested in combating the cold environment. The patient's level of consciousness begins to markedly decrease at 89.6° F (32° C); the patient becomes lethargic and disoriented and begins to hallucinate. The pupils become dilated. As the core body temperature falls to 82° F (28° C), the patient becomes apneic, the pulse becomes slower and weaker, and cardiac dysrhythmias occur. The profoundly hypothermic patient has a core temperature of less than 80° F (27° C) and usually appears dead, with no obtainable vital signs. Determination of death should be made only after aggressive core rewarming to at least 90° F (32° C).

Nursing Diagnosis

An example of an applicable nursing diagnosis includes the following:

- Hypothermia related to cold exposure

Planning

The patient's goal is to maintain a body temperature within normal limits (Nursing Care Plan Box 12–7).

Interventions

Initial treatment of the hypothermic patient consists of rewarming the patient, stabilizing vital functions, and preventing further heat loss. The patient is removed from the cold environment. All wet clothing is removed to prevent further heat loss. The patient's core body temperature guides treatment. If the body temperature is above 82.4° F (28° C), passive rewarming is preferred. The room temperature is set to 70° F to 75° F. The patient is wrapped in

TABLE 12–3 DEFINING CHARACTERISTICS AND OUTCOME CRITERIA FOR HYPOTHERMIA

Core Body Temperature	Defining Characteristics
Below 95° F (35° C)	<ul style="list-style-type: none"> • Skin cold to touch • Lack of coordination • Slurred speech
Below 91.4° F (33° C)	<ul style="list-style-type: none"> • Cardiac dysrhythmias • Cyanosis
Below 89.6° F (32° C)	<ul style="list-style-type: none"> • Shivering replaced by muscle rigidity • Hypotension • Dilated pupils
Below 82.4° F (28° C)	<ul style="list-style-type: none"> • Absent deep tendon reflexes • Hypoventilation (3–4 breaths per minute) • Ventricular fibrillation possible
Below 80.6° F (27° C)	<ul style="list-style-type: none"> • Coma • Flaccid muscles • Fixed, dilated pupils • Ventricular fibrillation to cardiac standstill • Apnea
Outcome Criteria	
<ul style="list-style-type: none"> • Core body temperature is greater than 95° F (35° C). • Patient is alert and oriented. • Cardiac dysrhythmias are absent. • Acid-base balance is normal. • Pupils react normally. 	

warm, dry blankets. Heat loss from the head is reduced by covering the head with warm towels.

For a patient with a core body temperature below 82.4° F (28° C), active rewarming is needed. A heating blanket (carbon-fiber) and radiant heat lights are used. Warm, humidified oxygen is administered. Warm IV fluids are administered. Body temperature is constantly monitored using a rectal probe. Heated **gastric lavage**, heated peritoneal lavage, or cardiopulmonary bypass may be performed for profound hypothermia. Cardiac drugs are given sparingly because as the body warms, peripheral vasodilation occurs. Drugs that were trapped in the peripheral circulation are

BOX 12–7 NURSING CARE PLAN FOR THE PATIENT WITH HYPOTHERMIA

▶ Hypothermia related to exposure to cold environment

OUTCOME

Body temperature and vital signs are within normal limits.

EVALUATION OF OUTCOME

Is patient's body temperature greater than 95° F (35° C)? Is patient alert and oriented? Is cardiac rhythm normal?

INTERVENTION

Monitor patient's core body temperature.
Monitor pulse and electrocardiogram (ECG) rhythm.
Monitor patient's level of consciousness.
Institute rewarming passively or actively as ordered.

RATIONALE

Abnormal body temperature can be detected and treated.
Cardiac dysrhythmias may occur at temperatures below 91.4° F (33° C).
Level of consciousness becomes markedly decreased at temperatures of 32° C (89.6° F).
Rewarming is necessary to return body temperature to desirable range.

EVALUATION

Is body temperature greater than 95° F (35° C)?
Is pulse rate and ECG rhythm normal?
Is the patient alert?
Is body core temperature rising to normal range?

then suddenly released during rewarming, leading to a bolus effect that may cause fatal dysrhythmias.

Evaluation

Desired outcome criteria for the patient with hypothermia is a core body temperature higher than 95° F (35° C), no cardiac dysrhythmias, pulse and blood pressure within normal limits and an alert and oriented status.

► FROSTBITE

The extremities are vulnerable to cold injury. Frostnip occurs when exposed parts of the body become very cold but not frozen. This condition usually is not painful. The skin becomes pale and blanched. Contact with a warm object such as someone's hand may be all that is needed to rewarm the part. During rewarming, the affected part may tingle and become red.

Frostbite occurs when body parts become frozen. The extremities are at increased risk because blood shunts away from them to maintain core body temperature. The affected tissue feels hard and frozen. Most frostbitten parts are white, yellow-white, or blue-white. When rewarmed, the skin appears deep red, hot, and dry to touch. The severity of a cold injury is determined by the duration of the exposure, the temperature to which the body part was exposed, and the wind velocity during exposure.

Interventions for frostbite include protecting the affected area from further trauma. To prevent additional damage, the frostbitten part is handled gently and never rubbed. The injured part is loosely covered with a dry, sterile dressing. The patient is not allowed to stand or walk on a frostbitten foot. The affected extremity is elevated to heart level to minimize edema and promote blood flow.

► HYPERTHERMIA

Usually the body's heat-regulating mechanisms work very well, allowing people to tolerate significant temperature changes. The body's most efficient mechanisms to decrease body heat are sweating and dilation of blood vessels in the skin. When blood vessels dilate, blood comes to the skin surface to increase the rate of radiation of heat from the body. However, when these mechanisms become overwhelmed, the consequences can be disastrous and irreversible. Those at greatest risk for heat illnesses include children, elderly people, and patients with cardiac disease.

Hyperthermia results when thermoregulation breaks down because of excess heat generation, an inability to dissipate heat, overwhelming environmental heat, or a combination of these factors. Unlike a fever, in which the thermal

set point is elevated, in heat illness the thermal set point remains normal and hyperthermia occurs because of an inability to dissipate heat. Antipyretics are of no use in hyperthermia and in fact may contribute to complications.

Stages of Hyperthermia

Assessment

Illness from heat exposure can take three forms: heat cramps, heat exhaustion, and **heatstroke** (Box 12–8). As heat illness progresses, circulating blood volume decreases, causing dehydration. Fluid intake is crucial in the prevention of heat illness.

Heat Cramps

Heat cramps, the mildest form of heat illness, involve painful muscle spasms, usually in the legs or abdomen, that occur after strenuous exercise. Large amounts of salt and water can be lost as a result of excessive sweating, causing stressed muscles to spasm. When heat cramps occur, the patient should be removed from the hot environment. Tight clothing should be loosened. The patient should sit or lie down until the cramps subside. The patient should be given water or a diluted (half-strength) balanced electrolyte solution to drink. With adequate rest and fluid replacement, the body adjusts the distribution of electrolytes and the cramps disappear.

Heat Exhaustion

Heat exhaustion occurs when the body loses so much water and electrolytes through heavy sweating that hypovolemia occurs. Heat exhaustion is largely a manifestation of the strain placed on the cardiovascular system attempting to maintain normothermia. Cerebral function is unimpaired, although the patient may show minor irritability and poor

BOX 12-8 Defining Characteristics and Outcome Criteria for Environmental Hyperthermia

Defining Characteristics

Early signs:

- Core body temperature 100.4° F to 102.2° F (38° C to 39° C)
- Diaphoresis
- Cool, clammy skin
- Dizziness
- Pulse rate > 100

Late signs:

- Increasing body core temperature of 106° F (41° C) or more
- Hot, dry, flushed skin
- Altered mental status
- Coma or seizures possible
- Hypotension

Outcome Criteria

- Core body temperature less than 101° F (38.3° C)
- Patient alert and oriented
- Skin warm and dry to touch

LEARNING TIPS

Older adults are vulnerable to hyperthermia. In times of extreme summer temperatures, elderly people who live alone should be checked to make sure they are not experiencing hyperthermia. If they do not have fans or air conditioning available, they should be taken to a cooler environment.

judgment. The ability to sweat remains. The skin is usually cold and clammy and the face gray. Sodium and water loss cause the patient to become dehydrated. The body temperature is usually normal or slightly elevated, from 100.4° F to 102.2° F (38° C to 39° C). The patient may complain of feeling dizzy, weak, or faint, with nausea or a headache. Vomiting and diarrhea may also be present.

The patient should be removed from the hot environment and tight clothing loosened. If the patient is fully alert, oral fluids (water or diluted balanced salt solution) are administered. If symptoms do not resolve promptly, the patient will need IV fluids.

Heatstroke

If symptoms of heat exhaustion are not treated, heatstroke can develop. Altered mental status and an inability to sweat are key symptoms in heatstroke. Some patients show confusion, irrational behavior, or psychosis; others develop a coma or seizures. Because the sweating mechanism has been overwhelmed, many heatstroke victims have hot, dry, flushed skin. The body temperature rises rapidly to 106° F (41° C) or more, and the patient's level of consciousness decreases. If heatstroke is not treated, death results.

Nursing Process for Hyperthermia

Nursing Diagnosis

Examples of applicable nursing diagnoses include the following:

- Hyperthermia related to exposure to hot environment
- Deficient fluid volume related to hypovolemia

Planning

The patient's goal is to maintain the body temperature within normal limits.

Interventions

Emergency treatment of heatstroke consists of reducing the body temperature and rapidly cooling the victim. The patient should be undressed and allowed to cool. Evaporative cooling is the most efficient method of cooling. Tepid water can be used as a mist spray over the patient, with a strong continual breeze from electric fans to enhance evaporation. If the patient is hypotensive, IV fluids are administered.

Patients suffering from heatstroke are admitted to the intensive care unit because late complications can appear suddenly and require immediate management. Relatively common occurrences include seizures, cerebral ischemia, renal failure, late cardiac decompensation, and gastrointestinal bleeding. Long-term prognosis is variable, depending on the patient's previous state of health and length of time under heat stress.

Evaluation

Desired outcome criteria for the hyperthermic patient include a core body temperature that is below 101° F (38.3° C), warm and dry skin, a strong pulse, blood pressure within normal limits, and an alert and oriented status.

► POISONING AND DRUG OVERDOSE

Poisons are introduced into the body by ingestion, inhalation, injection, absorption, or venom bites. Poisons act by changing cellular metabolism, causing damage to structures, or disturbing function. Many toxins and poisons alter the patient's mental status, making it difficult to obtain an accurate history.

Nursing Process for Poisoning

Assessment

The primary nursing responsibility is to recognize that a poisoning has occurred and then attempt to determine the nature of the poison. The method of exposure is established so that removal or interruption of the toxin can begin. Most ingested poisons are drugs, but about one-third of poisonings are caused by cleaners, soaps, insecticides, acids, or alkalis. Many household plants are poisonous if they are accidentally ingested. Some plants cause local irritation of the skin, and others can affect the circulatory system, gastrointestinal tract, or central nervous system.

Objects at the scene, such as empty bottles, scattered pills, or chemicals, should be sent with the patient to the hospital to help establish the identity of the substance. The patient's physical appearance may also give a clue to the type of substance taken. Intravenous needle tracks, burns, erythema, and flushed skin may help identify the poison or toxic exposure. Poison control centers have access to information concerning virtually all poisonous substances, available antidotes, and appropriate emergency treatment.

Nursing Diagnosis

An example of an applicable nursing diagnosis includes the following:

- Risk for injury related to absorption of poisoning agent

Planning

The patient's goal is to maintain normal vital signs and be free of injury.

Interventions for Ingested Poisons

Emergency treatment for the patient who has ingested poison includes rapid removal of the poison from the gastrointestinal tract and dilution of the remainder. Syrup of ipecac can be used to induce vomiting if the patient is fully alert and if the ingested substance is nonerosive and not petroleum based. The usual dose of syrup of ipecac is 15 mL for children ages 1 to 5 and 30 mL for ages 6 and up. The syrup is followed by several glasses of water. Vomiting usually occurs within 30 minutes. The dose may be repeated once if vomiting does not occur after 30 minutes.

Gastric lavage may be indicated to flush ingested poisons from the stomach. A large gastric tube is inserted via the nose or mouth into the patient's stomach. Water is instilled via the tube in 60-mL amounts and withdrawn to evacuate any remaining poison. This is repeated until 2 L of water

have been lavaged or until the gastric return is clear of any pill fragments or substance. Before removing the gastric lavage tube, activated charcoal with sorbitol can be administered to absorb toxins and facilitate rapid transit of the poison through the intestinal tract.

Evaluation

A desired outcome is that the patient remains free from injury and has stable vital signs.

Inhaled Poisons

Inhaled poisons include natural gas, pesticides, carbon monoxide, chlorine, and other gases. Carbon monoxide is odorless and can produce profound hypoxia by combining with hemoglobin molecules (and displacing oxygen) in red blood cells. The patient's carboxyhemoglobin levels are monitored to direct appropriate therapy. Inhalation of chlorine is very irritating to the respiratory system and can produce airway obstruction and pulmonary edema.

When an inhalation injury occurs, the patient must be moved into fresh air and away from the toxin. Supplemental oxygen is given as ordered. A patient exposed to prolonged inhalation of a poison may experience lung damage. Respiratory status must be closely monitored to detect complications.

Injected Poisons

Injected poisons pose compelling problems because they are difficult to remove or dilute. Usually they result from drug overdose, but they can also result from the bites and stings of insects or animals. Local swelling and tissue destruction may occur at the injection site. All jewelry is removed because swelling may occur. A cold pack is applied to decrease local pain and swelling around the injection site. The identity of the injected drug or toxin must be established so that adverse effects can be anticipated and managed.

Insects

Insect stings or bites cause anaphylaxis in a small percentage of people; however, symptoms are typically limited to localized pain, swelling, heat, and redness. Potentially dangerous stings or bites may come from bees, wasps, yellow jackets, hornets, certain ants, scorpions, and some spiders. Treatment involves applying ice to the site and elevating the affected part. Cellulitis can occur hours later and may require medical treatment.

When a patient has sustained a bee or wasp sting, examine the area for the stinger and remove it by gently scraping it off the skin. Tweezers or forceps are not used to remove the stinger because squeezing the stinger can inject more venom into the patient. Placing ice over the injury site may help slow the rate of toxin absorption.

Two types of spiders—the black widow and the brown recluse—can inflict serious and sometimes life-threatening bites. Both species are found throughout the United States, and antivenin is available for treatment. Black widow spiders are glossy black and have a distinctive, bright red-

orange marking in the shape of an hourglass on the abdomen. They are found in dry, dim places around buildings, in woodpiles, and among debris. Their venom is neurotoxic and causes systemic symptoms, including cramping of large muscle groups, dyspnea, weakness, sweating, nausea, vomiting, and rash. Death is uncommon, and symptoms generally subside in 48 hours.

The brown recluse spider is dull brown and has a dark violin-shaped mark on its back. It tends to live in dark areas, under rocks, in woodpiles, and in old abandoned buildings. The venom of the brown recluse causes severe local tissue damage. The area becomes red, swollen, and tender and develops a pale, mottled, cyanotic center. A large ulcer can develop within 48 hours if not treated promptly. Systemic symptoms include fever, chills, nausea, vomiting, arthralgia, and weakness.

Snake Bites

Only a small percentage of snake bites are caused by poisonous snakes. The most prevalent poisonous snakes are the coral snake and the pit vipers, which include rattlesnakes, copperheads, and cottonmouth moccasins. Envenomation occurs when the snake's hollow fangs puncture the skin and inject venom, which is stored in sacs located at the back of the snake's head. A poisonous snake bite has two small puncture wounds with surrounding discoloration, swelling, and pain. Envenomation by any of the pit viper snakes produces burning pain at the site of the injury. Swelling and discoloration occur within 5 to 10 minutes after the bite.

Interventions are focused on decreasing the circulation of venom throughout the patient's system by keeping the patient calm and immobilizing the affected part. Venous tourniquets placed above and below the fang marks help limit the spread of venom through the veins of the extremity. The tourniquets should not stop arterial flow. The patient's pulse should be palpable below the tourniquets after they are applied. The site of the bite is cleaned with soap and water. The patient is kept calm until antivenin can be given. Medical treatment of the patient with a poisonous snake bite should be directed by an experienced toxicologist.

▶ NEAR-DROWNING

Drowning is death from **asphyxia** after submersion in water. Near-drowning is submersion with at least temporary survival of the victim. Life-threatening complications of near-drowning are respiratory failure and ischemic neurological injury from hypoxia and acidosis. When submersion occurs, conscious victims hold their breath until reflex inspiratory efforts override breath holding. As water is aspirated, laryngospasm occurs, producing severe hypoxia. In wet drowning the laryngospasm is less prolonged and fluid enters the lungs after the vocal cords relax. In dry drowning the laryngospasm is prolonged and prevents fluid from entering the lungs. Most successfully resuscitated victims experience dry drowning.

If a person survives submersion, acute respiratory failure may follow. The incidence of serious pulmonary complications is high in this group. Symptoms of impaired gas ex-

change may be delayed as long as 24 hours after the incident. Contaminants in the water can irritate the pulmonary system and cause additional complications. Cardiovascular complications can occur secondary to hypoxia and metabolic acidosis, resulting in dysrhythmias.

Nursing Process for Near-Drowning

Assessment

Vital signs are assessed to detect abnormal readings. Respiratory rate and pattern are observed. Any dyspnea or signs of airway obstruction are noted. Skin color or cyanosis is noted. The patient's level of consciousness may be altered due to anoxia.

Nursing Diagnosis

An example of an applicable nursing diagnosis includes the following:

- Ineffective tissue perfusion related to severe anoxia

Planning

The patient's goal is to maintain level of consciousness and vital signs within normal range, with clear breath sounds that are equal bilaterally.

Interventions

Resuscitative efforts should always start with the ABCs of the primary survey. Supplemental oxygen is administered to increase tissue oxygenation. Adjunct airway equipment should be available. Endotracheal intubation and insertion of a nasogastric tube to decompress the stomach may be needed.

Aggressive resuscitative efforts should be used on victims of cold water drowning when submersion time is 1 hour or less. Hypothermia can decrease the metabolic needs of the brain and contribute to neurological recovery after prolonged submersion.

Evaluation

Factors that influence the outcome of near-drowning include the temperature of the water, length of time submerged, cleanliness of the water, and age of the victim. The younger the patient, the better the chance for survival. Expected outcome criteria to evaluate the near-drowning patient include normal respiratory rate and pattern and normal vital signs, an alert and oriented status, and skin that is warm and dry to touch with capillary refill of less than 3 seconds.

► PSYCHIATRIC EMERGENCIES

A psychiatric emergency exists when people no longer possess the coping skills necessary to maintain their usual level of functioning. The patient's moods, thoughts, or actions may be so disordered that the patient has the potential to endanger or harm self or others if the situation is not quickly controlled. If acute psychiatric episodes are not managed, they can result in life-threatening, suicidal, violent, or psychologically damaging behavior. If an emotional trauma is not managed successfully, a condition known as posttraumatic stress disorder may result in which tension,

anxiety, guilt, and fear concerning the traumatic event produce cognitive, affective, and behavioral responses to memories of the event long after the event has passed.

Nursing Process for Psychiatric Emergencies

Assessment

Causes of psychiatric emergency symptoms are varied and require thorough assessment of the patient's history and mental status. Information from the patient's medical history may produce possible organic causes contributing to the patient's presenting symptoms. Endocrine dysfunction, electrolyte abnormalities, and head trauma are examples of medical conditions that may cause changes in mental status. A medication history is obtained to determine compliance with medication regimens and any recent changes in medications. Information regarding recent use of alcohol or illicit drugs should be obtained because these substances can heighten psychiatric emergencies. A brief mental status examination is conducted. The patient's appearance, behavior, cognitive function, thought content, and thought processes are noted. The nurse determines whether the patient is having problems concentrating, following instructions, or recalling his or her medical history.

A crisis occurs when people enter a sudden state of emotional turmoil and are unable to resolve the situation with their own resources. Common emotional or behavioral manifestations of psychiatric crises include responses to stressful events, anxiety, depression, psychosis, and mania. Anxiety may range in severity from mild to panic. Panic evolves into complete disorganization and loss of control. The patient in panic is terrified and needs external controls to avoid harm. Depression is an affective disorder most commonly characterized by physical ailments and somatizations. An assessment of the person's suicide risk is important. Antidepressants are used to restore the balance of brain neurochemicals and diminish the symptoms of depression. Psychotic patients experience impaired thought processes and thought content characterized by hallucinations, delusions, ideas of reference, thought broadcasting, and thought insertion. Psychotic thinking and abnormal speech patterns interfere with the patient's attempt to communicate rationally. Manic behavior is most commonly the result of manic-depressive (bipolar) disorder. Manic persons typically exhibit bizarre, extreme, and hyperactive behaviors. Manic persons are also at high risk for injuring themselves or others.

Nursing Diagnosis

Examples of applicable nursing diagnoses include the following:

- Anxiety related to situational stress
- Risk for injury related to impaired judgment
- Fear related to alteration in thought content

Planning

The patient's goals are to reduce anxiety, remain free from injury, and reduce fear.

Interventions

During crisis intervention, strategies are designed to reduce the negative impact of a distressing event. It is important to establish an atmosphere of trust so the patient feels free to discuss problems. The patient's physical and emotional complaints are acknowledged by using active listening. The environment is made safe, and external sources of stimulation are reduced. When speaking to the patient, the nurse speaks directly and truthfully and never promises unachievable things. Trusted supportive members of the patient's family may be involved to calm the person and encourage cooperation. Bystanders or adverse family members who could create further complications are restricted. Do not threaten, challenge, or argue with a disturbed patient. Correct misconceptions, but not in an argumentative manner. Be firm but unthreatening and show respect for the patient by not laughing or joking.

Interventions involve reducing fear and potential harm to self or others. Sometimes physical restraint is necessary. Restraint equipment is not shown to the patient until sufficient help is available to use it. The patient's behavior is documented on the chart, along with written physician orders for the use of physical restraints. The restraints must not restrict circulation. Pulses and capillary refill are assessed frequently while the patient is restrained.

Antipsychotic medications are administered as ordered, and their response is monitored. Haloperidol (Haldol) is used if a patient needs rapid tranquilization.

Evaluation

The patient's goals are met if the patient reports reduced anxiety and fear and remains free from injury.

► DISASTER RESPONSE

Disaster is defined as any event that overwhelms existing personnel, facilities, equipment, and capabilities of a responding agency, institution, or community. Potential sources of disaster include internal events such as fires and explosions; external events such as floods, storms, fires, earthquakes, and tornados; and created events such as motor vehicle accidents, plane crashes, and acts of terrorism.

External disasters involve a communitywide response of several different agencies, including emergency medical system (EMS) providers, fire agencies, law enforcement, and hospitals. These agencies work together to coordinate search, rescue, transportation, communication, and treatment of multiple victims. Hospitals serve as the major treatment area for victims of a disaster, referred to as casualties. When a disaster occurs, the hospital activates its disaster plan, which outlines specific duties for each nursing unit

and the staff for each nonnursing department as well. Typically each nursing unit prepares for the influx of casualties by calling all available off-duty staff to report to work and by discharging noncritical patients. In a hospital disaster plan, each nursing unit is usually designated to receive specific types of casualties, such as major trauma, burns, medical, pediatric, or psychiatric. The emergency department serves as the **triage** and stabilization area for the casualties. To facilitate the triage (sorting for the purpose of assigning priorities), stabilization, and transportation of numerous casualties, additional emergency department staff may be called in to work. In addition, the hospital disaster plan may require assigning one or more staff from each nursing unit and each nonnursing department to a specific area or task within the emergency department, such as triage, first aid, critical care, burn treatment area, family room, or transportation.

During a disaster, decision making and prioritization of patient care are guided by the resources and personnel available. Patients who are seriously injured and have the greatest chance of full recovery are treated first. Each hospital, as well as each agency involved in responding to a disaster, follows a disaster response plan that outlines the roles and responsibilities of the agency staff and the procedures to follow when interacting with the media, families, other agencies, and casualties. Disaster drills are conducted on a regular basis to evaluate and rework plans. You should be familiar with your agency's disaster plans and policies and know your role and responsibilities in a disaster.

Answers to CRITICAL THINKING

Mr. Smith

1. The airway is the first priority because edema from inhalation burns can occlude the airway.
2. You know that Mr. Smith is at risk for respiratory burns because of the soot near his mouth and nose. He should be closely monitored. Assessment should include respiratory rate and pattern and the patient's ability to speak without a hoarse voice. Abnormal breathing sounds such as wheezing indicate partial upper airway occlusion.
3. The vital signs are within normal limits.
4. Deep partial-thickness burns should be covered with dry dressings. Because the skin can no longer protect the patient, wet dressings provide a medium for bacterial invasion. Wet dressings can also cause a decrease in body temperature because the skin can no longer maintain thermoregulation.
5. Jewelry should always be immediately removed before edema formation begins.
6. Mr. Smith was involved in an explosive incident and thrown 50 feet. He could have sustained fractures of the pelvis or back. He also may have internal organ injuries from blunt trauma.

REVIEW QUESTIONS

1. You are assessing a patient who is hypovolemic. Which of the following signs and symptoms indicate that the patient is experiencing profound shock?
 - a. Sacral edema
 - b. Jugular vein distention
 - c. Palpable, bounding pulse
 - d. Decreasing blood pressure
2. You are caring for a patient who is hemorrhaging from a puncture wound. Which one of the following interventions would you use first to control the arterial bleeding?
 - a. Application of a tourniquet
 - b. Application of pressure
 - c. Pressure point massage
 - d. Pressure dressing
3. Which one of the following is an immediate threat to life during acute anaphylaxis?
 - a. Airway obstruction
 - b. Generalized itching
 - c. Hypotension
 - d. Tachycardia
4. When interacting with a psychotic patient, which of the following interventions is helpful to gain the patient's trust?
 - a. Play along
 - b. Make promises
 - c. Avoid eye contact
 - d. Show respect
5. A patient whose home has burned is admitted to the emergency room. Which of the following symptoms would alert you to the potential for inhalation injury?
 - a. Peripheral edema
 - b. Singed nasal hairs
 - c. Jugular vein distention
 - d. Increased capillary refill time

UNIT THREE

UNDERSTANDING LIFE SPAN
INFLUENCES ON HEALTH
AND ILLNESS

13

INFLUENCES ON HEALTH AND ILLNESS

Linda S. Williams

KEY TERMS

chronic illness (KRAH-nick **ILL**-nes)
 developmental stage (DEE-vell-up-**MEN**-tal STAYJ)
 hopelessness (**HOHP**-less-nes)
 health (HELLTH)
 illness (**ILL**-ness)
 powerlessness (**POW**-er-less-nes)
 respite care (**RES**-pit CARE)
 spirituality (SPIHR-it-u-**AL**-it-tee)
 terminal illness (**TERM**-in-al **ILL**-nes)

QUESTIONS TO GUIDE YOUR READING

1. How would you define health and illness?
2. What are the eight developmental stages?
3. How would you define chronic illness?
4. What are the effects of chronic illness?
5. What special needs do caregivers have?
6. What are the benefits of respite care?
7. What are health promotion methods?
8. What nursing interventions would you use for a chronically ill patient?
9. What nursing care would you provide for terminally ill patients and their significant others?

► HEALTH, WELLNESS, AND ILLNESS

Nurses generally care for people who are ill and need assistance to meet their basic needs, so it may be difficult to visualize or imagine patients as healthy and productive people. Developing an understanding of health, wellness, and illness can positively affect nursing care. People are made up of physical, psychological, cultural, sociological, and spiritual aspects. All these aspects need to be considered when studying health, wellness, and illness.

LEARNING TIPS

To foster understanding of how an ill patient, especially an older patient, was once healthy and active, ask family members to bring in photos showing the patient at various ages or engaged in favorite activities. Displaying these photos in the patient's room or on a hallway bulletin board allows caregivers to see the patient in times not associated with illness.

The concept of illness is one of imbalance or disharmony resulting from a problem that causes one to be sick. Physical causes of illness are usually easily recognized, such as exercise that induces an asthma attack in an asthmatic person or a fall that breaks a bone. Illness can also result from a psychological, sociological, cultural, or spiritual imbalance. After the loss of a spouse, one may experience loneliness and depression and a loss of balance in the social and psychological aspects of life. A hospitalization may increase disharmony if cultural beliefs and practices are not understood or upheld by health care providers. A person faced with a terminal diagnosis may lose hope and direction in life, causing anxiety and despair. So rather than being exclusive concepts, **health** and **illness** are dynamic and ever-changing states of being. A health crisis such as a myocardial infarction (MI) overwhelms a patient's ability to maintain a normal level of wellness. Two months after the MI, however, this patient could be enjoying a higher level of wellness than before the MI if he has lost weight, is walking daily, and is eating a nutritious low-fat diet.

▶ THE NURSE'S ROLE IN SUPPORTING AND PROMOTING WELLNESS

The goal of nursing care can best be defined as helping patients achieve their highest possible level of wellness. To do this, consider the patient's strengths, assets, and resources, as well as weaknesses, liabilities, and disabilities. Encourage the patient to take a personal inventory and recognize what is required to attain wellness. Working together, the patient, family, and members of the health care team set wellness goals and develop a plan of action that will help meet those goals. The plan of care focuses on the following six main areas:

- Mobilizing resources
- Providing a safe and adaptable environment
- Assisting the patient to learn about his or her health problem and treatment
- Performing and teaching the patient to perform health care procedures
- Anticipating problems and recognizing potential crises
- Evaluating the plan and progress toward the goals with the patient and family

▶ DEVELOPMENTAL STAGES

The **developmental stages** of life focus on the balance a person must achieve for high-level wellness within that stage. Across the life span at various ages and stages of life there are recognized potential threats to health. Risk factors are related to growth and development, physical attributes, family, behavior, social interactions, environment, lifestyle choices, and ethnic background.

Developmental stages begin at birth and continue through death. Erik Erikson proposed eight stages of psychological development: 0 to 1 year—trust versus mistrust; 2 to 3 years—autonomy versus shame and doubt; 4 to 5 years—initiative versus guilt; 6 to 12 years—industry versus inferiority; 13 to 18 years—identity versus role confusion; young adult—intimacy versus isolation; middle-aged adult—generativity versus self-absorption; old adult—ego integrity versus despair.^{1,2} Developmental stages for the young adult, middle-aged adult, and older adult are discussed here.

The Young Adult

Developing intimacy versus isolation is the sixth psychological development task. The young adult's task is to develop relationships with a spouse, family, or friends that are warm, affectionate, and developed through fondness, understanding, caring, or love. When this stage is not successfully resolved, the individual often experiences isolation from others. This stage encompasses ages 18 to 45. Physically, growth is usually completed by age 20. Socially, young adults begin to move away from their parents to develop their own families. The young adult begins to attempt to develop a place in society through school, work, and social activities. This is the stage in which intimacy or closeness de-

velops with partners and friends. The decision to marry, have children, or have a pet is demonstration of the person's striving for intimacy. Challenges to intimacy are tasks that must be overcome in this stage. Within a marriage, communication, financial issues, and the needs of children must be successfully met to maintain the marriage. There are cultural issues facing the young adult. Melding one's traditions and customs with the traditions and customs of a spouse, family, or friends is a major responsibility, as is the passing on of culture to children. Values and beliefs, which arise from an individual's culture or conscience, serve as guidelines for behavior.

Common Health Concerns

The lifestyle choices of young adults may place their health at risk. Health promotion for this age group is mainly focused on preventing or limiting possible risk factors. Young adults need to understand the importance of diet and exercise in maintaining health. They are also in the position of teaching these lifelong habits to their children. Positive health practices in young adulthood help prevent long-term complications. Maintaining an aerobic exercise program and following a diet that is low in fat help keep weight down and avoid obesity, as well as promoting cardiovascular health. Blood cholesterol should be kept below 200 mg/dL. Avoiding sun exposure and using sunscreen are important to avoid sunburn and permanent sun damage to the skin. Years of sun exposure may cause skin cancer. Tobacco use started in the teen years is often carried on throughout young adulthood and is linked to chronic bronchitis, emphysema, and oral, throat, and lung cancer in later life.

In the early part of young adulthood, the individual is in the workforce or is preparing for the work world with a college or vocational education. Being a novice in the work world and accepting new independence, freedom, and responsibilities can introduce stressors into the young adult's life. Unfortunately, overeating, alcohol use, drug use, cigarette smoking, and family violence are all negative lifestyle choices and poor coping mechanisms for stress. Young adults need to be aware of their individual stress and be encouraged to develop positive coping mechanisms for stress. Exercise, support groups, music, and meditation are just a few positive ways to cope with stress.

Although marriage commonly occurs within this age group, this group also has the highest rate of divorce. Trying to make a marriage work is a hard task. The blending of two people into a couple requires a lot of creative communication and loving care. When stressors overwhelm the couple's coping mechanisms or coping strategy, the marriage relationship is in trouble. Sometimes because of the high rate of divorce many couples choose to live together without being married. However, the avoidance of making a commitment may set these relationships up for failure.

If young adults are sexually active with multiple partners, they are at risk for sexually transmitted diseases. Safer sex guidelines and information on birth control should be available for the sexually active young adult.

Pregnancy is a common health occurrence for women in this age group. Because research indicates that a mother's health practices directly affect the health of the developing fetus, nutrition, drug and alcohol use, physical health, and effective stress coping mechanisms are lifestyle issues that need to be discussed with every pregnant woman. Prenatal care should be encouraged and readily available to pregnant women.

CRITICAL THINKING

Rita
Rita, age 25, and her husband are trying to start a family. Rita visits her physician, who confirms that she is pregnant. Which information and health practices should Rita and her husband be instructed in during a prenatal health examination?

Answers at end of chapter.

The Middle-Aged Adult

People ages 45 to 65 are considered to be in the middle adult years. The psychological developmental task of this age group is developing generativity versus self-absorption. Generativity is demonstrated by a concern and support for others, along with a vision for future generations. The unresolved conflict would be preoccupation with personal needs or self-absorption. Physically, middle adults start to notice signs of decreased endurance and intolerance for physical exercise if they have not maintained healthy lifestyle choices. Socially, their children are adolescents or young adults who require extra attention and assistance with entering adulthood. Along with this, middle-aged adults may also be faced with the challenging demands of caring for aging parents. Middle adults also look over their lives and assess accomplishments versus unrealized goals. Midlife crisis may occur as this self-inspection leads to a desire to change work, social, or family situations to try to meet unrealized goals. Planning for retirement by developing meaningful pastimes and interests outside of work and preparing for financial security is another important task during this period.

Common Health Concerns

Adverse health choices, such as smoking, use of alcohol, drug use, sedentary lifestyle, diet high in saturated fat, and overeating, often have serious consequences for middle adulthood. Hypertension and heart disease are major health concerns, as are chronic bronchitis, emphysema, and lung cancer. Cardiovascular disease and cancer cause most of the deaths in this age group. However, middle adulthood is not too late to begin lifestyle changes that positively affect health. Replacing high-risk habits with lifestyle choices such as regular exercise, healthful eating, weight reduction, and positive stress-coping mechanisms are positive changes. Helping adults recognize the benefits of these lifestyle choices and empowering them to change is the major challenge for health care professionals for this age group.

CRITICAL THINKING

Mr. Paul
Fifty-four-year-old Mr. Paul calls the doctor's office for the fourth time this month complaining of severe indigestion and requesting a medication that will work to fix it. He has refused to have an x-ray examination or other diagnostic tests because he "can't fit them into" his "busy schedule." Mr. Paul has his own insurance business. His wife quit her job to monitor the activities of their 13-year-old son, who was not going to school every day. The couple's twin daughters are both in college out of state.

1. Why might Mr. Paul be experiencing health problems?
2. What is affecting the developmental tasks Mr. Paul needs to perform?

Answers at end of chapter.

The Older Adult

Development and aging seem to be terms that are directly opposite because aging is commonly viewed as deterioration or a "downhill slide" to inevitable death. This negative view of aging is supported by cultures that idolize and strive to maintain youthfulness. Being old is often equated with outliving one's usefulness. However, people are living productive, fulfilling lives into their 80s, 90s, and even 100s. Many of these older adults are likely to be found working in their gardens, exercising, or socializing (Fig. 13-1).

Figure 13-1 Socialization helps older adults maintain integrity.

The developmental goal for people age 65 or older is integrity versus despair. Health state, environment, relationships, and lifestyle choices influence the diversity found in this group. Physical health is often a concern for older adults. Chronic health problems that require medication and treatment often also require lifestyle changes or adaptations. Because psychological development for the older adult is characterized by striving for integrity, older adults often spend time reflecting on their lives. Integrity is measured by feeling satisfied with having lived a full and productive life. When this life reflection is characterized by misgivings, missed opportunities, dissatisfaction, and disappointment, the older adult feels hopeless despair.

Coping with loss is a major challenge for older adults. Life events such as retirement, illness, or death of a spouse and changes such as decreased physical ability are losses facing older adults. Coping with aging is also influenced by the individual's cultural beliefs. Cultural viewpoints on the social role and value of aged members affect the health of older adults. Sometimes the greatest loss for older adults is their lack of connection with the world and a lack of being part of a greater purpose.

Common Health Concerns

As a result of changes in older people's health, the focus of care is on assisting older adults to meet their physical, psychological, cultural, sociological, and spiritual needs. Encouraging the use of community services for seniors and promoting self-care are important. Most older adults continue to live in their own homes or apartments, but impairment in mobility and the ability to carry out instrumental activities of daily living, which include shopping for groceries, preparing meals, and cleaning and maintaining a home, threaten their independence. Having to ask or pay others to perform tasks that they formerly were able to do themselves is seen as a significant loss by many older adults. Adding the loss of a spouse, the death of friends, or the lack of social contacts may further isolate an older person, leading to depression and **hopelessness**. The accumulation of losses can overwhelm an older adult's resources and coping mechanisms and is related to a high rate of suicide, especially for older men. Suicide is the ultimate expression of hopelessness.

Older adults need to be encouraged to remain active and to continue to pursue interests. Most communities have transportation services such as buses and vans that operate to meet the needs of older adults. Senior centers offer diverse programs and services to older adults. Some senior groups are focused on community service; others mainly plan trips or sponsor activities such as dances or bowling leagues (Fig. 13-2). Seniors also have opportunities to continue to work in areas of interest as volunteers. Schools, hospitals, nursing facilities, parks, museums, zoos, community theaters, and youth groups all welcome older adult volunteers. Colleges and universities offer discounted tuition for senior citizens, and there are elder hostel programs across the country, which are programs especially designed for older adults. Elder hostels offer a variety of programs

Figure 13-2 Older adults can remain active by participating in activities such as dances. (From Anderson, M: *Nursing Leadership, Management and Professional Practice for the LPN/LVN*. FA Davis, Philadelphia, 1997, p 200, with permission.)

such as photography, Civil War history, nature survival, bird watching, and painting.

As people age, chronic illnesses and disability increase. Unfortunately, chronic diseases commonly limit an older person's ability to be independent in self-care and activities of daily living. Hypertension is common, as are heart disease and strokes in this age group. Managing blood pressure, losing weight, eating a low-fat diet, not smoking, enhancing effective stress-coping strategies, and regular exercise decrease the potential for cardiovascular disease.

Changes in mobility and chronic pain may limit an older person's activity and impede an active lifestyle. Falls are a serious concern for older adults. Falls and accidents can be prevented by in-home safety assessments and altering the home environment to ensure the safety of the older adult. Bathrooms should be equipped with grab bars and nonskid mats. Bath chairs or benches make getting into a bath or shower less risky. Removing clutter, throw rugs, small furniture, and electrical cords decreases the risk that an older adult will trip and fall.

Social stigmas related to memory changes such as forgetfulness, dementia, and senility are a serious worry for many older adults. The elderly often confuse their own depression with senility and attempt to hide their symptoms rather than seek treatment. Sensory impairments can further isolate the patient. Impaired vision can be caused by decreased peripheral vision, macular degeneration, cataracts, or glaucoma. One of the most dramatic losses for many older adults is not being able to safely drive a car. This is usually associ-

ated with a loss of independence and free will. Many older adults continue to drive during the day but not at night because of night vision problems. Decreased hearing is also common in older adults. Loss of high-pitch discrimination and reduced ability to filter background noises cause older adults to hear the background noise more clearly than a one-to-one conversation when in a crowded room.

CRITICAL THINKING

Mrs. Riccardi

Mrs. Riccardi, age 87, lives alone in her small apartment. Her daughter and son are both retired and live in the same community. Mrs. Riccardi had a dizzy spell, so her daughter brought her to the hospital emergency department (ED). Upon admission, Mrs. Riccardi's blood pressure was 208/128 and she had blurred vision in the left eye that resolved after 1 hour in the ED. She was diagnosed with hypertension, which had possibly contributed to a small stroke or transient ischemic attack (TIA). Mrs. Riccardi was started on furosemide (Lasix) 20 mg twice a day and digoxin (Lanoxin) 0.125 mg every day. She was discharged to her home. The plan of care addressed safety issues.

1. Why might Mrs. Riccardi be at increased risk of falling?
2. What nursing interventions would help promote Mrs. Riccardi's independence and safety?

Answers at end of chapter.

CHRONIC ILLNESS

Chronic illness is defined as an illness that is long-lasting or that recurs. Chronic illnesses usually interfere with the patient's ability to perform activities of daily living. Medical care and hospitalization, commonly at least once a year, are often required on an ongoing basis. A **terminal illness**, however, could or is expected to cause death within 6 months.

When caring for those with chronic illness, the goal of nursing care is to maintain and improve the patient's quality of life. A chronic illness also affects the patient's family's quality of life. Therefore, when planning patient care consider the family's needs for adapting to the chronic illness.

Fostering hope is an important intervention that should be a primary foundation of care planning for the chronically ill. A chronic illness may appear to be a hopeless situation if no cure is possible. If recovery from an illness is not possible, it might be thought that nothing can be done for the patient. However, whenever there is life, there is potential for growth in areas such as developmental tasks, health promotion, knowledge, or spirit. Individuals have developmental tasks to perform even as they cope with illness or prepare for a peaceful death.

Incidence of Chronic Illness

The incidence of chronic illness is rising for several reasons. First, people are living longer, in part because of better hygiene, nutrition, vaccinations, antibiotic development, and exercise. As a result, a larger elderly population is living long enough to develop many chronic illnesses. Second, medical

advances have resulted in reduced mortality from some chronic illnesses, so that patients live longer with these illnesses. Third, today's technology and modern lifestyles affect the development of some chronic illnesses. Examples include a sedentary lifestyle; exposure to air and water pollution, chemicals, and carcinogens; substance abuse; and stress.

Some of the most common chronic conditions include chronic sinusitis, arthritis, hypertension, orthopedic dysfunction, decreased hearing, heart disease, bronchitis, asthma, and diabetes. Preventive measures can be taught to reduce the incidence of these conditions.

Types of Chronic Illnesses

There are a variety of chronic illnesses resulting from several different causes (Box 13–1). These illnesses can have varying degrees of severity and can affect length of life. A chronic illness can lead to the development of other illnesses, such as hypertension that then causes chronic renal failure. Chronic illnesses can have onsets at various ages, but the elderly are most commonly affected, often having several chronic illnesses at one time (Box 13–2).

BOX 13-1 Examples of Chronic Illnesses by Causes

Genetic

- Cystic fibrosis
- Huntington's disease
- Muscular dystrophy
- Sickle cell anemia

Congenital

- Heart defects
- Malabsorption syndromes
- Spina bifida

Acquired

- Acquired immunodeficiency syndrome (AIDS)
- Arthritis
- Cancer
- Cataracts
- Chronic obstructive pulmonary disease
- Diabetes
- Head or spinal cord injury
- Multiple sclerosis
- Peripheral vascular disease

BOX 13-2 Examples of Chronic Illnesses in the Elderly

- Arthritis
- Cataracts
- Cerebrovascular accident
- Chronic lung disease
- Diabetes
- Hearing impairments
- Heart disease
- Hypertension
- Peripheral vascular disease
- Visual impairments

Gerontological Influence

The elderly are one of the largest age groups living with chronic illness. As people live longer, elderly spouses or older family members are increasingly being called on to care for a chronically ill family member. Children of elders who themselves are reaching their 60s are being expected to care for their parents. These elderly caregivers may also be experiencing a chronic illness themselves. In this case it is usually the less ill spouse that provides care to the other spouse. The elderly family unit is at great risk for ineffective coping or further development of health problems. Assess all members of the elderly family to ensure that their health needs are being met.

Elderly adults are very concerned about becoming dependent on and a burden to others. They may become depressed and give up hope if they feel that they are a burden to others. Establishing short-term goals or self-care activities that allow them to participate or have small successes are important nursing actions that can increase their self-esteem (Cultural Consideration Box 13–3).

BOX 13-3 CULTURAL CONSIDERATION

Traditional Appalachians believe that disability is natural with aging and is inevitable. This belief discourages the use of rehabilitation as an option. Thus to promote rehabilitation efforts among Appalachians, the nurse may need to stress self-help and a return to physical function.

Barriers to caring for a chronically ill elderly patient include a lack of information about treatments, medications, or special diets and being unfamiliar with supportive services in the community such as meal programs or **respite care**. You should be aware of these and provide this information, as well as a resource number for questions.

Effects of Chronic Illness

For the patient to live as normally as possible with a chronic illness, many adjustments are usually necessary. Lifelong routines and habits may need to be changed. Daily living patterns are affected by routines that are established to cope with the illness. Treatment needs such as going to therapy sessions, performing peritoneal dialysis exchanges, or monitoring blood sugars can interrupt daily life.

Chronic Sorrow

Chronic sorrow is a normal response felt by those affected by a chronic illness. It is an intermittently occurring permanent sadness in response to the loss caused by a chronic condition. It can be felt by the patient or the patient's significant others. It is a common feeling among those with chronic illness. The nursing diagnosis chronic sorrow may apply to those experiencing chronic illness. When this sadness occurs, nursing care should focus on being comforting and supportive. Providing information and assisting with

coping strategies such as fostering support systems are great interventions to help those with chronic sorrow.

Spiritual Distress

Patients with chronic illness can experience spiritual distress when faced with the limitations of their illness. Maintaining patients' quality of life includes assisting patients with their spiritual needs. Religious and spiritual needs are important to most people whose lives have been disrupted with new challenges from chronic illness. Patients must be helped to find meaning in the illness and realistic hope. Interventions that address **spirituality** may need to be performed first to allow success of subsequent nursing care.

Develop a comfortable approach in assessing and meeting patients' spiritual needs. Several factors may make one uncomfortable in caring for the patient's spiritual needs. These factors include a lack of training, a lack of understanding of one's own spiritual needs and beliefs, and not recognizing or believing that this is your role. Examine your own spiritual needs to define a personal spiritual view. By doing this, you will develop insight into others' spiritual needs and resources, as well as gain a greater understanding of issues surrounding your patients' spiritual needs.

Many people use spirituality to cope with chronic illness. It helps give them a sense of wholeness, hope, and peace during a time filled with uncertainty and anxiety. Spirituality plays an important role in empowering patients to handle their condition. It is a source of inner strength that allows the patient to experience a sense of unity. Hospital interventions may include use of a meditation room for quiet reflection or prayer, chaplain visits, or worship services. To help meet the patient's spiritual needs, assist the patient with transportation to the meditation room or worship services.

Accreditation agencies require the spiritual needs of patients to be addressed and documented by nurses. Nursing diagnoses related to spiritual needs include spiritual distress, risk for spiritual distress, and readiness for enhanced spiritual well-being.

LEARNING TIPS

Spiritual needs should not be thought of in only a religious focus. Spirituality is feeling connected with a higher power. Everyone has spiritual needs that involve hope, peace, and wholeness. Spiritual care goes beyond simply asking the patient's religion. It is assessing patients' perceptions of spirituality and then devising ways to assist them to meet their spiritual needs.

Powerlessness

Those with chronic illness often feel powerless because they are uncertain of their ability to control what may happen to them (Fig. 13–3). A chronic illness can take an unknown course in relation to its seriousness and controllability. This leaves the patient vulnerable to the many phases of a

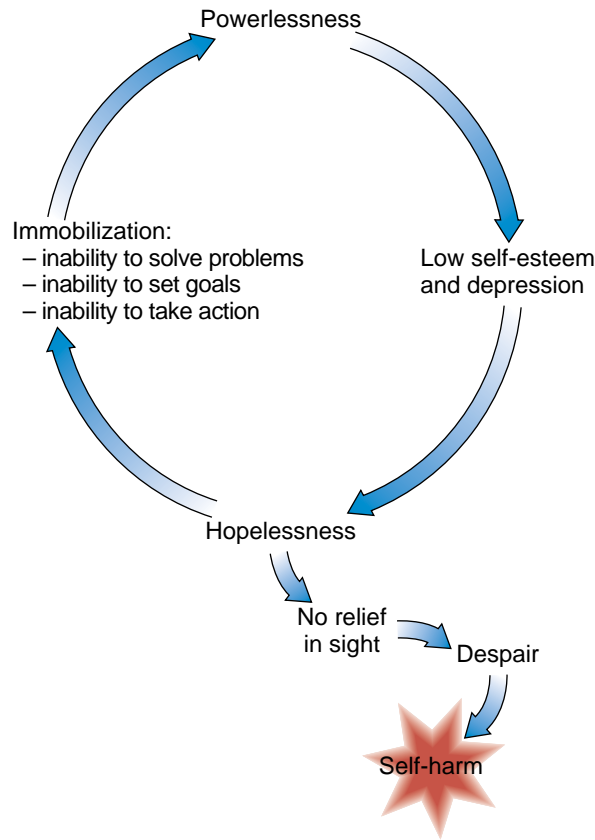

Figure 13-3 Powerlessness-hopelessness cycle. (Modified from Miller, J: *Coping with Chronic Illness. Overcoming Powerlessness*. FA Davis, Philadelphia, 2000, p 526.)

chronic illness (the diagnosis, the instability phase, an acute illness or crisis, remissions, and a terminal phase).

Treatments that the patient undergoes can be a new experience that is painful, frightening, and invasive. If patients do not understand what is happening, they can feel overwhelmed and alone. This contributes to a feeling of **powerlessness** because the patient cannot control the outcome. Patients with chronic illness are faced with a lack of control throughout their illness. It influences the reactions of the patient to the illness. The nursing diagnoses of powerlessness or risk for powerlessness may apply to many chronically ill patients.

COPING. Patients can be helped to feel more in control of their illness if you remember to include them in their care; listen to their feelings, values, and goals; and explain all procedures first. Complex medical language should be avoided when talking with patients to increase their understanding and feeling of being included in their care instead of isolated. In addition, coping with a chronic illness can be aided if the patient develops a positive attitude toward the illness. This can be accomplished if the patient gains knowledge, uses a problem-solving approach to difficulties, and becomes motivated to continue adapting to the illness and not succumb to a defeatist attitude.

A variety of coping techniques can be useful. Ask the patient's perception of the illness and identify coping techniques that the patient has previously used successfully.

New coping resources may need to be added to effectively deal with the patient coping tasks that are associated with chronic illness. Support services in the community should be made available to the patient and family. To cope effectively, the patient should become comfortable with the newly defined person he or she is to become. The nursing diagnoses of ineffective coping, compromised family coping, disabled family coping, and readiness for enhanced family coping may apply to those dealing with chronic illness.

HOPE. Before coping resources can be used, hope must be established by the patient. False hope is not beneficial and should be replaced with realistic hope. Providing patients with accurate knowledge regarding their fears helps do this. Hope should not be directed toward a cure that may not be possible but rather at living a quality life with the functional capacity that the patient has. Over the course of the illness, hope needs to be maintained for both the patient and family. Periodically assess if the patient is maintaining hope. Many studies have shown that patients adapt better when hope is high.

Many nursing interventions may increase hope. The use of humor helps patients be lighthearted and hopeful. Patients should be encouraged to live each moment to the fullest and experience the joy of being alive. Awakening the senses to appreciate the environment can bring a feeling of

CRITICAL THINKING

Mr. Soloman

Mr. Soloman, age 88, still lives in his own home with his wife of 60 years. He is in good health except for poor vision, which developed slowly over the last 8 years. He cares for his yard, which is his pride and joy, and grows prize-winning tomatoes each year. He plays golf three times a week and walks every day to the neighborhood grocery store or bank. The employees know him and cheerfully assist him with his vision limitations.

Mr. Soloman's wife had always been the homemaker, whereas he was the family provider. Now his wife is in the early stages of Alzheimer's disease, exhibiting confusion, fatigue, and paranoia. She is unable to perform activities of daily living, so he has willingly assumed the homemaker and caregiver roles. They complement each other's limitations because she can still see and is helpful to Mr. Soloman when she is not confused.

Over time, Mr. Soloman's wife's health declines and she must be institutionalized. Mr. Soloman remains in his home alone. His family is concerned about him being alone and eventually convinces him to move into a studio apartment in senior housing. He is very reluctant to leave his home and does not actively participate in moving and selling his home. Mr. Soloman rarely leaves his apartment, sleeps 14 hours a day, and eats one daily meal. He tries to visit his wife by taking the bus but finds it difficult because of his limited vision, so he rarely goes to see her. Within a year, Mr. Soloman develops pneumonia and after a brief illness dies in his sleep.

1. Why did Mr. Soloman exhibit the described behaviors after he moved?
2. What interventions could have been used to empower Mr. Soloman?
3. Why might Mr. Soloman have developed pneumonia and died?

Answers at end of chapter.

hope and peace. Simple things, such as the smell of baking bread, the clean scent of the air after a rain, or the scent of pine trees, can make one appreciate the beauty of nature and inspire hope. Family members need to be encouraged to help foster hope for the patient. By doing this, family members may gain hope as well. During times of acute illness, the patient needs to maintain as much control as possible and be told that any loss of control related to treatments is usually temporary. This prevents a continual feeling of loss of power. The use of music or inspirational reading material can reduce stress and help the patient find meaning in life. This in turn fosters hope. Hopeful patients are empowered and no longer feel powerless. The nursing diagnosis of hopelessness may apply to the chronically ill.

Sexuality

Chronic illness can affect a patient's sexuality. Sexuality includes femininity or masculinity, as well as sexual activity. Body image changes affect the way patients view themselves and are viewed by others. If patients have a negative body image perception, they may withdraw and become depressed. When interacting with patients, be aware of your facial expressions, nonverbal cues such as appearing hurried or keeping a distance, use of or lack of touch, and amount of time spent with the patient. When patients believe they have lost their femininity or masculinity, their self-worth decreases. Interventions to enhance sexuality should be used, such as obtaining a wig from the wig bank for patients undergoing chemotherapy.

There are many forms of sexual expression. Sexual intimacy can include touching, hugging, or sharing time together. Provide patients with the opportunity to discuss sexuality concerns or questions. Assume a professional and confidential approach to this topic, which is usually considered a private matter by patients. Chronically ill patients can be referred to sex counselors for information on ways to cope with sexual issues in relation to their illness. Support groups can also be helpful.

Patients in extended care facilities should be given private time with their significant other, if appropriate. Elderly patients need to have their sexuality needs met just as younger patients do. Because sexuality is a part of a person's lifelong identity, ensure that elderly patients' sexuality is addressed in their plans of care. Grooming methods can increase a patient's self-esteem and sexual identity. Women may get their hair and nails done; men can be shaved or get a haircut.

Roles

Chronically ill patients are usually faced with altering their accustomed roles in life. Common roles that may be affected for the adult patient include that of being a spouse, grandparent, parent, provider, homemaker, or friend. Not only is the patient faced with dealing with these role alterations, the family must also adapt to these changes. Family members may have to take on new roles themselves to compensate for roles the patient is no longer able to perform. The nursing diagnosis of ineffective role performance should be included in the plan of care for the patient and family.

The patient is faced with giving up aspects of old roles at the same time that new roles related to being chronically ill need to be assumed. Grieving accompanies the loss of old roles. If a patient is no longer able to participate in social events such as being a golf team member or a committee member, grief work occurs to help the patient accept the loss and maintain dignity. With other roles, only certain aspects of the role may change. For example, in the parenting role, patients may still be there as support systems for the child, although they are no longer able to be the disciplinarian. Whatever the role loss, the patient needs to be allowed to grieve the loss. The nursing diagnosis of grieving may help in planning care for the patient.

The new roles the patient may have to assume related to chronic illness include dependency, ongoing health care consumer, and self-care agent, and being chronically ill. Patients need to learn how to cope with these new roles. They need to gather knowledge and be given understanding as they become familiar with these roles. For patients used to being independent before the illness, being dependent on others to meet activities of daily living can cause a loss in self-esteem. Navigating the complex health care and financial reimbursement systems can be overwhelming. Transportation needs and waiting times for medical appointments can be difficult for the patient who must deal with them on an ongoing basis. Becoming a self-care agent requires assuming responsibility for meeting one's own care needs. Handling chronic illness covers many areas, such as living with pain, having altered mobility, or complying with daily treatments. Deficient knowledge is a nursing diagnosis helpful for fostering learning for these new roles.

As patients live with chronic illness over time, they become experts on their own illness. However, today's health care system tends to assume control over patients and does not respect the patient's own knowledge. Patients who are not given this respect take charge of caring for themselves by seeking knowledge and trying complementary healing methods. Be sensitive to the patient's knowledge and respect it, because respect increases patient's self-esteem.

Family and Caregivers

Families are affected by the chronic illness of a family member in many ways. Chronic illness care is usually provided in the home so that families become involved in the management of the illness (Home Health Hints). Family members may have to take on new family roles or assume the role of caregiver. Decreased socialization, lost income, and increased medical expenses can increase family stress and tension. For more information, visit www.caregiver.org or contact Family Caregiver Alliance, 425 Bush St., Suite 500, San Francisco, CA, 94108, (415) 434-3508.

Families must learn to cope with the stress of illness and its often unpredictable course. Most families develop ways to cope with the patient's illness the majority of the time and may become closer as a family unit. Children adapt better to a parent's illness when they receive parental support. Families often deal with the illness on a day-by-day basis and take a passive approach for most problems to let them

HOME HEALTH HINTS

- Home care nurses can strengthen a patient's self-care capacity by (1) saying "Let me assist you" instead of "Let me do this for you"; (2) being a partner in caring instead of being a caregiver; (3) empowering the patient instead of doing it all for him or her.
- Using humor can be helpful during a visit, unless the patient is distraught, anxious, or angry. Comics or jokes from magazines can be read. Humor can relieve the patient's and caregiver's stress and humanize the care that must be performed. Keep in mind, however, that humor may be irritating if it is taken as downplaying the seriousness of a situation.
- When patients have the use of only one hand or arm, provide a sponge for personal grooming instead of washcloth; it is easier to use and hold.
- Encourage the family of bed-confined patients to purchase an inexpensive portable intercom (such as a nursery monitor) to give the caregiver freedom to move about the house and hear the patient if help is needed.
- The home health nurse has an opportunity to increase a patient's self-concept by emphasizing the patient's existing abilities, joys, and talents. This can be done by observing the home environment for clues: photographs, trophies, hobby paraphernalia, flowers, or homemade items. Each clue observed can be a springboard to discussing triumphs and losses. It can help the nurse understand how the patient copes to assist in planning care.
- Being attentive to any of the patient's efforts or accomplishments, such as number of steps taken, shaving without help, interest in a book or TV show, or decisions on fixing up the house or cleaning, provides opportunities to offer support and praise for accomplishments.
- The home health social worker should be informed of any patient concerns regarding cost of medicines or equipment. There are many programs to assist the chronically ill to obtain resources.
- Always carry a pocket mask for cardiopulmonary resuscitation (CPR).
- Encourage discussion regarding advance directives with the patient and family/caregiver early in the care process. Decisions regarding resuscitation and the use of technology to prolong life are more difficult when the patient is in crisis.
- Refer families to community CPR classes as desired. Families can be empowered and the patient may feel more secure when families are taught CPR.
- Patients and families should be taught that if an ambulance is called they should turn on an outside light, open the door, and move furniture to enable the emergency medical technicians to get to the patient more easily if possible.

work themselves out. During times of exacerbation or crisis, however, the family may need coping assistance.

Patients are often concerned about being a burden to their families. It is important to determine both the family's and the patient's feelings about the care required by the patient. The family's ability to provide this care adequately must also be considered in care planning. If the family lacks the desire, skills, or resources to adequately care for the patient, alternative care options must be explored such as home health care, adult foster care, or extended care facilities.

Patient's caregivers often have certain ideas about the care that the patient should receive. This may come into conflict with the views of health care providers. Caregiver input into the patient's plan of care should be sought so that everyone has a clear understanding of goals and expectations for the patient's care.

Caregivers commonly experience depression, role strain, guilt, powerlessness, and grieving caused by caregiving. Be aware of this to detect indications that caregivers are in need of help in dealing with these feelings. Chronic care coaches are resources available to caregivers who can provide insight, encouragement, and support for caring for the chronically ill. Nursing diagnoses for caregivers include risk for caregiver role strain or caregiver role strain.

RESPIRE CARE. When caregivers are required to provide 24-hour care for a patient, they can experience burnout, fatigue, and stress, which, if extreme, in some cases can lead to patient abuse. Caregivers may not be able to leave patients alone even briefly because of wandering behaviors, confusion, or safety issues. They may not ever be able to get a normal night's sleep and suffer from sleep deprivation because of the patient's wandering or around-the-clock treatment needs.

Caregivers must be given periodic relief from their responsibilities of caregiving to reduce the stress of always having to be responsible. Everyone requires private time for reflection or pursuing favorite hobbies. Caregivers may need to get away overnight or for a weekend simply to sleep soundly and be refreshed.

Respite care is designed to provide caregivers with a much-needed break from caregiving by providing someone else to assume the caregiver role. Know your community's respite care services to share with caregivers. Unfortunately, there are often not enough respite care services available to meet the needs of caregivers. Most respite care is provided by volunteers who receive training. As the number of chronically ill persons grows, more respite care programs must be developed to promote the health of the caregiver and in turn the patient.

CRITICAL THINKING

Mrs. Burden

Mrs. Burden, age 64, is caring for her husband, who has Alzheimer's disease. He exhibits wandering behaviors. He gets up at night and in freezing winter weather is found walking down the street in only his pajamas. He attempts to cook and burns the pans. He is unable to express his needs. He disrobes frequently and is incontinent. Mrs. Burden quit her job to care for him. She no longer goes to lunch weekly with her friends. Her children live out of town. She places a chair and tin cans in front of the home's doors as an alarm in case her husband tries to open the doors.

1. What is Mrs. Burden at risk of developing?
2. What nursing diagnoses should be included in a plan of care for Mrs. Burden?
3. What nursing interventions would be beneficial for Mrs. Burden?

Answers at end of chapter.

Finances

Managing a chronic illness can be expensive. Income can be lost if the patient is unable to work or caregivers are forced to stay home. Family savings can quickly be wiped out. If the patient is covered by insurance, it may not cover all the patient's expenses or it may have caps on lifetime coverage amounts. Expenses may involve medications, medical equipment or supplies, therapy, acute care, and home care. Inadequate funds can place a strain on families. This can lead to the nursing diagnosis of compromised family coping, disabled family coping, or readiness for enhanced family coping. Nurses may need to refer patients to a social worker or sources of financial aid to help them meet their financial needs.

Health Promotion

Health promotion is possible and necessary at all levels of age or disability. With the increase in the elderly population, it is essential to understand the role of health promotion for the elderly who have chronic illness. Patients with chronic illness make daily lifestyle choices that affect their health. For example, the patient with chronic lung disease who smokes can make a choice to smoke or to quit smoking. Patients with degenerative joint disease can choose whether or not to keep their weight within ideal weight ranges to reduce wear and tear on their joints. Arthritic persons can reduce their fatigue levels by pacing their activities and scheduling daily rest periods.

Those with chronic illness consider health promotion important, so encourage health promotion efforts. Patients need to be assisted to strive toward high-level wellness. This can be achieved by looking at the patient's strengths and weaknesses holistically to develop a plan of care. Determine the patient's risk factors to plan methods of promoting health. Providing patients with knowledge to make informed decisions empowers them to take control of their lives and reach for their greatest potential. The nursing diagnosis of health-seeking behaviors can be used to assist patients in promoting their health.

Nursing Care

Nursing care is primarily devoted to caring for patients with chronic illness. Develop an understanding that the wishes of the patient must be respected even if you do not agree with them. Patients have the right to establish their own goals in partnership with the health care team. Because of the nature of chronic illness, understand the unique needs of patients and families experiencing chronic illness. These needs differ from acute care as far as depth of knowledge needs and the compounding problems that are usually faced by the patient.

Most chronic illness care occurs in the home and community rather than the acute care setting. Therefore family members and caregivers, even more so than in acute care, must be assessed and included in the plan of care. As the numbers of those with chronic illness grow, community support for the chronically ill and their caregivers needs to

grow. Training programs for caregivers must be available and offered affordably.

A major focus of nursing care for the chronically ill is teaching. These patients and their families have tremendous educational needs if they are to successfully learn to cope with a long-term illness. The following are primary tasks that the chronically ill need to perform:

- Be willing and able to carry out the medical regimen.
- Understand and control symptoms.
- Prevent and manage crises.
- Reorder time to meet demands caused by the illness, such as treatments, medication schedules, and pacing of activities.
- Adjust to changes in the disease over the course of time, whether positive or negative.
- Prevent social isolation from physical limitations or an altered body image.
- Compensate for symptoms and limitations in order to be treated as normally as possible by others.

Explain individualized interventions to deal with these tasks during teaching sessions. Unique approaches are needed to positively assist chronically ill patients and their families on their long-term journey.

► TERMINAL ILLNESS

Death is a natural occurrence after many illnesses, especially chronic illness. Reactions to death vary by culture and individuals' responses. Elizabeth Kübler-Ross described five stages of emotional reactions that people have to dying: denial and isolation, anger, bargaining, depression, and acceptance.³ These emotional stages assist the patient and family to deal with the news of a terminal illness. Each person experiences these stages uniquely and may move back and forth among them.

Denial allows hope to continue after being informed that death may occur and prevents the individual from being psychologically overwhelmed. Anger is reflected in the question, "Why me?" In bargaining, a deal is made with God if the patient is allowed to live just a little longer, usually to attend a special event such as a graduation. Depression indicates that the patient is sad and feels that nothing more can be done. With acceptance, the patient is at peace and simply seeks a comfortable and dignified death.

The main focus of terminal nursing care is providing the patient and family with a pain-controlled and dignified death that allows participation by family members. This care is given in many locations: the patient's home, a hospice facility, an extended care facility, or a hospital. Determine the goals of the patient and family in dealing with the terminal illness. Nursing diagnoses that may apply at this time include anticipatory grieving or grieving for either the patient or family. Families should be taught what to expect and do as death approaches, so they do not panic when signs of impending death occur (Table 13-1). If the patient becomes comatose and no further medical treatment is desired, comfort care is usually provided until death occurs. At this time, the primary focus may become the patient's significant others, who need assistance with emotional support and grief work.

TABLE 13-1 SIGNS AND SYMPTOMS OF APPROACHING DEATH

Signs and Symptoms	Cause	Nursing Care
Coolness, mottling	Vasoconstriction	Use blankets.
Sleeping	Metabolism changes	Sit quietly; remember that hearing is last sense to leave.
Disorientation	Metabolism changes	Orient if helpful.
Incontinence	Muscles relaxing	Keep clean and comfortable.
Chest congestion	Weakened cough to remove secretions	Give oral care to keep mouth moist.
Restlessness	Decreased brain oxygen	Calm and distract patient with music, massage, reading.
Oliguria	Less fluid intake	Consider if catheter is needed (often it is not).
Decreased fluid and food intake	Body is saving energy, may cause natural analgesia	Do not force intake; give oral care, sips of ice if desired.
Breathing pattern changes	Less circulation to organs	Position in semi-Fowler's or on side.

REVIEW QUESTIONS

- The nurse is assessing a 68-year-old patient's developmental stage and finds that the patient is retired and that the patient's spouse died 4 months ago. The nurse identifies the patient as being in which one of the following developmental stages?
 - Generativity versus self-absorption
 - Identity versus role confusion
 - Intimacy versus isolation
 - Integrity versus despair
- The nurse is planning care for a patient with diabetes. Which one of the following effects does the nurse understand is most likely to occur with a chronic illness?
 - Powerfulness
 - Hopefulness
 - Increased socialization
 - Spiritual distress
- The nurse is providing care for a chronically ill patient. Which one of the following is an appropriate nursing intervention for a chronically ill patient?
 - Decreasing educational information
 - Limiting visiting hours for family members
 - Including family members in teaching sessions
 - Setting goals for the patient
- The nurse is assisting with goal setting for a patient with a diabetes. Which one of the following goals should the nurse focus on as the primary goal of chronic illness treatment?
 - Ensuring a cure
 - Providing comfort care
 - Maintaining quality of life
 - Undergoing new experimental treatments
- The nurse is caring for a patient who is comatose and in respiratory failure. Which one of the following would the nurse correctly interpret as a sign of impending death?
 - Warmth of extremities
 - Increased body temperature
 - Insomnia during the night
 - Mottling of lower extremities

Answers to CRITICAL THINKING

Mr. Paul

1. Mr. Paul's physical health is being affected by poor diet choices, excessive stomach acid secretion or other gastrointestinal problems, and stress.
2. It is easy to recognize the psychological stress related to parenting skills when a child is in trouble. Decreased family income with increased family expenses (two children in college) can cause financial strains and more economic pressure on Mr. Paul's business. With family problems or health problems, Mr. Paul may be questioning why things are happening to him and his family, causing him spiritual distress.

Rita

Prenatal education information should be offered to Rita and her husband. This education should include an overview of Rita's health needs, what to expect during pregnancy, ways Rita's husband can be supportive, and information on prenatal classes. Rita's physical examination should include a vaginal examination, blood pressure, and blood work. It is important to be aware of any sexually transmitted diseases that may be transferred to the fetus or during birth. A rubella titer (a test for immunity to rubella or measles) is important because of potential birth defects if the mother has rubella while pregnant. Elevated blood glucose may be a sign of diabetes, and low red blood cell counts and low hemoglobin are related to anemia. To prepare a woman for pregnancy, prenatal vitamins or vitamins with iron and folic acid (necessary for effective neural tube development in the first 3 months of pregnancy) are recommended. Because of the increased workload of the heart during pregnancy, blood pressure needs to be closely monitored. A balanced diet, maintaining an exercise program, and continuing to develop effective and positive ways to deal with stress are very important for pregnant women. In preparation for pregnancy, Rita also needs information on the negative effects that cigarette smoking, alcohol use, and drug use can have on the developing fetus.

Mrs. Riccardi

1. Falls could be caused by environmental problems, such as throw rugs that may move or cause tripping, clutter, electrical cords in walking paths, lack of hand grips in the bathroom, or lack of nonskid mats in the shower or tub. Poor vision and altered depth perception can result in missing a stair step or obstacles. Weakness or orthostatic hypotension can cause an unsteady gait or fall. Furosemide can cause urinary urgency and incontinence. If incontinence occurs, falls may result from a wet, slippery floor.

2. It is important for the nurse to instruct the patient and family about home safety. Mrs. Riccardi may even benefit by using a cane or a walker if she is unsteady. Because Mrs. Riccardi lives alone, an emergency alert system, such as a small transmitter that is worn around the neck or wrist with a button that can be activated in emergencies, would be beneficial. When activated, the transmitter alerts an answering service to contact designated individuals to check on the patient. Safety with medications is also an important consideration. Patients who take diuretics or other medications that lower blood pressure must be aware of the potential for orthostatic hypotension. Orthostatic hypotension is a drop in blood pressure that happens when a person moves from a lying to sitting or sitting to standing position. It is often accompanied by dizziness or lightheadedness. Some people may even faint, causing a fall.

Mr. Soloman

1. Mr. Soloman had lost control of his world and felt powerless. His environment, both home and outdoors, was shrinking. He had to give up his daily routines and interactions with others. His purpose in life was gone when he was no longer caring for his wife. He was separated from his loved one. His visual limitations made his new environment unfamiliar and frightening.
2. Options to keep him safely in his home could have been explored with his input. After the move, he should have been thoroughly oriented to his environment. He should have been asked to explain what he wanted his life to be like as he adapted to this new developmental stage. Hobbies and interests should have been continued. Visual support services should have been contacted for ideas. Transportation should have been arranged to allow him to visit his wife. It should have been determined whether phone calls to his wife were possible.
3. He was depressed and slept from a lack of any interests. His lungs were at risk for pneumonia because of his long periods of immobility. He lost hope and gave up on living, which decreased his ability to fight the pneumonia.

Mrs. Burden

1. Mrs. Burden is at risk for sleep deprivation, fatigue, stress, and burnout.
2. Nursing diagnoses include disturbed sleep pattern, fatigue, social isolation, risk for caregiver role strain, and deficient knowledge.
3. Beneficial nursing interventions would include teaching about Alzheimer's, a chronic care coach, respite care referral, alarm devices for wandering, and stress management techniques.

QUESTIONS TO GUIDE YOUR READING

1. How would you define aging?
2. What are basic physiological changes associated with advancing age?
3. How would you describe psychological and cognitive changes associated with advancing age?
4. What are nursing implications for the physiological and psychological changes associated with advancing age?
5. What nursing practices promote safety for the older patient?

► WHAT IS AGING?

Over time it is easy to visually notice changes that occur in the human body. Both physical structures and body functions undergo changes and declines with advancing age. Although there is not one commonly accepted definition or theory to explain these declines, there is an understanding that aging is a universal and normal process that starts at conception and continues until death.

Older adults are increasing in number. In 2000, 34.7 million adults were older than age 65.1 By 2025 this number is expected to be 61.9 million. Within this group, those older than 84 are the fastest-growing segment. There were 4.9 million adults older than 84 in 2000, and by 2025 it is projected there will be more than 7 million. For more population data, visit www.census.gov.

For this chapter, aging is defined as a maturational process that creates the need for individual adaptation because of physical and psychological declines that occur during a lifetime. Even though aging truly begins at conception, the focus in this chapter is on the maturational process that is experienced after age 65 (older adult). Those older than age 84 are usually the frailest. The changes discussed do not always occur in the sixth decade of life, so chronological age should not be the basis for determining health issues. For some people, aging effects go unnoticed in their daily functioning; for others these effects cause varying degrees of impairment. Functional age (health, independence, and functional abilities) should be used as the basis of individual care needs. It is important to understand that most elderly people function independently in the home and community. Many are still working. With supportive, educative care as needed, these people are able to maintain their independent abilities. This chapter discusses aging

changes and resulting disabilities that may require more intensive nursing care than independent, healthy older adults need.

LEARNING TIPS

Placing older adults into age categories overlooks their unique aging experience. The concept of functional age recognizes that aging is individual and promotes individualized nursing assessment and development of plans of care for the older adult.

Although aging is universal, it remains a unique experience for each individual. Factors that contribute to this process can be grouped into two categories. **Intrinsic factors** focus on genetic theories of aging, such as biological clock theory or programmed aging theory, and some aspects of physiological theories of aging, such as wear-and-tear theory or stress adaptation theory. **Extrinsic factors** focus on environmental influences, such as pollutants, free radical theory, and stress-adaptation theory. Regardless of which factors have the greatest influence on this process of aging, **perception** and attitude also play key roles in how the changes over time affect the individual. It is through the filter of perception and attitude that the individual identifies, defines, and adapts to the changes that occur in structure and function over time. These factors have implications not only for older patients but also for their families and the health care providers working with them.

► PHYSIOLOGICAL CHANGES

Over time cells change, and they do not function as efficiently as in earlier years (Table 14–1). The physical changes that are seen when looking at the older patient are

TABLE 14–1 PHYSIOLOGICAL AGING CHANGES

Body System	Aging Change	Effect of Change
<i>Cardiovascular</i>	Increased conduction time Decreased cardiac output Decreased blood vessel elasticity Irregular heartbeats	Heart rate slows, unable to increase quickly Less oxygen delivered to tissues Increased blood pressure increases cardiac workload Poor heart oxygenation, decreased cardiac output, heart failure
<i>Endocrine and Metabolism</i>	Leg veins dilate, valves less efficient Basal metabolic rate slows Altered adrenal hormone production Decreased insulin release	Varicose veins, fluid accumulation in tissues Possible weight gain Decreased ability to respond to stress Hyperglycemia
<i>Gastrointestinal</i>	Reduced taste and smell Decreased saliva Decreased gag reflex, relaxation of lower esophageal sphincter Delayed gastric emptying Reduced liver enzymes	Appetite may be reduced Dry mouth, altered taste Increased aspiration risk
<i>Genitourinary</i>	Decreased peristalsis Kidney size decreases Decreased bladder size, tone, changes from pear to funnel shaped Muscles weaken Decreased concentrating ability Less sodium saved Reduced renal blood flow	Reduced appetite Reduced drug metabolism and detoxification Reduced appetite, constipation Able to live with 10% renal function Frequency of urination increased Incontinence Nocturia Risk for dehydration Decreased renal clearance of all medications

TABLE 14-1 PHYSIOLOGICAL AGING CHANGES — CONT'D

Body System	Aging Change	Effect of Change
<i>Immunological</i>	Decreased function	Infection and cancer risk greater
	Increased autoimmune response	Increased autoimmune diseases
<i>Integumentary</i>	Reduced cell replacement	Healing slower
	Water loss	Dryness of the skin
	Increased pigmentation	Aging spots
	Thinning of skin layers	Skin more fragile
	Decreased subcutaneous fat	Less insulation and protective cushioning
	Decreased sebaceous and sweat glands	Dryness and decreased temperature regulation
	Hard, dry nails	Brittle nails
	Thinning scalp hair	Baldness
	Decreased melanin	Gray hair
	Decreased skin elasticity	Wrinkle development
<i>Musculoskeletal</i>	Decreased muscle mass	Reduced strength
	Decreased muscle tone	Muscles look flabbier
	Decreased elasticity of tendons and ligaments	Movements are restricted
	Muscle responses slowed	Response time increased
	Bone thinning, softening	Decreasing bone density
	Joint stiffening	Decreased flexibility
	Vertebral disk water loss	Decreased height
<i>Neurological</i>		
Central nervous system	Loss of brain cells	Able to maintain function with remaining cells
	Decreased brain blood flow	Short-term memory loss
	Decreased regulation of body temperature	Hypothermia, hyperthermia risk
	Decreased endorphins	Increased depression
Peripheral nervous system	Decreased sensation	Risk for injury, burns
	Increased reaction times	Slow response, injury risk
	Decreased motor coordination	Unsteady, fall risk
Respiratory	Decreased lung capacity	Dyspnea with activity
	Decreased cough and gag reflexes	Aspiration, infection risk
	Reduced lung tissue tone	Shallow, faster respirations
	Reduced lung emptying on exhalation	CO ₂ retention
	Decreased fluid and ciliary action	Mucous obstruction, infection risk
<i>Sensory</i>		
Eye	Lens less elastic	Decreased near and peripheral vision
	Lens opaque, yellows	Cataracts
	Cornea more translucent	Blurry vision
	Smaller pupil	Decreased dark adaptation
	Decreased violet, blue, green color vision	See red, orange, yellow colors better
Ear	Arcus senilis—blue or milky lipid ring on iris edge	No effect on vision
	Degeneration of auditory nerve	Lose high-frequency tones, deafness
	Excess bone impairs sound conduction	Deafness
Nose	Decreased smell	Decreased ability to smell substances such as smoke, gas causing safety risk; appetite reduced
<i>Sexuality</i>		
	Availability of partner or privacy decreases	Lack of sexual expression, suppression of desires
	Slower sexual arousal time	Increased time needed for sexual stimulation
	Decreased erection, slower ejaculation	Psychologically causes concern
Men		Painful intercourse
Women	Less vaginal lubrication	Increased vaginal infection risk
	Vaginal acidity reduced	

slight as compared with the cellular changes that occur. Cellular decline in structure and function increases in severity and extent over time. Although the body works hard to maintain **homeostasis**, it is often unable to fully adapt to many of the declines that result from aging. Cells

that die cannot regenerate themselves. As a result, structures are altered, and the body tries to adapt to make the revised structure meet functional demands.

homeostasis: homios—similar + stasis—standing

Common Physical Changes in Older Patients and Their Implications for Nursing

Key Changes in the Muscular System with Aging

Key aging-related changes in the muscular system include the following:

- Decrease in muscle mass, so muscles look smaller
- Decrease in muscle tone, so muscles look flabbier
- Slower muscle responses, so response time is increased
- Decrease in elasticity of tendons and ligaments, restricting movements

NURSING IMPLICATIONS. Changes in the muscular system have implications for movement, strength, and endurance. Restricted movements are most commonly seen in the arms, legs, and neck of the older patient, who may demonstrate limited **range of motion** (ROM) in these areas. Because muscle response abilities are slowed, it will take longer for the older patient to move. This increased response time has implications on the older individual's confidence level regarding personal ability to perform routine tasks.

Key Changes in the Skeletal System with Aging

Key aging-related changes in the skeletal system include the following:

- Eroding cartilage
- Exaggerated bony prominence
- Joint stiffening and decreased flexibility
- **Osteoporosis**, a thinning and softening of the bone
- Shortening in height caused by water loss in the intervertebral disks of the spinal column, flexion of the spine, and stooped posture

NURSING IMPLICATIONS. Because muscles and bones work together for movement, aging skeletal changes are most obvious when the older patient is moving. **Contractures** of the fingers and hands can limit the individual's ability to perform self-care tasks called **activities of daily living** (ADL). It is important to assist the patient with ROM exercises if help is needed to prevent the long-term disabilities that contractures bring (Fig. 14-1). Performing ROM exercises in warm water helps the patient who experiences discomfort with these exercises. If the individual has arthritis, anti-inflammatory medications should be given so that their action peaks when the exercises begin. Older patients on anti-inflammatory medicines should be monitored closely for gastrointestinal upset or bleeding and taught the symptoms of bleeding to report.

Decreased bone density is influenced by diet and weight-bearing exercise, so balanced diets rich in calcium and vita-

Figure 14-1 Nurse assists patient in range-of-motion exercises to prevent the development of contractures.

min D and safe and sensible exercise programs should be promoted. Patients should be encouraged to ambulate whenever possible, using sensible shoes that have nonskid soles and sturdy assistive devices if needed, such as handrails, canes, or walkers (Home Health Hints). When the decreasing density of older bones is considered, it is easy to understand that broken bones do not always result from a fall but may indeed be the reason for the fall in many older patients.

Key Changes in the Integumentary System with Aging

Key aging-related changes in the integumentary system include the following:

- Increased dryness of the skin
- Increased pigmentation, causing liver or aging spots
- Thinning in the layers of the skin, which makes the skin more fragile
- Decreased elasticity of the skin, causing wrinkles to develop
- Decreased subcutaneous fat layer of skin, so older patients have less insulation and less protective cushioning
- Hardness and dryness of nails, making them more brittle
- Decrease in nail growth rate and strength
- Thinning of scalp hair (primarily men)
- Increased growth and coarseness of nose, ear, and facial hair
- Decrease in melanin, which results in gray hair
- Decreased sebaceous and sweat glands, which has implications for dryness and decreased temperature regulation

osteoporosis: osteon—bone + poros—a passage + osis—condition

HOME HEALTH HINTS

- Try to schedule therapy visits and nurse visits on the same day, to decrease fatiguing the older patient.
- Because many older patients keep their homes warm, the home health nurse should wear layers of clothing, removing a layer as needed, rather than adjusting the heat in the older patient's home.
- Pagers should be placed on a silent mode if possible to avoid startling or confusing the older patient.
- Nurses should not assume that the older patient remembers them when they answer the door. Nurses should state their name and why they are there. A large-letter name tag should be in clear view.
- To enhance the effectiveness of a visit, the older patient should be asked to visit in a quiet room of the home with the primary caregiver invited in at the appropriate time. This may help the older patient stay more focused, offer privacy, and assist hearing.
- Making a sign for the door of the home giving visitors instructions, such as ringing the doorbell several times, knocking loudly, or using the other door, may be helpful to the older patient. Do not provide information that would inform a stranger that an older patient lives in the home.
- Suggesting that limiting visitors or not allowing persons with colds to visit can be helpful in preventing illness for the older patient.
- Stressors in a patient's life, such as annoying visitors, chastisement by caregivers, and harassment by bill collectors, are often experienced firsthand by the home health nurse. Document and share those with the home care team, so a coordinated approach can be taken.
- When auscultating lungs, ask the older patient to take deep breaths in and out through the mouth. This may stimulate coughing, which is an opportune time to teach deep breathing and coughing exercises.
- If the older patient seems fatigued early in the day, ask about sleeping patterns and things that disturb it, such as barking dogs, traffic noise, and visitors. Recommend ear plugs or changing rooms to obtain a good night's rest. Check medications for insomnia listed as a side effect and suggest dosing of these medications early in the day if appropriate. A 15- to 30-minute nap in the early afternoon can be helpful.
- One of the first signs of infection in the older patient is confusion.
- One of the first signs of dehydration is tachycardia. Instruct the patient regarding adequate hydration.
- Assess the older patient's environment for safety hazards on each visit and promote safety.
- If the older patient has dentures, assess if they are worn for eating. If not, assess why they are not worn (e.g., sores, improper fit from weight loss) and discuss solutions.
- Checking the refrigerator for outdated food is helpful. The older patient is often on a limited budget and has been taught not to waste food. These factors along with a decreased sense of smell and taste can lead to food poisoning in the older patient.
- Encourage the uses of spices and herbs, such as parsley, oregano, lemon, garlic, and basil, instead of salt and sugar. Suggest keeping pared apples and slices of oranges in the refrigerator for snacks.
- If a Meals on Wheels program is available, ask if the older patient would like to be placed on the service.
- Use a warming tray when feeding an older patient who takes a longer time to eat.
- When swallowing is difficult, freezing liquids helps, so they can be eaten with a spoon or like a popsicle. Milkshakes, high-protein drinks, instant breakfast mix, or eggnog are thicker liquids that are easier to swallow.
- If an older woman wears perineal pads or adult briefs, ask how many are used in a 24-hour period to assess the degree of incontinency or amount of output. Have the patient keep a voiding diary to further assess the degree of incontinence.
- Suggest a bedside commode when a weakened older patient is on diuretics or has a history of falling or confusion. Placing it next to the bed at night helps reduce the risk of falls and eases the caregiver's burden.
- If the older patient reports constipation, review the diet and make suggestions regarding adequate fluid and fiber. A mixture of equal parts of applesauce, bran, and prune juice is often helpful to prevent or relieve constipation. Discourage the use of mineral oil because it can make vitamins less effective.
- When drawing blood from the hand of an older patient, use the smallest needle possible.
- Hold light pressure for at least 2 minutes after the needle is removed. Do not use a Band-Aid on the fragile skin of the older patient if the bleeding has stopped with pressure.
- When teaching, it is important to acknowledge the patient's knowledge and life experiences. When given a chance, patients tell how they have maintained their health over the years. Use open-ended scenarios for teaching, such as, "What would you do if you were alone and fell?" Teaching should occur with patients, not to them. The nurse is in the patient's home, which is a personal place. Patient dignity should always remain intact during home care visits and teaching sessions.

NURSING IMPLICATIONS. The skin, which is the first line of defense against infection and injury, does not work as effectively in older patients (Fig. 14–2). In the elderly, skin injuries take longer to heal, and those longer healing times are usually complicated by the fact that many older patients have multiple chronic diseases, such as diabetes and circulatory ailments.

The older patient with limited mobility is especially prone to developing pressure ulcers (Fig. 14–3). These ulcers usually develop over a bony prominence of the body

(e.g., ears, shoulders, elbows, tip of the spine, pelvic bone ridge, knees, heels, or ankles). Pressure ulcers are caused by ischemia that results from continuous pressure on an area of the body. Ischemia from unrelieved pressure can develop in 20 to 40 minutes. Early signs of **pressure ulcer** formation are warmth, redness, tenderness, and a burning sensation at the potential ulcer site. These potential ulcer sites are aggravated by lack of activity and the weight of the body. For this reason it is especially important to take the time to assess skin integrity daily.

Figure 14-2 Thin, fragile skin of older patient.

Figure 14-3 Pressure ulcer. (From Goldsmith, LA, Lazarus, GS, and Sharp, MD: *Adult and Pediatric Dermatology: A Color Guide to Diagnosis and Treatment*. FA Davis, Philadelphia, 1997, p 445, with permission.)

Skin care includes gently stimulating nonreddened intact skin sites with massage, moisturizing with creams regularly, avoiding the use of hot water and a complete daily bath, and limiting the use of soap. If able, patients should be taught to shift their weight every 15 minutes when sitting. For immobile patients, consistent repositioning is essential. Repositioning every 30 minutes is the most beneficial to help ensure ulcer prevention. Keeping bed linens clean, dry, and wrinkle free also aids in the prevention of pressure ulcer formation.

As with care of the skin, nail care is important for older individuals. Soaking in warm water helps soften nails to ease in their trimming while encouraging blood flow to the peripheral areas of the body. Filing the nails with an emery board is safer than cutting the nails. To prevent accidental injury to the feet, patients should be instructed not to walk barefooted. Potential pressure points of the feet should be identified and closely monitored, and the patient should be referred to a podiatrist for treatment should there be any concerns. Diabetics should assess their feet daily because they may have decreased sensation, causing lack of awareness of foot irritation or injury.

Key Changes in the Cardiovascular System with Aging

Key aging-related changes in the cardiovascular system include the following:

- Slowed heart rate
- Decreased cardiac output from less effective functioning of the heart and blood vessels, yielding less oxygen to body tissues
- Decreased elasticity of the blood vessels, so the circulatory system is less efficient
- Reduced ability of the heart to quickly increase its rate in response to an emergency because of thickening of the heart valves, left ventricle, and aorta (when rate finally does increase, the heart takes longer to return to resting rate)
- More irregular heartbeats, **arrhythmias**, which lead to poor oxygenation of the heart
- Commonly, a lack of classic symptoms of cardiac emergencies
- Increased peripheral vascular resistance in blood vessels, yielding increased blood pressure
- More visible superficial blood vessels of the legs
- Less efficiency of leg blood vessel valves, creating the risk for an accumulation of excess fluids in the leg tissues

NURSING IMPLICATIONS. Be a good observer when it comes to caring for older patients because many early symptoms related to circulatory problems are subtle. Cardiovascular disease, which is separate from the process of aging, accounts for half of all deaths in people older than 65 years. Older adults must be educated about prevention practices that promote healthy circulation and encouraged to take prescribed medications as ordered and maintain a balanced intake and output of fluids. Older patients receiving intravenous therapy should be monitored closely because fluid overload can occur quickly in older people.

Special care should be taken to maintain good skin integrity and provide appropriate stimulation. If **edema** is present in the legs, they should be elevated to assist the fluid return to the upper body and supportive, nonrestrictive stockings should be worn as ordered. Concerns regarding leg circulation should be identified and reported early to the physician before problems develop. It is important to identify whether the circulation problem is arterial or venous before treatment is ordered.

Because quick changes in body position can make the older patient feel weak and dizzy, it is important to stand next to older patients as they dangle their legs over the side of the bed before rising to stand. Changes in body positioning from lying to sitting to standing need to occur gradually to accommodate the less efficient circulatory systems of older patients. Older patients may find comfort in the security of an ambulatory belt or walker if they fear unsteadiness when in an upright position. Falls continue to rank as a

edema: oldema—swelling

leading cause of accidental death in older patients. Every effort should be made to decrease the risk of falling for the older patient. The fall history of patients should be assessed to identify whether they are at high risk of falling, so that preventive measures can be used.

Key Changes in the Respiratory System with Aging

Key aging-related changes in the respiratory system include the following:

- Decreased lung capacity
- Weaker cough or gag reflex, increasing risk for upper respiratory infections
- Reduced tone of lung tissue, so respirations increase to 16 to 25 per minute and are more shallow
- Reduced tone of the diaphragm muscle
- Less complete emptying of the lungs, with greater CO₂ retention
- Decreased blood flow to the lungs, contributing to cardiac arrhythmias

NURSING IMPLICATIONS. Because the respiratory system is less efficient with advancing age, the older patient has a decreased tolerance for activity in general. Nurses should therefore pace activities for older patients instead of letting them confine themselves to bed. It is important to prevent overexertion, so rest periods should be scheduled. However, the rest periods should not outnumber the activity sessions planned throughout the course of the patient's day.

Cough, marked fatigue, and confusion may be early signs of an inadequate oxygen uptake. Respiratory rates greater than 25 per minute may be an early indication of a lower respiratory tract infection. Because overall muscle strength is reduced, the older patient performs the O₂-CO₂ exchange in the less efficient upper lobes of the lung instead of the larger lower lobes specifically designed for this purpose. Because lung recoil strength is decreased, mucus may be more difficult for the older patient to **expectorate**. This situation is compounded by the fact that older individuals also have less effective cough and gag reflexes, which creates greater potential for lung problems. Because of the normal changes in the respiratory system that occur with aging, it is important to include coughing, deep breathing, and position changes in the exercise program designed to stimulate all lobes of the older patient's lungs. At the prevention level, encourage the older individual to receive a pneumonia vaccine and an annual flu shot. This is important because influenza and pneumonia combine to be the fourth leading cause of death in people over age 65. Be aware that lifelong habits, such as smoking and respiratory pollutant exposure in employment settings, secondhand smoke, or paints and glues used in hobbies, are cumulative over time and can contribute to respiratory sensitivity for the older patient.

expectorate: ex—out + pectus—breast

Key Changes in the Gastrointestinal System with Aging

Key aging-related changes in the gastrointestinal system include the following:

- Changes in taste and smell, which affect the enjoyment of eating
- Decreased saliva production
- Decreased gag reflex and relaxation of lower esophageal sphincter, increasing the risk of aspiration
- Delayed gastric emptying
- No functional changes in the small intestine
- Decreased tone in external sphincter
- Marked decline in liver enzymes, which affects drug metabolism and detoxification
- Decreased peristalsis from generalized weakness of muscle activity
- Alteration in bowel habits

NURSING IMPLICATIONS. Many factors can alter appetite, ingestion, digestion, and absorption of nutrients in food, regardless of an individual's age. However, the structural and functional changes that occur with advancing age put the older patient at greater risk for not obtaining the nutrients needed to sustain a healthy body (Nutrition Notes Box 14-1).

There is little that can be done to change the physical alterations in the older body that make getting needed nutrients more difficult. Being knowledgeable and committed to providing the support necessary to meet nutritional goals is important. Patients should be assisted with toileting before helping them eat. An appropriate amount of time for the patient to accomplish the task of eating needs to be provided. If the patient needs assistance with eating, be sensitive to the patient's pace while allowing the patient to have as much control as possible.

Additional forms of support can focus on the need to recognize that for some cultures eating has a strong social component. Encourage the patient to eat out of bed and with others as much as possible, while respecting the patient's right of refusal to eat in a designated social setting. Some patients may not eat as well when seated next to agitated or confused residents in a common dining hall.

Offer continuing support by maintaining a calm and comfortable environment that aids digestion. Certain food combinations enhance nutrient absorption, such as vitamin C foods taken with plant foods high in iron, which increase the iron's absorption rate. Offer these selections together whenever possible. Family members can be asked to bring in familiar seasonings patients used at home. If acceptable, familiar seasonings in shakers that patients apply themselves can be used to stimulate a lagging appetite. Work closely with the dietitian or nutritionist, who may provide other ideas to promote healthful eating for older patients.

Although many older patients wear dentures or partial plates, it is important not to stereotypically assume that all older individuals wear dentures. Tooth loss is not a normal change of aging. With proper lifelong dental care, teeth

BOX 14-1

Nutrition Notes

Meeting the Nutritional Needs of the Older Adult

Energy needs decrease 5% for every decade after age 40, partly because a 70-year-old has 40% less skeletal muscle than in younger days. Adipose tissue requires fewer calories to sustain than skeletal muscle does, so special attention must be given to maximizing nutritional content in fewer calories if a healthy weight is to be maintained. A modified food guide pyramid for adults age 70 and older adds eight servings of water to the base of the pyramid, increases milk servings to three, and recommends calcium, vitamin D, and vitamin B₁₂ supplements. New recommended daily allowances for vitamin B₁₂ specify that fortified foods or supplements furnish most of this vitamin for people over age 50.

Decreased visual acuity and impaired dexterity may make shopping for food and preparing it difficult or even hazardous. Arthritis affects not only mobility, but also jaw movements, so chewing may be problematic. By age 65, about 40% of U.S. residents have lost all their teeth and have to develop skill in the use of dentures. It is recommended that an individual learn to drink with them first, then learn to manipulate soft foods, and lastly learn to bite and chew with the dentures. Older persons produce less saliva than younger people. The sense of taste declines in most but not all aging patients, who as a result may increase their intake of salt and sugar to the detriment of a prescribed diet plan.

Achlorhydria may occur as a result of aging or from chronic ingestion of antacids. In either case, protein digestion and absorption of iron and vitamins B₁₂ and C can be impaired by the lack of gastric acid. Although anemia can be caused by poor nutrition, older patients should be evaluated for hidden blood loss just as younger ones are. High-protein supplements should be offered to older individuals with caution, because normal aging reduces kidney function significantly and excretion of nitrogenous products of excessive protein intake could stress the urinary system. In addition, a high-protein intake increases calcium excretion. The vitamin necessary to metabolize calcium, vitamin D, may be deficient in older persons who neither drink milk nor spend time outdoors.

Many mature patients are at increased risk for food, nutrient, and drug interactions. Situations associated with these interactions are the use of many drugs, including alcohol; the need for long-term drug therapy in chronic illness; and poor or marginal nutritional status. Identification of any of these factors should prompt a thorough nutritional assessment or referral to a registered dietitian.

should last a lifetime. If the older patient does have dentures, be aware that any significant change in body weight will affect their fit and comfort and the patient's nutritional intake. Because of this, it is important to conduct regular assessments of the mouth when assisting the older patient during oral care.

Medications may cause taste disturbances or problems with dry mouth that may also affect the older patient's ability to meet nutritional needs. Some medications create problems with bowel motility, resulting in **constipation**. Constipation can also result from a change in routine, stress, and anxiety. To gain a greater understanding of the situation, talk with the patient about previous assistive procedures and establish an expectation baseline for bowel

elimination. Educate the older patient about the important relationship between intake of fiber and water and exercise in the promotion of effective bowel evacuation. Enemas, suppositories, and medications should be considered for use only after dietary management is found to be ineffective.

Key Changes in the Endocrine-Metabolic System with Aging

Key aging-related changes in the endocrine-metabolic system include the following:

- Slowing in the basal metabolic rate, requiring a 5 percent reduction in calorie consumption to maintain weight
- Alteration in hormone production, including changes in estrogen, progesterone, and adrenal secretions
- Decreased pancreatic insulin release and peripheral sensitivity
- Decreased glucose tolerance with advancing age

NURSING IMPLICATIONS. Increased incidence of metabolic disease, such as diabetes, occurs with advancing years. Because of this, older patients should be encouraged to participate in screening programs for early detection of metabolic problems.

Because there is a notable decrease in the effectiveness and interaction of all hormones as one ages, it becomes especially difficult for the older body to respond appropriately to any stressful situations. Nurses should spend time addressing the psychological needs of patients by recognizing and addressing those actual and perceived stressors that affect their care. Preventive care to keep patients free from the stress of illness is also important.

Key Changes in the Genitourinary System with Aging

Key aging-related changes in the genitourinary system include the following:

- Decreased kidney size
- Decreased kidney function, urinary output, and adaptability
- Reduction of blood flow to the kidneys because of decreased cardiac output and increased peripheral resistance
- Diminished kidney filtration rate and tubular function, which cause a decrease in the renal clearance of all medications
- Decreased bladder size and tone
- Increased incidence of urinary tract infection with age, especially in women
- Longer correction times for fluid and electrolyte imbalances

NURSING IMPLICATIONS. Many older people have an urge to urinate at night, which is referred to as **nocturia**. Changes in the kidneys, lack of gravity influence when in the recumbent position, fluid retention, and medication use

nocturia: nocte—night + ouron—urine

contribute to nocturia. Approximately 30 minutes after lying down many older people need to urinate, because fluid that was held in the legs by gravity is circulated through the kidneys and urine is produced, causing the urge to void. Plan safe toileting access for older patients during the night. Emptying the bladder becomes more difficult to control from weakening of bladder and perineal muscles and also from a change in brain sensation regarding the need to void. As a result, the older patient may have difficulty controlling urination either knowingly or unknowingly, resulting in **urinary incontinence**.

LEARNING TIPS

With age, the urge to void is not felt as early as it once was. This aging change combined with other changes in the urinary system, such as the bladder becoming funnel shaped, contribute to the older patient's voiding urgency. If the patient is not assisted to void promptly on request, incontinence can result.

Incontinence is socially embarrassing and can occur in both male and female patients. It is said to be one of the major reasons that older people are admitted to nursing homes. The incidence in men is most often associated with prostate enlargement; women are more likely candidates because of weakened perineal muscles. Older women are more likely to experience urinary incontinence because they have short urethras that are not supported by strong perineal muscles and more urinary tract infections than older men.

Management of urinary incontinence needs to be tailored to the particular need of the patient. Bladder training programs have been effective when patients are reminded on a regular basis that it is time to urinate. If incontinence results from problems that affect the toileting task itself, such as clothing removal or distance to the bathroom, steps need to be taken to eliminate those obstacles that stand in the way of continence. Clothing with Velcro fasteners can replace buttons or zippers that are difficult for the patient to manipulate. Urinary briefs can help instill confidence in older patients who previously restricted activities because of fear of urine leakage. With use of the supportive incontinence brief, assess for early signs of perineal skin breakdown and proper application of the proper brief to meet individual needs.

Older patients who are aware of their incontinence may try to inappropriately decrease the chance for leakage by severely limiting fluid intake. This approach often results in dehydration, which disturbs the acid-base and electrolyte balance in the body. Over time, dehydrated patients may have problems with vomiting, diarrhea, weakness, and confusion. Because fluid intake needs to be encouraged in older patients, focus educational efforts on topics such as liquid intake timing and beverage selection (e.g., teaching that caffeine and alcoholic beverages should be avoided because they normally increase urinary output).

In addition, review patient medications and personal medication practices, such as taking diuretics late in the

day, which then causes nighttime urination. Teaching perineal muscle support exercises and techniques is successful for some. All patients with unexplained urinary incontinence should be referred to a specialist for further evaluation because it is not a normal condition of aging.

CRITICAL THINKING

Mr. Jones

Mr. Jones, age 72, lives at home. His home has wood floors with throw rugs. The bathroom is located in the hall outside his bedroom. Mr. Jones has nocturia and is occasionally incontinent from urgency to void. He takes bumetanide (Bumex) daily.

1. What additional assessment data should be obtained about Mr. Jones regarding his urinary status and home environment?
2. Are safety concerns present in the home environment?
3. What nursing diagnoses should be included in Mr. Jones's nursing care plan?
4. What should be included in a teaching plan for Mr. Jones?

Answers at end of chapter.

Key Changes in the Immunological System with Aging

Key aging-related changes in the immune system include the following:

- Decreased immune response
- Decreased number and function of T cells, leading to impaired ability to produce antibodies to fight disease

NURSING IMPLICATIONS. Older patients tend to have more chronic diseases that may increasingly depress their immune responses over time. Although older patients have fewer colds, they are at higher risk for influenza and other complications once they get a cold. It takes longer to recover from infections, so patients and their family members need to be told that a prolonged recovery is to be expected. It is also important to screen visitors for illness before they visit a recuperating older patient.

Efforts at prevention should focus on teaching the older patient about the importance of obtaining current immunizations, reducing stress, eating right, exercising, and maintaining a healthful lifestyle. Individuals on medications for conditions that put them at risk for immunosuppression, such as steroids, should be aware of the need to take additional safety precautions around others who are ill. Nurses can help patients help themselves by encouraging techniques such as proper hand washing that support universal precautions.

Key Changes in the Neurological System with Aging

Key aging-related changes in the neurological system include the following:

- Progressive loss of brain cells
- Decreased blood flow and oxygen utilization to the brain

- Decreased protein synthesis
- Decrease in sensitivity and the sensation pathways
- Increased reaction times
- Decreased motor coordination
- Decreased equilibrium
- Decreased ability of the hypothalamus to regulate body temperature
- Change in neurotransmitter secretion levels

NURSING IMPLICATIONS. Changes in the nervous system of the older patient can be seen in both the peripheral and central systems. These changes have significant meaning for the older individual, especially in the area of safety. With normal aging there is a slowed response to stimuli and a marked decrease in the speed of the psychomotor response to that stimuli. Because stronger stimuli are required to elicit any neurological response, the older patient is unable to perceive early signs of danger. To protect from accidental skin burns, the thermostat on water heaters should be lowered and electrical heating devices such as heating pads, electric blankets, and mattress pads should not be used.

Another safety issue of concern focuses on changes in balance. It is more difficult to maintain balance as one ages, especially when musculoskeletal changes are considered. Special caution should be taken to assist older patients with transferring and ambulation activities so optimum levels of safety can be maintained.

Fine tremors of the hand are a normal finding with advancing age and tend to increase when the older patient is cold, excited, hungry, or active. Assistive devices provided by an occupational therapist, such as handle grips or anchored equipment, can help eliminate the unsteadiness created when fine tremors make it more difficult to accomplish activities of daily living (Fig. 14-4). Accompanied by generalized muscle weakness, normal neurological changes that arise with advancing age usually occur on both sides of the body at the same time. One-sided weakness, sensory problems, and performance problems should always be referred for further evaluation. Coarse tremors of the finger, forearm, head, eyelids, or tongue that occur when the body part is at rest may be a sign of a neurological problem such as Parkinson's disease. These generally occur on one side of the body first and should always be referred for further evaluation.

Key Changes in the Sensory System with Aging

Key aging-related changes in the sensory system include the following:

- Decreased visual perception
- Decreased elasticity of the eardrum
- Decreased sense of smell
- Decreased taste perception
- Decreased touch sensation

Figure 14-4 Assistive devices for activities of daily living. (A) Sock and stocking aid. (B) Easy-pull hair brush. (C) Food guard. (Courtesy Sammons Preston, Inc., Bollingbrook, Ill, with permission.)

NURSING IMPLICATIONS. Problems that occur with normal changes in the aging sensory system are not inevitable with advancing age. Early identification and prompt referral can minimize sensory loss, which has a strong impact on the older person's psychological health.

Normal aging changes in the eye affect the focus ability of the lens and the maneuverability of the eye muscles to meet the needs of near and far vision. It is especially difficult for older patients to read fine print, although it is usually manageable with reading glasses or a bifocal lens. When caring for patients who wear glasses, it is important to remind patients to consistently wear their glasses as needed and to help the patient keep them clean and in good repair. When glasses are removed by the patient, keep them accessible and in a protective, labeled case.

The older patient has a more difficult time adjusting to changes between light and dark settings. Seeing in the dark can be enhanced with the use of a red night-light because red lighting is more easily detected by the cones and rods in the older patient's eye. Make every effort to reduce glare from bright sunlight because sensitivity to glare is enhanced with the normal changes that occur in the aging eye (Fig. 14-5). The glare from car headlights may impair vision in older patients and reduce their ability to drive at night.

Several eye disorders can affect the aging eye. (See Chapter 49.) **Cataracts**, one of the most common pathological problems affecting the aging eye, cloud the lens and impair vision. **Glaucoma** is a chronic disease characterized by increased intraocular pressure that can damage the optic nerve. Another common visual condition that occurs later in life is **macular degeneration**, which results in a loss of central vision. Regardless of the means, any visual loss in

older patients puts them at risk for developing psychological problems with disorientation, withdrawal, or self-imposed isolation caused by **sensory deprivation**.

Hearing loss is a common condition found in older individuals. Although the severity of the hearing loss caused by aging is variable, the stigma it carries is the same. For most older patients, the first difficult sounds to discriminate are the high-pitched tones. Therefore it is often more effective to whisper when communicating with the hearing-impaired individual, because whispering decreases the pitch of the sounds. Shouting is not helpful because both volume and pitch are increased. It is best to speak to a hearing-impaired person in a moderate volume and a lower tone. It is also helpful to stand in front of hearing-impaired patients so they can see the speaker's face during communication (Box 14-2).

Two types of hearing loss can occur separately or in combination in the hearing-impaired patient. Conduction loss is due to blockage or damage to the mechanisms that transmit sound to the middle ear, where it is carried by the acoustic

BOX 14-2 Communicating with Hearing-Impaired Patients

- Ensure that hearing aids are on with working batteries, if applicable.
- Face patient so the speaker's face is visible to patient.
- Speak toward patient's best side of hearing.
- Speak in a clear, moderate-volume, low-pitched tone.
- Do not shout because this distorts sounds.
- Recognize that high-frequency tones and consonant sounds are lost first—s, z, sh, ch, d, g.
- Eliminate background noise because it can distort sounds.

nerve to the brain. Conduction hearing loss can be due to a variety of factors, some as simple as ear wax buildup, and in most cases can be successfully managed. The other type of hearing loss, sensorineural loss, is due to damage to the structures in the inner ear and is much more difficult to manage. This type of loss can result from illness, medication use, or long-term abusive noise pollution that damages the sensitive structures involved with sensation and interpretation of sound. It is important to use hearing protection throughout life because damage to the ear is usually not reversible.

New-technology hearing aids can help most people with either type of hearing loss. Patients should be referred to an audiologist for further evaluation if hearing loss is suspected. Hearing aids are not well accepted by all older persons or their family members because they are a visual sign of a loss. Because of this, maintain patient privacy if a referral for further evaluation is made. If the older patient already has a hearing aid, it should be kept accessible to the patient at all times. The hearing aid should be kept clean with soap and water. A cotton swab removes wax buildup in tiny areas of the hearing aid. When not in use, the hearing aid should be stored in a labeled protective container and the battery turned off to conserve it. Extra batteries should be readily available.

As discussed in the gastrointestinal section of this chapter, the senses of taste and smell work closely together. Like other sensory losses, a declining ability to taste is not a problem exclusive to the older individual. Both ill-fitting dentures and poor oral care can contribute to an alteration in the sense of taste, as can certain medications, tobacco substances, and oral disease.

Although they are often treated together as one sensory loss, the incidence of loss of the sense of smell is more common than the disorder that focuses on the loss of taste. In some cases the loss of smell may be due to sinus problems, nasal obstruction, or allergies. If olfactory receptors are the primary cause for losing the sense of smell, there is little that can be done to treat the loss. Assess patients' medication charts, as well as their oral cavity, if they report a recent loss of smell or taste sensation.

Nurses also need to be aware of the care environment they provide for the older patient. Overstimulation produced by **sensory overload**, commonly experienced in intensive care hospital settings, can create psychological and physical strains that can make it difficult for the older patient to cope. As a patient advocate, be sensitive to the patient's care environment and changes in the patient's health care status, identifying and minimizing overload situations early in the recuperation period.

Key Changes in the Sexuality System with Aging

Key age-related changes in sexuality include the following:

- Chronic illnesses, which may affect sexual functioning
- Functional sexual changes in older men, commonly alteration in ability to obtain or maintain an erection and to ejaculate
- Functional sexual changes in older women, such as decreased vaginal lubrication
- Sexual problems caused by psychological factors, which are more common than physical ones in elderly patients
- Longer sexual arousal time in the older patient
- Increase in sexual activities that focus on nonintercourse intimacy behaviors, including various forms of touch

NURSING IMPLICATIONS. The older patient's sexuality is an important aspect to consider when providing care. It is essential to accept that sexuality is one of the basic physiological needs identified in Maslow's hierarchy for all individuals regardless of age. Be aware of personal attitudes and values about sexuality, sex, and aging, being careful that personal stereotypes and beliefs do not interrupt the older person's attempt to maintain sexual identity. Because privacy remains a common problem for individuals in health care settings, provide the patient some scheduled private time for sexual expression. As new sexual enhancement treatments become more available to patients, there may be a greater openness to discuss sexual expression in conversations with their older patients. Still, there remain many older patients who may have difficulty overcoming barriers to sexual expression because of cultural or religious beliefs, lack of a suitable partner, fear of failure, fear of consequences, illness, side effects of medications, and certain chronic diseases that may alter libido or sexual functional abilities. Because sexual discussions with these patients may be more difficult, it is important to address the sexual history section as sensitively, professionally, and completely as other sections of the patient assessment form (Table 14-2).

TABLE 14-2 NURSING ASSESSMENT OF SEXUALITY

As with any nursing skill, practice will increase your comfort in collecting sexuality data for the older patient so these needs are not ignored. Assessment of sexuality concerns may lead to the discovery of other health issues and is a valuable part of data collection. As you collect data, be aware of problems (e.g., pain, medication side effects, mobility, dexterity, elimination, angina, surgery) identified in the history that may impact sexual functioning. Also, establish rapport with the patient by collecting other data first and turning to sexuality data at the end of the history. Older patients often respond to sexuality questions but will not initiate the topic.

Naturally, you should use a professional approach and manner, and tell the patient that you will now ask questions about sexuality. Start with questions that are likely to be more comfortable for the patient, as follows:

- Address roles first. For example: What concerns (do you have or has your illness created) in carrying out your roles with your (spouse or sexual partner)?
- Address relationship issues next. For example: What effect on your relationship with your (spouse or sexual partner) has this (illness, symptom, chronic illness) had?
- Address body image. For example: What effect has your (illness, surgery [mastectomy, prostate, ostomy], chronic illness, aging-related changes) had on your self-concept of being a (man or woman)?
- Address sexually transmitted diseases. For example: Do you have any discharge or open sores (vaginal, penile)?

► COGNITIVE AND PSYCHOLOGICAL CHANGES IN THE OLDER PATIENT

Cognition

In addition to those physiological changes that occur with advancing age, older patients are also experiencing changes that have an effect on cognition. Cognition includes abilities related to intelligence, memory, orientation, judgment, calculation abilities, and learning. Cognition focuses on intake of information and storage, processing, and retrieval of stored information. For the most part, older patients store information without much conscious effort. If dealing with information becomes difficult, the older person may begin to worry. Unless this worry is addressed, the patient's concern may result in psychological problems and fears.

Many factors can affect cognition. Sensory changes and diseases associated with age can cause misinterpretation of information being collected. Pain from chronic diseases, such as arthritis, can limit cognition as pain takes over the body and mind. Sleep deprivation caused by worry or fear can make it more difficult to perform routine tasks. Medications that cause drowsiness as a side effect can also impair cognition.

Long-term memory retrieval is easier to accomplish in old age than short-term memory retrieval. Assist the patient having short-term memory problems by using written lists, visual cues, and other memory-enhancing systems to aid in strengthening short-term memory skills.

Intelligence does not decline as one ages if it is measured using an appropriate instrument that focuses on accuracy and not on speed of response. Although cognitive abilities do tend to slow down with advancing age, they are not lost. Most of the subtle declines that do occur with information processing and retrieval do not need to interfere with the older patient's abilities in performing activities of daily living.

Nurses need to assist in the identification of individual problem situations and work with older patients and their families in developing strategies to better address their needs. It is common knowledge that health, good nutrition, and adequate sleep are important factors for brain functioning. These factors should be the cornerstones in planning care for the older patient.

Coping Abilities

How the individual chooses to adapt to a change in functional ability over time has a significant impact on how that individual will work through the entire maturational process called aging. In addition to normal aging changes, many older patients are coping with compounding changes that occur because of chronic disease. Nurses must not lose sight of the fact that in addition to changes caused by some decline in physical and cognitive functioning, older persons simultaneously work to deal with many societal and culturally perceived losses associated with advancing age. Changes in employment status and societal and family roles and

shifts from independence to dependence may have a strong psychological impact on both older patients and significant others. With such a combination of "losses," an alteration in the confidence level of the older patient may be seen, requiring encouragement of self-care behaviors.

The older person's personality, attitude, past life experiences, and desire to adapt to change are all intrinsic influencing factors that assist the older patient in coping with changes brought on by advancing age. Extrinsic factors include things such as financial status, family support, and support provided by those who directly care for the patient. If older patients have the energy, desire, determination, and support of those who care for them, they will be better able to optimize use of their cognitive functions toward health.

Depression

There are times when the psychological impact of change is too difficult to cope with, and loneliness, grief, or sadness does not easily allow the older person to cognitively focus on health. When this happens, **depression** can result, with the potential to disable the older individual's mind and body. Depression is the most common psychiatric problem among older adults. This psychological condition, which causes a disturbance in mood, increases the risk for suicide, physical health complaints, and sleep disturbances.

It is important to understand that the frequency and intensity of depression generally increase with advancing age. Depression can result from physical changes in the brain caused by medications or conditions that affect the neurotransmitters in the brain or from psychological changes at an emotional level, such as maladaptive coping from a perceived loss. Regardless of the cause, depression is a condition that has the potential to be reversed with prompt identification and treatment. It is important, therefore, to be sensitive to what the older individual is and is not saying during communications. Patients should be referred for treatment if depression is suspected before maladaptive behaviors occur.

Dementia

Unlike depression, **dementia** involves a more permanent progressive deterioration of mental functioning. Dementia is often characterized by confusion, forgetfulness, impaired judgment, and personality changes. There are two main types of dementia: multi-infarct dementia and Alzheimer's disease.

The multi-infarct classification results from repeated strokes that affect the brain tissue. The onset for this condition can be sudden or gradual, but its course is marked by a cyclical worsening and lessening of signs and symptoms that vary with the intensity and location of the brain damage.

The cause of Alzheimer's disease is unknown, but symptoms gradually begin with impaired memory that progresses to language and motor function losses. The course of this disease is marked by stages that can occur up to 14 years before death. It is only on autopsy of the brain that a definitive diagnosis of Alzheimer's disease can be made. Until

then, Alzheimer's is suspected after other types of dementia have been ruled out with testing.

With any dementia, help the older patient maintain an **optimum level of functioning** in an atmosphere that provides for physical and emotional safety. In efforts to help ground the confused patient, incorporate **reality orientation** or validation into all nursing interventions. Sensory overload should be decreased for confused patients. Speak calmly and slowly and provide nonthreatening therapeutic touch if accepted by the patient.

In addition, it is important to address the education and support needs of the patient's family as they learn to deal with changes in behavior demonstrated by the older patient. Refer any patient with confusion for a mental status examination to help in determining whether the person suffers from depression or dementia. It is essential that a sensory status examination be conducted on the older patient before a mental status examination is conducted to help ensure the accuracy of the test results.

Sleep and Rest Patterns

The need for sleep in elderly patients does not decrease with age, but the pattern usually varies from earlier times in their lives. As in any age group, the lack of sleep leads to fatigue, irritability, increased sensitivity to pain, and increased likelihood of accidental behaviors. This is why it is important to obtain a baseline sleep and rest history when the older patient is admitted to the health care unit. Consider sleep patterns, bedtime rituals, rest and nap patterns, daily exercise patterns, stress level, dietary intake patterns, and lifestyle issues such as caffeine, alcohol, and nicotine intake when completing the sleep and rest assessment of an older patient.

Circulatory problems may disrupt normal sleep patterns for the older person and may be the only clue of an impending health problem. The anxious patient who is unable to sleep may be calmed with back rubs, foot rubs, a warm bath, warm milk, or a glass of wine, if not contraindicated, when patterned bedtime rituals prove to be unsuccessful. Sleep medications should be used only as a last resort because they can affect the quality or depth of the sleep the older person receives and may produce unwanted side effects.

Medication Management

One of the most difficult tasks for older patients, their family members, and the health care provider caring for them centers around the topic of medication management. Because older patients are more susceptible to drug-induced illness and adverse side effects for a variety of reasons already addressed in this chapter, nurses need to be especially aware of what the older patient is taking, how it is being taken, and what effect it is having.

Older patients use many medicines for various ailments (Fig. 14-6). Most have more than one chronic illness for which they take medications. Sometimes these different medications interact and produce side effects that can be dangerous. Not only do health care providers need to be

concerned about prescribed medicines, they also need to look at the types of over-the-counter medicines older patients take, as well as the self-prescribed extracts, elixirs, herbal teas, cultural healing substances, and other home remedies commonly used by individuals of their age cohort.

Health care providers not only need to be concerned about overuse and combinations of medications, but also misuse of them. If an older patient crushes a large enteric-coated pill so that it can be taken in food and easily swallowed, it destroys the enteric protection and can inadvertently cause damage to the stomach and intestinal system. Because the U.S. health care system does not have a universal medication program for older individuals, some patients intentionally skip prescribed doses in efforts to save money. When prescribed doses are not being taken as expected, problems do not clear up as quickly and new problems may result.

Work closely with older patients and their families on medication education. Patients need to know what each prescribed pill is for, when it should be taken, how it should be taken, and side effects to report. As a patient advocate, work with the pharmacist to remedy administration concerns so that the prescribed dose can be taken as directed. Write down early medication side effects, educating patients or designated care providers to be proactive in their care.

Medication use, abuse, and misuse need to be addressed regularly with older persons. Concerns need to be closely monitored and addressed before they evolve into problem situations. Helping older patients consistently adhere to a prescribed medication routine with visual and verbal supports helps all those involved in the process of their medication management. This method also encourages self-care and supportive independence, as able, making for easier and safer medication use.

► HEALTH PROMOTIONAL ROLE IN NURSING CARE OF THE OLDER PATIENT

Overall, the nurse who works with older patients must recognize the importance of developing strong skills in the areas of listening and observation. With competence in these skill areas, patterns of change can be readily identified and concerns can be addressed before they become problems for the elderly. Although this is important to consider for all patients who receive nursing care, it becomes especially important when working with older patients. This is because older persons often do not present with the typical symptom

patterns associated with health problems seen in younger individuals, and early signs of health problems are often not evident in older patients.

By learning about normal changes expected with advancing age, older patients and their families can be helped to recognize commonly held societal myths associated with aging. In efforts to help older patients meet their optimum level of functioning, it is important to assess the older patient holistically, remembering that nursing assessment is an ongoing process. To assist in focusing on health promotion with older patients, look to health education activities, screening efforts for disease detection, immunization programs, and specific safety practices (Table 14–3).

TABLE 14–3 NURSING CARE FOCUS ON SAFETY ALPHABET FOR OLDER PATIENTS

A is for ABILITIES	<ul style="list-style-type: none"> • Know your abilities. • Know patient's abilities. • Base nursing actions on your abilities. • Seek out assistance when needed.
B is for BODY MECHANICS AND ALIGNMENT	<ul style="list-style-type: none"> • Use proper body mechanics. • Use appropriate assistive devices. • Ensure patient is in proper body alignment.
C is for COMFORT	<ul style="list-style-type: none"> • Ensure physical and emotional comfort during care. • Use pain scale during each assessment.
D is for DELIBERATE MOVEMENTS	<ul style="list-style-type: none"> • Plan ahead and communicate plans to patient. • Demonstrate confidence during care. • Alert patient to planned movements by saying, "Moving on three. One, two, three." • Ensure patient assists with moves as able.
E is for ENVIRONMENT	<ul style="list-style-type: none"> • Always place call light within reach. • Keep environment uncluttered and safe. • Ask patient's permission before moving items.
F is for FALLS	<ul style="list-style-type: none"> • Put items back as patient prefers. • Remember falls are a primary concern for older patients. • Use interventions to prevent them: Assist patients with ambulation, use assistive devices, answer call lights promptly, provide accessible toileting facilities, use night-lights, avoid use of throw rugs.
G is for GIVING YOUR TIME	<ul style="list-style-type: none"> • Allow more time to perform actions. • Do not rush older patients. • Provide time for listening and observing, so concerns are addressed before becoming problems.
H is for HANDWASHING	<ul style="list-style-type: none"> • Use correct handwashing protocols to protect yourself and older patients. • Use standard precautions to protect yourself and older patients.

Answers to CRITICAL THINKING

Mr. Jones

- Does he live alone? Does he have a fall history? If so, does he wear a device to signal for help? What type of night-light is used? How far is it to the bathroom? Does he take his bumetanide early in the day rather than at night? Does he void before going to bed? Does he anticipate needing to void 30 minutes after lying down?
- Wood floors that are slippery when wet from incontinence are a safety hazard, as well as throw rugs that may slide or cause tripping. An appropriate night-light should be available.
- Nursing diagnoses include functional incontinence related to distance to bathroom; deficient knowledge related to safety, medication administration, and nocturia; and risk for injury related to slippery floors from incontinence, use of throw rugs, lighting.
- A teaching plan should include the following:
 - **Safety:** Place urinal at bedside to prevent incontinence on way to bathroom. Use red night-light to improve vision and prevent falls. Use easily cleaned floor covering that is secure and absorbent to avoid falls. Consider the need for wearing device that sends a signal for help.
 - **Medication administration:** Take diuretics early in the day to avoid having to get up frequently at night.
 - **Nocturia:** Void before lying down. Anticipate need to void after lying down by reclining in chair for 30 minutes before going to bed and then void on way to bed.

REVIEW QUESTIONS

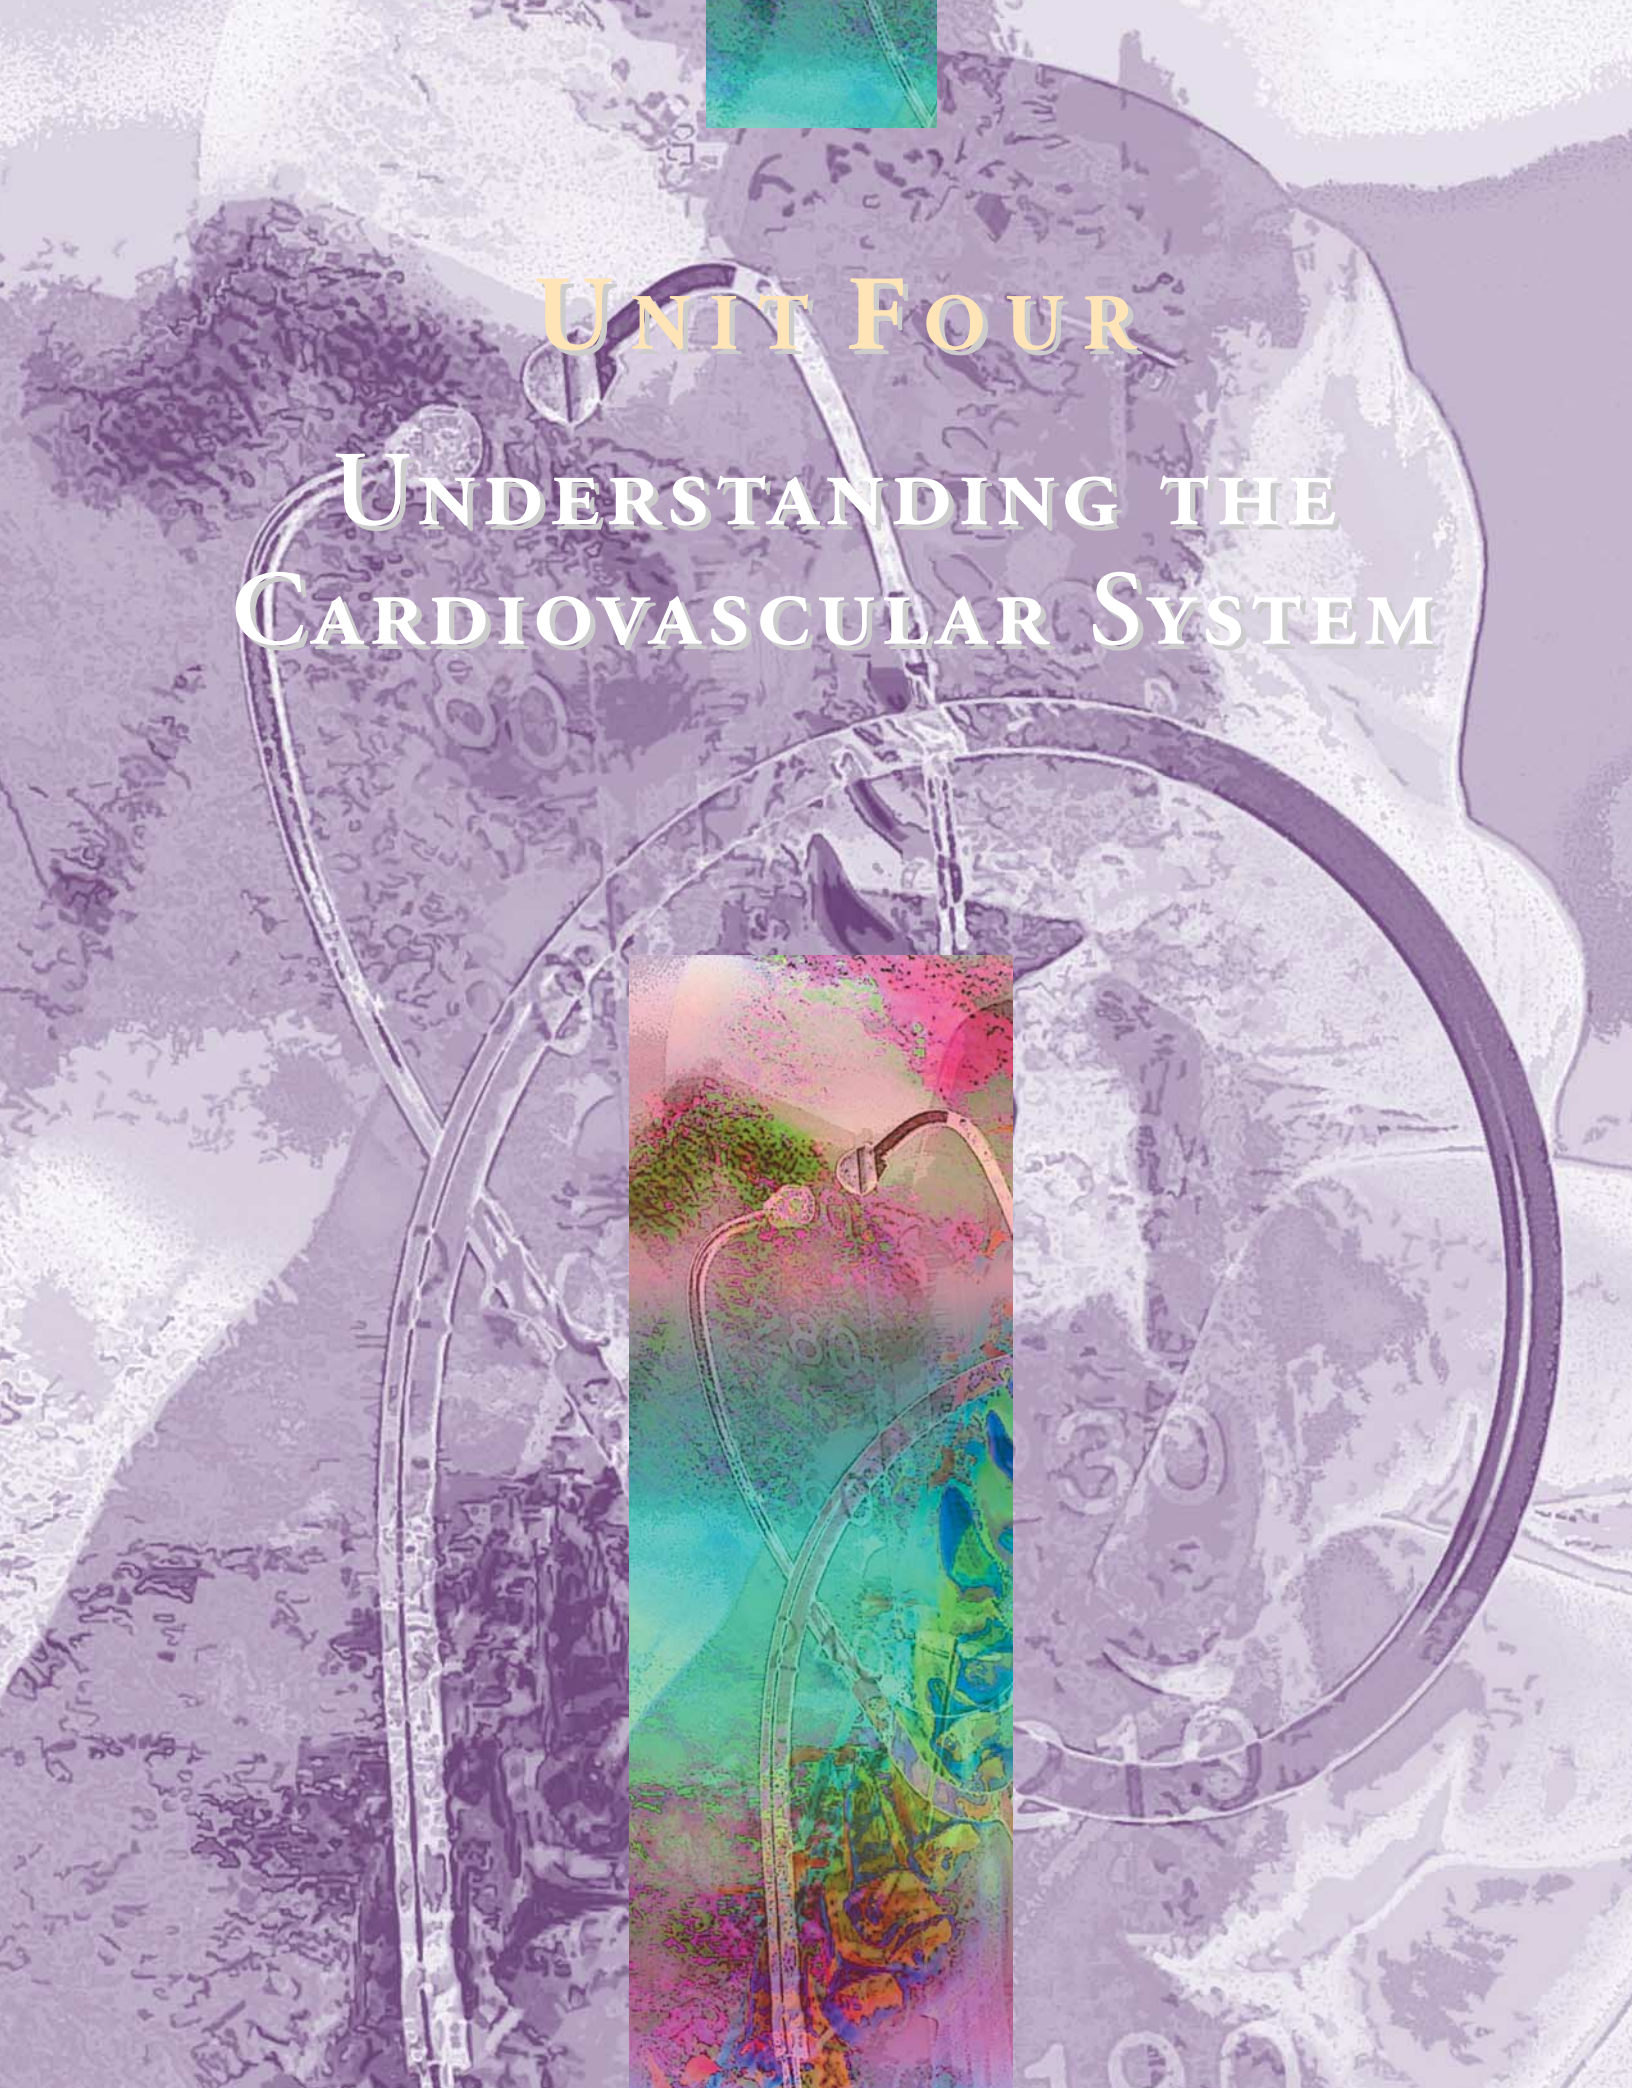

- The nurse is assessing a patient who says “I am shorter now.” The nurse responds based on the understanding that which of the following commonly contributes to individuals becoming shorter with age?
 - Contractures
 - Bone degeneration in the legs
 - Hyperextension of the cervical spine
 - Water loss from spinal intervertebral disks
- The nurse is caring for a patient on bedrest. The nurse is contributing to the plan of care based on the understanding that pressure ulcers occur at sites of ischemia, which can begin to develop in which of the following time frames?
 - 5 to 10 minutes
 - 20 to 40 minutes
 - 60 minutes
 - 120 minutes
- The nurse is teaching a patient who has hypertension about the disease. Which of the following does the nurse understand contributes to increased blood pressure with age?
 - Increased peripheral vascular resistance
 - Decreased peripheral vascular resistance
 - Increased cardiac output
 - Decreased cardiac output
- The nurse is planning care for a patient at risk of aspiration. Which one of the following does the nurse understand increases the older patient’s risk for aspiration?
 - Increased lung capacity
 - Decreased lung capacity
 - Decreased gag reflex
 - Increased gag reflex
- The nurse is assessing a patient’s sexuality. The nurse understand that which one of the following is the most common factor related to sexual problems in older patients?
 - Social
 - Financial
 - Physical
 - Psychological

QUESTIONS TO GUIDE YOUR READING

1. What is the normal anatomy of the cardiovascular system?
2. What is the normal function of the cardiovascular system?
3. What data should you collect when caring for a patient with a disorder of the cardiovascular system?
4. What are the diagnostic tests commonly performed to diagnose disorders of the cardiovascular system?
5. What nursing care should you provide for patients undergoing each of the diagnostic tests?
6. What are common therapeutic measures used for patients with disorders of the cardiovascular system?

► REVIEW OF NORMAL ANATOMY AND PHYSIOLOGY

The cardiovascular system consists of the heart and blood vessels, including arteries, capillaries, and veins. Its function is to pump and distribute blood throughout the body.

Heart

Cardiac Location and Pericardial Membranes

The heart is located in the mediastinum, the area between the lungs in the thoracic cavity. It is enclosed by three pericardial membranes that make up the pericardial sac. The

outermost of these membranes is the fibrous pericardium, which forms a loose-fitting sac around the heart. The second, or middle, layer is the parietal pericardium, a serous membrane that lines the fibrous layer. The third and innermost layer, the visceral pericardium or epicardium, is a serous membrane on the surface of the heart muscle. Between the parietal and visceral layers is serous fluid, which prevents friction as the heart beats.

Cardiac Structure and Vessels

The walls of the four chambers of the heart are made of cardiac muscle (myocardium) and are lined with endocardium, which is smooth epithelial tissue that prevents abnormal

clotting. The endocardium also covers the valves of the heart and continues into blood vessels as the lining. The coronary vessels include the arteries and capillaries that circulate oxygenated blood throughout the myocardium and the veins that return unoxygenated blood to the heart. The two main coronary arteries are the first branches of the ascending aorta, just outside the left ventricle (Fig. 15-1).

The upper chambers of the heart are the thin-walled right atrium and left atrium, which are separated by the interatrial septum. The lower chambers are the thicker-walled right and left ventricles, which are separated by the interventricular septum. Each septum is made of myocardium that forms a common wall between the two chambers.

The right atrium receives deoxygenated blood from the upper body by way of the superior vena cava and from the lower body by way of the inferior vena cava. (See Fig. 15-1.) This blood flows from the right atrium through the tricuspid valve into the right ventricle. Backflow during ventricular systole (contraction and emptying) is prevented by the tricuspid or right atrioventricular (AV) valve (Fig. 15-2). The right ventricle pumps blood through the pulmonary semilunar valve to the lungs by way of the pulmonary artery. The pulmonary semilunar valve prevents backflow of blood into the right ventricle during ventricular diastole (relaxation and filling).

The left atrium receives oxygenated blood from the lungs by way of the four pulmonary veins. This blood flows through the mitral or left AV valve into the left ventricle.

The mitral valve prevents backflow of blood into the left atrium during ventricular systole. The left ventricle pumps blood through the aortic valve to the body by way of the aorta. The aortic valve prevents backflow of blood into the left ventricle during ventricular diastole.

The tricuspid and mitral valves consist of three and two cusps, respectively. These cusps, or flaps, are connective tissue covered by endocardium and are anchored to the floor of the ventricle by the chordae tendineae and papillary muscles. The papillary muscles are columns of myocardium that contract along with the rest of the ventricular myocardium. This contraction pulls on the chordae tendineae and prevents inversion of the AV valves during ventricular systole. (See Fig. 15-2.)

Although each ventricle pumps the same amount of blood, the much thicker walls of the left ventricle pump with approximately six times the force of the right ventricle to distribute the blood throughout the body. This difference in force is reflected in the great difference between systemic and pulmonary blood pressure.

Cardiac Conduction Pathway and Cardiac Cycle

The cardiac conduction pathway is the pathway of electrical impulses that generates a heartbeat. The sinoatrial (SA) node in the wall of the right atrium is a specialized mass of cardiac muscle that depolarizes rhythmically and most rap-

Figure 15-1 Anterior view of the heart and major blood vessels. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 3. FA Davis, Philadelphia, 1999, p 260.)

Figure 15-2 Frontal section of the heart showing internal structures and cardiac blood flow. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 3. FA Davis, Philadelphia, 1999, p 260.)

idly, 60 to 80 times per minute, and therefore initiates each heartbeat. For this reason it is sometimes called the pacemaker, and a normal heartbeat is called a normal sinus rhythm. From the SA node, impulses travel to the AV node located in the lower interatrial septum, to the bundle of His in the upper interventricular septum, to the right and left bundle branches in the septum, and to the Purkinje fibers in the rest of the ventricular myocardium. If the SA node becomes nonfunctional, the AV node can initiate each heartbeat, but at a slower rate of 40 to 60 beats per minute. The bundle of His is capable of generating the beat of the ventricles, but at the much slower rate of 15 to 40 beats per minute.

A cardiac cycle is the sequence of mechanical events during one heartbeat. Simply stated, the two atria contract simultaneously, followed a fraction of a second later by the simultaneous contraction of the two ventricles. The contraction, or systole, of each set of chambers is followed by relaxation, or diastole, of the same set of chambers.

The atria in diastole continually receive blood from the veins. As pressure in the atria increases, the AV valves are forced open, causing most of the blood to flow passively into the ventricles. Atrial systole, referred to as atrial kick, pumps the remaining blood into the ventricles, and then the atria relax. Ventricular systole follows. The pressure in the ventricles causes the AV valves to close and forces the semilunar valves to open. Blood is then pumped into the aorta and pulmonary artery. There is no passive blood flow. Any blood leaving the ventricles must be pumped. Toward the very end of ventricular systole, as the pressure drops, the

blood tends to flow backward. It is this backflow of blood that closes the semilunar valves. The ventricles and atria are then all in diastole; the atria continue to fill until pressure opens the AV valves again, and the cycle is repeated.

The events of the cardiac cycle create the normal heart sounds. The first of the two major sounds (the lubb of lubb-dupp) is caused by the closure of the AV valves during ventricular systole. The second sound is created by the closure of the aortic and pulmonary semilunar valves.

Cardiac Output

Cardiac output is the amount of blood pumped by the left ventricle in 1 minute (the right ventricle pumps a similar amount); it is determined by multiplying stroke volume by pulse. Stroke volume is the amount of blood pumped by a ventricle in one beat and averages 60 to 80 mL. With an average resting heart rate of 70 beats per minute, an average resting cardiac output is 5 to 6 L (approximately the total blood volume of an individual that is pumped within 1 minute). During exercise, venous return increases and stretches the ventricular myocardium, which in response contracts more forcefully. This is known as Starling's law of the heart, and the result is an increase in stroke volume. More blood is pumped with each beat, and at the same time, the heart rate increases, causing cardiac output to increase to as much as four times the resting level, and even more for athletes.

The ejection fraction is a measure of ventricular efficiency and is usually about 60 percent. It is the stroke volume divided by total blood in the ventricle (also known as

the end-diastolic volume, which is approximately 120 to 130 mL). Lower values indicate that the ventricle is not pumping as forcefully and that more blood remains in the ventricle at the end of systole. The normal end-systolic volume is about 50 to 60 mL.

Regulation of Heart Rate

The heart generates its own electrical impulse, which begins at the SA node. The nervous system, however, can change the heart rate in response to environmental circumstances (Fig. 15-3). In the brain the medulla contains the cardiac centers: the accelerator center and the inhibitory center. Sympathetic nerve impulses—along sympathetic nerves from the thoracic spinal cord to the SA node, AV node, and ventricular myocardium—increase rate and force of contraction. Parasympathetic impulses—along the vagus nerve to the SA node and AV node—decrease heart rate.

The information for changes necessary in the heart rate comes to the medulla from pressoreceptors and chemoreceptors located in the internal carotid arteries and the aortic arch. The pressoreceptors, specialized cells in the carotid and aortic sinuses, detect changes in blood pressure. The chemoreceptors are located in the carotid and aortic bodies and are cells specialized to detect changes in the oxygen content of the blood. In response to either a drop in blood pressure or a decrease in blood oxygen level, the heart receives sympathetic impulses and beats faster in an attempt to provide sufficient oxygenation for tissues.

Hormones and the Heart

The hormone epinephrine, secreted by the adrenal medulla in stressful situations, is sympathomimetic in that it increases the heart rate and force of contraction and it dilates the coronary vessels. This in turn increases cardiac output and systolic blood pressure.

Aldosterone, a hormone produced by the adrenal cortex, is important for cardiac function because it helps regulate blood levels of sodium and potassium, both of which are needed for the electrical activity of the myocardium. The blood level of potassium is especially critical because even a small deficiency or excess impairs the rhythmic contractions of the heart.

The atria of the heart secrete a hormone of their own called atrial natriuretic peptide (ANP) or atrial natriuretic hormone (ANH). As its name suggests, ANP increases the excretion of sodium by the kidneys, perhaps by inhibiting secretion of aldosterone by the adrenal cortex or renin by the kidneys. Atrial natriuretic peptide is secreted when a higher blood pressure or greater blood volume stretches the walls of the atria. The loss of sodium is accompanied by the loss of more water in urine, which decreases blood volume and perhaps blood pressure as well.

Blood Vessels

Arteries and Veins

Arteries and arterioles carry blood from the heart to capillaries. Their walls are relatively thick and consist of three layers. Arteries carry blood under high pressure, and the outer layer

Figure 15-3 Nervous system regulation of the heart. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 3. FA Davis, Philadelphia, 1999, p 269.)

of fibrous connective tissue prevents rupture of the artery. The middle layer of smooth muscle and elastic connective tissue contributes to the maintenance of normal blood pressure (BP), especially diastolic BP, by changing the diameter of the artery. The diameter of arteries is regulated primarily by the sympathetic division of the autonomic nervous system. The lining is simple squamous epithelium, called endothelium, which is very smooth to prevent abnormal clotting.

Veins and venules carry blood from capillaries to the heart. Their walls are relatively thin because there is less smooth muscle (veins do not have as important a role in the maintenance of BP as arteries). Sympathetic impulses can bring about extensive constriction of veins, however, and this becomes important in situations such as severe hemorrhage. The lining of veins is endothelium that prevents abnormal clotting; at intervals it is folded into valves to prevent backflow of blood. Valves are most numerous in the veins of the extremities, especially the legs, where blood must return to the heart against the force of gravity.

Capillaries

Capillaries carry blood from arterioles to venules and form extensive networks in most tissues. The exceptions are cartilage, the epidermis, and the lens and cornea of the eye. Their walls, a continuation of the lining of arteries and veins, are one cell thick to permit the exchanges of gases, nutrients, and waste products between the blood and tissues (Fig. 15-4). Blood flow through a capillary network is regulated by a precapillary sphincter, a smooth muscle cell that contracts or relaxes in response to tissue needs. In an active tissue such as exercising skeletal muscle, for example, the rapid oxygen uptake and carbon dioxide production causes dilation of the precapillary sphincters to increase blood flow. At the same time, precapillary sphincters in less active tissues constrict to reduce blood flow. This is important because there is not enough blood in the body to fill all the capillaries at once; the fixed volume must constantly be shunted or redirected to where it is needed most.

The blood pressure in capillaries is 30 to 35 mm Hg at the arterial end of the network, and it drops to about 15 mm Hg at the venous end. This pressure is low enough to prevent rupture of the capillaries but high enough to permit filtration. Tissue fluid is formed from the plasma in capillaries by the process of filtration. Because capillary blood pressure is higher than the pressure of the surrounding tissue fluid, plasma and dissolved materials such as nutrients are forced through the capillary walls to become tissue fluid. Some of this tissue fluid returns to the capillaries, and some is collected in lymph capillaries. Now called lymph, it too is returned to the blood, by the system of lymph vessels. Should blood pressure within the capillaries increase, more tissue fluid than usual is formed, which is too much for the lymph vessels to collect. This is called edema.

Blood Pressure

Blood pressure is the force of the blood against the walls of the blood vessels and is measured in mm Hg, systolic over

diastolic. The normal range of systemic arterial pressure is 90 to 135/60 to 85 mm Hg. Blood pressure decreases in the arterioles and capillaries, and the systolic and diastolic pressures merge into one pressure. As blood enters the veins, BP decreases further and approaches zero in the caval veins. As mentioned previously, the blood pressure in the capillaries is of great importance, and normal blood pressure is high enough to permit filtration for nourishment of tissues but low enough to prevent rupture.

The arteries and veins are usually in a state of slight constriction that helps to maintain normal blood pressure, especially diastolic pressure. This is called peripheral resistance; it is regulated by the vasomotor center in the medulla, which generates impulses along sympathetic vasoconstrictor nerves to all vessels with smooth muscle to maintain slight constriction. More impulses per second increase vasoconstriction and raise blood pressure; fewer impulses per second bring about vasodilation and lower blood pressure. The information for changes needed in the vessel diameter comes to the medulla from the pressoreceptors and chemoreceptors located in the internal carotid arteries and aortic arch.

Blood pressure is also affected by many other factors. If heart rate and force increase, blood pressure increases up to a point. If the heart is beating very fast, the ventricles are not filled before they contract, cardiac output decreases, and blood pressure drops. The strength of the heart's contractions depends on adequate venous return, which is the amount of blood that flows into the atria. Decreased venous return results in weaker contractions.

Venous return depends on several factors: constriction of the veins so that blood does not pool in them, the skeletal muscle pumping to squeeze the deep veins of the legs, and the muscles of respiration compressing and expanding the veins in the chest cavity. The valves in the veins prevent backflow of blood and thus contribute to the return of blood to the heart.

The elasticity of the large arteries also contributes to normal blood pressure. When the left ventricle contracts, the blood stretches the elastic walls of the large arteries, which absorb some of the force. When the left ventricle relaxes, the walls recoil or snap back and put pressure on the blood. Normal elasticity, therefore, lowers systolic pressure, raises diastolic pressure, and maintains normal pulse pressure. Pulse pressure is the difference between the systolic and diastolic pressures. The usual ratio of systolic to diastolic to pulse pressure is 3:2:1.

Renin-Angiotensin-Aldosterone Mechanism

The kidneys are of great importance in the regulation of blood pressure. If blood flow through the kidneys decreases, renal filtration decreases and urinary output decreases to preserve blood volume. Decreased blood pressure stimulates the kidneys to secrete renin, which initiates the renin-angiotensin mechanism (Fig. 15-5). Renin splits the plasma protein angiotensinogen (from the liver) to form angiotensin I, which is changed to angiotensin II by a converting enzyme found primarily in lung tissue. Angiotensin

Figure 15-4 Structure of an artery, arteriole, capillary network, venule, and vein. (From Scanlon, V, Sanders, T: *Essentials of Anatomy and Physiology*, ed 3. FA Davis, Philadelphia, 1999, p 277.)

II causes vasoconstriction and stimulates secretion of aldosterone, both of which raise blood pressure.

Aldosterone, secreted by the adrenal cortex, increases the reabsorption of sodium ions by the kidneys. Water follows the sodium back to the blood; this increases blood volume and blood pressure. Other hormones that affect BP include those of the adrenal medulla: norepinephrine, which

causes vasoconstriction throughout the body, and epinephrine, which increases cardiac output and causes vasoconstriction in skin and viscera. Antidiuretic hormone (ADH), from the posterior pituitary, directly increases water reabsorption by the kidneys, thus increasing blood volume and blood pressure. Atrial natriuretic peptide, secreted by the atria of the heart, is believed to inhibit aldosterone and

Figure 15-5 The renin-angiotensin aldosterone mechanism.

renin secretion and thereby increase renal excretion of sodium ions and water, which decreases blood volume and subsequently blood pressure.

Pathways of Circulation

The two pathways of circulation are pulmonary and systemic. (See Fig. 15–2.) Pulmonary circulation begins at the right ventricle, which pumps deoxygenated blood into the pulmonary artery. The pulmonary artery branches into two arteries, one to each lung. The pulmonary capillaries around the alveoli of the lungs are the site of gas exchange. Oxygenated blood returns to the left atrium by way of the pulmonary veins. The blood pressure in the pulmonary circulation is always low because the right ventricle pumps with only about one-sixth the force of the left ventricle. The arterial pressure is approximately 20 to 25/8 to 10 mm Hg, and the pulmonary capillary pressure is lower still. This is important to prevent filtration in pulmonary capillaries, which keeps tissue fluid from accumulating in the alveoli of the lungs, causing pulmonary edema.

Systemic circulation begins in the left ventricle, which pumps oxygenated blood into the aorta, the many branches of which give rise to capillaries within the tissues. Deoxy-

genated blood returns to the right atrium by way of the superior and inferior vena cava. The hepatic portal circulation is a special part of the systemic circulation in which blood from the capillaries of the digestive organs and spleen flows through the portal vein and into the capillaries (sinusoids) in the liver before returning to the heart. This pathway permits the liver to regulate the blood levels of nutrients such as glucose, amino acids, and iron and to remove potential toxins such as alcohol or medications from circulation.

Aging and the Cardiovascular System

It is believed that the “aging” of blood vessels, especially arteries, begins in childhood, although the effects are not apparent until later in life. **Atherosclerosis** is the deposition of lipids on and in the walls of arteries over a period of years, which narrows their lumens, decreases blood flow, and forms rough surfaces that may stimulate intravascular clot formation. **Arteriosclerosis** is the gradual deterioration of the walls of arteries as a result of the pressure they have withstood over many decades. Average resting blood pressure tends to increase with age and may contribute to stroke or left-sided heart failure. The thinner-walled veins, especially those of the legs, may also weaken and stretch, making their valves incompetent.

With age, the heart muscle becomes less efficient, and there is a decrease in both maximum cardiac output and heart rate, although resting levels may be more than sufficient (Gerontological Issues Box 15–1). The health of the

atherosclerosis: ather—porridge + sklerosis—hardness

arteriosclerosis: arteria=artery + sklerosis—hardness

BOX 15-1 GERONTOLOGICAL ISSUES

Cardiovascular changes that occur in the older adult include the following:

- Decrease in heart size
- Thickening of left ventricular wall
- Increased collagen in the cardiac muscle
- Decreased elastin in the cardiac muscle
- Stiffer and thicker cardiac valves
- Fibrosis of the SA node
- Decreased number of pacemaker cells
- Calcification of blood vessels
- Loss of arterial distensibility
- More tortuous vessels
- Decreased response to baroreceptors

These age-related changes increase the risk of developing the following:

- Sinus bradycardia
- Atrial fibrillation
- Atherosclerotic heart disease
- Elevated systolic blood pressure
- Decreased cardiac output and cardiac reserve
- Hypertension
- Peripheral vascular disease
- Postural hypotension
- Vagal syncope

myocardium depends on its blood supply, and with age there is greater likelihood that atherosclerosis will narrow the coronary arteries. Hypertension causes the left ventricle to work harder, and it may hypertrophy and outgrow its blood supply. The heart valves may become thickened by fibrosis, leading to heart **murmur**. **Dysrhythmias** are more common in the elderly as the cells of the conduction pathway become less efficient.

► **CARDIOVASCULAR DISEASE**

Cardiovascular disease is a major health concern in the United States according to statistics of the American Heart Association. In 1998 the single leading cause of death in America was coronary heart disease (CHD), which was responsible for one of every five U.S. deaths. About 220,000 people a year die of sudden death without ever reaching the hospital, usually because of ventricular fibrillation. The greatest cause of death in women is cardiovascular disease, mainly from CHD.

With cardiovascular disease a significant health problem in the United States, efforts to reduce it that target those especially at risk are greatly needed. The prevalence of CHD is greatest for Mexican-American men and African-American women, followed by African-American men and Mexican-American women, and then non-Hispanic white men and women. The incidence of angina is greater in women than in men, with African-American women having the greatest incidence. High blood pressure, the silent killer, occurs in one in four adults, with approximately one-third unaware that they have it. Non-Hispanic blacks are more likely to suffer from high blood pressure than are non-Hispanic whites.

Lifestyle plays a major role in risk factors for cardiovascular disease. Smoking contributes to approximately one in five cardiovascular diseases deaths. Dietary fat intake accounts for approximately 34 percent of the American diet, which increases cholesterol. Americans continue to be sedentary. Exercise needs to be promoted for all, including children, to reduce cardiovascular disease. For more information on cardiovascular disease statistics visit www.americanheart.org.

► **NURSING ASSESSMENT OF THE CARDIOVASCULAR SYSTEM**

Nursing assessment of the cardiovascular system includes a patient health history and physical examination (Gerontological Issues Box 15–2). If the patient is experiencing an

dysrhythmia: dys—difficult or abnormal + rhythmia—rhythm

BOX 15-2 GERONTOLOGICAL ISSUES

Older patients commonly have signs and symptoms atypical of a disorder. For example, the only symptom of myocardial infarction in an older patient may be dyspnea. Chest pain, a typical symptom, may not be present.

acute problem, the nursing assessment should focus on the most serious signs and symptoms and physical assessment data until the patient is stabilized (Table 15–1). An in-depth nursing assessment can be completed when the patient is stable. For stable or chronic cardiac conditions, a complete nursing assessment is done on admission. The nurse provides privacy and makes the patient as comfortable as possible before beginning the nursing assessment.

Subjective Data

To understand the patient’s cardiovascular problems, the nurse asks about past and current symptoms, use of prescribed and over-the-counter medications, use of recreational drugs, surgeries, treatments, and such risk factors as diet, activity, tobacco use, and recent stressors. Assessment of symptoms includes asking questions for WHAT’S UP?: where it is, how it feels, aggravating and alleviating factors, timing, severity, useful data for associated symptoms, and perception by the patient of the problem.

Health History

The entire body can be affected by cardiovascular problems. Some symptoms can have more than one cause. For example, shortness of breath can be the result of either heart failure or chronic obstructive pulmonary disease. The health history can help determine the cause of the symptom. For cardiovascular problems, the assessment focuses on the areas listed in Table 15–2.

TABLE 15-1 ACUTE CARDIOVASCULAR NURSING ASSESSMENT

History	Significance
<i>Allergies</i>	For medication administration, diagnostic dyes
<i>Smoking history</i>	Risk factor for cardiovascular disorders
<i>Medications</i>	Toxic levels; influencing symptoms
<i>Pain</i>	Location—chest, calf; radiation—arms, jaw, neck; description—pressure, indigestion, tightness, burning, angina, myocardial infarction, thrombus, embolism
<i>Dyspnea</i>	Left-sided heart failure; pulmonary edema or embolism
<i>Fatigue</i>	Decreased cardiac output
<i>Palpitations</i>	Dysrhythmias
<i>Dizziness</i>	Dysrhythmias
<i>Weight gain</i>	Right-sided heart failure
Physical Assessment	Possible Abnormal Findings
<i>Vital signs</i>	Bradycardia, tachycardia, hypotension, hypertension, tachypnea, apnea, shock
<i>Heart rhythm</i>	Dysrhythmias
<i>Edema</i>	Right-sided heart failure
<i>Jugular vein distention</i>	Right-sided heart failure
<i>Breath sounds</i>	Crackles, wheezes with left-sided heart failure
<i>Cough, sputum</i>	Acute heart failure—dry cough, pink frothy sputum

TABLE 15-2 CARDIOVASCULAR HISTORY ASSESSMENT

Question	Rationale
Pain: WHAT'S UP? Format	
<ul style="list-style-type: none"> • Where is pain? Does it radiate? • How does it feel? Discomfort, burning, aching, indigestion, squeezing, pressure, tightness, heaviness, numbness in chest area? Fullness, heaviness, sharpness, throbbing in legs? • Aggravating/alleviating factors that increase/relieve the pain? • Timing of pain: onset, duration, frequency? • Severity of pain? • Useful data for associated symptoms? • Perception of patient about problem? 	<ul style="list-style-type: none"> • Cardiac pain may radiate to shoulders, neck, jaw, arms, or back. Vascular disorders cause extremity pain. • Pain can be associated with angina or MI. The quality of pain varies. Venous pain is a fullness or heaviness. Sharpness or throbbing is arterial pain. • Activity may cause or increase angina. Rest or medications may relieve angina. Leg activity pain, intermittent claudication, results from decreased perfusion that is aggravated by activity. Rest pain, from severe arterial occlusion, increases when lying. Dangling reduces the pain because blood flow is increased by gravity. • Pain may be continuous, intermittent, acute, or chronic. Arterial occlusion causes acute pain. • Rate pain on a scale of 0 to 10. • Accompanying symptoms and their characteristics guide diagnosis and treatment. • Patient's insight to problem is helpful in planning care.
Level of Consciousness (LOC)	
<ul style="list-style-type: none"> • What is your name? What is the month? Year? Where are you now? 	<ul style="list-style-type: none"> • A lack of oxygen caused by cardiac disease can decrease LOC.
Dyspnea	
<ul style="list-style-type: none"> • Are you short of breath? What increases your shortness of breath? What relieves your shortness of breath? 	<ul style="list-style-type: none"> • Dyspnea can be present with heart failure that reduces cardiac output, on exertion in angina pectoris or from a pulmonary embolus resulting from thrombophlebitis, heart failure, or dysrhythmias.
Palpitations	
<ul style="list-style-type: none"> • Are you having palpitations or irregular heartbeat? Does your heart ever race, skip beats, or pound? 	<ul style="list-style-type: none"> • Palpitations can occur from dysrhythmias resulting from ischemia, electrolyte imbalance, or stress. Dizziness can be associated with dysrhythmias.
Fatigue	
<ul style="list-style-type: none"> • Have you noticed a change in your energy level? • Are you able to perform activities that you would like to? 	<ul style="list-style-type: none"> • Fatigue occurs from reduced cardiac output resulting from heart failure. • Functional abilities can be limited from fatigue.
Edema	
<ul style="list-style-type: none"> • Have you had any swelling in your feet, legs, or hands? • Have you gained weight? 	<ul style="list-style-type: none"> • Right-sided heart failure can cause fluid accumulation in the tissues. • Fluid retention causes weight gain.
Paresthesia/Paralysis	
<ul style="list-style-type: none"> • Any numbness, tingling, or other abnormal sensations in extremities? • Can you move your extremity? 	<ul style="list-style-type: none"> • Numbness and tingling, pins and needles, and crawling sensations are paresthesia. • Paralysis is inability to move extremity. Reduced nerve conduction from decreased oxygen supply causes paresthesia and paralysis.

MEDICAL HISTORY. If previous medical records are available, they can provide objective patient data that can be supplemented with patient responses. If medical records are not available, the patient is asked about previous conditions that could affect the cardiovascular system. A history of childhood illnesses that can lead to heart disease, such as rheumatic fever or scarlet fever, is noted. Other conditions include pulmonary disease, hypertension, kidney disease, cerebral vascular accident or brain attack, transient **ischemic** attack, renal disease, anemia, strepto-

coccal sore throat, congenital heart disease, thrombophlebitis, and alcoholism. Patient allergies, previous hospitalizations, and surgeries are documented. Baseline diagnostic tests are helpful for comparison with current tests. Functional limitations that are related to cardiovascular problems, such as performing activities of daily living (ADLs), walking, climbing stairs, or completing household tasks, are also assessed.

MEDICATIONS. Medication use is noted. This includes prescription drugs, over-the-counter medications such as aspirin that can prolong clotting time, and recreational drugs. The medication history includes the patient's understanding of

ischemic: ischein—hold back + haima—blood

the medication and the medication name, dosage, reason for taking, last dose, and length of use.

FAMILY HISTORY. A family history of cardiovascular conditions is assessed because many cardiac problems are hereditary. Health histories of close relatives, such as parents, siblings, and grandparents, are the most significant.

HEALTH PROMOTION. Risk factors such as diet, activity, tobacco use, and recent stressors for the patient are assessed in the health history. The patient's health promotion activities are noted, especially for risk factors that are modifiable through changes in lifestyle.

Objective Data

Physical Assessment

The patient's general appearance is observed. The patient's level of consciousness, which is an indicator of oxygenation of the brain, is assessed. Height and weight are recorded. Vital signs are measured.

BLOOD PRESSURE. The average adult reading is 120/80 with a normal range of 100/60 to 140/90. For accurate measurement, the correct size cuff for the patient is used. Readings in both arms are done for comparison. A difference in the readings is reported to the physician. The arm with the higher reading is used for ongoing measurements. The leg may be used if necessary, with a larger blood pressure cuff. The reading in the leg is normally 10 mm Hg higher than in the arm.

Blood pressure measurements are done with the patient lying, sitting, and standing to detect abnormal variations with postural changes. When the patient sits or stands, a drop in the systolic pressure of up to 15 mm Hg and either a drop or slight increase in the diastolic pressure of 3 to 10 mm Hg is normal. In response to the drop in blood pressure, the pulse increases 15 to 20 beats per minute to maintain cardiac output. Orthostatic hypotension, also referred to as postural hypotension, is a greater than normal change in these pressures and indicates a problem that should be investigated by the physician. The patient may experience dizziness when changing positions, so fall prevention methods should be used during blood pressure measurement.

PULSES. The apical pulse is auscultated for 1 minute to assess rate and rhythm. Normal heart rate is 60 to 100 beats per minute. In athletic people the heart rate is often slower, around 50 beats per minute, because the well-conditioned heart pumps more efficiently. Apical pulse rhythm is documented as regular or irregular. The apical rate can be compared with the radial rate to assess equality. If there are fewer radial beats than apical beats, a **pulse deficit** exists and should be reported to the physician.

Arterial pulses are palpated for volume and pressure quality. They are palpated bilaterally and compared for equality. A normal vessel feels soft and springy. A sclerotic vessel feels stiff. The quality of the pulses is described on a 4-point scale as follows: 0 is absent; 1+ is weak, thready; 2+ is normal; and 3+ is bounding. An absent pulse is not pal-

LEARNING TIPS

Anticipate potential drops in blood pressure with position changes. Orthostatic or postural hypotension is a drop in systolic blood pressure greater than 15 mm Hg, a drop or slight increase in the diastolic blood pressure greater than 10 mm Hg, and an increase in heart rate greater than 20 beats per minute in response to the drop in blood pressure. It can be found in patients of any age but is most commonly found in the older patient. The patient often reports light-headedness or syncope because the drop in pressure decreases the amount of oxygen-rich blood traveling to the brain. The change from a lying to a sitting or a sitting to a standing position may cause the drop in pressure. This blood pressure drop increases the risk of fainting and falling. Factors that can contribute to orthostatic hypotension include fluid volume deficit, diuretics, analgesics, and pain.

To assess orthostatic hypotension, do the following:

1. Take patient's lying blood pressure and heart rate.
2. Assist patient to sitting position. Ask if dizzy or light-headed with each position change. If yes, ensure safety from fainting or falling. A gait or walking belt can be used. With any position change, if patient experiences additional symptoms with the dizziness and decreased blood pressure and increased heart rate, assist the patient into bed, take blood pressure, and notify the physician. Consider the possible cause of the orthostatic hypotension—hemorrhaging, dehydration, diuretics—to plan patient care.
3. Wait at least 1 minute, and then take patient's sitting blood pressure and heart rate. If patient remains dizzy or light-headed, continue sitting position for 5 minutes if tolerated. Do not attempt to bring the patient to standing. Repeat sitting blood pressure. If blood pressure has increased and patient is no longer dizzy, assist patient to stand.
4. Assist patient to stand. Wait at least 1 minute, and then take patient's standing blood pressure and heart rate. If blood pressure drops and patient is dizzy or light-headed, continue standing position for 5 minutes, if tolerated. Do not attempt to ambulate patient. Repeat standing blood pressure and heart rate.
5. Document all heart rate and blood pressure measurements, including extremity used and patient position when reading was obtained (e.g., right arm lying 132/78, sitting 118/68, standing 110/60). Also document patient tolerance, symptoms, and nursing interventions if symptomatic.
6. Report abnormal findings to physician.

pable. A thrady pulse is one that disappears when slight pressure is applied and returns when the pressure is removed. The normal pulse is easily palpable. The bounding pulse is strong and present even when slight pressure is applied. When the normal vessel is palpated, a tapping is felt. In the abnormal vessel that has a bulging or narrowed wall, a vibration is felt, which is called a **thrill**. When auscultating an abnormal vessel, a humming is heard that is caused by the turbulent blood flow through the vessel. This is referred to as a **bruit**.

RESPIRATIONS. The rate and ease of respirations are observed. Breath sounds are auscultated. Sputum characteristics such as amount, color, and consistency are noted. Pink, frothy sputum is an indicator of acute heart failure. A dry cough can occur from the irritation caused by the lung congestion resulting from heart failure.

Clubbing—early

Clubbing—severe

**Figure 15-6** Clubbing of the fingers.

INSPECTION. During the health history, inspection begins by noting any shortness of breath when the patient speaks or moves. The patient's skin is noted for oxygenation status through the color of skin, mucous membranes, lips, earlobes, and nailbeds. Pallor may indicate anemia or lack of arterial blood flow. Cyanosis shows an oxygen distribution deficiency. A reddish-brown discoloration (rubor) found in the lower extremities occurs from decreased arterial blood flow. A brown discoloration and cyanosis when the extremity is dependent may be seen in the presence of venous blood flow problems. Hair distribution on the extremities is observed. Decreased hair distribution, thick, brittle nails, and shiny, taut, dry skin occur from reduced arterial blood flow. Venous blood return is assessed by inspecting extremities for varicose veins, stasis ulcers, or scars around the ankles and signs of thrombophlebitis such as swelling, redness, or a hard, tender vein.

The internal and external jugular neck veins are observed for distention. Normally, in the upright position, the veins are not visible. Distention of the veins in an upright position of 45 to 90 degrees indicates an increase in the venous volume. This is most commonly caused by right-sided heart failure. To observe for this, the patient is gradually elevated to a 45- to 90-degree position and any distention noted.

Capillary refill time assesses arterial blood flow to the extremities. The patient's nailbed is briefly squeezed, causing blanching, and then released. The amount of time that it takes for the color to return to the nailbed after release of the squeezing pressure is the capillary refill time. Normal capillary refill time is 3 seconds or less. Longer times indicate anemia or a decrease in blood flow to the extremity.

Clubbing of the nailbeds occurs from oxygen deficiency over time. It is often caused by congenital heart defects or the long-term use of tobacco. The distal ends of the fingers and toes swell and appear clublike. With clubbing, the normal 160-degree angle formed between the base of the nail and the skin is lost, causing the nail to be flat (Fig. 15-6).

Later, the nail base elevates, the angle exceeds 180 degrees, and the nail feels spongy when squeezed.

PALPATION. In addition to palpating the arteries, the thorax can be palpated at the **point of maximum impulse** (PMI). The PMI is palpated by placing the right hand over the apex of the heart. If palpable, a thrust is felt when the ventricle contracts. An enlarged heart may shift the PMI to the left of the midclavicular line.

The temperature of the extremities is palpated bilaterally for comparison. Palpation begins proximally and moves distally along the extremity. In areas of decreased arterial blood flow, the ischemic area feels cooler than the rest of the body because it is blood that warms the body. In the absence of sufficient arterial blood flow, the area becomes the temperature of the environment. This is called **poikilothermy**. A warm or hot extremity indicates a venous blood flow problem.

LEARNING TIPS

Six Ps characterize peripheral vascular disease:

- Pain
- Poikilothermia
- Pulselessness
- Pallor
- Paralysis
- Paresthesia (decreased sensation)

Edema is palpated in the extremities and dependent areas such as the sacrum for the supine patient (Fig. 15-7). Edema can occur from right-sided heart failure, gravity, or altered venous blood return. The nurse assesses the severity of the edema by pressing with a finger for 5 seconds over a

poikilothermy: poikilos—varied + therme—heat

**Figure 15-7** Pitting edema. Application of pressure over a bony area displaces the excess fluid, leaving an indentation or pit.

bone, the medial malleolus or tibia, in the area of edema. If the finger imprint or indentation remains, the edema is pitting. Measuring the leg circumference is an accurate method for monitoring the edema.

Homans' sign is an assessment for venous thrombosis; however, in less than 50 percent of patients with thrombosis the test is not positive. A positive Homans' sign is pain in the patient's calf or behind the knee when the foot is quickly dorsiflexed with the knee in a slightly flexed position (Fig. 15-8). Homans' sign should not be performed if a positive diagnosis of thrombosis has been made.

PERCUSSION. Percussion is performed by a physician to detect cardiac enlargement. Usually only the left border of the heart can be percussed. The heart is heard as dullness, in contrast to the resonance heard over the lungs.

AUSCULTATION. The normal heart sounds heard with a stethoscope placed on the wall of the chest are produced by the closing of the heart valves. These areas indicate where the sounds are best heard because sound in blood-flowing vessels is transmitted in the direction of the blood flow. The first heart sound (S1) is heard at the beginning of systole as lubb when the tricuspid and mitral (AV) valves close (Fig. 15-9). The second heart sound (S2) is heard at the start of diastole as dupp when the aortic and pulmonic semilunar valves close. The diaphragm of the stethoscope is used to hear the high-pitched sounds of S1 and S2. Extra heart sounds, usually indicating a pathologic condition, may be heard with practice. Normally no other sounds are heard between S1 and S2. With the bell of the stethoscope placed at the apex, a third heart sound (S3) or a fourth heart sound (S4) may be heard. Having patients lean forward or lie on their left side can make the heart sounds easier to hear by

Figure 15-9 Heart sounds shown on electrocardiogram. S1 is heard at the beginning of systole, and S2 is heard at the beginning of diastole.

Figure 15-8 Assessment of Homan's sign for venous thrombosis. The foot is quickly dorsiflexed with the knee flexed. Calf or knee pain is noted. This assessment should not be performed if a positive diagnosis of thrombosis has been made.

bringing the area of the heart where the sound may be heard closer to the chest wall. S3 is normal for children and younger adults. It sounds like a gallop and is a low-pitched sound heard early in diastole. S3 may be heard with left-sided heart failure, fluid volume overload, and mitral valve regurgitation. S4 is also a low-pitched sound, similar to a gallop but heard late in diastole. It occurs with hypertension, coronary artery disease, and pulmonary stenosis.

LEARNING TIPS

This sentence can help you remember the heart's auscultation points:

- All (aortic)
- People (pulmonic)
- Eat (Erb's point)
- Three (tricuspid)
- Meals (mitral)

Murmurs are caused by turbulent blood flow through the heart and major blood vessels. A murmur is a prolonged sound caused by a narrowed valve opening or a valve that does not close tightly. A swishing sound that ranges in intensity from faint to very loud is produced. The intensity of the murmur is graded by the physician on a scale of 1 to 6. The timing of the murmur in relationship to the cardiac cycle of systole or diastole is also documented by the physician.

A **pericardial friction rub** occurs from inflammation of the pericardium. The intensity of a rub can range from soft and faint to loud enough to be audible without a stethoscope. A rub has a grating sound like sandpaper being rubbed together that occurs when the pericardial surfaces rub together during the cardiac cycle. (See the Learning Tip on pericardial friction rub in Chapter 17.) Having the patient sit and lean forward allows a rub to be heard more clearly. The rub is best heard to the left of the sternum using the diaphragm of the stethoscope. A pericardial friction rub may occur after a myocardial infarction or chest trauma.

Diagnostic Studies

Diagnostic test results provide valuable assessment information for the nurse (Table 15–3). These data are combined

CRITICAL THINKING

Mrs. Smith
Mrs. Smith, 78, is admitted to the hospital with shortness of breath. Initial assessment findings are BP 152/88, pulse 104, respiration 26, temperature 99.4° F, short of breath at rest, shortness of breath increases with activity, ankles swollen, heart tones sound far away, nailbeds are very light pink, no pain, has not eaten well for 2 weeks, 6-pound weight gain in 1 week, sleeps on three pillows, veins in neck are visible on both sides. A diagnosis of acute myocardial infarction with heart failure is made by a physician.

1. Why is Mrs. Smith not reporting chest pain with a diagnosis of acute myocardial infarction?
2. How should swollen ankles be assessed to provide complete and measurable data?
3. What should be documented for the assessment of the swollen ankles?
4. How should the assessment findings for the swollen ankles be documented?
5. How should the assessment findings be documented for the additional symptoms Mrs. Smith has?

Answers at end of chapter.

TABLE 15–3 DIAGNOSTIC TESTS AND PROCEDURES

Procedure	Definition	Nursing Management
Noninvasive		
<i>Chest x-ray film</i>	Anterior-posterior and left lateral views of chest taken to show heart size and contour and lungs.	Assess x-ray history and whether pregnant. Remove metal items. Teaching—no discomfort.
<i>Magnetic resonance imaging (MRI)</i>	Three-dimensional image of heart.	Assess for metallic items and claustrophobia. Give antianxiety medication as ordered before MRI. Teaching—must lie still in long, small cylinder with loud, pounding sounds. Can talk to technician, listen to music.
<i>Electrocardiogram (ECG)</i>	Electrodes on skin carry electrical activity of heart from different views to show rhythm of heart, size of chambers, and heart damage.	Teaching—no discomfort. Explain procedure.
<i>Holter monitor</i>	Recording of ECG for up to 48 hours to match abnormalities with symptoms recorded in client's diary.	Apply electrodes and leads. Teaching—keep accurate diary; push event button for symptoms. No showers or baths. Return visit.
<i>Transtelephonic event recorder</i>	Records ECG events infrequently occurring for transmission over phone to interpreting center for analysis. Pacemaker checks done.	Teaching—explain use of recorder and how to transmit. Ensure good skin contact for best ECG tracing.
<i>Pressure measurement</i>	Blood pressures taken at several sites along extremity to show area of occlusion or decreased blood flow at rest and with exercise.	Teaching—no discomfort. Explain procedure.
<i>Exercise treadmill test (ETT)</i>	Evaluates effects of exercise on heart and vascular circulation; ECG and vital signs are continuously monitored. Test stopped if symptoms develop.	Monitor vital signs and ECG before, during, and after test until stable. Teaching—explain procedure, wear walking shoes and comfortable clothes.
<i>Echocardiogram</i>	Transducer transmits sound waves that bounce off heart to produce heart images and show blood flow. Provides audio and graphic data.	May be done at bedside. Patient lies on left side. Teaching—no discomfort, gel applied.
<i>Transesophageal echocardiogram</i>	Probe with transducer on end inserted into esophagus, depth and angle directed by physician. Shows clearer images of heart because no lung or rib tissue is crossed. Dye injected for blood flow study.	Monitor vital signs and oxygen saturation. Encourage client to relax. Suction continually during procedure. Teaching—NPO 6 hours before test. Sedation and local throat anesthetic given.

TABLE 15-3 DIAGNOSTIC TESTS AND PROCEDURES — CONT'D

Procedure	Definition	Nursing Management
Radioisotopes		
	IV injection of radioactive isotopes, which are taken up by heart and scanned with scintillation camera to show cardiac contractility, injury, and perfusion.	Assist patient to lie supine with arms over head for about 30 minutes. Teaching—explain procedure, inform that radioactivity is small and gone within a few hours.
Thallium Imaging	IV injection of thallium 201 to evaluate cardiac blood flow. Cold spots show infarcted areas. With exercise, thallium given 1 minute before end of test to circulate the thallium. Scan done within 10 minutes and repeated in 2–4 hours for comparison.	Teaching—explain procedure, inform that radioactivity is small and gone within a few hours. Light meal only between scans.
Dipyridamole thallium imaging	Dipyridamole (Persantine) IV is a vasodilator given to increase blood flow to coronary arteries; test is same as thallium imaging.	Teaching—explain procedure, instruct no caffeine or aminophylline 12 hours before. Same as thallium imaging.
Technetium pyrophosphate imaging	Technetium 99m pyrophosphate IV given. Shows hot spot in heart injury area. Scanned 2 hours later.	Teaching—explain procedure, inform that radioactivity is small and gone within a few hours.
Blood pool imaging	Technetium 99m pertechnetate IV. Studies effects of drugs, recent MI, and congestive heart failure. Serial studies are done over several hours. May be done at bedside.	Teaching—explain procedure.
Positron emission tomography (PET)	Nitrogen-13-ammonia IV given and scanned for cardiac perfusion. Then fluoro-18-deoxyglucose IV given and scanned for cardiac metabolic function. In normal heart, scans match; in injured heart, they differ. Exercise may also be used.	Patient's blood glucose must be 60 to 140 mg/dL for accuracy. Teaching—explain procedure. Must lie still during scan. If exercise used, NPO and no tobacco use.
Doppler ultrasound	Sound waves bounce off moving blood, producing recordings. Evaluates PVD.	Teaching—explain procedure.
Plethysmography	After the leg being tested is raised 30 degrees with the patient supine, a pressure cuff is inflated on the leg to distend the veins. Blood flow is measured with electrodes. Cuff is then rapidly deflated and venous volume changes recorded. Thrombi detected by less venous volume.	Teaching—explain procedure. No discomfort. Takes 30–45 minutes.
Technetium 99m Sestamibi	Technetium 99m sestamibi is given IV and scanned 1.5 to 2 hours later. Areas of myocardial cell damage take up the radioisotope; when scanned, these areas appear as hot spots.	Explain procedure.
Serum Enzymes		
Creatine kinase (CK)	Heart, brain, skeletal muscle contain CK enzymes. Damaged cells release CK. With MI, CK elevates in 6 hours and returns to baseline in 48–72 hours. Normal: male 5–55 U/mL; female 5–25 U/mL.	Avoid IM injections and take baseline CK before inserting IVs to avoid elevating CK from muscle cell damage. Serial sampling done.
CK-MB	Only heart muscle contains MB isoenzyme, which rises with MI in 6 hours and returns to baseline in 72 hours. Normal: 0–7 IU/L.	Same as CK.
Lactic dehydrogenase (LDH)	Intracellular enzyme found in many tissues, including heart. Elevates with MI after 8 hours and returns to baseline in 7 days. Normal: 80–120 U.	Serial sampling done.
LDH ₁ and LDH ₂	LDH contains five isoenzymes. Normally LDH ₂ > LDH ₁ . In MI, ratio reverses: LDH ₁ > LDH ₂ .	Same as LDH.
Serum aspartate aminotransferase (AST)	Nonspecific for cardiac damage.	No special care.
Myoglobin	Rises in 8 hours after MI and returns to baseline in 4–8 days; 99% indicative of MI. Rises in 1 hour after MI and peaks in 4–12 hours so must be drawn within 18 hours of chest pain onset. Normal: 250–450 ng/mL.	No special care.

TABLE 15-3 DIAGNOSTIC TESTS AND PROCEDURES — CONT'D

Procedure	Definition	Nursing Management
Serum Enzymes		
<i>Cardiac troponin I</i>	Cardiac cell protein. Elevated levels sensitive indicator of MI. Levels elevated up to 7 days.	No special care.
Serum Lipids		
<i>Cholesterol</i> <i>Triglycerides</i>	Measure CAD risk. Normal: 140–200 mg/dL. Elevated in cardiovascular disease. Normal: 40–190 mg/dL.	Fasting not required. Eat normal diet for 2 weeks before test. Fasting required for 12 hours. Water allowed but no alcohol.
<i>Phospholipids</i>	May elevate in cardiovascular disease. Normal: 125–380 mg/dL.	Same as triglycerides.
<i>Lipoproteins</i>	Electrophoresis done to separate lipoproteins: VLDL, LDL, HDL. HDL protects against CAD; LDL increases CAD risk. Normal lipoproteins: 400–800 mg/dL. Desirable: LDL less than HDL (values vary with age).	Same as triglycerides.
Invasive		
<i>Angiography</i>	Dye injected into vessels to make them visible on x-rays to assess patency, injury, or aneurysms. Coronary—coronary arteries via cardiac catheter. Peripheral—peripheral arteries or veins.	Precare: Informed consent required. NPO 4–18 hours before test. Assess dye allergies. Teaching—sedative and local anesthesia may be used; burning sensation from dye; monitored continuously. Postcare: assess vital signs, circulation mobility sensation, catheter insertion site, or puncture site for hemorrhage, hematoma every 15 minutes for 1 hour, then every 30 minutes to 1 hour. Apply insertion site pressure (dressing, sandbag) as needed. Immobilize extremity for several hours as ordered.
<i>Cardiac catheterization</i>	Catheter inserted into heart for data on oxygen saturation and chamber pressures. Dye may be injected to visualize structures.	Same as angiography. Sensory teaching—table is hard, cool cleansing solution used, sting felt from local anesthetic, hear monitor beeping, feel pressure of catheter insertion, dye warm, burning feeling, headache, chest pain briefly, hear camera, feel table move.
<i>Hemodynamic monitoring</i>	Continuous readings of arterial BP, cardiac and pulmonary pressures, CO and SvO ₂ obtained with catheter attached to transducer and monitor to diagnose and guide treatment. Normal: BP 120/80; right atrial pressure 2–6 mm Hg; pulmonary artery systolic pressure/pulmonary artery diastolic pressure 20–30/0–10; pulmonary artery wedge pressure 4–12 mm Hg; CO 4–8 L/min; SvO ₂ 60–80%.	Informed consent signed for insertion. Continuous assessment to ensure proper placement of catheter is maintained and a permanent catheter wedge does not go undetected. Recording of readings and monitoring of insertion site for signs of infection.
<i>Central venous pressure (CVP)</i>	Catheter inserted into a vein and threaded into vena cava. Monitors CVP, which reflects fluid volume status. Normal: 2–6 mm Hg.	Informed consent signed for insertion. Recording of readings and monitoring of insertion site for signs of infection.

with the health history and physical assessment to plan care for the patient.

NONINVASIVE

Pulse Oximetry. A transdermal clip or patch placed on a finger, a toe, an ear, or the nose is attached to a monitor and used to assess arterial oxygen saturation. A light in the clip or patch passes through the artery and provides data to measure the oxygen saturation. Normal levels are 95 percent or greater.

Chest X-ray Examination. A chest x-ray examination shows the size, position, contour, and structures of the heart

(Fig. 15–10). It shows heart enlargement, calcifications, and fluid around the heart. Heart failure can be confirmed with a chest x-ray examination. Correct placement of pacemaker leads and pulmonary artery catheters in the heart can be confirmed.

Fluoroscopy uses a luminescent x-ray screen to show cardiac structures and pulsations. It is used as a guide when placing cardiac catheters or pacemaker leads.

Magnetic Resonance Imaging. A three-dimensional image of the heart is produced by magnetic resonance imaging (MRI). The patient must lie still in a long, small-diameter

Figure 15-10 Normal chest x-ray film. Note white outline of heart borders in center. (From McKinnis, LN: *Fundamentals of Orthopedic Radiology*. FA Davis, Philadelphia, 1997, p 15.)

cylinder with a strong magnetic field. Because of the small cylinder's close proximity to the patient, many experience claustrophobia. Patients are asked if they are claustrophobic before the test, and anti-anxiety medication is given 1 hour before the MRI as ordered. Music may help to ease the patient's anxiety as well. No metallic items are permitted in the machine, so some patients, such as those with pacemakers or metal implants, shavings, or shrapnel, are not candidates for this test.

Electrocardiogram. The electrocardiogram (ECG) assesses the electrical activity of the heart from different views. The ECG shows abnormalities related to conduction, rate, rhythm, heart chamber enlargement, myocardial ischemia, myocardial infarction, and electrolyte imbalances. Abnormalities in cardiac function can be detected and the area of abnormality pinpointed with the aid of the different views on the ECG.

When an ECG is requested, information that aids in its interpretation is provided, including the patient's sex, age, height, weight, blood pressure, and cardiac medications. The patient requires no special preparation but is given an explanation of the procedure and told that the ECG is painless.

To obtain an ECG, electrodes are placed on the skin to transmit electrical impulses to the ECG machine for recording. The electrical impulses from the heart appear as waves on graph paper. (See Chapter 20.) One electrode is placed on each limb and several across the chest. The right leg is a ground electrode. One view of the heart using a combination of the electrodes to obtain the view is called a lead. The standard 12-lead ECG, using a combination of the electrodes, provides 12 views of the heart.

Signal-averaged ECG. The signal-averaged ECG is used to diagnose whether a patient is at risk of developing ventricu-

lar tachycardia and possible sudden death. A computer records low level signals not detected by a regular ECG. These electrical signals, referred to as late potentials, occur at the end of the QRS and into the ST segment. Late potentials place the patient at risk for ventricular dysrhythmias.

Ambulatory Electrocardiogram Monitoring. Continuous monitoring of the ambulatory patient is possible with the use of tape recorders.

Holter Monitoring. A Holter monitor, which weighs 2 pounds, continuously records one lead for up to 48 hours. The patient wears loose-fitting clothing and may only sponge bathe while wearing the monitor. The patient records a diary of activities and symptoms and pushes the event button if symptoms occur. Symptoms are documented for later correlation with the ECG recordings. Dysrhythmias or myocardial ischemia that occurs infrequently can be detected. The recordings are scanned by a computer and interpreted by a physician.

Transtelephonic Event Recorders. This recorder is used for dysrhythmic events that occur so infrequently that they would not likely be captured in 48 hours, or for follow-up evaluation of permanent pacemakers. With this recorder the patient has greater flexibility because the device is worn when needed or when symptoms occur. The disadvantage is that if the event is brief it may be missed before the recorder is on. When an event is recorded, the patient can transmit it at a convenient time over the telephone for printout and analysis. The telephone mouthpiece is placed over the signal transmitter box for transmission. After transmission the recording can be erased and the recorder reused.

Pressure Measurement. Pressure readings are done to assess areas of occlusion or narrowing in vessels. Blood pressure readings are taken at intervals along the extremity. Reduced readings are found in areas with blood flow problems.

Tilt Table Test. The tilt table test is used to help diagnose the cause of syncope ("fainting spells"). Heart rate and blood pressure are monitored during a change in position from lying down to standing up.

Exercise Tolerance Testing. The exercise tolerance test or stress test measures cardiac function or peripheral vascular disease during a defined exercise protocol (Fig. 15-11). Before the test, patients are given an explanation of the test and told not to smoke, eat, or drink for 2 to 4 hours before the test. They are also instructed to wear comfortable walking shoes, a loose top, and for women a supportive bra. After the test, patients should rest and wait to eat. They should also avoid eating or drinking stimulants such as caffeine and temperature extremes such as going out into cold weather for a few hours after the test.

Cardiac Stress Test. This test simulates sympathetic nervous system (fight or flight) stimulation. It shows the heart's response to increased oxygen needs. Before the test, baseline vital signs are obtained. Then, while the patient exercises on a treadmill, on a stationary bicycle, or by climbing

Figure 15-11 Performance of stress test.

stairs, vital signs, oxygen saturation, skin temperature, physical appearance, chest pain, and ECG are monitored to help ensure patient safety. The test is completed when the patient reaches peak heart rate (patient's age subtracted from 220), experiences chest pain, is unable to exercise further, or develops vital sign or ECG changes. Vital signs and ECG continue to be monitored after the test until they return to baseline.

The cardiac stress test is used to evaluate coronary artery disease. It aids in diagnosing ischemic heart disease, the cause of chest pain and dysrhythmias. The functional capacity of the heart can also be measured after a cardiac event or to plan a physical fitness or rehabilitation program.

Peripheral Vascular Stress Test. The patient walks for 5 minutes at 1.5 miles per hour on the treadmill. At certain intervals, pulse volume measurements are taken, including baseline resting, during the test, and final resting after the test. This test assesses response to activity. If **claudication** occurs, the test is stopped.

Echocardiogram. An echocardiogram is an ultrasound test that records the motion of the heart structures, including the valves, as well as the heart size, shape, and position. No preparation is required for a cardiac ultrasound. This test transmits ultrasonic sound waves into the heart so that the returned echoes can be recorded on videotape as audio and visual information. An ECG is recorded at the same time

for comparison purposes. Abnormalities that may be seen on the echocardiogram include heart enlargement, valvular abnormalities, thickened cardiac walls or septum, and pericardial effusion.

Exercise echocardiography diagnoses CAD during exercise-induced cardiac ischemia by detecting cardiac wall motion abnormalities.

Transesophageal Echocardiogram. Transesophageal echocardiogram provides a clearer picture than transthoracic echocardiography. It produces images by using a transducer on a probe that is placed in the esophagus. The images are clearer because lung and rib tissue does not have to be penetrated by the sound waves. The physician controls the position of the probe and takes pictures as it travels within the esophagus. Patients take nothing by mouth (NPO) for about 6 hours before the test, receive a sedative, and have their throat locally anesthetized. After the procedure, patients remain NPO until their gag reflex returns.

Radioisotope Imaging. For this type of imaging, small amounts of radioisotopes are given intravenously. The patient is then scanned with a gamma camera and a radionuclide image is produced. Radiation exposure is similar to that of other x-ray examinations. These tests can provide information about myocardial ischemia or infarction, cardiac blood flow, and ventricle size and motion.

Thallium Imaging. Thallium 201, a radioactive analog of potassium, is used to detect impaired myocardial perfusion. It is injected intravenously (IV), and muscle cells absorb it. After 10 to 15 minutes the heart is scanned to see where the thallium has concentrated. Four hours later the scan is repeated to look for changes. Healthy myocardial cells with good blood flow take up the thallium. Areas in which the thallium is not seen are referred to as cold spots and indicate ischemia or infarction. The patency of a coronary artery graft may also be assessed with this test. This test is used often because the short half-life of thallium results in lower radiation exposure.

Exercise testing may be combined with thallium injection to detect blood flow changes with activity and after rest. The patient exercises and about 2 minutes before stopping is given thallium. Scans are taken immediately and again in 2 to 4 hours. Cold spots on initial images indicate ischemia. If the cold spots are gone in later images, it indicates exercise-induced ischemia. If the cold spots are still present in later images, they show scarred areas.

If patients are unable to participate in exercise for the thallium stress test, dipyridamole (Persantine) or adenosine, coronary vasodilators, can be given. These drugs simulate the increased blood flow to healthy myocardial cells that occurs with exercise.

Technetium Pyrophosphate Scan. Technetium 99m pyrophosphate is injected for this test. Areas of ischemia or myocardial cell damage take up the radioisotope, and when scanned these areas appear as hot spots. Acute myocardial infarction (MI) size and location can be detected, but old MIs cannot be detected.

Technetium 99m Sestamibi. Technetium 99m sestamibi is given IV and the patient is scanned 1.5 to 2 hours later. Areas of myocardial cell damage take up the radioisotope, and when scanned these areas appear as hot spots.

Blood Pool Imaging. Technetium 99m pertechnetate is injected IV and remains in the bloodstream; it is not taken up by myocardial cells. A camera follows the flow of the radioactivity, which shows ventricular function and wall motion and the ejection fraction of the heart.

Positron Emission Tomography. Positron emission tomography (PET) shows myocardial perfusion and viability with three-dimensional images. Nitrogen-13-ammonia is injected IV first and then scanned to show myocardial perfusion. Next, fluoro-18-deoxyglucose is given intravenously and then scanned to show myocardial metabolic function. If there is ischemia or heart damage, the two scans are different. For example, in ischemia of viable cells, blood flow is decreased but metabolism elevated. Treatment to increase blood flow improves cardiac function in this case. Before the test the patient's blood glucose should be normal, and caffeine and tobacco should be avoided for 4 hours before the test.

Doppler Ultrasound. In this test, sound waves are transmitted to an artery or vein to assess blood flow problems. The sound waves bounce off moving blood cells and return a sound frequency in relationship to the amount of blood flow. With decreased blood flow the sounds are reduced. This test requires no patient preparation, takes about 20 minutes to complete, and is painless.

Plethysmography. With this test, blood volume and changes in blood flow are measured to diagnose deep vein thrombosis and pulmonary emboli and to screen patients for peripheral vascular disease. The leg being tested is raised 30 degrees with the patient supine. A pressure cuff is then inflated on the leg to distend the veins. Blood flow is measured with electrodes, and the cuff is then rapidly deflated and venous volume changes are recorded. Thrombi are detected by reduction in venous volume.

BLOOD STUDIES

Cardiac Troponin. Cardiac muscle contains proteins called troponins, which control the muscle fibers that contract or squeeze the heart muscle. Troponin I and Troponin T are highly sensitive indicators of myocardial damage, which is helpful in diagnosing MI. They are proteins found only in cardiac cells. When injured or dead, cardiac cells release these proteins, which results in elevated levels within 4 to 6 hours of damage. These levels peak in 10 to 24 hours and remain elevated for up to 7 days after injury. Troponin T appears slightly earlier than Troponin I after cardiac damage. Troponin T is better at showing slight cardiac damage and predicting 30-day mortality for cardiac patients.

Cardiac Enzymes. When heart cells are damaged or die, they rupture and release their enzymes into the bloodstream. Levels of these enzymes rise in the serum as a result. Common cardiac enzyme tests are creatine kinase (CK),

also referred to as creatine phosphokinase (CPK), and lactic dehydrogenase (LDH). However, these enzymes are also found in body cells other than the heart, so a more organ-specific test, the enzymes' isoenzymes (or different forms), is measured. Serum aspartate aminotransferase (AST) is a nonspecific cardiac test formerly known as serum glutamic-oxaloacetic transaminase (SGOT).

Creatine Kinase. Creatine kinase (CK) is found in three types of tissue: brain, skeletal muscle, and heart muscle. Isoenzymes of CK contained in these tissues are CK-BB (brain), CK-MM (skeletal muscle), and CK-MB (heart muscle). Levels of CK-MB rise within 4 to 6 hours after cardiac cells are damaged, peak in 12 to 24 hours, and return to normal in 48 to 72 hours. Serial CK levels are drawn at intervals to track trends. It is important to avoid invasive procedures such as IVs and intramuscular (IM) injections before drawing the first CK to prevent elevation in the CK levels from cell trauma caused by the procedure. Medications are often given IV rather than IM to prevent this elevation.

Lactic Dehydrogenase. Another intracellular enzyme that is found in a variety of body cells is LDH. There are five types of isoenzymes for LDH: LDH₁ and LDH₂ are found in the heart, kidneys, and red blood cells (RBCs); LDH₃ is specific to the lungs; and LDH₄ and LDH₅ are found in skeletal muscle and the liver. Normally LDH₂ is higher than LDH₁. After an MI, the pattern reverses and LDH₁ rises higher than LDH₂. Levels of LDH rise 8 to 12 hours after an MI, peak at 24 to 48 hours, and return to normal in 5 to 7 days.

Myoglobin. Myoglobin is a protein found in skeletal and cardiac muscle and is released into the bloodstream when cell damage occurs. Because myoglobin is not site specific, it can only provide an estimate of damage and is used with other more specific tests such as troponin to diagnosis an MI. Myoglobin levels elevate within 1 hour of an acute MI. Peak levels are reached 4 to 12 hours after an MI, and levels return to normal within 18 hours after the onset of chest pain, so it is a test that must be done early when MI is suspected.

Blood Lipids. Lipids include triglycerides, cholesterol, and phospholipids. Lipoproteins carry these lipids attached to proteins. Triglycerides are found in very low density lipoproteins (VLDL). Cholesterol is mainly found in low-density lipoproteins (LDL). High-density lipoproteins (HDL) are a mixture of one-half protein and one-half phospholipids and cholesterol.

A lipid profile can screen for increased risk for coronary artery disease. Patients must fast for 12 hours before the test, and, although water is not withheld, alcohol is restricted for 24 hours before the test. High levels of LDL are linked to an increase in CAD because they circulate cholesterol in the arteries. High-density lipoproteins play a protective role against CAD because they carry cholesterol to the liver to be metabolized. Controlling lipids is very important in reducing CAD (Cultural Consideration Box 15-3).

BOX 15-3 CULTURAL CONSIDERATION

Among French-Canadians, familial chylomicronemia (hyperlipoproteinemia type I), an autosomal recessive disorder, occurs with the highest frequency worldwide. Familial hypercholesterolemia can lead to coronary thrombosis. Thus the nurse can improve the health of French-Canadians by encouraging early diagnostic workups for familial chylomicronemia and encouraging healthful lifestyles.

INVASIVE STUDIES

Angiography. Arteriography and venography are the two types of angiography (Fig. 15–12). Arteriography examines arteries. Venography studies veins. Angiography uses dye injected into the vascular system to visualize the vessels on radiographs. This test is used to assess blood clot formation, to assess peripheral vascular disease (PVD), and to test vessels for potential grafting use.

The patient must be assessed for allergies, give informed consent, be NPO for about 4 hours before the test, and be informed that the dye produces a hot, burning feeling when injected. After the procedure the patient is assessed for several hours. Vital signs, allergic reaction signs, hemorrhage at the injection site, and pulses are monitored.

Cardiac Catheterization. Cardiac catheterization allows the study of the heart's anatomy and physiology. It is an invasive diagnostic procedure that measures pressures in the heart chambers, great blood vessels, and coronary arteries and provides information on cardiac output and oxygen saturation. Fluoroscopy is used, and dye can be injected once the catheter is in place to visualize the heart chambers and vessels. This procedure is often done before heart surgery.

Right-sided Catheterization. In right-sided catheterization, a catheter with or without a fiberoptic tip is inserted into the basilic or cephalic vein or the femoral vein and advanced into the vena cava. It is then moved through the right chambers of the heart and into the pulmonary artery. The catheter can be wedged momentarily in the artery by inflating the balloon at the tip of the catheter. This position provides the pulmonary artery wedge pressure (PAWP),

Figure 15-12 Coronary angiography and cardiac catheterization.

which reflects pressures in the left side of the heart. Other pressures obtained with right-sided cardiac catheterization are right atrial pressure, which reflects central venous pressure, pulmonary artery systolic and diastolic pressures, and cardiac output, and mixed venous oxygen saturation (SVO₂) if a fiberoptic catheter is used.

Left-sided Catheterization. The left side of the heart can be directly assessed by inserting a catheter into the brachial or the femoral artery. It is advanced against the flow of blood into the aorta, through the aortic valve, and into the left ventricle. Coronary angiography, which visualizes the coronary arteries with dye, can be done with this approach. The catheter is inserted into the opening of the coronary arteries, the dye is injected, and x-ray films are taken. Coronary artery disease can be assessed with coronary angiography.

An informed consent must be obtained. The patient is assessed for allergies to iodine, seafood, and shellfish and kept NPO before the procedure. Patients should be told that during the test they are awake and a warm, flushing sensation may be felt when the dye is injected; the room has a lot of equipment; a movable table is used; the patient's vital signs and ECG are monitored constantly; and the length of the procedure is 2 to 3 hours.

Complications of the procedure can be allergic reaction, breaking of the catheter, hemorrhage, thrombus formation, emboli of air or blood, dysrhythmias, MI, cerebrovascular accident (CVA), and puncture of the heart chambers or lungs.

After the catheter is removed, firm pressure must be applied to the insertion site for several minutes to prevent hemorrhage or hematoma formation. A pressure dressing or sandbag may be applied to the site when bleeding is stopped and is removed in several hours. Vital signs are assessed according to the physician's orders and the institution's policies. During vital sign checks, the puncture site is assessed and peripheral pulses are verified. The extremity used for insertion must not be moved or flexed for several hours after the procedure. Patients usually may eat and are instructed to drink fluids to help eliminate the dye from the body. If the patient is stable and no significant findings are found, the patient may be discharged.

Hemodynamic Monitoring. Bedside monitoring can be done to monitor the pressures in the blood vessels or heart. A catheter attached to a transducer and monitor, called an arterial line, can be inserted into the radial or femoral artery to measure continuous arterial blood pressure.

Ongoing monitoring of cardiac pressures, cardiac output, and central venous pressure (CVP) can be done with either a central catheter or a pulmonary artery catheter. Central venous pressure is measured directly with a central catheter inserted into the vena cava via the brachial, femoral, subclavian, or jugular vein (Fig. 15–13). It is measured indirectly with the pulmonary artery catheter (Fig. 15–14). The right atrial pressure measurement obtained from the pulmonary artery catheter reflects the pressure in the vena cava. Central venous pressure measures **preload** or fluid

Figure 15-13 CVP measurement.

volume status; CVP readings used in fluid or diuretic therapy have been primarily replaced by pulmonary artery catheter measurements.

Electrophysiology Study. To study the heart’s electrical system, one or more catheters with electrodes are inserted via the femoral vein into the right side of the heart. The electrical impulses are recorded. Dysrhythmias can be triggered to help the physician diagnose problems. A consent is obtained and the patient is NPO 6 to 8 hours before the test.

▶ THERAPEUTIC MEASURES FOR THE CARDIOVASCULAR SYSTEM

Exercise

A prescribed walking program helps promote blood flow by contracting the skeletal muscles and may reduce symptoms of peripheral vascular disease. For patients recovering from cardiac surgery or a myocardial infarction, activity is gradually increased. Exercise is very important for optimum cardiac functioning. A cardiac rehabilitation program is usually prescribed, and individualized exercise goals are determined. After discharge from the hospital, exercise three times a week for 20 to 30 minutes is encouraged. Mild stretching should be done before and after the exercise.

Smoking Cessation

Smoking causes vasoconstriction that can last up to 1 hour after the smoking of one cigarette. For patients with cardiac or vascular disease, blood flow is reduced, which can exacerbate symptoms. Patients should be encouraged to stop smoking and should be provided with support information such as cessation programs and support groups. For more information on smoking cessation, visit www.americanheart.org.

Diet

Teaching the patient to eat a healthy, balanced diet is important to help reduce the risk for coronary artery disease. Weight reduction, if needed, is encouraged, as well as increasing physical activity. In May 2001 the National Heart, Lung, and Blood Institute released therapeutic lifestyle changes (TLC) that are recommended to help control CHD risk factors. The TLC diet is low in cholesterol (<200 mg/day) and saturated fats (<7 percent of calories). Soluble fiber (10 to 25 g/day) and plant stanols/sterols (2 g/day) are also recommended to reduce LDL levels. (See Chapter 18.) For more information on the therapeutic lifestyle changes, visit http://hin.nhlbi.nih.gov/cvd_frameset.htm.

A diet low in sodium may be prescribed if excess fluid volume is a problem. (See Chapter 5). If diuretics are used that promote potassium loss, potassium levels must be monitored and adequate amounts of potassium included in the diet. To reduce fat, red meats, fried foods, whole milk, and cheese should be limited or avoided. Cholesterol can be reduced by avoiding egg yolks, organ meats, animal fats, and shellfish. Five to six servings of fruits and vegetables should be eaten daily. Increasing fish intake and eating poultry without skin are parts of a healthy diet.

Oxygen

Supplemental oxygen is administered to patients with chest pain to help ensure that the heart receives sufficient oxygen

Figure 15-14 Pulmonary artery catheter (above) and placement of the inflated balloon in the pulmonary artery.

to function. Oxygen may be delivered via a nasal cannula or face mask. The patient must be taught safety precautions necessary for home use of oxygen if it is ordered, such as avoiding open flames and not smoking when the oxygen is in use.

Medications

The primary cardiovascular drugs are cardiac glycosides, vasodilators, antihypertensives, antidysrhythmics, antianginals, anticoagulants, and thrombolytics. They are discussed in further detail where the disorders they are used to treat are explained. (See Chapters 16 to 22.)

Antiembolism Devices

Antiembolism devices improve arterial blood flow and venous return to prevent the formation of blood clots. They are used for patients with peripheral vascular disease, on bedrest, or after surgery or trauma.

Elastic Stockings

Antiembolism stockings apply pressure over the leg to promote the movement of fluid and prevent stasis of fluid. These stockings may be knee or thigh length. They must be applied correctly so that a tourniquet effect is not produced by the stockings. For ease in application, the stocking is turned inside out to the heel, the foot portion is placed on the patient up to the heel, and then the remaining stocking is pulled up over the leg. The tops of the stockings should be 1 to 2 inches below the bottom of the kneecap. They should not roll down or they will cause stasis rather than prevent it. The stockings are removed for 20 minutes twice a day and the skin inspected for irritation. Elderly patients may require assistance in applying the stockings if they have impaired manual dexterity.

Intermittent Pneumatic Compression Devices

An intermittent pneumatic compression device consists of plastic inflatable stockings that are filled intermittently with air by an attached motor (Fig. 15–15). This device promotes fluid movement by simulating the contraction of the leg muscles to prevent thrombosis development. The compartments in the stockings inflate to 35 to 55 mm Hg of pressure, beginning in the ankle compartment and progressing next to the calf compartment and finally the thigh compartment. The nurse should monitor the device for proper pressure inflation.

Lifestyle and Cardiac Care

To reduce risk factors or promote recovery from cardiovascular disease, lifestyle changes are often needed. Long-standing habits are difficult to change. Support groups can offer encouragement that is helpful in promoting a healthy lifestyle. Patients should be referred to community support groups as needed.

Patients recovering from cardiac disorders are often anxious about resuming sexual activity but are embarrassed to discuss it. This is an area that is often overlooked when caring for patients. Sexual counseling should be offered to patients and their partners. Patients often have misconceptions that are unfounded but interfere with resuming their sexual activity. If patients have angina, nitroglycerin can be taken prophylactically before sexual activity. After a myocardial infarction, sexual activity can be resumed in 1 to 2 months or when the patient can climb two flights of stairs without symptoms, as ordered by the physician. Sexual activity is a form of physical activity. Patients should be given information to make an informed decision on when they are ready to resume this activity.

REVIEW QUESTIONS

- The mitral and tricuspid valves prevent backflow of blood from which of the following?
 - Ventricles to atria when the ventricles contract
 - Atria to ventricles when the ventricles relax
 - Ventricles to atria when the atria contract
 - Atria to ventricles when the atria contract
- Which of the following describes the purpose of the endocardium of the heart?
 - Cover the heart muscle and prevent friction.
 - Support the coronary blood vessels.
 - Line the chambers of the heart and prevent abnormal clotting.
 - Prevent backflow of blood from atria to ventricles.
- The function of the coronary blood vessels is to do which of the following?
 - Prevent abnormal clotting within the heart.
 - Bring oxygenated blood to the myocardium.
 - Carry deoxygenated blood to the lungs.
 - Carry oxygenated blood to the lungs.
- Which of the following is the location of the cardiac centers in the nervous system?
 - Cerebrum
 - Hypothalamus
 - Spinal cord
 - Medulla
- The functions of angiotensin II are to increase which of the following?
 - Vasodilation and ADH secretion
 - Vasoconstriction and aldosterone secretion
 - Heart rate and vasodilation
 - Heart rate and ADH secretion
- The increase of resting blood pressure with age may contribute to which of the following?
 - Dysrhythmias
 - Thrombus formation
 - Left-sided heart failure
 - Peripheral edema
- Which one of the following is a modifiable cardiovascular risk factor that should be noted during patient data collection?
 - Age
 - Gender
 - Ethnic origin
 - Tobacco use
- If it takes longer than 3 seconds for the color to return when assessing capillary refill, it may indicate which of the following?
 - Decreased arterial flow to the extremity
 - Increased arterial flow to the extremity
 - Decreased venous flow from the extremity
 - Increased venous flow from the extremity
- Which one of the following is an important safety intervention that should be used while assessing a patient for orthostatic hypotension?
 - Reality orientation
 - Gait or walking belt
 - Liquids at bedside
 - Standing patient quickly
- You are caring for a patient who is on bedrest. In which area will you assess for the presence of edema?
 - Arms
 - Ankles
 - Sternum
 - Sacrum
- Which of the following should be included in patient teaching for coronary angiography with femoral catheter insertion site?
 - Dye injection causes hot, flushing sensation.
 - General anesthesia is administered.
 - Claustrophobia may be experienced.
 - Ambulation is possible immediately after procedure.
- A high-fiber diet for cardiac patients is recommended to do which of the following?
 - Increase absorption of nutrients
 - Reduce cardiac workload
 - Reduce edema development
 - Reduce appetite

Answers to *CRITICAL THINKING*

Mrs. Smith

1. An older patient commonly does not experience typical disorder symptoms. Chest pain is often not present because of reduced nerve sensitivity with aging for an MI. Dyspnea is the classic symptom of MI in the older patient.
2. Inspect both legs to determine edematous areas. Determine location and severity of edema by pressing finger for 5 seconds over the medial malleolus and moving up the leg along the tibia until no edema is found. Assess bilaterally. Measure leg circumference.
3. Document location of edema and whether edema is nonpitting or pitting. Document findings for both legs.
4. Documentation should state "Bilateral pitting ankle edema" with leg circumference measurement number.
5. Additional symptoms should be documented as follows: Dyspnea at rest that increases with exertion, heart tones clear and distant, nailbeds pale, pain free, poor appetite for 2 weeks, 6-pound weight gain in 1 week, three-pillow orthopnea, bilateral jugular vein distention.

QUESTIONS TO GUIDE YOUR READING

1. How would you define hypertension and hypertensive crisis?
2. How would you explain the pathophysiology of hypertension?
3. What are the causes and risk factors, including ethnicity, for hypertension?
4. What are the signs and symptoms of hypertension?
5. What is the current medical treatment, including lifestyle modifications and medications, for hypertension?
6. What are four classifications of hypertension in adults and recommendations for treatment based on blood pressure?
7. What are common complications of hypertension?
8. What nursing care teaching and learning strategies will you provide for patients with hypertension in adjusting to a chronic illness?
9. How will you know if your nursing interventions have been effective?

Hypertension, also known as high blood pressure, is a condition in which the blood pressure, on at least two or more readings on different dates after an initial screening, is found to be higher than normal. If the **systolic blood pressure** is above 140 mm Hg or the **diastolic blood pressure** is above 90 mm Hg, an adult age 18 or older should be evaluated for hypertension by a health

care provider. As we age, the incidence of hypertension increases. Therefore we can expect to see more cases of hypertension as our population ages and life spans increase. For more information on hypertension, visit www.americanheart.org.

▶ PATHOPHYSIOLOGY OF HYPERTENSION

Normally the heart pumps blood through the body to meet the cells' needs for oxygen and nutrients. As it pumps, it forces blood through the blood vessels to the vital organs and tissues. The pressure exerted by blood on the walls of the blood ves-

hypertension: hyper—excessive + tensio—tension
systolic: systole—concentration
diastolic: diastole—expansion

sels is measured as blood pressure. Blood pressure is determined by **cardiac output** (CO), **peripheral vascular resistance** (PVR; the ability of the vessels to stretch), the **viscosity** (thickness) of the blood, and the amount of circulating blood volume. Decreased stretching ability and increased viscosity and fluid volume increase blood pressure. (See Chapter 15.)

Several processes influence blood pressure by controlling CO and PVR. These processes include nervous system regulation, arterial baroreceptors and chemoreceptors, the renin-angiotensin-aldosterone mechanism, and balancing of body fluids. One way blood pressure is influenced is through adjustment of the CO, which is the amount of blood that the heart pumps out each minute. The heart rate rises to increase CO in response to either physical or emotional activities that require more oxygen for the organs and tissue. PVR also influences blood pressure; it is the opposition that blood encounters as it flows through vessels. Anything causing blood vessels to become more narrow increases PVR. Any time PVR is increased, more pressure is needed to push the blood through the vessel, so blood pressure is increased as a result. If PVR is decreased, less pressure is needed. Increased arteriolar PVR is the main mechanism that elevates blood pressure in hypertension.

Factors that impair normal regulation of blood pressure may lead to hypertension. Many of these factors are not well understood. Sympathetic nervous system overstimulation, which causes vasoconstriction, can contribute to hypertension. Alterations in baroreceptors and chemoreceptors may also influence the development of hypertension. For example, baroreceptors may become less sensitive from prolonged increases in vessel pressure and subsequently fail to stimulate vasodilation through vessel stretching. Additionally, increases in hormones that cause sodium retention, such as aldosterone, lead to increased fluid retention. Changes in kidney function that alter the excretion of fluid also result in an increase in overall body fluid that may contribute to hypertension.

Primary Hypertension

Primary or essential hypertension is the chronic elevation of blood pressure from an unknown cause. These unknown causes influence the factors that control blood pressure, resulting in a hypertensive state.

Secondary Hypertension

Secondary hypertension has a known cause. In other words, it is a sign of another problem, such as a kidney abnormality, a tumor of the adrenal gland, or a congenital defect of the aorta. When the cause of secondary hypertension is treated before permanent structural changes occur, blood pressure usually returns to normal. Treatment may include surgery or medication.

Isolated Systolic Hypertension

Isolated systolic hypertension (ISH) is a systolic pressure of 160 mm Hg or greater and a normal diastolic pressure of

90 mm Hg or less. This is an abnormal finding. This type of hypertension occurs mainly in elderly people, although it can occur at any age. For people with a systolic pressure higher than 160 mm Hg and a normal diastolic pressure found on two separate visits, a referral to a physician for further evaluation is recommended. Treatment of ISH is recommended to decrease cardiovascular disease, especially risk of stroke. Lifestyle modifications are usually tried first if the systolic elevation is not too severe. If lifestyle modifications fail to reduce the systolic pressure, antihypertensive medication is added.

► SIGNS AND SYMPTOMS OF HYPERTENSION

Often hypertension causes no signs or symptoms other than elevated blood pressure readings. As a result, hypertension is referred to as the “silent killer.” Patients with hypertension are often first diagnosed when seeking health care for reasons unrelated to hypertension. In a small number of cases, a patient with hypertension may complain of a headache, bloody nose, or blurred vision, although it is usually impossible for a patient to correlate the absence or presence of symptoms with the degree of blood pressure elevation.

Most signs and symptoms of hypertension stem from long-term effects on the large and small blood vessels of the heart, kidneys, brain, and eyes. These effects are known as target organ disease.

► DIAGNOSIS OF HYPERTENSION

Diagnosis is based on a health history to assess a patient’s risk factors for hypertension, any previous diagnosis of hypertension, presence of any signs and symptoms, history of kidney or heart disease, and current use of medications. Although there are no diagnostic studies specifically for hypertension, there are diagnostic tests that can be helpful in identifying related information, such as damage to organs or blood vessels. The types of diagnostic tests performed depend on the stage of the hypertension (Table 16–1) or other medical conditions that may be present at the time of evaluation.

The Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure was created by the National Heart, Lung, and Blood Institute of the National Institutes of Health. The sixth report of the JNC (called the JNC VI) defines normal and abnormal blood pressures for adults age 18 years and older and reclassified blood pressure measurement and treatment guidelines for physicians, clinicians, nurses, and community programs to follow. (See Table 16–1.) For more information on the JNC guidelines, visit www.nhlbi.nih.gov.

Diagnostic Tests

Laboratory tests such as urinalysis, blood urea nitrogen, and creatinine may indicate kidney damage from high blood pressure. Serum levels of sodium, calcium, chloride, potassium, magnesium, and phosphate are essential to evaluate the patient’s fluid, electrolyte, and acid-base balance. A

viscosity: viscous—sticky

TABLE 16-1 THE STAGES OF HYPERTENSION AND RECOMMENDATIONS FOR FOLLOW-UP

Category	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)	Recommended Follow-up
Normal	<130	<85	2 years
High normal	130–139	85–89	1 year
Hypertension			
Stage 1	140–159	90–99	2 months
Stage 2	160–179	100–109	1 month
Stage 3	≥180	≥110	1 week-immediately

Adapted from The National Heart, Lung, and Blood Institute, The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Arch Intern Med 157(21):2413, 1997.

complete blood cell count detects blood disorders. Tests of blood glucose, uric acid, cholesterol, and triglyceride levels help determine possible causes of cardiovascular and hypertensive disease. An electrocardiogram or chest x-ray examination may assist in recognizing abnormal heart function. These diagnostic tests are also used to monitor the effects of prescribed treatment.

► RISK FACTORS FOR HYPERTENSION

A combination of genetic (nonmodifiable) and environmental (modifiable) risk factors are thought to be responsible for the development of hypertension, although the cause remains unknown. Nonmodifiable risk factors—those that cannot be changed—include a family history of hypertension, age, ethnicity, and diabetes mellitus. Modifiable risk factors—those that can be changed—include stress levels, blood glucose levels, activity levels, smoking, and salt and alcohol intake. Weight reduction, improved meal planning, reduced salt and alcohol intake, increased physical activity, not smoking, and managing stress can all help to decrease blood pressure.

Nonmodifiable Risk Factors

Family History of Hypertension

Hypertension is seen more commonly among people with a family history of hypertension. Indeed, people with a family history have almost twice the risk of developing hypertension as those with no family history. People with a family history of hypertension should be encouraged to have their blood pressure checked regularly.

Age

People age differently because of their genetic and environmental risk factors and lifestyle habits. Thus the results of the aging process may be reflected in wide variations of blood pressure among elderly people. As a person ages, **plaque** builds up in the arteries and the blood vessels become stiffer and less elastic, causing the heart to work harder to force blood through the vessels. These vessel changes increase cardiac output to maintain blood flow into the circulation and subsequently raise blood pressure in the elderly.

Race and Ethnicity

Cultural Consideration Box 16-1 discusses hypertension among various ethnic groups.

Diabetes Mellitus

Two-thirds of adults who have diabetes mellitus also have hypertension. The risk of developing hypertension with a family history of diabetes and obesity is two to six times greater than when there is no family history. Approximately 80 percent of people with type 2 diabetes mellitus (non-insulin dependent) are overweight. Lifestyle modifications

BOX 16-1 CULTURAL CONSIDERATION

Hypertension continues to be the most serious health problem for African-Americans in the United States. More than 5 million of the 26 million African-Americans living in the United States are hypertensive. They suffer higher mortality and morbidity rates related to hypertension and at an earlier age. African-Americans from lower socioeconomic backgrounds have higher blood pressure than African-Americans from higher socioeconomic backgrounds. Additionally, African-Americans are 3.2 times more likely to develop kidney failure related to hypertension than European-Americans.

Hypertension among African-Americans is usually caused by increased renin activity resulting in greater sodium and fluid retention. Thus African-Americans respond better to diuretics such as furosemide (Lasix) and hydrochlorothiazide (HydroDIURIL) than to beta blockers such as propranolol (Inderal). Hypertension among European-Americans is more often caused by chemical imbalances; thus they respond better to beta blockers.

Chinese people are more sensitive than Caucasians to the effects of propranolol on heart rate and blood pressure, requiring only half the blood level of European-Americans to achieve a therapeutic effect. Propranolol is eliminated from the bodies of many Chinese persons at double the rate of European-Americans. They are more likely to suffer fatigue as a side effect. Thus the nurse must carefully monitor the Chinese patient for therapeutic and side effects.

Hypertension among Japanese-Americans is primarily related to the high sodium content of the Japanese diet, stress, and a high rate of cigarette smoking.

High rates of hypertension among Koreans and Filipinos are due to the stress of immigration, preserving foods in salt, and using condiments high in sodium.

and adherence to therapy are crucial to prevent the heart attacks, strokes, blindness, and kidney failure associated with high blood glucose and blood pressure levels.

Modifying Risk Factors

The JNC VI suggests advising patients with hypertension to use lifestyle modifications. These modifications include weight reduction, stress management, moderation of dietary sodium and alcohol intake, increased physical activity, and smoking cessation (Box 16–2). Lifestyle modifications are most often used with antihypertensive drugs to control hypertension and enhance the drug effects (Nutrition Notes Box 16–3).

Weight Reduction

There is a strong relationship between excess body weight and increased blood pressure. Weight reduction is one of

BOX 16-2 Lifestyle Modifications for Hypertension

- Lose weight.
- Limit alcohol intake.
- Get regular aerobic exercise.
- Decrease amount of salt intake.
- Include daily allowances of potassium, calcium, and magnesium.
- Stop smoking.
- Reduce dietary saturated fat and cholesterol.
- Manage stress.

Adapted from The National Heart, Lung, and Blood Institute, The Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. *Arch Intern Med* 157(21):2413, 1997.

BOX 16-3

Nutrition Notes

Reducing Blood Pressure with Diet

In studies the Dietary Approaches to Stop Hypertension (DASH) diet reduced blood pressure significantly in **normotensive** people and produced even greater reductions in hypertensive people. Rather than emphasizing restriction of foods, the DASH diet increases the intake of certain commonly available, not specialty, foods. So that weight loss would not confound the results, participants in the clinical trial were given additional calories if they began to lose weight. All the tested diets contained about 3 grams of sodium. Also, everyone was instructed to consume no more than three caffeinated beverages and no more than two standard alcoholic beverages per day to minimize the effects of those substances on the results. On a 2000-calorie diet, an individual following the DASH diet would consume the following:

- 7 to 8 servings of grains
- 4 to 5 servings of vegetables
- 4 to 5 servings of fruits
- 2 to 3 servings of low-fat or nonfat dairy foods
- 2 or fewer servings of meats, poultry, and fish
- 4 to 5 servings per week of nuts, seeds, and legumes
- 2.5 servings of fats and oils

the most important, if not the most important, lifestyle modification to lower blood pressure. The health care provider and dietitian should be consulted to help the patient develop a weight-reduction diet and other methods of weight loss.

Stress Management

Reducing stress can play a major role in the treatment of patients with hypertension. Stress stimulates the sympathetic nervous system (fight-or-flight response). This stimulation causes the vessels to constrict and activates the renin-angiotensin mechanism. Those who have high stress levels tend to develop hypertension more often than those who do not. Additionally, studies have shown that an increase in stress can also raise the body's production of cholesterol, which can lead to cardiovascular disease. It is important for patients to learn how to deal with stress. For many patients, stress management techniques, such as exercise, relaxation therapies, yoga, meditation, and biofeedback, may be useful in controlling their response to stress and lowering their blood pressure.

Groups who are economically deprived typically have an increased incidence of hypertension. Factors such as poor nutritional habits, low-status jobs, frustration, discontent, and suppression of hostility contribute to stress-related hypertension. Other factors that may affect health include reduced access to quality health care and poor living conditions.

Meal Planning

SALT INTAKE. Research has shown that some people may develop high blood pressure by eating a diet high in salt. Patients whose blood pressure can be lowered by restricting dietary sodium are called salt sensitive. This sensitivity is particularly common among African-Americans, elderly persons, and patients with diabetes and obesity. Patients with hypertension should be instructed not to add salt while cooking and not to add table salt to their food. Processed foods or foods in which salt can be easily tasted (e.g., canned soups, ham, bacon, salted nuts) should also be avoided.

INTAKE OF POTASSIUM, CALCIUM, AND MAGNESIUM.

Recent studies are inconclusive as to the role that low dietary potassium, calcium, and magnesium intake play in the development of high blood pressure. A balanced diet that ensures adequate intake of these nutrients is important in maintaining general health. Foods rich in potassium include oranges, bananas, and broccoli. Milk, yogurt, and spinach are rich in calcium. Vegetables such as spinach, garbanzo beans, and lima beans are good sources of magnesium. Whenever possible, fresh or frozen foods should be selected rather than canned foods to increase intake of these nutrients.

Alcohol Consumption

The regular consumption of three or more drinks per day can increase the risk of hypertension and cause resistance to antihypertensive therapy. The nurse should counsel hypertensive patients who drink alcohol to avoid it or at least

limit their daily intake to 1 oz of alcohol per day (i.e., 2 oz of 100-proof whiskey, 8 oz of wine, or 24 oz of beer). Blood pressure may decrease or return to normal when alcohol consumption is limited or eliminated.

Exercise

People with sedentary lifestyles have an increased risk of hypertension compared with people who exercise regularly. Exercise helps prevent and control hypertension by reducing weight, decreasing peripheral resistance, and decreasing body fat. Moderate activity, such as 30 to 45 minutes of brisk walking three to five times weekly, is recommended by JNC VI. Patients with hypertension should be evaluated by a health care provider before starting any exercise program.

Smoking

Smoking is a major risk factor for cardiovascular disease and is associated with a high incidence of stage 3 hypertension.

Patients who smoke may show an increase in blood pressure because nicotine constricts the blood vessels. The nurse should instruct patients with hypertension to quit or decrease smoking to reduce the risk of myocardial infarction and stroke. A referral by the nurse to a smoking cessation program can be helpful.

► HYPERTENSION TREATMENT

The JNC VI has guidelines for selecting therapy based on severity of blood pressure risk factors and the presence of target organ disease or cardiovascular disease. If the no- or low-risk hypertensive patient's blood pressure remains at or above 140/90 mm Hg during the 6- to 12-month period of lifestyle modifications, the JNC VI advises the practitioner to add antihypertensive medications to the patient's antihypertensive therapy. The medication is selected by the physician or health care provider in collaboration with the patient. For patients with severe hypertension, high-risk factors, or target organ disease, drug therapy is started immediately together with lifestyle modifications.

The goal of drug therapy is to decrease diastolic pressure to 90 mm Hg or less and systolic pressure to 160 mm Hg or less. For patients with stage 1 or 2 hypertension, diuretics and beta blockers are recommended by the JNC VI for initial drug therapy. If the response is inadequate to achieve the blood pressure goal, the dosage may be increased, another drug may be substituted, or a drug from a different class may be added. There are eight categories of medications to treat hypertension: diuretics, alpha blockers, beta blockers, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, central agents, peripheral agents, and vasodilators. Examples of these medications are given in Table 16-2.

The treatment plan of lifestyle modifications and medications is effective only when patients accept the diagnosis

CRITICAL THINKING

Mrs. Miller
Mrs. Miller, age 54, visits a health clinic because she has a headache every morning. The nurse collects data on Mrs. Miller and finds that she is an office manager, smokes a pack of cigarettes a day, eats fast food for lunch at her desk, has two adult children, and is recently divorced. Mrs. Miller has been in good health and takes two aspirin for her headaches daily.

1. What are Mrs. Miller's risk factors for hypertension?
2. What is the most significant patient information identified? Why?
3. Why is hypertension referred to as the silent killer?
4. Why should Mrs. Miller be told of the need for lifelong therapy if she is diagnosed with hypertension?

Answers at end of chapter.

TABLE 16-2 ANTIHYPERTENSIVE MEDICATIONS

Medication	Action	Side Effects	Nursing Considerations
Diuretics			
<i>Thiazide and thiazide-like diuretics</i> Chlorothiazide (Diuril) Chlorthalidone (Hygroton) Metolazone (Zaroxolyn) Indapamide (Lozol) Hydrochlorothiazide (HydroDIURIL)	Inhibits sodium reabsorption in the distal tubule to remove sodium, extracellular fluid, and potassium, reducing cardiac output	Hypokalemia, hyponatremia, dehydration, muscle weakness, dry mouth, hypotension	Monitor electrolytes. Teach need for increased dietary or supplemental potassium. Geriatric: Teach about postural hypotension, especially in hot weather and need to get up slowly. Teach to take in morning to avoid getting up in night.
<i>Loop diuretics</i> Bumetanide (Bumex) Furosemide (Lasix)	Rapid action, block sodium and water reabsorption; diuresis profound	Same as thiazides	Monitor electrolytes. Must replace electrolytes. Geriatric: Same as thiazides.
<i>Potassium-sparing diuretics</i> Amiloride (Midamor) Spironolactone (Aldactone) Triamterene (Dyrenium)	Remove sodium and extracellular fluid but keep potassium	Hyperkalemia, hyponatremia, nausea, vomiting, diarrhea	Monitor electrolytes. Give after meals to decrease nausea. Geriatric: Mental confusion and unsteady gait may occur, so ensure safety.

TABLE 16-2 ANTIHYPERTENSIVE MEDICATIONS — CONT'D

Medication	Action	Side Effects	Nursing Considerations
Adrenergic Inhibitors			
<i>Beta blockers</i>			
Atenolol (Tenormin) Propranolol (Inderal) Pindolol (Visken) Carvedilol (Coreg) Metoprolol (Lopressor, Toprol XL) Labetalol (Normodyne)	Block beta ₁ heart receptors to reduce heart rate and blood pressure; some reduce peripheral vascular resistance	Heart failure Bradycardia, shortness of breath, fatigue, insomnia, numb hands, dizzy, weakness, hyperglycemia	Assess for signs of heart failure. Teach not to stop agent abruptly. Geriatric: Assess for toxicity. Teach about postural hypotension and need to get up slowly.
<i>Alpha blockers</i>			
Prazosin (Minipress) Terazosin (Hytrin)	Vasodilate to reduce peripheral vascular resistance	Dizziness, hypotension, headache, nausea, palpitations	Monitor for hypotension. Teach to make position changes slowly. Geriatric: May be weak and fatigued, so ensure safety.
<i>Central-acting adrenergic inhibitors</i>			
Clonidine (Catapres) Methyldopa (Aldomet) Guanfacine (Tenex) Guanabenz (Wytensin)	Suppress central nervous system	Drowsiness, sedation, dry mouth, constipation Weakness	Caution patient not to take alcohol. Suggest gum or hard candy. Encourage a high-fiber diet. Geriatric: Assess bowel routine and monitor for constipation.
Adrenergic Inhibitors			
<i>Peripheral-acting adrenergic inhibitors</i>			
Guanadrel (Hylorel) Doxazosin (Cardura) Terazosin (Hytrin)	Decrease production of norepinephrine to lower blood pressure	Dizziness, headache Orthostatic hypotension, lethargy, nasal stuffiness, edema	Monitor for first dose orthostatic hypotension. Inform patient to report signs of depression: mood swings, insomnia, anorexia. Geriatric: Postural hypotension common. Assess for depression.
Angiotensin-converting Enzyme Inhibitors			
Benazepril (Lotensin) Captopril (Capoten) Enalapril maleate (Vasotec) Lisinopril (Prinivil, Zestril) Fosinopril (Monopril) Quinapril (Accupril)	Block conversion of angiotensin I to angiotensin II	Cough, rash	Geriatric: Assess for toxicity and recognize need for reduced dose with renal impairment.
Calcium Channel Blockers			
Amlodipine (Norvasc) Nifedipine (Procardia) Diltiazem (Cardizem) Verapamil (Calan, Isoptin) Felodipine (Plendil) Isradipine (DynaCirc, DynaCirc CR) Nicardipine (Cardene, Cardene SR) Nisoldipine (Sular)	Block entry of calcium into smooth muscles to reduce afterload with vasodilation	Headache, dizziness, peripheral edema, heart failure, arrhythmias	Monitor for hypotension. Treat headache with acetaminophen. Geriatric: Decreased dosage may need to be used.
Vasodilators			
Hydralazine (Apresoline) Minoxidil (Loniten) Nitroprusside (Nipride)	Vasodilate arteries, arterioles to reduce afterload	Headache, palpitation	Treat headache with acetaminophen.

of hypertension and include lifelong treatment in their daily routine. Patients should be instructed that antihypertensive therapy usually must be continued for the rest of their lives. Patients should be reminded that although they may be feeling better with the modifications and medications, the hypertension is still present even if it is well con-

trolled. The patient should be told not to discontinue medications unless a physician or advanced practice nurse instructs the patient to do so.

Antihypertensive medications can have unpleasant side effects. Patients should be told what these side effects are and to report them if they do occur, so that alterations in

the medications can be made if possible. Impotence can be one of the side effects of these medications. Male patients may be reluctant to discuss this side effect and instead choose to discontinue the medication. The nurse should be proactive and inform male patients about this side effect, so they will understand that if impotence occurs and is reported, the physician can make adjustments in the medication regimen.

LEARNING TIPS

Hypertension Lifestyle Modifications

- L—Limit salt and alcohol.
- I—Include daily potassium, calcium, and magnesium.
- F—Fight fat and cholesterol.
- E—Exercise regularly.
- S—Stress management.
- T—Try to quit smoking.
- Y—Your medications are to be taken daily.
- L—Lose weight.
- E—End-stage complications will be avoided!

CRITICAL THINKING

Mrs. Bell

Mrs. Bell, 80 years old and a widow for 15 years, visits her physician. She lives alone in her own home with a bathroom down the hall from the bedroom. She has wood floors with throw rugs in the hall and a tile floor in the bathroom. Her son lives in the same city. She has a 10-year history of hypertension for which she is taking bumetanide (Bumex) and propranolol (Inderal), when she remembers them. She wears glasses and has a cataract. She has an unsteady gait and nocturia. She is 40 pounds overweight and is sedentary.

1. What are Mrs. Bell's modifiable and nonmodifiable risk factors for hypertension?
2. Why is Mrs. Bell taking bumetanide and propranolol to treat her hypertension?
3. What teaching methods could be used to help ensure that Mrs. Bell will understand and follow her treatment plan?
4. Why should safety needs be addressed in the nursing care plan?
5. What safety interventions should the patient and family be taught?

Answers at end of chapter.

► COMPLICATIONS OF HYPERTENSION

Common complications of hypertension include coronary artery disease, atherosclerosis, myocardial infarction (MI), stroke, and kidney or eye damage. The severity and duration of the increase in blood pressure determine the extent of the vascular changes causing organ damage. High blood pressure levels may also result in an increase in the size of the left ventricle, referred to as **hypertrophy**. Elevated blood pressure damages the small vessels of the heart, brain, kidneys, and retina. The results are a progressive functional impairment of these organs, or target organ disease.

► SPECIAL CONSIDERATIONS

Blood pressure should be well controlled before any invasive procedure. Hypertensive patients are at greater risk for strokes, MI, kidney failure, and pulmonary edema. These patients should be instructed to continue their blood pressure medications until the time of the procedure, unless otherwise directed by their physician or health care provider. They should resume their antihypertensive medications as soon as possible after the procedure, unless they are given new instructions by the physician.

► NURSING PROCESS

Nursing Assessment

Assessment of a patient with hypertension includes the patient's history, medications, and physical assessment. Assessing what hypertensive patients and their families know about hypertension and associated risk factors is essential for planning patient and family education and subsequent lifestyle modification needs.

Nursing Diagnosis

Based on the data and defining characteristics, a nursing diagnosis should be chosen in collaboration with the health care team and the patient (Nursing Care Plan Box 16–4). Because the risk of hypertension depends on the number and severity of modifiable risk factors, several nursing diagnoses may be applicable. Common diagnoses may include but are not limited to the following:

- Deficient knowledge related to lack of exposure to hypertension information.
- Ineffective therapeutic regimen management related to complexity of therapy, cost of medications, lack of symptoms, side effects of medications, need to alter long-term lifestyle habits, normal blood pressure controlled by therapy.

Planning

After nursing diagnoses have been identified, specific goals for blood pressure control should be set by the physician, nurse, patient, and family. Any barriers to meeting these goals should be discussed with the patient and family so that the plan can be carried out more effectively. The patient's goals are to (1) explain hypertension and needed medications, and (2) verbalize the ability to follow prescribed therapy.

Nursing Interventions

To meet their goals, patients may need more information, guidance, and support from the health care team. Referrals to other resources such as the dietitian, social worker, pharmacist, and home health nurse should be included (Home Health Hints). The patient and family should be allowed to maintain a sense of control, make informed decisions regarding care, and develop the skills necessary to make lifestyle modifications. Behavioral changes are the most difficult for the patient to initiate and maintain. The nurse plays a major role in therapy and treatment compliance for hypertensive patients. Elderly patients may have unique

▶ Ineffective therapeutic regimen management related to complexity of therapy, cost of medications, lack of symptoms, side effects of medications, need to alter long-term lifestyle habits, normal blood pressure controlled by therapy

OUTCOMES

Verbalizes ability and willingness to comply with treatment.

EVALUATION OF OUTCOMES

Is patient able to state how lifestyle will include therapy? Does patient identify and problem solve barriers for therapy?

INTERVENTION

Identify patient's modifiable risk factors and lifestyle modification needs.

Identify factors that are barriers to patient complying with therapy.

Develop plan to overcome barriers. Make referrals as needed.

Assess ability to take medications daily: financially, obtaining refills, understanding directions.

Teach patient to take medications as prescribed and not to skip dosages.

Teach patient to change positions slowly to prevent falls.

RATIONALE

Identifying risk factors is the first step in planning therapy. Patient must understand the relationship of these risk factors with hypertension and complication development.

Factors such as finances, transportation, aging changes, patient motivation, habits, and reading and educational level can be barriers for therapy. Identified barriers can be overcome with planning and intervention, such as referral to support groups or for financial assistance or prescription delivery service and instructions provided at level of patient's learning ability.

Elderly patients may be on a fixed income, lack transportation, or lack ability to take several medications several times a day. Simplifying this process, to one medication if possible, can increase compliance.

Elderly patients may skip dosages to save money, reduce side effects, or reduce need to void.

Antihypertensive medications can cause hypotension, resulting in dizziness and weakness and possibly leading to falls.

EVALUATION

Can patient state rationale for modifying risk factors to prevent complication development?

Are barriers present for patient?

Have barriers been eliminated?
Is patient willing to use referrals?

Is patient able to obtain medications? Can patient self-administer medications accurately on daily basis?

Does patient take dosages as prescribed?
Does patient express concern over cost, side effects, or frequent voiding?
Does patient understand how to change positions slowly?
Does patient experience dizziness or weakness?

GERIATRIC

HOME HEALTH HINTS

- For meal planning, most patients eat fast foods occasionally. Assist them in choosing foods that are low in fat, sugar, and salt (e.g., choose chicken salads with low-fat dressing or fajitas without sour cream and guacamole).
- Because medication and electrolyte interaction can occur with salt substitute, which often contains potassium, the physician should be consulted before the patient uses it.
- Teach patients how to read labels for fat and salt content. If patients are on a 2- to 3-g sodium diet, instruct them on eating breads or cereals that contain 200 mg or less of sodium per serving or canned vegetables of 150 mg of sodium per serving. Fresh vegetables are better, but cost and storage must be considered. Providing written suggestions for the caregiver who does the grocery shopping increases compliance with diet therapy.
- Home exercise using weights can be improvised using canned goods and bags of sugar as weights. The amount of weight being used is easily identified for documentation by the labeling on the food item.
- The following suggestions may help a patient decrease or stop smoking: Use cinnamon mouthwash on arising; put away all ashtrays but one and keep it in a place not normally used for smoking; find ways to keep hands busy at times when usually holding cigarette, such as when drinking coffee or alcohol.
- Encourage patients to put "No Smoking" signs on their door to avoid passive smoking.
- Medication compliance can be a challenge for the elderly hypertensive patient. Instruct patients to take medication as prescribed even if they are feeling well or if side effects, which they should report, are present. If the medicines are too expensive for the patient, check with the physician and pharmacist for less expensive alternatives.
- During home visits count the amount of pills in a bottle to assess compliance. Remind the patient to get refills and keep physician appointments by writing them on the calendar.
- Because many of the antihypertensive medicines can cause bradycardia, teach the patient or caregiver to take the patient's pulse and to call the nurse if it is below 60 or the parameters defined by the physician or agency.
- Monitor carefully for symptoms of congestive heart failure when the patient is on beta blockers. This is a side effect that needs to be caught early and reported to the physician.
- Encourage the patient to obtain a home blood pressure monitoring device. Instruct the patient caregiver on proper use and logging the date, time, and reading obtained. The home health nurse should review the log on each visit.
- Patients should be instructed to weigh themselves every morning after voiding, to wear the same amount of clothing each time, and to keep a log for the nurse to review.

needs related to hypertension therapy (Gerontological Issues Box 16–5).

Evaluation

One of the best outcome criteria for evaluation of the plan of care for reducing hypertension is reaching a lowered blood pressure with minimal side effects and no evidence of target organ damage. Other indicators of success in implementing the plan of care are weight loss, maintaining a low-sodium diet, decreasing alcohol intake, decreasing or not smoking, and managing stress on a daily basis. If the patient is satisfied and comfortable with the quality of life after the modifications, another goal has been met. Ongoing evaluation is necessary, because this is a lifelong condition that may require periodic teaching and reinforcement of knowledge as deficiencies are identified.

BOX 16-5 GERONTOLOGICAL ISSUES

Managing Antihypertensive Therapy

For safety, teach older adults who take antihypertensive drugs to rise slowly to prevent the effects of orthostatic hypotension. Dizziness may result, increasing the risk of falling. Deficiencies in fluid volume can be a common problem for older people as well, and diuretics can contribute to fluid volume deficiencies. Careful fluid balance assessment is important to prevent dehydration. Older adults may be more sensitive to medications, so monitor them carefully for adverse effects. Some older people may need lower dosages.

PATIENT EDUCATION

The use of educational programs in hospitals, clinics, churches, and health fairs helps increase patient motivation to adhere to antihypertensive therapy. Instructions provided by the nurse are directed toward helping patients control their blood pressure through self-care measures, as well as the prescribed medical regimen. To effectively control hypertension, patients must be knowledgeable about their condition. They need to be taught about hypertension, its treatment, and the need for a lifelong commitment to controlling it. (See Nursing Care Plan Box 16–4.)

HYPERTENSIVE EMERGENCY

Hypertensive crisis is a severe type of hypertension characterized by rapidly progressive elevations in blood pressure with diastolic values above 110 mm Hg. Patients who are untreated, fail to comply with antihypertensive therapy, or stop their medication abruptly are at risk for hypertensive crisis. A patient with hypertensive crisis may experience morning headaches, blurred vision, dizziness, nosebleeds, and dyspnea. A diminished level of consciousness, weakness, paralysis, palpitations, or complaints of chest pain may also indicate a hypertensive crisis and should be reported immediately. Patients with hypertensive crises are admitted to the critical care unit. In some cases the blood pressure may need to be reduced within 1 hour to prevent organ damage. An intravenous medication such as nitroprusside (Nipride) may be given to quickly reduce blood pressure during this crisis.

REVIEW QUESTIONS

- Which one of the following is true of the cause of primary hypertension?
 - It is caused by a tumor of the adrenal gland.
 - It is caused by renal artery stenosis.
 - It is caused by coarctation of the aorta.
 - There is no known cause.
- Which one of the following is often the only sign of hypertension?
 - Sacral edema
 - Elevated blood pressure
 - Tachycardia
 - Neck vein distention
- The nurse should give which one of the following instructions to a patient receiving a thiazide diuretic?
 - Eliminate salt in your diet.
 - Change positions slowly.
 - Take your medication before bed.
 - Empty your bladder after taking the first dose.
- For which one of the following blood pressure readings should a follow-up visit be recommended?
 - 128/70
 - 136/76
 - 140/94
 - 142/86
- Which one of the following is the most important lifestyle modification for the hypertensive patient who is obese?
 - Reduce weight.
 - Restrict salt intake.
 - Quit smoking.
 - Decrease alcohol intake.

Answers to CRITICAL THINKING**Mrs. Miller**

1. Risk factors include gender; age; smoking cigarettes; a diet high in fat, salt, and calories; recent divorce; a stressful occupation; and morning headaches.
2. Morning headaches. Mrs. Miller may be experiencing an episode of hypertensive crisis and should be evaluated immediately by a health care provider.
3. "Silent killer" refers to the fact that there are often no signs or symptoms associated with hypertension.
4. Lifelong therapy is required because there is no cure for hypertension and complications need to be prevented.

Mrs. Bell

1. Nonmodifiable risk factors include age, gender, and history of hypertension. Modifiable risk factors include weight and compliance with antihypertensive therapy.
2. Diuretics remove excess salt and water to decrease blood volume and lower blood pressure. Beta blockers stop the beta receptors from receiving the message from the brain for the heart to work harder. Therefore the heart rate and blood pressure decrease.

3. Assess patient's reading level and primary language. Provide patient with written instructions in large letters about medications. Include family members and encourage their support in reinforcing the importance of adhering to the treatment plan.
4. Patient is 80 years old, makes frequent trips to the bathroom related to diuretics, and a side effect of propranolol is weakness and fatigue.
5. Make arrangements for a bedside commode to reduce the distance and urgency to get to the bathroom. Encourage the family to place night-lights in the bedroom, hall, and bathroom. Explain that throw rugs increase the risk of falling and that wood or tile floors can be slippery when wet and hard if a fall occurs. Encourage removal of throw rugs, and suggest carpeting these areas if possible. Suggest the use of safety bars in hall and bathroom for support or other walking aids as needed. If incontinence is a concern, suggest wearing an adult brief to prevent a wet, slippery floor. Suggest discussing with the physician an exercise program to increase strength, such as lifting small, lightweight objects (e.g., canned foods), squeezing a rubber ball, or riding an exercise bike if able. These exercises can be done while sitting so they are not a fall-risk activity.

▶ INFLAMMATORY AND INFECTIOUS CARDIAC DISORDERS

The entire heart (**rheumatic carditis**) or layers of the heart (endocarditis, myocarditis, and pericarditis) can become inflamed or infected (Fig. 17-1).

Rheumatic Carditis

Pathophysiology and Etiology

A serious complication of **rheumatic fever** is rheumatic carditis. Rheumatic fever occurs as an autoimmune reaction to an upper respiratory (throat) group A **beta-hemolytic streptococci** infection (Table 17-1). Two to three weeks after the streptococcal infection, rheumatic fever occurs. Although rheumatic fever can occur at any age, it typically occurs between ages 5 and 15, and can recur along with rheumatic carditis.

With carditis from rheumatic fever, all layers of the heart become inflamed. Pericardial layers are covered with an ex-

myocarditis: myo—muscle + kardia—heart + itis—
inflammation

pericarditis: peri—around + kardia—heart + itis—
inflammation

Figure 17-1 Layers of the heart.

TABLE 17-1 RHEUMATIC FEVER SUMMARY

<i>Signs and symptoms</i>	Fever Polyarthritides Subcutaneous nodules Chorea with rapid, uncontrolled movements Rheumatic carditis Arthralgia Pneumonitis
<i>Diagnostic tests</i>	Throat culture (identifies streptococcal infection) Antistreptolysin O titer level greater than 250 IU/mL Elevated ESR and WBC
<i>Medical treatment</i>	Antimicrobial medication Anti-inflammatory medication Control of symptoms Prophylactic antibiotics
<i>Nursing diagnoses</i>	Acute pain related to joint or cardiac inflammation Anxiety related to disease process Decreased cardiac output related to valvular damage and carditis

ESR = erythrocyte sedimentation rate.

udate and become thickened. As healing takes place, the pericardial sac can be damaged or destroyed by fibrosis. Nodules (Aschoff's bodies) form in myocardial tissue that become scar tissue over time. The endocardium, specifically the mitral valve, is the most seriously affected. Tiny, pin-head-size vegetations from blood and fibrin form on the valve leaflets. This can lead to thickening, fibrosis, and calcification of the valve leaflets and support structures. If the valve leaflets do not close completely, regurgitation of blood can occur. If the valve leaflets do not open fully (valvular stenosis), blood movement is impaired and severe heart failure may result.

Signs and Symptoms

Rheumatic carditis signs and symptoms include tachycardia, heart murmur, **pericardial friction rub**, chest pain, heart enlargement, electrocardiogram changes (e.g., PR interval lengthening), and evidence of heart failure.

Prevention

Preventing rheumatic fever by detecting and treating streptococcal infections promptly with penicillin (or erythromycin [Erythromid] in the case of a patient with a penicillin allergy) is important to prevent rheumatic carditis. Signs and symptoms of a throat streptococcal infection include sudden sore throat, fever of 101° F to 104° F, chills, throat redness with exudate, sinus or ear infection, and lymph node enlargement. A throat culture provides an accurate diagnosis. For those who have had rheumatic fever, lifelong prophylactic antibiotics before dental or invasive procedures are given because of the risk of developing **infective endocarditis** (discussed later).

Medical Management

Antibiotics are started promptly. Activity is limited based on the severity of cardiac involvement. Other treatment for cardiac involvement is based on symptoms.

Nursing Management

A history of recent illnesses (e.g., sore throat, streptococcal infection, or scarlet fever) is obtained from the patient, including past episodes of rheumatic fever, heart disease, joint pain, and current medications. A physical assessment detects murmurs, pericardial friction rub, and heart failure signs (e.g., jugular vein distension, edema, dyspnea, crackles, cough, and fatigue). Vital signs are documented, noting fever and tachycardia.

Nursing care focuses on relieving the patient's pain and anxiety, maintaining normal cardiac function, and educating the patient about the disease. Pain is relieved with analgesics, aspirin, or corticosteroids as ordered. Vital signs are monitored and symptoms of heart failure are reported to the physician. An explanation of the disease and its treatment is provided to promote understanding of acute and lifelong prophylactic treatment. A patient statement of willingness to maintain health supports goal achievement.

Infective Endocarditis

Infective endocarditis (IE) is an infection of the endocardium. Males develop IE more often than females. Even with antibiotic treatment, this infection can be fatal.

Pathophysiology

Cardiac defects result in turbulent blood flow that erodes the endocardium. Infective endocarditis begins when the invading organism (such as bacteria) attaches to eroded endocardium where platelets and fibrin deposits have formed a vegetative lesion. Then more platelets and fibrin cover the multiplying organism. This covering protects the microbes, reducing the ability to destroy them. Damage to valve leaflets occurs as the vegetations grow. As blood flows through the heart, these vegetations may break off and become **emboli**.

With bacteremia, bacteria attach mainly to the valves of the heart, although any heart endothelial surface can be infected. Damaged valves from conditions such as mitral valve prolapse with regurgitation, rheumatic heart disease, congenital defects, and valve replacements are especially prone to bacterial invasion. The mitral valve is the valve most commonly infected, with the aortic valve the second most commonly infected. Heart failure may result from valve damage, especially of the aortic valve.

Etiology

Portals of entry for organisms into the bloodstream result from intravenous (IV) drug use; surgery; dental or invasive procedures; and infections of the skin and gastrointestinal or genitourinary tracts. Risk factors include the following:

- IV drug use
- Compromised immune system

- Congenital or valvular heart disease (e.g., mitral valve prolapse with regurgitation, valvular replacement surgery, or rheumatic carditis)
- Gingival gum disease

Prevention

Because dental disease is a common cause of IE, oral care is an important preventative measure. Additionally, antibiotic therapy before invasive or dental procedures is recommended for patients with cardiac disease or prior endocarditis.¹ It is important that these patients are taught to inform health care team members (including their dentists) of their history before a procedure. Ensure that this history is reported to the physician, so that prophylactic therapy can be given if needed.

Signs and Symptoms

Fever (99° F to 103° F [37.2° C to 39.4° C]) is a common sign, although the elderly may be afebrile (Table 17-2). A

TABLE 17-2 INFECTIVE ENDOCARDITIS SUMMARY

Signs and symptoms	Fever Murmur Night sweats Fatigue Weight loss Weakness Pain in abdomen, joints, muscles, back Nailbed splinter hemorrhages Petechiae
Diagnostic tests and findings	Blood cultures (identify causative organism) Transesophageal echocardiography (identifies vegetations on heart valves) WBC count with differential (identifies elevation)
Medical treatment and purpose	Acute therapy: IV antimicrobial medications such as penicillin, vancomycin, amphotericin B (to cure infection) Antipyretics (to reduce fever) Rest (to decrease cardiac workload) Surgical valve replacement (to restore normal valve function) Prophylactic antibiotic therapy (to prevent infection)
Complications	Emboli Heart failure
Nursing diagnoses	Acute pain related to fever from cardiac infection Activity intolerance related to reduced oxygen delivery from decreased cardiac output Decreased cardiac output related to impaired valvular function or heart failure Deficient diversional activity related to restricted mobility from prolonged IV therapy Ineffective tissue perfusion related to emboli

new murmur is usually heard as valvular damage occurs. Splinter hemorrhages may be seen in the distal nailbed (black or red-brown longitudinal short lines). **Petechiae** (tiny red flat spots) resulting from microembolization of the vegetation may occur on mucous membranes, conjunctivae, or skin (Fig. 17-2). Janeway lesions (small, painless red-blue lesion on palms and soles) are an acute finding. Osler's nodes (small, painful nodes on fingers and toes) from cardiac emboli are a late finding (Fig. 17-3).

Complications

Vegetative emboli can be a major complication of IE. If organ embolization occurs, signs and symptoms that reflect

Figure 17-2 Petechiae. (From Goldsmith, L: *Adult & Pediatric Dermatology*. FA Davis, Philadelphia, 1997, p 61.)

Figure 17-3 Osler's nodes. (From Goldsmith, L: *Adult & Pediatric Dermatology*. Philadelphia, FA Davis, 1997, p 188.)

petechiae: petecchia—skin spot

the organ that was affected by the emboli are seen. Brain emboli may produce changes in level of consciousness or stroke. Kidney emboli cause pain in the flank area, hematuria, or renal failure. Emboli in the spleen cause abdominal pain. Emboli in the small blood vessels can impair circulation in the extremities. Pulmonary emboli result in sudden dyspnea, cough, and chest pain. (See Chapter 28.)

Heart structures can be damaged or destroyed by IE. Stenosis or regurgitation of a heart valve may also result. As the infection progresses and causes more damage to heart structures, heart failure may occur. (See Chapter 21.)

Diagnostic Tests

Table 17-2 shows diagnostic tests for IE. Positive blood cultures identify the causative organism of IE, and echocardiography shows cardiac effects.

Medical Treatment

Initial treatment begins with hospitalization. An antimicrobial drug is selected that will destroy the organism identified by the blood culture. For bacterial infections, penicillin (or vancomycin for those allergic to penicillin) is commonly used. These medications are given intravenously over a period of 4 to 6 weeks, often once a day. A lengthy course of high-dose antibiotics is needed to penetrate the vegetations and reach the microbes. Rest and supportive symptom care are also used. If afebrile and without complications, the patient is discharged to continue IV antibiotic therapy at home. The patient's response to the drug is monitored via the home care nurse and through laboratory testing. Changes in antibiotics may be made in response to side effects, allergies, organism resistance to the drug, or relapses.

Surgical replacement or repair of valves is usually required for patients with severely damaged heart valves, prosthetic valve infection, recurrent infection, multiple emboli from damaged valves, or heart failure. (See Chapter 22.) Recovery from the disease can be greatly improved with surgery. Antimicrobial therapy continues after surgery.

Nursing Management

A patient history is obtained that includes risk factors for IE and recent infections or invasive procedures (Table 17-3). Vital signs are measured and recorded, and heart sounds are auscultated to detect murmurs. Signs of heart failure and emboli are noted. The physician is notified immediately if circulatory impairment, such as cold skin, decreased capillary refill, cyanosis, or absent peripheral pulses in an extremity, or symptoms of organ-related emboli are detected.

Nursing care aims to maintain the patient's normal cardiac function, monitor symptoms and complications, provide medications as ordered, and teach the patient about the disease, medications, treatments, and prevention techniques. See Nursing Care Plan Box 17-1 for the Patient with Infective Endocarditis for specific nursing interventions.

Teaching about the disease provides patients and families with the ability to provide IV antibiotics at home and promotes health maintenance to prevent IE. Good hygiene

TABLE 17-3 NURSING ASSESSMENT FOR PATIENTS WITH INFECTIVE ENDOCARDITIS

Subjective Data	
<i>Health History</i>	
Infections (rheumatic fever, previous endocarditis, streptococcal or staphylococcal, syphilis)?	
Cardiac disease (valvular surgery, congenital)?	
Childbirth?	
Invasive procedures (surgery, dental, catheterization, IV therapy, cystoscopy, gynecologic)?	
Malaise?	
Anorexia?	
<i>Medications</i>	
Steroids, immunosuppressants, prolonged antibiotic therapy, IV drug use, alcohol abuse?	
<i>Respiratory</i>	
Dyspnea on exertion or when lying (orthopnea)?	
Cough?	
<i>Cardiovascular</i>	
Palpitations, chest pain, fatigue, or activity intolerance?	
<i>Musculoskeletal</i>	
Weakness, arthralgia, myalgia?	
<i>Knowledge of Condition</i>	
Objective Data	
<i>Fever, Diaphoresis</i>	
<i>Respiratory</i>	
Crackles, tachypnea	
<i>Cardiovascular</i>	
Murmurs, tachycardia, dysrhythmias, edema, headache

is essential, including dental care. Skin care includes bathing, using proper handwashing technique with soap, avoiding nailbiting, not popping pimples or lancing boils, and washing and applying antibiotic ointment to cuts. Brushing with a soft-bristle toothbrush (prevents gum trauma) twice a day reduces plaque formation, which traps bacteria. Twice yearly dental cleaning using prophylactic antibiotics is important. It is essential that patients understand the need to request and take prophylactic antibiotics as needed before invasive procedures. Patients are also taught symptom recognition (e.g., fever, chills, sweats) and seeking of prompt medical care. The patient is educated on the importance of having blood cultures drawn before antibiotics are started. The patient's statement of understanding and a willingness to follow lifestyle changes supports goal achievement.

CRITICAL THINKING

Mrs. Jones

Mrs. Jones, 28 years old, is admitted to the hospital with a fever of 100° F (37° C), chills, fatigue, anorexia, and pain in her joints. A physical assessment reveals splinter hemorrhages in left index finger nailbed and petechiae on her chest. She is diagnosed with a heart murmur and infective endocarditis.

1. Why is a heart murmur heard with endocarditis?
2. What do splinter hemorrhages look like?
3. What do petechiae indicate?
4. How would you document Mrs. Jones's assessment findings?
5. What type of medication does the nurse expect to be ordered to treat the infection?
6. Why does Mrs. Jones have chills if her temperature is elevated?
7. What signs and symptoms might occur if the complications of heart failure develop?
8. Why does Mrs. Jones need to be taught that she needs prophylactic antibiotics before dental or invasive procedures?

Answers at end of chapter.

Pericarditis

Pathophysiology and Etiology

Pericarditis is an acute or chronic inflammation of the pericardium (the sac surrounding the heart). The inflammation creates a problem for the heart as it tries to expand and fill. As a result, ventricular filling is reduced, which then decreases cardiac output and blood pressure. Acute pericarditis can be caused by a variety of factors, including the following:

- Infections: viruses, bacteria, fungi, or Lyme disease
- Drug reactions
- Connective tissue disorders: systemic lupus erythematosus, rheumatic fever, or rheumatoid arthritis
- Neoplastic disease
- Postpericardiotomy (i.e., after cardiac surgery)
- Postmyocardial infarction, 1 to 12 weeks (**Dressler's syndrome**)
- Renal disease or uremia
- Trauma from chest injury or invasive thoracic procedures

Acute pericarditis resolves usually in less than 6 weeks. Recurrence is possible.

Chronic constrictive pericarditis is the result of fibrous scarring of the pericardium. The heart becomes surrounded by a thickened, stiff sac that limits the stretching ability of the heart's chambers for filling. Heart failure may result. Chronic constrictive pericarditis results from neoplastic disease and metastasis, radiation, or tuberculosis.

Signs and Symptoms

Chest pain is the most common symptom of pericarditis (Table 17-4). The pain is located substernally and over the heart and may radiate to the clavicle, neck, left scapula, or epigastric area. The intense, sharp, grating pain increases with deep inspiration, coughing, moving the trunk, or lying

BOX 17-1 NURSING CARE PLAN FOR THE PATIENT WITH INFECTIVE ENDOCARDITIS**▶ Decreased cardiac output related to impaired valvular function or heart failure****PATIENT OUTCOMES**

Has adequate cardiac output as evidenced by vital signs within normal limits, no dyspnea or fatigue.

EVALUATION OF OUTCOMES

Are patient's vital signs within normal limits with no dyspnea or fatigue?

INTERVENTIONS

Assess vital signs, murmurs, dyspnea, and fatigue.
Give oxygen as ordered.

Provide rest as ordered.

Elevate head of bed 45 degrees.

RATIONALE

Vital signs, dyspnea, and fatigue are indicators of cardiac output decline.

Supplemental oxygen provides more oxygen to the heart.

Cardiac workload and oxygen needs are reduced with rest.

Venous return to heart is reduced and chest expansion improved.

EVALUATION

Are vital signs within normal limits with no dyspnea or fatigue?

Are breathing pattern and oxygen saturation within normal limits?

Are vital signs within normal limits and no fatigue reported?

Are vital signs within normal limits and respirations easy?

▶ Activity intolerance related to reduced oxygen delivery from decreased cardiac output**PATIENT OUTCOMES**

Patient will state less fatigue in response to activity.

EVALUATION OF OUTCOMES

Does patient report less fatigue? Is patient able to participate in desired activities?

INTERVENTIONS

Assist with activities of daily living (ADLs) prn.

Provide rest and space activities.

RATIONALE

Assistance conserves energy.

Cardiac workload and oxygen needs are reduced with rest.

EVALUATION

Are ADLs completed?

Does patient report less fatigue?

▶ Deficient diversional activity related to restricted mobility from prolonged intravenous therapy**PATIENT OUTCOMES**

States participation in satisfying diversional activities.

EVALUATION OF OUTCOMES

Does patient participate in diversional activities? Does patient state satisfaction with activities?

INTERVENTIONS

Assess patient's preferred activities and hobbies.

Plan patient's schedule around relaxing and fun activities.

Use pet therapy.

Provide a mix of physical, mental, and social activities on a rotating schedule.

RATIONALE

Activity preference should be known to plan satisfactory diversional activities.

Self-esteem is fostered with increased patient control.

Individuals who can interact with pets live longer and healthier.

Rotating stimulating activities and visitors will keep patient interested and avoid fatigue.

EVALUATION

Are patient's preferred activities known?

Does patient offer input into scheduled care? Is input followed?

Does patient state enjoyment of pet therapy?

Does patient state satisfaction in activities with no fatigue?

flat. The pain may be relieved by sitting up and leaning forward. Other symptoms depend on the cause of the pericarditis and may include dyspnea, low-grade fever, and cough. Dyspnea occurs as a result of decreased cardiac output and reduced oxygenation.

The classic sign of pericarditis is a pericardial friction rub, a grating, scratchy, high-pitched sound that is heard when a rub is present. The rub is a result of friction from the inflamed pericardial and epicardial layers rubbing together as the heart fills and contracts. Depending on the severity of

the pericarditis, the rub may be faint when auscultated or loud enough to be audible without auscultation. The rub may be heard intermittently or continuously. It is usually heard over the lower left sternal border of the chest during each heartbeat. It is present in approximately 50 percent of those with pericarditis.

Chronic constrictive pericarditis produces the signs and symptoms of right-sided heart failure. Atrial fibrillation may also be seen in some patients with chronic constrictive pericarditis.

TABLE 17-4 PERICARDITIS SUMMARY

<i>Signs and symptoms</i>	Chest pain Dyspnea Low-grade fever Cough Pericardial friction rub
<i>Diagnostic tests</i>	Complete blood cell count Electrocardiogram Echocardiogram MRI CT
<i>Medical treatment</i>	Anti-inflammatory medication Corticosteroids Pericardiocentesis Pericardial window
<i>Complications</i>	Pericardial effusion Cardiac tamponade
<i>Nursing diagnoses</i>	Acute pain related to inflammation of pericardium Anxiety related to disease process Decreased cardiac output related to cardiac constriction

Diagnostic Tests

Table 17-4 lists diagnostic tests. The electrocardiogram reveals ST-T wave elevation in all leads. Echocardiogram results show **pericardial effusions**. Serum laboratory tests focus on causes of the pericarditis, such as an elevated white blood cell (WBC) count, indicating a bacterial or viral infection, or elevated blood urea nitrogen or creatinine levels, indicating uremia. Fluid obtained during **pericardiocentesis** is examined to diagnose the cause. In chronic constrictive pericarditis, computed tomography (CT) or magnetic resonance imaging (MRI) may show a thickened pericardium.

Medical Treatment

If the patient is unstable, prompt intervention is required, such as an emergency pericardiocentesis. When the patient is stable, the cause is determined so that appropriate treatment can be administered, such as antibiotics for bacterial infections. Bedrest is used to reduce the heart's workload during acute symptoms. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin (Indocin) are given to resolve inflammation and reduce pain. Corticosteroids may be used when NSAIDs are not effective. Hemodialysis is used to treat uremic pericarditis.

LEARNING TIPS

To simulate the sound of a pericardial friction rub, hold the diaphragm of a stethoscope against the palm of one hand; listen through the stethoscope as you rub the index finger of the opposite hand over the knuckles of the hand holding the diaphragm. The sound you hear is similar to that of a pericardial friction rub.

Chronic effusive pericarditis can be treated with a pericardial window to allow continuous drainage of pericardial fluid into the pleural space. A pericardial window is created surgically by removing a portion of the outer pericardial layer.

Chronic constrictive pericarditis is treated with **pericardiectomy**, which is the surgical removal of the entire tough, calcified pericardium. Pericardiectomy relieves constriction of the heart and allows normal filling of the ventricles.

Complications

A pericardial effusion (buildup of fluid in pericardial space) is the most common complication of pericarditis. A rapidly developing effusion, such as one occurring from trauma, can produce symptoms at smaller amounts of fluid than slowly developing effusions, such as pericarditis from tuberculosis, with larger amounts of fluid. The increasing fluid presses on nearby tissue. Pressure on lung tissue can produce dyspnea, cough, and tachypnea. The heartbeat sounds distant. The body's compensatory mechanisms attempt to maintain blood pressure.

As the fluid accumulation grows, **cardiac tamponade**, another complication of pericarditis, can occur. Cardiac tamponade is a life-threatening compression of the heart by fluid accumulated in the pericardial sac. Cardiac output drops and then blood pressure falls as compensatory mechanisms fail. The patient shows symptoms of decreased cardiac output, such as restlessness, confusion, tachycardia, and tachypnea. Jugular vein distention is present from increased venous pressure, and heart sounds are distant. Cardiac tamponade requires immediate treatment with pericardiocentesis to puncture the pericardium with a 16-gauge needle and remove the excess fluid in the pericardial sac (Fig. 17-4). After the procedure, the patient is monitored for complications, such as dysrhythmias, laceration of a coronary artery, or laceration of the myocardium or pneumothorax.

Nursing Management

A patient history is obtained that includes any cardiac disease, recent infections, and current medications. Chest pain, pericardial friction rub, heart sounds, and signs of heart failure are noted. Vital signs are documented, noting fever and tachycardia.

Nursing care focuses on relieving the patient's pain and anxiety and maintaining normal cardiac function. Symptoms are monitored to detect complications. Pain, which may be severe, is relieved by giving NSAIDs or corticosteroids as ordered. Allowing the patient to assume a position of comfort by sitting up and leaning forward also re-

pericardiocentesis: peri—around + kardia—heart + centesis—puncture

cardiac tamponade: kardia—heart + tamponade—plug

Figure 17-4 Pericardiocentesis.

relieves pain. Maintenance of normal cardiac function includes monitoring vital signs and observing for the presence of symptoms of cardiac tamponade or heart failure. The detection of these symptoms is immediately reported to the physician. Teaching the patient about pericarditis and its treatment relieves anxiety and allows a feeling of control by allowing the patient to make knowledgeable health care decisions.

Myocarditis

Pathophysiology and Etiology

In myocarditis, inflammation of the myocardium occurs. The amount of muscle destruction and necrosis that occurs as a result of myocarditis determines the extent of damage to the heart. The heart may enlarge in response to the damaged muscle fibers, although most cases of myocarditis are benign, with few signs or symptoms.

Myocarditis is a rare condition that most commonly develops following a virus. Other causes are bacteria, parasites, fungi, rickettsiae, spirochetes, medications, lead toxicity, autoimmune factors, human immunodeficiency virus (HIV), rheumatic fever, systemic lupus erythematosus, pericarditis or infective endocarditis, or cardiac transplant rejection.

Signs and Symptoms

Signs and symptoms of myocarditis vary from none to severe cardiac manifestations. Fatigue, fever, pharyngitis, malaise, dyspnea, palpitations, muscle aches, gastrointestinal (GI) discomfort, and enlarged lymph nodes may occur early from a viral infection. Cardiac manifestations such as chest discomfort, pain, or tachycardia may occur about 2 weeks after a viral infection. Occasionally, sudden death may occur.

Diagnostic Tests

A percutaneous endomyocardial biopsy during the first 6 weeks of inflammation is the preferred diagnostic test for myocarditis, although it is positive only about 30 percent of the time. MRI and gallium-67 scanning are helpful. An electrocardiogram (ECG) shows dysrhythmias, commonly sinus tachycardia.

Medical Treatment

Treatment is aimed at the cause, if known, such as antibiotics for bacterial infections. Interventions to reduce the heart's workload, such as bedrest, limited activity, and administration of oxygen, are used. Heart failure is treated with medication to strengthen the heart's contractility and slow the heart's rate, which reduces the heart's workload and oxygen needs. Digoxin is often used to treat heart failure. With myocarditis, the heart is sensitive to digoxin, which may be used to treat heart failure, and toxicity may occur even with small doses. The patient should be monitored closely for signs of digoxin toxicity, which may include anorexia, nausea, vomiting, bradycardia, dysrhythmias, or malaise.

Nursing Management

Recent illnesses, toxin exposure, cardiac diseases, activity tolerance, and current medications are documented. Vital signs and signs of heart failure, such as jugular vein distention, peripheral edema, crackles, and dyspnea are noted.

Nursing care is aimed at the patient's maintenance of normal cardiac function by monitoring vital signs and symptoms and administering medications as ordered. Reducing the patient's anxiety and increasing the patient's knowledge can be achieved through teaching about the disease. Determining diversion activities with the patient for times when activity is restricted further reduces anxiety.

Interventions to reduce fatigue include providing assistance as needed, having frequent rest periods, and teaching energy conservation methods.

Cardiomyopathy

Cardiomyopathy is an enlargement of the heart muscle. There are three types of cardiac structure and function

cardiomyopathy: kardia—heart + myo—muscle + pathy—disease

abnormalities in cardiomyopathy: (1) dilated, (2) hypertrophic, and (3) restrictive (Fig. 17-5). A consequence of all types of cardiomyopathy can be heart failure (Fig. 17-6). There is no cure for cardiomyopathy.

Dilated Cardiomyopathy

In dilated cardiomyopathy the size of the ventricular cavity enlarges. Contractile function decreases as the myocardial tissue is destroyed. Blood moves more slowly through the left ventricle, which often results in blood clot formation. Dilated cardiomyopathy is the most frequent type. Dilated cardiomyopathy may be hereditary, follow infectious myocarditis, or be caused by chronic alcohol or cocaine use, HIV, thiamine or zinc deficiencies, or infections.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is enlargement of the muscle walls of the left ventricle. The ventricular walls are rigid, which decreases ventricular filling. If the enlarged septum obstructs the outflow of blood through the aortic valve, it is known as obstructive hypertrophic cardiomyopathy. Hyper-

Figure 17-6 All types of cardiomyopathies can lead to heart failure.

trophic cardiomyopathy can be a hereditary disorder that is transmitted as a dominant trait. Sudden death in young athletes may be due to this condition and is often the first sign of the disease.

Restrictive Cardiomyopathy

Restrictive cardiomyopathy impairs ventricular stretch and limits ventricular filling. Cardiac muscle stiffness is present, although systolic emptying of the ventricle remains normal. Restrictive cardiomyopathy is the rarest form of cardiomyopathy. It may be caused by infiltrative diseases such as amyloidosis that deposit the protein amyloid within the myocardial cells, which makes the muscle stiff. Visit the American Heart Association at www.americanheart.org for more cardiac information.

Signs and Symptoms

Manifestation of cardiomyopathy depend on the type of abnormality. Most patients show varying degrees of signs and symptoms of heart failure (Table 17-5). With dilated cardiomyopathy, left ventricular and then right-sided heart failure with a poor prognosis is seen. Dyspnea on exertion, orthopnea, fatigue, and sometimes atrial fibrillation occur. In hypertrophic cardiomyopathy, exertional dyspnea related to the obstruction of cardiac output is the most common symptom. Atypical chest pain occurs at rest and is not relieved with nitrates. With restrictive cardiomyopathy, exertional dyspnea occurs because of the heart's inability to increase filling when needed during exertion. Syncope, angina, and palpitations are common manifestations related to reduced cardiac output.

Diagnostic Tests

Cardiomegaly is seen on a chest x-ray examination. Echocardiography shows muscle thickness and chamber size

cardiomegaly: kardia—heart + mega—large

Figure 17-5 Comparison of the normal heart structure with each type of the cardiomyopic heart structure.

TABLE 17-5 CARDIOMYOPATHY SUMMARY

<i>Signs and symptoms</i>	Angina Exertional dyspnea Fatigue Syncope
<i>Diagnostic tests</i>	Cardiac catheterization Echocardiography
<i>Medical treatment</i>	Anticoagulants Antidysrhythmics For dilated cardiomyopathy: vasodilators, cardiac glycosides, cardiomyoplasty, heart transplant For hypertrophic cardiomyopathy: beta blockers, calcium channel blockers, myectomy For restrictive cardiomyopathy: vasodilators, heart transplant
<i>Complications</i>	Heart failure
<i>Nursing diagnoses</i>	Decreased cardiac output related to impaired myocardial function Activity intolerance related to cardiac insufficiency Anxiety related to disease process

to differentiate between the types of cardiomyopathy. Changes related to enlarged chamber size, tachycardia, and dysrhythmias can be seen on the ECG. Cardiac catheterization with angiocardiology may also be useful.

Medical Treatment

Treatment is palliative and aimed at managing heart failure and the underlying cause if known. (See Chapter 21.) In dilated or restrictive cardiomyopathy, vasodilators may be given to reduce the heart's workload and digoxin may be given to increase cardiac output. Anticoagulants are given to prevent emboli formation in patients with atrial fibrillation. Antidysrhythmics or cardioversion are used for dysrhythmias.

For hypertrophic cardiomyopathy, beta blockers or calcium channel blockers are used. In obstructive hypertrophic cardiomyopathy, digoxin and vasodilators are not given because they can increase the obstruction. Exercise is often restricted to prevent sudden death.

If medical management is not successful, surgery is considered. (See Chapter 22.) For hypertrophied muscle, surgery to remove part of the ventricular septum (**myectomy**) is done to allow greater outflow of blood. Septal ablation that uses alcohol to reduce heart wall size is being studied. Cardiomyoplasty is used for dilated cardiomyopathy when heart transplant is not an option. (See Fig. 21–6.) The heart's contraction strength is aided by the patient's latissimus dorsi muscle, which has been wrapped around the heart and contracts with each heartbeat. For severe heart failure, primarily in those with dilated cardiomyopathy and sometimes those with restrictive cardiomyopathy, a heart transplant may be the only hope for survival. A ventricular

assist device may be used until a donor is found. Many patients die while waiting for a donated heart because donated organs are limited.

Nursing Management

A patient history is obtained that includes signs and symptoms and assessment of family support systems because of the chronic nature of the disease. A physical assessment is done, noting vital signs and any signs or symptoms of heart failure.

Nursing care focuses on maintaining normal cardiac function, increasing activity tolerance, relieving anxiety, and educating the patient about the disease and its treatment. Patients with cardiomyopathy can be very ill. Careful monitoring is done to detect complications, such as heart failure, emboli, or dysrhythmias. The physician is immediately notified of problems. Home health care is often used for these patients to maintain their functional ability and reduce hospitalizations.

Maintenance of normal cardiac function includes monitoring vital signs and symptoms of heart failure. Increasing activity tolerance includes planning rest periods, scheduling activities in small amounts, avoiding tiring activities, and providing small meals that require less energy to digest than large meals. Patients are taught to avoid alcohol because it decreases cardiac function.

Reducing anxiety is important and can be accomplished by providing explanations for procedures, as well as educating the patient about the disease and its treatment. This may allow patients to feel in control of their lives by being able to make knowledgeable decisions about their health care. Methods to incorporate necessary lifestyle changes such as avoiding fatigue and scheduling rest periods can be helpful. Emotional support is greatly needed by these patients and their families because of the chronic nature of this disease.

Patient and Significant Other Education

Patients need to be taught the importance of medication compliance to prevent heart failure. The patient and family should have emergency telephone numbers readily available. Families should learn cardiopulmonary resuscitation (CPR). In terminal stages of the disease, the patient and family should be informed about the availability of hospice care and be emotionally supported during the grieving process.

▶ VENOUS DISORDERS

Thrombophlebitis

Thrombophlebitis is the formation of a clot and inflammation within a vein. The clot usually forms first and then inflammation occurs. Thrombophlebitis is the most common disorder of veins, with the legs being most often affected. Any superficial or deep vein can be involved. Deep vein thrombosis (DVT) is the most serious form of thrombophlebitis because pulmonary emboli can result if the thrombus detaches. (See Chapter 28.)

Pathophysiology

A venous thrombus is made up of platelets, red blood cells, white blood cells, and fibrin. Platelets attach to a vein wall and then a tail forms as more blood cells and fibrin collect. As the tail grows, it drifts in the blood flowing past it. The turbulence of the blood flow can cause parts of the drifting thrombus to break off and become emboli that travel to the lungs.

Etiology

Three factors are involved in the formation of a thrombus: stasis of blood flow, damage to the lining of the vein wall, and increased blood coagulation (Table 17–6). Venous stasis occurs when blood flow is reduced, veins are dilated, muscle contractions are decreased, or vein valves are faulty. When the wall of a vein is damaged, it provides a site for a thrombus to form. Intravenous therapy and venipuncture cause trauma to the vein, and IV catheters in place longer than 48 to 72 hours increase the risk of inflammation and thrombus. Increased coagulation of the blood promotes thrombus formation. Patients on oral anticoagulants that are abruptly stopped experience increased clotting of the blood. Smoking, oral contraceptive use, and estrogen therapy also increase blood coagulation. Hematological disorders can also lead to altered blood coagulation and increased risk of thrombus formation.

Prevention

Identification of risk factors and patient education is important to allow the use of preventive interventions for thrombosis. Because the elderly are at increased risk for thrombus formation, a family member should be instructed along with the elderly person in techniques that may be difficult for the elderly person to perform. Dehydration, which is common in the elderly population, should be avoided to reduce thrombus risk.

thrombophlebitis: thromb—lump (clot) + phleb—vein + itis—
inflammation

IMMOBILITY. People with sedentary jobs that require long periods of sitting, standing, or traveling long distances should change positions, perform knee and ankle flexion exercises, or walk at regular intervals to prevent stasis of blood. Patients on bedrest should have legs elevated above the level of the heart if possible to prevent pooling of blood. Postoperatively or in times of bedrest, active or passive range-of-motion exercises should be done to increase blood flow. Postoperatively, early ambulation is a major preventative technique for thrombosis. Patients' pain should be controlled to facilitate their ability to participate in early ambulation. Deep breathing aids in improving blood flow in the large thoracic veins. Smoking should be avoided because nicotine causes vasoconstriction.

PROPHYLACTIC ANTIEMBOLOGISM DEVICES. Patients with peripheral vascular disease, those on bedrest, and those who have had surgery or trauma may use antiembolism devices to improve blood flow. Knee- or thigh-length elastic stockings apply pressure to the leg. They must be applied correctly to avoid a tourniquet effect. Older patients with decreased manual dexterity may need assistance. The stockings are removed for 20 minutes twice a day and the skin is inspected for irritation. Intermittent pneumatic compression (IPC) devices fill plastic inflatable stockings intermittently with air to move venous blood in the legs by simulating contraction of the leg muscles. (See Figure 15–15.) They may be used in combination with elastic stockings. Research that compares the various preventive measures for DVT and rates of DVT in surgical patients has shown that the lowest incidence of DVT occurs with elastic stockings and IPC devices used together.

PROPHYLACTIC MEDICATION. Low-molecular-weight heparin (LMWH) is given postoperatively to prevent thrombosis. Enoxaparin (Lovenox), given subcutaneously, is an example of a LMWH. Subcutaneous heparin may also be used postoperatively to prevent thrombosis. A common prophylactic dose of heparin is 5000 IU subcutaneously every 8 to 12 hours. Partial thromboplastin time (PTT) is not usually monitored with prophylactic doses of LMWH or heparin.

TABLE 17-6 PREDISPOSING CONDITIONS FOR THROMBOPHLEBITIS

Condition	Type	Examples
Venous stasis	Reduction of blood flow	Shock, heart failure, myocardial infarction, atrial fibrillation
	Dilated veins	Vasodilators
	Decreased muscle contractions	Immobility, sitting for long periods as in traveling, fractured hip, paralysis, anesthesia, surgery, obesity, advanced age
Venous wall injury	Faulty valves	Varicose veins, venous insufficiency
		Venipuncture, venous cannulation at same site for > 48 hours, venous catheterization, surgery, trauma, burns, fractures, dislocation, IV medications (potassium, chemotherapy drugs, antibiotics, IV hypertonic solutions), contrast agents, diabetes, cerebrovascular disease
Increased coagulation of blood		Anemia, malignancy, antithrombin III deficiency, oral contraceptives, estrogen therapy, smoking, discontinuance of anticoagulant therapy, dehydration, malnutrition, polycythemia, leukocytosis, thrombocytosis, sepsis, pregnancy

Oral anticoagulants such as warfarin (Coumadin) can be used in the high-risk patient to decrease thrombosis. Today the preferred indicator of warfarin effectiveness is the **international normalized ratio (INR)** value. The INR is preferred because it uses a standardized testing reagent. This means that it can be used around the world with no variation in results as occurs with prothrombin time (PT). Prothrombin time was previously the most commonly used test; however, PT control values can vary from laboratory to laboratory. Therefore a standardized test was developed, so that warfarin dosage variations would not occur as a result of differing laboratory control values. The INR value is reported along with the prothrombin time. These values correspond in meaning (i.e., normal, subtherapeutic, therapeutic, toxic). Some practitioners still order PT, so a discussion of how to interpret the PT is presented for understanding. For more information on these medications, visit www.fda.gov/cder/drug/default.htm.

LEARNING TIPS

Before administering anticoagulants, laboratory values must be assessed to ensure patient safety. INR normal and desired therapeutic values for the patient’s disorder are provided on the laboratory report. These INR values do not require calculation of a therapeutic range because the values are given on the report. Compare the patient’s INR value with the desired INR value to determine if it is safe to give the warfarin.

Understanding that INR is the preferred test for warfarin effectiveness, you may still want to know how to calculate a therapeutic range for prothrombin time. Prothrombin times are measured in seconds. The normal value range gives the seconds required for a fibrin clot to form during the test. If a patient is on warfarin, the purpose is to increase the time (seconds) it takes the blood to clot. It is therefore expected that the prothrombin time will be elevated by warfarin therapy.

Because a therapy, warfarin, is being given, a prothrombin time range that safely considers the expected effects of the warfarin is needed. This is called the therapeutic range (i.e., a high and a low value). Warfarin’s therapeutic range is 1.5 to 2 times the normal prothrombin time range. To monitor the patient’s therapeutic prothrombin time, compare the patient’s result with the therapeutic range that you calculate. For example:

Patient’s value on warfarin: 16 seconds
 Normal prothrombin time range: 9–12 seconds
 To calculate therapeutic range,
 multiply $1.5 \times 9 \text{ seconds}$ $2 \times 12 \text{ seconds}$
 The therapeutic range is: 13.5 seconds to 24 seconds

Compare the patient’s value of 16 seconds with the therapeutic range of 13.5 to 24 seconds to determine that the patient is safely within the therapeutic range.

INTRAVENOUS THERAPY. Monitoring of venous IV sites should be performed according to institutional policy time frames to detect signs of thrombophlebitis. Venous cannula sites should be changed regularly according to institutional

guidelines (e.g., every 48 to 72 hours) to prevent thrombus formation.

Signs and Symptoms

Up to 50 percent of patients have no symptoms with thrombophlebitis in the legs. For others the symptoms vary according to the size and location of the thrombus (Table 17–7). If adequate collateral circulation is present near the involved area, symptoms may be reduced. For some patients a pulmonary embolus is the only evidence of a DVT.

SUPERFICIAL VEINS. Thrombophlebitis in a superficial vein may produce redness, warmth, swelling, and tenderness in the area around the site of the thrombus. The vein feels like a firm cord, which is referred to as induration. The saphenous vein is the most commonly affected vein in the leg. Varicosity of the vein is usually the cause. In the arm, IV therapy is the most common cause.

DEEP VEINS. In a deep vein thrombus of the leg, swelling, edema, pain, warmth, venous distention, and tenderness with palpation of the calf may be present in the affected leg. Obstruction of blood flow from the leg causes edema and varies with the location of the thrombus. An elevated temperature may also be present. Pain in the calf with sharp dorsiflexion of the foot, a classic indication known as a positive Homans’ sign, is present in less than 40 percent of those with thrombophlebitis and is not specific to DVT. Once a DVT is positively diagnosed, it is important to avoid performing Homans’ sign because it may cause the clot to become dislodged. Cyanosis and edema may occur if the large veins such as the vena cava are involved.

TABLE 17-7 THROMBOPHLEBITIS SUMMARY	
Signs and symptoms	Superficial veins: redness, warmth, swelling, and tenderness Deep veins: swelling, edema, pain, warmth, venous distention, and tenderness
Diagnostic tests	D-dimer and coagulation tests Duplex ultrasound Impedance plethysmography MRI Venography
Medical treatment	Superficial veins: warm, moist heat; analgesics; NSAIDs; compression stockings Deep veins: LMWH; heparin; warfarin; bedrest with extremity elevation above the level of the heart for 5–7 days; warm, moist heat; compression stocking therapy; thrombolytic therapy; thrombectomy; vena cava filter
Complications	Pulmonary embolism Chronic venous insufficiency
Nursing Diagnoses	Acute pain related to inflammation of vein Impaired skin integrity related to venous stasis Anxiety related to uncertain prognosis of disease

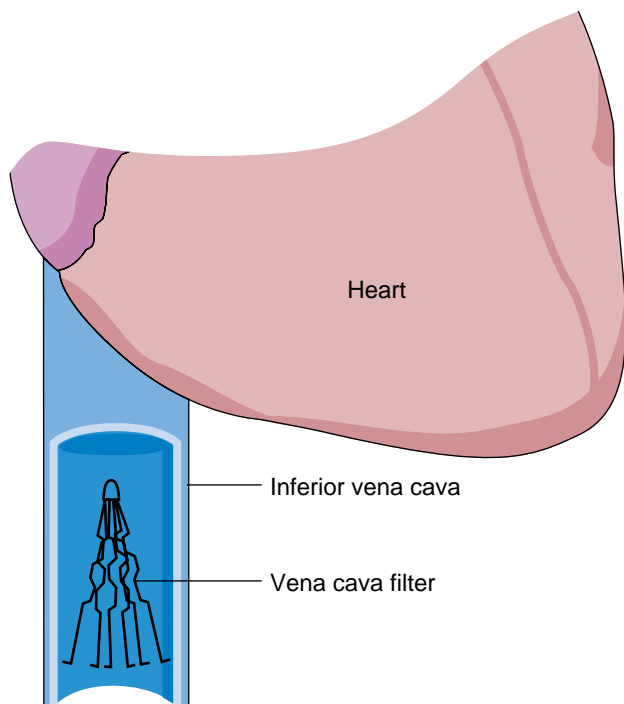

Figure 17-7 Vena cava filter placed in the inferior vena cava to prevent emboli from reaching the lungs.

Complications

The most serious complication of deep vein thrombophlebitis is pulmonary embolism, which is a life-threatening emergency. (See Chapter 28.) Another complication, chronic venous insufficiency, results from damage to the valves in the vein and causes venous stasis. Signs and symptoms from venous insufficiency that may appear years after a thrombus include edema, pain, brownish discoloration and ulceration of the medial ankle, venous distention, and dependent cyanosis of the leg. This condition can be difficult to treat.

Medical and Surgical Treatment

Diagnostic tests are done to guide treatment. (See Table 17-7.) The goals of treatment are to relieve pain and prevent pulmonary emboli, thrombus enlargement, and further thrombus development. Superficial thrombophlebitis is treated with warm, moist heat; analgesics; NSAIDs; and compression stockings.

Patients with a proximal DVT may be treated at home if they do not have pulmonary embolism, cardiovascular or pulmonary disease, obesity, or renal failure and are able to comply with follow-up care. A LMWH (e.g., enoxaparin, dalteparin, or ardeparin) is given subcutaneously daily or twice a day while oral warfarin is started. Both are taken until the INR is within therapeutic range (about 5 days); the LMWH is then stopped.

For some DVTs a hospital stay may be required. Treatment includes bedrest with leg elevation above heart level for 5 to 7 days; warm, moist heat; elastic stocking (initially on unaffected leg only until acute symptoms are gone on affected leg); and anticoagulants. A continuous heparin IV infusion is usually started for up to 10 days to prevent fur-

ther enlargement of the thrombus and development of new thrombi; it has little effect on the existing clot, which the body dissolves over time. An oral anticoagulant, warfarin, is begun 4 to 5 days before the heparin is stopped. When the therapeutic INR goal is reached, the heparin is stopped. Warfarin is continued for several months. In some cases of massive DVT, thrombolytic therapy (alteplase, tissue plasminogen activator [TPA], streptokinase, urokinase) may be used to dissolve the clot, but there is a high risk of bleeding with these drugs.

Surgical treatment is used to prevent pulmonary emboli or chronic venous insufficiency when anticoagulant therapy cannot be used or the risk of pulmonary emboli is great. Venous thrombectomy removes the clot through a venous incision. In some cases a vena cava filter is placed into the inferior vena cava through the femoral or right internal jugular vein (Fig. 17-7). Once in place, it is opened and attaches to the vein wall. The filter traps clots traveling toward the lungs without hindering blood flow.

Nursing Management

A patient history is obtained that includes recent IV therapy or use of contrast dyes, surgery, extremity trauma, childbirth, bedrest, recent long trip, cardiac disease, recent infections, and current medications. A physical assessment is done noting pain, fever, tenderness, positive Homans' sign, redness, warmth, swelling, edema, and a firm, cordlike vein in the affected extremity. Daily measurements are taken of bilateral thighs and calves and recorded to monitor swelling. Coagulation tests are monitored.

See Nursing Care Plan Box 17-2 for specific nursing interventions. Pain is relieved by giving analgesics and NSAIDs as ordered and applying warm, moist soaks. Legs are elevated to reduce edema. (See Home Health Hints.)

HOME HEALTH HINTS

- Home health nurses can assist patients to develop energy-conserving techniques by being observant of their lifestyle. For instance, notice the room and chair that they spend most of the day in. Television trays and baskets can be used to hold items they may need or want, such as water pitcher and glass, TV remote, reading material, paper and pen, mail, medicines, telephone and phone book, snacks, washcloth, or tissues. Answering the door should be done by the caregiver. When the patient is alone, a note can be placed on the door with instructions; however, the instructions should not convey that the patient is alone.
- Other techniques to conserve energy are putting a carrying pouch on the front bar of a walker to carry items such as a portable phone or tissues and, if the house has stairs, putting a chair at the top and bottom of the stairs so the patient can rest.
- When a patient with venous circulation problems is sitting in a recliner with the leg rest up, the nurse should note whether pressure is being applied on the popliteal area or calf muscle. The angle of the recliner and the patient's height affect the position of the pressure. A small, flat pillow is placed underneath the knees and lower legs to open the angle and relieve the pressure.

BOX 17-2 NURSING CARE PLAN FOR THE PATIENT WITH THROMBOPHLEBITIS**▶ Acute pain related to inflammation of vein****PATIENT OUTCOME**

Reports satisfactory pain relief.

EVALUATION OF OUTCOME

Does patient report satisfactory pain relief?

INTERVENTIONS

Assess pain using rating scale such as 0–10.
Provide analgesics and NSAIDs as ordered.
Apply warm, moist soaks.

Maintain bedrest with leg elevation above heart level.

RATIONALE

Self-report is the most reliable indicator of pain.
Pain is reduced when inflammation is decreased.
Heat relieves pain and vasodilates, which increases circulation to reduce swelling. Moist heat penetrates more deeply.
Elevation decreases swelling, which reduces pain.

EVALUATION

Does patient report pain using scale?

Is patient's rating of pain lower after medication?

Does patient report increased comfort with warm, moist soaks? Is swelling reduced?

Is swelling reduced?

▶ Impaired skin integrity related to venous stasis**PATIENT OUTCOME**

Skin remains intact without edema.

EVALUATION OF OUTCOME

Does patient's skin remain intact? Is edema present?

INTERVENTIONS

Assess skin for edema, skin color changes, and ulcers. Measure extremities.
Elevate legs.
Fit and apply elastic stockings after edema reduced as ordered.

Teach patient to avoid crossing legs or wearing constricting clothes.

RATIONALE

Assessment will detect signs of skin integrity impairment and extremity swelling.
Elevation decreases swelling.
Elastic stockings are fitted after edema is reduced to avoid constriction. They increase venous blood flow to reduce swelling.
Crossing legs and constrictive clothes impair venous return.

EVALUATION

Are skin changes seen? Do daily measurements show a change in swelling?

Is swelling reduced?

Is swelling reduced?

Does patient state understanding of teaching?

Elastic stockings are fitted and applied when edema is reduced. The presence of dyspnea, tachycardia, tachypnea, blood-tinged sputum, chest pain, or changes in level of consciousness are immediately reported to the physician.

Teaching the patient about the disease and treatment is important to reduce anxiety about complications and to enhance compliance with treatment to prevent complications.

REVIEW QUESTIONS

- The nurse evaluates the patient as understanding how to prevent rheumatic fever if the patient states that rheumatic fever can be prevented by treating streptococcal infections with which of the following?
 - Penicillin
 - Prednisone
 - Cortisone
 - Cyclosporine
- For patients recovering from infective endocarditis, discharge teaching to prevent recurrence should include which of the following?
 - Proper use of isolation techniques
 - Keeping vaccinations up to date
 - Need to obtain annual flu injection
 - Need for antibiotics before invasive procedures
- The nurse is planning care for a patient with cardiomyopathy. For which of the following complications of cardiomyopathy should the nurse assess?
 - Thrombophlebitis
 - Heart failure
 - Rheumatic fever
 - Pulmonary embolism
- Which of the following signs and symptoms indicates to the nurse the presence of a deep vein thrombus in the patient's leg?
 - Calf swelling
 - Crackles
 - Jugular vein distention
 - Negative Homans' sign
- The nurse is to give warfarin (Coumadin). Which of the following laboratory tests should the nurse review before giving the medication?
 - International normalized ratio
 - Partial thromboplastin time
 - Plasma fibrinogen level
 - Thrombin clotting time

REFERENCES

Answers to CRITICAL THINKING

Mrs. Jones

- A heart murmur is heard from damaged heart valves.
- Splinter hemorrhages appear as black or red lines in the nails.
- Petechiae indicate that tiny pieces of a lesion on the endocardium or valves have broken off and become microemboli.
- Subjective assessment findings might include patient statements such as, "I have pain in my joints and am chilled" or "I am fatigued and have no appetite."
Objective findings are as follows: temperature 100° F (37° C), red splinter hemorrhages in left index finger nailbed, many petechiae on chest.
- Expected medications include IV antibiotics.
- Removing blankets to decrease fever results in chills and shivering, which further increases body temperature from the heat generated by muscular activity during shivering. Therefore Mrs. Jones should be kept covered to prevent chills.
- For left-sided heart failure, crackles, wheezes, cough, or dyspnea might be seen. In right-sided heart failure, peripheral edema or jugular vein distention could be present.
- Prophylactic antibiotics are needed to prevent another episode of infective endocarditis, which can result from bacteria entering the circulation during the invasive procedure, attaching to areas of the endocardium damaged from the current infection, and growing.

QUESTIONS TO GUIDE YOUR READING

1. What are the etiologies, signs, and symptoms of coronary artery disease, angina pectoris, and myocardial infarction?
2. What are the current medical treatments for coronary artery disease, angina pectoris, and myocardial infarction?
3. What data should you collect when caring for patients with coronary artery disease, angina pectoris, and myocardial infarction?
4. What nursing care will you provide for patients with coronary artery disease or myocardial infarction?
5. What should you include in the education plan for the patient with coronary artery disease?
6. How will you know if your nursing interventions have been effective?
7. What are the etiologies, signs, and symptoms for each of the peripheral vascular disorders?
8. What is the current medical treatment for each peripheral vascular disorder?
9. What nursing care will you provide for patients with each peripheral vascular disorder?

Cardiovascular disorders are the leading cause of disability and death in the United States. Diseases of the heart and peripheral vessels can affect quality of life and alter the ability of the individual to perform tasks of everyday living. Long-term disability can place a burden on families and businesses and can create high insurance costs. Many factors leading to cardiovascular diseases can be controlled or modified. Education is important in preventing and treating occlusive cardiovascular diseases.

▶ ARTERIOSCLEROSIS AND ATHEROSCLEROSIS

Arteriosclerosis is a term used to describe conditions that affect arteries and may lead to occlusive cardiovascular disease. The lining of the artery and arteriole walls become thickened and hardened and lose elasticity. Arteriosclerosis is referred to as hardening of the arteries. Atherosclerosis, a type of **arteriosclerosis**, is the formation of **plaque** within the arterial wall. Arteriosclerosis and **atherosclerosis** are conditions that develop over a long period (beginning in early childhood). Arteriosclerosis and atherosclerosis usually occur together.

Pathophysiology

Atherosclerosis affects the inner lining of the artery. The first step in the development of atherosclerosis is injury to the endothelial cells that line the walls of the arteries. This injury causes inflammation and immune reactions. Lipids, platelets, and other clotting factors accumulate. Scar tissue replaces some of the arterial wall. An early indication of injury is a fatty streak on the lining of the artery. This buildup of fatty deposits is known as plaque. Plaque has irregular, jagged edges that allow blood cells and other material to adhere to the wall of the artery. Over time this buildup becomes calcified and hardened (arteriosclerotic), causing turbulence that damages cells and increases the buildup within the vessel. As the vessel becomes stenosed (narrowed), partial or total occlusion of the artery may occur, resulting in reduced blood flow. The area distal to the occlusion may become ischemic as a result.

Causes

There are many theories as to causes of arteriosclerosis and atherosclerosis:

- Genetics related to predisposition for **hyperlipidemia** (increase in blood lipids)
- Diabetes mellitus related to hyperglycemia
- Hypertension
- Smoking
- Obesity
- Sedentary lifestyle
- Increased serum homocysteine levels (an amino acid)
- Increased serum iron levels
- Infection

hyperlipidemia: hyper—above + lipos—fat + emia—blood

Signs and Symptoms

Arteriosclerosis or atherosclerosis are not usually symptomatic until later stages of development. If symptoms do occur, they may include chest pain or dizziness caused by decreased blood supply and oxygen to the heart. Reduced blood flow in the extremities is reflected by pallor in the nailbeds, a reddish-purple color in the lower extremities, thickened nails, dry skin, or loss of hair on the extremities. Peripheral pulses may be diminished or absent. Skin temperature in the extremities is cooler, and there is prolonged capillary refill (greater than 3 seconds).

Diagnostic Tests

Cholesterol and triglycerides are often elevated in patients with atherosclerosis. (See Table 15-3.) Total cholesterol levels above 200 mg/dL increase risk of myocardial infarction. Low-density lipoproteins (LDL) increase **coronary artery disease** (CAD) risks, but **high-density lipoproteins** (HDL) are protective against CAD. Blood glucose levels should also be checked because elevated levels may increase the risk for atherosclerosis. Radiological studies of the arteries can be performed to show narrowed or occluded vessels. (See Chapter 15.)

Treatment

A healthy lifestyle, cholesterol screening, frequent check-ups, and medications are helpful in controlling arteriosclerosis and atherosclerosis.

Diet

Saturated fats are the primary cause of increased cholesterol levels, which promote arteriosclerosis and atherosclerosis. Because the formation of plaque within arteries is primarily caused by fatty deposits, an adherence to a low-fat diet is recommended (Nutrition Notes Box 18–1). The American Heart Association has complete guidelines and diets for decreasing fat and cholesterol intake. For more information, visit <http://americanheart.org>.

Smoking

Smoking contributes to a loss of high-density lipoprotein (HDL). These proteins are considered the best cholesterol to have in the body to decrease the risk of cardiovascular disorders. The rate of progressive damage to blood vessels is increased with smoking. Smoking also causes vasoconstriction, which leads to **angina pectoris** and cardiac dysrhythmias. Education on the risks of smoking and exposure to secondhand smoke should be presented to patients. The American Cancer Society has many programs to help patients quit smoking. For more smoking cessation information, visit www.cancer.org.

Exercise

Increased activity raises HDL levels (the desirable cholesterol). Over time, exercise also leads to the development of **collateral circulation**, which allows blood to flow around

angina pectoris: angina—to choke + pectora—chest

BOX 18-1

Nutrition Notes

Controlling Blood Cholesterol with Diet

Two-thirds of the body's cholesterol is produced by the liver and intestines. The ability to reduce the amount of cholesterol manufactured in response to an increased dietary intake of it is believed to be genetically determined. Although only foods of animal origin contain cholesterol, some vegetable products contain trans fatty acids, potent risk factors for cardiovascular disease.

The National Cholesterol Education Program introduced a new diet called the therapeutic lifestyle changes (TLC) diet based on the following:

Monounsaturated fat	Up to 20% of total calories
Polyunsaturated fat	Up to 10% of total calories
Saturated fat	Less than 7% of total calories
Total fat	25 to 35% of total calories
Carbohydrate	50 to 80% of total calories
Fiber	20 to 30 grams per day
Plant stanols/sterols*	2 grams per day

*These compounds in plants, which structurally resemble cholesterol but are not absorbed in the human body to any extent, actually inhibit the absorption of cholesterol. Plant sterols have been useful, either alone or along with low-fat diets, in reducing low-density lipoprotein cholesterol. Table spreads and salad dressings containing plant sterols are commercially available. Plant sterols are contraindicated in a rare inherited metabolic disease (40 reported cases) called sitosterolemia, in which plant sterols are absorbed at a high rate and are not removed effectively by the liver, resulting in premature atherosclerosis.

occluded sites. Before beginning an exercise program, the patient should consult a physician.

Medications

Lowering lipid levels is the major treatment for atherosclerosis (Table 18–1). When dietary control is not effective, medication is also used. It may take 4 to 6 weeks before lipid levels respond to drug therapy. If one drug does not control the lipids, another drug can be added.

▶ CORONARY ARTERY DISEASE

Coronary artery disease is a term applied to obstructed blood flow through the coronary arteries to the heart muscle. The primary cause of coronary artery disease is atherosclerosis. If blood flow reduction resulting from CAD is severe and prolonged, a **myocardial infarction** (heart attack) can occur, causing irreversible damage.

Pathophysiology and Etiology

As discussed in the sections on atherosclerosis and arteriosclerosis, an accumulation of fatty deposits and minerals in the coronary arteries, called an **atheroma** or plaque, leads to stenosis and eventually occlusion of the artery. In CAD, blood flow to the myocardium is reduced. If myocardial oxygen demands are not met, ischemia results, which can lead to chest pain. The pain associated with CAD occurs from a lack of oxygen to the myocardium as a result of the CAD and is referred to as angina pectoris.

Risk Factors

Risk factors can be broken down into two components: those that cannot be changed and those that can be changed (Table 18–2). If coronary artery disease is not prevented or treated early, it can progress to more serious cardiac disorders. These include angina, myocardial infarction, heart failure, cardiac dysrhythmias, and even sudden death. Altering risk factors may help protect the patient from developing cardiovascular disease. To take a heart attack risk assessment, visit www.americanheartassociation.com/risk/quiz.html.

Medical Management

Prevention is the goal for patients with CAD. Educating patients on dietary changes, cessation of smoking, controlling hypertension, and diabetes can decrease their risk of CAD.

TABLE 18-1 LIPID-LOWERING DRUGS

Class	Drugs	Side Effects	Nursing Implications
Statins First-line drugs to reduce low-density lipoprotein by reducing cholesterol synthesis	Atorvastatin (Lipitor) Lovastatin (Mevacor) Pravastatin (Pravachol) Simvastatin (Zocor)	Impaired liver function Rhabdomyolysis (lethal breakdown of skeletal muscle)	<ul style="list-style-type: none"> • Tell patient to take in evening when cholesterol synthesis is highest. • Teach patient to report muscle pain. • Monitor liver function studies.
Fibrates Reduce triglycerides	Fenofibrate (Tricor) Gemfibrozil (Lopid)	Heartburn, gallstones	<ul style="list-style-type: none"> • Tell patient to take 30 minutes before morning and evening meals.
Bile acid sequestrants Lower cholesterol by binding bile acids, so stored cholesterol is used to make more bile acids	Colestipol (Colestid) Colesevelam HCl (WelChol, Sankyo) Cholestyramine (Questran)	Headache, heartburn, constipation, gas May interfere with absorption of fat-soluble vitamins A, D, E, K	<ul style="list-style-type: none"> • Fruits and vegetables high in fiber should be added to diet to reduce constipation and other GI effects noted with bile acid sequestrants.
Niacin Prevents conversion of fats into very-low-density lipoproteins. First antilipid agent used.	Niacin (Nicotinic acid)	Gastritis Gout Flushing	<ul style="list-style-type: none"> • Tell patient to take with liquids and meals and to take other drugs 1 hour before or 4 hours after. • Tell patient to take with meals or milk to avoid GI upset. Used with diet, exercise, and smoking cessation therapy to lower lipids.

GI = gastrointestinal.

TABLE 18-2 RISK FACTORS FOR CORONARY ARTERY DISEASE

Risk Factors That Cannot Be Changed	
Heredity	CAD risk factors can run in families.
Ethnicity	African-Americans have a higher incidence of atherosclerosis.
Gender	Men have more risk factors and higher incidence of CAD.
Age	Men have increased incidence after age 50. Women have increased incidence after menopause.
Risk Factors That Can Be Changed or Controlled	
Smoking	Causes vasoconstriction and increases myocardial oxygen demand. Decreases HDL.
Hypertension	Vasoconstriction increases myocardial oxygen demand.
Elevated serum cholesterol	Level above 240 mg/dL increases the risk of developing CAD.
Diabetes	Increases the risk of hypertension, obesity, and elevated blood lipids
Obesity	Increases heart workload and risk of hypertension, diabetes, glucose intolerance, hyperlipidemia.
Stress	Increases heart workload and risk for hypertension.
Elevated serum homocysteine	Increases CAD risk. Foods that contain folic acid (fruits, green leafy vegetables) reduce homocysteine levels.
Sedentary lifestyle	Increases obesity, hypertension, hyperlipidemia.

Dietary changes are made to reduce saturated fats to less than 10 percent of daily food intake. Cholesterol intake on the step 1 diet is less than 300 mg per day and less than 200 mg per day on the step 2 diet. Medication may be given to reduce cholesterol levels. Anticoagulants are used to prevent the formation of a thrombus.

Surgical Management
Percutaneous Transluminal Coronary Angioplasty

Percutaneous transluminal coronary angioplasty (PTCA) is a minimally invasive procedure that helps reduce symptoms of CAD (Fig. 18-1). A catheter is inserted via the femoral or brachial artery and is advanced into the heart. Once the blocked coronary artery is entered, the balloon on the catheter is inflated. This procedure compresses the plaque against the wall of the artery, thus restoring the opening of the artery. The symptoms of CAD are usually reduced, but the underlying progression of atherosclerosis continues. Re-occlusion of the artery often occurs within a few months. Over time, PTCA may need to be repeated.

Coronary Atherectomy

Coronary atherectomy is used to cut and remove plaque from atherosclerotic coronary arteries. The catheter has a central rotating blade that shaves off the plaque and contains it for removal and pathological analysis. Calcium

Figure 18-1 Percutaneous transluminal coronary angioplasty.

channel blockers are given before the procedure to prevent vasospasms from the vibrating cutter. To prevent clot formation, an antiplatelet agent is given after the procedure.

Coronary Artery Stents

Coronary artery stents are used to prevent closure of a coronary artery from an atherosclerotic lesion. Stents are placed in a procedure similar to PTCA. A stent provides support to a coronary artery wall at the area of stenosis to keep blood flowing through the artery. Different types of materials, such as bioabsorbable materials or stainless-steel mesh, and designs, such as self-expanding or balloon expandable, are used to make stents (Fig. 18-2). Complications associated

Figure 18-2 Insertion of a coronary artery stent: (A) A balloon catheter with a collapsed stent is advanced to the location of a coronary artery lesion. (B) The balloon is inflated, which expands the stent and compresses the lesion to increase the artery opening. (C) The balloon is then deflated and removed, leaving the expanded stent in place to prevent the artery from closing.

with stent placement include **thrombosis**, bleeding from anticoagulation, stent occlusion, or coronary artery dissection. An antiplatelet (ticlopidine [Ticlid]) and anticoagulant (warfarin [Coumadin]) are prescribed after the procedure. The antiplatelet agent is taken long term, but the anticoagulant is often only needed up to 6 weeks after the procedure.

Coronary Artery Bypass Graft

Coronary artery bypass graft (CABG) surgery involves bypassing one or more blocked coronary arteries. Patients who have severe CAD or have had myocardial infarctions may be candidates for a CABG. Patients usually have a cardiac catheterization to identify blocked coronary arteries and determine the need for surgery. (See Chapter 22.)

Transmyocardial Laser Revascularization

Transmyocardial laser revascularization is a newer treatment option for patients unable to have angioplasty or coronary artery bypass surgery. Channels are made through the myocardium into the ventricles in areas of ischemia with a fiberoptic catheter. However, it is not known why this procedure decreases symptoms of ischemia and improves quality of life.

Nursing Process

Caring for a patient with CAD includes monitoring blood pressure and heart rate and documenting abnormal values or reports of chest pain and any symptoms that may point to the presence of complications from CAD. The care of the patient is directed at teaching and working with the patient to change or modify risk factors. Teaching the patient how to control risk factors and manage symptoms is the major focus of nursing care for the patient with CAD.

► **ACUTE CORONARY SYNDROMES**

Acute coronary syndromes are a group of conditions that are caused by a lack of oxygen to the heart muscle. These conditions include unstable angina, non-Q wave myocardial infarction, and ST segment elevation myocardial infarction. Patients with acute coronary syndromes are at high risk for myocardial infarction and death.

► **ANGINA PECTORIS**

Pathophysiology

Angina pectoris (chest pain) is a symptom of ischemia. When an increased workload is placed on the heart, as in exercise or strenuous activity, there is an increased demand for oxygen. Normally, when the heart needs more oxygen, the coronary arteries dilate to carry more blood. However, with CAD, the narrowed vessels are unable to dilate and supply the heart with this extra blood and oxygen. This inability to supply more blood and oxygen causes myocardial ischemia. Chest pain results from the ischemia but usually lasts only for a few minutes, especially if activity is stopped. If adequate blood supply to the myocardium is restored with rest, no myocardial damage usually occurs.

LEARNING TIPS

Angina pectoris is not a disease. It is a symptom of ischemia that results from a lack of oxygen and blood flow to the heart muscle.

Signs and Symptoms

Anginal pain manifests itself in several ways. Patients often describe the pain as a heaviness, tightness, or viselike or crushing pain in the center of the chest. The pain can radiate down one or both arms, with the left arm being more common, into the shoulder, neck, jaw, or back. Patients may also describe a heaviness in their arms or a feeling of impending doom. During the episode of pain, the patient may be pale, diaphoretic, or dyspneic. The pain is usually brought on by exertion and subsides with rest. It can be relieved with a vasodilator medication such as nitroglycerin (NTG). Episodes of chest pain may increase in frequency and severity over time. If patients do not heed this warning to stop their activity and rest, they may be at risk for a myocardial infarction or sudden death.

Types

Stable Angina

Stable angina occurs when the atherosclerotic arteries cannot dilate to increase blood flow to the myocardium. When increased physical activity and stress place an added demand on the heart, the patient develops midsternal chest pain. The pain of stable angina usually subsides when the activity is stopped or with the use of a vasodilating drug.

Variant Angina (Prinzmetal's Angina)

The pain of variant angina is the same as in stable angina, except it has a longer duration and can occur at rest. The pattern of occurrence is often cyclical, with pain presenting about the same time each day. This type of angina is often caused by coronary artery spasms and usually does not cause damage to the myocardium.

Unstable Angina

Unstable angina occurs in patients with worsening CAD and is noted by its changing pattern. Rest does not decrease the chest pain of unstable angina. This pain may even occur when the patient is at rest. The episodes of chest pain with unstable angina increase in frequency and severity, placing the patient at risk for myocardial damage or sudden death.

Diagnostic Tests

Diagnostic tests are discussed in Chapter 15.

Electrocardiogram

An electrocardiogram (ECG) may help with the diagnosis of angina pectoris, although it remains normal in 20 to 30 percent of those with angina. ECGs obtained during an

episode of chest pain may identify which coronary artery is involved. The ECG changes that may be seen in patients with angina may include a depressed T wave, which indicates myocardial ischemia, or an elevated ST segment, indicating myocardial injury.

Exercise Electrocardiogram

In an exercise ECG (stress test), the patient gets on a treadmill or stationary bicycle. Exercise activity is increased until the patient has reached 85 percent of his or her maximum heart rate. If the patient experiences chest pain or if noticeable ECG or vital sign changes occur during the test, it may be an indication of ischemia.

Another type of stress test, the dipyridamole (Persantine) thallium stress test, uses an intravenous medication in place of exercise. This test is used for patients who cannot exercise. Dipyridamole dilates coronary arteries and produces the effect of exercise. The collateral vessels also dilate, taking blood away from the coronary arteries, which may cause ischemia if CAD is present. Radiological imaging is then done to determine the area of the heart that is ischemic.

Radioisotope Imaging

In radioisotope imaging, the injection of a radioisotope is performed during a stress test. When the maximum heart rate is reached or ECG changes or anginal symptoms, occur the test is stopped. The patient is taken to a room with special imaging equipment to identify myocardial areas that are poorly perfused (ischemic).

Coronary Angiography

Coronary angiography uses an intravenous dye to view the coronary arteries. Coronary arteries that are partially or totally blocked are identified.

Treatments

Treatment for angina is directed at relieving and preventing anginal episodes that could lead to a myocardial infarction. The risk factors identified for the patient determine the course of treatment. Weight reduction; a low-fat, low-cholesterol diet; and stress reduction may help decrease the number of attacks.

Most patients with angina are placed on medication that reduces oxygen demand and increases oxygen supply to the myocardium. The three major groups of medication used for angina are vasodilators, calcium channel blockers, and beta blockers (Table 18–3).

Vasodilators

Nitroglycerin (a nitrate) is the drug of choice for acute anginal attacks. NTG can be administered sublingually, orally, transdermally, intravenously, or as a lingual spray. When administered sublingually, NTG may relieve chest pain within 1 to 2 minutes (Box 18–2).

Long-acting nitrates can be given orally, by ointment, or by transdermal patches. Nitrates all act to maintain coronary artery vasodilation. Isosorbide dinitrate (Isordil) and isosorbide mononitrate (ISMO) are examples of long-acting nitrates. A problem with long-acting nitrates is the devel-

TABLE 18–3 PHARMACOLOGICAL TREATMENT FOR ANGINA PECTORIS

Class	Drug	Route	Side Effects
Vasodilators	Nitrates/nitroglycerin (Nitrostat)	Sublingual/spray	Headaches, light-headedness, postural hypotension, tachycardia, flushing
	Isosorbide dinitrate (Isordil)	Oral	
	Isosorbide mononitrate (ISMO)	Oral	
	Nitroglycerin (Transderm Nitro, Nitro-Bid)	Topical	
Calcium channel blockers	Diltiazem (Cardizem)	Oral	Headache, peripheral edema, dysrhythmias, flushing, dizziness, atrioventricular blocks
	Nifedipine (Procardia)	Oral	
	Verapamil (Calan, Isoptin)	Oral	
Beta blockers	Propranolol (Inderal)	Oral	Dizziness, bradycardia, hypotension, nausea, confusion, fatigue, agranulocytosis, laryngospasm
	Metoprolol (Lopressor)	Oral	
	Atenolol (Tenormin)	Oral	
Nursing Implications			
Vasodilators	Monitor blood pressure and heart rate before and after giving. Caution patient to rise slowly because of orthostatic hypotension, especially with sublingual nitroglycerin. Take up to three nitroglycerin tablets at 5-minute intervals. If pain is not relieved, call a doctor or emergency medical assistance immediately. Do not remove tablets from bottle. Vasodilators become inactive when exposed to heat, air, light, and moisture.		
Calcium channel blockers	Tell patient a burning or tingling sensation may be felt under the tongue with sublingual nitroglycerin. Monitor blood pressure and heart rate before and after administering.		
Beta blockers	Hold if blood pressure is less than 90 systolic or heart rate is less than 50 and call physician. Assess blood pressure and heart rate before and after giving. Administer with food. Propranolol should not be given to patients with asthma. Do not stop abruptly.		

BOX 18-2 Key Points for Using Sublingual Nitroglycerin

- Carry NTG at all times.
- Keep NTG tightly sealed in the original container.
- Replace NTG every 6 months for maximum effect.
- Take NTG before an activity known to cause chest pain.
- Take one NTG tablet and repeat every 5 minutes up to three doses if pain is not relieved. If pain is unrelieved after three doses, call for emergency medical care or have someone else drive to the hospital.
- Tingling may be felt under the tongue when NTG is used.
- NTG may cause a headache.
- NTG may cause light-headedness; rise slowly to prevent falls.

opment of a tolerance to the drug. To prevent tolerance, the patch or ointment is usually removed at bedtime and reapplied in the morning, giving the patient an 8- to 12-hour nitrate-free period.

Calcium Channel Blockers

Calcium is required for electrical excitability of cardiac cells and contraction of the myocardium. Calcium channel blockers relax vascular smooth muscle, which leads to decreased peripheral vascular resistance (afterload) and decreased myocardial oxygen demand. These drugs dilate main coronary arteries, increasing the myocardial oxygen supply. Nifedipine (Procardia) and verapamil (Calan, Isoptin) are potent inhibitors of coronary artery spasms and are used to treat variant (Prinzmetal's) angina. Calcium channel blockers are also used to decrease systolic and diastolic blood pressures and to slow the heart rate. These drugs are commonly given in conjunction with other vasodilators and beta blockers. Because these drugs are slow acting, they are ineffective in relieving acute anginal attacks.

Beta Blockers

Beta blockers decrease the workload on the heart and block the effects of epinephrine and norepinephrine on the heart (increased heart rate and vasoconstriction), thus preventing anginal attacks. There is decreased myocardial oxygen demand secondary to decreased heart rate, decreased myocardial contractility, and decreased blood pressure. Because of these decreased effects, beta blockers should be avoided in patients with any degree of heart failure, because the heart failure would become worse. There are nonselective and selective types of beta-adrenergic blockers. Patients with asthma or chronic obstructive pulmonary disease (emphysema, bronchitis, and bronchiectasis) should avoid nonselective beta-adrenergic blockers because they cause bronchoconstriction. Examples of beta-blocking agents used to treat chronic angina include propranolol (Inderal), metoprolol (Lopressor), and atenolol (Tenormin). Metoprolol and atenolol are more cardioselective and can be used in patients with asthma and chronic obstructive pulmonary disease (COPD). Beta blockers are not effective for coronary artery spasms.

LEARNING TIPS

To help you identify beta blockers, remember that their generic names end with *-ol*.

Nursing Process

Obtaining a thorough history on a patient admitted with a diagnosis of angina pectoris is important in developing a plan of care and should include the following:

- How long the patient has had angina
- Risk factors
- Triggering activities
- How pain is relieved

If the patient reports chest pain, areas of assessment and documentation should include the following:

- Type, location, and pain radiation to other areas of the body
- Vital signs and skin color and temperature
- Presence of dyspnea, labored respirations, diaphoresis, or nausea

Oxygen and sublingual NTG are given to the patient with chest pain as ordered. Blood pressure and heart rate are assessed before and after NTG is given. The nurse must promote rest and decrease anxiety for the patient with chest pain. A patient who is experiencing chest pain should never be left alone. Emotional support is important because patients and their families are often afraid that the patient may die.

► MYOCARDIAL INFARCTION

A myocardial infarction (MI), commonly known as a heart attack, results in the death of heart muscle. An MI occurs from a partial or complete blockage of a coronary artery, which decreases the blood supply to the cells of the heart supplied by the blocked coronary artery. The extent of the cardiac damage varies depending on the location and amount of blockage in the coronary artery. This is a potentially devastating condition. The ability of the heart to contract, relax, and propel blood throughout the body requires healthy cardiac muscle. When the patient has an MI, part of the heart muscle no longer functions as it should. Cardiac conduction, blood flow, and function can be dramatically altered by an MI.

Those with MIs are typically men over 40 with atherosclerosis development. Although MIs can occur at any age in men or women, women who smoke and use oral contraceptives are at greater risk for MI.

Pathophysiology

Myocardial infarction does not happen immediately. Ischemic injury evolves over several hours before complete necrosis and infarction take place. The ischemic process affects the subendocardial layer, which is most sensitive to hypoxia. This process leads to depressed myocardial contrac-

tivity. The body's attempt to compensate for decreased cardiac function triggers the sympathetic nervous system to increase heart rate. The change in heart rate increases myocardial oxygen demand, further depressing the myocardium.

Prolonged ischemia can produce severe cellular damage and necrosis of cardiac muscle. Once necrosis takes place, the contractile function of the muscle is permanently lost. The heart has a zone of ischemia and injury around the necrotic area (Fig. 18-3). The zone of injury is next to the necrotic area and is susceptible to becoming necrosed. If treatment is initiated within the first hour of symptoms of the MI, the area of damage can be minimized. Around the injury zone is an area of ischemia and viable tissue. If the heart responds to treatment, this area can rebuild and maintain collateral circulation. If prolonged ischemia takes place, the size of the infarction can be quite large. The size of the infarction depends on how quickly the blood supply from the blocked artery can be restored.

The area that is affected by an MI depends on the coronary artery involved and the extent of occlusive coronary disease (Fig. 18-4). Being familiar with the anatomy of the heart and the area of the MI helps the nurse anticipate dys-

rhythmias, conduction disturbances, and heart failure, which are the major complications of MIs (Table 18-4).

The anterior interventricular branch of the left coronary artery is the area that feeds the anterior wall of the heart, which also includes most of the left ventricle. An occlusion in this area causes an anterior wall MI. When the left ventricle is affected, there can be severe loss of left ventricular function, leading to severe changes in the hemodynamic status of the patient.

The right coronary artery (RCA) feeds the inferior wall and parts of the atrioventricular node and the sinoatrial node. An occlusion of the RCA leads to an inferior MI and abnormalities in impulse formation and conduction. Serious dysrhythmias can occur early in an inferior MI that may be life threatening.

The left circumflex coronary artery feeds the lateral wall of the heart and part of the posterior wall of the heart. A lesion in the circumflex leads to a lateral wall infarction of the left ventricle.

Figure 18-3 Myocardial infarction. Areas of ischemia, injury, and necrosis caused by a blockage in the left anterior coronary artery.

LEARNING TIPS

To remember what coronary artery occlusion results in a specific MI location, use coast-to-coast U.S. location initials such as those given below. You can personalize the locations with initials of landmarks familiar to you.

Location	Coronary Artery	Resulting MI Location
Los Angeles	Left anterior descending	Anterior
Cedar Point	Circumflex	Posterior
Rhode Island	Right	Inferior

Signs and Symptoms

Chest pain is a classic symptom of an MI. The pain begins suddenly and continues without relief with rest or NTG. The pain in the center of the chest is usually described as crushing, viselike, or as if an elephant is standing on the chest. The pain may radiate to the back, one or both arms and shoulders, neck, or jaw. The pain can imitate indigestion or a gallbladder attack with abdominal pain and vomiting. Other classic MI symptoms include shortness of breath, dizziness, nausea, and sweating (Box 18-3). When listening to lung sounds, crackles or wheezing may be heard. The pulse may be rapid or irregular, and an extra heart sound (referred to as S3 or S4) may be present. The presence of an extra heart sound can mean ventricular failure is imminent.

Women may not experience the classic symptoms of an MI. Research has only recently focused on understanding women and cardiac disease. Atypical symptoms reported by women may include extreme fatigue, epigastric pain, shortness of breath, or cramping in the chest. Women also often do not associate their symptoms with a heart attack because they believe it is a male disease.

Figure 18-4 (A) Coronary arteries, frontal view. (B) Coronary arteries, posterior view.

People often deny or fail to recognize that they are having an MI because they experience atypical MI symptoms or their symptoms are similar to other mild conditions such as indigestion. Patients have reported that the symptoms of an MI that they experienced were not what they expected. If people expect to have the dramatic heart attack symptoms seen on television (which are usually not the same as those in real life) and they do not, they are likely to wait to seek treatment. People often wait 2 to 24 hours before seeking medical care, yet the first hour after symptom onset is crucial for seeking the newer reperfusion treatments that restore blood flow, minimize tissue damage, and save lives.

Because so few patients arrive at the emergency room quickly enough to benefit from newer treatments, the National Heart, Lung, and Blood Institute (NHLBI) and the American Heart Association launched a major new heart attack education campaign on 9-11-01 called “Act in Time

to Heart Attack Signs.” The purpose of this campaign is to educate people on the importance of recognizing heart attack symptoms, working with a physician to create a heart attack survival plan, and calling 911 as soon as symptoms begin. For more information on the Act in Time to Heart Attack Signs, visit www.nhlbi.nih.gov, www.redcross.org, and www.americanheart.org.

The National Heart Attack Alert Program (NHAAP) is another public education program developed by the NHLBI. The message of this program is symptom recognition and “60 minutes to treatment” to improve survival and reduce tissue damage. For more information, visit www.nhlbi.nih.gov/nhlbi/othcomp/opcc/nhaap/nhaapage.htm.

Gerontological Implications

Some myocardial infarctions occur without the presence of pain. This is referred to as a silent MI and occurs most often

TABLE 18-4 COMPLICATIONS OF MYOCARDIAL INFARCTION

Complication	Types or Symptoms	Interventions
Dysrhythmias	Premature ventricular contractions, ventricular tachycardia, ventricular fibrillation, heart block	Continuous cardiac monitoring Protocols for treatment of dysrhythmias (see Chapter 20)
Cardiogenic shock	Decreased blood pressure; increased heart rate; diaphoresis; cold, clammy, gray skin	Immediate initiation of treatment to decrease infarct size, control pain and dysrhythmias Thrombolytic therapy Dopamine and dobutamine
Heart failure/pulmonary edema	Dizziness, orthopnea, weight gain, edema, enlarged liver, jugular venous distention, crackles	Correct underlying cause, relieve symptoms, increase cardiac contractility, administer furosemide (Lasix) and digoxin
Ventricular aneurysms, rupture of muscles or valves of the heart, septal rupture	Signs of cardiogenic shock, death	Mortality rate high; immediate treatment of MI to limit extent of damage
Pericarditis (inflammation of the heart muscle)	Chest pain, increased with movement, deep inspiration, or cough; pericardial friction rub (fine grating sound)	Relieved when sits up and leans forward Anti-inflammatory drugs (aspirin, indomethacin [Indocin])

BOX 18-3 Myocardial Infarction Summary**Signs and Symptoms****Classic**

Crushing, viselike chest pain with radiation to arm, shoulder, neck, jaw, or back with a combination of the following:

- Shortness of breath
- Dizziness
- Nausea
- Sweating

Atypical

Absence of classic pain with any one or a combination of the following:

- Epigastric or abdominal pain
- Cramping in the chest
- Fatigue
- Anxiety
- Falling

Diagnostic Tests

- ECG
- Serum cardiac troponin I or T
- Serum myoglobin
- Serum CK-MB
- Serum magnesium

Medical Treatment

Vital signs, oxygen saturations, intake and output monitored

Oxygen

Medications:

- Aspirin
- Morphine sulfate
- Thrombolytics
- Nitrates
- Vasodilators
- Beta blockers
- Anticoagulants
- Antidysrhythmics

Low-sodium clear liquids advanced to low-fat, low-cholesterol, and low-sodium diet; no caffeine

Fluid restriction

Bedrest with a bedside commode

Daily weight checks

Complications

- Dysrhythmias
- Heart failure

Nursing Diagnoses

Acute pain related to decreased coronary blood flow causing myocardial ischemia

Decreased cardiac output related to myocardial ischemia, heart rate changes, or dysrhythmias

Activity intolerance related to fatigue

Deficient knowledge related to lack of knowledge about myocardial infarction and its treatment

in the elderly patient. It may also occur in those with diabetes regardless of age. When pain is not present, the only symptom may be a sudden onset of shortness of breath or fainting, restlessness, or a fall experienced by the patient. Atypical presentation of MI symptoms is normal in the elderly patient, especially in those older than age 85. Because

the elderly have had more time to develop collateral circulation than younger people, they often do not have as many complications with an MI.

Diagnostic Tests

Patients with a strong familial history of MI should be considered at risk until an MI is ruled out. The most useful indicators of an MI are patient history, ECG, and serum cardiac troponin I or T, myoglobin, and CK-MB levels. (See Chapter 15.) Magnesium levels are also checked, especially for those on diuretic therapy. Before thrombolytic or heparin therapy, prothrombin time (PT) and partial thromboplastin time (PTT) are determined. The ECG usually shows the area that has infarcted, as well as the ischemic areas of the heart. Myocardial damage is seen as ST segment elevation, the presence of a Q wave, or T-wave abnormalities (Fig. 18-5). Serial ECGs are done to monitor changes indicating damage or ischemia.

Treatment

Treatment should be sought within 15 minutes for any unrelieved chest pain. The American Heart Association recommends taking one uncoated adult aspirin at the onset of chest pain. Delays in seeking care can limit treatment options and result in more cardiac damage (Box 18-4). Patients need to be educated that “time is muscle.” As time passes during an MI, more muscle is lost. Patients should not drive themselves to the hospital if they are having chest pain. Emergency medical care (911 or local emergency services number) should be called.

The presence of chest pain indicates a lack of oxygen to the myocardium. Patients reporting chest pain are treated as if they have an MI until it has been proven otherwise through testing. Treatment is given to increase oxygen supply to the heart muscle.

Figure 18-5 ECG changes during myocardial infarction. (A) Injury: ST segment elevation. (B) Ischemia: ST segment inversion. (C) Necrosis: large Q wave and ST segment elevation.

BOX 18-4 Preventing Delays in Myocardial Infarction Treatment

- Understand symptoms and “time is muscle” principle.
- Develop an action plan and rehearse it.
- Understand normal emotional responses of anxiety, denial, or embarrassment.
- Educate family to follow action plan.
- Establish protocols in workplaces for employees experiencing myocardial infarction.
- Establish emergency room policies that reduce delays, such as having equipment and medication readily available.

Oxygen

Oxygen is administered immediately, usually at 2 L per minute via nasal cannula. Arterial blood gases (ABGs) are drawn to determine the patient’s oxygen needs. Oxygen can be administered via mask if higher concentrations are needed. Mechanical ventilation can be provided when indicated by ABGs.

Medication

Table 18-5 summarizes pharmacological treatment of myocardial infarction.

ANALGESICS. Analgesics are given for relief of chest pain. Morphine sulfate is the most commonly used narcotic for several reasons. In addition to pain relief, it helps decrease anxiety, opens bronchioles, and reduces preload and afterload, which can help increase blood supply and oxygen to the myocardium. It is given intravenously in small doses that are titrated to meet the patient’s pain relief needs.

VASODILATORS. NTG sublingually, topically, or by intravenous (IV) drip can be administered for vasodilation to supply more blood to the myocardium to reduce pain and the workload of the heart. In the acute phase the IV route is usually used.

THROMBOLYTICS. Thrombolytic therapy is used to dissolve a blood clot that is occluding a coronary artery. Many communities allow initiation of thrombolytic therapy by paramedics in the field. Studies have revealed a decreased incidence of mortality and morbidity and less extensive tissue damage when thrombolytic treatment is used. Thrombolytic therapy must be started within a specified time range from the onset of symptoms, usually within 1 to 6 hours, before necrosis results.

Glycoprotein 11b/111a inhibitors (abciximab, tirofiban) may be used as an adjunct to thrombolysis or PTCA in patients with acute myocardial infarction. These drugs work by inhibiting platelet aggregation.

Activity

Initially patients are kept on bedrest with a bedside commode for bowel movements to decrease myocardial oxygen demand. Then activity is advanced gradually as tolerated.

Diet

During the acute phase of an MI, small, easily digested meals are served. Caffeine is usually restricted because it increases heart rate and causes vasoconstriction. Fluids may be restricted if the patient is in heart failure as well. Initially a low-sodium clear liquid diet may be ordered. Then a low-fat, low-cholesterol, and low-sodium diet may be ordered.

TABLE 18-5 PHARMACOLOGICAL TREATMENT FOR MYOCARDIAL INFARCTION

Drug	Purpose
Oxygen by nasal cannula, face mask, or face tent	Decreases myocardial oxygen demand and improves cellular oxygenation
Aspirin: one adult tablet PO. First dose not enteric coated. Daily dose enteric coated.	Decreases platelet aggregation to prevent clots
Analgesics: Morphine sulfate, IV push	Relieves pain, decreases anxiety, slows respirations, decreases preload and afterload
Nitrates: nitroglycerin by sublingual route, lingual spray, topical, IV infusion	Dilates coronary arteries to increase blood flow to the heart to relieve chest pain
Thrombolytics IV: alteplase (Ativase, tissue plasminogen activator [TPA]), anistreplase (Eminase), reteplase (Retavase), streptokinase (Streptase), urokinase (Abbokinase)	Lyses clots and prevents others from forming
Anticoagulants: heparin sodium by IV push or IV infusion, enoxaparin (Lovenox) subcutaneously	Prevents more clots from forming but has no effect on clots already present
Beta blockers IV or PO: propranolol (Inderal), metoprolol (Lopressor), atenolol (Tenormin)	Decreases heart rate and force of contraction and decreases oxygen requirements of the heart
Angiotensin-converting enzyme inhibitors PO: captopril (Capoten), lisinopril (Prinivil, Zestril), ramipril (Altace),trandolapril (Mavik)	Reduces death and heart failure after MI
Antidysrhythmics IV bolus or infusion: lidocaine (Xylocaine)	Used to control ventricular dysrhythmias (premature ventricular contractions, ventricular tachycardia)
Additional medications as needed:	
Antiemetic	Controls nausea and vomiting
Antianxiety	Reduces anxiety
Antacid	Relieves heartburn and indigestion
Stool softener/laxative	Reduces straining with bowel movement and prevents constipation

The number of grams of sodium is prescribed by the physician. If the patient is obese, a dietitian may work with the patient and family to devise a diet that is suitable and palatable for the patient.

Smoking

Smoking should be avoided, and patients are instructed on the hazards of continuing to smoke. Referral to a tobacco cessation program can be made. The nurse needs to work with patients to help them understand and accept lifestyle changes.

Nursing Process

Assessment

A thorough history is obtained to identify risk factors that may contribute to a myocardial infarction. All patients admitted with chest pain are treated as having a possible MI until it has been ruled out. Continuous cardiac monitoring, serial ECGs, and laboratory values help identify life-threatening dysrhythmias and determine the degree of cardiac damage. Controlling chest pain immediately helps diminish anxiety and the negative physiological effects pain has on the body.

Nursing Diagnosis

Nursing diagnoses may include but are not limited to the following:

- Pain related to reduced coronary artery blood flow and increased myocardial oxygen needs

- Decreased cardiac output related to ischemia or infarction, changes in heart rate and rhythm, and decreased contractility
- Anxiety related to threat of death, changes in lifestyle, and chest pain
- Activity intolerance related to imbalance between oxygen supply and demand, weakness, and fatigue
- Deficient knowledge related to disease process, lifestyle changes, and medication

See Nursing Care Plan Box 18–5 for the Patient with Myocardial Infarction for more information.

Planning

The patient and family should be included in planning care. They need to understand that the purpose of treatment is to prevent further myocardial damage. The plan of care should focus on reducing factors that contribute to an increased workload of the heart. The patient's goals are to (1) report that the pain management regimen relieves pain; (2) maintain palpable pulses, warm and dry skin, and vital signs within normal range; (3) state that anxiety is relieved; (4) maintain desired activities; and (5) understand the disease and its treatment.

Nursing Interventions

Nursing care focuses on relieving pain, reducing the workload of the heart, and relieving patient and family anxiety. The patient should be positioned for comfort and ease in breathing. Semi-Fowler's position is usually preferred by patients having respiratory distress. When patients are sitting

BOX 18-5 NURSING CARE PLAN FOR THE PATIENT WITH MYOCARDIAL INFARCTION

▶ Acute pain related to decreased coronary blood flow causing myocardial ischemia

PATIENT OUTCOMES

Patient will exhibit signs of decreased pain. Patient will exhibit signs of relaxation.

EVALUATION OF OUTCOMES

Does patient state pain is reduced?

INTERVENTIONS

- Assess for location, duration, intensity, and radiation; use a scale of 0 to 10.
- Assess blood pressure, pulse, and respiration.
- Obtain ECG as ordered.
- Administer oxygen as ordered.
- Instruct patient to report pain at first onset.
- Instruct patient to rest during pain.
- Remain with patient during chest pain until it is relieved.
- Explain and assist with alternative pain relief measures:
 - Positioning
 - Diversional activities
 - Relaxation techniques
- Medicate as ordered.

RATIONALE

- Identifies type and severity of pain.
- Vital signs may elevate episodes of pain.
- Identifies location of infarction or ischemia. Helps prevent hypoxia.
- Helps control pain quickly to prevent further ischemia.
- Activity increases oxygen demand and can increase chest pain.
- Provides comfort and reassurance to decrease anxiety and fear.
- These measures help decrease painful stimuli, allowing the patient to focus on other things.
- Helps eliminate pain.

EVALUATION

- What is pain level, location, duration, intensity, and radiation?
- Are vital signs within normal limits?
- Is ECG normal?
- Are ABGs within normal limits?
- Is oxygen saturation greater than 90 percent?
- Does patient report pain?
- Does patient remain quiet and relaxed?
- Are anxiety and fear decreased?
- Does patient express relief and decreased stress?
- Is pain relieved?

BOX 18-5 NURSING CARE PLAN FOR THE PATIENT WITH MYOCARDIAL INFARCTION—CONT'D**▶ Decreased cardiac output related to ischemia or infarction, changes in heart rate and rhythm, and decreased contractility****PATIENT OUTCOMES**

Patient will maintain adequate cardiac output and tissue perfusion. Patient will exhibit signs of improved cardiac output and tissue perfusion.

EVALUATION OF OUTCOMES

Does patient have heart rate greater than 60 and less than 100, blood pressure greater than 90/60 and less than 140/90, and urine output greater than 30 mL/h?

INTERVENTIONS	RATIONALE	EVALUATION
<ul style="list-style-type: none"> • Monitor blood pressure greater than 90/60, heart rate greater than 60 and less than 100, urine output greater than 30 mL/h. • Listen to lung sounds. • Monitor peripheral circulation, pulses, capillary refill, edema, color, and temperature. • Monitor ECG. • Administer medications as ordered by physician, such as vasodilators, beta blockers, calcium channel blockers, and cardiac glycosides. • Promote and provide for adequate rest, quiet environment, bedrest; place in semi-Fowler's position. 	<p>Indirect indicators of cardiac output.</p> <p>Crackles indicate heart failure. Indicators of adequate tissue perfusion.</p> <p>Identifies dysrhythmias. Helps improve contractility, cardiac output, and tissue perfusion.</p> <p>Decreases cardiac workload and stress and allows for improved breathing.</p>	<p>Are indicators within normal limits?</p> <p>Are lungs clear?</p> <p>Does patient have strong peripheral pulses, capillary refill less than 3 seconds, no edema, warm skin, pink nailbeds?</p> <p>Is patient's ECG within normal limits?</p> <p>Does patient show signs of improved contractility, increased cardiac output, and tissue perfusion?</p> <p>Is patient relaxed?</p>

upright in bed, supporting their arms on pillows reduces the workload of the heart by eliminating the force of gravity on unsupported arms. The patient is taught to avoid Valsalva's maneuver, which occurs when the patient bears down against a closed glottis, mouth, and nose. Valsalva's maneuver increases intrathoracic pressure, slows the heart rate, and decreases blood return to the heart. Valsalva's maneuver can occur when the patient moves or turns in bed or strains with bowel movements. Patients must be taught not to hold their breath when moving in bed and also not to strain with bowel movements. Stool softeners are usually ordered by the physician to prevent straining with bowel movements. A record of the patient's bowel movements is kept, and intake and output are monitored.

Emotional support should be provided. The patient should be allowed to verbalize fears. Procedures should be explained. Family support should also be offered. Spouses also experience anxiety and need support, including ongoing information and explanations, being allowed to stay with the patient, and being involved in the patient's care. Spouses or significant others often ignore their own needs to focus on the patient. Nurses need to help spouses or significant others meet their own needs, so that they are better able to support the patient.

Teaching about the therapeutic regimen includes information about the disease, medications, diet, activity, and rehabilitation needs that may require lifestyle changes. Diet, stress reduction, a regular exercise program, cessation

of smoking if necessary, and following a medication schedule require extensive patient and family teaching. This disease can affect all aspects of a patient's lifestyle. Issues about family and job roles and sexual activities need to be addressed. Patients need time to understand information that has been presented and should be encouraged to express any questions, needs, or fears.

Evaluation

Patient goals are met if the following occur:

1. Satisfactory pain relief is reported using a rating scale of 0 to 10
2. Vital signs are within normal limits, no pain is reported, and no alteration in level of consciousness is observed
3. Anxiety is reduced
4. Fatigue is reduced, and the patient gains the ability to complete tasks and engage in desired activities
5. Understanding of the disease, medications, and reasons for lifestyle changes and a willingness to follow the regimen are stated

Cardiac Rehabilitation

Cardiac rehabilitation is begun when the patient's acute symptoms are relieved. The purpose of cardiac rehabilitation is to improve cardiac function and assist the patient to return to as normal a life as possible. Cardiac rehabilitation protocols are used in many institutions. The first two phases

of rehabilitation occur in the hospital. Activities for each hospital day, such as types and amounts of self-care and activity, are specified in protocols. The third phase begins with hospital discharge and focuses on returning to prior levels of activity and function. Outpatient programs are often ordered for patients in this phase. In this phase, patients are encouraged to maintain optimum physical fitness and to continue healthy lifestyles.

CRITICAL THINKING

Mrs. Sims

Mrs. Sims, 43, is admitted to the intensive care unit with a diagnosis of atypical chest pain. She has a history of midsternal chest cramping. The pain is radiating to her left and right shoulders and down her left arm. Her pain increases with activity and decreases with rest. She smokes one and a half packs of cigarettes per day and is 50 pounds overweight. The cardiac monitor shows normal sinus rhythm without dysrhythmias. She has NTG sublingual ordered prn for chest pain.

One hour after admission, Mrs. Sims reports midsternal chest pain radiating to left neck and jaw. The cardiac monitor shows sinus tachycardia with occasional premature ventricular contractions (PVCs). Her blood pressure is 100/70, respirations are 20 and unlabored, and skin is warm and dry.

1. What actions should you take?
2. What is happening to Mrs. Sims?
3. How is angina differentiated from an MI?
4. What are four indicators of an MI?
5. What medical interventions can be used for an MI?
6. What education is indicated for Mrs. Sims?

Answers at end of chapter.

▶ PERIPHERAL VASCULAR SYSTEM

Peripheral vascular disease (PVD) may be either arterial or venous in origin. PVD is very common in people who are elderly or diabetic. You should understand if the origin of the problem is arterial or venous to prevent serious complications from occurring. Typically with arterial disease the patient reports leg pain with leg elevation or calf pain during activity that disappears with rest. Venous disease has a slower onset and is not associated with activity. Pain occurs when the legs are positioned dependently (down), causing pooling of blood at the ankles.

▶ ARTERIAL THROMBOSIS AND EMBOLISM

Pathophysiology

A thrombus (blood clot) adheres to the vessel wall. Acute arterial thrombi occur where there is injury to an arterial wall, sluggish flow, or plaque formation secondary to atherosclerotic changes. Other causes of arterial thrombosis are polycythemia, dehydration, and repeated arterial needle sticks. If a thrombus breaks off and travels, it becomes an **embolism** that occludes an arterial vessel that is too small to allow it to pass. Some of the causes of an arterial embolism are dysrhythmias, prosthetic heart valves, and rheumatic heart disease.

Signs and Symptoms

Usually there is an abrupt onset of symptoms with acute arterial occlusion. If a patient also has chronic arterial insufficiency, the symptoms may not occur as rapidly because collateral circulation has developed and can supply some blood to the occluded area. Symptoms depend on the artery occluded, the tissue supplied by that artery, and whether collateral circulation is present.

There are six clinical signs of acute arterial occlusion, known as the six Ps: pain, pallor, pulselessness, paresthesia (numbness), paralysis, and poikilothermia (temperature). The patient experiences pain, numbness, and decreased movement in the extremity, which is pale and without pulses distal to the occlusion. The extremity feels cold because blood normally provides warmth. If treatment is not initiated immediately, ischemia occurs and can progress to tissue necrosis and gangrene development within hours.

Medical Treatment

Early treatment is necessary to protect and save the affected limb. Anticoagulant therapy is started immediately. Intravenous heparin is the treatment of choice to prevent further clotting. Heparin has no effect on existing clots. An initial IV bolus of heparin, usually 5000 IU, is given. An IV infusion is then started as ordered. The patient remains on heparin therapy for several days. Daily PTTs are monitored to maintain therapeutic heparin levels. After 3 to 7 days, warfarin (Coumadin) is added. Warfarin, an oral anticoagulant, takes 3 to 5 days to reach therapeutic levels. The heparin is continued until a therapeutic warfarin level is reached. To monitor warfarin's effects, international normalized ratios (INRs) and PTs are done daily, and adjustments in warfarin doses are made based on the results.

For patients with severe occlusions, especially if the risk of limb loss is imminent, surgery or thrombolytic agents are used to save the extremity. During an emergency embolectomy or thrombectomy, the artery is cut open, the emboli or thrombus is removed, and the vessel is sutured closed. Thrombolytic agents dissolve the thrombus or embolus.

CRITICAL THINKING

Mrs. May

Mrs. May is admitted with severe rheumatoid arthritis, which has left her immobile for 7 months. She is returning to her room following a whirlpool treatment when she suddenly reports severe pain in her left groin.

1. What is your first action?
2. After assessing Mrs. May, what action should be taken next?
3. What are the possible causes of these sudden symptoms?
4. How would you document Mrs. May's symptoms?
5. What would the immediate interventions be?
6. What medical interventions would you anticipate?
7. What surgical procedure may need to be done if the risk of losing the limb is imminent?

Answers at end of chapter.

► PERIPHERAL ARTERIAL DISEASE

Peripheral arterial disease (PAD) causes chronic, progressive narrowing of arterial vessels that leads to obstruction. PAD usually affects the lower extremities. Atherosclerosis is the leading cause of occlusive disease.

Pathophysiology

The purpose of the arterial system is to deliver oxygen-rich blood to the vascular beds. Anything that impedes this flow causes an imbalance in supply and demand for oxygen. Decreased nutrition, cellular waste accumulation, and the development of ischemia occur at the area distal to the obstruction. With the increased debris and sluggish flow, thrombosis and embolism become major problems.

The body has several mechanisms to attempt to compensate for reduced blood flow, including peripheral vasodilation, anaerobic metabolism, and development of collateral circulation. However, these mechanisms are not intended to meet the ongoing blood supply needs of the body. It takes time for collateral circulation to develop, blood vessels eventually reach their limit of dilation, and anaerobic metabolism is only a very short term compensatory mechanism. Eventually this lack of blood supply produces signs of ischemia, and if not corrected, ulceration, gangrene, and necrosis of the extremity occur; amputation of the limb may then become necessary.

Signs and Symptoms

Symptoms usually occur late in the course of PAD. It is only when diminished blood flow begins to produce changes in the extremities that symptoms occur. Pain in the calves of the lower extremities associated with activity or exercise, called **intermittent claudication**, is a common symptom of arterial occlusive disease. When blood supply to the muscles is decreased, the muscles are unable to receive adequate oxygen and ischemia develops. As ischemia increases, the muscle develops a cramping-type pain that usually subsides when the activity is stopped. As PAD progresses, the pain is present even at rest, thus indicating severe arterial occlusion.

Skin color changes are associated with decreased blood supply. The extremity is pale when the leg is elevated. If the leg is in a dependent position, it becomes reddish-purple or cyanotic. The extremity is cool to touch even in warm environments. As occlusion of the arteries progresses, there are diminished or absent arterial pulses. The loss of circulation leads to tissue death and gangrene. See Box 18–6 for stages of peripheral arterial disease.

Diagnostic Tests

Noninvasive studies can be used to diagnose occlusive disorders. The ankle-brachial (arm) blood pressure index is used to determine pressures in the upper and lower extremities. Normally, pressures in the legs and arms should be equal. When an occlusion occurs in the lower extremities, the pressures between the upper and lower extremities become unequal. A Doppler ultrasound measures the velocity

of the blood flow. Magnetic resonance imaging (MRI) can give definitive images of blood vessels and degrees of arterial closure.

LEARNING TIPS

Arterial insufficiency risk assessment: ankle-brachial index

1. Take brachial blood pressure.
2. Take ankle blood pressure (use arm blood pressure cuff placed above the ankle).
3. Divide ankle systolic pressure by brachial systolic pressure (e.g., $98 \div 130 = 0.75$).
4. Arterial disease = 0.8 or less.
5. Do not treat arterial disease like venous disease!

Arteriography is an invasive procedure in which an x-ray examination of an artery is taken after dye has been injected. This invasive procedure requires a patient's consent and identification of any patient allergies to iodine. Arteriography is usually done before surgical intervention is considered.

Medical Treatment

Conservative medical treatment is initiated with mild to moderate occlusive disease. This includes patients who experience pain on activity that ceases with rest. This type of patient usually receives medication for vasodilation and diet management if necessary. Surgical intervention is used

for the patient who experiences pain at rest or who has leg ulcers that do not heal. Surgical treatment includes endarterectomy to remove the atherosclerotic lesion or grafting to bypass the occluded area. (See Chapter 22.)

Diet

To help control atherosclerosis development, the diet should be low fat, low cholesterol, and low calorie if the patient is overweight. Teaching the patient to avoid red meats, fried foods, whole milk, and cheese is important. Avoiding high-cholesterol foods, such as egg yolks, organ meats, animal fats, and shellfish, helps lower lipid levels.

Medications

Drug therapy is geared toward the symptoms and causes of the occlusive disease. The same drugs used to decrease cholesterol and lipid levels in atherosclerosis are used with occlusive disease. Vasodilators can be used, but their effectiveness is not the same for all patients. Pentoxifylline (Trental) is commonly the drug of choice for those patients with occlusive disorders who experience intermittent claudication. This drug makes red blood cells more flexible to improve perfusion. The major side effect is gastrointestinal upset, so it should be taken with meals. Thrombolytic therapy is used when an occlusion is caused by a thrombus or an embolus.

Invasive Therapies

Percutaneous transluminal angioplasty (PTA) can be used to dilate a narrowed peripheral vessel. It is similar to PTCA, which was discussed earlier. Complications that can occur with this procedure are a ruptured artery as a result of the stretching caused by the balloon and clot formation. Peripheral atherectomy is another invasive procedure used to remove plaque from atherosclerotic arteries. Intravascular stents can also be used to maintain patency of the artery. After stent placement, patients are given platelet aggregation inhibitors.

Nursing Process for Peripheral Arterial Diseases

Assessment

When dealing with patients having arterial occlusive disorders, monitoring peripheral circulation is important. Careful assessment of pulses, capillary refill, temperature, color, and presence of edema helps identify patients at risk for complications.

Nursing Diagnosis

The nursing diagnoses for PAD may include but are not limited to the following:

- Ineffective tissue perfusion related to decreased arterial perfusion
- Pain related to decreased blood supply to lower extremities
- Activity intolerance related to activity pain
- Deficient knowledge: peripheral arterial disease related to complications, medications, or postoperative care.

See Nursing Care Plan Box 18–7 for the Patient with Peripheral Arterial Occlusive Disorders.

Planning

Arterial occlusive disease is a progressive disorder that can be controlled or at least slowed. Including the patient and family in the development of the plan of care will help ensure their understanding of the reasons for the current therapy. The patient's goals include the following:

- Maintain palpable pulses and warm and dry skin
- Report that pain is relieved
- Maintain desired activities
- Understand the disease and its treatment

Nursing Interventions

The patient should be able to describe symptoms and complications associated with arterial occlusive disorders. Medication cards can be developed to help the patient understand the different medications being used and any special considerations required. The patient should be seen by a dietitian before discharge for instructions on a low-fat, low-cholesterol diet. Proper leg positioning should be taught to prevent complications and the potential loss of the extremity. Patients should not elevate their legs, especially if pain is increased. Legs should be kept in a dependent position to encourage blood flow with the assistance of gravity. Regular 30-minute walks have been shown to be helpful in maintaining circulation and reducing the incidence of blood clots for those with PAD.

Evaluation

The best indicators that outcomes for the patient with PAD have been achieved are that the patient is experiencing less pain with activity and that there are no complications with activity. If the patient states understanding of the disease and the need to comply with treatment, the goal for deficient knowledge is achieved. This disorder requires constant monitoring of its status and progression.

▶ ANEURYSMS

An **aneurysm** is a bulging or dilation at a weakened point of an artery. The artery diameter is often increased by 50 percent. The cause is unknown, but anything that weakens the artery wall or causes loss of elasticity in the artery can cause an aneurysm. Atherosclerosis, hypertension, smoking, trauma, and congenital abnormalities are risk factors for an aneurysm. Heredity may also play a role. Aneurysms can occur in any artery in the body but are common in the abdominal aorta, which is the focus of the rest of this discussion.

Abdominal aortic aneurysms (AAA) are often silent if they are less than 4 cm. Most people do not even know that they have an AAA. Men older than age 50 are at the highest risk of death from an AAA. The incidence of AAA increases with age.

BOX 18-7

NURSING CARE PLAN FOR THE PATIENT WITH PERIPHERAL ARTERIAL OCCLUSIVE DISORDERS

▶ **Acute pain related to impaired circulation to extremities causing intermittent or continuous pain****PATIENT OUTCOMES**

Patient will report that pain is controlled.

EVALUATION OF OUTCOMES

Does patient report relief from pain by nonpharmacological or pharmacological methods?

INTERVENTIONS

- Monitor for intermittent claudication or pain at rest.
- Note peripheral circulation, pulses, color, temperature, presence of edema, and skin breakdown.
- Administer medication as ordered:
 - Analgesics
 - Vasodilators
 - Calcium channel blockers
- Promote bedrest if pain is present.
- Position lower extremities below heart level.
- Protect extremities from cold or trauma.

RATIONALE

Helps determine degree of occlusive disease.

Determines the degree of tissue perfusion and complications.

Relieves chronic or acute pain. Increases blood flow to extremities. Decrease vasospastic episodes.

Rest decreases muscle contraction and prevents further ischemia in extremities. Increases arterial flow to lower extremities.

Extremities with decreased circulation have decreased sensation, which increases risk of injury.

EVALUATION

Does patient have pain during activity or at rest?

Does patient have pulses, warm skin, capillary refill less than 3 seconds, no evidence of skin breakdown?

Does patient show signs of increased circulation and relief of pain following administration of medications?

Is patient able to rest?

Are pulses strong, capillary refill less than 3 seconds, extremities pink and warm?

Are extremities injury free?

▶ **Ineffective tissue perfusion related to interruption of arterial flow in arms and legs****PATIENT OUTCOMES**

Patient will exhibit signs of increased arterial blood flow and tissue perfusion.

EVALUATION OF OUTCOMES

Does patient have strong peripheral pulses, capillary refill less than 3 seconds, warm skin, absence of edema?

INTERVENTIONS

- Check peripheral pulses, capillary refill, color, temperature, and presence of edema every 4 hours.
- Check skin for intactness, healed areas, signs of ulceration or infection.
- Place extremities lower than heart, feet on floor in sitting position, head of bed elevated on blocks.
- Avoid bending knees, pillows under knees, prolonged sitting or crossing legs.
- Inspect lower extremities frequently. Clean feet with mild soap; dry carefully. Protect from injury.

RATIONALE

Indication of adequate tissue perfusion.

Chronic arterial occlusion leads to decreased blood flow, resulting in tissue damage and poor wound healing.

Increases blood flow to the legs and feet.

These activities impede blood flow to extremities.

Cleaning prevents trauma to feet, protecting feet from things that can lead to ulcerations.

EVALUATION

Are peripheral pulses strong, nailbeds pink, capillary refill less than 3 seconds with no edema noted?

Is skin intact?

Does patient have adequate tissue perfusion signs?

Does patient exhibit understanding of improving blood flow?

Is patient free from trauma or breaks in skin of the lower extremities?

Figure 18-6 Types of aneurysms.

Types

There are different types of aneurysms (Fig. 18–6). A fusiform aneurysm is the dilation of the entire circumference of the artery. A saccular aneurysm is a bulging on only one side of the artery wall. A dissecting aneurysm occurs when a cavity is formed from a tear in the artery wall, usually the intimal (inner) layer. The layers of the artery are then separated as blood is pumped into the tear with each heartbeat, expanding the cavity, which is then prone to rupturing.

Signs and Symptoms

Usually there are few if any symptoms. As the AAA grows, symptoms may develop. Back or flank pain is the classic symptom; the pain is caused by the aneurysm pressing against nerves of the vertebrae. Depending on the location and size of the aneurysm, there may be complaints of abdominal pain, a feeling of fullness, or nausea caused by pressure on the intestines. Changing positions may temporarily relieve the symptoms. Because the symptoms are vague, they are often not associated with an AAA. There may be a pulsating mass in the abdomen caused by an

AAA that is only discovered during routine physical or x-ray examination.

Severe, sudden back, flank, or abdominal pain and a pulsating abdominal mass can indicate that the aneurysm may be about to rupture. With rupture, the patient's blood pressure may drop and signs of shock may be present. Immediate surgery is needed for a ruptured AAA. The mortality rate is high with a ruptured aneurysm.

Diagnostic Tests

Computed tomography (CT) and ultrasound are the most common diagnostic tools used to confirm the presence of an aneurysm. Small aneurysms may be watched over time to see if they enlarge. Aortography can be performed when surgical intervention is considered to identify the size and exact location of the aneurysm.

Medical Treatment

Medical treatment consists of medication to maintain lower blood pressures because patients with aneurysms often have hypertension. If the blood pressure is allowed to get too high, it can cause the arterial wall to rupture. Surgical treatment—a bypass graft—is performed when the patient is experiencing pain or showing signs of circulatory compromise. An aneurysm that is larger than 5 cm requires surgery. The risk of rupture is greatest when the aneurysm reaches 5 cm or greater.

A conventional open surgical repair or newer endovascular grafting may be done for an AAA. Endovascular grafting involves the transluminal placement (through the femoral artery) and attachment of a sutureless aortic endograft or stent-graft prosthesis at the site of the AAA. In the endograft procedure a balloon catheter positions and opens the graft. The graft remains attached to the inner wall of the aorta when the catheter is withdrawn. Blood flow continues through the aorta, bypassing the aneurysm. Another method uses a stent-graft that opens to fit the diameter of the aorta to reduce pressure on the aneurysm. Endovascular surgery requires less hospitalization time and a quicker recovery.

Nursing Care

Careful monitoring of those with an AAA is necessary. Patients must understand their medications and the importance of taking antihypertensives as prescribed. Stress may be a risk factor that should be addressed. Lifting heavy objects can increase pressure within the artery and may be restricted even in the individual being treated with more conservative measures. Postoperatively, the patient should avoid lifting heavy objects (Home Health Hints).

► RAYNAUD'S DISEASE

A vasoconstrictive response causing ischemia from exposure to cold and stress is known as Raynaud's disease. It occurs more often in women who live in cold climates. Raynaud's primarily affects the hands but can also occur in the

HOME HEALTH HINTS

Cardiac

- When a patient reports cardiac symptoms, the nurse should ask about possible precipitating factors, such as emotional stress, alcohol or drug abuse, or if a hot bath was taken.
- The elderly patient does not usually describe angina as pain but may say it feels like pressure, or burning, or a butterfly. Ask what the patient was doing when the angina began, such as yard work, eating, receiving emotional news, or engaging in sexual activity. Symptoms of accompanying nausea or sweating are common with an MI.
- Post-MI patients usually come home with a schedule of graduated activities. Review them with the patient and caregivers and post it in the home.
- Encourage the caregiver to walk with the patient outdoors when the weather is nice, avoiding extreme cold or heat. Caution them to avoid uneven sidewalks or areas with no sidewalks.
- When a patient is enrolled in a formal cardiac rehabilitation program, be sure to reinforce the exercises within the formal guidelines, incorporating them into the home health care plan. The nurse should inspect the layout of the house to identify those areas or the daily activities of the patient that cause more exertion than the patient realizes. Examples are the number of steps or stairs inside and outside and the amount of reaching, pulling, or pushing that the patient actually does.
- It may be appropriate to have a home health social worker visit a post-MI or postsurgical cardiac patient and provide input into the plan of care (anxiety and environmental stress reduction, relaxation techniques).
- When assessing the patient and the medication record, ask if the patient has regular bowel movements without straining. Reinforce

that straining should be avoided. Ask the physician to prescribe a stool softener or laxative as needed.

Vascular

- When a patient wears elastic compression stockings and the home health nurse has to check the appearance of the lower extremities, the patient should lie down to help remove them. The stockings should be put back on while the patient is still lying down.
- Remind the patient to put the elastic stockings on before getting out of bed in the morning when edema is decreased and to leave the stockings on all day.
- Compression stockings should be discarded when they become too easy to put on. Because they are expensive, many patients keep them even after they are ineffective.
- Instruct the home health patient on these easy exercises to enhance venous return: going up and down on toes when standing and pedaling (like using car brake and gas pedals) when sitting.
- Teach patients with varicose veins not to jump, lift weights, wear high heels, or use hot tubs. Legs should be elevated on a regular basis.
- When assessing edema of a bedridden patient, check all dependent areas, especially the sacral area.
- Remember that if a patient goes to bed with lower leg edema, that fluid returns to the circulatory system and eventually to the kidneys, requiring extra trips to the bathroom during the night. Have patients with edema recline for 30 minutes before bed and then void before going to bed. They will then have less interrupted sleep during the night.

feet, ears, or nose. To be diagnosed with Raynaud's disease, the patient must experience intermittent attacks of ischemia for at least 2 years.

Pathophysiology

Raynaud's disease is characterized by spasms of small arteries in the digits. These spasms prevent arterial blood from perfusing the fingertips and sometimes the toes. The spasms can occur unilaterally and in one or two digits, but most often they occur bilaterally and in all digits.

Signs and Symptoms

The hands, when exposed to cold, exhibit vascular spasms and a marked decrease in blood flow to the tissues. The resulting effect in the tissues is ischemic pain. After several minutes of ischemia, hyperemia occurs. Hyperemia is intense reddening of the hands from dilation of all the vessels of the hands. Pain becomes more intense at this time. Patients with Raynaud's disease goes through phases of

blanching of the skin, pain, and reddening of the skin. This disease can progress over time; the vessels remain constricted and the severe decrease in blood flow can lead to fingers becoming gangrenous and necrotic.

Medical Treatment

Conservative treatment is attempted first. The patient is instructed to keep the hands warm. Gloves should be worn when going outside, cleaning a refrigerator, or preparing cold foods. Patients are instructed in the importance of protecting the hands from injury and avoiding things that contribute to vasoconstriction, such as smoking, alcohol, and caffeine. Reducing stress levels can also help prevent vasoconstriction. Vasodilators are sometimes prescribed to help the patient avoid peripheral vasoconstriction. Low doses of nifedipine or long-acting nitrates can be used.

To treat Raynaud's disease surgically, the sympathetic reflex must be blocked. This is accomplished by interrupting the sympathetic nerve impulses from the spinal cord to the hand, which is known as sympathectomy.

Nursing Care

Education is the primary goal for patients with Raynaud's disease. Teaching the patient to protect the hands is very important. Stressing the use of gloves in cold climates, reducing vasoconstrictive activity, and decreasing stress levels helps reduce the number and severity of attacks.

▶ THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

Buerger's disease is a recurring inflammation of small and medium arteries and veins of the lower extremities. The disease is usually the result of occlusion of the vessels by thrombus formation. The cause is unknown, but heavy cigarette smoking is a major contributing factor. Some studies indicate an autoimmune response to tobacco products as a possible cause.

The inflammation and irritation of the vessels contribute to the development of vasospasms. These vasospasms lead to an obstruction in blood flow. The tissues become hypoxic, and the development of ischemic pain can occur. This ischemia, left untreated, can lead to ulceration and gangrene.

Intermittent claudication and other symptoms of occlusive disease are common in patients with Buerger's disease. Other symptoms include numbness or decreased sensation and cool extremities. Lower extremities can be red or cyanotic when in a dependent position, and pulses may be diminished. Depending on the degree of ischemia, ulceration or gangrene may be present.

Because the primary contributing factor is smoking, there is an urgency in helping the patient to cease smoking. The patient must be made aware of the effect smoking has on the body and that the disease will progress and further damage other vessels. Therapy and nursing care for Buerger's disease is the same as those used for other arterial occlusive diseases. The use of calcium channel blockers such as diltiazem (Cardizem) promotes vasodilation and may help with intermittent claudication. Careful inspection of the lower extremities for signs of breakdown is important, so early treatment can begin.

▶ VARICOSE VEINS

Varicose veins are elongated, tortuous, dilated veins. The exact cause is unknown. Varicose veins are divided into primary and secondary varicosities.

Pathophysiology

Primary varicosities are believed to be caused by a structural defect in the vessel wall. Along with the defect, the dilation of the vessel can lead to incompetent venous valves. The valves help prevent blood from refluxing. If reflux occurs, it can cause further dilation of the vessel. The superficial veins are the vessels most often involved in primary varicosities.

Secondary varicosities are caused by an acquired or congenital pathological condition of the deep venous system. This produces dilation of collateral and superficial veins. As a result, there is an interference of blood return to the heart,

which leads to stasis, or pooling, of the blood in the deep venous system. This increases the pressure within the system, pushing blood into the collateral vessels and producing varicosities in the superficial veins.

Causes

A number of factors can lead to varicose veins. The wall defects have been identified as a familial tendency and may be inherited. Any factor that may contribute to increasing hydrostatic pressure within the leg, such as prolonged standing, pregnancy, and obesity, may promote venous dilation. Incompetent valves within the veins can cause blockage of blood flow and lead to dilated veins.

Signs and Symptoms

The most common manifestation is the disfigurement of the lower extremity with primary varicosities. There may be dull pain, especially after prolonged standing. This usually can be relieved by walking or elevating the extremity. With secondary varicosities, the pain and disfigurement may be more severe. There can be development of edema or ulceration if circulation is severely compromised.

Medical Treatment and Nursing Care

The primary goals are to improve circulation, relieve pain, and avoid complications. Treatment is usually not indicated if the problem is only cosmetic. Conservative treatment is geared to reduction of factors that contribute to varicose veins. Patients are taught the importance of assessing peripheral circulation and avoiding trauma to the lower extremities. Weight reduction, elevation of the extremities, walking, and exercise help increase muscle strength and contraction. Tight-fitting clothes at tops of legs or waist should not be worn. Wearing support hose assists in blood flow return to the heart. Elastic compression stockings should be used as ordered. (See Home Health Hints.) Injection sclerotherapy is used to treat superficial varicosities. Surgical intervention involves stripping the vein to remove incompetent valves. Surgery is performed when venous insufficiency cannot be controlled or prevented with conservative treatment.

▶ VENOUS INSUFFICIENCY

Venous insufficiency is a chronic condition. Damaged or aging valves within the veins interfere with blood return to the heart, causing pooling of blood in the lower extremities.

Venous Stasis Ulcers

Venous stasis ulcers are the end result of chronic venous insufficiency. Dysfunctional valves in the venous system prevent or reduce venous blood return. As venous pressure increases, venous stasis occurs. Over time the congestion and decreased venous circulation lead to changes in the lower extremities. There may be edema and a brownish discoloration of the leg and foot, with the surrounding skin hardened and leathery in appearance. The brown color occurs when veins rupture, releasing red blood cells into the tissues; the red blood cells then break down and stain the tissue brown.

Stasis ulcers develop from the increased pressure and rupture of small veins. Signs of skin breakdown are most commonly seen at the medial malleolus of the ankle. Stasis ulcers are a serious complication of venous insufficiency that are difficult to cure and can affect the patient's quality of life.

Medical Treatment

The focus of treatment is to decrease edema and heal the skin ulcerations. Compression wraps such as elastic stockings or bandage wraps are necessary to decrease edema. Elastic wraps should be started at the foot, with greater tension applied there, and wrapped up the leg. Rewrapping the elastic bandage twice a day is necessary. It is important to ensure that the wraps are not too tight at the top, which prevents return of blood to the heart.

Bedrest and elevation of legs and feet above the heart are important to assist with drainage of lower extremities. Patients are advised not to keep legs dependent and to avoid long periods of standing or sitting. The foot of the bed should be elevated 5 to 6 inches. Additionally, patients should be encouraged to exercise and walk often during nonacute episodes. Patients should be taught not to cross their legs or wear constrictive clothing that would decrease venous blood return to the heart.

Skin ulcers are usually cultured and treated with topical antibiotics if needed. Wound care can be chronic and challenging. (See Chapter 51.) An Unna boot, which is a gauze dressing coated with zinc oxide, calamine, and glycerin, may be used to promote healing in severe ulcers. Zinc promotes wound healing and can be soothing. The Unna boot is applied snugly and provides compression therapy as well. It is changed every 2 to 7 days. Skin grafting may be necessary if ulcerations are severe or do not heal.

Nursing Interventions

The patient's leg is protected from injury. Heating devices are avoided because of decreased sensitivity. The patient is

taught treatment measures to reduce edema and pain. Emotional support is provided to patients with chronic ulcers that affect quality of life and require ongoing wound care.

► LYMPHATIC SYSTEM

The lymphatic system returns fluid from other tissues in the body to the bloodstream. It is a pumpless system with one-way valves that return the fluid to the heart. Any interruption in the flow of lymph results in edema.

Lymphangitis

Lymphangitis is an inflammation of the lymphatic channels. The infection can occur in the arms or legs and is commonly caused by *Staphylococcus* or *Streptococcus* bacteria.

Signs and Symptoms

Symptoms include pain at the site of the infected area, which may appear reddish. There may also be a red streak that follows the lymphatic channel. The patient may experience chills and fever. Lymph nodes in the area of infection can be enlarged and painful.

Medical Treatment

Medical therapy is initiated with a broad-spectrum antibiotic as the drug of choice. The use of heat on the extremity, as well as elevating it, can help improve circulation. Physicians may order the use of pneumatic pressure devices to help alleviate congestion.

Nursing Care

Frequent assessment and meticulous wound care, if needed, are performed. The nurse monitors the size of the extremity and notifies the physician of any increase in size or possible spread of infection.

REVIEW QUESTIONS

1. Which of the following is a risk factor that can be controlled to prevent the development of cardiovascular disease?
 - a. Family history of cardiovascular disease
 - b. Hypertension
 - c. Ethnicity
 - d. Family history of diabetes mellitus
2. The nurse is assessing a long-term care resident, 84 years old, who is not feeling well. Which of your assessment findings is an atypical symptom of a myocardial infarction when chest pain is not present?
 - a. Shortness of breath
 - b. Chest pain
 - c. Sweating
 - d. Nausea

3. You are scheduled to give a patient who had a myocardial infarction aspirin, 5 gr PO, now. How many milligrams of aspirin will you give?
 - a. 5 mg
 - b. 60 mg
 - c. 150 mg
 - d. 300 mg
4. Which one of the following is a classic symptom of peripheral arterial occlusive disease?
 - a. Angina
 - b. Edema
 - c. Intermittent claudication
 - d. Stasis ulcers
5. The nurse is caring for a patient, 64, who has had an MI and has peripheral arterial disease. Which of the following statements by the patient indicates understanding of how to manage the pain of peripheral arterial disease?
 - a. "I will lie down frequently."
 - b. "I will use a reclining chair."
 - c. "I will sit with my legs down."
 - d. "I will do knee flexion exercises."

Answers to CRITICAL THINKING

Mrs. Sims

1. Place on bedrest, administer oxygen via nasal cannula at 2 L per minute, assess blood pressure and pulse, administer nitroglycerin sublingual as ordered, obtain ECG, and notify physician.
2. She may be having an anginal attack versus acute MI.
3. Nitroglycerin usually stops chest pain associated with angina. Rest may also alleviate chest pain. Neither nitroglycerin nor rest will relieve the pain of an acute MI.
4. Indicators of an MI include patient history, ECG changes with ST segment elevation, elevated troponin I, and CK-MB elevation.
5. Medical interventions include nitroglycerin drip, morphine, anticoagulant therapy (heparin), and thrombolytic agents to dissolve the clot. A cardiac catheterization can determine which coronary artery is blocked. Angioplasty or a coronary artery bypass graft may be done to reroute blood.
6. Educate Mrs. Sims about the risks of smoking and being overweight.
3. The patient's symptoms could be caused by an embolism above left femoral artery.
4. To document finding, you would obtain more assessment data. A sample of SOAP charting for your additional findings is given:
S: "I have a severe pain in my left groin that just started. It is at 9."
O: Grimacing, moaning, and holding left upper leg. Left leg cool, color pale, nailbeds pale, capillary refill 10 seconds, unable to palpate pulses. Faint femoral and popliteal pulse, no dorsalis pedis or posterior tibial pulse heard with Doppler. Right leg warm, pink, capillary refill 3 seconds, with all pulses palpable.
A: Ineffective tissue perfusion
P: Notify physician stat.

Mrs. May

1. Assess the patient's left leg for color, temperature, capillary refill, and pulses: femoral, popliteal, dorsalis pedis, and posterior tibial. Compare findings with findings in the right leg.
2. If unable to palpate pulses, use a Doppler ultrasound that enhances sound to locate pulses.
5. Immediate interventions include complete bedrest, protecting the leg, and notifying the physician.
6. Medical interventions could include medication for pain and use of an anticoagulant, such as heparin. If no pulses are present, a thrombolytic agent, such as streptokinase or tissue plasminogen activator, which dissolves already formed clots, may be ordered. Surgery is possible.
7. Thrombolectomy or embolectomy may be necessary to save the limb.

QUESTIONS TO GUIDE YOUR READING

1. What are the pathophysiology, etiology, signs and symptoms, and diagnostic tests for mitral valve prolapse?
2. What are the pathophysiology, etiology, signs and symptoms, and diagnostic tests for mitral valve stenosis?
3. What are the pathophysiology, etiology, signs and symptoms, and diagnostic tests for mitral valve regurgitation?
4. What are the pathophysiology, etiology, signs and symptoms, and diagnostic tests for aortic valve stenosis?
5. What are the pathophysiology, etiology, signs and symptoms, and diagnostic tests for aortic valve regurgitation?
6. Why are prophylactic antibiotics prescribed for some patients with valvular disorders?
7. What nonsurgical and surgical procedures are used to treat valvular disorders?
8. What nursing care would you provide for a patient with a valvular disorder?

In the normal heart, blood flows in one direction because of the presence of heart valves. There are four valves in the heart: mitral, tricuspid, pulmonic, and aortic (see Fig. 15–2). The chordae tendineae and papillary muscles are attachment structures for both the mitral and tricuspid valves. They ensure that the valves close tightly. The pulmonic and aortic valves do not have these attachment structures.

Damage to the valves or their surrounding structures can result in abnormal valvular functioning (Fig. 19–1). The valves of the left side of the heart are most commonly affected and are discussed in this chapter. Forward blood flow can be hindered if the valve is narrowed, or stenosed, and does not open completely. If the valve does not close com-

pletely, blood backs up, which is referred to as **regurgitation** or insufficiency. The abnormal blood flow increases the workload of the heart and increases the pressures in the affected heart chamber.

Valvular damage may occur from congenital defects, rheumatic fever, or infections. Congenital defects occur mainly in children, and rheumatic heart disease occurs mainly in adults. Prophylactic antibiotic therapy helps prevent rheumatic fever and subsequent rheumatic heart disease and is recommended to prevent valvular disease.

regurgitation: re—again + gurgitare—to flood

Figure 19-1 Openings of stenosed and insufficient valves compared with a normal valve.

LEARNING TIPS

The opening of a stenosed valve and an insufficient valve look very similar, and the results of extra blood building up in a chamber are the same (see Fig. 19–1). However, the problem is different. Remember what the defect is in each disorder to understand why the blood is building up in a chamber.

A valve that does not open fully (stenosed) does not allow a chamber to empty normally. Blood builds up in that chamber as a result. For example, mitral **stenosis** does not allow the left atrium to empty easily, so blood builds up in the left atrium.

A valve that does not close fully (insufficient) allows blood to flow back into the chamber that emptied. Blood builds up in that chamber as a result. For example, mitral **insufficiency** allows blood to backflow from the left ventricle into the left atrium after the left atrium has emptied, so blood builds up in the left atrium.

▶ VALVULAR DISORDERS

Mitral Valve Prolapse

Pathophysiology

During ventricular systole, when pressure in the left ventricle rises, the flaps of the mitral valve normally remain closed and stay within the atrioventricular junction. In mitral valve prolapse (MVP), however, one or both flaps bulge backward into the left atrium during systole. This is due to one flap being too large or a defect in the chordae tendineae that secures the valve to the heart wall. If the bulging flaps do not fit together, mitral regurgitation can occur with varying degrees of severity.

Etiology

MVP tends to be hereditary, although the cause is unknown. Infections that damage the mitral valve may be a contributing factor. It is the most common form of valvular

heart disease and typically occurs in women 20 to 55 years of age who are thin and have slight chest deformities.

Signs and Symptoms

Most patients with MVP do not have symptoms. If symptoms do occur, they may include chest pain, dysrhythmias, palpitations, fatigue, dyspnea, anxiety, dizziness, or syncope.

Diagnostic Tests

Auscultation for a click or **murmur** is the first diagnostic step for MVP. Several other diagnostic tests can be used when MVP is suspected (Box 19–1). A normal electrocardiogram (ECG) is usually seen with MVP. A two-dimensional or Doppler echocardiogram that shows valve abnormalities is the best noninvasive test to detect MVP. For more severe cases, a cardiac catheterization can show the bulging flaps of the mitral valve on coronary angiogram.

Medical Treatment

Unless patients have severe mitral regurgitation, MVP is a benign disorder. No treatment is needed unless symptoms are present (Box 19–2). The severity of MVP and symptoms produced determine the treatment used. A healthy lifestyle, including a good diet, exercise, and avoidance of stimulants and caffeine, is important to prevent symptoms. Stress management may reduce the occurrence of symptoms. Beta blockers may be helpful for those with rapid heart rates to reduce the heart rate and the stress placed on the mitral

 Surgical
 Valvuloplasty
 Closed commissurotomy
 Open commissurotomy
 Annuloplasty
 Valve replacement

valve. Surgical repair or replacement of the valve can be done for severe cases of MVP.

Complications

Rare complications include dilation of the left side of the heart, heart failure, bacterial endocarditis, and emboli. Preventive antibiotic therapy before invasive procedures may be needed for some patients with thickened mitral valves to prevent endocarditis.¹ Aspirin or anticoagulants may be ordered to help prevent emboli.

CRITICAL THINKING**Sue Tepley**

Sue Tepley, 32, has mitral valve prolapse and reports palpitations whenever she experiences stress. She drinks three cups of coffee daily. Today she is admitted for an outpatient cystoscopy.

1. What might you hear when auscultating Sue's heart sounds?
2. Why does Sue experience palpitations?
3. What medication might you expect to be ordered preoperatively for Sue?
4. Why does Sue need to be informed that she may need prophylactic antibiotics before invasive procedures?
5. What other information does Sue need to manage her MVP?

Answers at end of chapter.

Mitral Stenosis Pathophysiology

Mitral stenosis results from thickening of the mitral valve flaps and shortening of the chordae tendineae, causing narrowing of the valve opening. Older patients with mitral stenosis usually have calcification and fibrosis of the mitral valve flaps. The narrowed opening obstructs blood flow from the left atrium into the left ventricle. The left atrium enlarges to hold the extra blood volume caused by the obstruction. As a result of this increased blood volume, pressure rises in the left atrium. Pressures then rise in the pulmonary circulation and the right ventricle as blood volume

backs up from the left atrium. The right ventricle dilates to handle the increased volume. Eventually the right ventricle fails from this excessive workload, reducing the blood volume delivered to the left ventricle and subsequently decreasing cardiac output.

Etiology

The major cause of mitral stenosis is rheumatic fever, with symptoms often taking two to four decades to appear after the illness. It is a continuous and progressive disease. Less common causes include congenital defects of the mitral valve, tumors, rheumatoid arthritis, systemic lupus erythematosus, calcium deposits, and rheumatic endocarditis.

Signs and Symptoms

At first, patients may be asymptomatic. A click or low-pitched murmur may be heard. Then mild symptoms progressing to more severe symptoms develop. Pulmonary symptoms are most commonly seen. Dyspnea, cough, and hemoptysis from pulmonary congestion are the major symptoms. Fatigue and intolerance to activity result from decreased cardiac output. Palpitations from atrial flutter or fibrillation caused by atrial enlargement and chest pain from decreased cardiac output may be experienced. Complications from emboli formed from the stasis of blood in the left atrium include stroke and seizures. If the right ventricle fails, symptoms related to heart failure are seen. (See Chapter 21.)

Diagnostic Tests

Mitral stenosis is diagnosed with data from the patient history and physical examination and findings from diagnostic tests. (See Box 19-1.) The ECG shows enlargement of the left atrium and right ventricle and changes in the P waveform. Atrial flutter or fibrillation may be seen. A chest x-ray examination confirms enlargement of the affected heart chambers. Two-dimensional and Doppler echocardiography are becoming the noninvasive gold standard for evaluation of valvular disease. They show the narrowed mitral valve opening and decreased motion of the valve. Cardiac catheterization, an invasive test, measures the pressures in the heart chambers and pulmonary vessels, as well as cardiac output. Elevated pressures and a reduced cardiac output are found. Angiography during the catheterization reveals the severity of the stenosis.

Medical Treatment

Individualized prophylactic antibiotic therapy may be given to prevent endocarditis.¹ Anticoagulants are given to patients with atrial fibrillation to prevent development of emboli from stasis of blood in the atrium. If heart failure develops, symptoms are treated with medications such as digitalis and diuretics and other therapies used for heart failure. (See Chapter 21.)

For less severe cases, percutaneous balloon **valvuloplasty**, which uses a balloon to dilate the stenosed heart valve, is done in a cardiac catheterization laboratory (Fig. 19-2). One approach for valvoplasty is to insert a balloon

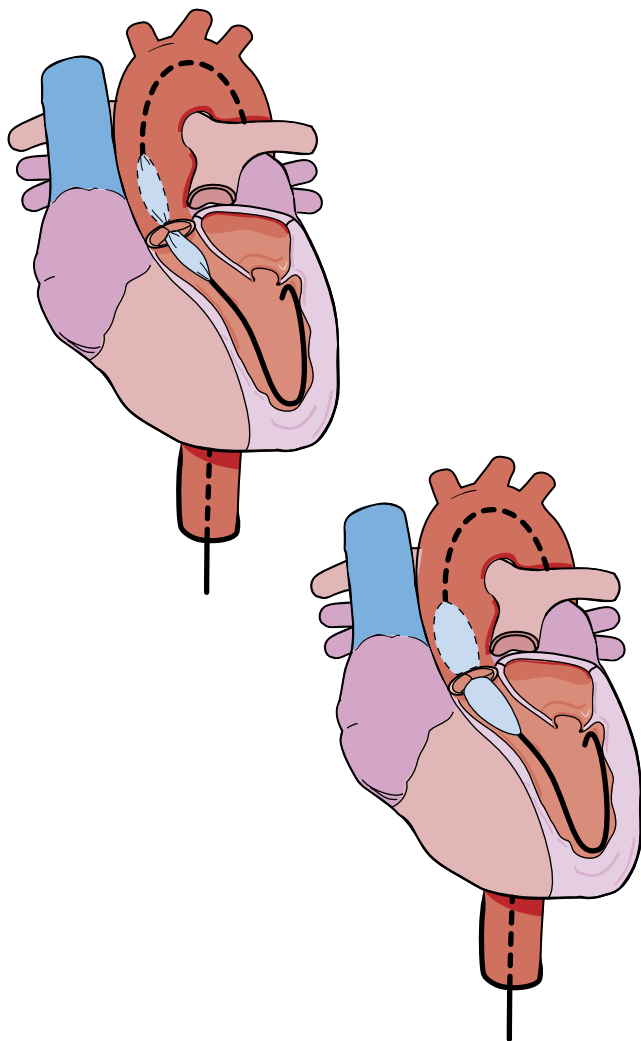

Figure 19-2 Percutaneous balloon valvuloplasty.

catheter via the venous circulation into the right atrium. Then the catheter is threaded through a small hole pierced in the atrial septum into the left atrium through the mitral valve. Inflation of the balloon opens the stenosed valve flaps. Complications may include dysrhythmias, emboli, hemorrhage, and cardiac tamponade. There are fewer complications with balloon valvuloplasty than with surgery.

Surgical treatment can include **commissurotomy** or **annuloplasty**, both forms of valvular repair (valvuloplasty) or valve replacement. Mitral valve replacement is used for more severe cases and when symptoms of ventricular failure develop. These procedures may require the use of cardiopulmonary bypass. In commissurotomy the valve flaps that have adhered to each other and closed the opening between them, known as the commissure, are separated to enlarge the valve opening. Annuloplasty is the repair or reconstruction of the valve flaps or annulus. It may involve the use of prosthetic rings. Valve replacement with prosthetic valves has

commissurotomy: commissura—joining together + tome—incision

annuloplasty: annulus—ring + plasty—formed

been done since 1952. Valve replacement uses mechanical or biologic valves from animal or human tissue (Fig. 19-3). Valvular surgery is discussed in Chapter 22.

Mitral Regurgitation

Pathophysiology

Mitral regurgitation, or insufficiency, is the incomplete closure of the mitral valve. It allows some backflow of blood into the left atrium with each contraction of the left ventricle. Factors that prevent the mitral valve flaps from fitting together tightly may include tearing, shortening or rigidity of a flap, or shortening of the chordae tendineae.

When the mitral valve does not close completely, backflow of blood into the left atrium occurs. This blood is then extra volume that is added to the incoming blood from the lungs. With chronic mitral regurgitation, the increase in blood volume dilates and increases pressure in the left atrium. In response to the extra blood volume delivered by the left atrium, the left ventricle compensates by dilating. If the compensatory mechanism of dilation is inadequate, pressures rise in the pulmonary circulation and then in the right ventricle as blood volume backs up from the left atrium. The left ventricle and eventually the right ventricle may fail from this increased strain.

Etiology

The major cause of mitral regurgitation is rheumatic heart disease. Other causes include endocarditis, rupture or dysfunction of the chordae tendineae or papillary muscle, MVP, or congenital defects.

Figure 19-3 Valve prosthesis. An SJM Masters Series valve. (Courtesy St. Jude Medical, Inc., St. Paul, Minn.)

Signs and Symptoms

Initially patients may be asymptomatic. The symptoms of chronic mitral regurgitation are similar to those of mitral stenosis. Dyspnea and cough occur from increased pulmonary congestion. Palpitations and an irregular pulse from atrial fibrillation may result. Weakness and fatigue from decreased cardiac output occur if the left ventricle begins to fail.

If acute mitral regurgitation develops, such as in papillary muscle rupture following myocardial infarction, pulmonary edema and shock symptoms will be exhibited.

Diagnostic Tests

The ECG shows enlargement of the left atrium and left ventricle and changes in the P waveform. Atrial flutter or fibrillation may be seen. A chest x-ray examination confirms hypertrophy of the affected heart chambers. Two-dimensional or Doppler echocardiography shows left atrial enlargement and regurgitation of blood. Cardiac catheterization with dye also shows regurgitation.

Medical Treatment

Without symptoms, there is no general medical treatment. Prophylactic antibiotic therapy may be given to prevent infectious endocarditis before invasive procedures.¹ If atrial fibrillation with rapid heart rate is present, it can be controlled with digitalis, calcium channel blockers, or beta blockers. Emboli occur less frequently, but anticoagulation is still prescribed. Symptoms of heart failure are treated with therapies for heart failure. (See Chapter 21.) When symptoms develop, surgical treatment includes mitral valve repair or replacement (Fig. 19-4).

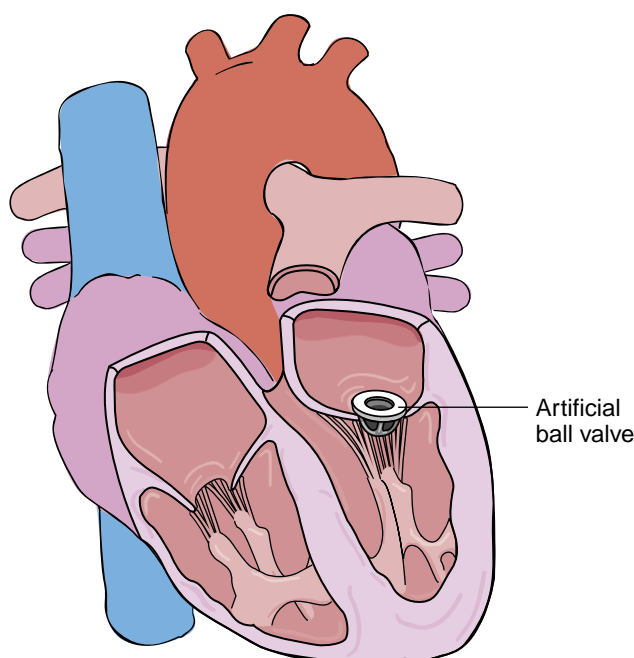

Figure 19-4 Mitral valve replacement with ball valve prosthesis.

Aortic Stenosis Pathophysiology

Blood flow from the left ventricle into the aorta is obstructed through the stenosed aortic valve. The opening of the aortic valve may be narrowed from thickening, scarring, calcification, or fusing of the valve's flaps. To compensate for the difficulty in ejecting blood into the aorta, the left ventricle contracts more forcefully. In chronic stenosis the left ventricle hypertrophies to maintain normal cardiac output. With increased narrowing of the valve opening, the compensatory mechanisms are unable to continue and the left ventricle fails to move blood forward. This results in decreased cardiac output and heart failure.

Etiology

The major causes of aortic stenosis are congenital defects or rheumatic heart disease. Mitral valve stenosis is often also present when the cause is rheumatic heart disease. Calcification of the aortic valve can be related to aging and is seen more with an increase in the elderly population.

Signs and Symptoms

It may take many years or decades before signs or symptoms of aortic stenosis are observed. When symptoms do occur, evaluation is essential because the disease can progress dramatically. If the mitral valve is diseased, signs and symptoms may appear earlier, allowing the detection of aortic stenosis.

Angina pectoris is a primary symptom that occurs as a result of the increased oxygen needs of the hypertrophied myocardium. The extra workload of the left ventricle and the hypertrophy of the cardiac muscle require more oxygen. Angina results if these oxygen needs are not met. In the young patient, angina indicates severe obstruction.

Other signs and symptoms include a murmur, syncope from dysrhythmias or decreased cardiac output, and heart failure signs and symptoms. Orthopnea, dyspnea on exertion, and fatigue are indicators of left ventricular failure. Progressive heart failure can result in pulmonary edema and right-sided heart failure.

Diagnostic Tests

ECG shows enlargement of the left ventricle and left atrium. A chest x-ray examination confirms hypertrophy of the left ventricle. Left atrial enlargement may be seen but occurs primarily when mitral stenosis is also present. Two-dimensional and Doppler echocardiography show thickening of the left ventricular wall, impaired movement of the aortic valve, and the severity of the disease. Serial echocardiography (e.g., annually or less often), may be recommended for those with moderate or severe disease. Cardiac catheterization will show elevated left ventricular pressure and decreased cardiac output.

Medical Treatment

Generally the treatment of choice is valve replacement because of the risk of sudden death when severe symptoms are present. Valvotomy may be considered for young adults. Pro-

phylactic antibiotics are considered before invasive procedures.¹ Heart failure symptoms are treated carefully. Medications that reduce the contractility of the heart and subsequently cardiac output are avoided to prevent further failure.

CRITICAL THINKING

Mrs. Hesche
Mrs. Hesche, 72, has aortic stenosis and is admitted to the hospital with angina. She had an episode of syncope 2 days ago. She reports that she tires easily.

1. Mrs. Hesche asks what aortic stenosis is. What will you tell her and how will you document it?
2. Why might Mrs. Hesche be experiencing angina?
3. What nursing care related to safety needs are important to include in Mrs. Hesche's plan of care?
4. What nursing diagnosis and care are relevant for Mrs. Hesche's report of being tired?
5. Digoxin (Lanoxin) 0.25 mg is prescribed for Mrs. Hesche. It is time to give her digoxin and you have available digoxin 0.125 mg tablets. How many tablets will you give?

Answers at end of chapter.

Aortic Regurgitation

Pathophysiology

The aortic valve cusps may be scarred, thickened, or shortened in chronic aortic regurgitation. A backflow of blood from the aorta into the left ventricle occurs if the aortic valve cusps do not close completely. The left ventricle's blood volume increases with this backflow of blood that is in addition to the normal flow of blood from the left atrium. To handle the increased volume, the left ventricle compensates with dilation and hypertrophy to deliver a stronger contraction. This stronger contraction ejects more blood volume with each beat to maintain cardiac output. Over time the heart's contraction is not effective and the left ventricle fails, causing a cardiac output drop and pulmonary edema.

Etiology

Rheumatic heart disease is the usual cause of aortic regurgitation. Other causes include congenital defects, syphilis, endocarditis, severe hypertension, and rheumatoid arthritis. An acute cause of aortic regurgitation is aortic dissection.

Signs and Symptoms

Exertional dyspnea and fatigue are the first symptoms of chronic aortic regurgitation. They appear after years of progressive valvular dysfunction. The patient may report feeling a forceful heartbeat. The palpated pulse is forceful and then quickly collapses (Corrigan's pulse). The diastolic blood pressure decreases to widen the pulse pressure. This compensates for an increase in systolic blood pressure. Angina pectoris may occur late. The angina is atypical, often happening at night, when a lower pulse rate results in delivery of less oxygen to the myocardium. Eventually heart failure symptoms develop if the left ventricle fails.

In acute dysfunction, profound symptoms of pulmonary distress, chest pain, and shock symptoms occur. The prognosis is poor.

Diagnostic Tests

The ECG shows left ventricle hypertrophy. A chest x-ray examination confirms hypertrophy of the left ventricle and aorta. With severe regurgitation, left atrial enlargement may be seen. An echocardiogram shows an enlarged left ventricle. Cardiac catheterization reveals elevated left ventricular diastolic pressure and, with dye injection, shows the regurgitation of blood into the left ventricle.

Medical Treatment

Vasodilator therapy such as nifedipine may be useful for some patients to reduce systolic blood pressure and subsequently cardiac workload. Prophylactic antibiotic therapy may be given before invasive procedures.¹ Surgical valve replacement is the treatment of choice for most patients, especially if symptoms or left ventricular dysfunction are present. (See Box 19–2.)

Nursing Process for Valvular Disorders

Nursing Assessment

A history that includes information presented in Table 19–1 is obtained. Vital signs are measured and recorded. Heart sounds are auscultated to detect murmurs. Any signs and symptoms of heart failure are noted. (See Chapter 21.)

Nursing Diagnoses

The major nursing diagnoses for all valvular disorders are the same and include those for heart failure as well if heart failure symptoms are present. (See Nursing Care Plan Box 19–3 for the Patient with Cardiac Valvular Disorders.) The diagnoses may include but are not limited to the following:

- Pain related to reduced coronary artery blood flow and increased myocardial oxygen needs
- Decreased cardiac output related to valvular stenosis or insufficiency or heart failure
- Activity intolerance related to decreased oxygen delivery from decreased cardiac output
- Excess fluid volume related to heart failure and the secondary reduction in renal blood flow for filtration
- Ineffective therapeutic regimen management related to lack of knowledge about disorder

Planning

The patient and family should be included in planning care. The patient's goals include the following:

- Report that the pain management regimen relieves pain.
- Maintain vital signs and oxygen saturation within normal range.
- Maintain desired activities.
- Remain free of edema and maintain clear lung sounds.
- Understand the disease and its treatment.

TABLE 19-1 NURSING ASSESSMENT FOR PATIENTS WITH CARDIAC VALVULAR DISORDERS

Subjective Data	
<i>Health history</i>	Infections—rheumatic fever, endocarditis, streptococcal or staphylococcal, syphilis Congenital defects Cardiac disease—myocardial infarction, cardiomyopathy
<i>Respiratory</i>	Dyspnea at rest, on exertion, when lying, or that awakens patient? Cough or hemoptysis?
<i>Cardiovascular Medications</i> <i>Knowledge of condition</i> <i>Coping skills</i>	Any palpitations, chest pain, dizziness, fatigue, activity intolerance?
Objective Data	
<i>Respiratory</i>	Crackles, wheezes, tachypnea
<i>Cardiovascular</i>	Murmurs, extra heart sounds, dysrhythmias, edema, jugular vein distention, Corrigan's pulse, increased or decreased pulse pressure
<i>Integumentary</i> <i>Diagnostic test findings</i>	Clubbing; cyanosis; diaphoresis; cold, clammy skin; pallor

BOX 19-3 NURSING CARE PLAN FOR THE PATIENT WITH CARDIAC VALVULAR DISORDERS **Decreased cardiac output related to valvular stenosis or insufficiency or heart failure****PATIENT OUTCOMES**

Patient has adequate cardiac output as evidenced by vital signs within normal limits (WNL), no dyspnea or fatigue.

EVALUATION OF OUTCOMES

Does patient have vital signs WNL with no dyspnea or fatigue?

INTERVENTIONS

Assess vital signs, chest pain, and fatigue.

Give oxygen as ordered.

Provide bedrest or rest periods as ordered.

Elevate head of bed 45 degrees.

RATIONALE

Vital signs, chest pain, and fatigue are indicators of cardiac output decline.

Supplemental oxygen provides more oxygen to the heart.

Cardiac workload and oxygen needs are reduced with rest.

Venous return to heart is reduced and chest expansion improved.

EVALUATION

Are vital signs WNL with no chest pain or fatigue?

Is breathing pattern normal?

Are vital signs WNL and no fatigue reported?

Are vital signs WNL and respirations easy?

GERIATRIC

Assess for cardiac medication side effects and teach patient side effects to report.

Toxic side effects are more common due to altered metabolism and excretion of medications in the elderly.

Are side effects present for medications patient is taking?

Does patient understand side effects to report?

 **Activity intolerance related to decreased oxygen delivery from decreased cardiac output****PATIENT OUTCOMES**

Patient will show normal changes in vital signs with less fatigue in response to activity.

EVALUATION OF OUTCOMES

Does patient have normal changes in vital signs with activity? Does patient report decreased fatigue with activity?

INTERVENTIONS

Assist as needed with activities of daily living (ADLs).

Provide rest and space activities.

RATIONALE

Energy is conserved with ADL assistance.

Cardiac workload and oxygen needs are reduced with rest.

EVALUATION

Are all ADLs completed?

Are vital signs WNL with activity?

Is patient able to perform activities when allowed extra time?

GERIATRIC

Slow pace of care and allow patient extra time to perform activities.

Ensure safety when mobilizing elderly patient.

Elderly patients can often perform activities if allowed time to slowly perform them and rest at intervals.

Orthostatic hypertension is common in the elderly.

Does blood pressure remain WNL when changing position?

Does patient ambulate without injury?

Nursing Interventions

Nursing care is aimed at relieving patients' pain, maintaining patients' normal cardiac function, improving patients' ability to participate in activity, maintaining fluid balance, educating patients to understand the therapeutic management of their valvular disorder, promoting prevention techniques, monitoring symptoms, and providing preoperative and postoperative care as needed. See Nursing Care Plan Box 19–3 for the Patient with Cardiac Valvular Disorders for specific nursing interventions.

Pain management is achieved by assessing pain on an ongoing basis using a rating scale such as 0 to 10 with 10 being the most severe pain. Providing pain medication such as nitroglycerin as needed can relieve the pain. (Before nitroglycerin is given, blood pressure is checked, because nitroglycerin lowers blood pressure). Teaching the patient to pace activities with frequent rest periods can reduce the workload of the heart. This helps prevent ischemia and subsequently angina.

Maintenance of normal cardiac function includes monitoring of vital signs, intake and output, and daily weights if heart failure is present or diuretics are given. Sodium may be restricted to reduce fluid retention. Smoking cessation information is provided. Medications are given as prescribed.

Interventions that improve the quality of life include activities of daily living that reduce fatigue. Assistance as needed, frequent rest periods, and energy conservation techniques are planned. (See Chapter 21.) Exercise tolerance is assessed and daily exercise is planned according to this tolerance.

Ongoing monitoring for signs or symptoms of excess fluid volume are important to allow early detection and treatment. Daily weights provide the most accurate assessment of weight gain caused by excess fluid. The weights should be obtained at the same time of day, using the same scale and type of clothing, for accuracy. Assessment for edema, jugular vein distention, lung crackles or wheezes, dyspnea, and orthopnea should be done. Restricting sodium intake and administering diuretics as ordered assist in decreasing fluid volume excess. Monitoring intake and output is also important to detect fluid imbalances. Potassium is also monitored because some diuretics (e.g., furosemide [Lasix]) decrease potassium levels. It is important to understand that fluid volume excess develops more easily in the elderly patient and can be very serious. Therefore assessing and monitoring risk factors for fluid volume excess in the elderly patient is critical.

PATIENT EDUCATION. Education, an important nursing intervention, promotes understanding of the disorder, as well as health maintenance, prevention of complications, and early recognition of symptoms, so medical care can be sought. Teaching is provided for any medications the patient is taking. If the patient is on anticoagulants for atrial fibrillation or valve replacement, a Medic-Alert bracelet should be worn and monthly appointments to check prothrombin time and international normalized ratio (INR) values should be kept. For elderly patients it is important to include caregivers or family members in teaching sessions to assist with understanding of the information being taught.

Information on endocarditis prevention is essential for patients with most valvular problems. Damaged cardiac valves are prone to developing infection from organisms such as *Streptococcus viridans* or *Staphylococcus epidermidis*. During invasive procedures in which bleeding is possible, these organisms can enter the circulation, attach to damaged valves, and multiply. Patients should be taught the possible need for prophylactic antibiotics before invasive procedures, including dental work or surgery, to prevent endocarditis.¹ Patients should consult their physician about the need for prophylactic antibiotics.

Evaluation

The goal for the nursing diagnosis of pain is met if the patient reports satisfactory pain relief. Satisfactory pain relief is measured by comparing the patient's stated level of pain on a 0 to 10 rating scale with the patient's predetermined goal for acceptable level of pain.

The goal for the nursing diagnosis of decreased cardiac output is met if the patient's vital signs are within normal range and no symptoms of heart failure are present.

The goal for the nursing diagnosis of activity intolerance is met if the patient reports reduced fatigue and the ability to complete tasks and engage in desired activities.

The goal for the nursing diagnosis of excess fluid volume is met if the patient remains free of edema, maintains appropriate weight, maintains clear lung sounds without dyspnea, has normal vital signs, and has no evidence of neck vein distention.

The goal for the nursing diagnosis of ineffective therapeutic regimen management is met if the patient verbalizes understanding of completed teaching and does not have recurrence of symptoms.

REVIEW QUESTIONS

- The nurse is evaluating patient teaching for mitral valve prolapse. The patient shows understanding of the prognosis of MVP if she states which of the following?
 - “The prognosis is poor.”
 - “This is usually a benign condition.”
 - “Heart failure often occurs.”
 - “Symptoms begin mildly and then quickly progress.”
- The nurse is assessing a patient with aortic stenosis. Which of the following symptoms would the nurse expect a patient with aortic stenosis to report?
 - Peripheral edema
 - Angina
 - Headache
 - Weight loss
- A patient just diagnosed with aortic regurgitation asks what this means. Which of the following is the nurse’s best response for describing what occurs in aortic regurgitation?
 - “Backflow of blood into the right ventricle”
 - “Backflow of blood into the left ventricle”
 - “Impaired emptying of the right ventricle”
 - “Impaired emptying of the left ventricle”
- A patient with mitral stenosis develops atrial fibrillation. Which one of the following medications does the nurse understand is given to the patient to prevent embolitic complications from atrial fibrillation?
 - Bumetanide (Bumex)
 - Furosemide (Lasix)
 - Penicillin (Bicillin)
 - Warfarin (Coumadin)
- A patient is scheduled for cardiac valve testing. Which of the following tests would the nurse explain will show the cardiac valves and how they function?
 - ECG
 - Chest x-ray examination
 - Echocardiogram
 - Cardiac catheterization

Answers to CRITICAL THINKING

Sue Tepley

- You might hear a murmur.
- Stress and caffeine increase the occurrence of palpitations.
- Prophylactic antibiotics might be ordered preoperatively.
- She might need prophylactic antibiotics to prevent infective endocarditis, which can result from bacteria entering the circulation during invasive procedures, attaching to the damaged valve, and growing.
- To help manage her condition, Sue needs a definition of MVP, stress management techniques, to know she should reduce caffeine intake (e.g., with decaffeinated coffee), and to understand symptoms of endocarditis to report to her physician.

Mrs. Hesche

- In aortic stenosis the valve is narrowed, which makes it more difficult for blood to leave the left ventricle and go into the aorta. This means there can be less blood flow to the body.

- Documentation: Asked “What is aortic stenosis?” Listened attentively during explanation that in aortic stenosis the valve is narrowed making it more difficult for blood to leave left ventricle to go to aorta. This means there can be less blood flow to the body. Stated interested in learning more about diagnosis.
- Angina results if the heart’s oxygen needs are not met because of reduced cardiac output.
 - Nursing care should include fall precautions due to syncope and fatigue.
 - Diagnoses and care include the following: Self-care deficits related to fatigue, so plan for meeting ADL needs. Activity intolerance related to fatigue, so plan rest periods between activity and monitor vital signs with activity.
 - You should give two tablets. An example of solving this problem is:

$$\frac{\text{Desired dose: } 0.25 \text{ mg}}{\text{Dose on hand: } 0.125 \text{ mg}} = 2 \text{ tablets}$$

ventricular tachycardia (ven-**TRICK**-yoo-lar TACK-ee-**KAR**-dee-yah)

► CARDIAC CONDUCTION SYSTEM

The heart's electrical conduction system (Fig. 20-1) initiates an impulse to stimulate the cardiac muscle to contract. The conduction system's electrical activity can be viewed on a cardiac monitor or recorded on an **electrocardiogram** (ECG) tracing. The activity seen on the ECG does not mean that the heart has contracted in response to the electrical impulse. To verify that contraction occurs, the patient's vital signs and pulses are monitored.

Located in the upper posterior wall of the right atrium is the **sinoatrial (SA) node**. The SA node is the primary pacemaker of the heart. It normally fires at a rate of 60 to 100 beats per minute (bpm). As a protective mechanism if the SA node does not function properly, other areas of the heart can initiate impulses to keep the heart beating. If the SA node fails, the **atrioventricular (AV) node** initiates an impulse at 40 to 60 bpm. The rhythm produced when the AV node initiates the impulse is called a **nodal or junctional rhythm**. The body can usually function adequately with this rhythm. If the AV node is unable to initiate an impulse, then the ventricles take

over at 20 to 40 bpm. When the ventricles initiate the impulse, it is referred to as complete heart block or a **ventricular escape rhythm**. These rhythms are the heart's last attempt to compensate for loss of SA and AV node conduction. The ventricular rate of 20 to 40 bpm is not adequate to meet the body's oxygen needs, so the patient begins to show signs of inadequate cardiac output such as dyspnea, abnormal vital signs, and changes in level of consciousness. Treatment is usually necessary to reestablish a normal heart rate as soon as possible when the SA node is not functioning normally.

After the SA node fires, the impulse travels across both atria, stimulating them to contract. This is known as **atrial systole**. This atrial contraction propels blood out of the atria and into the relaxed ventricles during **ventricular diastole**. The impulse travels down the atria to the AV node where it is delayed briefly. It then travels down the **bundle of His**, which divides into right and left bundle branches. From there the impulse quickly travels through the Purkinje fibers, stimulating both ventricles to contract. This is known as **ventricular systole**.

Figure 20-2 Components of the cardiac cycle. (From Scanlon, V, and Sanders, T: *Essentials of Anatomy and Physiology*, ed 3. FA Davis, Philadelphia, p 266, with permission.)

Cardiac Cycle

To interpret rhythms, a cardiac cycle must be identified. A cardiac cycle is the period from the beginning of one heartbeat to the beginning of the next. It is the electrical representation of the impulse that stimulates contraction and then relaxation of the atria and ventricles. Within the cardiac cycle, there is a P wave, a QRS complex, and a T wave. To be considered normal, a cycle must consist of each of these components. Figure 20–2 shows the components of a cardiac cycle.

▶ ELECTROCARDIOGRAM

A cardiac monitor or ECG tracing shows the electrical activity of the heart. It is used to verify normal heart function and detect abnormal heart function. Specialized training is required to interpret ECG abnormalities; this is usually done by physicians. You can learn characteristics of a normal heart rhythm and rules for common **dysrhythmias** so that you will be able to report rhythm changes to your supervisor or physician.

ECG monitoring provides a view of the heart’s electrical activity. Leads that are placed on the patient allow different views of the heart to be seen. A 12-lead ECG provides 12 different perspectives of the heart. Waveforms change in appearance in different leads. For continuous monitoring, lead II is the most commonly used. In lead II the waveforms can be expected to be upright.

Electrocardiogram Graph Paper

The intervals of each of the components of a cardiac cycle can be measured on the ECG graph paper on which the rhythm is recorded. The graph paper is calibrated in a grid with small squares divided into heavy lined blocks of 25 (five squares wide and five squares high; Fig. 20–3). Each small box is 0.04 seconds wide. There are five small squares, which equal 0.20 seconds of time, between two horizontally

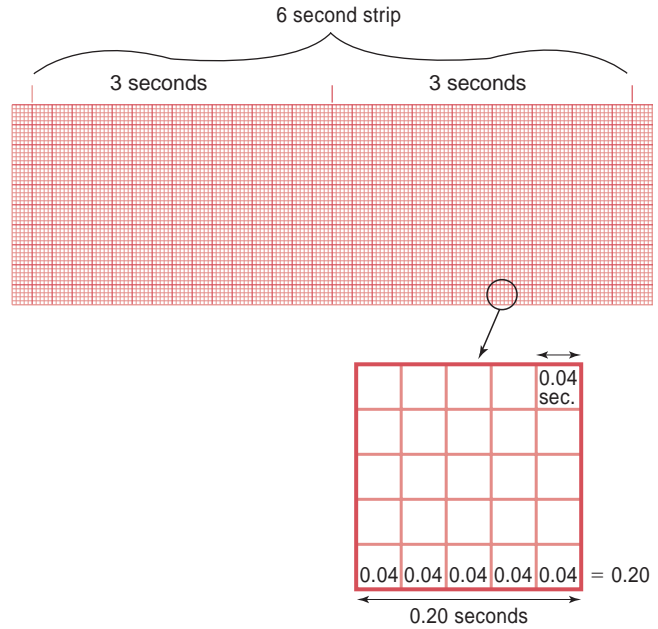

Figure 20-3 Electrocardiogram recording paper time intervals.

heavy vertical black lines. (See Fig. 20–3.) The height of waveforms (amplitude) is measured vertically. Each small square is 1 mm. Ten millimeters is the standard height that the ECG uses to measure patient waveforms.

When the ECG is on but there is no electrical activity detected, a straight line is produced. Known as the **isoelectric line**, this occurs when there are no positive or negative electrical wave deflections. Cardiac cycle impulses (seen as waves), depending on how they travel through the heart, are either upright (positive) or downward (negative) from the isoelectric line on the ECG graph paper.

▶ COMPONENTS OF A CARDIAC CYCLE

P Wave

The P wave is the first wave of the cardiac cycle and represents **atrial depolarization**. When the SA node fires, it normally appears rounded and symmetrical. There is one P wave in a normal cardiac cycle. Disorders that change atrial size cause alterations in P wave shape and size.

PR Interval

The PR interval represents the time it takes the electrical impulse to travel down the atrium to the AV node. It starts at the beginning of the P wave and ends at the beginning of the QRS complex. Counting the number of small boxes

LEARNING TIPS

To make measuring waves easier, try to find one that starts at the beginning of one small box. (See Fig. 20–4.) If the wave starts or ends in the middle of a box, count it as one-half of a box, which is 0.02 seconds.

dysrhythmia: dys—difficult or abnormal + rhythm—rhythm

horizontally that the interval covers determines the length of the PR interval (Fig. 20-4). The normal PR interval is 0.12 to 0.20 seconds.

QRS Complex

The QRS complex represents ventricular depolarization and is composed of three waves, the Q, R, and S. The Q wave is the first downward deflection after the P wave but before the R wave. The R wave is the first upward deflection after the P wave. The last part of the QRS complex is the S wave, which is the second negative deflection after the P wave when a Q wave is present or the first negative deflection after the R wave (see Fig. 20-2). The S wave ends when it returns to the isoelectric line. All three waves are not always present in every QRS complex. Even with absent waves, the QRS is still known as a QRS complex (Fig. 20-5).

Atrial repolarization occurs during the interval of the QRS but is not seen because of the more powerful ventricular activity. The presence of the P wave in the next cardiac cycle indicates that atrial repolarization has occurred.

QRS Interval

To measure the QRS interval, count the number of boxes from the wave that begins the QRS complex to the end of the wave that completes the QRS complex. For example, when a Q, R, and S are present, measure from the beginning of the Q wave to the end of the S wave (Fig. 20-6). The normal QRS interval is 0.06 to 0.10 seconds.

Figure 20-4 PR interval.

Figure 20-5 (A) QRS complex with a Q wave. (B) QRS complex without a Q wave. (C) QRS complex without a Q or an S wave.

Figure 20-6 QRS interval. This QRS interval covers 2½ boxes. Each full box is 0.04 seconds. One-half box is 0.02 seconds; $2.5 \times 0.04 = 0.10$ seconds.

T Wave

The T wave represents **ventricular repolarization**, the resting state of the heart, when the ventricles are filling with blood and preparing to receive the next impulse. The T wave starts at the next upward (positive) deflection, after the QRS complex, and ends with a return to the isoelectric line. The T wave can be a downward deflection after the QRS complex in some ECG leads, or it can indicate ischemia of the heart (Fig. 20-7).

U Wave

The U waveform is usually not present. It is seen in patients with hypokalemia, which is a low serum potassium level. It occurs shortly after the T wave and can distort the configuration of the T wave (Fig. 20-8).

ST Segment

The ST segment reflects the time from completion of a contraction (depolarization) to recovery (repolarization) of myocardial muscle for the next impulse. The ST segment starts at the end of the QRS and ends at the beginning of the T wave (Fig. 20-9). The ST segment is examined if a

Figure 20-7 (A) T wave with positive deflection. (B) T wave with inverted, negative inflection, indicating ischemia.

Figure 20-8 Different locations where U waves appear.

Figure 20-9 ST segment.

Figure 20-10 ST segment inverted or depressed.

Figure 20-11 ST segment elevated.

patient is experiencing chest pain. Changes in the ST segment can indicate the presence of ischemia or an injury pattern suggestive of myocardial damage. If a patient is experiencing ischemia, the ST segment can be inverted or depressed (Fig. 20–10). If the patient is experiencing an injury pattern, the ST segment elevates (Fig. 20–11).

► INTERPRETATION OF CARDIAC RHYTHMS

Five-Step Process for Dysrhythmia Interpretation

An orderly, systematic method for interpreting ECG rhythms should be used. Following this process, in order, increases understanding of items to examine and ensures that nothing is omitted. Five steps are examined in this process (Table 20–1). The findings of these five steps are then used to interpret the ECG rhythm according to the rules for each dysrhythmia. A 6-second ECG strip is used when interpreting rhythms. (See Fig. 20–3.)

1. Regularity of the Rhythm

The regularity or rhythm of the heartbeat can be determined by looking at the R-R interval on the ECG (Fig. 20–12). The same spacing between each R-R interval, with a variation of no greater than two small boxes, is seen in a normal rhythm. One way to determine the regularity of a rhythm is to count the number of small boxes between every R wave, which normally should remain the same. A more common way is to use a caliper to measure the spacing of the R-R interval.

TABLE 20-1 FIVE-STEP PROCESS FOR DYSRHYTHMIA INTERPRETATION

After assessing the topics listed here, you should be able to name the patient’s dysrhythmia.

Step	Topic	Assessment Questions
1	Regularity of rhythm	<ul style="list-style-type: none"> • Is the rhythm regular? Irregular? • Is there a pattern to the irregularity?
2	Heart rate	<ul style="list-style-type: none"> • What is the heart rate?
3	P waves	<ul style="list-style-type: none"> • Is there one P wave for every QRS complex? • Are the P waves regular and constant? • Do the P waves look alike? • Are the P waves upright and in front of every QRS complex?
4	PR interval	<ul style="list-style-type: none"> • Is the PR interval normal? • Is the PR interval constant or varying?
5	QRS interval	<ul style="list-style-type: none"> • Is the QRS interval normal? • Is the QRS interval constant? • Do the QRS complexes all look alike?

A caliper is a small, two-sided, movable metal instrument with a sharp point at the end of each side. It is V-shaped when spread apart to measure various distances. To use a caliper for measuring, one point is placed at the top of an R wave and the other point is spread apart until it rests on the top of the next R wave. Then, without changing the distance between the points, the caliper is moved from one R wave to the next across the whole ECG tracing (also known as a strip) to see if the distance remains the same for each R-R interval. If the distance is the same, the rhythm is regular. If the distance changes, the rhythm is irregular. An irregular rhythm can be regularly irregular, which means it has a predictable pattern of irregularity, or irregularly irregular, without any pattern of irregularity.

LEARNING TIPS

If a caliper is not available, a piece of paper can be placed on the ECG strip. A mark can be made at the top of one R wave and another mark made at the top of the next R wave. The marks on the paper can then be moved across the R-R intervals on the strip (just as caliper points would be) to determine whether the rhythm is regular or irregular.

2. Heart Rate

After the components of a cardiac cycle are identified and the rhythm regularity determined, the heart rate is counted. There are two methods to calculate the heart rate.

1. Six second method: At the top of the ECG graph paper there are vertical marks at 3-second intervals. (See Fig. 20–3.) Count the number of R waves in a 6-second strip and multiply the total by 10 (the number of 6 seconds in a minute) to obtain the beats per minute (6 seconds × 10 =

Figure 20-12 Normal cardiac waves are equal distances apart. (A) R-R waves. (B) P-P waves.

60 seconds or 1 minute) (Fig. 20-13). The 6-second method is used for irregular rhythms. It may also be used when a rapid estimate of a regular rhythm is needed, because it is not the most accurate method for regular rhythms.

- Count the number of small (0.04-second) boxes between two R waves and divide that number into 1500. This gives the bpm, because 1500 small boxes equal 1 minute (Fig. 20-14). This method is used only for regular rhythms and is very accurate.

3. P Wave

The P waves on the ECG strip are examined to see if (1) there is one P wave in front of every QRS; (2) they are regular; and (3) the P waves all look alike. (See Fig. 20-12.) If the P waves all meet these criteria, they are considered normal. If they do not, further examination of the strip is necessary to determine the dysrhythmia.

4. PR Interval

All PR intervals are measured to determine whether they are normal and constant. If the PR is found to vary, it is important to note whether there is a pattern to the variation.

5. QRS Complex

The QRS intervals are measured to determine whether they are all normal and constant. Then the QRS complexes are examined to see if they all look alike.

► NORMAL SINUS RHYTHM

Description

Normal sinus rhythm is the normal cardiac rhythm. It originates in the SA node and represents a series of complete and regular cardiac cycles with a normal heart rate. The heart rate must be 60 to 100 bpm and have a regular rhythm. Each cycle must consist of a P wave, QRS complex, and a T wave. The measurements of the PR intervals and QRS intervals must fall within normal limits. If all these elements exist, the rhythm is interpreted as normal sinus rhythm (Fig. 20-15).

Normal Sinus Rhythm Rules

The rules for normal sinus rhythm are as follows:

- Rhythm: regular
- Heart rate: 60 to 100 bpm

Figure 20-13 Counting R waves in a 6-second strip. There are six R waves in this 6-second strip, and $6 \times 10 = 60$ beats per minute.

Figure 20-14 Heart rate. Counting large boxes and dividing into 300. Count number of large boxes between two R waves and divide into 300; five large boxes, $300/5 = 60$ beats per minute.

Figure 20-15 Normal sinus rhythm.

3. P waves: rounded, precede each QRS complex, alike
4. PR interval: 0.12 to 0.20 seconds
5. QRS interval: 0.06 to 0.10 seconds

► DYSRHYTHMIAS

Two terms are used for rhythm disturbances: arrhythmia and dysrhythmia. An arrhythmia is an irregularity or loss of rhythm of the heartbeat, and a dysrhythmia is an abnormal, disordered, or disturbed rhythm. These two terms are used interchangeably, but dysrhythmia is the most accurate term for the discussion of abnormal rhythms. The American Heart Association provides cardiac information and guidelines for cardiac care for dysrhythmias. For more information about cardiac care for dysrhythmias, visit the American Heart Association Web site at www.american-heart.org/arrhythmia.

Several mechanisms can cause irregularity or a dysrhythmia. Two examples of these mechanisms are a disturbance in the formation of an impulse and a disturbance in the conduction of the impulse. When impulse formation is disturbed, the impulse may arise from the atria, the AV node, or the ventricles. This disturbance can be seen as an increased or decreased heart rate, early or late beats, or atrial or ventricular fibrillation. With a disturbance in conduction there may be normal formation of the impulse, but it becomes blocked within the electrical conduction system, resulting in abnormal conduction (as in heart block or bundle branch blocks).

Dysrhythmias Originating in the Sinoatrial Node

Rhythms arising from the SA node are referred to as sinus rhythms. The SA node, being the pacemaker of the heart, fires normally at 60 to 100 bpm. Disturbances in conduction from the SA node can cause irregular rhythms or abnormal heart rates. Dysrhythmias arising from the SA node are rarely dangerous. Patients, especially those with heart, lung, or kidney disease, who cannot tolerate rapid or slow heart rates as shown by symptoms may require treatment.

LEARNING TIPS

The origin and type of problem, such as sinus **bradycardia**, are used to name a dysrhythmia. A dysrhythmia originating in the SA node is a sinus rhythm, but it is not normal. Therefore the term *normal* is not used; the origin *sinus* is used, and the type of problem, *bradycardia*, is identified.

Sinus Bradycardia

DESCRIPTION. Bradycardia is a slower-than-normal heart rate. Sinus bradycardia has the same cardiac cycle components as a normal sinus rhythm. The only difference is a slower heart rate caused by fewer impulses originating from the SA node (Fig. 20-16). Can you see that the name sinus bradycardia tells you this difference? The name says the impulse is coming from the sinus node (sinus) but at a slower rate than normal (bradycardia). It's easy to understand what is happening in the dysrhythmia when you look at what the name is telling you!

CAUSES. Medications, myocardial infarction (MI), and electrolyte imbalances can cause bradycardia. Well-conditioned athletes also can have slower heart rates because their hearts work more efficiently.

SINUS BRADYCARDIA RULES. The rules for sinus bradycardia are as follows:

1. Rhythm: regular
2. Heart rate: less than 60 bpm
3. P waves: smoothly rounded, precede each QRS complex, alike
4. PR interval: 0.12 to 0.20 seconds
5. QRS interval: 0.06 to 0.10 seconds

SIGNS AND SYMPTOMS. Sinus bradycardia rarely produces symptoms unless it is so slow that it reduces cardiac output. Symptoms consist of fatigue or fainting episodes. Patients are monitored for their responses to bradycardia.

TREATMENT. Treatment is usually not required if the patient is asymptomatic. The patient is observed, and the underlying cause is determined for correction. Oxygen and intravenous (IV) access may be started. If bradycardia is due to a heart block dysrhythmia, insertion of a cardiac pacemaker may be required. If the patient is symptomatic, treatment includes atropine sulfate, transcutaneous pacing, and dopamine, epinephrine, or isoproterenol. The medications are given intravenously by a registered nurse for immediate effect. These treatments are used to increase heart rate for a short time until the cause can be determined and treated.

bradycardia: bradys—slow + kardia—heart

Figure 20-16 Sinus bradycardia.

Sinus Tachycardia

DESCRIPTION. Tachycardia is defined as a heart rate greater than 100 beats per minute. Sinus tachycardia has the same components as a normal sinus rhythm except the heart rate is faster (Fig. 20-17). This is due to more impulses originating from the SA node than normal.

CAUSES. Causes of sinus tachycardia include physical activity; hemorrhage; shock; medications such as epinephrine, atropine, or nitrates; dehydration; fever; MI; electrolyte imbalance; fear; and anxiety. Tachycardia occurs as a compensatory mechanism when hypoxia is present and more cardiac output is needed to deliver oxygen to organs and tissues.

SINUS TACHYCARDIA RULES. The rules for sinus tachycardia are as follows:

1. Rhythm: regular
2. Heart rate: 101 to 180 bpm
3. P waves: rounded, precede each QRS complex, alike
4. PR interval: 0.12 to 0.20 seconds
5. QRS interval: 0.06 to 0.10 seconds

SIGNS AND SYMPTOMS. Sinus tachycardia may not produce symptoms. If the heart rate is very rapid and sustained for long periods, the patient may experience angina or dyspnea. Elderly patients may become symptomatic more rapidly than younger patients (Gerontological Issues Box 20-1). Patients with MI may not tolerate a rapid heart rate because it increases cardiac workload; therefore more severe symptoms may occur.

TREATMENT. Treatment depends on the cause and the patient's symptoms. Treating the underlying cause usually cor-

BOX 20-1 GERONTOLOGICAL ISSUES

Factors that increase the risk of dysrhythmias in elderly people include the following:

- Digitalis toxicity (most common)
- Hypokalemia
- Acute infection
- Hemorrhage
- Angina
- Coronary insufficiency (exercise, stress)

Dysrhythmias that occur most often in elderly people include the following:

- Atrial fibrillation (atria beating 400 to 700 times per minute)
- Sick sinus syndrome (alternating episodes of bradycardia, normal sinus rhythm, tachycardia, and periods of long sinus pause)
- Heart block (delayed or blocked impulses to the atria or ventricles)

Age-related effects of dysrhythmias include the following:

- Weakness
- Fatigue
- Forgetfulness
- Palpitations
- Dizziness
- Hypotension
- Bradycardia
- Syncope

Elderly people are especially sensitive to changes in heart rate that increase the heart's workload. Whenever the heart works harder, as in tachycardia, the cardiac cells require more oxygen to function properly. Elderly patients have less ability to adapt to sudden changes or stressors, and they may not be able to tolerate tachycardia for very long. Any new-onset tachycardia in an elderly patient should be reported promptly.

Figure 20-17 Sinus tachycardia.

rects the tachycardia. For example, if the patient is hemorrhaging, immediate intervention is needed to stop the bleeding and restore normal blood volume. The treatment goal is to decrease the heart's workload and resolve the cause. Medications such as digoxin, calcium channel blockers (verapamil), or beta blockers (propranolol) may be given to slow the heart rate. Oxygen may also be prescribed to help ensure an adequate supply for the heart.

LEARNING TIPS

Tachycardia is often the first sign of hemorrhage. It is a compensatory mechanism to maintain cardiac output. If a patient develops sudden tachycardia, consider whether hemorrhage could be the cause, such as in postoperative patients, patients with gastrointestinal bleeding or cancer, or trauma patients. The bleeding may be external, or it may be internal and therefore not visible. Apply pressure to the site if the bleeding is obvious. Monitor the patient and report the tachycardia and any obvious bleeding promptly.

Dysrhythmias Originating in the Atria

As previously discussed, all areas of the heart can initiate an impulse. The SA node is the primary pacemaker, but if the atria initiate impulses faster than the SA node, they become the primary pacemaker. Atrial rhythms are usually faster than 100 bpm and can exceed 200 bpm. When an impulse originates outside the SA node, the P waves look different from the rounded P waves produced by the SA node (flatter, notched, or peaked), which indicates that the SA node is not controlling the heart rate. The atrial impulse travels to the ventricles to initiate a normal QRS complex after each P wave.

Premature Atrial Contractions

DESCRIPTION. The term *premature* refers to an “early” beat. When the atria fire an impulse before the SA node fires, a premature beat results. If the underlying rhythm is sinus rhythm, the distance between R waves is the same except where the early beat occurs. When looking at the ECG strip, a shortened R-R interval is seen where the premature beat occurs. The R wave preceding the premature atrial contraction (PAC) and the PAC's R wave are close together, followed by a pause, with the next beat being regular (Fig. 20–18).

CAUSES. Causes of PACs include hypoxia, smoking, stress, myocardial ischemia, enlarged atria in valvular disorders, medications (such as digoxin), electrolyte imbalances, atrial fibrillation onset, and heart failure.

PREMATURE ATRIAL CONTRACTIONS RULES. The rules for premature atrial contractions are as follows:

1. Rhythm: premature beat interrupts underlying rhythm where it occurs
2. Heart rate: depends on the underlying rhythm; if normal sinus rhythm (NSR), 60 to 100 bpm
3. P waves: early beat is abnormally shaped
4. PR interval: usually appears normal, but premature beat could have shortened or prolonged PR interval
5. QRS interval: 0.06 to 0.10 seconds (indicates normal conduction to ventricles)

SIGNS AND SYMPTOMS. Premature atrial contractions can occur in healthy individuals, as well as in the patient with a diseased heart. No symptoms are usually present. If many PACs occur in succession, the patient may report the sensation of palpitations.

TREATMENT. PACs are usually not dangerous, and often no treatment is required other than correcting the cause. Frequent PACs indicate atrial irritability, which may worsen into other atrial dysrhythmias. Quinidine or procainamide can be given to a patient having frequent PACs to slow the heart rate.

Atrial Flutter

DESCRIPTION. In atrial flutter the atria contract, or flutter, at a rate of 250 to 350 bpm. The very rapid P waves appear as flutter, or F waves, on ECG and appear in a saw-tooth pattern. Some of the impulses get through the AV node and reach the ventricles, resulting in normal QRS complexes. There can be from two to four F waves between QRS complexes. If impulses pass through the AV node at a consistent rate, the rhythm is regular (Fig. 20–19). The classic characteristics of atrial flutter are more than one P wave before a QRS complex, a saw-tooth pattern of P waves, and an atrial rate of 250 to 350 bpm.

CAUSES. Causes of atrial flutter include rheumatic or ischemic heart diseases, congestive heart failure (CHF), hypertension, pericarditis, pulmonary embolism, and postoperative coronary artery bypass surgery. Many medications can also cause this dysrhythmia.

Figure 20-18 Premature atrial contractions (PAC).

Figure 20-19 Atrial flutter.

ATRIAL FLUTTER RULES. The rules for atrial flutter are as follows:

1. Rhythm: atrial rhythm regular; ventricular rhythm regular or irregular depending on consistency of AV conduction of impulses
2. Heart rate: ventricular rate varies
3. P waves: flutter or F waves with saw-tooth pattern
4. PR interval: none measurable
5. QRS complex: 0.06 to 0.10 seconds

SIGNS AND SYMPTOMS. The presence of symptoms in atrial flutter depends on the ventricular rate. If the ventricular rate is normal, usually no symptoms are present. If the rate is rapid, the patient may experience palpitations, angina, or dyspnea.

TREATMENT. The ventricular rate and cardiac output guide treatment. The goal is to control the ventricular rate and convert the rhythm. A rapid ventricular rate or symptoms of decreased cardiac output require **cardioversion** (electrical shock). If the rate is greater than 150 bpm, immediate cardioversion is needed. Medications that may be used to control the rate include calcium channel blockers and beta blockers. For rhythm conversion, digoxin can be used to slow conduction through the AV node and increase cardiac contractility. Other medications, such as quinidine, procainamide, or propranolol, can also be used to slow the heart rate.

Atrial Fibrillation

DESCRIPTION. In atrial fibrillation the atrial rate is extremely rapid and chaotic. An atrial rate of 350 to 600 bpm can occur. However, the AV node blocks most of the impulses, so the ventricular rate is much lower than the atrial rate. There are no definable P waves because the atria are fibrillating, or quivering, rather than beating effectively. No P waves can be seen or measured. A wavy pattern is produced on the ECG. Because the atrial rate is so irregular and only a few of the atrial impulses are allowed to pass through

the AV node, the R waves are irregular. The ventricular rate varies from normal to rapid.

Atrial fibrillation can be self-limiting, persistent, or permanent. A complication of this dysrhythmia is an increased risk of thrombus formation in the atria from blood stasis caused by poor emptying of blood from the quivering atria (Fig. 20-20). This can result in stroke or pulmonary emboli.

CAUSES. Causes of atrial fibrillation include aging, rheumatic or ischemic heart diseases, heart failure, hypertension, pericarditis, pulmonary embolism, and postoperative coronary artery bypass surgery. Medications can also cause this dysrhythmia.

ATRIAL FIBRILLATION RULES. The rules for atrial fibrillation are as follows:

1. Rhythm: grossly or irregularly irregular
2. Heart rate: atrial rate not measurable; ventricular rate under 100 is controlled response; greater than 100 is rapid ventricular response
3. P waves: no identifiable P waves
4. PR interval: none can be measured because no P waves are seen
5. QRS complex: 0.06 to 0.10 seconds

SYMPTOMS. With atrial fibrillation, most patients feel the irregular rhythm. Many describe it as palpitations or a skipping heartbeat. When checking a patient's radial pulse, it may be faint because of a decreased stroke volume (volume of blood ejected with each contraction). If the ventricular rhythm is rapid and sustained, the patient can go into left ventricular failure.

TREATMENT. Treatment is based on the patient's stability. If the patient is unstable, cardioversion is done immediately to try to return the heart to normal sinus rhythm. If the patient is stable, medications to restore and maintain a normal sinus rhythm and control the ventricular rate may be used. The ventricular rate may be controlled with such medications as digoxin, beta blockers, or calcium channel blockers. Medications approved by the Food and Drug Administration to convert atrial fibrillation and maintain a normal sinus rhythm include dofetilide, quinidine, flecainide, propafenone, and ibutilide IV. Dofetilide is a newer drug that has proven to be very effective. Anticoagulant therapy (aspirin for low-risk patients, warfarin for those at high risk), which can be long term or lifelong, is given to reduce thrombi. International normalized ratio (INR) and pro-

LEARNING TIPS

- If a QRS complex measures less than 0.12 seconds, the dysrhythmia originated above the ventricles. This is known as a supraventricular dysrhythmia.
- Ventricular dysrhythmias produce wide QRS complexes that are greater than 0.11 seconds.

Figure 20-20 Atrial fibrillation.

thrombin time levels must be carefully monitored for patients on warfarin. Chemical or electrical cardioversion may be performed to convert the rhythm after sufficient anticoagulation (about 3 weeks). If known, the underlying cause of the atrial fibrillation should also be treated.

There are new advances in therapy for atrial fibrillation. Dual-chamber pacing for those with sinus node problems or biatrial pacing, as well as pacemaker recognition of atrial fibrillation, helps to prevent this dysrhythmia. Implantable cardioverter defibrillators (ICDs) can deliver a shock activated by the physician or patient to end the atrial fibrillation. Because this is a planned event, medications for comfort can be taken by the patient before the shock.

For patients with atrial fibrillation who do not respond to medications, **ablation** procedures may be performed. (These are discussed later.) A surgical procedure can be performed if other treatments fail. The maze procedure was first done as open heart surgery, but a percutaneous, nonsurgical catheter maze procedure is being investigated to eliminate the risks of open heart surgery (See Chapter 22.) In the open heart maze procedure incisions are made in the atria that create a “maze,” or route, for electrical impulses to

travel through to the AV node. These impulses cannot go off-course because scar tissue surrounds the incision sites. In many cases this cures atrial fibrillation. However, some patients may need continued medications or a pacemaker following this procedure.

Ventricular Dysrhythmias

Premature Ventricular Contractions

DESCRIPTION. Premature ventricular contractions (PVCs) originate in the ventricles from an ectopic focus (a site other than the SA node). The ventricles are irritable and fire prematurely, before the SA node. When the ventricles fire first, the impulses are not conducted normally through the electrical pathway. This results in a wide (greater than 0.11 seconds), bizarre QRS complex on an ECG (Fig. 20–21).

PVCs can occur in different shapes. The shape of the PVC is referred to as **unifocal** (one focus) if all the PVCs look the same because they come from the same irritable ventricular area. **Multifocal** PVCs do not all look the same because they are originating from several irritable areas in the ventricle. There can be several repetitive cycles or patterns of PVCs:

■ **Bigeminy** is a PVC that occurs every other beat (a normal beat and then a PVC) (Fig. 20–22).

ablation: ab—away from + lat—carry

Figure 20-21 Premature ventricular contractions. (A) Unifocal PVCs arise from one area and look the same. (B) Multifocal PVCs arise from different foci and may look different.

Figure 20-22 Bigeminal premature ventricular contractions.

- **Trigeminy** is a PVC that occurs every third beat (two normal beats and then a PVC).
- **Quadrigeminy** is a PVC that occurs every fourth beat (three normal beats and then a PVC).
- When two PVCs occur together, they are referred to as a couplet (pair).
- If three or more PVCs occur in a row, it is referred to as a run of PVCs or ventricular tachycardia.

CAUSES. Use of caffeine or alcohol, anxiety, hypokalemia, cardiomyopathy, ischemia, and MI are common causes of PVCs.

PREMATURE VENTRICULAR CONTRACTION RULES. The rules for premature ventricular contraction are as follows:

1. Rhythm: depends on the underlying rhythm; PVC usually interrupts rhythm
2. Heart rate: depends on underlying rhythm
3. P waves: absent before PVC QRS complex
4. PR interval: none for PVC
5. QRS complex: if PVC is greater than 0.11 seconds; T wave is in the opposite direction of QRS complex (i.e., QRS upright, T downward or QRS downward, T upright)

SIGNS AND SYMPTOMS. PVCs may be felt by the patient and are described as a skipped beat or palpitations. With frequent PVCs, cardiac output can be decreased, leading to fatigue, dizziness, or more severe dysrhythmias.

TREATMENT. Treatment depends on the type and number of PVCs and whether symptoms are produced. A few PVCs do not usually require treatment. However, if the PVCs are more than six per minute, regularly occurring, multifocal, falling on the T wave (known as “R-on-T phenomenon,” which can trigger life-threatening dysrhythmias), or caused by an acute MI, they can be dangerous. Antidysrhythmic drugs that depress myocardial activity are used to treat PVCs. Examples of drugs that may be given intravenously by the registered nurse and then followed by a continuous IV drip are procainamide (Procan) and lidocaine (Xylocaine).

Ventricular Tachycardia

DESCRIPTION. The occurrence of three or more PVCs in a row is referred to as **ventricular tachycardia (VT)** (Fig. 20-23). VT results from the continuous firing of an ectopic ventricular focus. During VT, the ventricles rather than the SA node become the pacemaker of the heart. The pathway

CRITICAL THINKING

Mrs. Mae
Mrs. Mae, age 70, is 5 days post-MI without complications. You assist her back to bed at 1400 after she ambulates. Her oxygen is on at 2 L/min via nasal cannula. Her vital signs are 126/78, 82, 18. She has no pain and says she feels good after walking. The cardiac monitor shows normal sinus rhythm. Five minutes later you see that the monitor shows sinus rhythm with PVCs of less than six per minute. Her vital signs are now 132/84, apical 92 irregular, 22. She reports no pain but says, “I can feel my heart skipping, it takes my breath away.” You call the RN while staying with the patient for reassurance.

1. What should you do first?
2. What should you do regarding the dysrhythmia?
3. What might be some of the causes for this dysrhythmia?
4. What symptoms, if any, would you expect to be present?
5. What would you do if symptoms were present?
6. What type of orders would you anticipate from the physician?
7. How would you document your findings?

Answers at end of chapter.

of the ventricular impulses is different from normal conduction, producing a wide (greater than 0.11 seconds), bizarre QRS complex.

CAUSES. Myocardial irritability, MI, and cardiomyopathy are common causes of VT. Respiratory acidosis, hypokalemia, digoxin toxicity, cardiac catheters, and pacing wires can also produce VT.

VENTRICULAR TACHYCARDIA RULES. The rules for ventricular tachycardia are as follows:

1. Rhythm: usually regular, may have some irregularity
2. Heart rate: 150 to 250 ventricular bpm; slow VT is below 150 bpm
3. P waves: absent
4. PR interval: none
5. QRS complex: greater than 0.11 seconds

SIGNS AND SYMPTOMS. The seriousness of ventricular tachycardia is determined by the duration of the dysrhythmia. Sustained VT compromises cardiac output. Patients are aware of a sudden onset of rapid heart rate and can experience dyspnea, palpitations, and light-headedness. Angina commonly occurs. The severity of symptoms can increase rapidly if the left ventricle fails and complete cardiac arrest results.

Figure 20-23 Ventricular tachycardia.

TREATMENT. If the patient is pulseless or not breathing, cardiopulmonary resuscitation (CPR) and immediate defibrillation are required, followed by antiarrhythmic drugs. Current advanced cardiac life support (ACLS) protocols for VT treatment should be used by individuals certified in ACLS.

If the patient is stable, medications can be tried first, such as amiodarone, procainamide, sotalol, lidocaine, phenytoin, or beta blockers following ACLS protocols. Magnesium can be used to help stabilize ventricular muscle excitability if the patient's magnesium level is low.

CAUSES. Hyperkalemia, hypomagnesemia, electrocution, coronary artery disease, and MI are all possible causes of ventricular fibrillation. Placement of intracardiac catheters and cardiac pacing wires can also lead to ventricular irritability and then ventricular fibrillation.

VENTRICULAR FIBRILLATION RULES. The rules for ventricular fibrillation are as follows:

1. Rhythm: chaotic and extremely irregular
2. Heart rate: not measurable
3. P waves: none
4. PR interval: none
5. QRS complex: none

SIGNS AND SYMPTOMS. Patients experiencing ventricular fibrillation lose consciousness immediately. There are no heart sounds, peripheral pulses, or blood pressure. These are all indicative of circulatory collapse. Additionally, respiratory arrest, cyanosis, and pupil dilation occur.

TREATMENT. Immediate defibrillation is the very best treatment for terminating ventricular fibrillation. Each minute that passes without defibrillation reduces survival. CPR is started until the defibrillator is available. Automatic external defibrillators (AEDs) provide quick access to easily used technology for defibrillation (see defibrillation section). Endotracheal intubation and ventilation support respiratory function. Medications are given according to ACLS protocols and may include epinephrine, vasopressin, amiodarone, lidocaine, magnesium, and procainamide.

hyperkalemia: hyper—above + kalium—potassium + emia—blood

hypomagnesemia: hypo—below + magnes—magnesium + emia—blood

CRITICAL THINKING

Mrs. Parker

You are caring for Mrs. Parker, age 66, on the cardiac medical unit. She had an MI and several episodes of ventricular tachycardia while she was in the ICU before transferring to your unit. At 1600 you find her unresponsive, with no palpable pulses and shallow respirations and in VT on the ECG. Vital signs are BP 80/40, P 150, R 6.

1. Why are there no palpable pulses?
2. What is occurring to the heart when it is in VT?
3. What action should you take?
4. How will you document your findings?

Answers at end of chapter.

Ventricular Fibrillation

DESCRIPTION. Ventricular fibrillation occurs when many, many ectopic ventricular foci fire at the same time. Ventricular activity is chaotic with no discernible waves (Fig. 20-24). The ventricle quivers and is unable to initiate a contraction. There is a complete loss of cardiac output. If this rhythm is not terminated immediately, death ensues.

Figure 20-24 Ventricular fibrillation.

Figure 20-25 Asystole.

Asystole

DESCRIPTION. Asystole (the silent heart) is the absence of electrical activity in the cardiac muscle. It is referred to as cardiac arrest. A straight line appears on an ECG strip (Fig. 20–25). Ventricular fibrillation usually precedes this rhythm and must be reversed immediately to help prevent asystole.

CAUSES. Ventricular fibrillation and a loss of a majority of functional cardiac muscle due to an MI are common causes of asystole. Hyperkalemia is another cause of asystole.

ASYSTOLE RULES. The rules for asystole are as follows:

1. Rhythm: none
2. Heart rate: none
3. P waves: none
4. PR interval: none
5. QRS complex: none

TREATMENT. CPR is started immediately. ACLS protocols for asystole are used. Endotracheal intubation to support respirations is performed. Transcutaneous pacing is considered, then epinephrine and atropine are administered.

Figure 20-26 Insertion of dual-chamber permanent pacemaker.

CRITICAL THINKING

Mr. Peet

You are making rounds. When you enter Mr. Peet's room, you note that he is having difficulty breathing and is unresponsive.

1. What are your initial actions?
2. What should you do after assessing and finding no pulse or respirations?
3. What is your responsibility during a cardiac/respiratory arrest code?

Answers at end of chapter.

► CARDIAC PACEMAKERS

Pacemakers can be external and temporary or internal and permanent (Fig. 20–26). They are used to override dysrhythmias or to generate an impulse when the heart is beating too slowly. Transcutaneous pacemakers are used in emergency situations because they are quick and easy to apply. Impulses are delivered to the heart through the skin from the external generator via electrodes that are attached to the chest and back.

Temporary pacemakers are used for bradycardias or tachycardias that do not respond to medications or car-

dioversion. They may also be used after an MI to allow the heart time to heal when the diseased myocardium is unable to respond to or is not receiving electrical conduction because of damage within the system. The temporary pacemaker becomes the electrical conduction system and stimulates the atria and ventricles to contract to maintain cardiac output. Temporary pacemakers can be inserted during valve or open heart surgery or in the cardiac catheterization laboratory or critical care unit at the bedside as emergency treatment until surgery can be scheduled to insert a permanent pacemaker.

Permanent pacemaker insertion is a surgical procedure in which **fluoroscopy**, a screen that shows an image similar to a radiograph, is used. The pacemaker generator is implanted subcutaneously and attached to one or two leads (insulated conducting wires) that are inserted via a vein into the heart. The lead can then deliver the impulse directly to the heart wall. A single-lead pacemaker paces either the right atrium or right ventricle depending on its chamber placement. Dual-chamber pacemakers have two leads, with one in the right atrium and the other in the right ventricle. This allows pacing of both chambers. Usually pacemakers are set at a prescribed rate of 72 bpm. Activity-responsive pacemakers provide a rate range (e.g., 60 to 115 bpm) in response to a person's activity level. This

provides the patient with greater flexibility for increasing cardiac output when needed, such as during exercise.

When a patient is in a paced rhythm, a small spike is seen on the ECG before the paced beat. This spike is the electrical stimulus. It can precede the P wave, QRS complex, or both depending on what is being paced (Fig. 20-27). Patients may have all paced beats (100-percent paced), a mixture of their own beats and paced beats, or all of their own beats. Pacemakers should not fire when patients have their own beats.

Problems that can occur with pacemakers include the following:

- Failure to sense the patient's own beat
- Failure to pace because of a malfunction of the pulse generator
- Failure to capture, which is a lack of depolarization

Nursing Care for Pacemakers

Patients are placed on a cardiac monitor and strict bedrest for 12 to 24 hours after insertion of a pacemaker. The patient's apical pulse is monitored frequently to detect changes in the heart rhythm. Irregular heart rhythms or a rate slower than the pacemaker's set rate can indicate pacemaker malfunction. The dressing at the pacemaker insertion site is monitored every 2 to 4 hours for signs of bleeding. Any change in heart rhythm, complaints of chest pain,

or changes in vital signs must be reported immediately. Patients may have a sling on the operative side arm for 24 to 48 hours to help prevent dislodgement of the pacemaker lead from the cardiac wall.

Patient education for pacemaker care before discharge includes the following:

- Incision care. The patient should check the incision daily and report evidence of inflammation or infection (redness, swelling, warmth, tenderness, pain, fever, or discharge) to a physician.
- Methods for taking a radial pulse. The patient should call a physician if the pulse is slower than the pacemaker's set rate.
- The patient should report symptoms of dizziness, fainting, irregular heartbeats, or palpitations.
- The patient should understand the importance of wearing medical alert jewelry and carrying a pacemaker information card.
- The patient should avoid radiation, magnetic fields (e.g., magnetic resonance imaging [MRI], industrial magnets), high voltage (e.g., power plant, arc welding, high-tension wires), antitheft devices, and large running motors (e.g., distributor coil of running engine).
- The patient will need to tell airport security about the pacemaker, because it may trigger metal detectors (they do not harm the pacemaker).

Figure 20-27 (A) Atrial-only pacemaker. (B) Ventricular-only pacemaker. (C) AV sequential pacemaker that paces both chambers.

- Grounded appliances (usually includes microwave ovens) and office equipment are safe to use.
- The patient must avoid lifting more than 10 pounds, making major arm movements, or participating in contact sports for 6 weeks after surgery. Normal activity is usually resumed after 6 weeks.
- The patient must keep scheduled appointments with the physician. Periodic pacemaker checks will be done by the physician or over the telephone. Reprogramming of the pacemaker can be done by the physician if needed.

CRITICAL THINKING

Mr. Treacher

Mr. Treacher, age 58, underwent pacemaker placement 6 days ago and is being transferred to the medical floor. After transfer, his vital signs are 138/72, 72 bpm, and 100-percent paced rhythm. Thirty minutes later, he says that he feels weak and tired. His vital signs are now 100/60, 60 bpm, and irregular.

1. What is your first action?
2. What actions should be taken next?
3. What might be happening to Mr. Treacher?
4. What interventions should you anticipate next?

Answers at end of chapter.

DEFIBRILLATION

Defibrillation is a lifesaving procedure used for lethal dysrhythmias. It delivers an electrical shock to reset the heart's rhythm. It is used to terminate pulseless ventricular tachycardia or ventricular fibrillation. Self-adhesive pads, conductive jelly, or saline pads are placed on the patient's chest to prevent electrical burns from the defibrillator and promote conduction of the electrical charge. After the defibrillator is charged, the paddles are pressed firmly and evenly against the chest wall at the second intercostal space, right of the sternum and on the anterior axillary line at the fifth intercostal space (Fig. 20–28).

If the paddles are not pressed firmly against the chest wall during defibrillation, burns or electrical arcing can result when the shock is delivered. For safety, the person defibrillating must announce “clear.” The phrase “One. I’m clear. Two. You’re clear. Three. All clear” is suggested. No one, including the person defibrillating, should touch the bed or patient during this time to avoid also being shocked. ACLS protocols specify guidelines for resuscitation. If the first shock is unsuccessful, a total of three shocks can be given initially, at increasing energy levels (200, 300, 360 Joules).

LEARNING TIPS

Atrial fibrillation is easy to identify based on its two classic characteristics: a lack of identifiable P waves and an irregularly irregular rhythm (R waves).

defibrillation: de—from + fibrillation—quivering fibers

Figure 20-28 Placement of defibrillator paddles on chest.

A defibrillator may have a synchronization mode that allows R waves, if present, to be sensed so that an electrical shock can be delivered at an appropriate time in the cardiac cycle. This timing is important to prevent a more life-threatening dysrhythmia from developing. When defibrillation of a pulseless ventricular dysrhythmia is desired, the synchronize mode must be off (unsynchronized cardioversion). In this mode the charge is immediately released when the trigger is pressed. In the synchronized mode (synchronized cardioversion) there is a delay in the release of the charge while the R wave is sensed for appropriate timing.

After successful defibrillation, the patient is assessed for a pulse and adequate tissue perfusion. Vital signs, peripheral pulses, and level of consciousness should be noted. The patient is treated in the critical care unit after successful resuscitation.

Emotional support for the patient having experienced cardiac arrest and defibrillation is a very important aspect of nursing care. This can be an extremely frightening event for the patient. It is important to explain what happened to the patient and to listen and allow the patient to express any concerns. The patient is reassured that continuous monitoring is done in the critical care unit. Families also require emotional support during resuscitation of a loved one.

OTHER METHODS TO CORRECT DYSRHYTHMIAS

Automatic External Defibrillators

An AED is an external device that automatically analyzes rhythms and either automatically delivers or prompts operators to deliver an electrical shock if a shockable rhythm (ventricular fibrillation or VT) is detected. Minimally trained laypersons or hospital and rescue personnel can use

these devices with little risk of injury to the patient because the analyzes the rhythm instead of the operator. The patient is connected to the AED with adhesive sternal-apex pads attached to cables coming from the device. This connection allows hands-free defibrillation. AEDs increasingly are being kept in public places such as shopping malls, airports, stadiums, casinos, golf courses, and airplanes for immediate access. The American Heart Association encourages increasing the availability of AEDs because defibrillation attempts must occur within minutes of cardiac arrest to increase chance of survival. In the future, AEDs may even be kept in the home.

Implantable Cardioverter Defibrillator

An implanted ICD is surgically placed during a minor procedure into the chest of a patient who experiences life-threatening dysrhythmias or is at risk for sudden cardiac death (Fig. 20–29). ICDs have decreased the number of deaths from these dysrhythmias by analyzing and treating these heart rhythms. When an abnormal rhythm is detected that could cause death (ventricular fibrillation), it automatically delivers an electrical shock. If the dysrhythmia does not convert on the initial shock, more shocks are delivered sequentially.

If the device detects VT, it cardioverts the rhythm using lower energy. ICDs also have antitachycardia pacing ability if a tachycardic rhythm is detected. Battery life depends on usage, but a battery may last up to 7 years. A physician can tell when the battery is getting low and that the entire unit needs to be changed within a few months. New technology, such as smaller defibrillators that are easier to implant and have a longer battery life, is continually being developed for ICDs.

Patients with ICDs are extremely anxious about having another cardiac arrest and receiving shocks from the ICD. Defibrillator or cardioversion shocks may feel like a kick in

the chest. Reinforcement of patient and family education is very important in preparing the patient for discharge. Those with ICDs should take precautions to prevent problems with the ICD by taking the following precautions:

- Avoiding MRIs
- Avoiding metal detectors and standing near security gates or store entrances
- Avoiding equipment with strong electrical or magnetic fields (e.g., amusement rides, slot machines, remote-control toys, stereo speakers)
- Keeping cell phones 6 inches from the ICD

The nurse provides emotional support, answers all questions, and ensures that any misunderstood information is corrected before discharge.

Cardioversion

Elective cardioversion is used for dysrhythmias such as atrial fibrillation, atrial flutter, and supraventricular tachycardias that are not responsive to drug therapy. Conscious sedation is often used. The patient is given a sedative and monitored by anesthesia personnel during the procedure. Cardioversion is performed with a defibrillator set in the synchronize mode. The defibrillator is attached to the patient by electrode wires, which enables the ECG to be viewed on a screen. On the defibrillator there is a switch labeled “synchronize,” which is on during cardioversion. When the defibrillator is in the synchronized mode, it marks a highlighted area on the patient’s R waves, which must be recognized to deliver a shock.

The number of joules delivered with each shock is determined by a physician but usually ranges from 25 to 50 joules. Self-adhesive pads or conduction jelly is placed on the chest. The paddles must be firmly and evenly pressed against the pads or jelly on the chest until the shock is delivered to prevent skin burns and electrical arcing. When the discharge trigger is pressed, the shock is released when the machine senses it is safe to do so. The cardiac monitor screen is observed to see the discharge of the shock and to note the patient’s ECG response. The patient’s pulse and vital signs are checked.

If cardioversion is successful, there should be a return to normal sinus rhythm. If the rhythm does not immediately convert, more cardioversion attempts can be made as determined by the physician. After the procedure, the patient is monitored for skin burns, rhythm disturbances, respiratory problems, hypotension, and changes in the ST segment.

Ablation

When medications or other treatments are not successful in treating a dysrhythmia, ablation of cardiac conduction pathways may be used to stop the dysrhythmia. Intracardiac echocardiography and intracardiac mapping with fluoroscopy are done before ablation to determine the area of the heart requiring treatment. A newer mapping technique, tridimensional mapping, which may be more accurate and does not need fluoroscopy, is being investigated.

Figure 20-29 An implanted cardioverter defibrillator in place.

Forms of ablation include mechanical, chemical, and radiofrequency. Mechanical ablation destroys the involved tissue with cryosurgery or through surgical removal. Chemical ablation inserts alcohol or phenol through an angioplasty catheter into the area of the heart producing the unwanted beats. Radiofrequency ablation delivers high-frequency energy via a catheter to necrose selected conduction pathway areas. Following any of these ablation procedures, a temporary or permanent pacemaker may be needed if normal conduction tissue is damaged. Postprocedural care is similar to postangioplasty or postcardiac catheterization care. (See Chapter 15.)

► NURSING PROCESS FOR THE PATIENT WITH DYSRHYTHMIAS

Assessment

Assessment of the cardiac system, respiratory rate, breath sounds, and urinary output is important. Monitoring apical and radial pulses at frequent intervals helps detect dysrhythmias. Most dysrhythmias are not life threatening. Patients at risk for dysrhythmias require careful monitoring so that any dysrhythmias are detected and treated. A patient's complaints of dizziness, chest pain, or palpitations should always be reported to the physician.

Nursing Diagnoses

The major nursing diagnoses for dysrhythmias may include but are not limited to the following:

- Decreased cardiac output related to dysrhythmias or response to medications

- Ineffective tissue perfusion related to decreased cardiac output
- Activity intolerance related to decreased cardiac output
- Anxiety related to fear of dying, knowledge deficit, and diagnostic procedures
- Deficient knowledge related to dysrhythmias, diagnostic procedures, medications, and treatment

Planning

The goal of therapy is to identify patients at risk for dysrhythmias and promote adequate cardiac output. You need to identify factors that may contribute to increased cardiac workload. Careful assessment of all systems will focus on areas that might be affected by decreased cardiac output.

The patient's goals include the following:

- Maintain vital signs and oxygen saturation within normal range.
- Maintain warm, dry skin; palpable pulses; and normal vital signs.
- Maintain desired activities.
- Decrease anxiety.
- Understand the disease and its treatment.

Implementation

To implement the plan of care, the patient and family should be included. Assist them in understanding the plan and the reasons for the prescribed interventions. The patient and family need to be given time to understand the plan of care and to express their needs and fears. See Nursing Care Plan Box 20-2 for the Patient with Dysrhythmias for nursing interventions.

BOX 20-2 NURSING CARE PLAN FOR THE PATIENT WITH DYSRHYTHMIAS

► Decreased cardiac output related to dysrhythmias

PATIENT OUTCOMES

(1) Patient cardiac status stabilizes. (2) Patient tolerates activities of daily living (ADL).

EVALUATION OF OUTCOMES

(1) There is an absence of dysrhythmias. (2) Patient is able to perform ADL without tachycardia, chest pain, or weakness.

INTERVENTIONS

Assess apical and radial pulses every 2 to 4 hours. Assess blood pressure and urinary output. Monitor mental status every 2 to 4 hours. Assess lung sounds every 2 to 4 hours. Administer O₂ as ordered.

Ensure that patient gets adequate rest and does not exceed activity tolerance.

Administer medications as ordered and observe for adverse reactions.

RATIONALE

Monitors for dysrhythmias, impending cardiac arrest, or shock. Blood pressure, pulse, and urinary output are indicators of cardiac output. Dizziness, confusion, and restlessness may indicate decreased cerebral blood flow. Dysrhythmias can cause heart failure.

Increases oxygenation to the heart and brain.

Reduces dyspnea and decreases O₂ demand on the myocardium.

Older patients may have decreased renal and liver function that may lead to rapid development of toxicity.

EVALUATION

Is the patient free of dysrhythmias with vital signs within normal limits?

Does patient show signs of decreased cerebral perfusion, such as confusion? Are lungs clear with no report of dyspnea?

Is patient free of chest pain, confusion, and light-headedness?

Does patient rest and tolerate activity without dyspnea or chest pain?

Does patient have signs of toxicity?

GERIATRIC

BOX 20-2 NURSING CARE PLAN FOR THE PATIENT WITH DYSRHYTHMIAS—CONT'D**Anxiety related to situational crisis****PATIENT OUTCOMES**

(1) Patient is able to effectively manage anxiety. (2) Patient will report decreased anxiety.

EVALUATION OF OUTCOMES

(1) Patient uses effective coping mechanisms to manage anxiety. (2) Patient expresses decreased anxiety.

INTERVENTIONS

Assess level of anxiety.
Encourage patient and family to verbalize fears.
Explain procedures to patient and family.
Identify and reduce as many environmental stressors as possible.
Teach patient relaxation techniques to be performed every 4 to 6 hours, such as guided imagery, muscle relaxation, and meditation.
Medicate with antianxiety agents as ordered.

RATIONALE

Establishes a baseline.
Helps correct and clarify their concerns.
Lack of knowledge increases anxiety. Also will help with compliance of therapy.
Anxiety often results from lack of trust in the environment.
These measures can restore psychological and physical equilibrium and help decrease anxiety.
Aids the patient in decreasing anxiety.

EVALUATION

What is patient's level of anxiety?
What are patient's feelings or fears?
Does patient express understanding of therapy with decreased anxiety?
Can patient describe two situations that increase tension?
Is patient successful in demonstrating relaxation methods?
Does patient show decreased anxiety?

Family members should be taught CPR or given information on local CPR classes. This training gives the patient and family a sense of control and hope. In the event the patient requires CPR, the family can take action instead of simply standing by and feeling helpless. The patient will feel more secure in knowing that immediate help from family members is available at home until medical help arrives (Home Health Hints).

Evaluation

Evaluation of the outcome stems from regulation of dysrhythmias. Compliance with medication and therapy is the best indicator of understanding. Involvement of the patient and family in asking questions and being involved in the plan of care leads to positive outcomes and control of dysrhythmias.

**HOME HEALTH HINTS**

- The nurse should have a pocket mask for CPR available at all times.
- A car phone or portable phone affords a home health nurse safety, convenience, and efficiency, especially if emergency help is needed, because some patients do not have phones.
- Patients prone to dysrhythmias should avoid straining with bowel movements. If the patient reports straining, request a laxative or stool softener order from the physician.
- Patients who come home with a pacemaker should be instructed to wear loose tops. Women should not wear tight bras.
- Symptoms of infection to watch for after a pacemaker is implanted are redness, swelling, warmth, and pain at the site.
- Instruct patients with a pacemaker to take their pulse once a day, in the morning, for a full minute. Assist them in setting up a log to record date, time, and pulse reading. Instruct them to call if the pulse varies outside parameters set by the physician.
- Patients on beta blockers need to know how to take their pulse, because bradycardia is a major side effect. For pulse below 50, call the nurse or physician.
- Advise patients who are leaving home for weekend or holidays to refill medicines ahead of time. Also, the physician may write a prescription for patients to keep in their wallet for emergencies.

REVIEW QUESTIONS

- Which of the following is the correct sequence for normal electrical impulse movement through the cardiac conduction system?
 - Vena cavae, right atrium, right ventricle, pulmonary artery
 - SA node, AV node, bundle of His, Purkinje fibers
 - Pulmonary veins, left atrium, left ventricle, aorta
 - Purkinje fibers, AV node, bundle of His, SA node
- If a patient is in pulseless ventricular tachycardia, which of the following is the first choice of treatment?
 - Synchronized cardioversion
 - Pacemaker
 - Defibrillation
 - Antiarrhythmic medication
- The nurse is ambulating a patient who is recovering from an MI and the patient develops chest pain with an irregular pulse. What is the safest way to return the patient to his bed?
 - Ambulate to room with one assistant
 - With assistance by stretcher
 - With assistance by a wheelchair
 - After completion of ambulation
- You are to give a patient amiodarone 800 mg/day PO in two divided doses. You have available 200-mg tablets. How many tablets will you give for each dose?
 - 2
 - 4
 - 6
 - 8
- A patient has a radial pulse of 58 bpm. Which of the following is the appropriate term for documenting this rhythm?
 - Normal
 - Bradycardia
 - Tachycardia
 - Asystole

Answers to CRITICAL THINKING

Mrs. Mae

- Assess the patient's vital signs and heart sounds; note symptoms; obtain an ECG per agency protocol.
- Report the patient findings to the RN or physician.
- Possible causes include hypokalemia or ischemia leading to irritability of the heart.
- Symptoms might include light-headedness, feeling of heart skipping, chest pain, or fatigue.
- To alleviate symptoms, elevate head of bed to comfort, monitor vital signs, and maintain oxygen at 2 L/min via nasal cannula per agency protocol. Remain with the patient to help alleviate anxiety. Notify the RN.
- Orders might include ECG, oxygen, potassium, or electrolytes.
- Documentation should include the following:
1400: Ambulated 20 feet with one assist. Vital signs stable. Stated "feel good. Pain zero."
Tolerated well. Assisted to bed. Oxygen at 2 L/min via nasal cannula.
1405: See ECG strip with intermittent PVCs. Vital signs: 132/84, apical 92 irregular, 22.
"Pain zero. I can feel my heart skipping, it takes my breath away."
RN notified.

Mrs. Parker

- A heart in VT has an ectopic focus firing. The heart is unable to maintain adequate cardiac output with such a rapid heart rate. The rapid and irregular heart rhythm does not allow the heart chambers time to adequately fill and empty, thereby reducing the blood volume with each beat. This in turn affects the peripheral circulation, causing the absence of palpable pulses.
- In VT one or more sites in the ventricle may be initiating impulses. The rapid rate of VT overrides the normal pacemaker of the heart. The rhythm can be regular or irregular. The inability of the heart to conduct impulses along normal pathways prevents the chambers from emptying and filling properly. This leads to a de-

creased cardiac output and can lead to cardiac arrest if the rhythm is not converted.

- Call a code and begin CPR. Report findings to code team upon their arrival.
- Documentation should include the following:
1600: Patient found in bed unresponsive to verbal and tactile stimuli. Respirations shallow. No palpable pulses. BP 80/40, P 150, R 6. Monitor shows VT (see strip). Code called from room. CPR started. Code team arrived at 1602. Report given to code team leader.

Mr. Peet

- Initially you should assess responsiveness and the presence of a carotid pulse. Check for breathing.
- Open the airway. Call for assistance or use the patient's phone to report a cardiac arrest. Initiate CPR until help arrives.
- Once help or the code team arrives, the licensed practical nurse/licensed vocational nurse (LPN/LVN) reports the patient's status. The code team leader delegates responsibilities. Many facilities have protocols for each team member in a code. The LPN/LVN assists in the code as delegated by the RN in charge.

Mr. Treacher

- Your first actions should be to obtain an ECG per agency protocol and to notify the RN and physician.
- You should keep the head of the bed elevated and administer oxygen at 2 L/min via nasal cannula per protocol. Turn the patient onto his side because this may help float the pacemaker wire to the chamber wall for better contact. Monitor the patient's ECG, vital signs, and symptoms, and remain with patient to provide emotional support.
- Mr. Treacher could be experiencing pacemaker malfunction.
- Interventions could include transfer to a step-down unit or intensive care unit (ICU), reprogramming of the pacemaker, or a return to surgery for manipulation or replacement of the pacer.

QUESTIONS TO GUIDE YOUR READING

1. How would you describe the pathophysiology of left- and right-sided heart failure?
2. What is acute heart failure?
3. What are causes of acute and chronic heart failure?
4. What are signs and symptoms of acute and chronic heart failure?
5. What nursing care would you provide for diagnostic tests for heart failure?
6. What is the medical treatment for acute and chronic heart failure?
7. What nursing care would you provide for acute and chronic heart failure?
8. What would you include in your teaching plan for patients with heart failure and their families?

► HEART FAILURE

Heart failure is a syndrome that occurs as a result of the progressive inability of the heart to pump enough blood to meet the body's oxygen and nutrient needs. It can cause decreased tissue perfusion, fatigue, fluid volume overload in the intravascular and interstitial spaces, and reduced quality and length of life. Causes of heart failure include coronary artery disease, myocardial infarction, cardiomyopathy, heart valve problems, and hypertension. In the elderly the most common cause of heart failure is cardiac ischemia. It may develop rapidly (acute), as with cardiogenic shock and **pulmonary edema**, or over time (chronic) as a result of another disorder, such as hypertension or pulmonary disease.

The incidence of heart failure is increasing as the elderly population and patient survival rates increase. Heart failure is the most common reason for hospital admission in the elderly. Quality of life is often impaired. The patient may experience many functional limitations and symptoms, and there is a high mortality rate. Readmission rates to hospitals soon after discharge for heart failure treatment are high and

pose a challenge for health care providers. For more information, visit the American Heart Association at www.americanheart.org or the Heart Failure Society of America at www.hfsa.org.

Pathophysiology

The heart is divided into two separate pumping systems. The right side of the heart forms one pump. The left side of the heart forms the other pump. Normally these pumps work together to ensure that equal amounts of blood enter and leave the heart.

Blood flow through the heart begins in the right atrium. (See Chapter 15.) Unoxygenated blood from the body's venous system enters the right atrium from the inferior and superior venae cavae. Next the blood enters the right ventricle to be pumped into the pulmonary artery and into the lungs for oxygenation. After receiving oxygen in the lungs, the blood is returned to the left atrium via the four pulmonary veins. The oxygenated blood then enters the left ventricle and is pumped out into the aorta and the systemic circulation.

Proper cardiac functioning requires each ventricle to pump out equal amounts of blood over time. If the amount of blood returned to the heart becomes more than either ventricle can handle, the heart can no longer be an effective pump. Conditions that cause heart failure may affect one or both of the heart's pumping systems. Therefore heart failure can be classified as right-sided heart failure, left-sided heart failure, or biventricular heart failure. The ventricle is the area of the heart's pumping system that commonly fails. Of the two ventricles, the left ventricle is typically the one to weaken first because it has the greatest workload. The right and left sides of the heart's pumping system work together in a closed system to continuously move blood forward, so failure of one side eventually leads to failure of the other side.

LEARNING TIPS

To visualize and understand the effects of heart failure, trace the flow of blood backward from each ventricle. Along the backward path from the failing ventricle, congestion develops and produces the signs and symptoms seen in heart failure. If you understand the backward path of congestion, you can identify the signs and symptoms specifically associated with right- or left-sided heart failure.

LEARNING TIPS

To understand heart failure, compare it to a dam in a river: In a river without a dam, the water flows freely; in the normal circulatory system, blood flows freely.

- In a river with a dam, the water is blocked by the dam and builds up behind it; in heart failure, the failing ventricle acts like the dam in the river, causing blood to back up behind it.
- When the dam on the river malfunctions, too much water builds up behind it and the riverbanks flood; in heart failure, if too much blood builds up behind the failing ventricle, the lungs or peripheral tissues are flooded (edema).
- Heart failure can be the result of systolic (contractile) dysfunction, diastolic (relaxation) dysfunction, or a mixed systolic and diastolic dysfunction. Systolic dysfunction is a contractile problem in which the ventricle is unable to generate enough force to pump blood from the ventricle. Diastolic dysfunction is a problem with the ventricle's ability to relax and fill. Mixed systolic and diastolic dysfunction is a combination of the two defects.

Left-Sided Heart Failure

A certain amount of force must be generated by the left ventricle during a contraction to eject blood into the aorta through the aortic valve. This force is referred to as **afterload**. The pressure within the aorta and arteries influences the force needed to open the aortic valve to pump blood into the aorta. This pressure is called **peripheral vascular resistance (PVR)**.

Hypertension is one of the major causes of left-sided heart failure because it increases the pressure within arteries. Increased pressure in the aorta makes the left ventricle work harder to pump blood into the aorta. Over time the

strain caused by the increased workload causes the left ventricle to weaken and fail. Other conditions that can lead to left-sided heart failure are described in Table 21-1. Among these conditions are disorders that (1) restrict the outflow of blood from the left ventricle, as in aortic valve stenosis or coarctation of the aorta, which is a malformation causing narrowing; (2) impair contractility of the heart, as in myocardial infarction or cardiomyopathy; and (3) allow blood to flow backward into the left atrium, as in valvular disorders.

With left-sided heart failure, blood backs up from the left ventricle into the left atrium and then into the four pulmonary veins and lungs (Fig. 21-1). This increases pulmonary pressure, causing movement of fluid first into the interstitium and then the alveoli. Alveolar edema is more serious because it reduces gas exchange across the alveolar capillary membrane. Shortness of breath and **cyanosis** may

TABLE 21-1 CAUSES OF LEFT-SIDED HEART FAILURE

Cause	Primary Effect on Left Ventricular Workload
<i>Hypertension</i>	Resistance increased from elevated pressure
<i>Coarctation of the aorta</i>	Resistance increased from elevated pressure
<i>Myocardial infarction</i>	Increased workload from poor contractility
<i>Cardiomyopathy</i>	Increased workload from poor contractility
<i>Aortic stenosis</i>	Increased volume to pump
<i>Mitral regurgitation</i>	Increased volume to pump

Figure 21-1 Left-sided heart failure. Shaded areas indicate areas of congestion from blood backup caused by the failing left side of the heart.

result from the decreased oxygenation of the blood leaving the lungs. If the fluid buildup is severe, pulmonary edema occurs, which requires immediate medical treatment.

Right-Sided Heart Failure

Causes of right-sided heart failure are described in Table 21-2. The major cause of right-sided heart failure is left-sided heart failure. When the left side fails, fluid backs up into the lungs and pulmonary pressure is increased. The right ventricle must continually pump blood against this increased fluid and pressure in the pulmonary artery and lungs. Over time this additional strain eventually causes it to fail.

Conditions causing right-sided heart failure increase the work of the right ventricle. They increase the amount of contractile force needed or they require pumping of excess blood volume (**preload**). Among these conditions are disorders that (1) increase pulmonary pressures, such as emphysema or congenital heart defects; (2) restrict the outflow of blood from the right ventricle, as in pulmonary valve stenosis; and (3) allow left atrial blood to flow into the right atrium, thereby increasing blood volume in the right ventricle, as in septal defects. When the right ventricle hypertrophies or fails because of increased pulmonary pressures, it is referred to as **cor pulmonale**.

When the right ventricle fails, it does not empty normally and there is a backward buildup of blood in the systemic blood vessels. As the blood backs up from the right ventricle, right atrial and systemic venous blood volume increases. The jugular neck veins, which are not normally visible, become distended and can be seen when the person is in a 45-degree upright position. Edema may occur in the peripheral tissues, and the abdominal organs can become engorged (Fig. 21-2). Congestion in the gastrointestinal tract causes anorexia, nausea, and abdominal pain. As the failure progresses, blood pools in the hepatic veins and the liver becomes congested, known as **hepatomegaly**. Pain in the right upper quadrant and impaired liver function are caused by this liver congestion. Systemic venous congestion also leads to engorgement of the spleen, known as **splenomegaly**.

TABLE 21-2 CAUSES OF RIGHT-SIDED HEART FAILURE

Cause	Primary Right Ventricular Workload Effect
Pulmonary hypertension	Resistance increased from elevated pressure
Cor pulmonale	Resistance increased from elevated pressure
Pulmonary stenosis	Increased volume to pump
Atrial septal defect	Increased volume to pump

cor pulmonale: cor—heart + pulm—lung
hepatomegaly: hep—liver + mega—large
splenomegaly: splen—spleen + mega—large

Figure 21-2 Right-sided heart failure. Shaded areas indicate areas of congestion from blood backup due to the failing right side of the heart.

LEARNING TIPS

To understand the signs and symptoms of left-sided versus right-sided heart failure, remember that left-sided signs and symptoms are found in the lungs. *Left* begins with *L*, as does *Lung*:

Left = Lungs, L = L

Any signs and symptoms not related to the lungs (L) are caused by right-sided failure.

► COMPENSATORY MECHANISMS TO MAINTAIN CARDIAC OUTPUT

Compensatory mechanisms help ensure that an adequate amount of blood is being pumped out of the heart. Although these mechanisms are designed to maintain cardiac output, they can also contribute to heart failure and create a cycle that instead of being helpful leads to further heart failure.

When the sympathetic nervous system detects low cardiac output, it speeds up the heart rate by releasing epinephrine and norepinephrine. Although this raises cardiac output (cardiac output = heart rate × stroke volume), the increased heart rate also increases the oxygen needs of the heart. In response to low renal blood flow, the kidneys activate the renin-angiotensin-aldosterone system, and antidiuretic hormone is released from the pituitary gland to conserve water, causing decreased urine output. This adds to the fluid retention problem already found in heart failure.

Over time the heart responds to the increased workload by enlarging its chambers (dilation) and increasing its muscle mass (hypertrophy). In dilation the heart muscle fibers stretch to increase the force of myocardial contractions,

which is known as the Frank-Starling phenomenon. In hypertrophy the muscle mass of the heart increases, creating more contractile force. Both these compensatory mechanisms also increase the heart's oxygen needs.

► PULMONARY EDEMA

Pulmonary edema, also known as acute heart failure, is severe fluid congestion in the alveoli of the lungs and is life threatening. Pulmonary edema occurs in an acute event such as a myocardial infarction (MI) or when the heart is severely stressed, causing the left ventricle to fail. Complications of pulmonary edema include dysrhythmias and cardiac arrest.

Pathophysiology

First, pressure rises in the lung's venous blood vessels and blood builds up. As pressures continue to rise, fluid moves into the interstitial spaces. Then, with continued pressure increases, fluid containing red blood cells moves into the alveoli. Finally, the alveoli and airways become filled with fluid, reducing gas exchange and oxygen levels.

Signs and Symptoms

Signs and symptoms of pulmonary edema are listed in Table 21-3. Pink, frothy sputum is a classic symptom of pulmonary edema caused by the increased lung congestion and pres-

ures that allow leaking of fluid into the alveoli. Compensatory mechanisms increase the heart rate and blood pressure; however, as pulmonary edema worsens, the blood pressure may fall.

Diagnosis

Diagnostic studies are listed in Table 21-3. The congested pulmonary system can be seen on x-ray examination. Arterial blood gases (ABGs) will show a decrease in PaO₂ that continues as the edema worsens and an increase in PaCO₂, causing respiratory acidosis (pH < 7.35). The pulmonary artery catheter will show elevated pulmonary pressures and a decreased cardiac output.

Medical Management

Immediate treatment is necessary to prevent patients from drowning in their own secretions. (See Table 21-3.) The goal of therapy is to reduce the workload of the left ventricle in order to improve cardiac output and reduce the patient's anxiety. Care for the patient is usually provided in an intensive care unit. Treatment for the underlying cause occurs at the same time that the patient is being treated for the pulmonary edema.

Treatment includes positioning the patient upright to make breathing easier. In Fowler's position, the lungs can more easily expand. Ask the patient what position is preferred. Oxygen is given usually by mask to provide higher amounts. In severe cases of pulmonary edema, endotracheal intubation and mechanical ventilation may be necessary. Medications are given intravenously to reduce anxiety, relax airways, and increase peripheral blood pooling to decrease preload (morphine); reduce fluid congestion; reduce preload; strengthen heart contractions; reduce arterial pressure and sodium and water retention to relieve dyspnea (nesiritide [Natrecor]). Nesiritide is part of a newer drug class called human B-type natriuretic peptide (hBNP). hBNP is normally secreted by the ventricular myocardium in response to heart failure.

► CHRONIC HEART FAILURE

Signs and Symptoms

The signs and symptoms of chronic heart failure are influenced by the patient's age, the underlying cause and severity of the heart disease, and the ventricle that is failing. Chronic heart failure is a progressive disorder, so signs and symptoms may worsen over time. Signs and symptoms caused by a specific failing ventricle are listed in Table 21-4.

Fatigue and Weakness

Fatigue and weakness are the earliest symptoms of heart failure. They occur from the decreased amount of oxygen reaching the tissues. Throughout the day the fatigue worsens, especially with activity.

Dyspnea

A failing left ventricle produces prominent respiratory effects. Dyspnea is a common symptom of left-sided heart

TABLE 21-3 ACUTE HEART FAILURE SUMMARY

 Total artificial heart
 Surgery
 Cardiomyoplasty
 Cardiac transplant

ACE, angiotensin-converting enzyme; BUN = blood urea nitrogen.

failure. It occurs from the pulmonary congestion that impairs gas exchange between the alveoli and capillaries. Dyspnea stimulates compensatory mechanisms that produce short, rapid respirations. Dyspnea is classified in several ways:

- Exertional dyspnea is shortness of breath that increases with activity.
- **Orthopnea** is dyspnea that increases when lying flat. In an upright position, gravity holds fluid in the lower extremities.

orthopnea: orth—straight + pnea—to breathe

In a supine position, gravitational forces are removed, allowing fluid to move from the legs to the heart, which overwhelms the already congested pulmonary system. When orthopnea is present, two or more pillows are often used for sleeping, and the documentation should state the number of pillows used. For example, use of three pillows would be three-pillow orthopnea.

- **Paroxysmal nocturnal dyspnea (PND)** is sudden shortness of breath that occurs after lying flat for a time. PND results from excess fluid accumulation in the lungs. The sleeping person awakens with feelings of suffocation and anxiety. Relief is obtained by sitting upright for a short

time, which reduces the amount of fluid returning to the heart.

Cough

A chronic, dry cough is common in heart failure. The coughing increases when lying down from increased irritation of the lung mucosa. This irritation is due to the increase in pulmonary congestion that occurs when gravity no longer keeps fluid in the legs and more fluid returns to the heart and lungs.

Crackles and Wheezes

Pulmonary congestion causes abnormal breath sounds such as crackles and wheezes. These sounds indicate the presence of increased fluid in the lungs. Crackles are produced from fluid buildup in the alveoli resulting from increased pressure in the pulmonary capillaries. Wheezes occur from bronchial constriction caused by the increased fluid.

LEARNING TIPS

To simulate the sound of crackles, open a piece of Velcro or rub hair together next to your ear. These sounds are similar to the sound of crackles heard with a stethoscope.

Tachycardia

The sympathetic nervous system compensates for the decreased cardiac output in heart failure by releasing epinephrine and norepinephrine to increase the heart rate. Normally this is helpful because the increased heart rate increases the amount of blood ejected by the heart to maintain an adequate cardiac output. However, whenever the heart works faster it also requires more oxygen, which a failing heart finds it difficult to supply.

Chest Pain

Chest pain may occur from ischemia in the patient with heart failure. Decreased cardiac output results in decreased oxygen delivery to the heart itself, via the coronary arteries. Compensatory mechanisms designed to maintain cardiac output increase the workload and oxygen needs of the heart and are counterproductive in heart failure. Tachycardia increases the oxygen needs of the heart. The kidneys compensate by retaining sodium and fluid, which increases the fluid volume returning to the heart (preload) and therefore the heart's workload and oxygen needs. Pain also increases oxygen requirements, adding further to the cycle of heart failure.

Cheyne-Stokes Respiration

A breathing pattern of shallow respirations building to deep breaths followed by a period of apnea characterizes Cheyne-Stokes breathing. The apneic period occurs because the deep breathing causes carbon dioxide levels to drop to a level that does not stimulate the respiratory center. This ap-

nea may last up to 30 seconds and is then followed by the shallow-to-deeper respiratory pattern of Cheyne-Stokes as carbon dioxide levels rise again.

Edema

Edema occurs in heart failure as a result of (1) systemic blood vessel congestion and (2) sympathetic compensatory mechanisms that cause the kidneys to activate the renin-angiotensin-aldosterone system, in which antidiuretic hormone is released from the pituitary gland, causing sodium and water to be retained. Systemic or pulmonary edema can occur in heart failure. The effect of backward buildup of pressure in the systemic blood vessels is seen with distention of the jugular veins, swelling of the legs and feet, sacral edema in the individual on bedrest, and increased fluid within the abdominal cavity and organs. An acute buildup of fluid in the lungs produces pulmonary edema.

Nocturia

Nocturia is an increase in urine output at night. After lying down, fluid in the lower legs returns to the circulatory system. Renal blood flow and filtration is increased, resulting in greater urine production and the need to urinate frequently during the night. Nocturia may occur up to six times per night, contributing to the patient's fatigue from lack of sleep.

LEARNING TIPS

Patients often have to get up to void shortly after going to bed. This is due to fluid in the legs returning to the heart and then the kidneys for filtering after a person lays down. To help patients get as much undisturbed rest as possible, teach them to recline with legs at or above heart level for at least 30 minutes before going to bed. Then they can void before going to bed, instead of soon after going to bed.

Cyanosis

The skin, nailbeds, or mucous membranes may appear blue, or cyanotic, from decreased oxygenation of the blood. Cyanosis is a late sign of heart failure. It is associated primarily with left-sided heart failure.

Altered Mental Status

Less cardiac output decreases the amount of oxygen delivered to the brain. As a result, restlessness, insomnia, confusion, and impaired memory may occur. A decrease in level of consciousness may occur.

Malnutrition

Several factors contribute to malnutrition in the person with chronic heart failure. Altered mental status, dyspnea, and fatigue interfere with the ability to eat. Anorexia and gastrointestinal (GI) upset occur from pressure exerted by excess fluid surrounding the GI structures. Absorption of food may also be impaired by this pressure.

CRITICAL THINKING

Mr. Shepard (1)

Mr. Shepard, 66, has a family history of cardiac disease. He has been hypertensive for 10 years and takes captopril daily. His baseline vital signs are blood pressure 122/78, pulse 80, respiration 18, height 66 in, and weight 170 lb. During a visit to his physician, he states that he has been short of breath during his daily 2-mile walk and has been using two pillows at night for sleep. As he talks, the physician notes that he has an intermittent dry cough. His physical examination shows blood pressure 140/86, pulse 106, respiration 24, weight 178 lb, and bilateral crackles in the lung bases.

1. What signs and symptoms of heart failure does Mr. Shepard have?
2. Do the signs and symptoms reflect right- or left-sided heart failure?
3. Why are each of the signs and symptoms occurring?
4. Why is Mr. Shepard using two pillows for sleeping?

Answers at end of chapter.

Complications of Heart Failure

Complications of heart failure are listed in Table 21-4. The liver and spleen enlarge from the fluid congestion, which causes impaired function, cellular death, and scarring. Pleural effusion, a leakage of fluid from the capillaries of the lung into the pleural space, can occur. The elevated pressures in the capillaries of the lung cause this leakage. Thrombosis and emboli can occur as a result of poor emptying of the ventricles, which leads to stasis of blood. Aspirin or anticoagulants are often prescribed to prevent thrombus formation in patients with heart failure. Cardiogenic shock, often caused by a myocardial infarction that damages the left ventricle, occurs when the left ventricle is unable to supply the tissues with enough oxygen and nutrients to meet their needs. Cardiogenic shock is a life-threatening condition that requires immediate treatment. (See Chapter 8.)

Diagnostic Tests

Diagnostic tests are done to identify the cause of the failure and determine the degree of failure present (see Table 21-4):

- A chest x-ray examination shows the size, shape, and enlargement of the heart and congestion in the pulmonary vessels.
- Cardiac dysrhythmias that precipitate and contribute to heart failure can be diagnosed with electrocardiogram (ECG; see Chapter 20). Chamber enlargement in the atrium from heart failure is shown by P-wave changes and in the left ventricle by increased voltage and deeper S waves in some V leads.
- Exercise stress testing and nuclear imaging studies provide information on activity tolerance, which is usually limited in heart failure.
- Echocardiography measures the size of the heart chambers to detect enlargement and assess valvular function and motion of the ventricles.

- Cardiac catheterization and angiography are used to detect underlying heart disease that may be the cause of heart failure.
- Direct assessment of the heart's pressures is done with hemodynamic monitoring. A catheter is inserted into the heart and pulmonary artery to transmit pressures to a cardiac monitor. These cardiac and pulmonary pressures are then used to guide medical therapy.
- Serum laboratory tests may show elevated serum blood urea nitrogen (BUN) and elevated serum creatinine from renal failure and elevated liver enzymes from liver damage.

CRITICAL THINKING

Mr. Shepard (2)

Mr. Shepard's chest x-ray examination shows an enlarged heart (cardiomegaly).

1. Why is Mr. Shepard's heart enlarged?
2. What is the significance of an enlarged heart?

Answers at end of chapter.

Medical Management

The overall goal of medical treatment for chronic heart failure is to improve the heart's pumping ability and decrease the heart's oxygen demands. Treatment of heart failure focuses on (1) identifying and correcting the underlying cause, (2) increasing the strength of the heart's contraction, (3) maintaining optimum water and sodium balance, and (4) decreasing the heart's workload (Fig. 21-3). Heart failure management requires a team approach that may involve physicians, case managers, nurses, dietitians, physical therapists, occupational therapists, pharmacists, social workers, and clergy. Heart failure critical pathways (treatment guidelines), as well as heart failure clinics, are being used to ensure quality-based outcomes while reducing treatment costs.

The severity of heart failure determines the individualized therapy selected. Noninvasive approaches are usually tried first. (See Table 21-4.) If noninvasive treatment is not effective, invasive approaches may be used.

Oxygen Therapy

One of the major problems caused by heart failure is a reduction in oxygen delivered to the tissues. The heart failure signs and symptoms of this are fatigue, dyspnea, altered mental status, and cyanosis. Oxygen therapy assists in supplying the oxygen needs of the tissues. In mild heart failure, oxygen may be delivered via nasal cannula. For more severe cases, arterial blood gas values guide oxygen delivery, either via masks that provide high concentrations of oxygen or with mechanical ventilation.

Activity

Activity tolerance depends on the severity of heart failure signs and symptoms. Severe symptoms may require bedrest

Figure 21-3 Management of heart failure is a balancing act. (Modified from Stanley, M, and Beare, P: *Gerontological Nursing*. FA Davis, Philadelphia, 1995, p 198.)

with restricted activity until treatment reduces the symptoms. For stable heart failure, a regular exercise program can be helpful in improving cardiac function and reducing heart failure effects. Patients should be encouraged to stay as active as possible within the parameters the physician has pre-

scribed. An individualized walking program that increases activity over time is often prescribed. Patients should be taught how to exercise safely without causing symptoms and to understand that overexertion can produce fatigue the next day. Referral to a cardiac rehabilitation program can be helpful.

Nutrition

Dietary sodium is often restricted to decrease fluid retention. Restricting sodium is challenging. (See Nutrition Notes Box 5-4.) Compliance is often low because low-sodium foods are not very appealing. A referral to a dietitian is important. Diet counseling helps the patient and family understand the need for dietary compliance and the need to provide menus that are appealing and easy to use. Salt substitutes often use potassium in place of sodium, so the patient and physician should discuss their use. Spices, herbs, and lemon juice may be suggested to flavor unsalted foods. Eating should remain pleasurable for the patient to avoid malnutrition. Focus on showing patients the foods that they like and can still have rather than talking about only the foods they cannot have.

LEARNING TIPS

In severe heart failure with abdominal discomfort present, malnutrition is a concern. The patient can be anorexic, but the weight gain that occurs with fluid retention can mask the weight loss occurring from the anorexia. Monitor food intake to ensure weight gain from fluid retention does not allow malnutrition to be undetected.

Drug Therapy

The major classifications of oral drugs used to treat heart failure are listed in Table 21-5. Potassium supplements,

TABLE 21-5 ORAL MEDICATIONS FOR HEART FAILURE

Class	Drugs	Side Effects	Nursing Implications
ACE inhibitor plus a diuretic is first-line therapy to decrease afterload. Decreases cardiac hypertrophy.	captopril (Capoten) enalapril (Vasotec) fosinopril (Monopril) lisinopril (Prinivil, Zestril) moexipril (Univasc) perindopril (Aceon) quinapril (Accupril) ramipril (Altace) trandolapril (Mavik)	Cough, hypotension, altered taste, rash, proteinuria, hyperkalemia, angioedema (dyspnea, facial swelling), neutropenia (with captopril)	Check blood pressure before giving. Monitor WBC with captopril. Teach patient to change positions slowly to reduce orthostatic hypotension. Take captopril and moexipril on an empty stomach (1 hour before or 2 hours after meals). Teach to report development of cough, so drug can be changed. Teach to check blood pressure weekly and report changes to physician. Teach to report rash, sore throat/mouth, fever, swelling of hands/feet/face/tongue, difficulty breathing/ swallowing, chest pain or irregular heartbeat.
Angiotensin II receptor inhibitor decreases cardiac hypertrophy and apoptosis.	losartan (Cozaar) valsartan (Diovan)	Headache, dizziness, angioedema (dyspnea, facial swelling)	Assess blood pressure and pulse before giving. Correct dehydration before initiating therapy. Teach to change positions slowly to reduce orthostatic hypotension.

ACE = angiotensin-converting enzyme; WBC = white blood cell.

TABLE 21-5 ORAL MEDICATIONS FOR HEART FAILURE — CONT'D

Class	Drugs	Side Effects	Nursing Implications
May be used if ACE inhibitor not tolerated. Survival effects currently being studied.			Teach to report rash, sore throat/mouth, fever, swelling of hands/feet/face/tongue, difficulty breathing/ swallowing, chest pain or irregular heartbeat.
Diuretics			
Loop diuretics (<i>potassium wasting</i>) decrease fluid overload.	bumetanide (Bumex) furosemide (Lasix) torsemide (Demalex)	Hypokalemia, hypochloremia, hypomagnesemia, hyponatremia, dehydration, hypotension	Do not give to sulfa-allergic patients. Assess blood pressure and pulse before giving. Monitor electrolyte levels (especially potassium level and for those on digitalis), and fluid status (daily weight, intake, output, thirst, dry mouth, weakness, oliguria) throughout therapy. Administer in A.M. to avoid nocturia.
Thiazide diuretics (<i>potassium wasting</i>) decrease fluid overload.	chlorothiazide (Diuril) chlorthalidone (Hygroton, Thalitone) hydrochlorothiazide (HydroDiuril, HCTZ, Microzide)	Hypokalemia, dizziness, hypotension, photosensitivity	Assess blood pressure, intake, output, daily weight, and edema. Do not give to sulfa-allergic patients. Administer in A.M. to avoid nocturia. Monitor potassium level throughout therapy. Teach to report signs of hypokalemia: weakness, fatigue, arrhythmias. Teach about potassium supplements and, if on digitalis, about increased risk of toxicity with hypokalemia. Teach to monitor weight daily and report changes. Teach use of sunscreen to prevent photosensitivity reaction.
Beta blockers reduce sympathetic nervous system input, which decreases heart rate and improves cardiac output. Also reduce cardiac remodeling.	bisoprolol (Zebeta) carvedilol (Coreg), specific for heart failure, contains beta blocker plus antioxidant, effective in slowing progression of heart failure metoprolol tartrate (Toprol XL, Lopressor)	Dizziness, hypotension, hyperglycemia, fluid retention, diarrhea, bradycardia, heart blocks, impotence, bronchospasm (carvedilol)	Avoid carvedilol in patients with asthma (causes bronchospasm). Check apical heart rate and blood pressure. If heart rate is below 50 or blood pressure below 100 systolic, contact physician before giving. Teach to take pulse daily and blood pressure biweekly and to contact physician before taking drug if pulse rate is below 60. Teach to change positions slowly to reduce orthostatic hypotension. Diabetic patients should closely monitor blood sugar. Teach to monitor for worsening of heart failure symptoms.
Aldosterone antagonist blocks effects of aldosterone and has positive effect on sodium and potassium balance.	spironolactone (Aldactone)	Hyperkalemia, nausea, vomiting, anorexia, diarrhea, headache, clumsiness, gynecomastia	Do not give if hyperkalemic. Administer in A.M. to avoid nocturia. Monitor potassium level and fluid status throughout therapy. Teach signs of hyperkalemia: weakness, fatigue, confusion, dyspnea, arrhythmias, confusion. Elderly patients are at higher risk for electrolyte imbalances.
Inotropes—cardiac glycoside (positive inotrope and negative chronotrope) increase the force and contraction of the myocardium, which increases cardiac output. Slows heart rate to reduce workload of heart and controls atrial fibrillation if present.	digoxin (Lanoxicaps, Lanoxin)	Fatigue, nausea, vomiting, anorexia, headache, bradycardia, cardiac arrhythmias Toxicity: abdominal pain, anorexia, nausea, vomiting, visual changes (blurred, yellow-green halos, photophobia, diplopia) bradycardia, dysrhythmias	Take apical pulse for 1 minute; if below 60, contact physician before giving. Instruct patient to take medication exactly as directed, at the same time each day. Teach patient to take pulse and to contact health care professional before taking medication if pulse rate is below 60 or above 100. Therapeutic digoxin levels: 0.5 to 2 mg/mL. Elderly are more susceptible to toxicity. Teach signs and symptoms of digitalis toxicity to patient and family. Periodically monitor drug level and electrolytes (hypokalemia, hypomagnesemia, hypercalcemia make patients more susceptible to toxicity). Antidote for toxicity is digoxin immune FAB (Digibind).

TABLE 21-5 ORAL MEDICATIONS FOR HEART FAILURE — CONT'D

Class	Drugs	Side Effects	Nursing Implications
Vasodilators decrease afterload, which increases cardiac output and reduces cardiac workload. Used for patients who cannot take ACE inhibitors.	isosorbide dinitrate (ISDN, Isorbid, Isordil, Isonate) hydralazine (Apresoline)	Headache, dizziness, hypotension, tachycardia	Assess blood pressure and pulse before giving. Teach to change positions slowly to reduce orthostatic hypotension. Isosorbide dinitrate: Administer 1 hour before or 2 hours after meals for faster absorption. Chewable tablets should be chewed well before swallowing and held in the mouth for 2 minutes. Extended-release tablets and capsules should be swallowed whole. Do not chew, crush, or break. Sublingual tablets should be held under tongue until dissolved; no eating, drinking, or smoking until tablet is dissolved; replace sublingual tab if swallowed. Headache is common initially and is treated with aspirin. Hydralazine: Take with meals to enhance absorption. Teach to avoid sudden changes in position to avoid orthostatic hypotension. Teach to immediately report fatigue, fever, aching, rash, chest pain, sore throat, numbness, tingling, or weakness of hands/feet.

anticoagulants, and antidysrhythmics may be given on an individualized basis.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS.

Angiotensin-converting enzyme (ACE) inhibitors are now considered a standard in therapy for heart failure. ACE inhibitors are used for vasodilation. It is now known that ACE inhibitors also offer additional benefit by preventing some structural cardiac changes that occur in heart failure. These remodeling changes lead to progressive cardiac deterioration, so inhibiting these changes is of great benefit in treating the condition.

LEARNING TIPS

To help you identify ACE inhibitors, remember that their generic names end with *-pril*.

DIURETICS. Diuretics are used to reduce fluid volume and decrease pulmonary venous pressure, so the heart does not have to work so hard. Diuretics act on various areas of the kidneys to promote the excretion of edema fluid. A combination of diuretics may be used to achieve the desired effect. Electrolytes (especially potassium levels, to prevent hypokalemia) and fluid balance (to prevent dehydration) should be carefully monitored during therapy. Potassium supplements are often given with potassium-wasting diuretics.

LEARNING TIPS

Always check potassium levels before giving a potassium-wasting diuretic such as furosemide (Lasix) or bumetanide (Bumex) or before giving a potassium supplement, which the patient may be taking due to diuretic therapy. Do not give diuretic if potassium levels are low or potassium supplement if potassium is high.

BETA BLOCKERS. Beta-blocker therapy is a newer recommendation for some heart failure patients along with standard therapy. Beta blockers are started at low doses and gradually increased. Improved cardiac output and activity tolerance are benefits with this therapy.

LEARNING TIPS

To help you identify beta blockers, remember that their generic names end with *-ol*.

INOTROPIC AGENTS. Inotropic drugs strengthen ventricular contraction to increase cardiac output. Inotropic agents include the cardiac glycosides (digitalis, digoxin), sympathomimetics (dopamine, dobutamine), and phosphodiesterase inhibitors (amrinone, milrinone). The sympathomimetics and phosphodiesterase inhibitors are usually used short term.

Digitalis. In addition to improving contraction strength, digitalis preparations decrease conduction time within the

heart, which slows the heart rate to allow more complete emptying of the ventricles. Digitalis may increase myocardial oxygen needs, so it is being used more cautiously. Monitoring of serum drug levels is necessary to detect toxic levels of the drug. If toxic levels are present, the drug is stopped to allow digitalis levels to decrease over time. If life-threatening dysrhythmias occur, a digoxin antibody, digoxin immune FAB (Digibind), can be administered.

ALDOSTERONE ANTAGONIST. An aldosterone antagonist, spironolactone (Aldactone), blocks the effects of aldosterone and has a positive effect on sodium and potassium balance. The use of this drug in combination with other drugs (ACE inhibitor and loop diuretic) has been shown to reduce morbidity and mortality for heart failure. Potassium must be monitored carefully as spironolactone is a potassium-sparing agent.

Pacemaker for Congestive Heart Failure

The InSync biventricular cardiac pacing system is a new device similar to a pacemaker to reduce symptoms of heart failure. The device paces both ventricles at the same time so that they beat together. In heart failure, one of the problems is that the ventricles do not always beat together. This results in a slight delay between the beats of each ventricle that impairs cardiac function. Resetting the heartbeat reduces symptoms and improves quality of life.

Mechanical Assistive Devices

Mechanical assistive devices can provide temporary support to patients in cardiogenic shock or awaiting cardiac transplant. These devices increase the cardiac output of the patient. Research is ongoing into the development of mechanical pumps that may become heart replacements. These mechanical assistive devices are used primarily in critical care settings.

INTRA-AORTIC BALLOON PUMP. The intra-aortic balloon pump (IABP) increases circulation to the coronary arteries. More oxygen is then available to the myocardium, which reduces the workload of the heart. The IABP is inserted into the femoral artery and positioned in the descending aortic arch (Fig. 21-4). The IABP is attached to a machine that senses ventricular contraction. During diastole the balloon inflates, forcing increased blood into the coronary arteries. During systole the balloon deflates to allow blood to flow past it.

VENTRICULAR ASSIST DEVICES. A ventricular assist device (VAD) temporarily supports cardiac output and allows the failing ventricle to rest. There are several types of VADs (Fig. 21-5). VADs can pump blood directly from either the right atrium to the pulmonary artery (right ventricular failure) or the left atrium to the aorta (left ventricular failure). Two devices can be used for biventricular failure. A newer VAD (Novacor Left Ventricular Assist System) is an electromechanical pump, about the size of a human heart, which is implanted into the abdominal wall. This pump is used for patients awaiting transplant and is being studied for long-term use.

Figure 21-4 Intra-aortic balloon pump.

Surgical Management

CARDIOMYOPLASTY. Cardiomyoplasty is a surgical procedure that uses the patient's own skeletal muscle (latissimus dorsi) to enhance the function of the heart and improve circulation (Fig. 21-6). The muscle is positioned around the aorta or heart, and a cardiomyostimulator and leads are implanted to stimulate muscle contraction. The muscle is rested for 2 weeks after surgery and then programmed to gradually start stimulation. After 4 months, the muscle can be stimulated either at a 1:1 or 1:2 heartbeat ratio.

For patients with end-stage heart failure, cardiac transplantation is an option. (See Chapter 22.) Mechanical assistive devices may be used to support cardiac function while the patient awaits a donor heart.

CRITICAL THINKING

Mr. Shepard (3)
 During Mr. Shepard's visit, the physician tells him to continue the ACE inhibitor, the diuretic, and a 2-g sodium diet.

1. Why is the ACE inhibitor continued?
2. Will the ACE inhibitor affect preload or afterload?
3. Why is the diuretic ordered?
4. Why is a 2-g sodium diet ordered?
5. What is the overall goal of the ordered treatment?

Answers at end of chapter.

Figure 21-5 Different types of ventricular assist devices. (Modified from Ruppert, S, Kernicki, J, and Dolan, J: Dolan’s Critical Care Nursing. FA Davis, Philadelphia, 1996, p 336.)

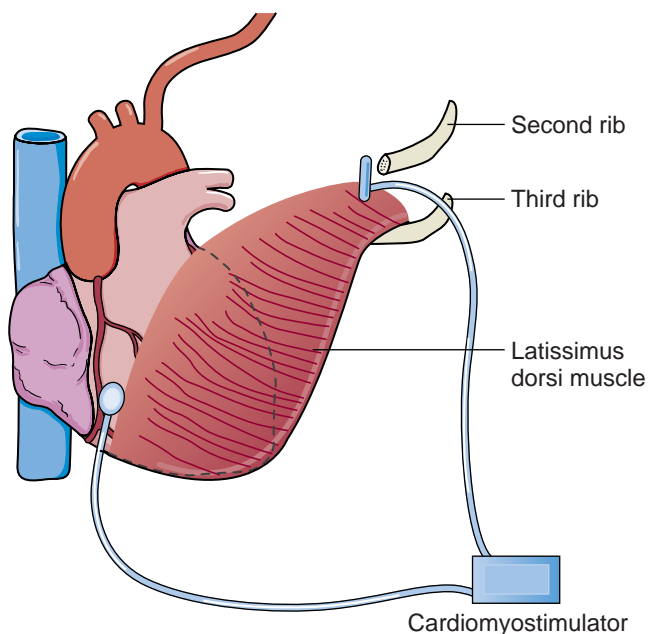

Figure 21-6 Cardiomyoplasty. (Modified from Ruppert, S, Kernicki, J, and Dolan, J: Dolan’s Critical Care Nursing. FA Davis, Philadelphia, 1996, p 329.)

Nursing Process for Chronic Heart Failure

Nursing Assessment

A nursing history and physical examination are done to gather subjective and objective data. While obtaining data, focus on areas that might indicate the presence of heart failure (Table 21-6).

Planning

The patient and family should be included in planning care. The patient’s goals include the following:

- Maintain desired activities
- Remain free of edema and dyspnea
- Awaken refreshed with less fatigue
- Reduce anxiety
- Follow a mutually agreed on health maintenance plan

Nursing Diagnosis

See Nursing Care Plan 21-1 for the Patient with Chronic Heart Failure for common nursing diagnoses.

Nursing Interventions

The major focus of nursing care for chronic heart failure patients includes the following:

- Improving oxygenation
- Educating patients about their condition and health maintenance needs
- Promoting self-care with energy conservation techniques
- Facilitating patient and family coping

Oxygenation can be improved with oxygen therapy and a decrease in the body’s need for oxygen. Decreased metabolic oxygen needs can be achieved with rest, positioning, medications, fluid balance, and oxygen consumption control.

OXYGEN. Oxygen therapy is ordered by the physician and guided by blood gas analysis. Before starting oxygen therapy, explain the therapy to the patient. For chronic heart failure, oxygen is administered at 2 to 6 L/min via nasal cannula.

TABLE 21-6 NURSING ASSESSMENT FOR THE PATIENT WITH CHRONIC HEART FAILURE

Subjective Data	
History	
<i>Respiratory</i>	
Lung disease?	
How many flights of stairs can be climbed without dyspnea?	
How many pillows used for sleeping?	
Dyspnea at rest or that awakens from sleeping?	
<i>Cardiovascular</i>	
Any cardiac disease history: hypertension, myocardial infarction, valvular problem, anemia, dysrhythmias, palpitations	
Chest pain—precipitating factors, severity, relieving factors	
Can activities of daily living be performed?	
Can activities performed 6 months, 4 months, 2 months, 2 weeks ago still be done?	
Any dizziness (vertigo) or fainting (syncope)?	
<i>Fluid retention</i>	
Daily sodium intake?	
Weight gain?	
Are shoes tight? Do ankles swell?	
<i>Gastrointestinal</i>	
Is appetite good?	
Any nausea, vomiting, or abdominal pain?	
<i>Urinary</i>	
Decrease in daytime urine output?	
How often does patient go to the bathroom at night (nocturia)?	
<i>Neurological</i>	
Any change in behavior?	
Medications	
Knowledge of condition	
Coping skills	
Objective Data	
Respiratory	
Tachypnea, crackles, wheezing, respiratory effort, dyspnea with exertion	
Cardiovascular	
Tachycardia, dysrhythmias, jugular vein distention, peripheral edema—degree of pitting	
Gastrointestinal	
Abdominal distention, ascites, hepatomegaly, splenomegaly	
Neurological	
Confusion, decreased level of consciousness, restlessness, impaired memory	
Integumentary	
Cold, clammy skin; pallor; cyanosis	
General	
Weight	
Diagnostic test findings	

The effects of the oxygen should be monitored carefully. Oxygen should be used cautiously in all patients, so that their stimulus to breathe is not diminished (especially if the patient has chronic obstructive pulmonary disease [COPD]).

Home Oxygen Therapy. If a patient will be using home oxygen therapy, instructions must be given on the proper use of the oxygen and safety precautions for oxygen use.

The family must also understand oxygen safety precautions and be willing to comply with them. Smoking is prohibited when oxygen is in use.

REST AND ACTIVITY. Reduction of the body's oxygen demands decreases the workload of the heart. A balance of rest and activity that does not produce signs or symptoms of oxygen deprivation is essential. The activity level of the patient is determined by the severity of the heart failure. During times of exertion, monitor the patient's vital signs and respiratory effort for oxygen deprivation. If activity intolerance develops, the activity should be stopped.

POSITIONING. Semi-Fowler's or high Fowler's position makes breathing easier. In upright positions the lungs are able to expand more fully and gravity decreases the amount of fluid returned to the heart, thereby reducing the heart's workload.

FLUID RETENTION. Monitoring daily weights for weight gain is important in detecting fluid retention. Edema usually is not observed until there is 5 to 10 pounds of extra fluid present. A baseline weight should be obtained when heart failure is diagnosed. Daily weights should be measured on the same scale, at the same time of day, and with the same type of clothing worn to ensure accuracy. A good time to obtain a daily weight is in the morning after the bladder is emptied. Documentation of daily weights should include the date and time of the weight, the scale used, the clothing worn, and the weight measurement. A weight journal can be kept by the patient. Tell patients to report weight gains of 2 to 3 pounds over 1 to 2 days.

OXYGEN CONSUMPTION. Increased oxygen consumption by the heart should be avoided. Tachycardia increases the oxygen needs of the heart and should be reported promptly to the physician for treatment. Elderly patients are especially vulnerable to the effects of tachycardia because of their decreased reserves. Constipation should be prevented because straining during defecation, Valsalva's maneuver, increases the heart's workload by increasing venous return to the heart. Stool softeners should be administered, as ordered, to prevent straining.

Patients should be taught methods of saving energy while performing activities of daily living (ADL). Activities should be alternated with periods of rest. Fatigue should be avoided. A referral to occupational therapy and physical therapy can be helpful in developing techniques that allow the patient to conserve energy during self-care. Some suggestions for conserving energy include placing frequently used objects at waist level to avoid reaching overhead, planning bathing activities to include rest periods, and using Velcro fasteners to make dressing easier.

MEDICATIONS. Because heart failure is a progressive, chronic condition, patients may require lifetime medications. Combination drug therapy is often needed. Taking many pills each day can be challenging. Financial resources, compliance, and ongoing monitoring are issues that must be considered.

BOX 21-1 NURSING CARE PLAN FOR THE PATIENT WITH CHRONIC HEART FAILURE

▶ Activity intolerance related to fatigue caused by oxygen imbalance

PATIENT OUTCOMES

Patient will show increased activity tolerance with vital signs within normal limits (WNL) in response to activity.

EVALUATION OF OUTCOMES

Does the patient participate in activities and maintain vital signs WNL?

INTERVENTIONS	RATIONALE	EVALUATION
Provide rest, space activities, and conserve energy. Assist as needed with activities of daily living (ADL). Teach use of assistive devices and lifestyle changes.	Myocardial oxygen need is decreased with rest and energy conservation. Conserve energy by assisting with ADL. Assistive devices can overcome limitations to increase activity.	Does patient participate in activity with no pulse rate or ECG changes? Are patient's ADLs met? Does patient incorporate assistive devices into lifestyle changes?

GERIATRIC

Increase time allowed to complete activities.	Independence and participation are increased if extra time is allowed for tasks.	Does patient report greater ability to complete activities with fewer symptoms?
---	--	---

▶ Excess fluid volume related to heart failure and the secondary reduction in renal blood flow for filtration

PATIENT OUTCOMES

Patient remains free from edema and dyspnea, has clear lung sounds, and maintains baseline weight.

EVALUATION OF OUTCOMES

Does patient have clear lung sounds with baseline weight maintained?

INTERVENTIONS	RATIONALE	EVALUATION
Monitor for edema, weight gain, jugular vein distention (JVD), lung crackles. Decrease sodium intake as ordered. Administer diuretics or inotropics as ordered. Monitor intake and output.	Excess fluid is indicated by edema, sudden weight gain, JVD, and crackles in the lungs. Sodium retains fluid. Diuretics promote fluid excretion. Inotropics increase cardiac contraction strength. Intake and output will show imbalances.	Is edema, weight gain, JVD, or crackles present? Does patient restrict sodium intake? Is output increased and edema or dyspnea reduced? Are intake and output balanced for 24 hours?

▶ Disturbed sleep pattern related to nocturia and inability to lie down and sleep comfortably

PATIENT OUTCOMES

Patient awakens refreshed and is less fatigued during the day.

EVALUATION OF OUTCOMES

Does patient wake up less frequently during the night and feel more refreshed with less fatigue during the day?

INTERVENTIONS	RATIONALE	EVALUATION
Identify barriers to sleep. Assist patient in identifying positions of comfort for sleeping. Teach patient cause of dyspnea at night. Encourage patient to recline for 30 to 60 minutes before bedtime.	Anxiety, nocturia, diuretics, orthopnea, or paroxysmal nocturnal dyspnea can make sleep difficult. Use of pillows or a recliner can decrease orthopnea. Anxiety about falling asleep and waking up short of breath is reduced. Reclining before bedtime redistributes fluid and increases voiding that can occur before going to sleep instead of after going to sleep.	Does patient identify sleep barriers? Can patient identify a position of comfort? Can patient explain cause of dyspnea? Is patient awakened to void after going to bed less often?

GERIATRIC

Encourage patient to take diuretics early in the day.	Nocturia is reduced if diuretics are taken earlier in the day.	Does patient take diuretics early and report less nocturia?
---	--	---

Diuretics require monitoring of the patient's potassium levels and blood pressure. To prevent hypokalemia, potassium supplements may be prescribed during diuretic therapy, and a diet with high-potassium foods is encouraged. If too much fluid is removed, the patient may become hypotensive and orthostatic hypotension can develop. The patient may then be dizzy and at risk of falling. Caution the patient to change positions slowly to prevent falls during diuretic therapy.

Inotropic agents such as digitalis strengthen heart contractions and slow the heart rate. Before administration of a digitalis drug, the patient's apical pulse should be counted for 1 minute. If the pulse is below 60 beats per minute, notify the physician to determine if the drug should be given. Some patients are given digitalis even if their heart rates are between 50 and 60 beats per minute, as long as their heart's conduction system is normal or if it is due to other medications such as a beta blocker. When giving digitalis, be aware that hypokalemia increases the heart's sensitivity to digitalis. A patient can become toxic on a normal dose of digitalis when hypokalemia is present. This is important to note because many people on digitalis also take diuretics, which may lower potassium levels. Monitoring for signs and symptoms of digitalis toxicity should be done routinely during patient assessment. Early symptoms of digitalis toxicity are anorexia, nausea, and vomiting. Other signs and symptoms include bradycardia or other dysrhythmias, visual problems, and mental changes. The elderly are especially prone to toxic effects of this drug and may exhibit confusion when levels are toxic.

Medications with vasodilating effects reduce the heart's workload by decreasing vascular pressure. Blood pressure is monitored when administering vasodilators.

Medication Teaching. Patients and their families are taught the purpose, side effects, and precautions for prescribed medications. Teach them to report side effects to the physician. If dizziness occurs from drugs that reduce blood pressure, the drugs can be staggered so that they are not all taken at the same time. Patients taking a digitalis preparation should be taught to take their pulse. They should hold the medication and call their physician if their heart rate is less than 60 beats per minute or below the lower-limit heart rate set by their physician. Patients on diuretics should be taught the following:

1. Take them during the day before 4 P.M. to decrease being awakened at night to void (if desired).
2. Have a readily available and obstacle-free bathroom or commode to prevent incontinence and falls.
3. Eat high-potassium foods if taking a potassium-wasting diuretic.
4. Weigh themselves daily and report weight gains.

Patients should understand the importance of taking their medication as prescribed, even if they do not have symptoms. A schedule should be developed so patients remember to take their medications.

LOW-SODIUM DIET AND WEIGHT CONTROL. A diet assessment should be completed to help establish an appealing diet plan for the patient with heart failure. Factors such

as the patient's food likes and dislikes, cultural influences, economic status, and food preparation resources (e.g., shopping ability, storage, refrigeration, and cooking equipment) influences compliance with any restricted diet and therefore should be assessed. It is helpful to include a dietitian in the planning process, as well as the food preparer or a support person, to increase diet compliance.

Excess weight influences heart failure by increasing the heart's workload. For overweight patients, weight reduction may help eliminate the underlying cause of heart failure. Diet counseling and support should be given to the obese patient to encourage weight loss. If anorexia occurs in the later stages of heart failure, the patient's intake should be evaluated. Several small meals rather than three large meals will decrease the heart's workload. If the patient's nutritional needs are not being met, the physician should be informed for a referral to a dietitian.

Patients should be taught which foods are high and low in sodium content. With this knowledge, patients can help design a daily meal plan using low-sodium foods that are appealing to them. Food preparers should be taught not to salt food during cooking, and table salt should be eliminated. Explaining seasoning alternatives such as spices, herbs, and lemon juice is helpful in making food taste better.

EDUCATION. Chronic management of heart failure requires patient and family understanding of the disease process, management of home oxygen therapy, diet and weight control, and medications (Home Health Hints). The patient and family must recognize the importance of each of these factors in order to foster a productive life for the patient with chronic heart failure. A discussion of the pathology of heart failure using simple terms should be included in the teaching plan for the patient. Signs and symptoms that the patient is to report to the physician should also be highlighted (Box 21-2).

COPING. Living with a chronic illness can be frustrating for both patients and their families. An assessment of coping skills used by patients and their families can be used to develop a plan for coping with this current illness. Available support systems are explained to patients. A referral to a social worker can be helpful in providing resources that may make living with heart failure easier. Understanding the chronic na-

BOX 21-2 Patient and Family Education

Heart Failure Signs and Symptoms to Report to the Physician

Shortness of breath
 Fatigue
 Dry cough
 Shortness of breath when lying down (orthopnea)
 Episodes of sudden awakening with shortness of breath (PND)
 Weight gain of 2 to 3 pounds over 1 to 2 days
 Ankle or foot edema
 Nocturia
 Anorexia

ture of heart failure is important for patients, families, and caregivers to positively deal with the emotions and feelings that can result. Referral to a nurse managed heart failure clinic has been shown to decrease hospitalization rates and increase effective management of the therapeutic regimen.

Evaluation

Goals are met if the patient:

- reports reduced fatigue and the ability to complete tasks and engage in desired activities.
- has less edema and no dyspnea and maintains a baseline weight.
- is able to sleep and wake up refreshed without being fatigued during the day.
- reports anxiety levels are reduced.
- follows the health maintenance plan without complication development.

HOME HEALTH HINTS

- Some patients may not have a scale in their home. It may be necessary to assist them in obtaining one or to leave an agency scale in the home for daily weights.
- The most objective way to document edema is to use a tape measure on the abdominal girth, thigh, calf, and ankle in centimeters. Measure at the same place each visit, such as measuring the girth of the calf at a specified distance above the medial malleolus.
- The sacrum, back, and sides of a bedridden patient should be checked to note edema. These are dependent areas in the bedridden patient, so fluid accumulates in these areas instead of the ankles.
- Blood drawn for potassium levels needs to be transported to the lab within 1 hour. Ice should not be put directly on the tube because this can cause destruction of the cells and a false elevation in the potassium level.
- Blood drawn for digoxin levels should be taken to the lab within 2 to 3 hours.
- Patients on sodium-restricted diets who already have canned vegetables in their home can still use them even though they are not the low-sodium type. They should be instructed to pour off the liquid and rinse the vegetables before heating them for serving. The use of herbs and spices helps make them more flavorful.
- For the patient on a low-sodium diet, an effective diet teaching technique is to have the patient name the foods highest in sodium. Asking the patient to rename the list on each visit helps knowledge retention and compliance.
- If patients have a poor appetite, ask their caregiver if they eat well when eating with others. Anorexia could be a sign of loneliness and depression if they eat well with others instead of an effect from the heart failure.
- Assist patients in taking medications at times that fit their lifestyle. A morning dose of a diuretic may limit what they can do for the next few hours. An afternoon dose might encourage compliance. Lack of compliance is a major factor in the rehospitalization of patients with heart failure.
- A dose of diuretic too late in the day may cause frequent awakenings during the night to void.
- The home health nurse should periodically check the contents of medicine bottles. If pills have been cut in half, ask about this. Often it is an attempt by the patient to “stretch” the medicine to decrease expenses. There are community or drug company programs that help purchase medicines for patients with financial need. Eligible Medicaid patients can apply for medication cards.
- Visual disturbances can occur from digitalis toxicity. If the patient sees halos around lights or red-green tinting on everything, report this to the physician.
- Troublesome side effects of an ACE inhibitor such as captopril (Capoten) are an intractable cough and hypotension. It should be noted how much coughing the patient is doing. The physician sets parameters for the blood pressure and reporting of abnormal findings.
- Oxygen concentrators are widely used in home care. Long tubing allows the patient ease in moving about the home. Patients need to be cautioned about keeping the tubing out of their way and not kinking it. If the patient also has chronic obstructive pulmonary disease (COPD), the oxygen flow rate is generally limited to 2 L/min, so the patient’s drive to breathe is not decreased. A note stating this should be placed near the gauge as a reminder to the patients.
- As the home health nurse becomes acquainted with the patient, it is easier to pick up on signs of oxygen deprivation and hypoxia, such as confusion, combativeness, or unusual expressions of anger.
- For patients with orthopnea, a foam wedge can be obtained from a medical equipment company to use under their head when sleeping, instead of pillows.
- As patients with heart failure feel better, they may go back to the old habits that cause an increase in fluid. The home health nurse can help by providing information about the disease and help patients foster their own independence and ways of coping with the condition. Each home health visit is a teaching opportunity that empowers patients with a knowledge base to empower them to take control of their health.

CRITICAL THINKING

Mr. Shepard (4)

The nurse meets with Mr. Shepard after the physician orders the ACE inhibitor to be continued, a diuretic, and 2-g sodium diet.

1. What information should the nurse teach Mr. Shepard based on the prescribed treatment?
2. What types of foods should be included in Mr. Shepard’s diet?
3. Why does the nurse instruct Mr. Shepard to weigh himself daily?
4. Why does the nurse tell Mr. Shepard to weigh himself at the same time of day, on the same scale, and with the same type of clothing?

Answers at end of chapter.

REVIEW QUESTIONS

- A patient asks the nurse what heart failure is. Which of the following is the nurse's best response?
 - "In heart failure the heart pumps too much blood into the pulmonary veins."
 - "In heart failure the heart is unable to pump enough blood for the body's oxygen needs."
 - "Heart failure is a buildup of blood in the aorta from the heart's left ventricle."
 - "With a failing heart, the heart stops beating, so blood is not pumped out."
- Which of the following does the nurse understand is a major cause of left-sided heart failure?
 - Hypertension
 - Congenital heart defects
 - Pulmonary valve stenosis
 - Septal defects
- A patient who has been treated for heart failure is being discharged from the hospital. He is taking 20 mg furosemide (Lasix) daily. Which of the following statements by the patient would indicate understanding of instructions for his medications?
 - "I will take the Lasix in the morning."
 - "I will take the Lasix in the evening."
 - "I will drink lots of fluids with the Lasix."
 - "I will take it with meals."
- The nurse is caring for a patient receiving bumetanide (Bumex) to reduce preload for heart failure. While assessing the patient the nurse notes the patient has less ankle edema and jugular vein distention than earlier. The next dose of bumetanide is scheduled in 1 hour. Which of the following actions should the nurse take next?
 - Notify the physician.
 - Hold the bumetanide.
 - Give the bumetanide as scheduled.
 - Give the bumetanide early.
- Which of the following assessments should the nurse teach the patient to perform to monitor fluid status at home?
 - Weigh daily.
 - Weigh weekly.
 - Weigh biweekly.
 - Weigh monthly.

Answers to CRITICAL THINKING

Mr. Shepard (1)

- Signs and symptoms of heart failure include shortness of breath, two-pillow orthopnea, dry cough, tachycardia (pulse 106), tachypnea (respiration 24), and bilateral crackles.
- Left-sided heart failure is indicated by the findings.
- Shortness of breath: fluid in the lungs impairs gas exchange; orthopnea: lying flat increases fluid accumulation in the lungs, causing dyspnea; dry cough: fluid in the lungs irritates the mucosal lining of the lungs; tachycardia: sympathetic compensation to increase cardiac output; tachypnea: sympathetic compensation to increase blood oxygenation; bilateral crackles: fluid trapped in the lungs.
- The two pillows help prevent orthopnea by using a more upright position, which allows gravity to decrease fluid accumulation in the lungs.

Mr. Shepard (2)

- Mr. Shepard's heart is enlarged to compensate for the strain caused by increased peripheral vascular resistance from hypertension in order to maintain an adequate cardiac output.
- An enlarged heart requires more oxygen, which often cannot be supplied in heart failure.

Mr. Shepard (3)

- The ACE inhibitor is needed for vasodilation, which reduces peripheral vascular resistance and decreases the heart's workload, and to prevent cardiac remodeling.
- The ACE inhibitor will affect afterload.
- The diuretic is ordered to decrease fluid volume, which reduces preload and decreases the heart's workload.

- The diet is ordered to reduce water retention, which decreases preload and decreases the heart's workload.
- The goal is to decrease the heart's workload and increase its efficiency by reducing preload and peripheral vascular resistance.

Mr. Shepard (4)

- After assessment of Mr. Shepard's knowledge base, medication teaching should be given on the ACE inhibitor and diuretic that includes their purpose, side effects, and precautions. A schedule for taking the medications can be planned. An explanation of the purpose of a low-sodium diet and menu planning based on Mr. Shepard's likes and dislikes should be done.
- Low-sodium foods should be selected to prevent fluid retention, and high-potassium foods should be included to prevent hypokalemia from the diuretic if appropriate. Low-sodium foods include puffed rice, wheat cereals, fruits, chicken, beef, eggs, and potatoes. High-sodium foods include tomato juice, sauerkraut, softened water, buttermilk, cheese, smoked meats, canned tuna, canned soup, pickles, instant rice, and instant potatoes. High-potassium foods include bran products, avocado, bananas, prunes, oranges, baked potato, sweet potato, spinach (cooked), chocolate, nuts, and molasses.
- Daily weighing is necessary to detect a rapid weight gain that indicates fluid retention (2 to 3 lb over 2 days) and to measure weight loss resulting from the diuretic.
- These instructions ensure accuracy of the weight so that comparison to the baseline weight detects a weight gain or loss.

QUESTIONS TO GUIDE YOUR READING

1. What are the preoperative and postoperative routines and procedures for cardiac surgery?
2. What is the purpose and complications of cardiopulmonary bypass?
3. How would you describe the myocardial revascularization procedures?
4. What are the differences between commissurotomy, annuloplasty, and valve replacement?
5. What are the differences in postoperative care for the two types of cardiac valves?
6. What are the complications of cardiac and valve surgery?
7. What are an embolectomy and endarterectomy?
8. What nursing care will you provide for patients having cardiac or vascular surgery?
9. How will you know if your nursing interventions have been effective?

► CARDIAC SURGERY

As heart disease symptoms increase in severity and frequency or the disease process worsens, cardiac surgery may be used as treatment. Although cardiac surgery has become commonplace, it is still a major surgery with numerous complications, as well as physical, emotional, and social stressors.

Preparation for Surgery

For elective heart surgery, patients may be admitted to the hospital on the morning of surgery or 1 to 3 days before the surgery based on their medical history. A nursing assessment is important to provide baseline data that can be used for postoperative comparison and early discharge planning. In addition to routine admission testing, patients with chronic obstructive pulmonary disease (COPD) may have pulmonary function tests and baseline arterial blood gases (ABGs) done (Box 22–1). Patients with carotid bruits have carotid studies to determine the amount of occlusion in the carotid artery. If the occlusion is significant, a carotid **endarterectomy**, which removes the plaque on the lining of the blocked or diseased carotid artery, is performed, usually several weeks before having cardiac surgery.

Medications that may increase bleeding or reduce fluid volume may be ordered by the physician to be held before surgery. Drugs that increase bleeding include aspirin, often stopped 3 to 7 days preoperatively; warfarin (Coumadin), often stopped 4 to 5 days preoperatively; and heparin, stopped 4 hours preoperatively. During surgery fluid volume and blood pressure may be decreased by blood loss or medications. Therefore diuretics, which could further reduce fluid volume and blood pressure, are withheld up to 2 days before surgery. Because the patient takes nothing by mouth (NPO) 8 to 12 hours before surgery, insulin and oral hypoglycemic agents are reduced or withheld the morning of surgery.

Patients recover more quickly and have less postoperative stress when they have thorough preoperative teaching. Explanations of pain management, endotracheal tube (ETT), methods of communicating, ventilator, chest tubes, coughing and deep breathing exercises, intravenous (IV) lines, urinary catheter, incision care, and various equipment alarms are provided to the patient and family. It should be emphasized that patients are not able to talk while the ETT

is in place. Additionally, a preoperative family tour of the patient's initial postoperative unit and the waiting area helps prepare them for the surgical experience. A referral to pastoral care, if desired, can be comforting to the patient and family.

The anesthesiologist assesses the patient before surgery and orders preoperative medications. An antiseptic scrub shower is taken the night before and the morning of surgery. The patient is NPO after midnight the night before surgery.

Cardiopulmonary Bypass

The majority of cardiac surgeries use a cardiopulmonary bypass (CPB) pump in which blood is temporarily diverted away from the heart and lungs to the special pump. This diversion allows for a bloodless and motionless surgical field while the function of the heart and lungs is maintained by the pump. After the **sternotomy** is made, the vena cava and ascending aorta are cannulated (a small tube with multiple holes is placed into each of them). The aorta is cross-clamped between the heart and the cannula by clamping two large hemostats over the aorta in opposite directions. The cannulas are then attached to the pump tubing. Blood then flows from the body through the vena cava cannula to the CPB pump for oxygenation. After the pump oxygenates and removes carbon dioxide from the blood, the blood is returned to the body. The blood flows through the cannula into the ascending aorta, where it then circulates through the body (Fig. 22–1).

Using the CPB pump can have a unique set of complications. Before going on the pump, the patient is anticoagulated with heparin until the partial thromboplastin time (PTT) is five to six times greater than normal. Immediately before the patient comes off the pump, the effects of the heparin are reversed with protamine sulfate (antidote for heparin). Heparin is absorbed and stored in organs and tissue and can be sporadically released hours after surgery. As a result, the patient may have excessive bleeding. The risk of an air embolism is minimized by priming the pump with lactated Ringer's solution and maintaining careful observation. The priming solution increases circulating volume, which then results in a shifting of fluid into the interstitial tissue and edema formation. These fluid shifts can continue up to 6 hours after surgery and can cause hypotension.

Methods for providing closed-chest cardiopulmonary bypass and **cardioplegia** are being studied. With closed-chest methods, the chest is not opened to provide CPB or cardioplegia. Instead, small incisions are made in the chest and a video-assisted thoracoscope is inserted and used to perform the entire surgery. This technique of closed-chest surgery, with or without CPB, is termed minimally invasive direct coronary artery bypass (MIDCAB) surgery. When CPB is not used, mechanical devices are used to stabilize the portion of the heart being bypassed while the remainder of the heart continues to beat. Unfortunately, these techniques are not

sternotomy: stern—sternum + otomy—incision into
cardioplegia: cardio—heart + plegia—paralysis

Figure 22-1 Cardiopulmonary bypass pump components.

options for all patients. Risk for complications associated with MIDCAB are much lower than with the traditional CABG procedure, and the recovery time is often weeks less. It is hoped that MIDCAB performed on a beating heart can become a common surgical option for qualified patients.

General Procedure for Cardiac Surgery

After the patient is placed on CPB, a cardioplegia solution is infused into the aortic root along with iced saline. This solution is placed around the heart to cause cardiac standstill. When the surgery is completed, the patient's blood is warmed in the CPB circuit and the patient is slowly weaned from CPB. The heart starts beating again after it is warmed and defibrillated. Temporary pacing wires are attached to the heart before the CPB pump is discontinued, so an external temporary pacemaker can be used if bradycardia develops. Once the heart is beating, CPB is stopped. Mediastinal chest tubes are placed to drain remaining blood and fluid from the chest. The sternotomy is closed with wires through the sternum and then sutures for the layers of tissue and skin. While still under anesthesia, the patient is transferred to an intensive care unit (ICU). Patients usually stay in ICU for 1 to 2 days, although those undergoing MIDCAB may not need an ICU stay.

Surgical Procedures

Myocardial Revascularization

CORONARY ARTERY BYPASS GRAFT. Coronary artery bypass graft (CABG) surgery is a procedure used to increase blood flow and oxygen to the myocardium and alleviate anginal symptoms. Significant occlusions in the coronary arteries are bypassed with vein or artery grafts (Fig. 22-2).

One or more vessel bypasses can be performed during the procedure. The saphenous vein from the leg or an internal mammary artery from the chest wall is generally used. The right **gastroepiploic** artery (RGEA), a branch of the gastroduodenal artery, and the inferior epigastric artery (IEA) have also been used for repeat CABG operations.

While the sternotomy is made, the vein graft is being removed from the body. The graft is flushed with a heparinized solution to check for leaks, then set aside for use during the surgery. The patient is then placed on CPB. After cardiac standstill occurs, one end of the graft is **anastomosed** (joined to the coronary artery distal to the occlusion) while the proximal end of the graft is anastomosed, usually to the ascending aorta. The surgery then continues as described in the general surgery procedure section.

Resecting the mammary arteries for grafting is more difficult and time consuming than resecting the saphenous vein, but their patency is longer. The proximal end of the artery is left attached to its origin, and the distal end is anastomosed to the coronary artery distal to the occlusion. See Patient Perspective Box 22-2.

TRANSMYOCARDIAL LASER REVASCULARIZATION. For patients who are not candidates for either MIDCAB or traditional CABG revascularization procedures, there is an alternative procedure called **transmyocardial** laser revascularization (TMR) or percutaneous transluminal myocardial laser revascularization (PTMR). A laser is used to make 20 to 30 small channels into the myocardium to reduce angina.

Figure 22-2 Myocardial revascularization: coronary artery bypass graft surgery.

BOX 22-2 Patient Perspective

Keith: Coronary Artery Bypass Graft

I was 72 when I had coronary artery bypass surgery. I had some very minor symptoms, and a heart catheterization showed significant coronary artery blockage. I ended up having five bypass grafts performed. It was a long surgery. I felt disoriented for several days afterward—mostly while I was in the intensive care unit.

I felt absolutely no pain of any type after surgery. However, I have had a strange sensation in my legs at the incision sites ever since surgery, but not pain! I also have experienced no depression and have assumed an attitude that I am in better condition than before surgery, so why should I worry?

I was provided with excellent care at home after discharge from the hospital. The nursing and rehab personnel were outstanding. I had a capable visiting nurse, physical therapist, or occupational therapist practically every day. Physical therapy was difficult at first but shortly became routine and easy.

My experience during cardiac rehab was outstanding. I had three sessions per week for 12 weeks. I have always exercised a lot, so I had no problems attaining the exercise levels suggested. It was a very positive experience, and I enjoyed the association with others in the same situation. We even staged a graduation when we finished. I wore a tuxedo jacket with my gym shorts! Since completing my rehab, I have religiously maintained a minimum 40-minute exercise schedule three times per week. I do this because I want to stay healthy for a long time.

The only negative aspect I experienced was a minor stroke during surgery. As a result, my balance is not as good as I would like. I need to be more careful, particularly when running or bike riding. Perhaps this is just older age, but it started just after surgery, so that is the reason I assume it is due to the minor stroke.

The impact on my life and family has been minimal. The primary change is being more conscious of my diet and an emphasis on exercise. Otherwise, I live pretty much the same as before.

An advantage of TMR over PTMR is that the heart is exposed, which allows channels to be made through the entire thickness of the heart, not just the inner surface as in PTMR. Future treatments may combine coronary bypass surgery with TMR for anginal relief when widespread blockages exist.

Heart Valve Repairs

A **commissurotomy** is a heart valve repair for a stenosed valve. For commissurotomy, the patient is placed on CPB and a left atriotomy (incision into the atrium) is made to expose the valve. The valve cusps are either incised with a knife or broken apart with a dilator. The atrium is sewn closed, CPB is discontinued, and surgery continues as described in the general surgery procedure section. Commissurotomy is most commonly performed on the mitral valve.

A balloon **valvotomy** is a procedure that repairs a stenosed heart valve. The balloon catheter is inserted through a diseased valve and then inflated to open the stenosed valve. This has been found to have effects similar to the commissurotomy, but the valvotomy must be performed blindly.

Another type of valve repair is **annuloplasty**, which repairs the annulus of a valve. The mitral valve is the most common valve repaired in this way. Sutures or a ring may be placed in the valve annulus to improve closure of the leaflets. Similar procedures are used on the tricuspid valve; however, the aortic valve is not readily repaired in this manner.

- commissurotomy:** commissur—connecting band of tissue + otomy—incision into
- valvotomy:** valv—valve + otomy—incision into
- annuloplasty:** annulo—annulus + plasty—repair

Heart Valve Replacement

Valves used for cardiac valve replacement may be either mechanical or biologic. There are three types of mechanical valves: caged ball, monoleaflet, and bileaflet (Fig. 22–3). Mechanical valves are durable but create turbulent blood flow. The turbulent flow can lead to clot formation, requiring lifelong anticoagulant therapy. Biologic (tissue) valves come from three sources: porcine (pig), bovine (cow), or allografts (human). Tissue valves have a very low incidence of thrombus formation and do not require lifelong anticoagulant therapy, but they may not last as long as mechanical valves (Cultural Consideration Box 22–3).

BOX 22-3 CULTURAL CONSIDERATION

Because the pig is considered a dirty animal to religious Jews and Muslims, only bovine, synthetic, or human valves should be used for these patients. Likewise, because the cow is sacred among Hindus, only porcine, synthetic, or human valves should be used for Hindu patients.

For mitral valve replacement (MVR), a left atriotomy is made after the patient is on CPB. For an aortic valve replacement (AVR), an incision is made above the right coronary artery in the aorta. Then in either valvular procedure, the diseased valve is excised and the new valve sutured in place. The incision is closed, and surgery then continues as described in the general surgery procedure section.

Just as coronary artery revascularization procedures are becoming less invasive, so are surgical interventions for cardiac valves. These minimally invasive techniques continue to use CPB but involve small incisions, which increase pa-

tient comfort and reduce recovery time while decreasing costs.

Ventricular Aneurysm Repair

Indications that a ventricular aneurysm requires surgery include persistent angina, symptoms of heart failure, large aneurysms impeding the function of the heart, left ventricular failure, or **tachydysrhythmias**. Once the patient is on CPB, an incision is made exposing the heart and then the aneurysm is resected (cut out), leaving a fibrous border (Fig. 22–4). The ventricle is wiped clean and irrigated to ensure all thrombi are removed. The opening is then closed with sutures or patched with a graft. Air that entered the ventricle while it was open is aspirated, and the surgery continues as described in the general surgery procedure section.

Cardiomyoplasty

Cardiomyoplasty uses the patient's own muscle (latissimus dorsi) to improve the contractile function of the heart. (See Chapter 21.) The muscle is wrapped around the aorta or heart, and a cardiomyostimulator and leads are implanted to stimulate muscle contraction. The muscle is rested for 2 weeks after surgery and then programmed to gradually start stimulation. After 4 months, the muscle can be stimulated at either a 1:1 or 1:2 heartbeat ratio. Benefits from cardiomyoplasty include the improved contractility of the failing heart and reduced changes in heart failure remodeling from the wrapping or enclosing effects of the muscle. Cardiomyoplasty may reduce the need for heart transplantation by delaying or preventing end-stage heart failure.

Cardiac Trauma

Two types of cardiac trauma can occur: nonpenetrating and penetrating. Nonpenetrating injuries, or contusions, occur from blunt trauma such as motor vehicle accidents or contact sports in which direct compression or force is applied to the upper torso. Contusions may vary from small bruises to hemorrhage.

There may be few or no external injuries indicating traumatic cardiac injury. The patient may be asymptomatic or exhibit signs and symptoms identical to a myocardial infarction. In severe contusions, laboratory results may show elevated creatine kinase MB (CK-MB) or troponin-I levels.

If bleeding occurs into the pericardial sac, cardiac tamponade (compression of the heart from the blood collecting in the sac) may occur. When the heart is compressed, it cannot expand to fill with blood. As a result, cardiac output drops, which can be life threatening. If signs of shock occur, a **pericardiocentesis** must be performed. (See Chapter 17.) A needle is inserted into the pericardial sac to aspirate the collecting fluid. With its own pressure, the tamponade may seal the area of bleeding, so no cardiac decompen-

pericardiocentesis: peri—around + cardio—heart + centesis—surgical puncture

Figure 22-4 Ventricular aneurysm repair.

curs. In this case only bedrest and observation are required. There are no long-term effects with most contusions. With severe contusions, however, scarring and necrosis of the myocardium may decrease cardiac output and increase the risk for cardiac rupture.

Penetrating traumas may be an external injury to the chest, such as a stab or gunshot wound, or an internal injury, such as invasive lines that penetrate the cardiac muscle. Complications vary depending on the size, location, and cause of injury. Tamponade occurs from bleeding into the pericardial sac if the pericardium is sealed off by clot formation. A hemothorax develops if blood drains into the pleural space in the chest. A pneumothorax occurs if air collects in the pleural space. Signs and symptoms of hemorrhage and myocardial ischemia may be noted. Cardiac trauma treatment usually requires surgery to repair the damage so that hemostasis can be regained.

Cardiac Tumors

Cardiac tumors are either primary or secondary in origin and can be benign or malignant. Primary cardiac tumors are less common than secondary (metastatic) cardiac tumors. Benign primary tumors are commonly myxomas.

A myxoma is a soft, gelatinous, intracavitary mass that is attached to the endocardium by a narrow stalk (peduncle). Myxomas are found in any of the four chambers of the heart but are more common in the left atrium. Symptoms vary depending on the location of the tumor and its effect on valve function. There is a high risk of emboli formation with this type of tumor because it breaks apart easily. Surgical excision of the tumor offers the patient a good prognosis.

The majority of malignant primary cardiac tumors are sarcomas. Secondary cardiac tumors are generally carcinomas that have metastasized. The symptoms depend on the location and size of the mass. Treatment consists of palliative measures such as surgery, radiation, and chemotherapy. For **pericarditis**, a pericardiocentesis may be performed. If pericarditis recurs, a window (opening) is cut into the pericardium for fluid drainage to prevent fluid buildup and cardiac tamponade. The prognosis is poor for malignant or metastatic cardiac tumors.

Complications of Cardiac Surgery

Cardiovascular Complications

Several cardiovascular complications can occur from cardiac surgery, including postoperative bleeding, cardiac tamponade, dysrhythmias, perioperative myocardial infarction, pericarditis, and myocardial depression.

Postoperative bleeding into the **mediastinum** is a common complication. Bleeding may come from oozing blood vessels within the chest, graft anastomoses, or myocardial incisions. These oozing areas may result from increased blood pressure, which may occur if patients are shivering until they are rewarmed after surgery, or coagulation problems occurring from platelet, fibrin, and other coagulation factors being destroyed in the CPB circuit. Inadequate reversal of the heparin used for CPB or a delayed release of heparin stored in organs and fatty tissue can add to postoperative bleeding. Conservative treatment is instituted before taking the patient back to surgery to find the cause of bleeding.

Cardiac tamponade can occur if clots block the chest tubes, preventing blood from draining out of the pericardial sac. This heart constriction can lead to cardiac arrest without prompt treatment.

Dysrhythmias are fairly common and have many causes: **hypoxia**, **hypoxemia**, acidosis, electrolyte imbalance (especially hypokalemia), pain, anxiety, inflammation from the **pericardiotomy**, presence of the CPB cannulas, or gastric distention. Varying degrees of heart block are associated

mediastinum: medi—middle + stinum—sternum

hypoxia: hypo—below normal + ox—oxygen + ia—condition

with valve replacement due to the close proximity of the atrioventricular node to all the valves.

A perioperative myocardial infarction can occur from graft thrombosis, embolus, inadequate myocardial preservation during aortic cross-clamping, or inadequate revascularization.

Pericarditis, an inflammation of the pericardial sac, is due to the handling of the pericardium. This inflammation may occur immediately or months later. Should pericarditis recur numerous times, it is termed postpericardiotomy syndrome.

Myocardial depression, which results in decreased cardiac output, is usually a temporary occurrence caused by hypoxemia, acidosis, interstitial fluid accumulation, or electrolyte imbalance. Hemodilution and diuretics can cause hypomagnesemia (low serum magnesium) and hypocalcemia (low serum calcium), which also depress myocardial function.

LEARNING TIPS

Hemodilution occurs when excess fluid is present in the vascular system. This excess fluid dilutes the particles normally found in the fluid, such as minerals, electrolytes, and blood cells. So even though there may have been a normal amount of a particle before the excess fluid developed, the excess fluid dilutes or makes this normal amount less concentrated. As a result the values of the particles are low.

Try this example: Stir 1 drop of food coloring into $\frac{1}{4}$ cup of water. In a second container, stir 1 drop of food coloring into 1 cup of water. Compare the color of the two containers. The color of the first container simulates a normal value for the coloring particles. When more fluid is added (hemodilution), there is less color, indicating that the particles have been diluted and are now at a lower value than normal.

Pulmonary Complications

The most common postoperative problem is **atelectasis**, which is the collapse of airways caused by hypoventilation. Atelectasis can occur from pain, exhaustion, prolonged anesthesia, shallow breathing, poor cough effort, and decreased ambulation and movement. Atelectatic areas contribute to hypoxemia and become sites for infections such as pneumonia.

LEARNING TIPS

Deep breathing and coughing are important for most surgical patients to perform to prevent atelectasis.

Pleural effusions occur when fluid accumulates within the pleural lining. Heart failure, inflammation, and hypoalbuminemia (low serum albumin) cause changes in cell wall

atelectasis: atel—imperfect + ectasis—stretching

permeability and pressures that lead to an imbalance in the production and reabsorption of pleural fluid. Treatment involves the insertion of a chest tube to drain the fluid and allow lung re-expansion.

The phrenic nerve conducts the motor impulses to the diaphragm. Phrenic nerve paralysis can occur from direct injury during the resection of the internal mammary artery or from the cold saline used for CPB. Symptoms include dyspnea and paradoxical (conflicting) abdominal breathing. On chest x-ray examination, the diaphragm is elevated on inspiration. The paralysis may be unilateral or bilateral. Patients with pre-existing pulmonary disease require continued ventilator support. Phrenic nerve paralysis resolves itself, but the time required varies.

Renal Complications

Low arterial pressure on CPB activates the renin-angiotensin-aldosterone system, thereby creating vasoconstriction, which decreases renal perfusion and function. Other factors that decrease renal function are **nephrotoxic** antibiotics, **hypothermia**, and **hemolysis** from CPB. If the kidneys do not recover, the patient may be started on hemodialysis until renal functioning improves.

Gastrointestinal Complications

Postoperative complications in the gastrointestinal (GI) tract can range from the minor annoyance of medication-induced diarrhea (quinidine or various antibiotics) to a life-threatening bowel infarction. Gastric distention can occur if the nasogastric tube is not properly functioning while the patient is on the ventilator. This distention can be uncomfortable and may impede the ability of the lungs to expand, causing decreased ventilation. As with any surgery, a paralytic ileus can develop, necessitating a longer gastric decompression time with a nasogastric tube and NPO status.

Bowel infarction secondary to ischemia of the mesenteric vasculature is rare yet life threatening. Bowel infarction can be caused from low blood flow while the patient is on CPB, myocardial depression, or emboli. Patients with bowel infarction are extremely ill and may have sepsis, respiratory distress, severe abdominal pain, metabolic acidosis, or diarrhea. Surgery to resect the necrotic bowel may be indicated. This low blood flow state can also cause a necrotic injury to the pancreas, leading to **pancreatitis**.

Immune and Humoral System Complications

As blood passes along the foreign surfaces of the CPB circuit, the complement system (an immune response involving plasma proteins and immunoglobulins) is activated. This immune response leads to fever, **leukocytosis**,

nephrotoxic: nephro—kidney + tox—poison + ic—pertaining to
hypothermia: hypo—below normal + therm—temperature + ia—pertain to
hemolysis: hemo—blood + lysis—destruction
pancreatitis: pancreat—pancreas + itis—inflammation
leukocytosis: leuko—white + cyto—cell + sis—condition

vasodilation, and increased vascular permeability, resulting in interstitial fluid accumulation.

Neurological Complications

Several neurological complications can develop with cardiac surgery, including peripheral nerve injury, central nervous system deficits, and pain. Peripheral nerve injury can be associated with improper or prolonged positioning on the operating table. Examples of peripheral nerve injury include the following:

- Brachial plexus injury—weakness, numbness, and burning in the hand
- Ulnar nerve injury—numbness and tingling in the fourth and fifth fingers
- **Paresthesia** and burning in the leg from which the saphenous vein was taken for a coronary artery bypass graft

Central nervous system deficits include **encephalopathy** (brain dysfunction) and brain embolism. Encephalopathy involves the entire brain, unlike an embolism. Cause of encephalopathy include hypoxia, hypoperfusion, and volume overload resulting in brain tissue edema. An embolism results from dysrhythmias or aortic cross-clamping. Either of these conditions can lead to altered level of consciousness and confusion.

Pain from cardiac surgery is subjective and varies from patient to patient (Patient Perspective). Chest pain is usually due to the sternotomy, during which there is retracting of the ribs and stretching of the chest muscles and ligaments. With internal mammary artery grafts, anterior or posterior chest pain may be considerable resulting from manipulation and resection of the mammary artery.

Other Complications

Patients may experience varying degrees of memory loss, depression, immobilizing fear, frustration in role adjustments, hallucinations, cognitive dysfunction, or sexual dysfunction. Sleep disturbances such as insomnia, nightmares, and frequent waking are common and tend to prolong the symptoms.

Valve Replacement Complications

Tissue valves, over time, can undergo degenerative changes and calcification, leading to valve failure. The most common complication associated with mechanical valves is thrombus formation. An embolism can occur when thrombi form on the mechanical valve and then break off. Embolism rarely occurs with tissue valves and is prevented with anticoagulant therapy for mechanical valves. When the patient is on warfarin, ongoing monitoring of interna-

tional normalized ratio (INR) and prothrombin time is important.

Other complications include anemia and endocarditis. Anemia is due to hemolysis of red blood cells (RBCs) as they come in contact with mechanical valve structures. Endocarditis is an infection of the inner lining of the heart. Microorganisms tend to grow on the valve leaflets or the sewing ring of mechanical valves. These growths can make valves incompetent or break off to become emboli.

CRITICAL THINKING

Mr. Jones
Mr. Jones is transferred to the nursing unit 12 hours after a quadruple CABG. Preoperative vital signs were blood pressure 164/88, apical pulse 62 regular, respiratory rate 18, temperature 98.4° F. Assessment findings are blood pressure 100/56, apical pulse 105 and irregular, respiratory rate 28 and shallow, temperature 99.8° F, lung sounds diminished with crackles in bilateral bases, pedal pulses weak bilaterally, chest and leg dressings dry and intact, and no urinary catheter. Mr. Jones is being monitored for first postoperative voiding.

1. Which findings may indicate pulmonary problems?
2. List four nursing interventions for the altered pulmonary status.
3. What are three reasons why the apical pulse could be elevated?
4. What are two reasons why the blood pressure could be low?

Answers at end of chapter.

► CARDIAC TRANSPLANTATION

Cardiac transplantation is reserved for patients with end-stage cardiac disease. Strict criteria for the selection of recipients and donors are applied to optimize survival (Box 22–4). Preoperative teaching is done once the recipient is accepted into the transplant program. For more information on heart transplantation, visit <http://www.nlm.nih.gov/medlineplus/hearttransplantation.html>.

Surgical Procedure

Once a donor heart is found, the recipient is notified, admitted to the hospital, and immediately prepared for surgery. The general procedures for this surgery are similar to those described in the cardiac surgery section. Two types of cardiac transplant procedures are performed: orthotopic and heterotopic. In the orthotopic procedure, once the patient is on CPB, the recipient's diseased heart is removed, leaving the posterior wall of the atria, superior vena cava and inferior vena cava, and pulmonary vein (Fig. 22–5). The aorta and pulmonary artery are cut. The donor's atria, aorta, and pulmonary artery are then anastomosed to the recipient's atria, aorta, and pulmonary artery. Surgery then continues as previously described. The heterotopic procedure joins the donor heart and vessels to the recipient's heart and vessels without removing the recipient's heart. The donor heart rests in the right side of the chest.

paresthesia: para—abnormal + esthes—sensation + ia—pertaining to
encephalopathy: en—inside + cephalo—head + pathy—disease

Figure 22-5 Heart transplantation.

BOX 22-4 Cardiac Transplant Criteria

Donor Criteria	Recipient Criteria
Younger than 40 years of age	Younger than 55 years of age
No significant cardiac or malignant disease	Class IV cardiac disease (not treatable with other medical or surgical treatment, less than 6–12 months survival)
No active infections	No irreversible pulmonary hypertension
No severe hypertension or diabetes mellitus	No unresolved pulmonary infarcts
Only \pm 20 lb difference in weight between donor and recipient	No systemic disease limiting survival
	No drug addiction or peptic ulcer disease

Immunosuppressive therapy begins preoperatively with high loading doses of cyclosporine, azathioprine, steroids, or other medications. The risk for rejection is highest immediately after surgery and decreases with time, so doses of immunosuppressive medication are also highest initially after surgery and decrease with time (Nutrition Notes Box 22-5). Lifelong antirejection therapy is required.

Complications

Heart transplantation complications may include all those stated for cardiac surgery, as well as heart rejection, which is the major cause of death within the first year. Immunosuppressive therapy is required to prevent rejection of the heart. To detect rejection, biopsies of cardiac muscle are commonly performed weekly during the first 3 to 6 weeks after surgery, then every 3 months for 1 year, and then yearly. If a biopsy shows damaged cells, indicating rejection, antirejection drug therapy may be changed.

In addition, infection and malignancies may occur as a result of the immunosuppressive therapy. The medications used for immunosuppressive therapy also may cause adverse reactions. Cyclosporine is nephrotoxic and hepatotoxic. Azathioprine is also hepatotoxic and may cause bone marrow depression or skin sensitivity to the sun. Steroids can cause osteoporosis, hyperglycemia, sodium and water retention, gastritis, hypertension, and cataract formation. muromonab-CD3 (Orthoclone OKT3), used to treat rejection reactions in spite of immunosuppressive therapy, can cause fever, malaise, and headaches.

BOX 22-5**Nutrition Notes**

The potency of antirejection medications may be reduced if patients drink grapefruit juice with them. Grapefruit increases body metabolism.

Individuals who drink wine may not get the desired therapeutic effects of certain immunosuppressive medications.

CRITICAL THINKING**Mrs. Eden**

Mrs. Eden, 45, a single mother of two, is transferred to a surgical unit 5 days after a cardiac transplant. She is withdrawn and has a poor appetite. Her vital signs are stable. However, on ambulating to the bathroom, she is very weak, requiring two nurses to help her. Her respiratory rate increases from 20 to 32 and is slightly labored, and her apical pulse increases from 88 to 103.

1. Is Mrs. Eden tolerating this activity? Why or why not?
2. List four reasons why Mrs. Eden has a poor appetite.
3. Give four nursing interventions for Mrs. Eden's poor appetite.
4. Give three reasons why Mrs. Eden is withdrawn.

Answers at end of chapter.

Medical Management

The patient receives a diuretic when CPB is stopped to aid in excretion of excessive circulating fluid. Intake and output are monitored hourly, and the patient is observed for fluid overload. Lung sounds are monitored frequently for crackle, and weight and electrolyte levels are checked daily.

Postcardiotomy syndrome (PCS) may occur from day 2 to 5 after surgery and last a few weeks. Patients may arouse normally and be oriented but exhibit mild confusion or psychosis. Pupillary reaction and motor response are assessed. The safety of the patient is maintained with side rails up, bed in low position, and nursing call light within reach. The patient is given as much rest and as little sensory stimulation as possible. The family is kept informed and involved in the patient's recovery.

Sleeping is difficult because of postoperative pain and the continuous level of activity in the ICU. Sleep is promoted in 90-minute intervals by dimming lights and decreasing all sensory stimulation near the patient. Additionally, listening to a favorite soothing tape recording with earphones or the use of ordered narcotics for pain may also help sedate and relax the patient.

Temperature is monitored every 4 hours and complete blood cell count (CBC) and white blood cell (WBC) results are monitored for indications of infection. If oral thrush (white patches) develops, an antifungal agent is ordered. A urine culture to diagnose a urinary tract infection is ordered if cloudy urine or urinary tract burning occur.

▶ ARTIFICIAL HEART AND VENTRICULAR ASSIST DEVICES

Newer technology is being used to aid the failing heart. The purpose of these artificial hearts or ventricular assist devices is to be a bridge to transplantation or a long-term solution when other options are not available to treat the failing heart. Because there are not enough donor hearts, this technology may benefit many patients. Several trials of these devices are occurring now. For more information about artificial hearts and ventricular assist devices, visit the National Institutes of Health or a manufacturer's Web site at the following addresses:

www.worldheart.com

► NURSING PROCESS: PREOPERATIVE CARDIAC SURGERY OR CARDIAC TRANSPLANT

Preoperative and postoperative needs for the patient undergoing cardiac surgery are discussed here and in Chapter 11.

Assessment

A baseline assessment is important for postoperative comparison and to begin discharge planning (Box 22–6). Pain control needs and circulatory status are essential items. Results of diagnostic laboratory tests, x-ray examinations, and other studies are reported if abnormal. Typing and cross-matching of ordered units of blood are placed on hold.

Nursing Diagnosis

The nursing diagnoses for preoperative cardiac surgery or transplant may include but are not limited to the following:

- Anxiety related to threat of death, pain, powerlessness, or lifestyle changes
- Deficient knowledge: knowledge of preoperative and postoperative procedures related to unfamiliar process.

► NURSING PROCESS: POSTOPERATIVE CARDIAC SURGERY OR CARDIAC TRANSPLANT

Assessment

The patient is accompanied to the ICU by the anesthesiologist, who gives the nurse a report of the procedure, complications, and hemodynamic and ventilatory management of the patient. The patient is connected to a cardiac monitor and mechanical ventilator. The mechanical ventilator is used for 4 to 24 hours. A temporary pacemaker is connected to the epicardial pacing wires if they were placed during surgery as a precaution to treat bradycardia. The patient is

placed under a warming device, such as a light or blanket. The chest tubes are monitored, the nasogastric tube is placed to suction, and the urinary catheter is placed for gravity drainage. A head-to-toe assessment of the patient, including dressings, tubes, and IV lines, is performed. Of importance are signs of awakening, shivering, pain, lung and heart sounds, and palpation of the entire chest and neck to detect crepitus (air in the subcutaneous tissue from opening the chest). Blood is drawn for a CBC, electrolytes, coagulation studies, and arterial blood gases. Cardiac transplant patients may be in isolation for their own protection, depending on the agency's policy.

After the initial transfer assessment, vital signs, oxygen saturation, and cardiac pressures are monitored and recorded every 15 to 30 minutes, with decreasing frequency as the patient stabilizes. Body temperature is monitored continuously while warming measures are used. Intake and output are measured and vital signs are checked. A 12-lead electrocardiogram (ECG) is done to detect perioperative myocardial infarction. A chest x-ray examination is done to check central line and endotracheal tube placement and to detect a pneumothorax or hemothorax, diaphragm elevation, or mediastinal widening from bleeding. At this point the family may see the patient, and patient care is explained.

Nursing Diagnosis

The nursing diagnoses for the patient who has had cardiac surgery may include but are not limited to the following:

- Acute pain related to surgical incision or reperfusion of tissue
- Ineffective airway clearance related to intubation, anesthesia, pain, or sedation
- Impaired gas exchange related to volume overload, atelectasis, phrenic nerve injury, or preexisting pulmonary dysfunction
- Decreased cardiac output related to myocardial depression, hypothermia, or dysrhythmias
- Risk for infection related to surgical incisions or immunosuppression
- Deficient knowledge: therapeutic regimen related to lack of previous exposure

Nursing diagnoses for postoperative cardiac surgery or transplant are discussed in Nursing Care Plan Box 22–7 for the Postoperative Patient Undergoing Cardiac or Transplant Surgery.

Planning

The patient's goals include the following:

- Maintain pain relief.
- Maintain a patent airway and clear lung sounds.
- Maintain oxygen saturation greater than 95 percent.
- Maintain vital signs within normal limits.
- Remain free from infection.
- Understand the surgery and the therapeutic regimen.

Nursing Interventions

Pain

After cardiac surgery, pain is monitored in relation to the patient's preoperative anginal or infarction-associated pain. Chest pain after surgery can be frightening for patients. Knowing that chest pain can occur from the surgical incision rather than the heart is important to the patient. Other-

wise the patient may not associate surgical chest pain with the incision and instead think the pain is anginal or infarction pain.

Ineffective Airway Clearance

Coughing and deep breathing and using incentive spirometry every hour while awake are important to prevent respiratory complications. Elevating the head of the bed, sitting

BOX 22-7

NURSING CARE PLAN FOR THE POSTOPERATIVE PATIENT UNDERGOING CARDIAC OR TRANSPLANT SURGERY

▶ Acute pain related to sternotomy, leg incisions, internal mammary artery resection, or pericarditis

PATIENT OUTCOMES

Patient will state pain is relieved or tolerable. Patient is able to rest and perform respiratory treatments.

EVALUATION OF OUTCOMES

Does patient state pain is within acceptable levels? Is patient able to rest and perform respiratory therapies?

INTERVENTIONS

- Assess characteristics of pain with each episode.
- Splint chest incision with all movement and coughing and deep breathing.
- Encourage patient to report pain even when pain is mild.
- Turn, reposition every 2 hours.
- Offer back rubs frequently.
- Instruct patient to take a deep breath before movement and exhale slowly during movement.

RATIONALE

A thorough description is needed to determine cause and plan actions.
Stabilizes sternum and incision to increase comfort.
It is easier to keep pain under control when mild.
Changes muscle position, relieving stiffness.
Relaxes tense muscles retracted during operation.
Keeps muscles relaxed, minimizing tension with guarding and pain.

EVALUATION

Does patient describe pain on scale of 0 to 10?
Can patient splint chest incision independently?
Does patient report pain when mild?
Is patient comfortable without stiffness?
Is patient able to rest in comfort?
Can patient perform coughing and deep breathing techniques as instructed?

▶ Decreased cardiac output related to myocardial depression, hypothermia, bleeding, unstable dysrhythmias, or hypoxemia

PATIENT OUTCOMES

Patient will remain free of major side effects of pharmacological support. Patient will maintain vital signs within normal limits (WNL), palpable peripheral pulses, urine output greater than 30 mL/h, and normal sinus rhythm.

EVALUATION OF OUTCOMES

Is patient free of major side effects? Are vital signs WNL?

INTERVENTIONS

- Monitor vital signs.
- Assess peripheral circulation.
- Monitor intake and output.
- Assess lung sounds and character of sputum.
- Monitor temperature closely while rewarming the patient.
- Assess for shivering.
- Monitor chest tube drainage for increase or sudden decrease.
- Monitor ECG.
- Monitor electrolytes.
- Monitor ABGs.

RATIONALE

Trends reflect problems.
Mottling or weak pulses may indicate poor cardiac output (CO).
Fluid deficit or excess can alter CO.
Wet lung sounds may indicate heart failure or pulmonary edema.
Febrile state increases heart rate and myocardial oxygen consumption.
Shivering increases the blood pressure, decreasing CO and increasing risk for bleeding.
Drainage >200 mL/h may lead to hypovolemia and a decrease in CO.
Premature ventricular contractions and atrial fibrillation decrease CO.
Low calcium and magnesium and high potassium decrease contractility and CO.
Acidosis decreases heart function, and a low CO may lead to further acidosis.

EVALUATION

Are vital signs WNL?
Do peripheral pulses remain strong with normal skin color, temperature, capillary refill?
Does total intake equal output?
Are lungs clear?
Does temperature remain less than or equal to 98.6° F (37° C)?
Is patient's shivering controlled?
Is patient free from tamponade and hypovolemia?
Does patient remain in normal sinus rhythm or controlled dysrhythmia?
Are electrolytes WNL?
Are ABGs WNL?

BOX 22-7

NURSING CARE PLAN FOR THE POSTOPERATIVE PATIENT UNDERGOING CARDIAC OR TRANSPLANT SURGERY—CONT'D

Risk for infection related to inadequate primary defenses from surgical wound or immunosuppression (transplants)**PATIENT OUTCOMES**

Patient will remain free from infection.

EVALUATION OF OUTCOMES

Does patient remain free from infection?

INTERVENTIONS

- Observe incision for signs and symptoms of infection.
- Monitor drainage and maintain drains.
- Maintain sterile technique for dressing changes.
- Monitor and report abnormal findings for temperature, lung sounds, sputum, and urine consistency.
- Encourage coughing and deep breathing and incentive spirometer use.

RATIONALE

Redness, warmth, fever, and swelling indicate infection.
Drains remove fluid from the surgical site to prevent infection development.
Sterile technique reduces infection development.
Low-grade (immunosuppressed) or high-grade fever, crackles, yellow-green sputum color, or cloudy urine can indicate infection.
Lung infections can be prevented with lung expansion and secretion removal.

EVALUATION

Are signs and symptoms of infection present?
Are drainage amount and color normal for procedure? Are drains functioning?
Is incision free of signs and symptoms of infection?
Is the patient's temperature WNL and are lung sounds, sputum, and urine clear?
Does patient perform coughing and deep breathing and use incentive spirometer?

upright, splinting the chest incision with a pillow or blanket roll, and relieving pain increase the patient's ability to cough and deep breathe. Elderly patients have a weakened cough force. These patients should be encouraged and assisted to cough as effectively as possible.

Impaired Gas Exchange

Daily chest x-ray examination results are monitored for diaphragm elevation, atelectasis, pulmonary effusions, and pneumothorax or hemothorax. The patient is given oxygen and suctioned as needed. Chest tubes are maintained. Respiratory treatments with bronchodilators may be given while the patient is on the ventilator and after extubation. Diuretics and steroids are given to reduce excess fluids and improve air exchange.

Decreased Cardiac Output

Trends in the patient's cardiac output are monitored. Body temperature is continuously monitored until warming measures are discontinued, which occurs when the core body temperature nears 37° C (98.6° F). While patients are being rewarmed, they are assessed for shivering, which may be felt as a fine vibration at the mandibular angle of the jaw. Shivering greatly increases cardiac oxygen needs. Paralyzing agents given with narcotics eliminate shivering.

Risk for Infection

Hand washing is extremely important to prevent infection. Dressings are kept dry and intact. Sterile technique is used to change dressings, and incisions are assessed with every dressing change. All IV solutions and tubing are changed according to the agency's protocol for immunosuppressed patients (often every 24 hours). IVs and invasive lines

should be discontinued as early as possible. The cardiac transplant patient may be in reverse (protective) isolation.

For the immunosuppressed patient, the risk of infection is great. Observation is the key to early detection of infection. A fever is usually low grade in an immunosuppressed patient because the suppressed immune system cannot produce a normal response to an infection. Sputum color is noted and a sputum culture is requested if changes occur. Urine appearance is noted, and a request for a urine culture is made if changes occur. The patient's oral mucosa is checked every shift for sores or thrush resulting from immunosuppression.

Deficient Knowledge

Awakening with many questions, strange auditory and tactile sensations, and the inability to speak are very frightening and frustrating to the patient. Keeping eye contact with the patient and using touch appropriately can be very soothing. If lip reading is unsuccessful, using simple closed-ended questions, nonverbal gestures, communication boards, and magic slates may be effective. Explanations regarding procedures are given in simple terms.

The family is taught to promote self-care by the patient. Cardiac transplant patients commonly have memory deficits, cognitive dysfunction, and short attention spans resulting from long-term decreased cerebral perfusion. Information must be given in small increments. Family involvement in teaching sessions is important to promote understanding and retention.

Discharge teaching should include treatment, complications, activity, medications, and how to enhance one's quality of life. Sexual functioning questions and concerns should also be discussed with the patients and their part-

ners. In addition to written materials, audiotapes can be used to provide discharge information.

Additional Nursing Care for Cardiac Transplant Patients

Cardiac transplant patients may have feelings of sadness and grief for the donor and his or her family. These feelings may be offset by great elation, relief, and hope after a long wait for the transplant. Patients should be told that these feelings are normal. They should be allowed to express their feelings when they are ready. Emotional support may be needed.

Transplant rejection is a possible complication of this surgery. Patients need to understand the importance of following instructions regarding medications and testing that are related to preventing or detecting rejection.

Cardiac transplant patients are followed in an exercise rehabilitation program that closely monitors their activity progression in relation to myocardial oxygen consumption and signs of activity intolerance. Progression may be slow depending on the patient's condition before surgery. Most patients reach an activity level allowing them to participate in many recreational sports.

► VASCULAR SURGERY

Vascular impairments requiring surgery may be acute or chronic and involve arteries, veins, or lymphatic vessels.

Embolectomy and Thrombectomy

When an artery becomes completely occluded by an embolus or thrombus, it is considered a surgical emergency. Surgical removal to restore blood flow and oxygenation to the tissue distal to the occlusion is imperative to decrease ischemia and necrosis. Fogarty catheters (long narrow catheters with an inflatable balloon tip) are used to remove the thrombus or embolus. A small incision is made in the blood vessel near the occlusion, and the catheter tip is inserted past the occlusion. The balloon is inflated, and the catheter with the occlusive material is drawn back through the incision. The blood vessel and wound are sutured as circulation is assessed.

Vascular Bypasses and Grafts

Vascular bypass surgery involves the use of either autografts, such as the patient's own saphenous vein, or a synthetic graft material. The graft is anastomosed to the artery proximal to the occlusion and tunneled past the occlusion, where the distal end of the graft is anastomosed to the artery (Fig. 22-6). The graft is assessed for hemostasis and function, and then the wound is sutured closed.

Repair of a diseased area of a blood vessel, such as an aortic abdominal aneurysm, is performed with resection of the diseased area and replacement with a graft (aortic aneurysmectomy). This is usually an elective procedure. However, if an aneurysm is dissecting or ruptures, it is a surgical emergency.

Figure 22-6 Aortic-femoral bypass.

Newer techniques are being used for bypass surgery. One technique uses video-assisted aortofemoral bypass without laparotomy. This method reduces length of hospital stay and patient recovery times.

Arteriovenous (AV) grafts or fistulas are created when permanent circulatory access is needed, such as for hemodialysis. Grafts are created by attaching one end of a synthetic graft to an artery and the other end to a nearby vein. An AV fistula is formed when a selected artery and vein are directly anastomosed to each other. The radial artery and cephalic vein in the forearm are most commonly used for these procedures. Local anesthesia is usually used.

Endarterectomy

Arteriosclerotic plaques are dissected from the lining of the arterial wall and removed in a procedure called an endarterectomy. This is most commonly performed on the carotid artery. To control blood flow, the artery is clamped on both sides of the occlusion, and an incision is made into the artery. The plaque within the artery is removed with forceps. The artery is irrigated to remove any further debris and then closed with sutures. The clamps are removed, and

the skin incision is closed. A drain may be placed to help prevent hematoma formation.

Angioplasty

Minimally invasive techniques can also be used to open plaque-blocked arteries. These techniques include balloon or laser angioplasty. A flexible laser-tipped catheter is inserted into an artery and advanced to the site of the blockage. The laser sends out pulsating beams of light, which vaporize the plaque.

Stents

Stents are placed inside an artery to provide support to the artery walls and keep them open. (See Chapter 18.) Stents are placed in a procedure similar to percutaneous transluminal coronary angioplasty (PTCA). Stents may also be used in combination with other procedures such as angioplasty.

Complications of Vascular Surgeries

Bleeding and hemorrhage can occur with all vascular surgeries. Drainage can be expected with most surgeries. Drainage is usually small when peripheral vessels are involved. But with involvement of the great vessels, drainage is usually heavier and drains are often placed to prevent swelling and hematoma formation. If hemorrhage occurs, manual pressure is applied to the site of bleeding and the physician notified immediately.

Reocclusion is possible with any vascular surgery. If thrombi or emboli develop and block blood flow, it is a surgical emergency.

Hematoma formation is a complication of carotid surgery that can compress and compromise the airway. Monitoring the operative site visually for a hematoma is essential.

Neurological dysfunction may occur if plaque embolizes to the brain during surgery.

Extensive surgeries may also result in significant blood loss, leading to fluid volume deficit or shock.

Medical Management

Frequent assessments are ordered postoperatively. Neurological checks following carotid surgery are initially ordered hourly. Neurovascular checks of extremities every 1 to 4 hours are usually ordered. The incisional area is monitored for hematoma formation. Abdominal girth measurements (for aortic aneurysm repair) are ordered. An increase in abdominal girth may indicate hemorrhage. Any abnormal change is reported immediately to the physician. A loss of a pulse can indicate that circulation has been impaired in the vessel. The patient's need to return to surgery is anticipated if signs of impaired circulation are found.

CBC, prothrombin time (PT), PTT, and electrolytes may be ordered daily. Intake and output monitoring may be initially ordered hourly, then every 4 to 8 hours. Imbalances in fluid status should be reported. IV crystalloid solutions, volume expanders, or blood may be ordered for fluid deficits.

► NURSING PROCESS: PREOPERATIVE VASCULAR SURGERY

Assessment

A baseline assessment is important for postoperative comparison and discharge planning. Pain control needs and circulatory status are assessed. Diagnostic test (CBC, electrolytes, PT, PTT, and bleeding time) results are reviewed, and typing and crossmatching of blood to be placed on hold is performed.

Nursing Diagnosis

The nursing diagnoses for preoperative vascular surgery may include but are not limited to the following:

- Acute or chronic pain related to ischemia of tissue distal to occlusion or aneurysm
- Anxiety related to unknown outcome, pain, powerlessness, or threat of death
- Deficient knowledge: preoperative and postoperative procedures related to unfamiliar process.

► NURSING PROCESS: POSTOPERATIVE VASCULAR SURGERY

Assessment

On transfer postoperatively to either the ICU or surgical unit, the patient is positioned comfortably and a head-to-toe assessment is performed and documented, with abnormal findings reported to the physician. Once a patent airway is ensured, vital signs are monitored according to institutional policy, or more frequently if they are unstable. The patient's pain level is rated on a scale of 0 to 10. All IVs and drains are monitored. Patients with extensive surgery may have a nasogastric tube. Measurement of intake and output is usually done hourly. Laboratory tests are also monitored.

Arteriovenous grafts and fistulas are assessed for patency by palpating for a thrill (a tremor) and auscultating for a bruit (swishing sound) at the site of the graft or fistula. If a thrill or bruit is not present, the physician is notified immediately. Dressings or incisions are checked, and any drainage or hematoma development is noted and marked.

For carotid surgeries, airway and neurological checks are performed hourly or as ordered. Airway checks involve assessment of respirations and tracheal position. Any respiratory distress is reported for prompt intervention. If the trachea is not midline, the shift to either side is noted and reported immediately. Impaired respiratory function may occur rapidly, with tracheal shifting from bleeding or hematoma development in the neck. Neurological checks include level of consciousness; orientation; pupil size and reaction; cranial nerve function, such as eye and tongue movements; movement, strength, and sensation of extremities; and speech. Temporal pulses are also assessed (located at the hairline near the outer end of the eyebrow).

Initially, neurovascular checks are performed hourly for aortic or extremity vascular surgery. Neurovascular checks include extremity movement and sensation, presence of numbness or tingling, pulses, temperature, color, and capillary refill (less than 3 seconds normally). Peripheral pulses are palpated, or assessed with Doppler ultrasound if not palpable, marked, and compared with the unaffected extremity to detect deficits. If a pulse is absent or weak or the extremity is cool or dusky, the physician is notified immediately. A return to surgery for an embolectomy or other procedure is anticipated.

LEARNING TIPS

Neurovascular checks refer to the assessment of an extremity. (Neurological checks refer to assessment of the central nervous system). The following are areas to examine on an extremity when doing neurovascular checks. They are identified under the category for which they provide information:

Neurological	Vascular
Movement	Pulses
Sensation	Capillary refill
Numbness	Color (nailbed or skin)
Tingling	Temperature

Nursing Diagnosis

The nursing diagnoses for postoperative vascular surgery may include but are not limited to the following (Nursing Care Plan Box 22–8):

- Acute pain related to surgical incision or reperfusion of tissue
- Ineffective airway clearance related to intubation, anesthesia, pain, or sedation
- Risk for infection related to surgical incisions
- Ineffective tissue perfusion related to hypotension, hypothermia, emboli, or vascular reocclusion
- Deficient knowledge: surgical recovery needs related to lack of prior exposure

Planning

The patient and family should be included in planning postoperative care goals. The patient's goals include the following:

- Have pain relieved.
- Maintain vital signs and oxygen saturation within normal range.
- Remain free from infection.
- Maintain peripheral pulses and tissue perfusion.
- Remain free of edema and maintain clear lung sounds.
- Understand the disease and its treatment.

Nursing Interventions

Acute Pain

Pain is usually mild and can be easily controlled after peripheral surgery. If pain is severe, it may indicate ischemia caused by spasm or reocclusion. With great vessel surgery, severe pain may be experienced, requiring more than one pain management method for relief. All characteristics of the pain are assessed to compare with previous pain episodes.

Ineffective Airway Clearance

After carotid endarterectomy, the head of the bed should be elevated 30 to 45 degrees. Elevation minimizes venous oozing and helps prevent hematoma formation in the neck, which can compromise respiratory function. Patients are encouraged to deep breathe to expand the alveoli. Depending on the procedure, coughing may need to be avoided to prevent increased pressure on the surgical site.

Risk for Infection

Hand washing is important to prevent infection. Temperature is monitored every 4 hours. Dressings are kept dry and intact and incisions are assessed with every dressing change. Sterile technique is used to change dressings.

Ineffective Tissue Perfusion

Circulatory parameters should be double-checked between nurses changing shifts, so that the oncoming nurse has a baseline for comparison. The presence and quality (strength) of a pulse and how it was assessed (palpated or via Doppler ultrasound) is documented.

Deficient Knowledge

The patient's and family's understanding regarding the postoperative recovery period is assessed. Physician's orders and routines regarding ambulation, exercise or restrictions, pain management, incision care, coughing and deep breathing, medications (heparin or warfarin), prevention, and early signs and symptoms of thrombus or embolus formation are explained. Written, as well as verbal, information should be given for future reference by the patient (Home Health Hints). Audiotapes are also a helpful method of providing discharge information. The patient can listen to the tapes in the hospital and have questions answered by the nurse; then the tapes can be taken home for review as needed or to share with other family members who may not have been able to participate in hospital teaching sessions.

Evaluation

For evaluation of nursing diagnoses for postoperative vascular surgery, see Nursing Care Plan Box 22–8.

BOX 22-8

NURSING CARE PLAN FOR THE POSTOPERATIVE PATIENT UNDERGOING VASCULAR SURGERY

Acute pain related to surgical incision and reperfusion of tissue**PATIENT OUTCOMES**

Patient will state that the pain is relieved or is tolerable. Patient will rest comfortably, perform respiratory treatments as necessary, and perform activities of daily living (ADLs).

EVALUATION OF OUTCOMES

Does patient state pain is relieved or acceptable? Is patient able to rest and participate in respiratory treatments and ADLs?

INTERVENTIONS

- Assess severity of pain, as well as all other qualities.
- Ask patient to rate pain after analgesic is given.
- Notify physician if pain is unrelied.

RATIONALE

Peripheral vascular surgery pain is usually mild, and severe pain may indicate reocclusion. Major vascular surgery pain is severe. Pain relief is individualized. Different analgesic may be needed to give relief.

EVALUATION

Does patient state pain is at a tolerable level with a patent vessel?
Does patient state pain is controlled at a tolerable level?
Are patient's pain relief needs met?

GERIATRIC

- Ensure that elderly patient's pain is relieved.
- Use opioid pain medications cautiously. Consider reducing frail elderly patient's first opioid dose by 25%-50%, and increase as safe and needed and as ordered.

Pain is not a normal part of aging, and elderly patients need and are entitled to adequate pain relief. Elderly patients are more susceptible to peak effects and duration of analgesia of opioids.

Does patient rate pain as none or at a tolerable level using a scale of 0 to 10?
Are patient's vital signs and sedation levels within normal limits (WNL)?

Ineffective tissue perfusion related to hypotension, hypothermia, emboli, vascular spasm, or reocclusion**PATIENT OUTCOMES**

Patient will have palpable peripheral pulses: adequate capillary refill; and normal color, temperature, motor, and sensory function of extremities. Patient will have reactive pupils and baseline cognitive function.

EVALUATION OF OUTCOMES

Is patient's circulatory status WNL? Does patient have reactive pupils and baseline cognitive function intact?

INTERVENTIONS

- Assess circulation, movement, and sensation to extremities every 1 to 4 hours.
- Mark location of pulses on affected extremity.
- Perform neurological checks every 2 to 4 hours (carotid).
- Perform circulation or neurological check between nurses when changing caregiver.
- Measure abdominal girth every shift (abdominal aortic surgery).
- Take temperature every 4 hours.
- Monitor CBC as ordered.
- Avoid constricting measures on affected extremity: knee gatch of bed, adhesive tape, tight dressings.
- Auscultate AV shunts and grafts for bruits and palpate for thrills.

RATIONALE

Early detection of spasm or reocclusion minimizes risk of ischemia and necrosis. Allows for quick location of pulses. Allows early detection of complications. Subtle changes can be detected and new caregiver has baseline for comparison. Increasing girths may indicate bleeding into abdomen. May indicate infection or hypothermia with need for further warming. RBC count, hemoglobin, and hematocrit decrease with insidious bleeding into abdomen or significant hematoma formations. Prevent further decrease in blood flow to compromised extremity. Any decrease or cessation of bruit or thrill indicates occlusion.

EVALUATION

Does graft or vessel remain patent?
Are pulses located easily?
Are major neurological or circulatory problems detected?
Is baseline assessment done?
Does abdominal girth remain unchanged?
Does patient remain normothermic?
Is CBC WNL?
Is blood flow to affected extremity maintained?
Does AV shunt or fistula remain patent?

HOME HEALTH HINTS

- A copy of the discharge instructions should be reviewed with the patient and family to ensure consistent understanding between the nurse and the family of the plan of care.
- A home health social worker visit to a postsurgical cardiac patient may be useful to help the patient and family plan for lifestyle changes to reduce anxiety and environmental stress.
- The ability of the patient caregiver to provide necessary care should be assessed. The support and resources available to the caregiver should be explored to prevent caregiver role strain.
- The need for caregiver respite care should be assessed, especially over time. If respite care is needed, assist the caregiver in identifying respite care resources in the family or community.
- Assist the caregiver to identify a plan to distribute the care workload among family members, if possible.
- Teach the caregiver stress management techniques to use.
- The importance of taking medications as prescribed needs to be reinforced, especially for immunosuppressive medications for cardiac transplant patients.
- Advise patients who are leaving home for the weekend or holidays to refill medicines ahead of time to ensure that they do not run out. The physician can write a prescription for the patient to have for emergency refills.
- Patients with cardiac transplants should not be exposed to people with illnesses such as colds or the flu. This should be explained to family members and visitors.
- Monitor the patient following cardiovascular surgery for complication development such as incisional infection, pneumonia, thrombophlebitis, or pulmonary emboli. Report any abnormal findings.
- Chest pain from esophageal reflux can mimic cardiovascular symptoms. The home health nurse should ask if the pain is related to consuming large meals, lying down, or bending over, or if it is relieved with antacids or food. Inform the physician of these findings.

CRITICAL THINKING

Mr. Smith

Mr. Smith has just returned to the surgical unit from the postanesthesia recovery room after undergoing a right carotid endarterectomy. His assessment findings include sleepy but arousable; oriented to person, place, and time; pupils equal and reactive to light; moving all extremities spontaneously and in response to commands equally and strongly; right neck dressing dry and intact; blood pressure 146/82, apical pulse 74, and respiratory rate 16.

1. How should Mr. Smith be positioned?

One hour later Mr. Smith is very sleepy but arouses to verbal and tactile stimulation. His pupils are equal, but the right pupil reacts more slowly than the left. He is only moving all extremities with repeated commands, with the left side moving less than the right. There is a 2-cm shadow of drainage on the right neck dressing. His vital signs are BP 176/88, P 64, R 26.

2. What are seven areas of concern found during this assessment of Mr. Smith?
3. What should your first action be?
4. List four priority items you should continue assessing as the physician is contacted.

Answers at end of chapter.

CRITICAL THINKING

Mr. Jangles

You are caring for Mr. Jangles, age 63, who has just returned from surgery after an embolectomy of the right lower leg. He has a history of insulin-dependent diabetes mellitus, hypertension, renal insufficiency, and a myocardial infarction 2 weeks ago. He is 6 feet tall and weighs 316 pounds.

1. What are four priority assessment areas for you to perform for Mr. Jangles?
2. What other information might you want to know regarding Mr. Jangles's medical history?
3. List three priority nursing diagnoses for Mr. Jangles.
4. State one outcome for each nursing diagnosis.
5. What are nursing interventions for each nursing diagnosis that you will perform?

Answers at end of chapter.

REVIEW QUESTIONS

- A patient is scheduled for vascular surgery. The patient is taking digoxin, furosemide, potassium, warfarin, and famotidine. Which medication may be stopped several days before surgery?
 - Digoxin (Lanoxin)
 - Furosemide (Lasix)
 - Warfarin (Coumadin)
 - Famotidine (Pepcid)
- Which one of the following is the purpose of CABG surgery?
 - Cure coronary artery disease
 - Increase blood flow to the myocardium
 - Prevent spasms of the coronary arteries
 - Decrease blood flow to the coronary arteries
- The nurse is planning care for a patient having a cardiac valve replacement. With which type of valve will the patient be on anticoagulant therapy to prevent thrombus formation?
 - Mechanical valves
 - Porcine valves
 - Allograft valves
 - Bovine valves
- Which one of the following can cause postoperative bleeding in a patient who has had an abdominal aortic aneurysm repair?
 - Coronary artery spasm
 - Hypotension
 - Hypertension
 - Heparin reversal
- The nurse is assessing a patient who has had an AV fistula created. How is the patency of the fistula assessed?
 - Check the pulse proximal to the fistula.
 - Palpate the skin temperature proximal to the fistula.
 - Check skin color and capillary refill proximal to the fistula.
 - Palpate the thrill and auscultate the bruit over the fistula.

Answers to CRITICAL THINKING

Mr. Jones

- Apical pulse 105, respirations shallow, lung sounds diminished with crackles, respiratory rate 28, temperature 99.8° F, and irregular apical pulse all could indicate pulmonary problems.
- Nursing interventions include the following: Have patient turn, cough, and deep breathe; provide incentive spirometry; elevate head of bed; culture sputum; administer pain medication as ordered; splint the incision; administer diuretics if ordered; assess lungs every 2 to 4 hours.
- Hypovolemia, hypoxemia, and a febrile state could cause apical pulse to be elevated.
- Hypovolemia and irregular rhythm could cause low blood pressure.

Mrs. Eden

- No, Mrs. Eden is not tolerating this activity, as evidenced by her increased respiratory rate and apical rate.
- Steroids, immunosuppressive therapy, depression, and fatigue could be causing her poor appetite.
- Nursing interventions related to Mrs. Eden's poor appetite could include the following: offering small, frequent meals; having family bring favorite foods from home; allowing the patient to rest before meals; providing oral hygiene before meals; administering antiemetics before meals; giving a high-calorie meal at peak appetite.
- Mrs. Eden could be withdrawn because of changes in her lifestyle as a result of her transplant, extreme fatigue and concerns regarding how she will raise her children, grieving for the donor, and fear that she will reject her new heart.

Mr. Smith

- The head of the bed should be elevated 30 to 45 degrees.
- Areas of concern include increased blood pressure, increased respiratory rate, decreased apical pulse, drainage on dressing, more difficult to arouse, unequal movement, unequal pupillary reaction.

- Have the registered nurse notify the physician and stay with the patient.
- Priority assessments include respiratory status (rate, depth, stridor), bleeding (increased drainage, swelling around neck, tracheal shift to left), neurological status (decreased level of consciousness, movement of extremities), and vital signs (increased blood pressure, decreased apical pulse).

Mr. Jangles

- Priority assessments include respiratory status, circulatory status of right leg and foot, vital signs, and pain level.
- A medical history should include Mr. Jangles's usual blood sugar values, insulin dose, ambulation aids, gait, knowledge base regarding his various disease processes, and what led to this hospitalization.
- (1) Priority nursing diagnoses include pain related to surgery of right lower leg; (2) ineffective tissue perfusion related to embolectomy of right lower leg, renal insufficiency; (3) risk for injury related to leg surgery, diabetes, obesity.
- Outcomes include (1) verbalizes relief of pain; (2) maintains adequate tissue perfusion as evidenced by palpable peripheral (pedal) pulses, warm and dry skin; (3) remains free from injury.
- Nursing interventions include the following: (1) Position (especially right leg) for comfort; keep the right leg slightly elevated; educate the patient regarding the need to ask for pain medication before pain is too severe; educate the patient regarding the need to take pain medication to minimize the negative physiological effects of pain; assess pain on a pain scale; evaluate the effectiveness of medication using the same pain scale, report ineffective pain measures. (2) Check pedal pulses, surgical dressing, pedal sensation and movement, and color, initially every hour; report changes; check capillary refill; assess for pain in extremities; assess for edema in extremities; keep leg elevated slightly. (3) Make sure the nursing call light is within reach; provide assistance with ambulation; use walking aids.

UNIT FIVE

UNDERSTANDING THE
HEMATOPOIETIC AND
LYMPHATIC SYSTEMS

23

HEMATOPOIETIC AND LYMPHATIC SYSTEM FUNCTION, ASSESSMENT, AND THERAPEUTIC MEASURES

Valerie C. Scanlon and Cheryl L. Ivey

KEY TERMS

ecchymoses (ECK-ih-**MOH**-sis)
lymphedema (LIMPF-uh-**DEE**-mah)
petechiae (puh-**TEE**-kee-eye)
purpura (**PUR**-pur-uh)
thrombocytopenia
(THROM-boh-SIGH-toh-**PEE**-nee-ah)

QUESTIONS TO GUIDE YOUR READING

1. What are the components of blood?
2. How are changes in the blood or blood-producing processes manifested as disease processes?
3. What is the sequence of events in the process of blood clotting?
4. What data should you collect when caring for a patient with a disorder of the hematological or lymphatic system?
5. What laboratory and diagnostic studies are used when evaluating the hematological and lymphatic systems?
6. What nursing care should you provide for patients undergoing each of the diagnostic tests?
7. What are common therapeutic measures for patients with hematological and lymphatic disorders?
8. What is the role of the licensed practical vocational nurse (LVN) in administering blood products?

► NORMAL ANATOMY AND PHYSIOLOGY

Blood

Hematology is the study of blood and its parts, functions, and abnormalities. The lymphatic system includes the lymph nodes and nodules that destroy pathogens. The lymphatic system produces many of the white blood cells that fight infection, and it returns lymph back to the blood via the lymph vessels.

The general functions of blood are transportation of oxygen, nutrients, and cellular waste products; regulation of body temperature, pH, and fluid balance; and production of cells that offer the body protection. Specific aspects of these functions are discussed with the particular part of the blood that is responsible for each.

A human body holds between 4 and 6 L of blood; 52 to 62 percent is plasma, and 38 to 48 percent is cells. The blood cells are the red blood cells (RBCs or erythrocytes), white blood cells (WBCs or leukocytes), and platelets (thrombocytes). All these blood cells are produced by the red bone marrow (RBM), a hematopoietic (blood-producing) tissue found in flat and irregular bones. The red bone marrow contains the undifferentiated stem cells that are the precursor cells for all blood cells. The other hematopoietic tissue is the lymphatic tissue of the lymph nodes, lymph nodules, spleen, and thymus, which produces only lymphocytes and monocytes. Table 23–1 shows normal cell counts.

Plasma

Plasma is the liquid portion of the blood and is about 91 percent water. It is the transporting medium for nutrients,

TABLE 23-1 REVIEW OF BLOOD CELL VALUES AND DISORDERS

Blood Cells Tested	Normal Value	Sample Disorders
Red Blood Cells		
Number of circulating RBCs	4.1–6.0 million/mm ³	Increased in chronic hypoxia; decreased in anemia or blood loss
Hematocrit (cellular portion of blood)	38–48%	Increased in dehydration or chronic hypoxia; decreased in anemia or blood loss
Hemoglobin (reflects oxygen carrying capacity of blood)	12–18 g/100 mL	Increased in chronic hypoxia; decreased in blood loss or anemia
Reticulocytes (number of circulating immature RBCs)	0–1.5%	Increased in hypoxia or anemia; decreased in RBC maturation defect
White Blood Cells		
Number of circulating WBCs	5000–10,000/mm ³	Increased in infection
Neutrophils	55–70%	Increased in infection
Eosinophils	1–3%	Increased in allergic response, some leukemias
Basophils	0.5–1%	Increased in hyperthyroidism, some bone marrow disorders, ulcerative colitis
Lymphocytes	20–35%	Increased in viral infections, chronic bacterial infection, some leukemias
Monocytes	3–8%	Increased in chronic inflammatory disorders, some leukemias
Platelets		
Number of circulating thrombocytes	150,000–300,000/mm ³	Increased from trauma; decreased with blood disorders; low platelet count causes risk for bleeding

wastes, hormones, antibodies, and carbon dioxide. Plasma proteins include clotting factors, albumin, and globulins. Clotting factors such as prothrombin and fibrinogen are synthesized by the liver and circulate until activated in the clotting mechanism. Albumin is also synthesized by the liver, and it helps maintain blood volume and blood pressure by pulling tissue fluid into the venous ends of the capillary networks. Alpha and beta globulins are synthesized by the liver to be carrier molecules for substances such as fats, and gamma globulins are the antibodies produced by lymphocytes.

Plasma is also important in maintaining temperature because blood carries heat. The water of plasma is warmed by passage through active organs, such as the liver or skeletal muscles, and this heat is distributed as blood circulates throughout the body. This process may be visible in people with light skin. The flush of fever or vigorous exercise is caused by vasodilation in the dermis, allowing blood to circulate near the body surface and lose heat. A person in a cold environment may be pale, as vasoconstriction in the dermis keeps blood circulating in the core of the body to preserve heat.

The normal pH range of blood is 7.35 to 7.45, which is slightly alkaline. Chemical buffer systems in the blood prevent sudden fluctuations in pH and contribute to the body's acid-base balance.

Red Blood Cells

Mature RBCs are biconcave disks without nuclei; they carry oxygen bonded to the iron in hemoglobin (Hgb). Oxyhemoglobin is formed in the pulmonary capillaries where the hemoglobin combines with the oxygen in the lungs. Once hemoglobin gives up its oxygen to the cells of the body, it becomes reduced hemoglobin. The amount of hemoglobin in RBCs and the amount of iron in that hemoglobin are (in

addition to the number of RBCs) the determining factors for the amount of oxygen the blood can carry. A lack of iron, hemoglobin, or RBCs is a form of anemia, which causes symptoms such as shortness of breath and weakness.

The rate of RBC production by the red bone marrow is most influenced by blood oxygen level. Hypoxia stimulates the kidneys to secrete erythropoietin, which increases the rate of RBC production and thus the oxygen-carrying capacity of the blood. At such times, immature RBC stages may be found in greater abundance in peripheral blood. A normoblast is the last RBC stage with a nucleus; a reticulocyte has visible fragments of its endoplasmic reticulum. These cells usually remain in the red bone marrow until mature; their presence in large numbers in peripheral blood indicates an insufficient amount of mature RBCs to meet the oxygen demands of the body.

Also required for normal production of RBCs is dietary intake of sufficient protein and iron to synthesize hemoglobin. The vitamins folic acid and vitamin B₁₂ are necessary for DNA synthesis in the stem cells of the red bone marrow. The continuous mitosis of these cells depends on their ability to produce new sets of chromosomes. Vitamin B₁₂ is also called extrinsic factor because its source is food. The parietal cells of the stomach lining produce intrinsic factor, which is a chemical that combines with vitamin B₁₂ to prevent its digestion and promote absorption in the small intestine.

Red blood cells live for about 120 days and then become fragile and are phagocytized by fixed macrophages in the liver, spleen, and red bone marrow. The iron is returned to the red bone marrow for synthesis of new hemoglobin or is stored in the liver. The heme portion of the hemoglobin is converted to bilirubin, a bile pigment that the liver excretes into bile for elimination in the feces. Diseases such as malaria and sickle cell anemia cause an accelerated destruction of red

blood cells. This hemoglobin release may cause the blood level of bilirubin to rise. When the bilirubin level is elevated, it stains the body fluids bright yellow to dark orange, depending on the bilirubin levels. This is known as jaundice.

Each person has a hereditary blood type, which refers to the antigens present on the RBCs. The two most important types are the ABO group and the Rh factor. The ABO type (A, B, O, or AB) indicates the antigens present (or not present, as in the case of type O) on the RBCs. In the plasma are antibodies for antigens that are not present in the blood; these antibodies can interact with antigens in transfused blood if the donor's blood does not match the recipient's blood (Table 23–2). To be Rh positive means that the D antigen is present on the RBCs; being Rh negative means that the antigen is not present. Rh-negative people do not have natural antibodies to the D antigen but will produce them if given Rh-positive blood.

White Blood Cells

White blood cells are larger than RBCs and have nuclei when mature. The granular WBCs (neutrophils, eosinophils, and basophils) are produced only in the red bone marrow. The agranular WBCs (lymphocytes and monocytes) are produced in the lymphatic tissue, as well as the red bone marrow. Table 23–1 shows normal values and percentages for each type in a differential count. WBCs carry out their functions in tissue fluid, as well as the blood, and all are involved in immunity or inflammation (response to injury).

Monocytes become macrophages, which phagocytize pathogens and dead tissue; neutrophils are more numerous but phagocytize only pathogens. Eosinophils detoxify foreign proteins during allergic reactions and parasitic infections. Basophils release histamine as part of inflammatory reactions. There are two groups of lymphocytes: T cells and B cells. T cells may be helper, suppressor, killer, or memory T cells. B cells become plasma cells, which produce antibodies to foreign antigens and also become memory cells.

Platelets

Platelets are formed in the red bone marrow; they are pieces of large cells called megakaryocytes. Platelets are involved in all mechanisms of hemostasis: vascular spasm, platelet plugs, and chemical clotting.

When a blood vessel is damaged, platelets release serotonin, which promotes contraction of smooth muscle and thereby vasoconstriction of an artery or a vein. Such constriction makes the break smaller, perhaps small enough to be covered by a clot. The clot is more likely to stay in place

and stop any continued bleeding because it covers a smaller area. Capillaries have no smooth muscle and cannot constrict but are so small that breaks can be closed by platelet plugs. Platelets become sticky, adhering to the rough edges of the broken capillary and to one another, eventually forming a platelet plug that stops the bleeding.

Platelets also produce platelet factors, chemicals whose release is stimulated by contact of blood with a rough surface (either a break or damaged vessel lining), which are necessary for the first of the three stages of chemical clotting. In stage 1, platelet factors, clotting factors from the liver, tissue thromboplastin, and calcium ions react to form prothrombin activator (also called prothrombinase). In stage 2, prothrombin activator converts prothrombin (synthesized by the liver) into thrombin. In stage 3, thrombin converts soluble fibrinogen (also from the liver) to insoluble fibrin, strands of which form the clot. Calcium ions are also required for stages 2 and 3.

Excessive clotting in the vascular system is prevented in several ways. The very smooth endothelial lining of blood vessels repels platelets so that they do not stick to intact vessel walls. Heparin produced by mast cells inhibits the clotting mechanism. Antithrombin (synthesized by the liver) inactivates excess thrombin to prevent the clotting mechanism from becoming a vicious cycle.

The Lymphatic System

The lymphatic system consists of lymph, the system of lymph vessels, the lymph nodes and nodules, the spleen, and the thymus. Functions of the lymph system are to return tissue fluid to maintain blood volume and to protect the body against pathogens and other foreign material (the latter is called immunity and is covered in Chapter 52).

Lymphatic Vessels

Lymph is tissue fluid that has entered lymph capillaries (tissue fluid is formed from plasma by filtration in blood capillaries); it must be returned to the blood to maintain blood volume and blood pressure. Lymph capillaries are found in most tissue spaces; they anastomose, forming larger and larger lymph vessels, which have valves to prevent backflow of lymph. Lymph from the lower body and the upper left quadrant enters the thoracic duct (in front of the vertebral column) and is returned to the blood in the left subclavian vein (Fig. 23–1). Lymph from the upper right quadrant enters the right lymphatic duct and is returned to the blood in the right subclavian vein.

Lymph Nodes and Nodules

Lymph nodes are masses of lymphatic tissue (producing lymphocytes and monocytes) along the pathways of the lymph vessels. As lymph flows through the nodes, the WBCs produced enter the lymph, foreign materials are phagocytized by fixed macrophages, and fixed plasma cells produce antibodies to foreign antigens. The major paired groups of lymph nodes are the cervical, axillary, and inguinal nodes. These areas are located at the junction of the head (cervical) and

TABLE 23–2 ABO BLOOD TYPES

Type	Antigens Present on RBCs	Antibodies Present in Plasma
A	A	Anti-B
B	B	Anti-A
AB	Both A and B	Neither anti-A nor anti-B
O	Neither A nor B	Both anti-A and anti-B

Figure 23-1 System of lymph vessels and major groups of lymph nodes. (From Scanlon, V, Sanders, T: Essentials of Anatomy and Physiology, ed 3. FA Davis, Philadelphia, 1999, p 307, with permission.)

extremities (axillary and inguinal) with the trunk to remove pathogens in the lymph from the extremities before the lymph is returned to the blood.

Lymph nodules are small masses of lymphatic tissue found just beneath the epithelium of all mucous membranes. The body tracts lined with mucous membranes are those that have openings to the environment: the respiratory, digestive, urinary, and reproductive systems. Any natural body opening is a potential portal of entry for

pathogens; any pathogens that penetrate the epithelium usually are destroyed by the macrophages in the lymph nodules. The tonsils, which protect the oral and nasal portions of the pharynx, are familiar examples of lymph nodules, although most lymph nodules do not have names.

Spleen

The spleen is located in the upper left quadrant of the abdominal cavity, just below the diaphragm, behind the stom-

ach. The lower ribcage protects the spleen from mechanical injury. In the fetus, the spleen produces red blood cells, a function assumed by the red bone marrow after birth. The spleen has several functions after birth.

The spleen produces lymphocytes and monocytes, which enter the blood. It also contains fixed plasma cells that produce antibodies to foreign antigens. It also contains fixed macrophages that phagocytize pathogens or other foreign material in the blood. These macrophages also phagocytize old RBCs and form bilirubin. By way of portal circulation, the bilirubin is sent to the liver for excretion in the bile.

The spleen is not considered a vital organ because other organs compensate for its functions if the spleen must be removed (although a person without a spleen is somewhat more susceptible to certain bacterial infections, such as pneumonia and meningitis). The liver and red bone marrow remove old RBCs from circulation, and the many lymph nodes and nodules produce lymphocytes and monocytes and phagocytize pathogens (as does the liver).

Thymus

The thymus is located below the thyroid gland on the front of the trachea; in the fetus or infant it extends under the sternum. With increasing age, the thymus shrinks, and relatively little thymus tissue is found in adults. The thymus produces T lymphocytes, or T cells, and hormones that contribute to the maturation of the immune system; that is, the ability to destroy foreign material. This ability is usually established by age 2. Immunity is covered in Chapter 52.

Aging and the Hematopoietic and Lymphatic Systems

Elderly people undergo a number of changes in these systems. Erythrocytes are produced more slowly. Iron deficiency is common, which leads to low hemoglobin levels. Plasma volume decreases, which increases the risk for dehydration. Immune responses become less efficient, making

the elderly person more susceptible to infection, such as flu or pneumonia, and even cancer. Elders should take advantage of both flu and pneumonia vaccines. Autoimmune diseases such as rheumatoid arthritis are also more common in the elderly.

► NURSING ASSESSMENT

History

A thorough nursing assessment starts with an in-depth patient history (Table 23–3). Specific problems usually seen in patients with hematological disorders include abnormal bleeding, **petechiae** (small purplish hemorrhagic spots under the skin), **ecchymoses** (larger areas of discoloration from hemorrhage under the skin), and **purpura** (hemorrhage into the skin, mucous membranes, and organs), as well as fatigue, weakness, shortness of breath, and fever.

Begin by obtaining the patient's biographical data, marital status, occupation, religion, age, sex, and ethnic background. This information can give you valuable clues to risk factors. For example, even though hemophilia almost always occurs in males, females may carry the gene. Sickle cell anemia occurs mostly in African-Americans but also affects people of Mediterranean or Asian ancestry. Pernicious anemia occurs most often in people of northern European ancestry. By carefully collecting this information, you may be obtaining important clues that will help pinpoint the patient's problem. Finally, focus on the assessment of symptoms by using the WHAT'S UP? format presented in Chapter 1.

A complete review of past illnesses and family history is always indicated and can provide some valuable information. The social history is also useful. After developing good rapport with the patient, explore dietary and alcohol intake habits, any drug use or abuse, and sexual habits, all of which may cause changes in the hematological system.

An occupational review may reveal exposure to some hazardous substances that can cause bone marrow dysfunction.

TABLE 23-3

QUESTIONS ASKED DURING ASSESSMENT OF THE HEMATOLOGICAL AND LYMPHATIC SYSTEMS

Question	Rationale
"Why are you seeking health care?"	Signs and symptoms of hematological/lymphatic disorders may be nonspecific. Any body system can be involved.
"How is the health of your blood relatives?"	Some blood and immune disorders are hereditary.
"Describe your usual diet."	Dietary deficiencies can lead to anemia or altered immune response.
"How much alcohol do you drink each day?"	Excess alcohol intake can lead to folic-acid deficiency anemia.
"What herbs or alternative therapies do you use?"	Herbs are drugs and can cause adverse reactions in the blood and immune system.
"What is your occupational and military history?"	Exposure to certain hazardous substances can lead to leukemias, other cancers, or anemias.
"Have you noticed any change in your energy level?"	Anemia and many cancers are associated with fatigue.
"Have you experienced nosebleeds or any other unusual bleeding?"	Bleeding may indicate low platelet levels or a clotting factor deficiency.
"Have you had bloody or black bowel movements?"	
"Do you experience shortness of breath or faintness?"	These are symptoms of anemia.
"Have you noticed any changes in your skin?"	Bleeding into the skin or mucous membranes can indicate a bleeding disorder.
"Have you noticed swelling in your neck, armpits, or groin?"	Swollen lymph nodes may indicate inflammation, infection, or some cancers.

tion. Certain occupations, such as working in a paint factory, tool and dye processing, and even dry cleaning are sometimes implicated in the formation of some hematological cancers. Military information may also reveal sources of exposure that can help during the diagnostic phase for hematological and lymphatic disorders.

Physical Examination

Hematological disorders can involve almost every body system, so each system must be carefully assessed. First, assess vital signs, which can reveal important clues. For example, frequent fevers indicate a poorly functioning immune system. Markedly subnormal temperatures may indicate an overwhelming gram-negative infection when combined with other abnormal assessment data. Heart and respiratory rate abnormalities may indicate decreased blood volume or decreased oxygen supply. Finally, check the level of consciousness; changes may occur with hypoxia, fever, and intracranial bleeding.

An inspection of physical structures most relevant to the blood and lymph systems includes the skin, mucous membranes, fingernails, eyes, lymph nodes, liver, and spleen. Observe the patient's skin color, noting pallor (indicating anemia), cyanosis (indicating poor oxygenation of RBCs), or jaundice (indicating liver disease or hemolysis). Observe the face, neck, and hands for areas of local inflammation, enlargements, or obvious sites of infection. Check the entire skin surface for purpura or other signs of bleeding, and examine the oral mucosa for color changes and petechiae or ecchymoses. These findings may indicate a bleeding disorder. Other important findings can be obtained after careful examination of the skin, looking for dryness and coarseness, which can indicate anemia. Inquire about itching, which may also indicate blood or lymph disorders.

Fingernails can give important clues about the patient's health. For instance, long striations (lines) on the nails or spoon-shaped nails may indicate anemia. Clubbed fingertips and raised nailbeds may indicate long-term hypoxia, which can be caused by anemia or heart disease.

Abdominal assessment should include the use of auscultation, or listening with the stethoscope. Listen intently and try to identify high-pitched, tinkling sounds, which might indicate intestinal obstruction, versus the regular, gurgling, and lower-pitched noises normally heard in the intestines. In some cases you will measure the abdominal girth and record the measurement in the nurse's notes. This baseline measurement might be useful if the patient begins to exhibit abdominal enlargement secondary to ascites or bleeding.

Next, progress to palpation, making sure that the patient is comfortable and that the patient's privacy is protected. Make sure to warm your hands. You can start with an examination of the lymph nodes, although this is more commonly done by the registered nurse or physician. The nodes of the neck can be gently palpated while the patient is sitting by simply running the hands over the neck and axillary surfaces. When examining the axillary nodes, the patient

may lie down. Any nodes that are palpable, with or without **lymphedema**, indicate some type of lymphatic disorder. Note the location, size, tenderness, texture, and fixation of the node groups. Enlarged or tender nodes indicate current or previous inflammation. Sternal tenderness may or may not be present. If present, this finding indicates that the bone marrow is being "packed" with an abnormal number and type of cells.

▶ DIAGNOSTIC TESTS

A number of diagnostic tests can help rule out or confirm a suspected diagnosis based on the analysis of the formed elements of the blood and the bone marrow. Specific studies include a complete blood cell count (CBC), coagulation studies, agglutination studies, bone marrow aspiration, and needle biopsy.

Blood Tests

Examples of laboratory studies routinely done for patients with hematological disorders include CBC, total hemoglobin concentration (Hgb), hematocrit levels (Hct), and platelet levels. (See normal values in Table 23-1.)

LEARNING TIPS

If abdominal girth must be monitored for changes, use a marker to identify the site where you measure so it will be measured at the same spot each time.

Coagulation Tests

Tests in this category include bleeding times, capillary fragility test, prothrombin time (PT), international normalized ratio (INR), partial thromboplastin time (PTT), and thrombin clotting time (TCT) (Table 23-4). Agglutination tests include ABO blood typing, Rh typing, crossmatching blood samples, and direct antiglobulin tests (also known as a Coombs' test).

CRITICAL THINKING

Mrs. Brown

Mrs. Brown is on warfarin (Coumadin) therapy because of a blood clot in her leg. She has a PT drawn at the lab, and the result is 12 seconds. Will the physician most likely increase her daily dose of warfarin, decrease it, or leave it the same? (Use Table 23-4 to figure out the answer.)

Answer at end of chapter.

Bone Marrow Biopsy

Biopsy information may be obtained through bone marrow aspiration, which in most states is obtained by a physician.

lymphedema: lymph—fluid found in lymphatic vessels + edema—swelling

TABLE 23-4 COAGULATION STUDIES

Test	Normal Value	Comments
Prothrombin time (affected by activity of clotting factors V, VII, X, prothrombin, and fibrinogen)	Men 9.6–11.8 seconds Women 9.5–11.3 seconds	Desired results 1.5 to 2 times longer for patient on warfarin (Coumadin) therapy
International normalized ratio	2.0–3.0 seconds for patient using anticoagulants (3.0–4.5 for recurrent problems)	Monitored with prothrombin time for warfarin therapy Standardized test adopted by World Health Organization
Partial thromboplastin time (affected by activity of clotting factors, prothrombin, and fibrinogen)	30–45 seconds	Desired results 1.5 to 2 times longer for patient on heparin therapy
Thrombin clotting time (measures time for fibrin clot to form after addition of thrombin)	10–15 seconds	Desired results 1.5 to 2 times longer for patient on heparin therapy
Bleeding time (measures time for small puncture wound to stop bleeding)	2.5–9.5 minutes	Indicates platelet function
Capillary fragility test	Fewer than 10 petechiae appearing in a 2-inch circle after application of a blood pressure cuff at 100 mm Hg for 5 minutes	Tests ability of capillaries to resist rupture under pressure Excessive fragility may be associated with thrombocytopenia

Aspiration of the bone marrow is done to obtain a specimen that can be viewed under the microscope. Purposes of this test include the diagnosis of hematological disorders; monitoring the course of treatment; discovery of other disorders, such as primary and metastatic tumors, infectious diseases, and certain granulomas; and isolation of bacteria and other pathogens by culture.

An accurate bone marrow specimen in an adult can be obtained from the sternum, the spinous processes of the vertebrae, or the anterior or posterior iliac crests. If a biopsy is also required, the latter are the preferred sites. Bone marrow biopsy, as well as aspiration, is considered a minor surgical procedure. Both are carried out under aseptic conditions. For iliac crest aspiration, the patient is placed comfortably on the side with the back slightly flexed. The posterior iliac crest is cleansed and covered with antiseptic solution. The skin, the subcutaneous tissue, and the periosteum are anesthetized using 1- or 2-percent lidocaine (Xylocaine). A 2- to 3-mm incision is made to facilitate penetration with a 14-gauge, 2- to 4-cm bone marrow needle. The incision is made to avoid introducing a skin plug into the marrow cavity, which can cause infection.

The nurse's role in bone marrow biopsy is multifaceted. First, it is often the nurse who helps coordinate between the laboratory and the physician, establishing a time to do the procedure and determining who obtains the supplies, such as the disposable bone marrow aspiration tray or other specialized needles, from the central supply area. The nurse may also assist in the following before the procedure takes place: administering analgesics according to the physician's order, helping to position the patient before and during the procedure, helping the patient maintain the necessary position, and observing the aspiration site for bleeding and infection. The nurse should also provide emotional support to the patient before, during, and after the procedure.

Lymphangiography

Disorders of the lymph system can be evaluated using lymphangiography. This procedure involves injection of a dye into the lymphatic vessels of the hand or foot. Various x-ray views are then taken to determine lymph flow or blockages. X-ray examinations are repeated in 24 hours to assess lymph node involvement.

Following the procedure, the physician may order a pressure dressing and immobilization of the injected limb to prevent leakage at the site. Continue to monitor the limb for swelling, circulatory status, and changes in sensation. Warn the patient that the skin, urine, or feces may be blue-tinged from the dye for about 2 days.

Lymph Node Biopsy

If a lymph node is enlarged, it may be biopsied to determine whether the cause is infection or malignancy. A biopsy may be done with a needle aspiration or surgical incision. A small dressing or Band-Aid is applied. Following the procedure, review signs of bleeding and infection with the patient and recommend that they be reported to the physician.

► THERAPEUTIC MEASURES

Therapeutic nursing measures are based on information obtained during the nursing assessment. A nursing diagnosis commonly used in patients with hematological disorders is fatigue related to decreased oxygen supply, secondary to decreased hemoglobin level. A patient with this nursing diagnosis should be taught to conserve energy through careful planning of rest and activity cycles, reducing stress, structuring the environment, enhancing dietary intake of iron and minerals, and avoiding highly emotional situations that can aggravate the fatigue level.

A second nursing diagnosis is ineffective protection: risk for bleeding, which may be associated with the medical diagnoses of hemophilia, **thrombocytopenia**, or disseminated intravascular coagulation. Monitor vital signs every 4 hours and assess sites of bleeding for change. Assess for changes in mental status, hypotension, and tachycardia, which may indicate bleeding and impending shock. See Chapter 24 for nursing interventions for patients at risk for bleeding.

Blood Administration

Blood is administered by a registered nurse. The licensed practical nurse/licensed vocational nurse (LPN/LVN) may be called on to assist with proper identification procedures and monitoring of vital signs during the transfusion. Table 23–5 lists blood components that may be ordered. The main goal is to give them safely and avoid mistakes. Make sure to use proper identifying information to ensure that the right patient is receiving the right blood products. A careful system most often used in health care institutions is outlined next.

Safety Steps

IDENTIFICATION. Safety is the first priority. This includes checking and double-checking the patient's identity. Great care is taken in the blood bank to match the donor's blood type with the recipient's blood type. After obtaining the unit of blood from the blood bank but before hanging the unit, two nurses (at least one of them a registered nurse) will check the following information at the patient's bedside (Fig. 23–2). Do not take this identification step for granted, because if the nurse makes an error and accidentally transfuses blood that does not match the patient's blood type, the results can be fatal.

- Ask the patient to state his or her name aloud, if alert and able to speak.
- Use the patient's identification band to confirm the identity and compare it with the information on the paperwork obtained from the blood bank.

Figure 23-2 Two nurses check a patient's identification before administering a unit of blood.

- Examine the blood bag and verify that the patient information and any other information, such as the ABO type, Rh type, and unit number, all match.
- Finally, check the expiration date on the blood bag.

Do not give the unit of blood if any of the information does not match. Notify the blood bank immediately of any discrepancies, and delay the transfusion until the differences are cleared up. Remember, there is no room for error when transfusing blood products.

FILTERING. Filters are used with the blood administration tubing to prevent potentially harmful particles from entering the patient. Most often, the filter that comes with the transfusion tubing is sufficient for each unit of packed RBCs. In some situations, special filters may be needed to remove leukocytes or microaggregates. The blood bank can advise in these situations.

WASHED OR LEUKOCYTE DEPLETED. There are instances when packed RBCs (PRBCs) are ordered as “washed,” often arriving from the blood bank in a round bag. The washing process removes almost all the plasma and can decrease the occurrence or severity of a febrile reaction. In addition, leukocyte filters may be used to completely remove all WBCs. This removal process is used in cases in which many transfusions are anticipated and decreases the chance of antigen sensitization, as well as transmission of certain viruses, such as cytomegalovirus.

WARMED. If the patient has had a severe bleeding episode and the nurses are helping to give replacement therapy through rapid, multiple transfusions, the physician may consider ordering a blood warmer. It works just as the name implies, warming the cold blood from the blood bank to the standard body temperature of 98.6° F. This warming helps prevent hypothermia, which can cause heart dysrhythmias, or shivering, which destroys blood cells and platelets.

Administration

GUIDELINES. It is important to use the correct intravenous needle size to infuse blood. The best sizes are 18- and 20-gauge needles. In a pinch a 22-gauge cannula can be used,

TABLE 23-5 BLOOD PRODUCTS

Product	Use
Packed red blood cells	Severe anemia or blood loss
Frozen red blood cells	Autotransfusion (blood taken from patient and saved for future surgery), prevention of febrile reactions
Platelets	Bleeding caused by thrombocytopenia
Albumin	Hypovolemia caused by hypoalbuminemia
Fresh frozen plasma	Provides clotting factors for bleeding disorders, occasionally used for volume replacement
Cryoprecipitates	Bleeding caused by specific missing clotting factors

thrombocytopenia: thrombocyte—platelet + penia—lack

but an infusion pump may be needed to help the thick blood move through the smaller lumen. Make sure to use only normal saline solution to help dilute the blood and to flush the intravenous lines before and after the transfusions. Any other type of fluid or medication may cause the blood product to clump, clot, or not infuse at all. Generally, 2 hours is a good time frame to transfuse each unit of packed cells. If it must transfuse more slowly because of the patient's condition, make sure that the unit does not hang longer than 4 hours. After that time, the blood is too warm and begins to deteriorate.

MONITORING. Careful monitoring of the patient's response to the transfusion is done to prevent complications or to detect and treat them quickly if they occur. Vital signs are taken and documented before starting the transfusion, after the blood has begun to infuse, and after the infusion. Some institutions require vital sign monitoring every 15 to 30 minutes during the earliest part of the transfusion, and then slightly less often for the duration of the infusion. Always follow institution guidelines. During the transfusion, the patient is assessed for signs and symptoms of transfusion reactions.

Complications

You can assist the registered nurse in the quick detection of complications. Many health care workers think of transfusing blood components as a routine procedure because it is a

common activity. Do not be fooled. It is a serious procedure that can be life threatening if errors occur. Complications may include febrile reactions, hypersensitivities, hemolytic reactions, anaphylaxis, circulatory overload, and even death. Regular monitoring according to institution policy can help detect complications early, when treatment is most effective.

FEBRILE REACTION. By far the most common reaction is fever (febrile reaction), occurring up to 2 percent of the time. The risk of a febrile reaction goes up with each unit of blood product given to the patient. Many times, febrile reactions occur after the transfusion is completed, but they can occur at any time. This is the reason for obtaining a set of baseline vital signs, including the patient's temperature. Once a febrile reaction begins, the most common signs are an increasing fever and shaking chills, which can be severe. Other symptoms may include chest pain, headache, hypotension, and nausea or vomiting. If these symptoms occur, stop the transfusion and notify the physician. The physician usually treats the reaction symptomatically with acetaminophen. Often the physician orders the transfusion to continue once the patient is more comfortable. Make sure that the 4-hour hang rule is not violated.

URTICARIAL REACTION. Urticarial (hive) reactions are usually associated with antigens in the plasma accompanying the transfusion. There may be a fever, but the cardinal sign is the appearance of urticaria or a hivelike rash. On discovery of this reaction, notify the physician immediately. Expect that the patient will be given a dose of diphenhydramine (Benadryl) and then the transfusion will be restarted. Again, make sure the 4-hour hang rule is not violated.

HEMOLYTIC REACTION. The most deadly and, fortunately, the rarest of the possible reactions is an acute hemolytic reaction. The cause of this reaction is transfusion of incompatible blood. The result is hemolysis (destruction) of RBCs. Generally this type of serious reaction is noticed within minutes of starting the transfusion. The patient may report back pain, chest pain, chills, fever, shortness of breath, nausea, vomiting, or a feeling of impending doom. As the reaction progresses, the patient begins to show signs of shock, hypotension, oliguria, and decreased consciousness. Late signs and symptoms include those associated with disseminated intravascular coagulation: uncontrollable bleeding from many different sites at the same time, usually ending in death. At the first sign of this type of reaction, immediately stop the transfusion and stay with the patient. Institute emergency procedures to notify the charge nurse, the physician, and the blood bank. The vein is kept open with normal saline using a new administration set (ensuring that no more incompatible blood is administered) so that emergency drugs can be administered. High volumes of fluids are administered to decrease shock and hypotension, and high doses of diuretics are given to promote urine flow, because the kidney is the most likely organ system to be damaged. Dialysis may be instituted.

LEARNING TIPS

When a patient has a bacterial infection, the neutrophils, which are one type of WBC, rise in number to help fight it. There are two forms of neutrophils: segmented (mature) and bands (immature). Initially the number of segmented neutrophils goes up. Then, as the infection becomes more severe, the number of bands begins to rise.

An easy way to remember this is that the WBCs are part of the body's defenses, just like the military is part of a country's defenses. When needed, sergeants who are fully trained or mature are called to battle first. If they are unable to fight off the invading enemy, new recruits being trained in boot camp are called in to help.

So segmented neutrophils (segs) are like the sergeants, fully mature and ready to fight. The bands are like boot camp recruits, immature and not fully trained. However, in an acute infection bands are necessary to prevent the body from being overwhelmed by the infection and losing the battle.

As you look at the differential WBC count, if the segs are elevated but the bands are normal, it is probably a new infection. If the bands are also elevated, the infection is worsening. The more elevated they are, the more severe the infection.

Lymphocytes fight viral infections and are elevated during a virus. A common pattern in the WBCs is produced for either a bacterial or viral infection. If the infection is acute bacterial:

Segs ↑ Bands ↑ Lymphocytes ↓

If the infection is viral:

Segs ↓ Bands ↓ Lymphocytes ↑

This can be remembered as the bone marrow producing the cells most needed during the time of viral infection and reducing production of those cells least needed. When the infection is resolved, all the cells should return to their normal production levels.

ANAPHYLACTIC REACTION. Anaphylactic reactions are not common but may be seen more often in patients who have received many transfusions or have had many pregnancies. Usually the source of the anaphylaxis is from sensitization to immune globulins passed from the donor's unit of blood product. In this type of reaction the very first milliliters of blood containing the allergens to pass into the patient's system may be enough to cause the patient to develop respiratory or cardiovascular collapse. Other more common symptoms include severe gastrointestinal cramping, instant vomiting, and uncontrollable diarrhea. If the patient exhibits these signs and symptoms, stop the transfusion at once and stay with the patient. Have someone else notify the registered nurse and the physician, using institutional emergency procedures. Emergency resuscitation measures must be instituted until the code team arrives, up to and including cardiopulmonary resuscitation. Expect the patient to be intubated and receive oxygen, steroids, and other drugs as needed for life support. After the emergency has passed, this patient will likely need to receive transfusions from frozen, deglycerolized blood cells.

CIRCULATORY OVERLOAD. Circulatory overload is caused by rapid transfusion in a short period, particularly in elderly and debilitated patients. Usual signs and symptoms include chest pain, cough, frothy sputum, distended neck veins, crackles and wheezes in the lung fields, and increased heart

rate. If symptoms occur, stop the transfusion and notify the physician. Anticipate administration of diuretics, which help get rid of the excess fluid. Later the transfusion may be restarted, but at a much slower rate (Gerontological Issues Box 23–1).

BOX 23-1 GERONTOLOGICAL ISSUES

Elderly patients have less cardiac and renal ability to adapt to changes in blood volume, so they have a much higher risk of fluid overload when receiving blood transfusions. Carefully monitor lung sounds and vital signs both before and during a transfusion. New onset of dyspnea, crackles, hypertension, or bounding pulse should be reported to the registered nurse or physician immediately.

Answers to CRITICAL THINKING

Mrs. Brown

The physician will most likely increase Mrs. Brown's warfarin dose. Note in Table 23–4 that the PT for a patient on warfarin therapy should be 1.5 to 2 times longer than normal. That is the reason the warfarin is ordered—to prolong the time it takes for blood to clot. If a normal PT is 9.5 to 11.3 seconds, a therapeutic PT for Mrs. Brown would be 14.25 (or 9.5×1.5) to 22.6 (or 11.3×2). Her result of 12 seconds is not therapeutic.

REVIEW QUESTIONS

- Clotting factors such as prothrombin are produced by which of the following?
 - Red bone marrow
 - Liver
 - Spleen
 - Lymph nodes
- Which of the following best describes the function of erythropoietin?
 - Increase production of platelets to promote clotting
 - Decrease production of platelets to prevent abnormal clotting
 - Increase RBC production to correct hypoxia
 - Decrease RBC production to prevent hypoxia
- The return of tissue fluid to the blood is important to maintain normal functioning in which of the following?
 - Blood clotting
 - Blood volume
 - White blood cell formation
 - Red blood cell formation
- Which of the following refers to the portion of the blood in which cellular elements are suspended?
 - Cytoplasm
 - Platelets
 - Plasma
 - Hemoglobin
- Mrs. Lee has a platelet count of $23,000/\text{mm}^3$. Which of the following actions should you take?
 - Request an order for an anticoagulant.
 - Protect Mrs. Lee from injury.
 - Encourage Mrs. Lee to drink plenty of fluids.
 - No action is necessary. This is a normal level.
- You are assessing Ken and find small red-purple dots over most of his skin surfaces. He says that he has not noticed them before. Which action should you take first?
 - Report your findings immediately to the registered nurse or physician.
 - Document your findings objectively in the medical record.
 - Assist Ken to apply a soothing lotion.
 - Administer an antihistamine as needed.

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the pathophysiology of each of the hematological disorders discussed in this chapter?
2. What are the etiologies, signs, and symptoms of each of the disorders?
3. What is current medical treatment for each of the disorders?
4. What data should you collect when caring for patients with disorders of the hematological system?
5. What nursing care will you provide for patients with each of the covered disorders?
6. How will you know if your nursing interventions have been effective?
7. What care should you provide for the patient with sickle cell anemia? For patients with cancers of the hematological system?
8. What precautions should you institute to prevent bleeding in patients with clotting disorders?

Patients with hematopoietic disorders have problems related to their blood. Some problems are caused by too many cells, others by too few or defective cells. When red blood cells (RBCs) are affected, oxygen transport is also affected, causing symptoms of poor oxygenation. When white blood cells (WBCs) are affected, the patient is unable to effectively fight infections. If platelets or clotting factors are affected, bleeding disorders occur.

► DISORDERS OF RED BLOOD CELLS

Anemias

The term **anemia** describes a condition in which there is a deficiency of RBCs, hemoglobin, or both in the circulating blood. Because hemoglobin carries oxygen, this results in a reduced capacity to deliver oxygen to the tissues, producing symptoms such as weakness and shortness of breath, which lead the patient to seek medical help.

Pathophysiology

A decrease in the numbers of RBCs can be traced to three different conditions: (1) impaired production of RBCs, as in aplastic anemia and nutrition deficiencies; (2) increased destruction of RBCs, as in hemolytic or sickle cell anemia; or (3) massive or chronic blood loss. Some anemias are related to genetic problems in certain cultures (Cultural Consideration Box 24–1). It is important to remember that the general term *anemia* refers to a symptom or a condition secondary to another problem and is not a diagnosis in itself. Different types of anemia are discussed later in this chapter.

BOX 24-1 CULTURAL CONSIDERATION

In the past, Iranian cross-cousin marriages have resulted in an increased incidence of several forms of anemia and hemophilia. These marriages are now being addressed through genetic counseling and premarital screening for carriers. People are also tested for vitamin B₁₂ or folic acid deficiencies linked to an enzyme deficiency.¹

A sex-linked genetic disease common in the Chinese is glucose-6-phosphate dehydrogenase (G6PD) deficiency, an enzyme deficiency affecting the person's red blood cells and resulting in anemia. Mediterranean G6PD is common, causing a hemolytic crisis when fava beans are eaten, when aspirin or certain other drugs are taken, or in acidotic or hypoxemic states. Mediterranean-type G6PD deficiency is an inherited disorder most fully expressed in males, with a carrier state in females.

Among Asian Indians, sickle cell disease is highly prevalent; the gene is detected in 16.5 percent of selected populations. Sickle cell anemia is the most common genetic disorder among African-American populations. Sickle cell anemia also is found in individuals who live in areas where malaria is endemic, such as the Caribbean, the Middle East, the Mediterranean region, and Asia.

anemia: a—not + emia—blood

Etiologies

DIETARY DEFICIENCIES. Iron, folic acid, and vitamin B₁₂ are all essential to production of healthy RBCs. A deficiency of any of these nutrients can cause anemia. Pernicious anemia is associated with a lack of intrinsic factor in stomach secretions, which is necessary for absorption of vitamin B₁₂. See Nutrition Notes Box 24–2 for more information.

HEMOLYSIS. Hemolysis is the destruction, or lysis, of RBCs. Destruction of RBCs leads to anemia and is termed hemolytic anemia. This may be a congenital disorder, or it may be caused by exposure to certain toxins.

OTHER CAUSES. Thalassemia anemia is a hereditary anemia found in persons from Southeast Asia, Africa, Italy, and the Mediterranean Islands. Individuals with thalassemia do not synthesize hemoglobin normally. Individuals with chronic disease also develop anemia (Gerontological Issues Box 24–3). Additional causes of anemia are discussed under the separate headings of aplastic and sickle cell anemias.

Signs and Symptoms

Symptoms of anemia include pallor, tachycardia, tachypnea, irritability, fatigue, and shortness of breath (Table 24–1). In addition to these symptoms, the patient with pernicious (vitamin B₁₂) anemia may experience numbness of the hands or feet and weakness, because vitamin B₁₂ is necessary for normal neurological function. Pernicious anemia is also associated with a sore, beefy red tongue. Patients with iron deficiency may also have fissures at the corners of the mouth, an inflamed tongue (**glossitis**), and spoon-shaped fingernails.

Diagnostic Tests

A complete blood cell count (CBC) is done to determine the number of RBCs and WBCs per cubic millimeter. The size, color, and shape of the blood cells are determined by microscopic examination. Hemoglobin and hematocrit are below normal in anemia. Serum iron, ferritin, and total iron-binding capacity measurements are done to diagnose iron deficiency anemia. Serum folate is measured if folic acid deficiency is suspected. A bone marrow analysis may also be done.

Patients with pernicious anemia have low gastric acid levels, and many have antibodies to intrinsic factor. Both abnormalities are associated with poor absorption of vitamin B₁₂. If blood loss is suspected, additional tests are done to determine the source of bleeding.

Medical Treatment

Treatment begins with elimination of the contributing causes. Intake of the deficient nutrient can sometimes be increased in the diet or by administration of a supplement. Changing cooking habits, taking dietary supplements, decreasing

hemolysis: heme—blood + lysis—dissolution

glossitis: glos—tongue + itis—inflammation

BOX 24-2

Nutrition Notes

Understanding Common Nutritional Anemias

Although not its only cause, nutritional deficiencies can produce anemia. Nutrients vital to the construction of red blood cells include iron, folic acid, and vitamin B₁₂. Even if the cause of the anemia is dietary, other therapies may be employed in addition to nutritional interventions.

Iron deficiency anemia, the most common nutrient deficiency in the world, is characterized by smaller than normal RBCs. Insufficient intake of iron, excessive blood loss, or lack of stomach acid can lead to iron deficiency anemia. Individuals at greatest risk of iron deficiency are women of childbearing age and young children. Even before frank anemia is seen, cognitive abilities can be impaired. In early iron deficiency, serum transferrin, a blood protein that carries iron, rises in an attempt to increase iron-carrying capacity. Later the hemoglobin and hematocrit levels drop. A new measure of iron status is plasma transferrin receptor. It increases even in mild deficiency, making it a useful diagnostic aid for patients with inflammatory diseases.*

Relatively good sources of iron that are commonly included in Western diets are red meat; dark green leafy vegetables; dried fruits; and enriched, fortified, or whole grain products. Foods rich in vitamin C can be used to enhance absorption of iron from nonmeat sources. Iron supplements are often given to treat iron deficiency. This therapy should be continued for several months after hemoglobin and hematocrit levels return to normal to enable the body to rebuild iron stores.

Folic acid or vitamin B₁₂ deficiencies produce anemias characterized by larger than normal RBCs. Both these vitamins are necessary for normal RBC production. Folic acid aids in the formation of DNA and heme, the iron-containing portion of hemoglobin. Conditions that increase the metabolic rate increase the need for folic acid. Many drugs, including alcohol,

anticonvulsants, and oral contraceptives, interfere with its absorption, metabolism, or excretion and can contribute to the development of anemia. Good food sources of folic acid include liver, green leafy vegetables, legumes, and enriched grain products. Because folic acid markedly decreases the occurrence of fetal neural tube defects such as spina bifida, women capable of becoming pregnant are advised to consume 400 µg of synthetic folic acid from fortified foods or supplements in addition to the folic acid furnished by a varied, balanced diet.

Vitamin B₁₂ is essential for the manufacture of RBCs and for synthesis and maintenance of myelin, the fatty covering of nerves that facilitates rapid transmission of impulses. Vitamin B₁₂ requires a highly specific protein-binding factor called intrinsic factor, secreted by glands in the stomach, to be absorbed. Intrinsic factor and vitamin B₁₂ (also called extrinsic factor) combine in the proximal small intestine to form a complex to transport vitamin B₁₂ to the ileum, where it is absorbed. Extrinsic factor (vitamin B₁₂) is found in foods from animal sources such as meat, fish, shellfish, poultry, and milk. Anyone eating these foods regularly is not at risk of vitamin B₁₂ deficiency, but strict vegetarians are at risk. Because the deficiency here is dietary, a dietary supplement is the treatment.

In contrast, pernicious anemia is a disease caused by lack of intrinsic factor. Pernicious anemia occurs more frequently in older persons and is attributed to antibodies against gastric parietal cells and intrinsic factor. Extensive gastric resection can also result in insufficient intrinsic factor. Because the deficiency is not dietary, neither is the treatment. Pharmaceutical vitamin B₁₂ is usually given by injection to circumvent the absorption problem. Symptoms of vitamin B₁₂ deficiency are, in usual order of appearance, numbness and tingling in hands and feet, followed by RBC changes. Moodiness, confusion, depression, delusions, and overt psychosis appear next. Lastly, irreparable nerve damage occurs, and eventually, death. Because of the neurological damage, vitamin B₁₂ deficiency should be considered in a person being evaluated for dementia.

*Connor, JR, and Beard, JL: Dietary iron supplements in the elderly: To use or not to use? *Nutrition Today* 32:102, 1997.

BOX 24-3 GERONTOLOGICAL ISSUES

Anemia of chronic disease is often diagnosed in an older patient who has an underlying medical condition that causes altered iron metabolism, deficiency of erythropoietin, or shortened life span of red blood cells. Unfortunately, anemia of chronic disease

is often mistaken for iron deficiency anemia. Nutritional deficiencies and blood loss are common causes of iron deficiency anemia.

TABLE 24-1 CLINICAL MANIFESTATIONS OF ANEMIA

Body System	Mild (Hgb = 10–14 g/dL)	Moderate (Hgb = 6–10 g/dL)	Severe (Hgb < 6 g/dL)
Skin	None	None	Pallor, jaundice, pruritis
Eyes	None	None	Jaundiced conjunctiva and sclera, retinal hemorrhages, blurred vision
Mouth	None	None	Glossitis, smooth tongue
Cardiovascular	Palpitations	Increased palpitations	Tachycardia, increased pulse pressure, systolic murmurs, angina, congestive heart failure, myocardial infarctions
Lungs	Exertional dyspnea	Frank dyspnea	Tachypnea, orthopnea, dyspnea at rest
Neurological	None	None	Headache, vertigo, irritability, depression, impaired thought processes
Gastrointestinal	None	None	Anorexia, hepatomegaly, splenomegaly
Musculoskeletal	None	None	Bone pain
General	None	Fatigue	Sensitivity to cold, weight loss, lethargy

Hgb = hemoglobin.

alcohol intake, and controlling chronic diarrhea can help correct folic acid deficiency. If symptoms of anemia are acute, a blood transfusion may be necessary.

Nursing Process for the Patient with Anemia

ASSESSMENT. Monitor hemoglobin and hematocrit levels and other laboratory studies as ordered and report any downward trend. Monitor responses to therapy. Assess the patient's fatigue level and ability to ambulate safely and perform activities of daily living (ADLs). Monitor degree of dyspnea. Assess for pallor in the skin and conjunctivae.

NURSING DIAGNOSIS. Nursing diagnoses are based on assessment data and may include the following:

- Activity intolerance related to tissue hypoxia and dyspnea
- Imbalanced nutrition: less than body requirements related to disease, treatment, and lack of knowledge of adequate nutrition
- Risk for injury: falls related to weakness and dizziness
- Impaired oral mucous membranes

PLANNING AND INTERVENTION

Activity Intolerance. Plan care to conserve energy after periods of activity. Assist the patient with self-care activities as needed. Place articles within easy reach of the patient to reduce physiological demands on the body. Encourage the patient to limit visitors, telephone calls, and unnecessary interruptions. Allow rest periods between activities.

Monitor vital signs to evaluate tolerance to activity. If the pulse or respiratory rate increases more than 20 percent from baseline during activity, the activity is too strenuous. Administer oxygen as ordered to relieve dyspnea. Blood transfusions may be ordered if hemoglobin levels are very low or symptoms are severe.

Imbalanced Nutrition. If the anemia is caused by a dietary deficiency, consult the dietitian to provide diet modifications and instruction. Teach the patient with folic acid deficiency that daily requirements can be met by including foods from each food group at every meal. If the patient has a severe deficiency, dietary folic acid will not be enough; supplementation is the only way to correct the imbalance. Instruct the patient to continue taking the supplements until advised to stop by the physician.

Vitamin B₁₂ is administered by intramuscular (IM) injection. The patient with pernicious anemia needs B₁₂ injections for life.

Instruct the patient with iron deficiency in the use of iron supplements and side effects, which include nausea, diarrhea or constipation, and dark stools. If liquid supplements are used, give them with a straw to avoid staining the teeth. Iron is sometimes given as an intramuscular injection (Imferon). It should be given by the Z-track method to avoid staining at the site. Foods high in iron should be included in the diet; vitamin C enhances absorption of iron. (See Nutrition Notes Box 24-2.)

Risk for Injury. Assist the patient to change positions slowly to decrease dizziness and risk of falls. Assist with am-

bulation as needed. Protect the patient with pernicious anemia from injuries resulting from decreased sensation. Take special care with heating pads, turning and positioning, and other potential sources of injury because the patient may not feel pain.

Impaired Oral Mucous Membranes. If the patient has glossitis, provide good oral hygiene and soft, bland foods until healing occurs. Instruct the patient to use a very soft toothbrush and perform oral care after each meal and at bedtime.

Evaluation. When successfully treated, the patient will tolerate a normal level of activity without shortness of breath or excess fatigue. The patient should be able to explain the correct treatment plan and therapeutic measures for long-term prevention.

Aplastic Anemia

PATHOPHYSIOLOGY. Aplastic anemia differs from other types of anemia in that the bone marrow becomes fatty and incapable of production of the necessary numbers of RBCs. Also known as hypoplastic anemia, the cells that are produced are normal in size and shape, but there are not enough of them to sustain life. The resulting **pancytopenia** (reduced numbers of all the formed elements from the bone marrow—RBCs, platelets, and WBCs) is the indicator that something is wrong with the bone marrow. Left untreated, aplastic anemia is almost always fatal.

CAUSES. Aplastic anemia may be congenital—that is, the person is born with bone marrow incapable of producing the correct number of cells. In addition, it may be due to exposure to toxic substances such as industrial chemicals (e.g., benzenes and insecticides), chemotherapy medications, or use of cardiopulmonary bypass during surgery. Other causes include some bacterial and viral infections, such as tuberculosis and hepatitis.

SIGNS AND SYMPTOMS. The clinical features of aplastic anemia vary with the severity of the bone marrow failure. As with other anemias, early symptoms include progressive weakness, fatigue, pallor, shortness of breath, and headaches. As the disease progresses and the anemia and pancytopenia worsen, other symptoms, such as tachycardia and heart failure, may appear. Ecchymoses and petechiae appear on the skin surface because of the reduced platelet count (Fig. 24-1; also see Fig. 24-5). Blood may ooze from mucous membranes. Puncture sites may progress from oozing to frank bleeding. Often there is overt bleeding into vital organs. When aplastic anemia is left untreated, most patients die from infection or bleeding secondary to the lack of production of WBCs and platelets.

DIAGNOSTIC TESTS. The diagnosis of aplastic anemia begins with a CBC. Usually all values are reported as very low, with the occasional exception of the red blood cell count,

pancytopenia: pan—all + cyto—cell + penia—poverty

Figure 24-1 Petechiae on the skin from thrombocytopenia. (From Goldsmith, LA, et al: *Adult and Pediatric Dermatology*. FA Davis, Philadelphia, 1997, p 61, with permission.)

in part because of the longer life span of RBCs. Eventually the RBCs are also depleted. If the patient is having gross bleeding internally or externally, the RBC level drops rapidly and dramatically. The most definitive test is the bone marrow biopsy. Because the bone marrow is essentially dead, the result is often described as a “dry tap,” in which pale, fatty, yellow, fibrous bone marrow is extracted instead of the red, gelatinous bone marrow normally seen. Not surprising, the more fatty and pale the marrow is at the bone marrow biopsy, the more dysfunctional the bone marrow is. Other diagnostic tests include total iron-binding capacity (TIBC) and serum iron level. It is common to find both these levels elevated because the RBCs are not being produced to use up the stores of iron in the production of hemoglobin.

TREATMENT. Early identification of the cause of the anemia and correction of the underlying problem are important to survival. Unfortunately, it is often difficult to determine the cause, and there is no way to reverse the damage already done. Aggressive supportive measures may be the only treatment. Most of these measures are aimed at prevention of infection and bleeding.

Today the most effective treatment for aplastic anemia is bone marrow transplantation (Patient Perspective Box 24-4). Another common therapy is the administration of steroids to stimulate production of cells in the weakened bone marrow. Occasionally the administration of hormones may work to increase the viability of the marrow. Steroid and other hormone treatments may be tried before attempting a bone marrow transplant.

A new line of therapy is also available. In many treatment institutions, limited success is being obtained with the use of colony-stimulating factors, natural elements now being produced synthetically. For example, erythropoietin (Epoen) stimulates the production of RBCs and filgrastim (granulocyte colony stimulator [Neupogen]) stimulates the

production of WBCs. The major drawback to this type of therapy is the high cost. Many of the pharmaceutical manufacturers have patient access programs that help with the costs of these medications.

NURSING INTERVENTIONS. Nursing care of patients with symptoms of reduced hemoglobin levels is presented under Nursing Process for the Patient with Anemia. If the patient’s platelet count is low (usually less than 20,000), the patient is also placed on bleeding precautions (Box 24-5). If the white count is low, the patient must be protected from infection (Box 24-6).

Sickle Cell Anemia

PATHOPHYSIOLOGY. Sickle cell anemia is an inherited anemia in which the RBCs have a specific mutation that makes the hemoglobin in the red cells very sensitive to oxygen changes. Any time a decrease in the oxygen tension is sensed, the cells begin an observable physical change process from their usual spherical shape to a sickle or crescent shape (Fig. 24-2). Sickled cells are very rigid and easily cracked and broken. The abnormal shape also causes the

BOX 24-4 Patient Perspective

Bone Marrow Transplant

In June of 1997 I took my daughter to the doctor for her sports physical. Later that day, I received a call telling me to take her to the university hospital immediately because she had a serious life-threatening illness. I kept telling myself and my husband that our small-town hospital must have made some sort of error. As it turned out, they had not. My daughter was diagnosed with aplastic anemia and needed a bone marrow transplant. I became obsessed with the illness, poring over every tidbit of medical information I could find. Sometimes I found myself out in the car unable to remember where I was going; sometimes I had to pull over because my eyes were filled with tears and I could no longer see.

My daughter was 16 at the time of her illness, yet it is the parents who sign consent forms and make the choices in care. When the chemotherapy was started and running through the IV tubing, I felt like grabbing the tubing and pinching it off, yelling “I need more time to think about this decision,” but time was running out. Without the transplant, she had about 8 months to live.

After transplantation, my daughter was in an isolation room for a month. I stayed with her every day, and at night I stayed at the inn that was attached to the hospital. If I was needed, I wanted to be no more than a minute away. I was one of the luckier parents because I had the financial means to manage this process. I thought about how horrible it would be if I had other children at home. Sometimes I would have such an urge to run away and escape from it all. I attended support groups that were held on the hospital unit. I got to know a lot of other parents with sick kids, and it became very upsetting to me at times. One day parents told me how well their child was doing; the next day I saw the child’s room empty and thought he must have gone home, only to find out later that he had died during the night. I wondered if my daughter would be next.

I look at my daughter now, 4 years later, alive and perfectly healthy, and I tell myself that I made the right choices for her. But she tells me that, if it happens again, she will not go through chemotherapy. I wonder, is chemo worse than death?

BOX 24-5 Interventions to Prevent Bleeding in the Patient with Thrombocytopenia

1. Use an electric razor instead of a safety razor for shaving.
2. Use a soft toothbrush or gauze to clean the teeth.
3. Avoid invasive procedures as much as possible, including enemas, douches, suppositories, and rectal temperatures.
4. Avoid intramuscular injections.
5. To avoid injury when checking blood pressure, pump cuff up only until pulse is obliterated.
6. Avoid blood draws whenever possible. Use established access sites or group draws into once daily.
7. Maintain pressure on intravenous (IV), blood draw, and other puncture sites for 5 minutes.
8. Encourage use of shoes or slippers when out of bed.
9. Keep area clutter free to prevent bumps and bruises.
10. Avoid use of drugs that interfere with platelet function, such as aspirin products and nonsteroidal anti-inflammatory drugs.
11. Administer stool softeners as ordered to prevent straining to have a bowel movement.
12. Move and turn patient gently to avoid bruising.
13. Instruct patient to avoid blowing the nose.

BOX 24-6 Interventions for the Patient at Risk for Infection

1. The patient should be in a private room.
2. All personnel and visitors should wash hands before entering the room.
3. The patient should be taught to wash hands before and after using the toilet and before and after eating.
4. The patient and family should be instructed to wash hands before touching.
5. Staff or visitors with known infections should not enter the patient's room.
6. The patient should not handle flowers or plants brought into the room.
7. Raw fruits, vegetables, and milk products should be avoided.
8. Foley catheters and other invasive devices should be avoided.
9. If invasive procedures are necessary, strict aseptic technique should be used.
10. Use acetaminophen if an antipyretic is necessary; aspirin may induce bleeding.

cells to become tangled in the vessels, veins, and organs. The result is congestion, clumping, and clotting.

As red cells are broken, the cellular contents spill out into the general circulation. The resulting increase in the bilirubin level causes jaundice. Gallstones (cholelithiasis) may develop because of the increased amounts of bile pigments. The spleen and liver may enlarge because of the increase in retained cells and cellular materials.

Because of the differences in shape and texture, there is a significant decrease in life span of the RBCs in patients

Figure 24-2 Sickled cells in sickle cell disease.

with sickle cell anemia. Normal red cells live about 120 days. Sickled cells survive only about 15 to 20 days, an 80- to 90-percent decrease in cell survival.

ETIOLOGY. Sickle cell disease is an autosomal recessive hereditary disorder. This means that if both parents pass on the abnormal hemoglobin, the child will have the disease. If only one parent passes on the abnormal hemoglobin, the child will have the sickle cell trait and will be able to pass the trait (or the disease if the other parent is also affected) on to his or her child.

In the United States, sickle cell anemia is most often found in those of African or Eastern Mediterranean origin. Worldwide, many persons residing in Asia, the Caribbean, the Middle East, and Central America are affected. Nearly 10 percent of African-Americans have the sickle cell trait; 1 out of every 400 African-American infants born has inherited the two sets of abnormal genes necessary to have the disease. Symptoms do not appear in infants until after the age of 6 months, because up to that age the infant is using hemoglobin manufactured during fetal life, which is not affected by the sickling process.

SIGNS AND SYMPTOMS. The sickling changes just described are a daily occurrence. The rapid return of the oxygen level to normal returns the cells to their normal shape for the most part.

Occasionally the sickling process cannot be reversed and the problem continues unabated. This sudden and severe sickling is called a sickle cell crisis. As more and more sickling occurs, the blood becomes sluggish and does not flow easily. It tends to collect in the capillaries and veins of the organs of the chest and abdomen, as well as joints and bones, and cause infarction (tissue necrosis resulting from lack of blood supply). Tissue necrosis results in pain, fever, and swelling.

Factors that contribute to the development of a sickle cell crisis include those related to decreased oxygenation. Some examples include pneumonia with hypoxia, exposure to cold, diabetic acidosis, and severe infection. Sickle cell anemia presents problems for the patient who needs surgery. Anesthesia and blood loss during surgery and postoperative dehydration can trigger a crisis.

Common symptoms produced during sickle cell crises include severe pain and swelling in the joints, especially of the elbows and knees, as the sickled cells impede circulation. Abdominal pain is common with swelling of the spleen and engorgement of the vital organs. Hypoxia occurs as fever and pain increase, causing the patient to breathe rapidly. The male patient may have a continuous, painful erection (priapism) from impaired blood flow

through the penis. Symptoms of renal failure are common as circulation is slowed and the kidneys become clogged with cellular debris.

Repeated crises and infarctions lead to chronic manifestations such as hand-foot syndrome, an unequal growth of fingers and toes from infarction of the small bones in the hands and feet (Fig. 24-3). Additional manifestations of sickle cell disease are shown in Figure 24-4.

Figure 24-4 Clinical manifestations of sickle cell anemia.

The patient with sickle cell anemia has impaired quality of life. Often, strenuous exercise or more exotic activities, such as scuba diving, are impossible because of the risk of crisis. Dehydration exacerbates the symptoms of sickle cell disease. Crises may occur without any apparent cause. In general, crises last from 4 to 6 days. They may occur in cycles close together for a time and then may become dormant for months to years. The cause of death in patients with sickle cell anemia is usually infection, stroke, or organ involvement.

DIAGNOSTIC TESTS. The most telling feature of sickle cell disease is a blood smear that shows sickle-shaped RBCs in circulation. The Sickledex test is a screening test that shows sickling of RBCs when oxygen tension is low. Hemoglobin electrophoresis is a test used to determine the presence of hemoglobin (Hgb) S, the abnormal form of hemoglobin. Also, there is a decreased amount of hemoglobin, a lowered RBC count, an elevated WBC count, and a decreased erythrocyte sedimentation rate.

TREATMENT. No cure is available for sickle cell anemia. Treatment is aimed at continual patient education to prevent crises and supportive care when crises occur. Some patients may be placed on low-dose oral penicillin to help prevent infections, decreasing the risk of crises.

During acute crises, the patient is admitted to the hospital for 5 to 7 days. The nurse can anticipate that the patient will require sedation and analgesia for severe pain and blood transfusions to replace the sickled red cells lost by being caught, crushed, and destroyed. Oxygen therapy decreases the dyspnea caused by the anemia, and large amounts of oral and intravenous fluids are given to flush the kidneys of the byproducts of the many broken cells' debris. Antibiotics are used to treat infection that may have triggered the crisis.

New treatments are being developed to treat sickle cell disease. Frequent blood transfusions, often monthly, are one of the newest treatment recommendations. A drug, hydroxyurea, has been shown to decrease crises, but it can cause life-threatening side effects. Bone marrow transplantation is also being investigated as a potential cure.

NURSING CARE. In the patient in crisis, assess circulation in the extremities every 2 hours, including pulse oximetry, capillary refill, peripheral pulses, and temperature. Frequent pain assessment is also necessary.

Encourage oral fluids, and assist the registered nurse (RN) to monitor intravenous (IV) fluids. Administer opioid analgesics such as morphine as ordered for acute pain. They are often given intravenously by the RN or through use of patient-controlled analgesia (PCA). Warm compresses to the painful areas, covering the patient with a blanket, and keeping the room temperature above 72° F reduce the vasoconstricting effects of cold. Cold compresses are contraindicated because they decrease circulation and increase the number of sickled cells caught in the painful area. Avoid restrictive clothing and raising the knee gatch of the bed, because these can also restrict circulation. Administer acetaminophen (Tylenol) to control fever; avoid aspirin because

it may increase acidosis, which can worsen the crisis. Encourage bedrest during the acute phase of the crisis.

PATIENT TEACHING. During remission, teach the patient how to prevent acute episodes. Advise the patient to avoid tight-fitting clothing that restricts circulation. Also encourage the patient to avoid strenuous exercise, which increases oxygen demand, and cold temperatures and smoking, which cause vasoconstriction. Alcoholic beverages can also trigger a crisis and should be avoided. Patients should never fly in unpressurized aircraft or undertake mountain climbing or other sports that can cause hypoxia. Encourage patients to get a pneumococcal vaccine and yearly flu vaccines. Encourage fluids to maintain hydration and reduce blood viscosity. Genetic counseling is important to prevent passing on the trait or disease to children. For more information, visit www.sicklecelldisease.org.

Polycythemia

Pathophysiology and Etiology

Polycythemia is really two separate disorders that are easily recognizable by similar characteristic changes in the RBC count. In both forms of polycythemia, the blood becomes so thick with an overabundance of RBCs that it closely resembles sludge. This thickness does not allow the blood to move easily. Laboratory tests show a hemoglobin greater than 18 mg/dL, the RBC mass greater than 6 million, and the hematocrit more than 55 percent.

Polycythemia vera (PV) is known as primary polycythemia. Its cause is unknown. Because the RBCs, platelets, and WBCs are overproduced, the bone marrow becomes packed with too many cells. As this overabundance of cells spills out into the general circulation, the organs become congested with cells and the tissues become packed with blood. The skin takes on a ruddy appearance from the buildup of red cells. PV is usually found in patients over age 50.

In contrast, secondary polycythemia is the result of long-term hypoxia. Common coexisting conditions that may predispose a patient to develop secondary polycythemia include pulmonary diseases such as chronic obstructive pulmonary disease (COPD), cardiovascular problems such as chronic heart failure, living in high altitudes, and smoking. The body makes more red cells in response to the low oxygenation associated with these conditions. Secondary polycythemia is a compensatory mechanism rather than an actual disorder.

Signs and Symptoms

The patient with PV commonly presents with hypertension, visual changes, headache, vertigo, tinnitus, and dizziness. Laboratory results show an increased level of all the bone marrow components (RBCs, WBCs, platelets), which is called **panmyelosis**. The patient may exhibit nosebleeds and bleeding gums, retinal hemorrhages, exertional dyspnea, and chest pains because of the increased pressure exerted by the excess cells. The patient with PV usually has a ruddy (or reddish) complexion and abdominal pain with an

early feeling of fullness because of the enlarged liver and spleen. Nearly all the symptoms in PV are due to the major problems of hypervolemia, hyperviscosity, and engorgement of capillary beds. Without treatment, patients with PV die of thrombosis or hemorrhage.

Treatment

Treatment of PV takes place in two stages. The first stage is to decrease the hyperviscosity problem. The most common first-line treatment is therapeutic **phlebotomy**. Phlebotomy involves withdrawal of blood, which is then discarded. From 350 to 500 mL of blood are removed each time on an every-other-day basis, with the goal being a hematocrit of 40 to 45 percent. This reduces the RBC levels, and the patient usually feels more comfortable quickly. Repeated phlebotomies eventually cause iron deficiency anemia, which in turn stabilizes RBC production; phlebotomies can then be reduced to every 2 to 3 months.

The problem that remains is the increased white blood cell and platelet counts, because phlebotomy does very little to correct these overloads. Chemotherapeutic agents or radiation therapy may be used to suppress production of these cells in some patients. **Leukemia** is a side effect of this therapy, so it is used only if the benefits outweigh the risks.

Nursing Care

Explain the phlebotomy procedure and reassure the patient that the treatment will relieve the most distressing symptoms. The procedure is the same as that used for donating blood. The patient should be active and ambulatory to help prevent thrombus formation. When bedrest is necessary, passive and active range-of-motion exercises should be implemented. Monitor the patient for complications such as hypovolemia and bleeding. Advise the patient to report any signs or symptoms of bleeding immediately.

If the patient has more advanced manifestations, such as an enlarged liver or spleen, offer several small meals each day so that the patient will be more comfortable while still receiving adequate nutrition. In addition, encourage the patient to increase his or her daily intake of fluids to reduce the viscosity of the blood. A dietitian can be consulted to discuss ways to maintain good nutrition. If the patient is on drug therapy, monitor CBC and platelet counts.

Teaching should emphasize the need for continued follow-up with the physician once the patient begins to feel better. Instruct the patient on specific symptoms to report, such as chest pain, increased joint pain, decreased activity tolerance, and fever.

Patient Education

Instruct the patient to drink at least 3 L of water daily to reduce blood viscosity. Encourage avoidance of tight or restrictive clothing and elevation of feet when resting to prevent impairment of circulation. Use of support hose when active also promotes circulation. Teach the patient to watch for and report any signs of iron deficiency anemia, such as pallor, weight loss, and dyspnea. If anticoagulants or antiplatelets are ordered, instruct the patient about side effects

to watch for and the importance of routine laboratory tests. Routine bleeding precautions are implemented (Box 24–5). Warn the patient to stop activities at the first sign of chest pains.

▶ HEMORRHAGIC DISORDERS Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) involves a series of events that result in hemorrhage.

Pathophysiology

As its name implies, this syndrome is a catastrophic, overwhelming state of accelerated clotting throughout the peripheral blood vessels. In a short period, all the clotting factors and platelet supplies are exhausted and clots can no longer be formed. This results in bleeding from nearly every route possible. DIC is not a disease but is a syndrome that develops secondary to some other severe physical problem. Once this deadly syndrome develops, the progression of symptoms is rapid.

Massive clotting in blood vessels leads to organ and limb necrosis. Organs most often affected include the kidneys and the brain, but other blood-engorged organs, such as the lungs, the pituitary and adrenal glands, and the gastrointestinal mucosa, are commonly involved. DIC is usually acute in onset, although in some patients it becomes a chronic condition. The prognosis depends on early diagnosis and intervention and the severity of the hemorrhaging. DIC has a very high mortality rate.

Etiology

DIC can develop after any condition in which the body has sustained major trauma. The sources of trauma are varied and can include an overwhelming infection and sepsis or an overt viral infection. Obstetric complications such as abruptio placentae, amniotic fluid embolism, or a retained dead fetus can trigger the onset of DIC. Cancer-related causes of DIC include acute leukemia and widely metastatic cancers of the lung. Massive tissue necrosis found in severe crush or burn injuries may increase the risk for development of DIC. Tissue necrosis secondary to extensive abdominal surgery with leakage of the intestinal contents can be related to DIC onset. Rarer causes of this condition have included heatstroke, shock, and poisonous snakebites, as well as fat embolism secondary to broken long bones.

Signs and Symptoms

Abnormal bleeding without a history of a serious hemorrhagic disorder is a cardinal sign of DIC. Early signs of bleeding include petechiae, ecchymoses (Fig. 24–5), and bleeding from venipuncture sites. Bleeding may progress to IV sites, skin tears, surgical sites, incisions, and the gastrointestinal tract and oral mucosa. Pain and enlargement of joints develop if bleeding into the joints occurs. All these signs and symptoms may occur at the same time. Massive bleeding may also be accompanied by nausea, vomiting, dyspnea, oliguria, convulsions, coma, shock, major organ

system failure, and severe muscle, back, and abdominal pain.

Diagnostic Tests

Initial laboratory findings in DIC include a prolonged prothrombin time (PT) and partial thromboplastin time (PTT), decreased platelet count, and increased evidence of fibrin degradation products. A decrease in hemoglobin is the result of spilled hemoglobin from the increased numbers of broken red cells. Blood urea nitrogen (BUN) and serum creatinine levels may also be increased. See Table 24–2 for additional findings.

Medical Treatment

Effective treatment of DIC depends on early recognition of the condition. Treatment is first aimed at correcting the underlying cause. Additional treatment consists of supportive interventions, including administration of blood, fresh frozen plasma, and platelets and the infusion of cryoprecipitates to support hemostasis. Some health care organizations include the use of intravenous heparin to help prevent the

initial microembolization, but this practice is controversial. Additional therapies are being investigated.

Nursing Care

Care of the patient with DIC is a nursing challenge. Early intervention requires early recognition and reporting of signs of bleeding. In addition to supportive care, focus on the prevention of further bleeding episodes. Care should be taken to avoid any trauma that might cause bleeding. Be careful not to dislodge clots from any site because another clot may not form and the patient will hemorrhage. See Box 24–5 for bleeding precautions.

Patient Teaching

Because a patient with DIC is often placed in the intensive care unit, there are many chances for patient and family teaching. Explain all diagnostic tests to the patient if he or she is alert. If not, keep the family informed. A large part of family education is preparing the family for what the patient may look like in terms of bleeding and bruising, as well as specific equipment that may be in place, such as IV lines, nasogastric (NG) tube, and Foley catheter. It may be helpful to enlist the aid of social workers, chaplains, and other members of the health care team to help support the family.

LABORATORY ABNORMALITIES IN DISSEMINATED INTRAVASCULAR COAGULATION	
Screening Test	Finding
Prothrombin time (PT)	Prolonged
Partial thromboplastin time (PTT)	Prolonged
Activated partial thromboplastin time (APTT)	Prolonged
Thrombin time (TT)	Prolonged
Fibrinogen	Reduced
Platelets	Reduced
Fibrin split products (FSP; also known as fibrin degradation products [FDP])	Elevated
Protamine sulfate	Strongly positive
Dimers (cross-linked fibrin fragments)	Elevated
Antithrombin III	Reduced
Factor assays (for factors V, VII, VIII, X, and XIII)	Reduced

CRITICAL THINKING

Mrs. Johns
Mrs. Johns is admitted to your unit with DIC following the difficult delivery of her new baby.

1. What will you assess as you care for Mrs. Johns?
2. What treatment do you anticipate?
3. What concerns is Mrs. Johns likely to have?

Answers at end of chapter.

Figure 24-5 Extensive hemorrhage into the skin in DIC. Note how the area is outlined in pen so the nurse can assess if the area is spreading. (From Harmening, DM: Clinical Hematology and Fundamentals of Hemostasis, ed 3. FA Davis, Philadelphia, 1997, p 520, with permission.)

Idiopathic Thrombocytopenic Purpura Pathophysiology and Etiology

This disease results from increased platelet destruction by the immune system. Any time platelets are reduced, the risk for bleeding increases. Acute **idiopathic thrombocytopenic purpura (ITP)** usually affects children between the ages of 2 and 6, whereas chronic ITP mainly affects adults younger than age 50. The major population affected is women between ages 20 and 40.

Acute ITP usually occurs after an acute viral illness such as rubella or chickenpox. It may also be drug induced or associated with pregnancy. ITP is generally thought to be related to an immune system dysfunction. Antibodies responsible for platelet destruction have been found in nearly all diagnosed patients.

idiopathic thrombocytopenic purpura: idio—unknown + pathic—disease + thrombo—clot + cyto—cell + penic—lack + purpura—hemorrhage in the skin

Signs and Symptoms

ITP produces clinical changes that are common to all forms of **thrombocytopenia**: petechiae, ecchymoses, and bleeding from the mouth, nose, or gastrointestinal (GI) tract. Bleeding may occur in vital organs, such as the brain, which may prove fatal. In the acute type, onset may be sudden and without warning, causing easy bruising, nosebleeds, and bleeding gums. Onset of chronic ITP is usually insidious.

Diagnostic Tests

A platelet count of less than 20,000/mm³ and a prolonged bleeding time suggest ITP. The greatly decreased platelet level places the patient at serious risk for hemorrhage. Examination of the platelets under the microscope shows them to be small and immature. Anemia may be present if there has been a bleeding episode. If a bone marrow aspiration is performed, the results show an adequate amount of the precursor cells for platelets, the megakaryocytes. However, instead of the 7- to 10-day life span that platelets usually have, these immature platelets have a life span of just a few hours.

Treatment

Most cases of acute ITP resolve spontaneously without treatment. Initial treatment, if necessary, is often the administration of steroids. The purpose of the steroids is to prolong the life of the platelets and strengthen the capillaries, making them less likely to break and cause bleeding. Some physicians order the use of chemotherapy drugs. The spleen may be removed, because it is the primary site involved in platelet destruction. Often the patient undergoing splenectomy has tried all other courses of treatment unsuccessfully and may be experiencing bleeding episodes. Acute bleeding episodes are treated with transfusions of blood, platelets, and vitamin K.

Nursing Interventions

Care for the patient with ITP is the same as any patient with a bleeding disorder. See Box 24-5 for bleeding precautions. Teach the patient to watch for and report signs and symptoms of bruising and bleeding (Box 24-7). The patient should avoid trauma and restrict activity during severe episodes.

thrombocytopenia: thrombo—clot + cyto—cell + penia—lack

BOX 24-7 Patient Teaching: Signs and Symptoms of Bleeding

Notify your health care provider if the following occur:

- Easy bruising of skin
- Petechiae (small red spots on skin)
- Blood in urine
- Black tarry stools
- Bleeding from nose or gums
- New onset of painful joints

Hemophilia

Hemophilia is a group of hereditary bleeding disorders that result from a severe lack of specific clotting factors. The two most common are hemophilia A (classic hemophilia) and hemophilia B (Christmas disease). Von Willebrand's disease is another related bleeding disorder, but it represents a minority of cases and is not discussed in this chapter.

Pathophysiology

Recall that many different clotting factors make up the clotting mechanism. Hemophilia A accounts for 80 percent of all types of hemophilia and results from a deficiency of factor VIII. Hemophilia B is a factor IX deficiency; approximately 15 percent of persons with hemophilia have this type. The severity and prognosis of hemophilia depend on the degree of deficiency of the specific clotting factors. Mild hemophilia has the best prognosis because it does not cause spontaneous bleeding and joint deformities as does severe hemophilia.

After an injury, the person with hemophilia forms a platelet plug (which differs from a clot) at the site of an injury as would normally be expected, but the clotting factor deficiency keeps the patient from forming a stable fibrin clot. Continued bleeding washes away the platelet plug that initially formed. Contrary to popular myths, people with hemophilia do not bleed “faster” and are not at risk from small scratches.

Etiology

Hemophilia A and B are inherited as X-linked recessive traits. This means that the female carrier (daughter of an affected father) has a 50 percent chance of transmitting the gene to each son or daughter. Daughters who receive the gene are carriers, and sons who receive the gene are born with hemophilia. It is technically possible for daughters to be affected with hemophilia, although it is very rare.

Signs and Symptoms

Bleeding occurs as a result of injury or, in severe cases, spontaneously (unprovoked by injury). Bleeding into the muscles and joints (**hemarthrosis**) is common. Severe and repeated episodes of joint hemorrhage cause joint deformities, especially in the elbows, knees, and ankles, which decreases the patient's range of motion and ability to walk.

In mild hemophilia, excessive bleeding is usually associated only with surgery or significant trauma. However, once a person with mild hemophilia begins to bleed, the bleeding can be just as serious as that of the patient with a more severe form.

The patient with moderate hemophilia has an occasional bout of spontaneous bleeding. In severe hemophilia, spontaneous bleeding occurs more frequently. It would be possible for the patient to develop hemarthrosis or bleeding

hemophilia: hemo—blood + philia—to love

hemarthrosis: hem—bleeding + arthr—joint + osis—condition

into the brain without any precipitating trauma. Severe episodes may produce large subcutaneous and deep intramuscular hematomas. Major trauma can cause bleeding so severe that it becomes life threatening.

Another unfortunate problem related to hemophilia treatment is the frequent need to replace clotting factors and other blood products. Before 1986, blood banks and other centers did not routinely test for human immunodeficiency virus (HIV) antibodies. Depending on the patient's age and frequency of treatment, many patients may have been exposed to HIV or hepatitis. Blood banks and pharmacies have checked their blood supplies for the presence of HIV since 1986. Today the plasma proteins are artificially created or thoroughly cleansed to prevent transmission of disease.

Diagnostic Tests

Laboratory data reveal a prolonged PTT. The various factor levels are then measured to determine which is missing. Once the missing factor is identified, the type of hemophilia is determined and necessary treatments can be implemented.

Medical Treatment

Hemophilia is not curable. However, treatment advances have improved outcomes and many patients can now live a normal life span. Treatment is aimed at the prevention of crippling deformities and at increasing life expectancy. Treatment involves stopping bleeding episodes by increasing the blood levels of the missing clotting factors. Hemophilia A is treated with factor VIII; hemophilia B is treated with factor IX. Each is available in a freeze-dried powder that is reconstituted with water and administered intravenously. The newest treatment is factors made using recombinant DNA technology, without the use of any human blood products. Blood transfusions are uncommon but may be necessary after severe trauma or surgery.

Complications related to therapy usually occur if therapy is started too late. Minor trauma generally needs to be treated with at least 72 hours of added clotting factors; major traumas and surgeries may require up to 14 days of added factors to prevent sudden bleeding. Health care workers should pay careful attention to the patient who says that bleeding is starting, even when no outward signs are evident. The patient usually knows from experience if bleeding is starting. If treatment is delayed at this time, the results can be disastrous. Some patients with severe disease are treated prophylactically to prevent bleeding.

Nursing Process

ASSESSMENT. Because one goal is prevention of bleeding episodes, assess the patient and family for knowledge of the disease and its treatment and understanding of preventive measures. Most patients care for themselves at home, starting their own IVs and administering treatment independently. Hospitalization is necessary only for surgery or major trauma. During an acute episode of bleeding, the hemoglobin and hematocrit are carefully monitored. Factor VIII or IX levels are monitored to determine if factor replacement has reached adequate levels. Vital signs are monitored for

falling blood pressure and rising pulse rate, which are signs of hypovolemic shock. All body systems are assessed for signs of bleeding (see Box 24–7). A pain assessment is done using the WHAT'S UP? format.

NURSING DIAGNOSIS. Priority nursing diagnoses include the following:

- Pain related to bleeding into tissues
- Risk for injury related to effects of bleeding
- Risk for ineffective management of therapeutic regimen related to knowledge deficit

PLANNING AND IMPLEMENTATION. Goals of treatment are to prevent bleeding and to access quick treatment and prevent complications if bleeding occurs.

Pain. Pain during acute bleeding episodes is managed with opioids as prescribed. Use of patient-controlled analgesia is helpful, especially because this uses the intravenous route. Intramuscular injections are contraindicated because of the risk of causing bleeding into the muscle.

Risk for Injury. Routine precautions to prevent bleeding are summarized in Box 24–5. In the event of an acute episode of bleeding, the patient is transfused with factor concentrates (or in rare circumstances, fresh frozen plasma, cryoprecipitate, blood, or a combination of these). See Chapter 23 for transfusion of blood products. Ice or pressure on bleeding sites may help slow bleeding. Special preventive care is exercised if the patient requires surgery or dental procedures; these can be life-threatening events for the patient with hemophilia.

Risk for Ineffective Management of Therapeutic Regimen. You can assist the RN to instruct the patient and family in care of the disorder. They must learn to prevent bleeding episodes, recognize signs and symptoms of bleeding, and obtain emergency care in the event that bleeding does occur. Many patients are taught to administer treatment at home. A nationwide system of comprehensive hemophilia treatment centers coordinates care for these patients. Periodic multidisciplinary clinics are held, at which social service, dental, rehabilitation, nursing, financial, and medical needs can be addressed.

EVALUATION. If nursing care is effective, the patient will be comfortable and bleeding will be prevented or complications minimized. The patient and family will be able to state appropriate measures to prevent and treat bleeding episodes.

► DISORDERS OF WHITE BLOOD CELLS

Leukemia

The term *leukemia* literally means “white blood.” It was first identified in 1845 when the blood of victims was examined and found to have an excess of “colorless” cells.

Pathophysiology

Leukemia is a malignant disease of the WBCs that affects all age groups. The immature WBCs (blast cells) generate

in an explosive fashion in the bone marrow, lymph tissue, and spleen. These cells are abnormal and unable to effectively fight infection. There are so many abnormal cells developed and dumped into the peripheral circulation that they tend to collect in the body organs and tissues, especially where circulation is sluggish. Areas especially prone to infiltration with these immature WBCs are the oral mucosa, anus, sinuses, and lungs. At the time of diagnosis, these areas are often inflamed, painful, and infected. It is common for some patients to be diagnosed only after suffering with an infection that does not clear up easily.

As the disease progresses, the bone marrow continues to produce large numbers of the useless cells, the peripheral circulation is filled with the abnormal cells, and the bone marrow is packed with blast cells; production of most other normal cells is impossible. The patient becomes anemic because of the lack of RBC production, and bleeding becomes a problem as fewer and fewer platelets are manufactured. But most importantly, even though the WBC count is very high, there are very few normal, mature, and active white cells with which to fight infection. Thus the patient often begins to have raging infections that do not respond to antibiotics. Without treatment, the leukemia leaves the patient unable to fight infection, unable to control bleeding, and in a downward spiral of fatigue and anorexia. Leukemia, untreated, is almost always fatal.

Classifications

Leukemias are classified as either acute or chronic and either lymphoid or myeloid. Symptoms of the acute leukemias begin very suddenly and the patient is very sick, whereas chronic leukemias develop very slowly and patients can be surprised by the diagnosis because they feel well. Lymphoid leukemias affect the lymphocytes. Myeloid leukemias originate in the stem cells of the bone marrow that develop into monocytes, granulocytes, erythrocytes, and platelets. The most common leukemias are discussed next.

ACUTE LEUKEMIAS. Acute lymphocytic leukemia (ALL) commonly affects children younger than age 15 and involves abnormal growth of the lymphocyte precursors (lymphoblasts). Acute myelogenous (myeloblastic) leukemia (AML) usually affects persons older than age 20 and has a poor prognosis. The patient with acute leukemia may present with sudden onset of high fever, abnormal bleeding from the mucous membranes, petechiae, ecchymoses, and easy bruising after minor trauma. Death usually results from infection.

CHRONIC LEUKEMIAS. Chronic lymphocytic leukemia (CLL) predominantly affects the B and T lymphocytes and usually occurs in adults older than age 40. Chronic myelogenous leukemia (CML) is characterized by the Philadelphia chromosome and occurs most often between the ages of 40 and 45.

Chronic leukemia usually develops in a three-stage process. First is the insidious phase, characterized by anemia and mild bleeding abnormalities. During this stage, the patient often feels well and is not even aware that he or she is sick. After a time, generally years, the disease progresses to

the accelerated and acute phases, in which the scenarios are similar to the events seen in acute leukemias. Chronic leukemia is almost always fatal; the average survival time is 3 to 4 years after onset of the chronic phase and 3 to 6 months after onset of the acute phase. With advances in treatments, it is not uncommon to encounter patients who have been living with chronic leukemia for 10 years or more.

Etiology

The cause of leukemia is unknown. Risk factors are thought to include certain viruses, because remnants of viruses have been found in leukemic cells. Often there are genetic and immunological factors involved. For example, persons with Down syndrome are more likely to develop leukemia. Other authorities point to exposure to radiation, in part because radiologists have been found to have a higher-than-average development of leukemia. Some patients have developed leukemia after being treated for another unrelated malignancy using radiation or chemotherapy. Researchers note the higher occurrence rate in persons who lived through the Hiroshima and Nagasaki bombings during World War II. Water polluted with benzenes and other chemicals may be a factor. There is no single clear-cut cause for the development of leukemia.

Signs and Symptoms

Symptoms are similar for all types of leukemia and include low-grade fever caused by infection, pallor, weakness, lassitude, shortness of breath, and malaise caused by anemia. These symptoms may be present weeks or months before the appearance of other symptoms. The patient may also have dyspnea, fatigue, tachycardia, palpitations, and abdominal pain. Sternal pain and rib tenderness may result from crowding of bone marrow. If the leukemia has invaded the central nervous system, the patient may experience confusion, headaches, and personality changes. During the acute phase the patient may exhibit high fevers from infection. Ecchymosis or petechiae may result from thrombocytopenia.

Diagnostic Tests

Although a simple CBC often points toward the diagnosis, only bone marrow aspiration can show the degree of proliferation of the malignant WBCs and confirm the diagnosis of leukemia. The complete blood cell count may also show a decrease in the numbers of platelets, RBCs, and mature WBCs. A lumbar puncture helps determine if the central nervous system is involved. Genetic analysis of the peripheral blood and bone marrow components may show the presence of the Philadelphia chromosome in patients with CML.

Medical Treatment

Systemic chemotherapy aims to eradicate the leukemic cells and induce a remission. Remission means that the bone marrow is free to produce normally occurring cells in normal proportions without production of the immature

WBCs. Chemotherapy types vary with the types of leukemia and the level of involvement. Radiation therapy is also sometimes used for initial treatment of leukemia.

The overall goal of the first treatments is to get the patient to a state of remission. Occasionally, partial remission is achieved, when everything looks good except for an occasional leukemic cell seen in the bone marrow. Remission is not the same as cure.

There are four phases to the treatment of leukemia: induction, intensification, consolidation, and maintenance. Induction is the period in which an attempt to get the patient into remission is made. This first phase is difficult because chemotherapy is given in extremely high doses and on an aggressive timetable. Often the patient becomes quite ill from complications of the treatment. The patient may become depressed because the treatment seems worse than the disease at this stage. The nurse must help the patient deal with the side effects of anemia, thrombocytopenia, and leukopenia (see also Leukemia Summary, Table 24-3). (See Boxes 24-5 and 24-6 and Chapter 10.)

If the first remission is accomplished, the other phases of treatment are begun. Intensification is similar to the initial induction phase, using the same drugs at even higher doses. The next phase, consolidation, is used to ensure that all leukemic cells have been eradicated from the body. Finally the patient graduates to maintenance therapy, in which the

patient is kept free of leukemic cells (and in remission) for a period of years (and hopefully a lifetime). This requires years of continued chemotherapy treatments, often on a monthly basis. Radiation therapy may be used throughout this course of treatment to decrease the size of the liver or spleen or to decrease the numbers of leukemic cells in the central nervous system.

Bone marrow transplantation (BMT) is sometimes used to treat leukemia. Often the precursors to BMT include total body irradiation and high-dose chemotherapy. The goal of these seemingly radical treatments is to destroy all the patient's malignant bone marrow and then, at the last possible moment, replace it with a donor's clean and healthy bone marrow (allogenic transplant). One other type of bone marrow transplant, known as an autologous transplant, uses the patient's own diseased bone marrow, which is harvested, chemically treated and cleaned, stored, and later reinfused. This stage of bone marrow replacement is sometimes called bone marrow rescue. Transplanted bone marrow is given to the patient like a blood transfusion—generally through a central line placed in the chest. Once infused into the bloodstream, the new marrow travels to the bones, where, under the best of circumstances, it begins to grow and function normally.

Bone marrow transplants are being performed at more and more centers across the United States. Common reasons for BMT include leukemia, lymphoma, breast cancer, aplastic anemia, and congenital immunodeficiency disorders.

A new and promising treatment for leukemia is peripheral blood stem cell transplantation. Hematopoietic stem cells can be collected from the patient during remission, then reinfused at a later time. Donor stem cells are also sometimes used if a good match can be found.

Nursing Care

The patient with leukemia is at risk for many problems, including fatigue, bleeding, infection, and other complications of the disease and its treatment. The patient must understand his or her disease process and treatment regimen in order to participate in self-care. See Nursing Care Plan Box 24-8 for the Patient with Leukemia for interventions to

TABLE 24-3 LEUKEMIA SUMMARY

<i>Symptoms</i>	Fever (related to infection) Pallor Weakness, malaise Tachycardia Dyspnea Bone pain Headaches, confusion
<i>Diagnostic tests</i>	CBC Bone marrow aspiration Lumbar puncture
<i>Therapeutic management</i>	Chemotherapy Radiation therapy Bone marrow transplant

BOX 24-8 NURSING CARE PLAN FOR THE PATIENT WITH LEUKEMIA

Risk for injury from infection or bleeding related to pancytopenia

PATIENT OUTCOMES

The patient is free from infection and bleeding. Signs and symptoms of infection or bleeding are reported promptly.

EVALUATION OF OUTCOMES

Is the patient free from infection and bleeding, or are problems reported so that quick intervention can prevent further complications?

INTERVENTIONS

- Monitor vital signs every 4 hours and as needed.
- Monitor for swelling, redness, purulent drainage.

RATIONALE

- Elevated temperature is a sign of infection. Falling blood pressure and elevated pulse rate may indicate sepsis or blood loss.
- These are signs of infection and should be reported promptly.

EVALUATION

- Are vital signs stable?
- Are signs of infection present?

BOX 24-8 NURSING CARE PLAN FOR THE PATIENT WITH LEUKEMIA—CONT'D

Protect patient from sources of infection (see Box 24-6).
Observe for tarry stools, petechiae, ecchymosis (see Box 24-7).
Protect patient from injury that could cause bleeding (see Box 24-5).

Patient is at risk for infection because of ineffective WBCs.
These are signs of bleeding and should be reported promptly.
Patient is at risk for bleeding because of reduced platelet count.

Are precautions being observed to prevent infection?
Are signs of bleeding present?
Are precautions being observed to prevent injury and bleeding?

▶ Fatigue related to decreased red cell count and oxygenation and effects of treatments**PATIENT OUTCOMES**

Patient is able to participate in activities that are important to him or her.

EVALUATION OF OUTCOMES

Is patient able to identify and participate in activities that are important to him or her?

INTERVENTIONS

Assess fatigue using the WHAT'S UP? format.
Assist patient to identify activities that are important to him or her (e.g., activities of daily living [ADLs] attending a child's wedding, taking a trip). Assist in setting goals to work toward the desired activity.
Encourage a balanced diet. Contact dietitian as needed.
Allow periods of rest between activities.
Ensure adequate sleep. Obtain order for sleeping aid if indicated.
Provide for ADLs when patient is unable to do so independently.

RATIONALE

A good assessment establishes a baseline and aids in planning.
If the patient cannot do everything he or she wishes, it may help to focus on the most important things.
Poor nutrition contributes to fatigue.
Any activity (ADL, x-rays, even talking) can increase fatigue.
Lack of sleep worsens fatigue.
Extreme fatigue may prevent the patient from participating in self-care.

EVALUATION

Is fatigue present? To what degree?
Can patient identify important activities? What are they? How can the nurse assist the patient to reach activity goals?
Is patient eating a balanced diet? Is weight stable?
Is patient able to rest?
Does patient state feeling rested on awakening? Is medication needed?
Does patient need total assistance?

▶ Impaired oral mucous membranes related to chemotherapy and pancytopenia**PATIENT OUTCOMES**

The patient's oral mucous membranes will remain intact.

EVALUATION OF OUTCOMES

Are oral mucous membranes intact, without lesions?

INTERVENTIONS

Assess mouth daily for redness, edema, and lesions.
Encourage adequate nutrition and fluids.
Encourage patient to brush teeth after meals with a soft toothbrush. If irritation is severe or if the patient is at risk for bleeding, use swabs or sponge Toothettes instead of a toothbrush.
Avoid use of lemon-glycerin swabs for mouth care.
Obtain an order for a mouthwash such as 1 oz of diphenhydramine (Benadryl) elixir diluted in 1 qt of water or normal saline. Obtain an order for a topical anesthetic if mouth is very inflamed and painful.

RATIONALE

Routine assessment helps identify problems early so treatment can be implemented.
Poor nutrition and dehydration increase the risk of oral lesions.
Brushing the teeth controls tooth and gum disease; a toothbrush may be too harsh if the patient is at risk for bleeding.
Lemon-glycerin swabs are drying to oral mucosa.
Diphenhydramine reduces inflammation; anesthetics reduce pain.

EVALUATION

Are mucous membranes intact?
Is patient eating and drinking?
Is mouth care being provided after meals? Is mouth care irritating? Are alternative methods needed?
Are products used appropriate?
Does mouthwash soothe pain?

BOX 24-8 NURSING CARE PLAN FOR THE PATIENT WITH LEUKEMIA—CONT'D

Encourage the patient to avoid smoking, alcohol, acidic food or drinks, extremely hot or cold foods and drinks, and commercial mouthwash.

These things can be irritating to the mucosa.

Does patient state understanding of things to avoid?

GERIATRIC

Advise patient to remove dentures for cleaning and at bedtime.

Dentures left in for long periods can impair circulation and increase risk of lesions.

Are dentures removed for cleaning and at night?

deal with these problems. Additional diagnoses include knowledge deficit and anxiety. The following Web sites provide resources for patients and families with leukemia. See also Chapter 10 for general care of the patient with cancer.

- American Cancer Society at www.cancer.org
- Leukemia and Lymphoma Society at www.leukemia.org
- National Cancer Institute at www.nci.nih.gov

CRITICAL THINKING

Mr. Washington
 Mr. Washington is on your unit undergoing initial treatment for leukemia. You enter his room and find it full of visitors.

1. What concerns do you have?
2. What do you do?

Answers at end of chapter.

MULTIPLE MYELOMA

Multiple myeloma is a deadly cancer of the plasma cells in the bone marrow. When the disease is caught in its early stages, treatment can prolong life by 3 to 5 years. More important, early detection can decrease the amount of pain and disability due to bony destruction and **pathological fractures**. Unfortunately, almost half the patients die within the first 3 months after diagnosis because of the silent and deadly nature of the disease. Another 40 percent of patients die within 2 years after diagnosis. Because early diagnosis is not often made, only 10 percent of patients can expect to live to the 5-year mark. Multiple myeloma most often affects men ages 50 to 70.

Pathophysiology

In this disorder, cancerous plasma cells in the bone marrow begin reproducing uncontrollably. These cells infiltrate bone tissue all over the body and produce hundreds of tumors that begin to devour the bone tissue. X-ray examination may show holes in the bones, forming a Swiss cheese pattern (Fig. 24-6). As more and more of these holes are formed, the bone integrity becomes compromised and weak. Multiple myeloma usually affects the bones of the skull, pelvis, ribs, and vertebrae.

As the disease continues, the plasma cells infiltrate the major organs, including the liver, spleen, lymph nodes,

Figure 24-6 X-ray of bone destruction in multiple myeloma. (From Huether, SE, and McCance, KL: Understanding Pathophysiology. Mosby, St Louis, 1996, p 548, with permission.)

lungs, adrenal glands, kidneys, skin, and GI tract. Because the diagnosis is usually made only after widespread invasion of the bones is well underway, the overall prognosis of patients with this disease is poor. Although the overall result of the disease is the devastating destruction of the bone and widespread osteoporosis, death is often from sepsis.

Etiology

The cause of multiple myeloma is unknown, although it is being researched. Some authorities believe this disease to be related to chronic allergies and hypersensitivity reactions. This line of thought stems from the fact that plasma cells are the first line of defense and are the producers of the immunoglobulins that help fight foreign bodies. For some reason these defenders get out of control and begin to attack the host, as well as foreign invaders. People who work in rubber, leather, farming, and petroleum industries are more likely to develop multiple myeloma. Radiation and chemical exposure may also be factors.

Signs and Symptoms

Skeletal pain is the most common complaint. The patient may describe the pain as constant severe back pain that in-

creases with exercise or movement. The patient may complain about pain in the ribs. Other signs and symptoms include achiness of the long bones, joint swelling and tenderness, low-grade fever, and general malaise. Sometimes there is evidence of early peripheral neuropathy secondary to vertebral collapse and mild spinal cord compression. The patient may be unable to feel the true temperature of bath water and be burned or may be unable to feel wounds and infections on the feet. In more severe cases of cord compression, the patient may lose control of bladder and bowels. This is a true oncological emergency. Prompt emergency treatment is necessary to keep the patient from becoming paralyzed.

Occasionally the patient will have pathological fractures of the long bones. These are fractures that occur with no trauma, such as the person who breaks a leg just turning over in bed or breaks a rib while sneezing. In advanced disease there is anemia, weight loss, thoracic spinal deformities from multiple rib destruction, and a loss of height because of pathological fractures and compacting of the vertebrae.

Because calcium is mobilized from the bones and into the blood, the patient is at risk for hypercalcemia. Signs and symptoms include anorexia, nausea, vomiting, mental changes (especially confusion), seizures, and weakness and fatigue. Kidney stones may result as the excess calcium passes through the kidneys.

Patients are susceptible to infection because of compromised immune function. Pneumonia is a common finding in patients with multiple myeloma. They may develop anemia because of bone marrow dysfunction and reduced erythropoietin formation by diseased kidneys.

Patients often develop kidney failure as the filtering capacity of the kidney is blocked with calcium. Other factors include recurrent infections and deposits of myeloma cells in the kidneys.

Diagnostic Tests

A CBC shows moderate to severe anemia. Examination of the WBC count may show an increase in the number of white cells secondary to infection. X-ray examinations may show changes in the lungs and diffuse osteoporosis in the bones not already riddled with holes. Urine studies are positive for the M-type globulins (Bence-Jones proteins) in 40 percent of patients. Bone marrow biopsy is done to confirm the diagnosis and determine the disease's stage.

Blood chemistries often show an increased amount of calcium in the blood. Hypercalciuria results as the calcium released out of the bones is flushed out in the urine. An intravenous pyelogram may be done to see how much calcium is blocking the kidneys. A 24-hour urine collection is done to evaluate protein excretion.

Medical Treatment

Long-term treatment of multiple myeloma consists of a two-pronged approach: (1) managing the disease and (2) managing the symptoms. To manage the disease, high-dose steroids (prednisone) and oral or intravenous chemotherapy agents are given. The goal of drug therapy is to suppress the

plasma cell proliferation, which then helps decrease the amount and speed of bone destruction.

The second approach is control of symptoms. The nurse monitors the patient for signs and symptoms of hypercalcemia, hyperuricemia, dehydration, respiratory infection, renal problems, and pain. External beam irradiation may be given to especially painful areas of bone involvement. Fortunately this treatment is quite effective, usually decreasing pain intensity in just a few days. The patient can expect to have a daily (or perhaps a twice-daily) therapy treatment over a course of 10 to 14 days, delivered directly to the painful bony areas. Vigorous attention to administering pain medications during the early course of treatment greatly reduces the patient's pain levels.

The patient may need a laminectomy if vertebral collapse occurs. Because of demineralization of the bone, with resulting large amounts of calcium in the blood and urine, surgery for kidney stones and eventual dialysis for acute or chronic kidney failure may be necessary.

A newer treatment involves high-dose chemotherapy combined with stem cell transplantation. The patient's own peripheral stem cells can be removed and reinfused. These stem cells can then differentiate into new, healthy cells. Methods of cleaning the cells to prevent contamination with malignant cells are being researched.

Nursing Care

Assess for fever or malaise that can signal the onset of infections. Other conditions to be alert for include anemia, hypercalcemia, fractures, and renal complications. Monitor intake and output, and strain urine for stones. Elevated BUN and creatinine levels will alert you to possible renal failure. Report back pain, leg weakness, sensory loss, or loss of bowel or bladder function, because these might indicate spinal cord compression.

Keeping the patient mobile is very important. The physical therapist and occupational therapist can help the patient continue to be active. Bones in use are strongest, so the patient should remain up and moving as much as possible to help stimulate calcium resorption and decrease demineralization. Assist the patient with walking because of the risk of pathological fractures of the long bones. If the patient is unsteady, use a walker or a support belt. Keeping the patient up and active also decreases the risk of respiratory complications. Urination also is enhanced in the patient who does not need to rely on the use of a bedpan or urinal.

If the patient is bedridden, reposition him or her every 2 hours to prevent complications related to immobility; use a lift sheet to move the patient gently and decrease the risk of pathological fractures. Provide passive range-of-motion exercises and encourage deep breathing.

Teach the patient the importance of good hydration at all times to minimize complications of hypercalcemia. Administer fluids so that daily output is never less than 1500 mL. Depending on time of year and the type and level of patient activities, the patient may need to have an intake of more than 4 L daily.

If hypercalcemia occurs, the physician will order an IV of normal saline to infuse at a high rate followed by regular administration of diuretics. The goal is to get the serum calcium level below 10 mg/dL. Oral compounds are also available to help keep the calcium level within normal limits. See Home Health Hints for additional suggestions for patients being cared for at home.

HOME HEALTH HINTS

- Patients who are at risk for infection can place a sign on the front door of their homes to limit visitors or ask persons with colds to come back when they are well. The patient may appreciate the home nurse's giving permission to be assertive in such circumstances.
- To prevent bruising, have the patient cut the feet off of white sport socks and wear them on the arms. They can be hidden under long-sleeve shirts and blouses and provides a cushion when doing housework.
- Patients with sickle cell anemia usually have lower blood pressures. It is important to report even mild hypertension for these patients.

REVIEW QUESTIONS

- Which assessment finding would you expect to find in the patient who has anemia?
 - Pain
 - Dyspnea
 - Vision changes
 - Skin rash
- Which of the following activities is contraindicated for the patient with sickle cell anemia?
 - Riding in an elevator
 - Taking a long car trip
 - Running in a marathon
 - Listening to a concert
- Which explanation for bleeding should you give to the wife of a patient with DIC?
 - "He is bleeding because he does not have enough RBCs."
 - "He is bleeding because his white cells are depleted."
 - "He is bleeding because his blood pressure is so high that it forces blood from mucous membranes."
 - "He is bleeding because his body's clotting factors have all been used up."
- Which instruction will help the mother of a child with hemophilia prevent bleeding episodes?
 - "Your son should avoid contact sports."
 - "Your son will have to avoid all potentially irritating foods."
 - "Your son must never shave."
 - "Your son should always live near a major hospital system."
- Which family member should not be permitted to visit a patient with newly diagnosed leukemia?
 - The one who has a new baby at home.
 - The one who has a history of asthma.
 - The one who has received recent radiation treatment for cancer.
 - The one who has a runny nose.
- Which of the following assessment findings is most frequently encountered in patients with multiple myeloma?
 - Pathological fractures
 - Mental status changes
 - Raging infections
 - Bleeding tendencies
- Which of the following nursing interventions is most appropriate for a patient with thrombocytopenia?
 - Avoid intramuscular injections.
 - Keep visitors who are ill away from the patient.
 - Encourage 4 L of fluid daily.
 - Allow rest between activities.

REFERENCES

1. Purnell, L, and Paulanka, B (eds): *Transcultural Health Care: A Culturally Competent Approach*. FA Davis, Philadelphia, 1998.

Answers to CRITICAL THINKING**Mrs. Johns**

1. Monitor Mrs. Johns's vital signs and report falling blood pressure and rising pulse immediately. Inspect her skin for petechiae and ecchymoses. Outline ecchymotic areas with an ink pen in order to see if the area is increasing in size. Monitor urine for signs of blood. Test stools for occult blood. Monitor vaginal discharge for increasing bleeding. Report any changes promptly.
2. Anticipate assisting the RN with administration of blood or blood products. Instruct Mrs. Johns in the importance of preventing injury that could cause further bleeding. Other care will be supportive.
3. Mrs. Johns will be concerned for her new baby, who is most likely on another unit or already discharged home. Allow Mrs. Johns to talk about her concerns. Arrange visits with her family and baby if permitted by her condition and her physician.

Mr. Washington

1. Because of his leukemia and his treatment, Mr. Washington is at risk for infection. If he develops an infection, he will have great difficulty getting over it. With so many visitors in the room, it is likely that one or more has a cold or virus. They may not be aware of the risk this poses to Mr. Washington. Mr. Washington is probably also fatigued because of his disease and treatment, and visiting requires energy.
2. You should kindly explain that he is very susceptible to catching colds or other illnesses and that it would be best to limit visitors to one or two at a time. Point out that persons with symptoms of colds or flu should not enter the room at all. Visits should also be brief to prevent overtiring the patient.

25

NURSING CARE OF PATIENTS WITH LYMPHATIC DISORDERS

Cheryl L. Ivey

KEY TERMS

lymphoma (lim-**FOH**-mah)
splenectomy (sple-**NEK**-tuh-mee)
splenomegaly (SPLEE-noh-**MEG**-ah-lee)

QUESTIONS TO GUIDE YOUR READING

1. What is the most distinguishing feature of Hodgkin's disease?
2. What are the differences between non-Hodgkin's lymphoma and Hodgkin's disease in terms of age of onset, symptoms, and curability?
3. What data should you collect when caring for patients with lymphatic disorders?
4. What nursing care will you provide for patients with lymphatic disorders?
5. What nursing care will you provide for patients undergoing a splenectomy?
6. What will you teach the patient undergoing therapeutic splenectomy?

Lymphatic disorders include Hodgkin's disease and the non-Hodgkin's **lymphomas**. Because the spleen is part of the lymph system, this chapter also discusses **splenectomy**.

► HODGKIN'S DISEASE

Despite its name, Hodgkin's disease (HD) is a lymphoma, which is a cancer of the lymph system. Its distinguishing feature is Reed-Sternberg cells, which make it different from all the other forms of lymphoma. HD is more prevalent in men than in women and occurs most often in young adults ages 15 to 40. After a decrease in incidence in persons ages 40 to 55, the incidence peaks again in adults older than age 55. Of all the lymphomas, HD is the most curable type, even when the disease is widely spread at the time of diagnosis.

Pathophysiology

Lymph nodes are made of tightly bound fibers and cells that serve as filtering devices for the body's immune system. Most

often, HD begins as a single changed lymph node, usually in the cervical lymph nodes of the neck. As the disease progresses, the cancer invades the lymph node chains, node by node. The path of cancer infiltration is usually the same as the path for lymph fluid flow. Left untreated, other lymphoid tissues such as the spleen become infiltrated with HD. The major organs eventually become involved with Hodgkin's disease. Common complaints of patients with organ involvement may include shortness of breath, feelings of fullness, weakness, and malaise. These organ-related symptoms usually motivate the patient to seek medical help.

A tentative diagnosis of HD is based on one or more painlessly enlarged nodes in the cervical, axillary, or inguinal areas. A biopsy of several of the enlarged nodes is performed with the intent of searching for the presence of Reed-Sternberg cells, which confirms the diagnosis.

Etiology

The exact cause of HD is unknown. A possible viral origin has been proposed; it is more common in people who have had mononucleosis. Sometimes it occurs in families, suggesting a genetic link. Patients with impaired immune function, such as those with acquired immunodeficiency

lymphoma: lymph + oma—tumor

syndrome (AIDS) or those taking immunosuppressive drugs after organ transplant are also at higher risk.

Signs and Symptoms

Painless swelling in one or more of the common lymph node chains is a usual presentation (Fig. 25-1). This swelling can range from barely perceptible to a size similar to that of a softball, occasionally even larger. The patient may complain of generalized pruritus. One other curious event, alcohol-induced pain, is occasionally present. With just a few sips of any type of alcohol-containing beverage (beer, wine, or liquor), the patient may complain of intense pain at the site of disease. Because the lymph nodes in the upper chest and neck are often involved, the patient may have symptoms of obstruction, such as cough, dysphagia, and even stridor.

Other common symptoms may include persistent low-grade fever, night sweats, fatigue, weight loss, and malaise. When these additional symptoms are present, the prognosis is worse. In older adults there may be no enlarged lymph nodes visible and these secondary symptoms may be the only presenting symptoms. Other symptoms associated with late-stage disease include edema of the neck and face, possible jaundice, nerve pain, enlargement of the retroperitoneal nodes, and infiltration of the spleen; liver and bones may also be involved.

Diagnostic Tests and Staging

Diagnosis usually begins with a lymph node biopsy of the easiest lymph node to access. Lymph node biopsies are done to check for abnormal histiocyte proliferation, nodular fibrosis, and necrosis. Other tests include bone marrow biopsy and aspiration, liver and spleen biopsies, routine chest x-ray examination, abdominal computed tomography (CT) scan to check for presence of disease in the liver and spleen, lung scan, and bone scan. In some larger cancer centers, lymphangiography may be performed to view the flow of lymph in the lymph network. This test is accomplished

by a skilled physician injecting dye into the lymph tracts located between the toes. The dye is observed as it migrates up the lymph chains, signaling blockages where present.

Hematological tests (e.g., complete blood cell count [CBC]) may show wide variability of red blood cells, indicating mild to severe anemia. The white blood cell (WBC) count is often abnormal and extreme (either very high or very low) because of bone marrow infiltration by disease. This places the patient at increased risk for infection.

These same tests are used for staging. HD is staged based on the Ann Arbor Clinical Staging Classification and is as follows:

- Stage I disease is limited to a single lymph node or site.
- In stage II disease, two or more nodes are involved on the same side of the diaphragm. Limited organ involvement may or may not be present.
- Stage III disease is characterized by nodes on both sides of the diaphragm, with or without organ involvement.
- Stage IV, the most serious form of the disease and the least curable, includes widely disseminated disease in several organs or tissues with or without associated lymph node involvement.

Medical Treatment

Appropriate therapy includes the use of radiation and chemotherapy, depending on the stage of the disease. Radiation therapy, administered on an outpatient basis over a 4- to 6-week period, can cure most patients with stage I or stage II disease. Combinations of chemotherapy and radiation therapy are used for patients with stage III and stage IV disease, with results based on the location and the stage of disease.

Nursing Care

Most nursing interventions are aimed at symptom management. If the patient is experiencing pruritis or night sweats, nursing interventions are aimed at alleviation of discomfort. These may include changing the gown and bed linens

Figure 25-1 Cervical Hodgkin's disease. (A) Young boy with extensive cervical Hodgkin's disease. (B) Appearance several years later, when axillary manifestation developed. (C) Appearance 23 years after initial treatment with radiation. (From del Regato, JA, Spjut, HJ, and Cox, JD: *Cancer: Diagnosis, Treatment, and Prognosis*, ed 6. Mosby, St Louis, 1985, with permission.)

several times a night and helping the patient remain clean and dry. Keeping the patient and family involved in the plan of care may relieve anxiety.

After the diagnosis is established, the licensed practical nurse/licensed vocational nurse (LPN/LVN) collaborates with the registered nurse (RN) to teach the patient and the family about the treatments required. Specific information regarding chemotherapy and radiation therapy is necessary. Most oncology units have helpful pamphlets or other printed material. Type and length of therapy is based on the stage of the cancer at the time of diagnosis.

Later, nursing interventions are tailored to alleviate problems that arise secondary to chemotherapy and radiation therapy. See Chapter 10 for nursing interventions for these problems. Also see Nursing Care Plan 25–1 for the Patient with Lymphoma.

Patient Teaching

In addition to the teaching needs outlined above, make sure that the patient and the family know about local chapters of the American Cancer Society and the Leukemia and Lymphoma Society. Both of these organizations have information, financial assistance, and counseling referral sources, which most patients find valuable. Another source for chemotherapy and radiation therapy information is the National Cancer Institute (NCI). The NCI can send as much information as the patient requests regarding all aspects of treatment at no charge. For more information about Hodgkin’s lymphoma, visit www.cancer.org. Or visit the Leukemia and Lymphoma Society at www.leukemia.org or the National Cancer Institute at www.nci.nih.gov.

BOX 25-1 NURSING CARE PLAN FOR THE PATIENT WITH LYMPHOMA

▶ Activity intolerance related to fatigue and anemia

PATIENT OUTCOMES

Patient will have activities of daily living (ADLs) needs met by self or caretaker.

EVALUATION OF OUTCOMES

Is patient able to carry out ADLs or are ADL needs met by a caretaker?

INTERVENTIONS

Assess amount of activity that causes fatigue.
 Assist patient with activities as necessary.
 Provide oxygen therapy as ordered.
 Instruct patient to space rest with activities.

RATIONALE

Assessment helps guide plan of care.
 The patient may need assistance with ADLs if fatigue is extreme.
 Oxygen therapy can increase oxygen levels and activity tolerance.
 Rest periods decrease oxygen need and allow patient to conserve energy for next activity.

EVALUATION

How much can patient do before becoming fatigued?
 Does the patient need assistance? Can family members assist?
 Does patient tolerate activity better with oxygen therapy?
 Is patient able to tolerate activity better after a rest period?

▶ Risk for infection related to bone marrow involvement and side effects of treatment

PATIENT OUTCOMES

Patient will have no signs or symptoms of infection.

EVALUATION OF OUTCOMES

Are signs and symptoms of infection absent? Is temperature within normal limits?

INTERVENTIONS

Assess patient for risk factors for infection.
 Monitor patient for signs and symptoms of infection, such as cough, fever, malaise, erythema, pain, or drainage and report immediately.
 Teach patient and significant other signs and symptoms of infection to watch for and report.
 Teach the patient to avoid exposure to others with influenza or other infections.
 Teach patient proper hand washing and good oral and personal hygiene.

RATIONALE

The WBC count may be very high or very low, placing the patient at risk for infection.
 Early detection and treatment of infection provides the best results.
 The patient must be involved in monitoring for infection when at home.
 Exposure increases risk for infection, especially with compromised immune function.
 These activities reduce risk of infection.

EVALUATION

Is the patient at risk? Are additional interventions indicated?
 Are signs and symptoms of infection present?
 Does patient verbalize understanding of signs and symptoms of infection and importance of reporting?
 Does patient verbalize understanding of sources of infection to avoid?
 Does patient demonstrate proper hand washing and hygiene?

BOX 25-1 NURSING CARE PLAN FOR THE PATIENT WITH LYMPHOMA—CONT'D**Risk for ineffective coping related to new diagnosis and potential lifestyle changes to accommodate treatments****PATIENT OUTCOMES**

The patient states ability to manage lifestyle changes and medical management of condition.

EVALUATION OF OUTCOMES

Does patient carry out self-care necessary to manage treatment?

INTERVENTIONS

Assess patient's level of distress related to uncertainty of the future, bothersome symptoms, changes in self-concept, and past coping mechanisms.

Assess for signs of maladaptive behaviors that interfere with responsible health practices, such as missed appointments or failure to attend to symptoms.

Assist the patient to identify support systems and resources. Refer to social worker or other community resources as needed.

Refer patient and family to a cancer survivors' support group.

RATIONALE

Obtaining information regarding past experiences helps the nurse identify and correct misconceptions. The nurse can support effective coping mechanisms that worked in the past.

Long-term survival depends on keeping therapy schedule. The ability to manage and report symptoms early keeps the patient out of the hospital and in control of his or her own life.

Resources can assist with participation in treatment plan, home care, or financial assistance.

Others who have been through treatment themselves can be a good support for patients with cancer.

EVALUATION

Is patient able to identify sources of anxiety? Are past coping mechanisms effective?

Does the patient keep appointments? Does the patient participate in self-care activities and report symptoms promptly?

Are resources identified and helpful?

Does the patient state that the support group is helpful?

CRITICAL THINKING**Jeanine**

Jeanine is a 60-year-old nurse diagnosed with stage II Hodgkin's disease. She wishes to continue working at her job on a respiratory unit at the local hospital while she undergoes treatment. What concerns do you have about this?

Answers at end of chapter.

▶ NON-HODGKIN'S LYMPHOMAS

All of the other types of lymphomas are clumped into a diverse classification known as the non-Hodgkin's lymphomas (NHLs). It is possible to sort these other types of lymphomas into different categories based on the degree of malignancy. Non-Hodgkin's lymphomas arise in the lymphoid tissues of the body, just as Hodgkin's disease does, but they differ in several ways. See Table 25-1 for a comparison of Hodgkin's and non-Hodgkin's lymphomas.

Pathophysiology

The most distinguishing difference is the absence of the Reed-Sternberg cells in non-Hodgkin's lymphomas. Instead, many of these lymphomas arise from the B cells and T cells. The B cells are involved in recognizing and destroying specific antigens. Cells specifically involved include the memory B cells and the plasma cells. The T cells also are involved in registering antigens, but there are many more kinds of T cells. These include the amplifier T cells, helper T cells, suppressor T cells, memory T cells, cytotoxic T cells, and delayed hypersensitivity T cells. An abnormality in any of these cells can result in a type of NHL. Most cases of NHL are of B-cell origin.

Etiology

The cause of non-Hodgkin's lymphomas is unclear, but some viruses, such as Epstein-Barr virus and herpesvirus, are thought to play a role in their development. Immune prob-

TABLE 25-1 HODGKIN'S DISEASE VERSUS NON-HODGKIN'S LYMPHOMA

	Hodgkin's Disease	Non-Hodgkin's Lymphomas
Age	Younger	Older
Degree of debilitation (overall)	Less	More
Presence of fever, night sweats (indicating more advanced disease)	More likely	Less likely
Spread to other areas at time of diagnosis	Local to regional area of spread	Advanced cancer—spread to many different areas
Types	Just one	Many different types

lems such as AIDS increase risk. Exposure to nuclear waste and some toxic chemicals may also increase risk.

Signs and Symptoms

Clinical features of malignant lymphomas include enlarged, painless, rubbery nodes in the cervical and supraclavicular areas; enlarged tonsils and adenoids; and occasional symptoms of dyspnea and cough. As the disease progresses, the patient may report fatigue, malaise, weight loss, and night sweats, similar to Hodgkin's disease. NHL usually progresses more rapidly than HD.

Diagnostic Tests

Diagnosis is confirmed by histological evaluation of biopsied lymph nodes, tonsils, bone marrow, liver, bowel, skin, or any other affected tissues. Other relevant tests include bone scans, chest x-ray examination, lymphangiography, liver and spleen scan, CT of the abdomen, and intravenous pyelogram to determine the extent of the disease. Laboratory tests include a CBC, which often indicates anemia; serum uric acid level; and liver function studies. Serum calcium level may be elevated if bone lesions are present.

Medical Treatment

Treatment usually involves multimodal therapy, including the use of chemotherapy and radiation therapy given in combination. Chemotherapy treatments are given on a set schedule of approximately once every month for about 6 months. These treatments may be performed on an inpatient or an outpatient basis. Radiation therapy is given to affected areas in advanced stages of NHL. Stem cell transplant may be tried in patients with advanced disease.

Nursing Care

The nurse provides emotional support by keeping the patient and family informed during the testing phase. Symptoms such as night sweats can be managed with frequent linen and gown changes. If the patient has severe anemia and is symptomatic, arrange his or her daily schedule to conserve energy. Transfuse packed red blood cells as ordered.

Give antibiotics as ordered if the patient has an infection or if the WBC count is especially low. Observe standard precautions and teach the patient and family about the need for hand washing and avoiding large crowds. Teach the patient to avoid others with colds and flu to decrease the chance of infection.

Help the patient maintain nutrition with attractively prepared meals. Involve other professionals in the care of the patient. Include the chaplain if available and if the patient is exhibiting spiritual distress. Spend time listening to the patient's concerns. Refer the patient and family to the resources listed earlier for more information.

► SPLENIC DISORDERS

The spleen is involved in a number of disorders, including cancers of the blood, lymph, and bone marrow; hereditary

conditions such as sickle cell disease; and acquired problems such as idiopathic thrombocytopenia. Under normal circumstances, the spleen is not paid much attention; it generally performs its functions without much fanfare.

If the spleen enlarges markedly, the condition is referred to as **splenomegaly**. Other times, the spleen may or may not be enlarged, but the function is out of control so that too many red blood cells and platelets are removed from the peripheral circulation. Sometimes the spleen is not able to perform its job because of bleeding into the pulp of the organ, which renders it useless. Bleeding into the spleen can occur from various illness or from trauma. Regardless of the nature of the malfunction, an occasional treatment option is splenectomy.

Splenectomy

Splenectomy is the surgical removal of the spleen. This is sometimes used to treat select hematological disorders and is also used, under different circumstances, to stage (or determine spread) in lymphomas. Splenectomy is performed fairly often in the United States, but, like any surgery, it is not without risk.

Patient Teaching

Explain to patients that this surgery removes the spleen, usually under general anesthesia. Inform patients that they can live a normal life after the surgery but that they may be more prone to infection and that they should receive the influenza vaccine each year, preferably in the early fall.

Preoperative Care

Before the surgery, ensure that the CBC and coagulation profile are completed and reported to the physician. If ordered, you may assist the RN in the transfusion of blood to correct the underlying anemia and to prepare for the loss of a great deal of blood stored in the spleen. Vitamin K is often ordered to correct clotting factor deficiencies.

Take the patient's vital signs and perform a baseline respiratory assessment. Note especially any signs of respiratory infections such as fever, chills, crackles, wheezes, or cough. If any of these are noted, make sure that the physician is aware of them because surgery may need to be delayed. Teach the patient routine coughing and deep breathing techniques to help prevent postoperative respiratory complications.

Postoperative Care

During the early postoperative period, watch carefully for bleeding, either external or internal. Be prepared to administer narcotics for pain, usually on an around-the-clock schedule so the patient is comfortable enough to deep breathe, cough, and ambulate. After narcotic administration be sure to observe for side effects, which may include incomplete pain relief or hypoventilation. Monitor for fever every 4 hours, and expect a mild, low-grade, transient fever postoperatively. A persistent fever may indicate abscess or hematoma formation.

If the surgery was performed to decrease the numbers of cells being removed from the peripheral circulation, monitor the platelet count. Often the count begins to rise in just a few days, but it may take up to 2 weeks for the platelets to normalize.

Complications

A splenectomy can cause complications such as bleeding, pneumonia, and atelectasis. Respiratory problems occur because of the spleen's position close to the diaphragm. This placement requires the need for a high surgical incision that is very painful. Often the patient tries to restrict lung expansion after surgery to keep from hurting, but this splinting behavior may leave the patient at risk for pneumonia and respiratory problems. In addition, splenectomy patients are usually more vulnerable to infection, especially influenza, because the spleen's role in the immune response is no longer filled.

Other possible complications from splenectomy include the development of pancreatitis and fistula formation. This is due to the fact that the tail of the pancreas is very close to the spleen, and irritation may have occurred.

Another serious complication is that of overwhelming postsplenectomy infection (OPSI). The causative agents in OPSI include streptococci, *Neisseria* spp., and influenza bacteria. Patients at greatest risk of OPSI may include patients

who had a splenectomy secondary to a cancer condition or during childhood.

Early symptoms of OPSI include fever and malaise that seem unremarkable. However, the infection may progress within a few hours to sepsis and death. Unfortunately, OPSI has a mortality rate as high as 70 percent. Be sure to include the signs and symptoms of OPSI in presplenectomy patient education. Also stress the need to promptly obtain medical attention for the patient at the first signs and symptoms of OPSI. The patient should be directed to continue to receive lifetime vaccinations against these bacteria.

Answers to CRITICAL THINKING

Jeanine

Jeanine will probably be fatigued from her disease, and fatigue may increase further from side effects of treatment. Staff nursing jobs can be tiring even for healthy nurses. In addition, she will be around patients with respiratory diseases, many of which are contagious. Because of risk for infection secondary to the disease process and the treatment regimen, Jeanine might want to take a leave of absence during treatment or ask to be reassigned to a different area that is less demanding and away from direct patient care until her treatments have been completed.

REVIEW QUESTIONS

- Which of the following signs is most commonly present at diagnosis with the lymphomas?
 - High fever
 - Painful lymph nodes
 - Enlarged lymph nodes
 - Abdominal pain
- Stage III Hodgkin's disease is defined as which of the following?
 - Lymphatic involvement on both sides of the diaphragm
 - Localized involvement of more than two adjacent or nonadjacent regions on one side of the diaphragm
 - Diffuse involvement of one or more extralymphatic organs or tissues such as the bone marrow or liver
 - Localized involvement of a single lymph node site, usually located in the cervical or supraclavicular area
- Which of the following interventions is appropriate for the patient at home who is at risk for infection?
 - Advise the patient to stay indoors.
 - Encourage the patient to avoid crowds.
 - Maintain strict isolation.
 - Instruct the patient to avoid blood draws.
- Which of the following circumstances places the patient at most risk for respiratory complications following a splenectomy?
 - Disturbance of clotting factors
 - Nothing by mouth (NPO) status
 - Need for frequent dressing changes
 - Location of surgical incision
- Which of the following postsplenectomy symptoms should the patient report immediately?
 - Fever and malaise
 - Pain at the incision site
 - Discomfort with coughing
 - Fatigue

QUESTIONS TO GUIDE YOUR READING

1. What are the structures of the respiratory system, and what is the function of each?
2. How does aging affect the respiratory system?
3. What questions should you ask when you take a history for a patient with a respiratory problem?
4. What findings do you expect when you inspect, palpate, percuss, and auscultate the chest?
5. What are the common diagnostic tests performed to diagnose disorders of the respiratory system?
6. What nursing care should you provide for patients undergoing each of these diagnostic tests?
7. What are common therapeutic measures used for patients with respiratory disorders?

► NORMAL ANATOMY AND PHYSIOLOGY

The respiratory system consists of the nose, nasal cavities, pharynx, larynx, trachea, bronchial tree, lungs, and respiratory muscles. The parts outside the chest cavity are collectively called the upper respiratory tract, and those within the chest cavity make up the lower respiratory tract (Fig. 26–1). The lungs are the site of gas exchange between the air and the blood; the rest of the system moves air into and out of the lungs.

Nose and Nasal Cavities

The nose is made of bone and cartilage covered with skin; hairs inside the nostrils block the entry of dust and other particles. The two nasal cavities are inside the skull and are separated by the nasal septum, which is made of the vomer and ethmoid bones. The nasal mucosa is ciliated epithelium that is highly vascular; it warms and moistens inhaled air. Dust and microorganisms are trapped on mucus produced by goblet cells and swept backward and down to the pharynx by the cilia.

The paranasal sinuses are air cavities in the maxillae and the frontal, sphenoid, and ethmoid bones that open into the nasal cavities. They are lined with ciliated epithelium, and the mucus produced usually drains into the nasal cavities. Their functions are to make the skull lighter in weight and to provide resonance for the voice.

Pharynx

The pharynx is posterior to the nasal and oral cavities and has three parts: nasopharynx, oropharynx, and laryngopharynx. The nasopharynx is an air passage above the level of the soft palate, which rises to block the nasopharynx during swallowing. The eustachian tubes from the middle ear cavities open into the nasopharynx; the adenoid is a lymph nodule on its posterior wall. The oropharynx is behind the oral cavity and is both an air and a food passage. The palatine tonsils are on the lateral walls, and together with the lingual tonsils on the base of the tongue and the adenoid, they form a ring of lymphatic tissue around the pharynx and destroy pathogens that penetrate the mucosa. The laryngopharynx is both an air and a food passage; it

Figure 26-1 Respiratory system, anterior view, with microscopic view of alveoli and pulmonary capillaries. (Modified from Scanlon, VC, Sanders, T: *Essentials of Anatomy and Physiology*, ed 3. FA Davis, Philadelphia, 1999, p 330, with permission.)

opens anteriorly into the larynx and posteriorly into the esophagus.

Larynx

The larynx is the voice box and the airway between the pharynx and trachea. It is made of nine pieces of cartilage, a firm yet flexible tissue that keeps the airway open, and is lined with ciliated epithelium. The thyroid cartilage, commonly called the Adam's apple, is the largest of these cartilage pieces and is palpable on the front of the neck. The epiglottis is the uppermost cartilage and covers the larynx like a flap when the larynx is elevated during swallowing. On either side of the glottis (the airway) are the vocal cords. When pulled together across the glottis and vibrated by exhaled air, the vocal cords produce sounds that may be turned into speech. The vagus and accessory cranial nerves are the motor nerves to the larynx.

Trachea and Bronchial Tree

The trachea is a tube 4 to 5 inches long that extends from the larynx to the primary bronchi. C-shaped pieces of cartilage in the wall keep the trachea open. The mucosa is ciliated epithelium; mucus with trapped dust and microorganisms is swept upward toward the pharynx and is usually swallowed.

The bronchial tree is the series of air passages within the lungs, a succession of progressively smaller tubes that terminate in the alveoli. The right and left primary bronchi are branches of the trachea. Each gives rise to secondary bronchi; their structure is like that of the trachea. The bronchioles, however, have no cartilage in the walls to maintain patency, and they may be closed completely by contraction of their smooth muscle.

Lungs and Pleural Membranes

The lungs fill the chest cavity on either side of the heart, extending from the clavicles to the diaphragm. On the medial surface of each lung is an indentation called the hilus, where the primary bronchus and the pulmonary artery and veins enter the lung.

The pleural membranes are the serous membranes of the thoracic cavity. The visceral pleura is the membrane that covers the lungs; the parietal pleura lines the chest cavity. A small amount of serous fluid between these membranes prevents friction and keeps the membranes together during breathing.

The functional units of the lung are the millions of alveoli, the air sacs that are the site of gas exchange. Both the alveoli and the surrounding pulmonary capillaries (see Fig. 26-1) are made of simple squamous epithelium; that is,

their walls are only one cell in thickness to permit diffusion of gases.

Each alveolus is lined with a thin layer of tissue fluid that is essential for the diffusion of gases, but the surface tension of the fluid tends to make the walls of an alveolus stick together internally. Certain alveolar cells secrete pulmonary surfactant, a lipoprotein that mixes with the tissue fluid and decreases surface tension to permit inflation. Also in the alveoli are the alveolar macrophages, which phagocytize pathogens or bits of particulate matter (such as air pollution) that have not been trapped and swept out by the cilia.

Between clusters of alveoli is elastic connective tissue; it is capable of recoil when stretched (during inhalation) and contributes significantly to normal exhalation. The recoil of this tissue ensures that normal exhalation is a passive process that does not require the expenditure of energy.

Mechanism of Breathing

Ventilation is the term for the movement of air into and out of the alveoli. Air moves from high-pressure to low-pressure areas (pressure gradients), some of which are created by the respiratory muscles, which in turn are controlled by the nervous system. The respiratory centers are in the medulla and pons. The main respiratory muscles are the diaphragm below the lungs and the external and internal intercostal muscles between the ribs. Accessory muscles of respiration are used during exercise and times of respiratory distress; these include the sternocleidomastoid and scalene muscles.

Pressures important to breathing include atmospheric pressure, intrapleural pressure, and intrapulmonic pressure. Atmospheric pressure is the pressure of the air around us, which at sea level is 760 mm Hg; atmospheric pressure decreases as altitude increases. Intrapleural pressure is in the potential pleural space between the pleural membranes. Serous fluid causes the two membranes to adhere to each other, and because the elastic lungs are always tending to collapse and pull the visceral pleura away from the parietal pleura, the pressure in this potential space is always below atmospheric pressure (about 756 mm Hg). This is called a negative pressure. Intrapulmonic pressure is the pressure inside the alveoli and bronchial tree. This pressure fluctuates below and above atmospheric pressure during each cycle of breathing.

Inhalation

Inhalation, also called inspiration, occurs when motor impulses from the medulla cause contraction of the respiratory muscles. Impulses along the phrenic nerves cause the diaphragm to contract and move downward (its dome shape flattens). Impulses along the intercostal nerves cause the external intercostal muscles to pull the ribcage upward and outward, expanding the chest cavity in all directions. This then expands the pleural membranes. Intrapleural pressure becomes even more negative, but the serous fluid keeps the membranes together and the lungs expand as well. As the lungs expand, intrapulmonic pressure falls below atmospheric pressure and air enters the nose and respiratory pas-

sages. Entry of air continues until intrapulmonic pressure equals atmospheric pressure; this is a normal inhalation. A deeper inhalation requires a more forceful contraction of the respiratory muscles to expand the chest cavity and lungs even further and permit the entry of more air.

Exhalation

Normal exhalation is a passive process that begins when motor impulses from the medulla decrease and the diaphragm and external intercostal muscles relax. The lungs are compressed as the chest cavity becomes smaller and the recoil of the elastic lung tissue compresses the alveoli. Intrapulmonic pressure rises above atmospheric pressure, and air is forced out of the lungs until the two pressures are again equal. Under normal circumstances, energy is not required for exhalation (as it is for inhalation) because the elasticity of the lungs causes recoil and forces air out. A forced exhalation beyond the normal amount is an active process that requires contraction of the internal intercostal muscles to pull the ribcage downward and inward and contraction of the abdominal muscles to force the dome of the diaphragm upward, increasing compression of the lungs.

Transport of Gases in the Blood

Oxygen is carried in the blood by iron in the hemoglobin (Hgb) of red blood cells (RBCs). The iron-oxygen bond is formed in the lungs, where the partial pressure of oxygen (PO_2) is high. In tissues where the PO_2 is low, hemoglobin releases much of its oxygen.

Most carbon dioxide is carried in the blood in the form of bicarbonate ions in the plasma. These ions are formed when carbon dioxide enters RBCs and is converted to carbonic acid (H_2CO_3), which ionizes to bicarbonate ions (HCO_3^-) and hydrogen ions (H^+). The bicarbonate ions leave the RBCs for the plasma, and the remaining hydrogen ions are buffered by the hemoglobin in the RBCs. When the blood reaches the lungs, an area of lower partial pressure of carbon dioxide (PCO_2), these reactions are reversed—carbon dioxide is reformed and diffuses into the alveoli to be exhaled.

Regulation of Respiration

Respiration is regulated by both nervous and chemical mechanisms. The medulla contains an inspiration center and an expiration center. The inspiration center generates impulses that bring about contraction of the respiratory muscles; the result is inhalation. Sensory impulses from baroreceptors in the inflating lungs to the medulla depress the inspiration center; this is called the Hering-Breuer inflation reflex and helps prevent overinflation of the lungs. In the pons the apneustic center prolongs inhalation and the pneumotaxic center helps bring about exhalation. These centers provide a normal breathing rhythm, 12 to 20 breaths per minute with exhalation slightly longer than inhalation. When there is a need for more forceful exhalations, the inspiration center activates the expiration center, which brings about contraction of the internal intercostal muscles.

Normal breathing is essentially a reflex, but because the respiratory muscles are skeletal (or voluntary) muscles, it is possible to make changes. The cerebral cortex may override the medulla to permit voluntary changes in breathing, such as faster or slower breathing, holding one's breath, or singing. Eventually, however, the medulla resumes control and breathing again becomes a reflex.

Chemical regulation of respiration involves the blood levels of oxygen and carbon dioxide. Decreased blood oxygen is detected by chemoreceptors in the carotid body and aortic body; the response by the medulla is to increase respiration to take more air into the lungs. Increased blood carbon dioxide is detected by central chemoreceptors in the medulla (actually responding to the lowered pH); the response is increased respiration to exhale more carbon dioxide, which raises the pH back toward normal.

Carbon dioxide is usually the major regulator of respiration because even small changes in its blood level change the pH. Fluctuations in oxygen level have no effect on pH, and an adequate oxygen level in the blood can be maintained even if breathing ceases for a few minutes. Residual air in the lungs is a contributing factor, as is the fact that air contains much more oxygen than we usually use (exhaled air is 16 percent oxygen), with the excess available if necessary. Oxygen becomes the major regulator only when its blood level is very low, as may occur with severe, chronic pulmonary disease.

Respiration and Acid-Base Balance

Because of its role in regulating the amount of carbon dioxide in body fluids, the respiratory system is important in the maintenance of acid-base balance, measured by blood pH. Any decrease in the rate or efficiency of respiration permits excess carbon dioxide to accumulate in the blood. Accumulation of excess hydrogen ions lowers pH. This is called respiratory acidosis and can occur as a consequence of pulmonary disease or any impairment of gas exchange in the lungs.

Respiratory alkalosis occurs when the rate of respiration increases and carbon dioxide is very rapidly exhaled. Less carbon dioxide in the blood means that fewer hydrogen ions are formed and the pH rises. Although not a common condition, respiratory alkalosis may occur during states of anxiety accompanied by hyperventilation or when accommodating to a high altitude, before RBC production increases to provide sufficient oxygenation of tissues.

The respiratory system may also help compensate for pH changes that are said to be metabolic; that is, of any cause

other than respiratory. Metabolic acidosis occurs when the concentration of hydrogen ions in body fluids is above normal. Common causes include kidney disease, untreated diabetes mellitus, and severe diarrhea. Respiratory compensation involves an increase in the rate and depth of respiration to exhale more carbon dioxide, which decreases hydrogen ion formation and raises the pH toward normal. Metabolic alkalosis may be caused by overingestion of antacid medications or by vomiting of stomach contents only. Respiratory compensation involves a decrease in the breathing rate to retain carbon dioxide in the body, increasing the formation of hydrogen ions, which lowers the pH toward normal.

Respiratory compensation for an ongoing metabolic pH imbalance (such as kidney failure) cannot be complete because there are limits to the amounts of carbon dioxide that may be exhaled or retained. At most, respiratory compensation is only about 75 percent effective.

Acid-base balance is discussed further in Chapter 5.

Effects of Aging on the Respiratory System

The respiratory muscles, like all skeletal muscles, weaken with age. Lung tissue loses its elasticity, and even alveoli are lost as their walls deteriorate. These changes result in decreased ventilation and lung capacity and a corresponding decrease in blood oxygen level. Chronic alveolar hypoxia, from diseases such as emphysema or chronic bronchitis, may lead to pulmonary hypertension, which in turn overworks the right ventricle of the heart. The cilia of the respiratory mucosa deteriorate with age, and the alveolar macrophages are not as efficient, which makes elderly people more prone to respiratory infections. See Table 26–1 for more information.

► NURSING ASSESSMENT

Health History

Many factors in a patient's personal and family history affect respiratory function. Questions to ask while assessing the patient with a history of respiratory dysfunction are presented in Table 26–2. If at any time while you're taking the history the patient relates a specific symptom, redirect the line of questioning to further assess that symptom. One such line of questioning, as presented in Chapter 1, is the WHAT'S UP? format. For example, if the patient admits to shortness of breath (SOB), respond with the following questions (*Where is it?* doesn't apply to shortness of breath, so it may be skipped):

TABLE 26-1 EFFECTS OF AGING ON RESPIRATION

Aging change	Effect
Weakened respiratory muscles	Decreased force of cough, increased work to breathe
Decreased elasticity of lung tissue	Decreased ventilation
Fewer alveoli	Decreased gas exchange, reduced activity tolerance
Deterioration of cilia	Reduced ability to raise secretions
Reduced efficiency of alveolar macrophages	Increased risk for infection

TABLE 26-2 QUESTIONS ASKED DURING NURSING ASSESSMENT OF THE RESPIRATORY SYSTEM

Question	Rationale
Do you often have headaches or sinus tenderness? Do you often experience nosebleeds?	These may indicate sinusitis. A history of nosebleeds may indicate an abnormality that can predispose to future nosebleeds.
Has your voice changed?	A voice change may indicate a variety of disorders of the nose or throat. Further investigation is necessary.
Do you ever feel short of breath, like you can't get enough air? Do you have a cough? Is it productive? What does the sputum look like?	Many respiratory and cardiac problems result in shortness of breath. A cough indicates respiratory irritation or excessive secretions. Yellow or green sputum may accompany an infection. Blood in the sputum may occur with tuberculosis, pulmonary embolism, or cancer.
Have you recently experienced night sweats, chills, fever? Do you ever feel confused, light-headed, or restless?	These are symptoms of tuberculosis. These symptoms might indicate a low PO ₂ , reducing oxygen to the brain.
Have you had any chest surgeries? Do you have any allergies that cause respiratory symptoms? How do you treat them?	This may reveal problem areas the patient has not yet mentioned. The patient may take over-the-counter medications for allergies that affect respiratory function or interact with prescribed medications.
Do you smoke? How many packs per day? For how many years? Are you exposed to secondhand smoke?	Many respiratory disorders are caused or aggravated by exposure to tobacco smoke.
Are you or have you been exposed to airborne pollutants at work?	Pollutants such as asbestos, coal dust, or chemicals can cause lung disease.
Do you take any medications or use inhalers (prescribed or over-the-counter) for your respiratory problems?	Information about medications gives further information about disorders, severity, and treatment. The nurse should also consider drug interactions and side effects.
Do you use home oxygen or other home respiratory treatments?	This helps the nurse determine the severity of disease and the treatment.
Do any of your blood relatives have emphysema, asthma, or tuberculosis?	Some respiratory disorders have a hereditary tendency. Tuberculosis is contagious.

- How does it feel? Does breathing feel tight, gasping, suffocating?
- Aggravating and alleviating factors? How much activity causes the SOB? Does anything else aggravate it? What do you do to lessen your SOB?
- Timing? When did you first experience SOB? Does it happen more at any particular time of day or year?
- Severity? Rate your SOB on a scale of 0 to 10, with 0 being easy breathing and 10 being the worst shortness of breath you can imagine.
- Useful other data? Do you have any other symptoms that occur along with the shortness of breath?
- Patient's perception? What do you think is causing your shortness of breath?

You must also be aware of cultural influences on the patient's health (Cultural Consideration Box 26-1).

Physical Assessment

Inspection

Inspection begins during the nursing history and continues during the physical assessment. Start with the nose, observing for symmetry, swelling, or other abnormalities. Note whether the patient is short of breath (dyspneic) while speaking or moving. If the patient is very dyspneic, he or she may speak in short sentences.

Observe the patient for use of accessory muscles of breathing. Use of the sternocleidomastoid muscles causes the shoulders to raise during labored inspiration. During forced expiration, the abdominal and intercostal muscles

BOX 26-1 CULTURAL CONSIDERATION

Pulmonary diseases associated with Japanese people include asthma related to dust mites in the straw mats that cover floors in Japanese homes, air pollution from living in urban areas, and cardiac and pulmonary sequelae of cigarette smoking, which is prevalent among Japanese.¹ The nurse should encourage patients who have straw mats and who wish to keep them to have them sterilized.

Patients from Poland, Ireland, or other countries where mining is a primary occupation may have an increased incidence of respiratory disease. Mining and heavy industry are health risk factors related to the development of pulmonary diseases. It is essential that health care providers carefully screen Polish and Irish immigrants for respiratory conditions.

Health care practitioners should be aware of the variations among ethnic peoples of color when assessing for cyanosis. Cyanosis and decreased blood hemoglobin levels in darker-skinned individuals gives the skin an ashen color instead of a bluish color. Thus the nurse must examine the sclera, conjunctiva, buccal mucosal, tongue, lips, nailbeds, and palms and soles of the feet to assess for lowered oxygen levels.

Smoking is deeply ingrained in the Arab-American culture. Offering cigarettes is a rite of Arab hospitality. Arabs may have difficulty stopping smoking because of these cultural rituals.²

Populations living in inner cities are at increased risk for respiratory diseases related to pollution.³ Strategies to increase the effectiveness in getting African-Americans to stop smoking include working with community and church groups in African-American communities.

Appalachians, with a preponderance of jobs in pottery making, mining, furniture making, textiles, and fabricated materials, are at increased risk for respiratory diseases.⁴ Nurses can improve the health status of their Appalachian patients by encouraging the use of face masks when working in these industries.

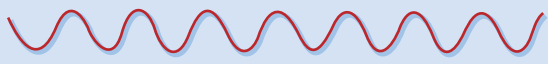

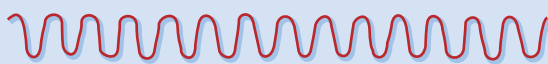

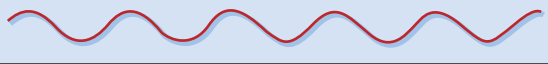

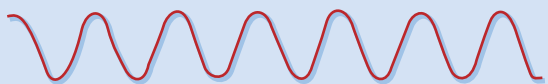

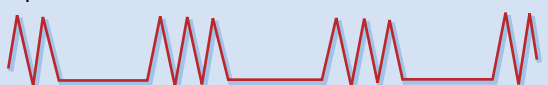

Respiratory patterns	
When assessing a client's respirations, the nurse should determine their rate, rhythm, and depth. These schematic diagrams show different respiratory patterns.	
Eupnea Normal respiratory rate and rhythm	
Tachypnea Increased respiratory rate	
Bradypnea Slow but regular respirations	
Apnea Absence of breathing (may be periodic)	
Hyperventilation Deeper respirations; normal rate	
Cheyne-Stokes Respirations that gradually become faster and deeper than normal, then slower; alternates with periods of apnea	
Biot's Faster and deeper respirations than normal, with abrupt pauses between them; breaths have equal depth	
Kussmaul's Faster and deeper respirations without pauses	
Apneustic Prolonged, gasping inspiration followed by extremely short, inefficient expiration	

Figure 26-2 Abnormal respiratory patterns. (Modified from Morton, PG: Health Assessment in Nursing, ed 2. FA Davis, Philadelphia, 1993, p 98, with permission.)

contract. The use of accessory muscles for breathing indicates respiratory distress. Retraction of the chest wall between the ribs can indicate serious distress.

Note color of skin, lips, mucous membranes, and nailbeds. A bluish color is called **cyanosis** and is a late sign of oxygen deprivation. Observe the trachea and chest for symmetry. Count respirations per minute, noting depth and rhythm. Irregular respirations, or periods of **apnea**, can indicate a pathological condition and are described in Figure 26-2. Observe the shape of the chest. Normally the chest is about twice as wide (side to side) as it is deep (front to back). If it is more rounded, it is called a barrel chest, which is associated with air trapping.

Palpation

Palpate the frontal and maxillary sinuses if sinus inflammation is suspected (Fig. 26-3). Use your thumbs to palpate gently below the eyebrows and below each cheekbone. Tenderness may indicate sinus inflammation or infection.

Respiratory excursion can be palpated. This is a rough measurement of chest expansion on inspiration. It is not necessary to palpate expansion on every patient, but it may be helpful if hypoventilation or asymmetry is suspected. See Figure 26-4 for how to palpate respiratory excursion. You can also palpate for **crepitus** (also called subcutaneous emphysema). Crepitus feels like Rice Krispies under the skin when felt with the fingers. It occurs when

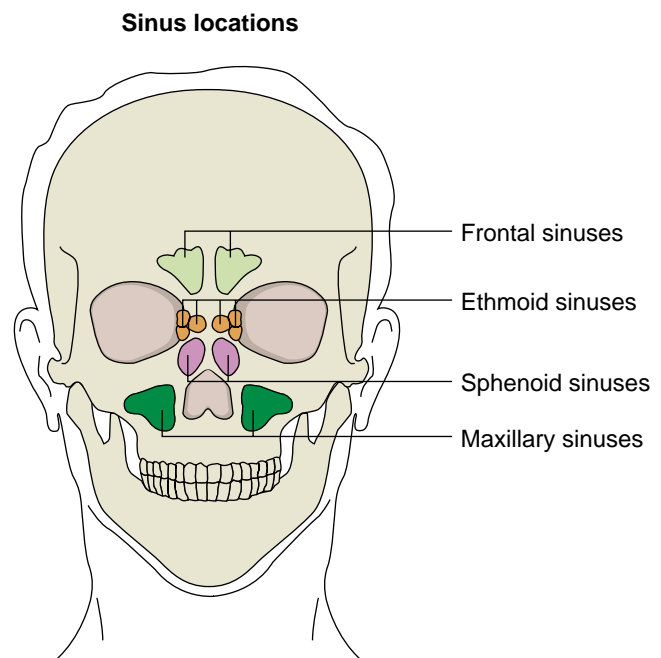

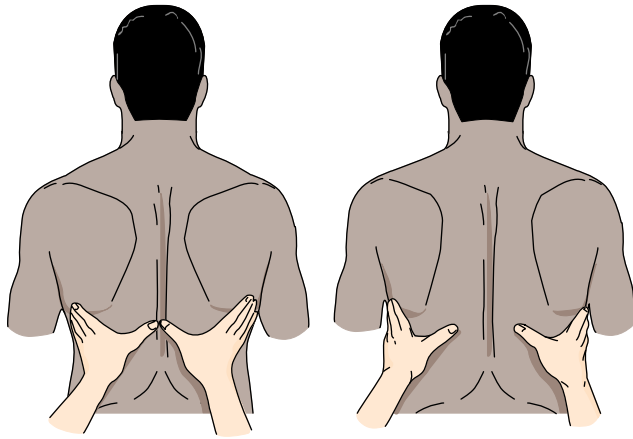

Figure 26-3 Paranasal sinuses. (Modified from Morton, PG: Health Assessment in Nursing, ed 2. FA Davis, Philadelphia, 1993, p 194, with permission.)

cyanosis: cyan—dark blue + osis—condition
apnea: a—not + pnea—breath

Posterior respiratory excursion

Stand behind the patient and place your thumbs beneath the scapulae area on either side of the spine at the level of the tenth rib. Grasp the lateral rib cage and rest your palms gently over the lateroposterior surface. Avoid applying excessive pressure to prevent restricting the patient's breathing.

As the patient inhales, the posterior chest should move upward and outward and your thumbs should move apart. When the patient exhales, your thumbs should return to midline and again touch.

Figure 26-4 Palpation of respiratory excursion. (Modified from Morton, PG: *Health Assessment in Nursing*, ed 2. FA Davis, Philadelphia, 1993, p 267, with permission.)

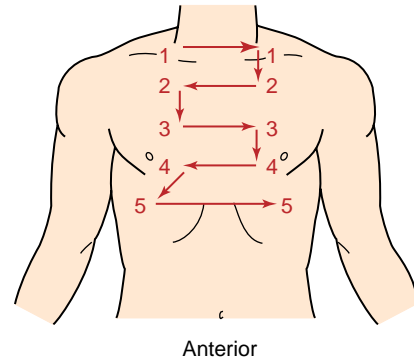

air leaks into subcutaneous tissues because of pneumothorax or a leaking chest tube site. Palpation for crepitus is not done routinely, but rather when the possibility of an air leak exists.

Percussion

Percussion is done by the experienced nurse. It involves tapping on the anterior and posterior chest, in each interspace, and comparing sounds from side to side. A normal chest sounds resonant and is the same on both the right and left sides, except over the heart. If other percussion notes are heard, they may indicate a pathological condition and should be reported. See Chapter 1 for additional information on percussion.

Auscultation

Auscultation provides valuable information about respiratory status. Use the diaphragm of the stethoscope to listen to the anterior and posterior chest during an entire inspiration and expiration at each interspace (Fig. 26-5). Auscultation of the posterior chest is easiest if the patient is sitting, but if necessary it may be done with the patient in a side-lying position. Asking the patient to breathe deeply through the mouth can help enhance the sounds. Allow the patient to rest at intervals to prevent hyperventilation. Regular and frequent practice helps you learn to distinguish normal from abnormal breath sounds. Abnormal extra sounds (another term is **adventitious**) indicate a pathological condition and are described in Table 26-3.

Anterior

Lateral

Posterior

Figure 26-5 Auscultation of the chest. Use a systematic approach to auscultate the chest, comparing sounds from side to side. (Modified from Morton, PG: *Health Assessment in Nursing*, ed 2. FA Davis, Philadelphia, 1993, p 268, with permission.)

CRITICAL THINKING

Timothy

Timothy is a 16 year old brought into the emergency room by his mother because of an asthma attack. He says he feels short of breath, but when you listen to his lungs you hear no wheezing.

1. Does Timothy really need to be in the emergency room?
2. What should you do?
3. What do you think could be happening?

Answers at end of chapter.

TABLE 26-3 ABNORMAL LUNG SOUNDS

Abnormal (Adventitious) Sound	Cause of Sound	Description	Associated Disorders
Coarse crackles (sometimes called rales)	Fluid in airways	Moist bubbling sound, heard on inspiration or expiration	Pulmonary edema, bronchitis, pneumonia
Fine crackles (rales)	Alveoli popping open on inspiration	Velcro being torn apart, heard at end of inspiration	Heart failure, atelectasis
Wheezes	Narrowed airways	Fine high-pitched violins mostly on expiration	Asthma
Stridor	Airway obstruction	Loud crowing noise heard without stethoscope	Obstruction from tumor or foreign body
Pleural friction rub	Pleura rubbing together	Sound of leather rubbing together, grating	Pleurisy, lung cancer, pneumonia, pleural irritation
Diminished	Decreased air movement	Faint lung sounds	Emphysema, hypoventilation, obesity, muscular chest wall
Absent	No air movement	No sounds heard	Pneumothorax, pneumectomy

► DIAGNOSTIC TESTS

Laboratory Tests

Blood Tests

Measurement of red blood cells and hemoglobin can give information about the oxygen-carrying capacity of the blood. **Dyspnea** can be caused by a reduction in RBCs or Hgb. See Table 26-4 for normal values.

Sputum Culture and Sensitivity

A sputum culture identifies pathogens present in the sputum. The sensitivity test determines which antibiotics will be effective against those pathogens. To obtain a sputum specimen, first obtain a sterile container. Some institutions have special containers for sputum that help prevent transmission of infection to the health care worker (Fig. 26-6). Instruct the patient to take several deep breaths and cough sputum into the sputum container. It is important that the patient does not simply spit saliva or sinus drainage into the cup. The specimen must come from the lungs. It may be easiest to obtain a specimen first thing in the morning (after mouth care) because secretions build up during the night.

dyspnea: dys—bad + pnea—breathing

TABLE 26-4 COMMON LABORATORY TESTS

Test	Normal Values	Associated Conditions
Red blood cell count	Male: 4.5–6.2 million Female: 4.2–5.4 million cells/mm ³ venous blood	↑ in chronic lung disease, dehydration ↓ in anemia, hemorrhage, overhydration with intravenous fluids
Hemoglobin	Male: 13.5–18 g/dL Female: 12–16 g/dL	Same as RBC count
White blood cell count	5000–10,000 cells/mm ³ venous blood	↑ in infection

Figure 26-6 A special container that helps prevent transmission of infection is often used to collect sputum for culture. (Photo courtesy Becton Dickinson Microbiology Systems.)

The specimen is sent to the laboratory immediately. If the patient is unable to cough up sputum, extra fluids or a bedside humidifier may help. A respiratory therapist (RT) may be able to help obtain a specimen with a nebulized mist treatment or with a special suction catheter with a sputum trap. A physician order may be needed for these procedures.

LEARNING TIPS

If the physician orders a “sputum for AFB,” tuberculosis is suspected, which is caused by an acid-fast bacillus. Ask whether the patient should be isolated while waiting for test results.

Throat Culture

A throat culture is done to determine the presence of viral or bacterial pathogens in the pharynx. Use a culture tube with an attached swab (Culturette) to reach into the phar-

ynx (without touching the patient’s mouth) and rub the red area or lesions. Use a tongue blade to help hold the tongue down while obtaining the culture. Once the culture is obtained, squeeze the end of the culture tube to release the culture medium and return the swab to the tube. Send it immediately to the laboratory for analysis.

Arterial Blood Gas Analysis

Arterial blood gases (ABGs) are measured to determine the effectiveness of gas exchange. The “Pa” portion of the ABG results refer to the partial pressure of the gas in arterial blood. See Table 26–5 for a basic interpretation of ABGs. The blood sample is usually taken from the radial artery in the wrist by a physician or laboratory technician specially trained to do this. This can be painful for the patient. You may be asked to place pressure on the site for 5 minutes after the test to prevent bleeding.

LEARNING TIPS

Remember 50. If the PaO₂ falls below 50 and the PaCO₂ is above 50, the patient is in trouble and the physician should be notified. This is a crude analysis, but it is helpful when a quick assessment is needed.

Oxygen Saturation

The oxygen saturation test (also called pulse oximetry, O₂ sat, and SaO₂) is simple and noninvasive. A sensor is placed on the patient’s finger or ear that measures the percentage of hemoglobin that is saturated with oxygen. Oxygen saturation can be measured at rest or while the patient is walking to determine the patient’s exercise tolerance. It is also often done with and without supplemental oxygen to determine the patient’s need for oxygen supplementation at

home. See Table 26–5 for normal values. An SaO₂ value below 95 percent should be reported to the physician. If the SaO₂ is less than 75 percent, prepare for emergency intervention.

Other Tests

Chest X-ray Examination

A chest x-ray examination may be ordered to help diagnose a variety of pulmonary disorders. Usually, posterior-anterior (PA) and side views (lateral) are taken. If a hospitalized patient is too ill to go to the radiology department, a portable chest x-ray machine can be used to obtain a PA view.

Ventilation-Perfusion Scan

During a ventilation-perfusion scan (also called a lung scan or VQ scan), a radioactive substance is injected intravenously and a scan is done to view blood flow to the lungs (perfusion). Another radioactive substance is inhaled, and scanning shows how well oxygen is distributed in the lungs (ventilation). If an area of the lungs is well ventilated but has no blood supply, a pulmonary embolism is suspected. Chronic lung disease may cause poor ventilation and perfusion.

Pulmonary Function Studies

Pulmonary function studies are a series of tests done to determine lung volume, capacity, and flow rates. These are commonly used to help diagnose and monitor restrictive or obstructive lung disease. The patient is asked to use a special mouthpiece to blow into a cylinder that is connected to a computer. A computer printout is generated to show the results. See Table 26–6 for normal values. Some patients use handheld peak expiratory flow rate (PEFR) meters at home to monitor asthma symptoms. They might notice changes in PEFR before symptoms occur, allowing them to begin treatment before the problem becomes more serious.

Pulmonary Angiography

Pulmonary angiography involves an x-ray examination of the pulmonary vessels after intravenous (IV) administration of a radiopaque dye. A catheter is inserted into the femoral, brachial, or jugular vein and threaded through the heart to the pulmonary artery, where the dye is injected. Pulmonary angiography is used to help diagnose pulmonary embolism or other pulmonary vessel disorders. Patients receive nothing by mouth (NPO) for 4 to 8 hours before the procedure. Question the patient about allergies to x-ray dyes before scheduling the test. As with any procedure involving dye, the patient is informed that the dye may cause a warm feeling when injected. A signed consent form is required before any invasive procedure is performed. Medications may be administered before or during the test for patient comfort.

After angiography, place the patient flat in bed for 3 to 8 hours, as ordered by the physician. Monitor vital signs and observe the injection site for bleeding. A sandbag may be used to place pressure on the site. Encourage fluid intake to promote excretion of the dye.

TABLE 26-5	ARTERIAL BLOOD GAS ANALYSIS	
	Normal Values	Interpretation
PaO ₂	75–100 mm Hg	↑ in hyperventilation ↓ in impaired respiratory function
PaCO ₂	35–45 mm Hg	↑ in impaired gas exchange ↓ in hyperventilation
PH	7.35–7.45	↑ in respiratory alkalosis with low PaCO ₂ ↓ in respiratory acidosis with high PaCO ₂
HCO ₃ ⁻	22–26	↑ to buffer PaCO ₂ in acidosis ↓ to buffer PaCO ₂ in alkalosis
Oxygen saturation	95–100%	↑ in hyperventilation ↓ in impaired respiratory function

TABLE 26-6 PULMONARY FUNCTION VALUES

Test	Definition	Normal Values*
Tidal volume (TV)	Air inspired and expired in one breath	400–600 mL at rest
Residual volume (RV)	Air remaining in lungs after maximum exhalation	1000–1500 mL
Functional residual capacity (FRC)	Air remaining in lungs after normal expiration	2300 mL
Vital capacity (VC)	Maximum amount of air expired after maximum inspiration	4600 mL
Inspiratory reserve	Amount of air beyond tidal volume that can be taken in with the deepest possible inhalation	2000 to 3000 mL
Expiratory reserve	Amount of air beyond tidal volume in the most forceful exhalation	1000 to 1500 mL
Forced vital capacity (FVC)	Maximum amount of air expired forcefully after maximum inspiration	3000–5000 mL
Peak expiratory flow rate (PEFR)	Maximum flow of air expired during FVC (this is a rate rather than a volume)	450 L/min

*Normal values are approximate—computer determines normal values based on patient's height and weight.

Bronchoscopy

A bronchoscopy involves the use of a flexible endoscope to examine the larynx, trachea, and bronchial tree. A bronchoscopy can be used diagnostically for visualization or to obtain a biopsy specimen for examination. It can also be used therapeutically to remove an obstruction, foreign body, or thick secretions. The patient is told that he or she will be able to breathe through the nose and that oxygen can be administered through the tube if necessary. A signed consent is necessary for this procedure.

The patient is NPO for 6 to 8 hours before the procedure. Be prepared to administer a sedative, and commonly an injection of atropine to dry excess secretions, before the procedure. An anesthetic spray may be used to numb the throat. After the test, monitor vital signs and watch for signs of laryngeal edema. Sputum may be blood tinged. The patient is NPO until the gag reflex returns. Check for the gag reflex by touching the pharynx with a cotton swab. Once the gag reflex is positive, ask the patient to swallow a sip of water before offering foods or fluids. A sore throat may be relieved with lozenges.

► THERAPEUTIC MEASURES

Smoking Cessation

Probably the most important intervention for preventing and treating respiratory disease is smoking cessation. Many respiratory disorders are caused or aggravated by smoking, and stopping can prevent disease from occurring or slow its progression significantly. See Table 26-7 for interventions used to help patients stop smoking. Remind patients that if they have tried quitting before and failed, that does not mean that they will never be able to quit. Many patients try

several times before quitting successfully. Formal smoking cessation programs and support groups can be helpful.

Many internet sites have information to help people stop smoking. Among these are the American Lung Association site at www.lungusa.org and the National Lung Health Education Program at www.nlhep.org. Or simply type *smoking cessation* into any search engine.

Deep Breathing and Coughing

Effective coughing can keep the airways clear of secretions. An ineffective cough is exhausting and fails to bring up secretions. Instruct the patient to take two or three deep breaths, using the diaphragm. This helps get the air behind the secretions. After the third deep inhalation, tell the patient to hold the breath and cough forcefully. This is repeated as necessary. Good hydration can facilitate this process.

Breathing Exercises

Breathing exercises are essential for patients with chronic lung disease. Diaphragmatic and pursed-lip breathing increase the effectiveness of breathing and help reduce panic when dyspnea occurs.

Diaphragmatic Breathing

The diaphragm is the major muscle of breathing, but patients often use less efficient accessory muscles when they are short of breath. Conscious use of the diaphragm during breathing can be relaxing and conserves energy. With practice, the patient should be able to use diaphragmatic breathing all the time without thinking about it. The patient is taught to do the following:

TABLE 26-7 INTERVENTIONS TO STOP SMOKING

Intervention	Rationale
Counseling	Counseling alone can result in a 3–5% quit rate.
Setting a quit date	The cold turkey method is more effective than slow tapering, although the patient may choose to taper before the quit date.
Nicotine replacement	Nicotine gum and patches are available without a prescription and can reduce withdrawal symptoms.
Drug therapy (bupropion [Zyban], buspirone [BuSpar])	Better success rates are achieved with a combination of nicotine and bupropion.

Source: Modified from Petty, TL: COPD: Interventions for smoking cessation and improved ventilatory function. *Geriatrics* 55(12):30–39, 2000.

1. Place one hand on the abdomen and the other on the chest.
2. Concentrate on pushing out the abdomen during inspiration and relaxing the abdomen on expiration. The chest should move very little.

Pursed-Lip Breathing

This technique can be used any time the patient feels short of breath. It helps keep airways open during exhalation, which promotes carbon dioxide excretion. It should be done with diaphragmatic breathing. Counting during breathing also distracts the patient, reducing panic. The patient is taught to do the following:

1. Inhale slowly through the nose to the count of two.
2. Exhale slowly through pursed lips to the count of four.

Positioning

The patient who is short of breath should be positioned to conserve energy while allowing for maximum lung expansion. The patient in bed can use a Fowler's or semi-Fowler's position. Most respiratory patients do not tolerate lying flat. Some patients prefer to sit in a chair while leaning forward and placing their elbows on their knees. Others may sit at a desk or use an over-bed table with a pillow on it to lean on.

Recent research shows that in patients with unilateral (one-sided) lung disease, oxygen saturation is increased in the "good lung down" lateral position. This is a side-lying position with the good lung in the dependent position. Researchers believe that gravity causes greater blood flow to the dependent, "good" lung, thereby increasing oxygenation.

Oxygen Therapy

Oxygen therapy is ordered by the physician when the patient is unable to maintain oxygenation. Many patients are placed on supplemental oxygen when their oxygen saturation is less than 90 percent on room air. The physician's order should include the method of administration and the flow rate. A variety of delivery methods are described in the following sections. The role of the nurse in oxygen therapy includes monitoring the flow rate, ensuring that the cannula and tubing or other device remain properly placed, and monitoring the patient's response to treatment. If the patient becomes short of breath while on oxygen therapy, an RT or a physician should be notified. Instruct the patient to avoid smoking, using electrical equipment, and performing other activities that can cause fire in the presence of oxygen. The RT is knowledgeable about oxygen therapy and is an excellent resource when questions arise.

LEARNING TIPS

If a patient suddenly becomes confused, check the oxygen delivery system. The patient may have taken off the cannula, or the tubing may be kinked or disconnected, resulting in hypoxia and confusion.

Low-Flow Devices

NASAL CANNULA. The nasal cannula is the most common method of oxygen administration. Oxygen is delivered through a flexible catheter that has two short nasal prongs (Fig. 26–7). For the nasal cannula to be most effective, the patient must breathe through his or her nose. The cannula allows the patient to eat and talk, and it is generally more comfortable than other methods of administration. If the nasal mucous membranes become dry, an RT can place a water source on the system to humidify the oxygen. Oxygen can be delivered at 1 to 6 L/minute via a nasal cannula, according to the physician's order.

MASKS. Masks are used when a higher oxygen concentration is needed (Fig. 26–8). A disadvantage to masks is that they make some patients feel claustrophobic. Also, a mask must be replaced by a cannula for eating.

Simple Face Mask. A rate of 5 to 10 L/minute can deliver oxygen concentrations from 40 to 60 percent with a simple face mask.

Partial Rebreather Mask. A partial rebreather mask uses a reservoir to capture some exhaled gas for rebreathing. Vents on the sides of the mask allow room air to mix with oxygen. It can deliver oxygen concentrations of 50 percent or greater.

Nonrebreather Mask. A nonrebreather mask has one or both side vents closed to limit the mixing of room air with oxygen. The vents open to allow expiration but remain closed on inspiration. The reservoir bag has a valve to store oxygen for inspiration but does not allow entry of exhaled air. It is used to deliver oxygen concentrations of 70 to 100 percent.

When a patient is using a partial rebreather or nonrebreather mask, ensure that the reservoir is never allowed to collapse to less than half full.

Figure 26-7 Nasal cannula for oxygen delivery.

Figure 26-8 Oxygen masks. (A) Simple mask. (B) Partial rebreather mask. (C) Nonbreathing mask. (D) Venturi mask.

High-Flow Devices

VENTURI MASK. A Venturi mask is used for the patient who requires precise percentages of oxygen, such as the patient with chronic lung disease with CO_2 retention. A combination of valves and specified flow rates determines oxygen concentration.

Transtracheal Catheter

A transtracheal catheter is a small tube that is surgically placed through the base of the neck directly into the trachea to deliver oxygen (Fig. 26-9). This is an attractive alternative for some patients who are on long-term oxygen therapy at home, because it does not obstruct the nose or mouth and can be easily covered with a loose scarf or collar. The patient is taught to remove and clean the catheter two or three times a day to prevent mucus obstruction. Check

institution policy and procedure and the respiratory care department for specific care instructions.

Risks of Oxygen Therapy

Patients with chronic airflow limitation (CAL) have chronically high PaCO_2 levels. Therefore they depend on low PaO_2 levels to stimulate breathing, and high supplemental oxygen flow rates can depress respirations. Patients with CAL should be maintained on no more than 1 to 2 L of oxygen per minute.

In addition, any patient can suffer lung damage from high oxygen concentrations delivered for more than 24 hours. If a patient exhibits symptoms of dry cough, chest pain, numbness in the extremities, lethargy, or nausea, the physician should be contacted. A PaO_2 greater than 100 mm Hg should also be reported.

Figure 26-9 Transtracheal oxygen catheter.

Nebulized Mist Treatments

Nebulized mist treatments (NMTs) use a nebulizer to deliver medication directly into the lungs (Fig. 26-10). Such topical use of medication reduces systemic side effects. Bronchodilators such as albuterol or metaproterenol, mixed with normal saline solution and sometimes with supplemental oxygen, are most commonly administered. Other medications, including corticosteroids, mucolytics, and antibiotics, may also be given. An RT or a specially trained nurse administers the NMT. The patient uses a handheld reservoir with tubing and a mouthpiece to breathe in the medication. NMTs are commonly ordered every 4 to 6 hours and as needed. You may call for an NMT as needed (prn) when a patient with chronic pulmonary disease becomes acutely dyspneic. Some patients are taught to administer their own NMTs at home.

Metered Dose Inhalers

Metered dose inhalers (MDIs) are another way to administer topical medication directly into the lungs, minimizing systemic side effects. Medications delivered in this way in-

Figure 26-10 Patient receiving nebulized mist treatment.

clude corticosteroids, bronchodilators, and mast cell inhibitors (cromolyn sodium). Figure 26-11 shows one way to use an MDI. An alternate method is the open-mouth technique, in which the patient keeps the mouth open in step 3 rather than closing the lips around the inhaler. It is important that the RT or nurse carefully instruct the patient, because improper use can reduce the effectiveness of the medication. It is also important to teach the patient to never overuse adrenergic bronchodilator inhalers. Patients with chronic disease tend to use extra puffs when they feel short of breath. Adrenergic bronchodilators, when used too often, can cause severe bronchoconstriction and even death.

Incentive Spirometry

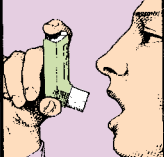

Incentive spirometers are devices used to encourage deep breathing in patients at risk for collapse of lung tissue, a condition called atelectasis (Fig. 26-12). These devices are

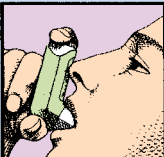

PHARMACIST—DETACH HERE AND GIVE INSTRUCTIONS TO PATIENT

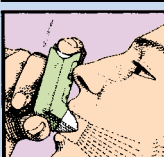

Information For The Patient

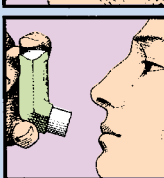

INTAL® INHALER (cromolyn sodium inhalation aerosol)
Metered Dose Inhaler

- 

1. Make sure the canister is properly inserted into the Inhaler unit. Take the cover off the mouthpiece. **Shake the Inhaler gently.**
- 

2. Hold Inhaler and breathe out slowly. **Do not breathe into the Inhaler** – it could clog the Inhaler valve.
- 

3. Place the mouthpiece into your mouth, close your lips around it, and tilt your head back. Keep your tongue below the opening of the Inhaler.
- 

4. Press the top of the metal canister down firmly and breathe in through your mouth **at the same time.**
- 

5. Remove the Inhaler from your mouth. Hold your breath for several seconds, then breathe out slowly. This step is very important. It allows the INTAL to spread throughout your lungs. Repeat steps 2-5, then replace the mouthpiece cover.

Figure 26-11 Sample instructions for use of a metered dose inhaler. Patient instructions for Intal inhaler. (Reprinted with permission from Rhône-Poulenc Rorer Pharmaceuticals, Inc. © 1996, Fisons Corporation, a Rhône-Poulenc Rorer company. All rights reserved. See package insert for specific product instructions.)

Figure 26-12 Incentive spirometers. (A) Voldyne volumetric deep breathing exerciser. (B) Triflow II incentive breathing exerciser. (Modified from Barnes, TA: *Respiratory Care Principles*. FA Davis, Philadelphia, 1991, p 434, with permission.)

commonly ordered for postoperative patients. Patients are instructed to use the spirometer 10 times each hour they are awake. Because a variety of spirometers are available, consult with an RT and read package inserts for specific directions for use.

Chest Physiotherapy

Chest physiotherapy (CPT), which includes postural drainage, percussion, and vibration, helps move secretions from deep inside the lungs (Fig. 26-13). It is indicated for the patient who has a weak or ineffective cough and is therefore at risk for retaining secretions. Patients with chronic obstructive pulmonary disease, cystic fibrosis, or bronchiectasis and patients on ventilators benefit from CPT.

Figure 26-13 Patient receiving chest physiotherapy.

CPT is performed by an RT or specially trained nurse. For postural drainage, the patient is placed in various positions (head down, to help drain secretions) and turned periodically during the treatment so all lobes of the lungs are drained. The therapist uses cupped hands to strike the chest repeatedly (percussion), producing sound waves that are transmitted through the chest, loosening secretions. The therapist may also apply vibration to the patient's chest, using the hands or a vibrator, to loosen secretions. A nebulizer treatment should be given before CPT to humidify secretions. The patient is instructed to cough and deep breathe at intervals during and after the treatment.

Flutter Mucus Clearance Device

An alternative to chest physiotherapy is a small handheld device called the Flutter mucus clearance device. When the patient blows into the mouthpiece, it makes a heavy steel ball inside bounce around in its chamber, which then sends vibrations back into the airways. This helps to loosen mucus and open the airways.

Thoracentesis

Thoracentesis involves the insertion of a needle into the pleural space. It is commonly done to aspirate fluid in patients with pleural effusion (fluid trapped in the pleural space). The procedure may be diagnostic, to determine the source of fluid, or therapeutic, to remove fluid and reduce respiratory distress. It may also be performed to aspirate blood or air or to inject medication.

When assisting a physician with a thoracentesis, first verify that the patient understands the procedure and that written consent has been obtained if required by institution policy. Have the patient void before the procedure. The patient should be aware that a sensation of pressure may be felt, but that severe pain is rare. An analgesic may be administered if ordered before the procedure. A special procedure tray is obtained that has the equipment needed by the

thoracentesis: thoraco—chest + centesis—puncture

physician. The patient is placed in a sitting position, bending over the bedside table, or in a side-lying position if unable to sit. You can position yourself in front of the patient and encourage relaxation during the procedure. If you are asked to hand equipment to the physician, be sure to keep everything sterile. The physician uses a local anesthetic before inserting a needle into the patient's back through the desired interspace. Specimens are withdrawn through the needle, labeled, and sent to the laboratory. If the thoracentesis is being done for therapeutic reasons, a sterile container is used to collect the remaining fluid. As much as 2 L can be removed, sometimes more, and the patient will report immediate reduction of dyspnea.

After the procedure, the physician may apply a petroleum jelly dressing to prevent air leakage into the wound. Assess vital signs, breath sounds, and the puncture site according to the physician's orders (e.g., every 15 minutes times two, every 30 minutes times two, then every 4 hours for 24 hours). The patient is usually maintained on bedrest for 1 hour after the procedure. Label and send specimens to the laboratory as ordered. The physician may order a post-procedure x-ray examination to ensure that the lung was not punctured, causing a pneumothorax.

Chest Drainage

Continuous chest drainage involves insertion of one or two chest tubes by the physician into the pleural space to drain fluid or air. The tubes are connected to a chest drainage system that collects the fluid or allows escape of the air.

Indications

Chest tubes and a chest drainage system are used when fluid or air has collected in the pleural space. This can occur with a pneumothorax, pleural effusion, or penetrating chest injury or during chest surgery. These conditions are covered in Chapter 28.

Chest Tube Insertion

The physician inserts drainage tubes through the chest wall into the pleural space, either in surgery or at the bedside. If removal of air is the goal, the tube is inserted into the upper anterior chest, in the second to fourth intercostal space. If removal of fluid is the goal, the tube is inserted in the lower lateral chest, in the eighth or ninth intercostal space. If a patient has both air and fluid to drain, two tubes are inserted and may be joined with a Y connector before connecting to the tubing that leads to a drainage system. You can assist the physician by obtaining a chest tube insertion tray and chest drainage system and preparing it according to the manufacturer's directions. Ensure that the patient understands the procedure and that written consent has been obtained according to institutional policy. An analgesic is administered if ordered. Chest tube insertion is sometimes an emergency intervention, which necessitates that the nurse help prepare the patient quickly.

Once the tube has been inserted and the system is in place, ensure that each connection is securely taped with

adhesive tape, to prevent a break in the system. Vaseline gauze and a sterile occlusive dressing are applied over the insertion site to prevent air leakage.

Obtain two padded clamps to keep at the bedside. These are used to clamp the chest tube if the chest drainage system becomes accidentally disconnected from the tubing, for changing the drainage system, or for a trial period before chest tube removal. The tubes are never clamped for more than a few seconds, however, because this prevents air escape and causes buildup of air in the pleural space. This creates a tension pneumothorax, which is a life-threatening emergency. (See Chapter 28.)

Chest Drainage System

The drainage system has evolved from a set of glass bottles to a one-piece molded plastic system with chambers that correspond to the bottles. Some newer one-piece systems use special valves to eliminate the need for water. Some physicians, however, continue to use the bottle system. Studying the bottle system helps to understand the one-piece system (Fig. 26-14). One, two, or three bottles can be used. Study the pictures as you read the following sections.

WATER SEAL BOTTLE OR CHAMBER. Each time the patient exhales, air trapped in the pleural space travels through the chest tube to the water seal bottle or chamber, under the water, then bubbles up and out of the bottle. The water acts as a seal, allowing air to escape from the pleural space but preventing air from getting back in during the negative pressure of inspiration. Water in the tube fluctuates up with each inspiration and down with each expiration, as much as 5 to 10 cm. This is called **tidaling**. When the lung is reinflated, tidaling stops. If tidaling stops before the lung is reinflated, the tubing should be checked for a

Figure 26-14 Pleur-Evac chest drainage system. (Courtesy Deknatel Snowden Pencer, Inc., Tucker, Ga.)

kink or occlusion. If constant bubbling occurs in the water seal chamber, the system should be checked immediately for leaks.

SUCTION BOTTLE OR CHAMBER. Sometimes a suction source is used to speed lung reinflation. A separate bottle with tubing attached to suction is used. The amount of suction depends on the level of water in the bottle, not the amount of suction set on the machine. The suction level is ordered by the physician and is almost always negative 20 cm of water. The suction should be turned on far enough to cause gentle bubbling in the suction bottle or chamber. Vigorous bubbling causes water evaporation and alter the amount of suction. If water evaporates, more must be added to maintain the correct amount of suction.

DRAINAGE BOTTLE OR CHAMBER. Sometimes a third bottle is needed to drain fluid from the pleural space. Drainage may be from pleural effusion, chest trauma, or surgery. Sometimes a small amount of drainage occurs because of the insertion of the chest tube. The drainage chamber is not emptied to measure drainage. Rather, the drainage level in the bottle or chamber is marked and timed each shift to monitor the amount. It is documented as output on the intake and output record. If drainage suddenly increases or becomes very bloody, notify the physician.

Nursing Care

Nursing care of a patient with a chest tube involves regular assessment of the patient and the drainage system. See Box 26–2 for specific assessment and care. If permitted by the physician, patients can be free to move around with the chest tube and drainage system. The drainage system must always be kept upright and below the level of the chest. If the patient must be transported, the drainage system is transported with the patient. Ask the physician if the patient can be safely transported without suction. The suction control chamber is then left open to allow air to escape. Tubing is not clamped for transport.

If a chest tube is accidentally pulled out before the pneumothorax is resolved, air can reenter the pleural space. Some physicians want an occlusive dressing placed over the site to prevent air from reentering. However, an occlusive dressing increases the risk of trapped air building up and placing pressure on the heart. You should be aware of the preferences of the patient's physician.

Stripping and Milking

In the past it was routine to strip and milk the tubing from the patient to the drainage system, to dislodge clots and maintain patency. Stripping is done by holding the proximal end of the tubing and using the other hand to squeeze the tubing between two fingers while sliding the fingers toward the drainage system. This is repeated on small sections of tubing until all have been stripped. It is now known, however, that this process can create negative pressure at the openings in the tubing that are within the pleural space, which can suck lung tissue in and cause damage. Stripping should be done only if it is ordered by the physician.

BOX 26–2 Care of the Patient with a Chest Drainage System

Assess the patient according to institution policy. Start with the patient and move toward the drainage system.

1. Observe respiratory rate, effort, and symmetry.
2. Assess shortness of breath, pain, or other discomforts.
3. Auscultate lung sounds (lung sounds may initially be muffled or absent on the side of a collapsed lung but should gradually return to normal as the lung reinflates).
4. Confirm that dressing is intact; observe for drainage. If necessary, reinforce the dressing and notify the physician. Do *not* change the dressing.
5. Palpate around insertion sites for crepitus.
6. Check all tubing for kinks, breaks, or broken connections. Verify that all connections are securely taped.
7. Ensure that there are no dependent loops of tubing. Excess tubing should be coiled on the bed.
8. Verify that drainage system is below level of patient's chest at all times.
9. Check drainage system or bottles for cracks or leaks.
10. Check water seal chamber for correct water level and for tidaling (unless lung reinflated). Add water if evaporation has decreased level. If continuous bubbling is present, check entire system for leaks and notify physician.
11. Check suction control chamber for gentle bubbling (or open to air). Confirm correct amount of water if indicated. Add water if needed.
12. Check and mark amount of drainage in collection chamber every 8 hours and prn or as ordered. Report any marked increase in bloody drainage. Record drainage as output.
13. Document findings.

Notify physician if

- The patient suddenly complains of increasing dyspnea.
- The drainage chamber is full and needs to be changed.

Milking is done by gently squeezing portions of tubing from the patient to the system, without any sliding motion. This is somewhat safer for the patient but is still not done routinely. If tubing appears to be occluded, consult with the physician for specific orders.

Removal of Chest Tube

When the reason for the chest tube is resolved, the physician removes it and places a petroleum jelly gauze and a sterile occlusive dressing over the site. Continue to watch for development of crepitus and to monitor the dressing site and respiratory status.

CRITICAL THINKING

Miss Israel

Miss Israel has a chest tube in place for a spontaneous pneumothorax. You note that the water seal chamber is bubbling vigorously. What could cause bubbling in the water seal chamber? What should you do?

Answers at end of chapter.

Tracheostomy

A **tracheostomy** is a surgical opening through the base of the neck into the trachea. It is called a **tracheostomy** when it is more permanent and has a tube inserted into the opening to maintain patency (Fig. 26–15). The patient breathes through this opening, bypassing the upper airways. A tracheostomy is performed for a variety of reasons, such as in patients who have had a laryngectomy for cancer, patients with airway obstruction caused by trauma or tumor, patients who have difficulty clearing secretions from the airway, and patients who need prolonged mechanical ventilation.

The tracheostomy tube consists of three parts: an outer cannula, an inner cannula, and an obturator (Fig. 26–16). The obturator is a guide that is used only during insertion of the tube. After insertion, the obturator is immediately removed and kept at the bedside (commonly taped to the wall above the bed) for emergency use if the tracheostomy tube is accidentally removed. The outer cannula remains in place at all times and is secured by ties to prevent dislodging. The inner cannula is removed at intervals, usually every 8 hours and as needed for cleaning. Some newer tracheostomy tubes eliminate the need for an inner cannula. The tube may be metal or plastic. Plastic tubes generally have disposable inner cannulas, which can be replaced rather than cleaned. Plastic tubes may also have balloonlike cuffs that are inflated to prevent air escape during mechanical ventilation and to prevent aspiration of food or secre-

tracheotomy: trach—trachea + otomy—incision
tracheostomy: trache—trachea + ostomy—opening or mouth

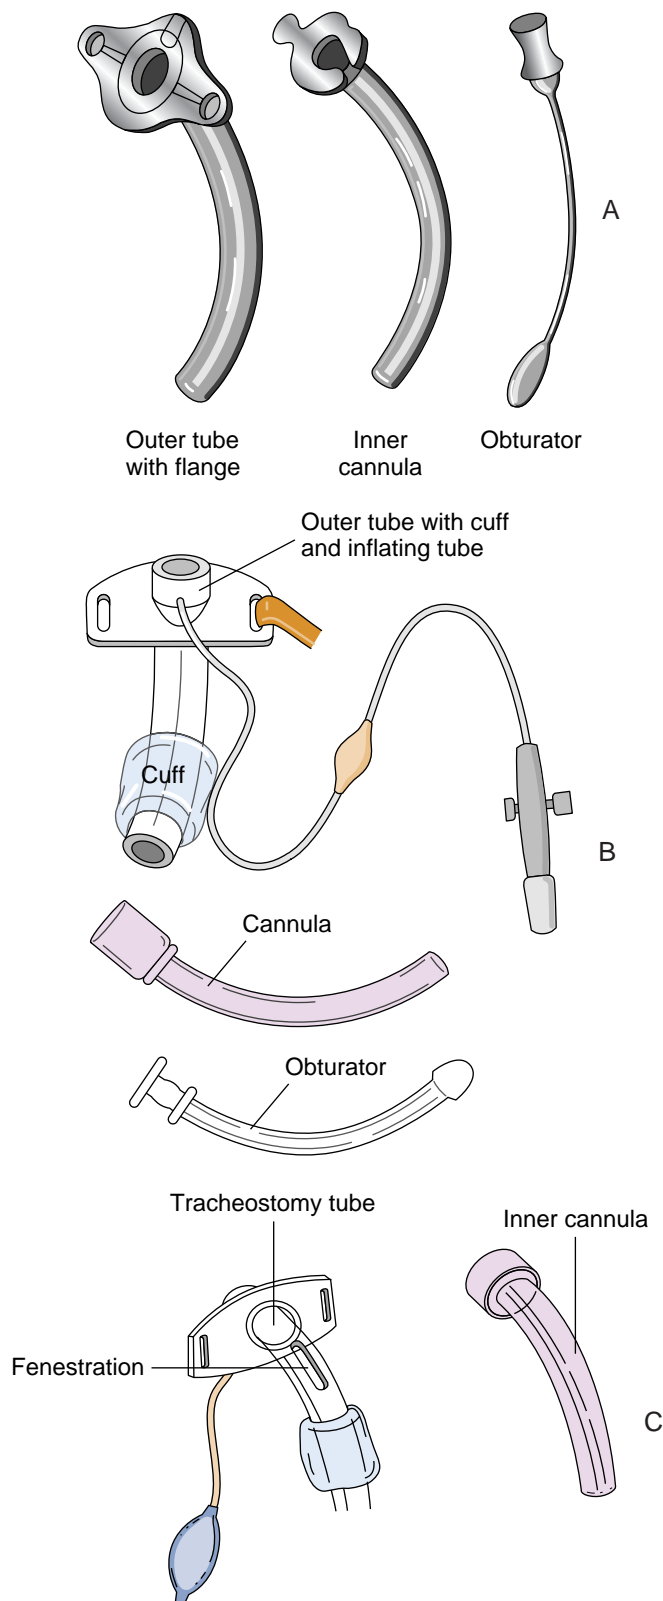

Figure 26-16 Tracheostomy tube. (A) Metal tube. (B) Cuffed plastic tube. (C) Fenestrated tube.

tions. Institution policy may dictate that cuffs be deflated routinely to prevent tissue damage. See Box 26–3 for routine tracheostomy cleaning.

Communication is problematic for the patient with a tracheostomy tube, because air is diverted out the tube rather

BOX 26-3 Tracheostomy Cleaning Procedure

1. Assemble equipment: tracheostomy care kit, sterile water or saline, suction equipment, hydrogen peroxide.
2. Explain the procedure to the patient.
3. Suction inner cannula if necessary. See Box 26-2.
4. Open and prepare the kit, keeping all equipment sterile. Fill one side of basin with half peroxide and half saline and the other with saline.
5. Don clean gloves.
6. Remove old tracheostomy dressing.
7. Remove inner cannula from tracheostomy tube and place it in peroxide solution.
8. While inner cannula is removed, the patient may be suctioned if necessary.
9. Don sterile gloves.
10. Use brush and pipe cleaners to clean inner cannula. Place in water or saline to rinse. Dry inside of cannula with pipe cleaner. Reinsert into tracheostomy tube.
11. Use cotton swab and sterile gauze with sterile peroxide and saline to clean around tracheostomy site. Rinse with saline to prevent skin irritation.
12. Replace ties. Remove old ties after new ties are securely in place.
13. Apply sterile tracheostomy dressing (drain sponge or "trach pants"). Use precut or folded dressing. Cutting gauze creates fibers that can enter the tracheostomy.

NOTE: A procedure manual should be consulted for more detailed instruction.

than past the vocal cords and out the mouth. Fenestrated tubes are tubes with openings (fenestra) in the cannula to allow air to flow up into the larynx for speaking (see Fig. 26-16). The patient is taught to plug the opening of the tube while speaking to divert air through the fenestra. A newer option is the Passy-Muir tracheostomy speaking valve. This is a special valve that allows air into the tracheostomy during

inspiration but closes and redirects air up and out the nose and mouth on expiration, allowing the patient to speak. For the valve to work, the tracheostomy tube must be small enough for air to flow around it or it must be fenestrated.

Some tracheostomies are permanent. However, some patients can be weaned from the tracheostomy tube when their condition has improved enough to allow breathing without it. The physician may replace the tube with a smaller tube to prepare the patient for its removal. This allows a plug to be inserted into the tracheostomy tube at intervals to force the patient to breathe around the tube through the nose and mouth. When the tracheostomy tube has been removed, the opening may be taped shut and covered with gauze until it is healed. The gauze often becomes saturated with secretions and is changed as needed.

Nursing Process for the Patient with a Tracheostomy

See Nursing Care Plan Box 26-4 for the Patient with a Tracheostomy.

CRITICAL THINKING

Mr. Smith
 Mr. Smith had a plastic cuffed tracheostomy tube that was small enough to allow airflow around it for talking when the cuff was deflated. The cuff was inflated for lunch to prevent him from aspirating. A friend stopped by for a chat and assisted Mr. Smith to plug his tracheostomy so he could talk. Mr. Smith's face turned dark red, and his expression showed extreme anxiety.

1. What happened?
2. How could you help prevent this in the future?
3. How would you document this occurrence?

Answers at end of chapter.

BOX 26-4 NURSING CARE PLAN FOR THE PATIENT WITH A TRACHEOSTOMY

Risk for ineffective airway clearance related to increase in secretions

PATIENT OUTCOME

Airway is free of secretions.

EVALUATION OF OUTCOME

Is airway free of secretions?

INTERVENTION	RATIONALE	EVALUATION
<ul style="list-style-type: none"> • Assess lung sounds every 4 hours and prn. • Encourage patient to deep breathe and cough as able. • Encourage fluids if not contraindicated. • Encourage ambulation as able, or turn every 2 hours. • Suction patient using sterile technique prn. Suction only when necessary. • Monitor and document amount, color, and character of secretions. Report increase in secretions accompanied by fever. 	<p>Coarse crackles or wheezes may indicate secretions in airways.</p> <p>Patients may be able to clear own secretions without suctioning.</p> <p>Fluids help hydrate secretions, making them easier to cough up.</p> <p>Movement helps mobilize secretions.</p> <p>Suctioning clears secretions from airways. Unnecessary suctioning irritates airways.</p> <p>Purulent sputum accompanied by fever may indicate pneumonia.</p>	<p>Are coarse crackles or wheezes present?</p> <p>Is patient able to cough up secretions effectively?</p> <p>Is patient taking adequate fluids? Are secretions thin?</p> <p>Is patient mobilized as much as possible?</p> <p>Is suction necessary? Is airway free of secretions after suctioning?</p> <p>Is sputum clear or white, and scant in amount? Does purulent sputum need to be reported?</p>

BOX 26-4 NURSING CARE PLAN FOR THE PATIENT WITH A TRACHEOSTOMY—CONT'D**Risk for infection related to bypass of normal respiratory defense mechanisms****PATIENT OUTCOME**

Patient is free from symptoms of infection.

EVALUATION OF OUTCOME

Is patient free from symptoms of infection?

INTERVENTION

- Use good hand-washing practice.
- Monitor and report signs and symptoms of infection: fever, increased respiratory rate, purulent sputum, elevated white blood cell (WBC) count.
- Protect tracheostomy opening from foreign material: food, sprays, powders.
- Use meticulous sterile technique for all tracheostomy care and suctioning.
- Encourage a well-balanced diet. Consult dietitian prn.
- Take measures to prevent aspiration of food or secretions (see Chapter 46).

RATIONALE

Hand-washing is important in preventing infection.
Early recognition and treatment of infection enhances outcome.

Foreign materials in the tracheostomy may cause pneumonia.

Use of nonsterile technique may introduce microorganisms into the respiratory tract.

A well-balanced diet enhances immune function.
Aspiration can cause pneumonia.

EVALUATION

Do all caregivers use good hand-washing technique?
Are signs of infection present?

Is tracheostomy adequately protected?

Is sterile technique used by all caregivers?

Is patient eating a balanced diet or receiving adequate supplementation?
Is there evidence that the patient is aspirating?

Impaired verbal communication related to presence of tracheostomy tube**PATIENT OUTCOMES**

Patient uses alternate methods of communication effectively. Patient expresses satisfaction with ability to communicate needs.

EVALUATION OF OUTCOME

Is patient able to use alternative methods to express needs? Does patient express satisfaction with ability to do so?

INTERVENTION

- Take time to allow patient to communicate needs.
- Watch for patient's nonverbal cues.
- Offer pen and paper or magic slate (if patient is literate).
- Use picture board (see sample in Chapter 46).
- Teach patient with fenestrated or small tracheostomy tube how to cover opening with a plug or clean finger in order to talk.
- Consult with speech therapist.

RATIONALE

Communication takes time; patient may become frustrated if hurried.
Gestures and facial expression can provide valuable cues.
The patient may be able to write out his or her needs/concerns.
The patient can point to a picture (water, toileting) that indicates his or her need.
Covering opening diverts air into larynx and allows speech.

Speech therapist may have additional methods for communicating with patient.

EVALUATION

Does patient feel he or she is given adequate time for communication of needs?
Is the patient attempting to communicate with nonverbal cues?
Is patient able to write out needs?

Is patient able to point appropriately to needs?

Is patient able to communicate in this manner?

Did speech therapist provide alternative communication techniques?

Disturbed body image related to presence of tracheostomy**PATIENT OUTCOMES**

Patient verbalizes acceptance of tracheostomy. Patient is willing to participate in tracheostomy care.

EVALUATION OF OUTCOMES

Does patient verbalize acceptance of tracheostomy? Does patient participate in learning to care for tracheostomy?

INTERVENTION

- Assess patient's feelings about tracheostomy.

RATIONALE

Assessment provides basis for care.

EVALUATION

Are the patient's feelings within an expected range for such a change in body image?

BOX 26-4 NURSING CARE PLAN FOR THE PATIENT WITH A TRACHEOSTOMY—CONT'D

- | | | |
|--|---|---|
| <ul style="list-style-type: none"> • Approach patient with an accepting attitude. • Allow patient opportunity to verbalize concerns about tracheostomy. • Refer patient to support group if available. • Assist patient in finding attractive ways to conceal tracheostomy if desired. | <p>The patient will be aware of the nurse’s non-verbal body language. Verbalizing concerns helps the patient to sort out feelings and problem solve.</p> <p>The patient may benefit from talking with others with tracheostomies. Loose scarves or collars can help conceal and protect the tracheostomy.</p> | <p>Does the patient indicate a feeling of acceptance from the nurse?
Does the patient verbalize feelings as needed? (Note: Some patients do not wish to share feelings and should not be forced to do so.)
Is patient receptive to a support group referral?

Is patient satisfied with appearance of tracheostomy?</p> |
|--|---|---|

▶ Deficient knowledge related to care of new tracheostomy

PATIENT OUTCOMES

Patient and significant other will verbalize understanding of self-care, demonstrate tracheostomy self-care procedures, and state resources for help after discharge.

EVALUATION OF OUTCOMES

Are patient and significant other able to verbalize self-care actions and rationale? Are patient and significant other able to correctly demonstrate care procedures? Is patient able to state how to obtain help after discharge?

INTERVENTION	RATIONALE	EVALUATION
<ul style="list-style-type: none"> • Assess patient’s and significant other’s baseline knowledge of self-care. • Instruct patient and significant other in the following (see text for specific instruction): <ul style="list-style-type: none"> • Tracheostomy cleaning • Deep breathing and coughing • Suctioning • Prevention of infection and symptoms to report to health care provider • Protection of tracheostomy from pollutants, water (no swimming, careful showering) • Provide follow-up with home health nurse after discharge. 	<p>Teaching should only be initiated if a knowledge deficit exists.</p> <p>The patient will need to care for self after discharge.</p> <p>A home health nurse can provide reinforcement of instruction at home.</p>	<p>Does patient exhibit knowledge of self-care?</p> <p>Is patient able to verbalize understanding of self-care and demonstrate all procedures correctly?</p> <p>Is patient receptive to having a home health nurse assist?</p>

Suctioning

Suctioning involves the use of a flexible catheter to remove secretions from the respiratory tract of a patient who is unable to cough effectively. This may be the patient with a tracheostomy or endotracheal tube, or one with overwhelming secretions.

The procedures for suctioning are presented in Boxes 26–5 and 26–6. A procedure manual should be consulted for more detailed instruction. Remember that suctioning is both frightening and uncomfortable for a patient. Patients sometimes feel as though oxygen is being “vacuumed” from their lungs. Suctioning can cause hypoxia, vagal stimulation with resulting bradycardia, and even cardiac arrest. It is done only when necessary, rather than on a routine basis. Coughing is the most effective way to clear secretions and should be encouraged if the patient is capable. Each step should be explained to the patient, even if he or she is unresponsive.

LEARNING TIPS

Hold your own breath while suctioning your patient. It will keep you mindful of how the patient feels, because suctioning removes not only secretions but also oxygen from the respiratory tract.

Intubation

Some patients are unable to breathe effectively because of airway obstruction or respiratory failure. These patients are intubated with a special endotracheal (ET) tube through the nose or mouth and into the trachea (Fig. 26–17). Patients in cardiopulmonary arrest are intubated during advanced cardiac life support, and patients undergoing general anesthesia during surgery are intubated and mechanically ventilated. Most intubated patients are also mechanically ventilated. Some patients have advance di-

BOX 26-5 Oropharyngeal or Nasopharyngeal Suction Procedure

1. Gather equipment: sterile suction catheter, sterile gloves, sterile container (these items may be found in a single "cath and glove" kit); sterile water or saline, suction machine with tubing.
2. Explain procedure to patient.
3. Connect catheter to suction tubing, keeping catheter inside sterile sleeve. Turn on suction to level specified by institution policy (usually 80–120 mm Hg for wall suction).
4. Pour saline into sterile container.
5. Put on sterile gloves. Keep dominant hand sterile at all times.
6. Suction small amount of saline into catheter to rinse catheter and test suction.
7. Have patient take several deep breaths.
8. With thumb control uncovered to stop suction, insert suction catheter through mouth or nose into the trachea until resistance is met or patient coughs.
9. Slowly withdraw catheter, suctioning intermittently while rotating it. The entire procedure should take no more than 10 to 15 seconds.
10. After allowing patient to rest, repeat steps 6 through 9 two more times if needed.

NOTE: A procedure manual should be consulted for more detailed instruction.

BOX 26-6 Suctioning Procedure for the Patient with a Tracheostomy

1. Gather equipment: sterile suction catheter, sterile gloves, sterile container (these items may be found in a single "cath and glove" kit); sterile water or saline, suction machine with tubing, manual resuscitation bag.
2. Explain procedure to patient.
3. Connect catheter to suction tubing, keeping catheter inside sterile sleeve. Turn on suction to level specified by institution policy (usually 80–120 mm Hg for wall suction). Connect oxygen source to manual resuscitation bag.
4. Pour saline into sterile container.
5. Put on sterile gloves. Keep dominant hand sterile at all times.
6. Suction small amount of saline into catheter.
7. Oxygenate patient with three ventilations using a manual resuscitation bag connected to an oxygen source, using the nonsterile hand. If the patient is mechanically ventilated, use manual sigh.
8. With thumb control uncovered to stop suction, insert suction catheter through tracheostomy tube until patient coughs or resistance is met.
9. Slowly withdraw catheter, suctioning intermittently while rotating it. The entire procedure should take no more than 15 seconds.
10. Allow patient to rest.
11. Repeat steps 6 through 10 two more times if needed.

Some older sources recommend instilling sterile saline into the tracheostomy to loosen secretions. *This should be avoided.* It is now known that this procedure is not effective and may actually cause a drop in the patient's SaO_2 .

NOTE: A procedure manual should be consulted for more detailed instruction.

Placement of tube in airway

Figure 26-17 Endotracheal tube. (Modified from Barnes, TA: Respiratory Care Principles. FA Davis, Philadelphia, 1991, p 425, with permission.)

rectives that indicate that they do not wish to be intubated. You should be familiar with the patient's wishes and bring them to the attention of the physician if necessary.

Because intubation can damage the vocal cords and surrounding tissues, it is usually a short-term intervention. Patients who need long-term support have a tracheostomy tube placed.

Nursing care of the intubated patient includes regular assessment of the patient's respiratory status and tube placement. Lung sounds are auscultated bilaterally to ensure that the tube has not been displaced into one bronchus. The tube is carefully secured with tape or a Velcro holder to avoid dislodging. Oral tubes are repositioned and resecured to the opposite side of the mouth every 24 hours or according to institution policy to prevent tissue damage. An adhesive skin barrier should be applied under the tape to protect the skin. If the patient is alert, he or she is instructed to be careful not to pull on the tube. You may need to obtain an order for soft wrist restraints if absolutely necessary for the confused patient. Restraints can be avoided if a family

member is available to sit with the patient. Some nursing interventions for the patient with a tracheostomy are also appropriate for the intubated patient. (See Nursing Care Plan 26-4 for the Patient with a Tracheostomy.)

Endotracheal tubes have a cuff (a balloonlike area around the tube) to help maintain proper placement and to prevent leakage of air around the tube. An RT usually inflates the cuff and maintains a specific cuff pressure and should be consulted for assistance with this activity.

Patients with ET tubes may need suctioning if they are unable to cough effectively. Visible secretions in the tube, crackles or wheezes heard with or without the stethoscope, or a drop in SaO₂ without another obvious cause are signs that suctioning is necessary. The ET tube suctioning procedure is sterile and is the same as suctioning a tracheostomy tube. Some institutions have in-line suctioning devices, which are connected to the ET tube within a sterile sleeve. This maintains sterility, protects the nurse, and simplifies the suctioning procedure. Oral suction keeps the mouth free of secretions. Meticulous mouth care is done every 4 hours and as needed. The intubated patient is often extremely anxious, especially if he or she is alert. Explain the purpose of all care activities. Suctioning is particularly anxiety-producing and should be explained carefully, even if the patient is unresponsive. Because the ET tube passes between the vocal cords, the patient is unable to speak. Provide paper and pencil or a picture board for communication. Yes/no questions can be answered by a nod or shake of the head.

Monitor arterial blood gas and oxygen saturation values and notify the physician of changes. If oxygen values drop or the patient becomes confused or agitated, the patient should be immediately inspected for a disconnected oxygen source or excessive secretions.

If the physician determines that the patient can breathe effectively without the tube, the tube will be removed. Before removal, the patient's mouth and tube are suctioned and the cuff is deflated. After removal, the patient is observed closely for laryngeal edema or respiratory distress. The patient is maintained in high Fowler's position to maximize chest expansion.

Mechanical Ventilation

Ventilators are devices that provide ventilation (respirations) for patients who are unable to breathe effectively on their own (Fig. 26-18). Ventilators use positive pressure to push oxygenated air via a cuffed ET or tracheostomy tube into the lungs at preset intervals. Patients may need mechanical ventilation after some surgeries, after cardiac or respiratory arrest, for declining arterial blood gases related to worsening respiratory disease, or for neuromuscular disease or injury that affects the muscles of respiration.

Ventilator Modes

Ventilators can control ventilation or assist the patient's own respirations. See Table 26-8 for terms that aid understanding of ventilator function. There are many types and models of ventilators. Consult with the respiratory care de-

Figure 26-18 Patient on ventilator.

partment for an explanation of a patient's ventilator and how to troubleshoot alarms that may sound.

Ventilator Alarms

Several types of alarms are found on ventilators. Low-pressure alarms sound if the ventilator senses reduced pressure in the system. This can be caused by disconnected tubing, leaks in tubing or around the ET tube, or an underinflated cuff. A low-pressure alarm may also sound if the patient has attempted to remove the tube.

TABLE 26-8 VENTILATOR TERMINOLOGY

FIO ₂	Fraction of inspired oxygen.
Tidal volume	Amount of air delivered with each breath.
Rate	Frequency of breaths delivered.
Assist control mode (AC; also called continuous mechanical ventilation, or CMV)	Ventilator delivers a breath each time patient begins to inspire. If patient does not breathe, the machine continues to deliver a preset number of breaths per minute.
Synchronized intermittent mandatory ventilation (SIMV)	Allows patient to breathe independently but delivers a minimum number of ventilations per minute as necessary. Synchronized to patient's own respiratory pattern.
Pressure support (PS)	Provides positive pressure on inspiration to decrease the work of breathing.
Continuous positive airway pressure (CPAP)	Provides positive pressure on inspiration and expiration to keep alveoli open in a spontaneously breathing patient.
Positive end-expiratory pressure (PEEP)	Provides positive pressure on expiration to help keep small airways open.

High-pressure alarms sound for higher-than-normal resistance to air flow. This might occur if the patient needs to be suctioned; if the patient is biting on the tube, coughing, or trying to talk; if tubing is kinked or otherwise obstructed; or if worsening respiratory disease causes decreased lung compliance. In addition, the high-pressure alarm may be triggered if the patient is anxious and is unable to time his or her breaths with those of the ventilator. Water in the tubing might also cause a high-pressure alarm. Consult with the respiratory care department for guidance in disconnecting and draining the tubing.

A loss of power alarm may signal a power failure or a disconnected plug. Be aware of emergency power sources and be prepared to manually ventilate if necessary.

Volume and frequency alarms sound when tidal volume or number of breaths per minute fall outside preset parameters.

When an alarm sounds, always check the patient first. If the patient is stable, the machine may then be checked. Determine why the alarm is sounding and correct the problem quickly. If no cause can be found, disconnect the patient from the ventilator and call for help. Use a manual resuscitation bag until an RT arrives.

NURSING RESPONSIBILITIES. Before initiating mechanical ventilation, it is important that the health care team be aware of advance directives and consult with the patient and family, because many patients do not wish to be intubated and mechanically ventilated. Some patients accept mechanical ventilation if it is a temporary measure but not if it might be a permanent intervention.

Until recently, ventilators were used only in intensive care units. Now ventilators are seen on medical-surgical units, in nursing homes, and even in patients' homes. It is important that a team approach be used when caring for a mechanically ventilated patient. The social worker; RT; physical, occupational, and speech therapists; dietitian; nurse; and physician all work together to provide the comprehensive care needed by this patient. Respiratory therapists usually take responsibility for routine monitoring and equipment maintenance. The nurse is responsible for monitoring the patient, ensuring that ventilator settings are maintained as prescribed, providing initial response to alarms, keeping tubing free from water accumulation, and keeping the patient's airway free from secretions. In addition, the nurse keeps a manual resuscitation bag at the bedside for emergencies.

Patients who are mechanically ventilated are unable to talk and can become very uncomfortable and anxious with no easy way to communicate. See Box 26-7 for one nurse's tips for making ventilated patients feel more secure. These tips were developed after the author interviewed 12 patients who had been intubated. They shared their fears, anxieties, and physical discomforts.

Noninvasive Positive-Pressure Ventilation

Noninvasive positive-pressure ventilation (NIPPV) is an alternative to intubation and mechanical ventilation for patients who are able to breathe on their own but are un-

BOX 26-7 Tips for Caring for Mechanically Ventilated Patients

- Introduce yourself to the patient each time you enter the room. Make sure he or she can see you.
- Explain everything you are about to do.
- Check ventilator settings regularly.
- Give sedatives or anti-anxiety drugs as ordered. Request an order if necessary. Find out cause of unexplained anxiety (patient may be hypoxemic).
- Reassure the patient that anxiety is normal and that relaxing will help the ventilator to work with him or her.
- Assess for comfort and reposition at regular intervals. Be careful not to pull on the ventilator tubing. (Pulling hurts.)
- Suction quickly and smoothly, without jabbing. Avoid the use of saline with suctioning.
- Provide good oral care, moistening the lips with a cool washcloth and water-based lubricant. (Patients get thirsty.)
- Use restraints only as a last resort.
- Take the time to communicate with the patient. Talk to him or her, and provide a magic slate or pen and paper for the patient to talk to you. Make sure the call light is within reach at all times.
- Answer patient's call light and ventilator alarms promptly.

Source: Modified from Jablonski, RAS: If ventilator patients could talk. RN, Feb 1995, p 32.

able to maintain normal blood gases. Patients with severe respiratory disease, sleep apnea, or neuromuscular diseases such as amyotrophic lateral sclerosis (ALS) that weaken respiratory muscles can benefit from this treatment. Instead of the invasive endotracheal or tracheostomy tube, NIPPV uses an external masklike device that fits over the nose and mouth and nose (Fig. 26-19). It can be successful in patients who are alert, able to cooperate, do not have excessive secretions, and are able to breathe on their own for periods of time. It can be used with or without supplemental oxygen. In an acutely ill patient, oxygen saturations are monitored.

Figure 26-19 Noninvasive positive-pressure ventilation. (Courtesy Respironics, Inc.)

Two basic types of NIPPV are available: continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP, Respironics, Inc.). In CPAP the same amount of positive pressure is maintained throughout inspiration and expiration to prevent airway collapse. In BiPAP a different level of positive pressure is used on inspiration and expiration.

Problems to be alert for in patients receiving NIPPV include skin irritation from the mask and gastric distention from swallowing air. Apply an adhesive skin barrier to the areas that come in contact with the mask to prevent irritation. To prevent gastric distention, place the patient in semi-Fowler's position and consult with the RT to adjust air delivery pressure if necessary. Topical saline or a special humidifier on the machine can reduce nose and mouth dryness.

An air leak around the mask can cause air to blow in the patient's eyes, which can be irritating. If this happens, remove the mask and reposition it. Another problem is patient acceptance of NIPPV. Many patients do not like the tight mask covering their nose or mouth. Be patient in explaining the reason for this treatment and check the patient frequently to help control anxiety. Be sure to assess the patient's goals for therapy. Some patients may choose not to use NIPPV, but they must be fully aware of possible consequences.

Patients can use NIPPV nearly continuously, removing it to eat or use the bathroom. Other patients use it only when they are sleeping and are able to breathe effectively on their own during the day. Some use it for a few days until an acute exacerbation of disease is resolved, and others continue its use indefinitely at home.

REVIEW QUESTIONS

- During inhalation, which of the following muscle contractions takes place to enlarge the chest cavity from top to bottom?
 - Diaphragm moves down.
 - External intercostal muscles move down.
 - Diaphragm moves up.
 - Internal intercostal muscles move up.
- Deteriorating cilia in the respiratory tract predispose the elderly to which of the following?
 - Chronic hypoxia
 - Pulmonary hypertension
 - Respiratory infection
 - Decreased ventilation
- Which of the following terms is used to describe violinlike sounds heard on chest auscultation?
 - Crackles
 - Wheezes
 - Friction rub
 - Stridor
- Which of the following is a normal value for oxygen saturation?
 - Less than 60 percent
 - 61 to 85 percent
 - 86 to 95 percent
 - More than 95 percent
- The purpose of pursed-lip breathing is to promote which of the following?
 - Carbon dioxide excretion
 - Carbon dioxide retention
 - Oxygen excretion
 - Oxygen retention
- Which of the following instructions is correct when teaching a patient how to use a metered dose inhaler?
 - "Inhale deeply, place canister in mouth, depress top of canister, exhale."
 - "Exhale, place canister in mouth, depress canister and inhale at the same time."
 - "Cough, place canister in mouth, inhale deeply, cough again."
 - "Exhale, depress canister, place in mouth, inhale deeply."
- Which of the following actions by the nurse is appropriate when vigorous bubbling is noted in the suction control chamber of a chest drainage system?
 - Check the tubing for leaks.
 - Notify the physician.
 - Reduce the level of wall suction.
 - Clamp the chest tube.
- You hear a high-pressure alarm sounding on a mechanically ventilated patient. Which of the following should you check first?
 - Tubing
 - Power to the ventilator
 - Ventilator settings
 - The patient

Answers to CRITICAL THINKING

Timothy

1. There is no way to know whether Timothy needs to be in the emergency room without further assessment. Remember that shortness of breath is very subjective and must be evaluated before discharge.
2. Collect further data. Have Timothy rate his shortness of breath. Look at his color and use of accessory muscles. Check his vital signs, peak expiratory flow rate, and oxygen saturation.
3. If Timothy is having an asthma attack, one explanation for the absence of wheezing on auscultation is that he is not moving enough air to generate the wheezing sound. If his airways are extremely tight, breath sounds may be so diminished that wheezing is not heard. This is a bad sign rather than a good one. If you suspect that this is happening, call for help. The physician may want to begin treatment quickly before further evaluation is done.

Miss Israel

Bubbling in the water seal chamber indicates a leak in the system. Vigorous bubbling may indicate a large leak, and the physician should be contacted immediately. After you check the patient, check the entire system for cracks or leaks and correct any problems discovered.

Mr. Smith

1. Mr. Smith plugged his tracheostomy while the cuff was still inflated, so no air could get to his lungs. If the plug is not removed immediately he will be totally unable to breathe. Whenever the plug is in place, air must be able to travel around the tracheostomy tube or through the opening of a fenestrated tube for the patient to breathe.
2. To prevent this from happening in the future, Mr. Smith should be taught how his tracheostomy tube works and how to care for it.
3. "Trach tube cuff inflated for lunch as ordered. Answered call for help at 1230, found patient dark red in color, unable to breathe, trach plugged. Trach unplugged, respirations restored, vital signs stable. Patient stated he plugged trach so he could talk to his friend. Function of trach cuff explained to patient and friend. Both verbalize understanding to only plug trach when cuff is deflated or to call for nurse if unsure."

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the pathophysiology of the disorders of the upper respiratory tract?
2. What are the etiologies, signs, and symptoms of disorders of the upper respiratory tract?
3. What is current medical treatment for disorders of the upper respiratory tract?
4. What nursing care should you be prepared to provide for the patient with an upper respiratory disorder?
5. How will you know if your care has been effective?
6. What are the special needs of the patient who has undergone a laryngectomy?

Disorders of the upper respiratory tract include problems occurring in the nose, sinuses, pharynx, larynx, and trachea. Many of these problems are minor illnesses that can be cared for at home. Others can become serious if they are not recognized and treated in a timely manner.

► DISORDERS OF THE NOSE AND SINUSES

Epistaxis

Pathophysiology

Epistaxis is more commonly known as a nosebleed. The nose can bleed either from the anterior or posterior region. Anterior bleeds are much more common and originate from a group of vessels called the Kiesselbach plexus. Anterior bleeds are easier to locate and treat than poste-

rior bleeds, because the blood vessels of the posterior nose are larger and bleeding can be severe and difficult to control.

Etiology

The most common cause of epistaxis is dry, cracked mucous membranes. Trauma, forceful nose blowing, nose picking, and increased pressure on fragile capillaries from hypertension are also factors. Anything that reduces the blood's ability to clot, such as hemophilia or leukemia, regular aspirin use, anticoagulant therapy, or chemotherapy, can also predispose a patient to nosebleeds.

Treatment

Instruct the patient with a nosebleed to sit in a chair and lean forward slightly to avoid aspirating or swallowing blood. If the patient swallows blood, it will be difficult to

assess the extent of bleeding. Be sure to wear gloves and follow standard precautions. Place pressure on the nares for 5 to 10 minutes to stop bleeding. However, avoid placing pressure on the nose if a fracture is suspected, to avoid further trauma. Ice packs to the nose and eye area may be used to constrict the vessels that are bleeding. Once the bleeding has stopped, instruct the patient to avoid blowing the nose for several hours to prevent further bleeding.

If first aid measures are ineffective in stopping bleeding, a physician may attempt more invasive treatment. Local application of a vasoconstrictive agent might be used to constrict the bleeding vessels. If the bleeding vessel can be located, the physician may cauterize it by use of an electrical cauterizing device, or by application of silver nitrate.

Gauze may be used to pack the anterior or posterior nasal cavity. The anterior cavity is packed firmly but gently, usually with half-inch petroleum gauze. To pack the posterior cavity, the physician must use a catheter and string via the nose to draw the packing through the mouth and into the posterior nasal cavity (Fig. 27-1). The strings are then brought out the mouth and taped to the patient's face so they can be used 2 to 4 days later to remove the packing. Placement and removal of packing can be very uncomfortable for the patient. If there is time, administration of an analgesic before the procedure is helpful. Petroleum jelly on the packing helps prevent gauze from adhering to the nasal mucosa. If the packing is to remain in place for a prolonged period, it is coated with an antibiotic ointment to reduce the risk of infection.

Another method to stop bleeding is the use of a nasal balloon catheter. This device employs a catheter with a balloon on the end that is inflated after placing it near the bleeding vessels in the nasal cavity. The inflated balloon places pressure on the bleeding vessels to stop the bleeding.

If the patient has lost a significant amount of blood, a transfusion may be necessary. Nosebleeds rarely cause death, because blood loss lowers blood pressure, which in turn slows the bleeding. Ultimately the cause of the epistaxis is determined and corrected if possible.

Nursing Care

Monitor bleeding, noting the amount and color of drainage. Monitor vital signs and hemoglobin level for signs of excessive blood loss. If the patient swallows repeatedly, inspect the back of the throat for bleeding. If bleeding does not stop or if it worsens, notify a registered nurse (RN) or physician immediately.

If posterior packing has been used, monitor the patient for airway obstruction from slipped packing. Know how to remove the packing in case of emergency. Institute comfort measures, and maintain the placement of the strings that will be used to remove the packing. Once bleeding is controlled, caution the patient not to blow the nose for several hours and to avoid nose picking. The packing will be removed by the physician. If the cause of the bleeding is known, teach the patient how to prevent recurrence.

Figure 27-1 Nasal packing. (A) Catheters are used to pull packing into place. (B) Nasal packing in place.

CRITICAL THINKING

Mr. Jondahl

Mr. Jondahl is brought to the emergency room with a nosebleed. His vital signs are 140/90, 92, 20. He states that he has never had a nosebleed before. He denies any history of coagulation disorders. His current medications include captopril (Capoten), furosemide (Lasix), and ibuprofen (Motrin). What are two areas you should assess further in trying to determine a cause? (Hint: If you are not familiar with Mr. Jondahl's medications, look them up.)

Answers at end of chapter.

Nasal Polyps

Pathophysiology and Etiology

Polyps are grapelike clusters of mucosa in the nasal passages. They are usually benign, but they can obstruct the nasal passages. Though the exact cause is unknown, people with allergies are prone to developing polyps. Some patients with nasal polyps also have asthma and are allergic to aspirin. This is called a triad disease because the three components often occur together.

Treatment

Control of allergy symptoms may help control polyp development. If polyps obstruct breathing, they can be removed. This is done as an outpatient procedure under local anesthesia, using laser or endoscopic surgery. Patients are taught to avoid aspirin products following surgery because they increase the risk of postoperative bleeding and recurrence of the polyps.

Deviated Septum

Pathophysiology and Etiology

The septum dividing the nasal passages is slightly deviated in most adults. This may result from nasal trauma but often has no cause. Some may be so deviated that they block sinus drainage or interfere with breathing.

Signs and Symptoms

The patient may complain of a chronically stuffy nose or discomfort from blocked sinus drainage. Some patients experience headaches and nosebleeds.

Medical Treatment

If the deviated septum is causing chronic discomfort, a submucous resection (SMR), or **nasoseptoplasty**, is done. This surgery involves making an incision through the mucous membrane covering the septum and removing the deviated portion. Nasal packing is then placed to reduce bleeding. This is generally done as an outpatient surgical procedure, under local anesthetic.

Nursing Care

Monitor vital signs and bleeding until the patient is stable following surgery. Excessive swallowing should alert you to check for blood running down the back of the throat. The patient will have nasal packing and a “mustache dressing” of folded gauze under the nose to catch drainage.

Most patients are discharged home once they are stable, so teaching is important. The patient should maintain a semi-Fowler’s position as much as possible and avoid anything that might increase pressure and cause bleeding, such as sneezing, coughing, or straining to move the bowels. Stool softeners and cough suppressants may be ordered by the physician if necessary. Aspirin and related medications

are avoided because they increase the risk of bleeding. Antibiotics may be ordered if packing is in place because of the risk of infection from nasal bacteria. The physician should be contacted for specific orders if the patient is on anticoagulant therapy at home. Ice can be used to reduce swelling and bruising. Instruct the patient to contact the physician if fever, excessive pain, swelling, or bleeding occur and to return in 24 to 48 hours for removal of nasal packing. See Box 27–1 for patient teaching after nasal surgery.

Rhinoplasty

Rhinoplasty is the surgical reconstruction of the nose, usually for cosmetic purposes. It may also be done to correct deformity caused by trauma. Nursing care is similar to that for the patient after SMR, described previously and in Box 27–1.

Sinusitis

Pathophysiology and Etiology

Sinusitis is inflammation of the mucosa of one or more sinuses. It can be either acute or chronic. Chronic sinusitis is diagnosed if symptoms are present for more than 2 months and are unresponsive to treatment. The maxillary and ethmoid sinuses are the most commonly affected. The inflammation is often the result of a bacterial infection and may follow a viral upper respiratory illness. Because the mucous lining of the nose and sinuses is continuous, nasal organisms easily travel to the sinuses. When the infected mucous lining of the sinuses swells, drainage is blocked. Bacteria that normally reside in the sinuses multiply in the retained secretions. The most common infecting organisms are *Streptococcus pneumoniae* and *Haemophilus influenzae*. Other causes of sinusitis include swelling caused by allergies, fungal infection, or intubation with a nasotracheal or nasogastric tube.

BOX 27-1 Patient Teaching after Nasal Surgery

1. Your nose will feel stuffy and may drain. Change the mustache dressing as often as needed. *Do not* blow your nose. If you must sneeze, do so with your mouth open.
2. Drink plenty of fluids unless your physician advises otherwise.
3. Use a cool mist vaporizer to humidify air and prevent nasal drying.
4. Keep your head elevated on two pillows or sleep in a recliner chair.
5. An ice pack on your face may help reduce swelling.
6. Take pain medication as prescribed.
7. Call your physician if you have a fever higher than 101° F.
8. Return to see your physician in _____ days.

nasoseptoplasty: naso—nose + septo—septum + plasty—plastic surgery

rhinoplasty: rhin—nose + plasty—to mold
sinusitis: sinu—sinus + itis—inflammation

Signs and Symptoms

The patient usually has pain over the region of the affected sinuses and purulent nasal discharge. If a maxillary sinus is affected, the patient experiences pain over the cheek and upper teeth. In ethmoid sinusitis, pain occurs between and behind the eyes. Pain in the forehead typically indicates frontal sinusitis. Fever may be present in acute infection, with or without generalized fatigue and foul breath.

Complications

The patient who has received inadequate treatment, or who has not complied with treatment, is at risk for complications. Uncontrolled sinusitis may spread to surrounding areas, causing osteomyelitis, cellulitis of the orbit (infection of the soft tissues around the eye), abscess, or meningitis.

Diagnostic Tests

Uncomplicated sinusitis may be diagnosed based on symptoms alone. If repeated episodes occur, x-ray examination, a computed tomography (CT) scan, or magnetic resonance imaging (MRI) may be done to confirm the diagnosis and determine the cause. Nasal discharge may be cultured to determine appropriate antibiotic therapy.

Medical Treatment

Treatment is aimed at relieving pain and promoting sinus drainage. Adrenergic nasal sprays such as oxymetazoline (Afrin, Allerest) constrict blood vessels and therefore reduce swelling, but they should be used cautiously by patients with heart disease or hypertension because vasoconstriction increases blood pressure. Sprays may be used for up to 3 days; longer use may cause rebound congestion. Hot moist packs over the affected sinus for 1 to 2 hours twice a day may help decrease inflammation. Nasal irrigation with normal saline solution and a bulb syringe has helped some sufferers of chronic sinusitis. Acetaminophen is given for pain and fever. Codeine or meperidine may be used if pain is severe. Expectorants such as guaifenesin (Robitussin), fluids, and room humidification help liquefy secretions. Antihistamines dry and thicken secretions and are generally avoided. Antibiotics are used only if bacterial infection is suspected, as in the patient with purulent drainage and fever. If conservative treatment does not relieve symptoms, the physician may surgically drain the affected sinus and irrigate it with normal saline or an antibiotic solution.

One drainage procedure is the Caldwell-Luc procedure. The surgeon enters the maxillary sinus above the upper teeth, under the upper lip. The infected mucosa and bone are removed, and a new, larger opening is made to drain the sinus. Newer procedures use endoscopy to open and drain a chronically infected sinus.

Nursing Care

Patients with uncomplicated sinusitis are cared for at home. Instruct the patient to increase water intake to 8 to 10 glasses per day unless contraindicated. Excess water might be contraindicated in patients with fluid overload, such as those with cardiovascular compromise or kidney disease. Pressure

may be relieved if the patient maintains a semi-Fowler's position, as in a reclining chair. Explain use of hot moist packs, acetaminophen, and prescribed medications. Instruct the patient to finish the antibiotic prescription even if he or she is feeling better before it is completed and to call the physician if pain becomes severe or if signs of complications such as a change in level of consciousness occur.

▶ INFECTIOUS DISORDERS

Rhinitis/Common Cold

Pathophysiology and Etiology

Rhinitis (also called coryza) is inflammation of the nasal mucous membranes. The release of histamine and other substances causes vasodilation and edema, which result in symptoms. It may occur as a reaction to allergens (sometimes called hay fever) such as pollen, dust, molds, or some foods, or it may be caused by viral or bacterial infection. Viral rhinitis is another name for the common cold.

Signs and Symptoms

Common symptoms include nasal congestion, localized itching, sneezing, and nasal discharge. Viral or bacterial rhinitis may also be accompanied by fever and malaise.

Diagnostic Tests

If allergic rhinitis is suspected, skin testing may be done to determine the offending allergens. A blood test for IgE antibodies might also be done.

Treatment

Treatment of viral rhinitis is symptomatic. Because most colds are caused by viruses, antibiotics are not effective. In one study, however, researchers found that 60 percent of patients who visited their physician for cold symptoms received a prescription for an antibiotic. This practice is not only expensive, it also increases the risk of developing strains of bacteria that are resistant to antibiotics. Explain to the patient that requesting antibiotics for a viral infection is not only ineffective but potentially dangerous. Teach the patient that rest and fluids are the most effective treatment (Nursing Care Plan Box 27–2).

Antihistamines may be used to help control symptoms by inhibiting the histamine response. Decongestants cause vasoconstriction, which reduces swelling and congestion. Any drugs that cause vasoconstriction should be used cautiously in patients with heart disease or hypertension. Severe allergies may be treated with desensitization (“allergy shots”).

Pharyngitis

Pathophysiology and Etiology

Pharyngitis, or inflammation of the pharynx, is usually related to bacterial or viral infection. It may also occur as a result of trauma to the tissues. The most common bacterial

rhinitis: rhin—nose + itis—inflammation

pharyngitis: pharyng—pharynx + itis—inflammation

BOX 27-2 NURSING CARE PLAN FOR THE PATIENT WITH AN UPPER RESPIRATORY INFECTION**▶ Acute pain related to infectious process****PATIENT OUTCOMES**

Patient will be comfortable as evidenced by (1) statement of increased comfort and (2) ability to sleep at night.

EVALUATION OF OUTCOMES

(1) Does patient express comfort? (2) Is patient able to sleep?

INTERVENTIONS

- Assess for cause of discomfort: malaise, muscle aches, fever.
- Offer acetaminophen or other analgesic/antipyretics as ordered.
- Offer throat lozenges and salt-water gargles as ordered for irritated throat.
- Encourage rest.

RATIONALE

Knowing cause of discomfort helps guide intervention.
 Analgesics relieve pain.
 Antipyretics relieve fever, which may contribute to discomfort.
 Lozenges soothe irritated mucous membranes. Saltwater gargles may reduce swelling.
 Physical stress increases need for sleep. Rest boosts immune function.

EVALUATION

Can interventions be directed toward specific symptoms?
 Do analgesics/antipyretics relieve discomfort?
 Do measures relieve throat irritation?
 Is patient resting comfortably?

▶ Hyperthermia related to infectious process**PATIENT OUTCOMES**

(1) Temperature lower than 103° F. (2) No signs/symptoms of dehydration.

EVALUATION OF OUTCOMES

(1) Is fever controlled at safe level? (2) Is patient well hydrated?

INTERVENTIONS

- Monitor temperature daily; every 4 hours if fever present.
- If patient begins chilling, recheck temperature when chilling subsides.
- Monitor for signs of dehydration: dry skin and mucous membranes, thirst, weakness, hypotension.
- Encourage oral fluids if not contraindicated.
- Administer antipyretic such as acetaminophen if fever is higher than 102.5° F or for discomfort.

RATIONALE

Screening helps detect temperature changes early.
 Chilling indicates rising temperature.
 Fever causes loss of body fluids.
 Fluids prevent or treat dehydration.
 Antipyretics reduce fever. Fever enhances immune function, so should only be treated if very high, if patient has a history of febrile seizures, or if patient is uncomfortable.

EVALUATION

Is patient febrile?
 Is chilling present?
 Should temperature be checked more often?
 Are signs of dehydration present?
 Is patient taking fluids well?
 Is fever higher than 102.5° F? Are antipyretics indicated? Are they effective?

▶ Risk for infection: transmission to others related to presence of infectious disease**PATIENT OUTCOMES**

Risk for infection of others is reduced, as evidenced by the following: (1) Patient states measures to prevent transmission. (2) Patient takes precautions against spread.

EVALUATION OF OUTCOMES

Is transmission to others prevented?

INTERVENTIONS

- Assess patient's understanding of infection transmission.
- Based on patient's previous knowledge, teach patient and all caregivers the importance of good handwashing after contact with patient or patient's belongings, covering nose and mouth when coughing or sneezing, and not sharing eating or drinking utensils.

RATIONALE

Understanding of mode of transmission is essential to prevention.
 The nurse should build on patient's previous understanding and not repeat information.
 Handwashing prevents spread of infection.
 Covering nose and mouth prevents spread of infectious droplets. Many infections are transmitted via contaminated objects.

EVALUATION

Does patient understand how infection is transmitted?
 Does patient take precautions to prevent spread of infection?

infection is caused by beta-hemolytic streptococci, commonly referred to as strep throat. If strep throat is not treated with antibiotics, it can lead to rheumatic fever, glomerulonephritis, or other serious complications.

Signs and Symptoms

The most common symptom of pharyngitis is a sore throat. Some patients may also experience **dysphagia** (difficulty swallowing). The throat appears red and swollen, and **exudate** (drainage or pus) may be present. Exudate usually signifies bacterial infection and may be accompanied by fever, chills, headache, and generalized malaise.

Diagnostic Tests

A physician may order a throat culture and sensitivity test (explained in Chapter 26) to identify the causative organism and determine which antibiotic will be effective.

Treatment

If the pharyngitis is bacterial, antibiotics are ordered. Acetaminophen or throat lozenges may be used to relieve discomfort. Saltwater gargles help reduce swelling, and increased fluids (if not contraindicated) and rest are encouraged. (See Nursing Care Plan Box 27–2.)

Laryngitis

Pathophysiology and Etiology

Laryngitis is an inflammation of the mucous membrane lining the larynx (voice box). It can be caused by irritation from smoking, alcohol, or chemical exposure; or a viral, fungal, or bacterial infection. It often follows an upper respiratory infection.

Signs and Symptoms

The most common symptom is hoarseness. Cough, dysphagia, or fever may also be present.

Diagnostic Tests

A physician may use a laryngeal mirror to view the larynx. If hoarseness persists for more than 2 weeks, a laryngoscopy is done to rule out cancer of the larynx.

Treatment

Treatment includes rest, fluids, humidified air, and aspirin or acetaminophen. Antibiotics are used if bacterial infection is present. Encourage the patient to avoid speaking to rest the voice. Obtain a “magic slate” (from the speech therapy department) or paper and pen to help the patient communicate. Throat lozenges may help increase comfort. Instruct the patient to identify and avoid causative factors. (See Nursing Care Plan Box 27–2.)

dysphagia: dys—bad + phagia—to swallow
exudate: to sweat out
laryngitis: laryng—larynx + itis—inflammation

Tonsillitis/Adenoiditis

Pathophysiology and Etiology

The tonsils are masses of lymphoid tissue that lie on each side of the oropharynx. They filter microorganisms, thus protecting the lungs from infection. Tonsillitis occurs when the filtering function becomes overwhelmed with a virus or bacteria, and infection results. The adenoids, a mass of lymphoid tissue located at the back of the nasopharynx, can also become involved. Tonsillitis is more common in children, but it is more serious when it occurs in adults. The most common organisms causing tonsillitis are *Streptococcus* species, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pneumococcus* species.

Signs and Symptoms

Tonsillitis usually begins suddenly with a sore throat, fever, chills, and pain on swallowing. Generalized symptoms include headache, malaise, and **myalgia**. On examination, the tonsils appear red and swollen and may have yellow or white exudate on them. The patient’s voice may sound like the patient has a hot potato in his or her mouth. If the adenoids are involved, the patient may have complaints of snoring, nasal obstruction, and a nasal tone to the voice.

Diagnostic Tests

A throat culture is done to discover the causative organism and determine effective treatment. A white blood cell count helps identify whether the infection is viral or bacterial. A chest x-ray examination may be done if respiratory symptoms are present.

Treatment

Antibiotics are prescribed for bacterial infection. Acetaminophen, lozenges, and saline gargles help promote comfort. For care of the patient who is not having a tonsillectomy, see Nursing Care Plan Box 27–2.

TONSILLECTOMY. If tonsillitis becomes chronic or if an abscess occurs, a tonsillectomy may be performed, although this is not a common procedure in an adult. An adenoidectomy may be performed at the same time. After the tonsillectomy, the patient is maintained in a semi-Fowler’s position to reduce swelling and promote drainage. Monitor the patient for bleeding and airway patency, and provide comfort measures. Encourage fluids for hydration; cold fluids may

CRITICAL THINKING

Mrs. Hiler

You are assessing Mrs. Hiler after a tonsillectomy. She is sleeping, but you notice that she swallows every few seconds. She has an intravenous (IV) line of normal saline solution running at 100 mL per hour. How do you respond? How many drops per minute do you set on her IV if the tubing has a drop factor of 15?

Answers at end of chapter.

myalgia: myo—muscle + algia—pain

help reduce pain and bleeding. Red-colored drinks are avoided because they interfere with observation for bleeding. Suction equipment should be available for emergencies.

Influenza

Pathophysiology and Etiology

Influenza, commonly referred to as the flu, is a viral infection of the respiratory tract. Many different flu viruses have been identified, and new strains appear each year, making immunization difficult. Influenza is the cause of millions of lost work days each year. The elderly are at particular risk for complications and even death from influenza because of pre-existing chronic disease and compromised immune function.

Influenza is easily transmitted via droplets from coughs and sneezes of infected individuals, or it may be transmitted by physical contact with a person or object that harbors the virus. The incubation period from time of exposure to onset of symptoms is 1 to 3 days.

Prevention

Yearly immunization is recommended for prevention of influenza. The Centers for Disease Control and Prevention (CDC) recommends a yearly vaccine for people over age 50 and for residents of extended care facilities. People with chronic illnesses such as lung disease or asthma should also be immunized. Immunization of healthy adults can reduce the risk of influenza and decrease absenteeism from work. Immunization of health care workers helps prevent the spread to at-risk patients. Although Medicare covers the cost of a flu shot, many elders do not get one. Stress that they will not get the flu from the shot, because it does not contain any live virus. Once the shot has been administered, it takes about 2 weeks for antibodies to develop; it is then effective for about 4 months. Other preventive measures include handwashing and avoidance of individuals with influenza.

Signs and Symptoms

Symptoms of flu include abrupt onset of fever, chills, myalgia, sore throat, cough, general malaise, and headache. It can last for 2 to 5 days, with malaise lasting up to several weeks.

Complications

The most common complication of influenza is pneumonia, which may be caused by the same virus as the flu or by a secondary bacterial infection. This should be considered if the patient experiences persistent fever and shortness of breath or if the lungs develop crackles or wheezes.

Diagnostic Tests

Sputum or throat cultures may be done to determine whether there is a bacterial cause of the symptoms.

Medical Treatment

Treatment is primarily symptomatic. Acetaminophen is given for fever, headache, and myalgia. Aspirin is avoided

in children because it increases the risk for Reye's syndrome. Rest and fluids are essential. Antibiotics are used only if a secondary bacterial infection is present.

Antiviral drugs such as amantadine (Symmetrel), zanamivir (Relenza) and oseltamivir (Tamiflu) may be helpful for high-risk patients if given within 48 hours of exposure. These drugs may reduce the severity and duration of symptoms. They may also be given prophylactically to high-risk people who have not been immunized.

Nursing Care

Elderly or other high-risk patients may be hospitalized for treatment of influenza. These patients are closely monitored for signs of complications. Assess lung sounds and vital signs every 4 hours and report changes to an RN or physician. Encourage rest and fluids (if not contraindicated), and provide comfort measures. Parents are educated about avoiding aspirin to treat influenza symptoms in children under 18 to prevent Reye's syndrome. (See Nursing Care Plan Box 27–2.)

CRITICAL THINKING

Murdie
Murdie is a 97-year-old nursing home resident who develops flu symptoms. She is lethargic, confused, and feverish. Because of her mental status changes, you want to send her to the hospital, but her son asks you to please keep her where she is. She has a history of chronic obstructive pulmonary disease (COPD) and diabetes.

1. How could Murdie have caught the flu?
2. How could it have been prevented?
3. What can be done now to prevent her from developing complications that could lead to her death?
4. What other concerns do you have?

Answers at end of chapter.

► MALIGNANT DISORDERS

Cancer of the Larynx

Pathophysiology

Cancer of the larynx usually develops in the mucosal epithelium. It is evaluated based on the tumor-node-metastasis (TNM) staging system described in Chapter 10. It is usually a primary cancer and can spread to the lungs, liver, or lymph nodes. The prognosis for a patient with laryngeal cancer is often poor because metastasis (spread) may have occurred before the patient sought help.

Etiology

Risk factors for cancer of the larynx include a history of alcohol and tobacco use. Exposure to industrial chemicals, hardwood dust, and chronic overuse of the voice are also factors. Men are five times as likely to be affected as women.

Prevention

Prevention begins with education; you can help educate patients about the relationship between cancer of the larynx and abuse of alcohol and tobacco. It is also important to

teach patients to seek help when symptoms first occur, because a delayed diagnosis may mean metastasis of the cancer and a poor prognosis. Teach them that any hoarseness that lasts longer than 2 weeks should be investigated by a physician.

Signs and Symptoms

The most common symptom is hoarseness, because the vocal cords are located in the larynx (Box 27-3). The patient may also have pain, shortness of breath, a chronic cough, and difficulty swallowing. Stridor may indicate a tumor obstructing the airway. Late signs include weight loss and halitosis (foul breath).

Diagnostic Tests

The larynx can be examined with a laryngeal mirror. Laryngoscopic examination and biopsy are used to diagnose and determine the stage of laryngeal cancer. A CT scan, MRI, or other diagnostic tests may be done to determine the presence or extent of metastasis.

Medical Treatment

If laryngeal cancer is diagnosed early in the disease, it may be treatable with radiation therapy; this treatment can preserve the patient's voice. Chemotherapy may be used with radiation or surgery, but usually it is not used alone. In more advanced cases, surgical intervention is necessary. The larynx will be either partially or completely removed (Fig. 27-2). If cancer has spread beyond the larynx, a radical neck dissection, which removes adjacent muscle, lymph nodes, and tissue, may be done. Surgery can be done using laser technology, endoscopy, or traditional methods. After a partial laryngectomy, the patient may have a permanently hoarse voice. If a total laryngectomy is done, the patient will have a permanent tracheostomy and no voice. Alternative methods of communication must be employed. A

BOX 27-3 Laryngeal Cancer Summary

Symptoms

Hoarse voice
Pain
Cough
Shortness of breath
Difficulty swallowing
Weight loss
Foul breath

Diagnostic Tests

Examination with laryngeal mirror
Laryngoscopy with biopsy
Additional blood and radiographic studies to detect metastasis

Therapeutic Management

Radiation therapy
Chemotherapy (adjunct to radiation or surgery)
Endoscopic laser surgery to destroy tumor
Partial laryngectomy (preserves some voice)
Radical neck dissection with total laryngectomy (loss of voice)

person who has had a laryngectomy is sometimes referred to as a **laryngectomee**.

Nursing Process: The Patient Undergoing Laryngectomy

PREOPERATIVE CARE. In addition to routine preoperative teaching, the patient undergoing laryngectomy surgery must be prepared for the loss of ability to breathe through the mouth and nose and the loss of ability to speak. Initial instruction in communication techniques should take place before surgery to prevent the patient from feeling panicky

laryngectomee: laryng—larynx + ectome—excision (person who has undergone laryngectomy)

Figure 27-2 Laryngectomy. (A) Before laryngectomy. (B) After laryngectomy.

after surgery when he or she is unable to communicate any needs. A variety of techniques and devices are available. Consult the speech therapist before surgery to provide a picture board, magic slate, or paper and pencil. (See Chapter 46.) The patient is instructed to point to the picture that corresponds with the need or to write out his or her concern. A dietary consult is also important before surgery if the patient has been undernourished.

POSTOPERATIVE CARE

Assessment. Assessment of physical and psychosocial status, comfort, nutritional status, and ability to swallow is important both before and after surgery. After surgery, assessment of airway patency and respiratory function is vital. Monitor lung sounds, oxygen saturation, and arterial blood gases. In addition, be sure to assess the patient's understanding of the disease process and self-care needs after surgery. It is important to evaluate the patient's support systems and ability to cope with the partial or total loss of voice after surgery.

Nursing Diagnosis, Planning, Implementation, and Patient Education

Ineffective airway clearance related to excessive secretions and new tracheostomy. The patient will have a laryngectomy tube in place after surgery. A laryngectomy tube is shorter and has a larger diameter than a tracheostomy tube, but care is the same. Provide routine tracheostomy care and suctioning according to hospital policy to keep the airway clear. (See Chapter 26.) Strict sterile technique is essential. Place the patient in a semi-Fowler's position to make breathing easier, and encourage the patient to deep breathe and cough every hour. A special tracheostomy collar may be used to provide oxygen and humidification. Avoid use of powders, sprays, or other airborne materials near the patient. Monitor and record amount, color, and consistency of secretions; vital signs; oxygen saturation; lung sounds; and signs of respiratory distress. Report signs of infection or respiratory distress to the physician immediately.

Acute pain related to surgical procedure. Analgesics are given as ordered, on an around-the-clock basis or via a patient-controlled pump rather than as needed, for the first few days after surgery. If the liver has been damaged from alcohol abuse, dosages are adjusted by the physician. Narcotics are given carefully because they may reduce the cough reflex, which is vital to clearing the airway. Distraction and relaxation are also helpful.

Impaired verbal communication related to loss of vocal cords. After surgery, the nurse, speech therapist, and physician work together to provide the patient with a method of communication that best fits his or her needs (Fig. 27-3). Esophageal speech involves swallowing air and forming words as it is regurgitated back up the esophagus. Electronic devices are also available, which the patient places next to the neck or mouth. These devices use sound waves to help the patient form words. Another alternative is a surgically implanted voice prosthesis that creates a valve between the trachea and esophagus. If the patient holds a finger over the tra-

Figure 27-3 Devices to aid speech in laryngectomy patient. (Courtesy Siemens Hearing Instruments, New York.)

cheostomy, air is diverted into the esophagus and the patient forms words as the air exits via the mouth. All these devices take time to adjust to, and the patient will need support after discharge to continue to develop communication skills.

Imbalanced nutrition, less than body requirements related to absence of oral feeding. Most patients receive parenteral nutrition or tube feedings after surgery until the neck has begun to heal and swallowing can be evaluated. If the patient has a history of alcohol abuse, he or she may have been undernourished before surgery. You may need to advocate for the patient and ensure that he or she is receiving adequate calories for healing. A dietitian consult is essential.

Impaired swallowing related to edema or laryngectomy tube. The patient should be carefully assessed for the ability to swallow safely before oral feedings begin. The speech therapist may be consulted to assist with a swallowing assessment and recommendations. Assure the patient that aspiration will not occur because there is no longer a connection between the mouth and the lungs. Stay with the patient during the first attempts to eat to help alleviate anxiety.

Ineffective health maintenance related to knowledge deficit regarding self-care. The patient must be taught self-care measures for his or her laryngectomy, including how to perform tracheostomy care and suctioning. (See Chapter 26.) This is begun after an assessment of the patient's readiness to learn. Involve the significant other or family whenever possible. Referral to home nursing after discharge will provide assess-

ment of the home environment, as well as follow-up instruction. A social service referral may be made for financial or psychosocial concerns if needed. Consult with the physician or check the local phone directory for laryngectomy support groups, and refer the patient to them if appropriate. The local branch of the American Cancer Society may also be able to provide information.

Grieving related to loss of voice. Inability to speak is a loss that cannot be overemphasized. Patients will grieve over this loss. In addition to voice loss, the patient may also be facing a career change if job-related exposure contributed to the disease or if loss of voice prevents returning to a previously held job. Assessing and involving support systems is important. The family is encouraged to communicate with the patient, even though it is often difficult, and to exercise patience as the patient learns to communicate with them. Local support groups may have names of people who have had similar experiences who are willing to visit with the patient. Of course, whenever referring to this type of visitor, it is important that the visitor has a positive attitude and has dealt effectively with a similar loss.

Disturbed body image related to change in body structure and function. In addition to changes in voice, the laryngectomy also now breathes through a hole in his or her neck. In time the patient may not need a tracheostomy tube, but the hole remains intact. This causes a change in body image. Again, a visitor who has been through this experience, and much support from staff and family, can be helpful. Portray an accepting attitude and allow the patient to share his or her feelings if the patient indicates a need to do so.

The patient must also be instructed to perform gentle range-of-motion exercises of the neck. Some patients may avoid extending the neck because of the location of the incision, causing muscle contracture and eventual inability to do so.

Many more nursing diagnoses may also be identified based on individual assessment, because of the many implications of this disease and surgery. To find more information for laryngectomees, visit the National Cancer Institute Web site www.cancer.gov. For information about ways laryngectomees can communicate, visit http://www.voice-center.com/larynx_ca.html. Many other Web sites can be found by using a search engine and to search for the term “laryngectomy.”

Evaluation. When evaluating the patient’s progress toward goals, ask the following questions: Does the patient verbalize an acceptable level of comfort? Is the airway clear, with-

out signs of infection? Do the patient and significant others demonstrate understanding of self-care at home or have referrals to continue learning self-care at home? Does the patient indicate satisfaction with the level and quality of communication? Are nutritional needs met, as evidenced by albumin levels greater than 3.0 and stable weight? Is the patient able to swallow if taking oral nutrition? Is the patient able to grieve appropriately, and does the patient have someone to talk to if he or she wishes? Finally, does the patient show acceptance of the laryngectomy by learning to look at it and care for it? It should be noted that many of these evaluative criteria are long term and may not be seen while the patient is hospitalized, so follow-up by a home care nurse is essential.

Answers to CRITICAL THINKING

Mr. Jondahl

Consider the possibility of hypertension as a contributing factor. Mr. Jondahl’s blood pressure is currently 140/90, which may be lower than normal for him because he has been bleeding. He is also on an antihypertensive drug and a diuretic. Explore the amount of ibuprofen being taken daily, because nonsteroidal anti-inflammatory drugs can prolong clotting time.

Mrs. Hiler

Mrs. Hiler may be swallowing blood. Examine the back of her throat with a flashlight. Check vital signs for evidence of impending shock. Notify a physician if bleeding is confirmed. Use this formula to determine drops per minute: $100 \text{ mL}/60 \text{ minute} \times 15 \text{ drops/mL} = 25 \text{ drops/minute}$.

Murdie

1. Murdie may have contracted the flu from a visitor or a staff person at the nursing home. She is susceptible because of her age and comorbid conditions (COPD, diabetes).
2. Murdie’s flu could probably have been prevented with a flu vaccination, but her son refused it because he believed it could cause her to get the flu.
3. If it is within 48 hours of symptom onset, a physician can prescribe an antiviral agent to help reduce her symptoms and shorten the course of her illness. In addition, you can provide fluids, acetaminophen, and comfort measures. You should also monitor her closely for evidence of bacterial infection or pneumonia, and report signs or symptoms immediately to a physician.
4. A major concern is that Murdie could transmit the flu to other residents or staff. Hopefully they have all been vaccinated. In addition, you must decide whether or not to send Murdie to the hospital. Check her advance directives, and talk to her son about goals for her care. If necessary, educate him about differences in nursing home and hospital care.

REVIEW QUESTIONS

1. Which of the following positions is recommended for a patient experiencing a nosebleed?
 - a. Lying down with feet elevated
 - b. Sitting up with neck fully extended
 - c. Lying down with a small pillow under the head
 - d. Sitting up leaning slightly forward
2. Which of the following is the best explanation by a nurse for why a physician did not prescribe antibiotics for influenza?
 - a. "Most cases of influenza are caused by antibiotic-resistant bacteria."
 - b. "Influenza is caused by viruses."
 - c. "Antibiotics have too many serious side effects."
 - d. "Antibiotics can interact with other medications used for influenza."
3. Which of the following responses is correct when a patient asks why her physician didn't order that new antiviral drug for her flu?
 - a. "The antiviral drugs are for AIDS, not the flu."
 - b. "The side effects of the antiviral drugs are worse than having the flu."
 - c. "Antiviral drugs are only for children."
 - d. "These drugs only work if you start them within 48 hours after flu symptoms start."
4. After a laryngectomy, which of the following assessments takes priority?
 - a. Airway patency
 - b. Nutritional status
 - c. Lung sounds
 - d. Patient acceptance of surgery
5. Which of the following communication methods will not work for the patient with a laryngectomy?
 - a. Placing a finger over the stoma
 - b. Providing a special valve that diverts air into the esophagus
 - c. Obtaining a picture board
 - d. Teaching the patient esophageal speech
6. Which of the following statements best explains why the nurse is careful when administering narcotics to a laryngectomee?
 - a. Most laryngectomees have been drug addicts in the past.
 - b. Even low doses of narcotics may cause respiratory arrest in the laryngectomee.
 - c. Narcotics can depress the cough reflex.
 - d. Laryngectomy patients have very little pain after surgery.

QUESTIONS TO GUIDE YOUR READING

1. How would you explain the pathophysiology of each of the disorders of the lower respiratory tract?
 3. What are the etiologies, signs, and symptoms of each of the disorders?
 4. What care would you provide for patients undergoing tests for each of the disorders?
 5. What is current medical treatment for disorders of the lower respiratory tract?
 6. What data should you collect when caring for patients with disorders of the lower respiratory tract?
 7. What nursing care will you provide for patients with disorders of the lower respiratory tract?
 8. What specific nursing care can you provide for patients experiencing impaired gas exchange, ineffective airway clearance, or ineffective breathing pattern?
 9. How will you know if your nursing interventions have been effective?
- pneumothorax (NEW-moh-**THAW**-raks)
 polycythemia
 (PAH-lee-sigh-**THEE**-mee-ah)
 status asthmaticus
 (**STAT**-us az-**MAT**-i-kus)
 tachypnea (**TAK**-ip-NEE-uh)
 thoracotomy (THAW-rah-**KAH**-tah-mee)

Disorders of the lower respiratory tract include problems of the lower portion of the trachea, bronchi, bronchioles, and alveoli. These disorders may be related to infection, noninfectious alterations in function, neoplasm (cancer), or trauma. Any pathological condition of the lower respiratory tract can seriously impair carbon dioxide and oxygen exchange.

▶ INFECTIOUS DISORDERS

Acute Bronchitis

Bronchitis is an inflammation of the bronchial tree, which includes the right and left bronchi, secondary bronchi, and bronchioles. When the mucous membranes lining the bronchial tree become irritated and inflamed, excessive mucus is produced. The result is congested airways. Acute bronchitis is usually an isolated episode. It becomes chronic when it occurs more than 3 months out of the year for 2 consecutive years. See Chronic Bronchitis later in this chapter for more information.

Bronchiectasis

Pathophysiology

Bronchiectasis is a dilation of the bronchial airways (Fig. 28-1). The dilated areas form sacs that can remain localized or spread throughout the lungs. Secretions pool in these sacs and frequently become infected.

Etiology

Bronchiectasis usually occurs secondary to another chronic respiratory disorder, such as cystic fibrosis, asthma, tuberculosis, bronchitis, or exposure to a toxin. Infection and inflammation of the airways weakens the bronchial walls and reduces ciliary function. Airway obstruction from excessive secretions, then predisposes the patient to development of bronchiectasis.

Signs and Symptoms

The patient with bronchiectasis has recurrent lower respiratory infections. Sputum is copious and purulent and pools in the dilated airways. The accompanying cough can produce as much as 200 mL of thick, foul-smelling sputum in a single episode of coughing. Extreme airway inflammation may cause sputum to be bloody. If bronchiectasis is widespread throughout the lungs, the patient may experience dyspnea even with minimal exertion. Wheezes and crackles may be auscultated. Fever is present during active infection. Cor pulmonale (right-sided heart failure, covered in Chapter 21) and clubbing of the fingers may develop with chronic disease.

Figure 28-1 Bronchiectasis. Note dilated airway.

Diagnostic Tests

A chest x-ray examination may be done, but it may not show early disease. A computed tomography (CT) scan provides a better view of the dilated airways. Sputum cultures determine infecting organisms and guide antibiotic therapy. Additional testing is done to determine the cause of bronchiectasis.

Medical Treatment

Treatment of bronchiectasis is aimed at keeping the airway clear of secretions, controlling infection, and correcting the underlying problem. Antibiotics may be used intermittently or for prolonged periods. **Bronchodilators** improve airway obstruction. **Mucolytic** agents help thin secretions, and chest physiotherapy helps mobilize secretions so they can be more effectively expectorated. Oxygen is used if hypoxemia is present. If the affected area of the lung is localized and symptoms are severe, surgery may be considered to remove the diseased area.

bronchitis: bronch—airway + itis—inflammation

bronchiectasis: bronch—airway + ectasis—dilation or expansion

bronchodilator: broncho—airway + dilator—to expand

mucolytic: muco—mucus + lytic—break up

Pneumonia

Pneumonia is the cause of more than 10 percent of hospital admissions each year and is the most common cause of death from infection.

Pathophysiology

Pneumonia is an acute infection of the lungs, occurring when an infectious agent enters and multiplies in the lungs of a susceptible person. Infectious particles can come from the cough of an infected individual, from contaminated respiratory therapy equipment, from infections in other parts of the body, or from aspiration of bacteria from the mouth, pharynx, or stomach. Organisms from the mouth and pharynx may be related to poor oral hygiene or may be present because of a cold or influenza virus. In a healthy person, normal respiratory defense mechanisms and the immune system prevent the development of infection. In a person who is **immunocompromised**, however, even microorganisms that are normally present in the oropharynx can develop into an infection. Persons at risk for pneumonia are the very young, the elderly, and those who are immunocompromised, such as people with acquired immunodeficiency syndrome (AIDS) or another chronic illness.

When the microorganisms multiply, they release toxins that induce inflammation in the lung tissue, causing damage to mucous and alveolar membranes. This leads to the development of edema and **exudate**, which fills the alveoli and reduces the surface area available for exchange of carbon dioxide and oxygen. Some bacteria also cause necrosis of lung tissue.

Pneumonia may be confined to one lobe, or it may be scattered throughout the lungs. If it affects only one lobe, it is called lobar pneumonia. Generalized pneumonia is much more serious and is called bronchopneumonia. Bronchopneumonia occurs more often as a nosocomial (hospital-acquired) infection in hospitalized patients, the very young, or the very old.

Etiology

Pneumonia has a variety of causes, listed next.

BACTERIAL PNEUMONIA. The most common cause of bacterial pneumonia acquired in the community is *Streptococcus pneumoniae*. This is often termed pneumococcal pneumonia. This organism accounts for approximately 90 percent of all bacterial pneumonias. Other community-acquired infections are caused by *Staphylococcus aureus* and *Mycoplasma pneumoniae*. Hospital-acquired pneumonias are often more serious and may be caused by *Escherichia coli*, *Haemophilus influenzae*, and *Pseudomonas aeruginosa*, among others.

VIRAL PNEUMONIA. Influenza viruses are the most common cause of viral pneumonia. The presence of viral pneumonia increases the patient's susceptibility to a secondary bacterial pneumonia. Generally, patients are less ill with viral pneumonia than with bacterial pneumonia, but they may be ill for a longer period because antibiotics are ineffective against viruses.

FUNGAL PNEUMONIA. *Candida* and *Aspergillus* are two types of fungi that can cause pneumonia. *Pneumocystis carinii* is a fungus that typically causes pneumonia in patients with AIDS.

ASPIRATION PNEUMONIA. Some pneumonias are caused by aspiration of foreign substances. This most often occurs in patients with decreased levels of consciousness or an impaired cough or gag reflex. These conditions can occur with alcohol ingestion, stroke, general anesthesia, seizures, or other serious illness. Aspiration pneumonia increases the risk for subsequent bacterial pneumonia.

HYPOSTATIC PNEUMONIA. Patients who hypoventilate because of bedrest, immobility, or shallow respirations are at risk for **hypostatic** pneumonia. Secretions pool in dependent areas of the lungs and can lead to inflammation and infection.

CRITICAL THINKING

Mr. Smith
Mr. Smith is an 86-year-old gentleman who was watching television when he couldn't sleep one night. After seeing a commercial for toilet cleaner, he decided his own toilet could use some attention. He used bleach and ammonia "to get it really clean." The combination created toxic fumes, which caused a severe chemical pneumonia. He was brought to the emergency room in acute respiratory distress.

- As his nurse, what questions might you ask as you further assess the cause of his pneumonia?
- What will you teach Mr. Smith related to prevention of similar episodes in the future?

Answers at end of chapter.

CHEMICAL PNEUMONIA. Inhalation of toxic chemicals can cause inflammation and tissue damage, which can lead to chemical pneumonia.

Prevention

A vaccine is available to help prevent *Streptococcus pneumoniae* pneumonias in high-risk patients and people older than age 65. It is effective about 80 to 90 percent of the time and requires only a one-time injection. Some individuals may require a repeat vaccination after 5 years. Yearly influenza vaccination is also recommended for high-risk individuals.

immunocompromised: immune—referring to immune system + compromised—lacks resistance
exudate: to sweat out

hypostatic: hypo—below + static—standing

Nursing care plays an important role in the prevention of nosocomial pneumonia. Regular coughing and deep breathing for patients on bedrest or after surgery, prevention of aspiration for patients at risk, and good handwashing practices by health care personnel can help prevent many cases (Gerontological Issues Box 28–1).

BOX 28-1 GERONTOLOGICAL ISSUES

Advanced age is a significant risk factor for serious complications from respiratory infections such as influenza and pneumococcal pneumonia. Therefore it is recommended that people over the age of 65 and individuals with chronic disease have yearly influenza vaccines and a once-in-a-lifetime pneumococcal vaccine.

Signs and Symptoms

Patients with pneumonia present with fever, shaking chills, chest pain, dyspnea, and a productive cough. Sputum is purulent or may be rust colored or blood tinged. Crackles and wheezes may be heard on lung auscultation.

Some bacterial and many viral pneumonias cause **atypical** symptoms. The patient may experience fatigue, sore throat, dry cough, or nausea and vomiting.

Elderly patients may not exhibit expected symptoms of pneumonia. New-onset confusion or lethargy in an elderly patient can indicate reduced oxygenation and should alert you to look for other symptoms or request further testing. New onset of fever or dyspnea should also cause suspicion of possible pneumonia in the elderly.

Complications

Complications from pneumonia most commonly occur in patients with other underlying chronic diseases. Pleurisy and pleural effusion (discussed later in this chapter) are two of the most common complications and generally resolve within 1 to 2 weeks. **Atelectasis** (collapsed alveoli) can occur as a result of trapped secretions and may be resolved with efforts to keep the airways clear. Other complications result from spread of infection to other parts of the body, causing meningitis, septic arthritis, pericarditis, and endocarditis. Treatment for each of these is antibiotics. Although antibiotics have greatly reduced the incidence of death related to pneumonia, it is still a common cause of death in the elderly.

Diagnostic Tests

A chest x-ray examination is done to identify the presence of pulmonary infiltrate, which is fluid leakage into the alveoli from inflammation (Fig. 28–2). In addition, sputum and blood cultures are obtained to identify the organism causing the pneumonia and determine appropriate treatment. Cultures should be obtained before antibiotics are started to avoid altering culture results. If the patient is unable to pro-

Figure 28-2 Chest x-ray examination showing infiltrates in pneumonia.

duce a sputum specimen, a nebulized mist treatment may be ordered to promote sputum expectoration. If this is unsuccessful, a bronchoscopy may be done to obtain a specimen from the very ill patient.

Medical Treatment

Broad-spectrum antibiotics are initiated before culture results are completed (be sure to obtain the specimen before starting the antibiotics). Once the culture and sensitivity report is available, specific antibiotics are ordered if the cause is bacterial. Many patients can be treated with oral antibiotics as outpatients, but hospitalization and intravenous (IV) therapy may be necessary in the elderly, chronically ill, or acutely ill individual.

Expectorants, bronchodilators, and analgesics may be given for comfort and symptom relief. Nebulized mist treatments or metered dose inhalers may be used to deliver bronchodilators. Supplemental oxygen via nasal cannula or mask is used as necessary.

Tuberculosis Pathophysiology

Tuberculosis (TB) is an infectious disease caused by the *Mycobacterium tuberculosis* bacteria. TB primarily affects the lungs, although other areas, such as the kidneys, liver, brain, and bone, may be affected as well. *M. tuberculosis* is an acid-fast bacillus (AFB), which means that when it is stained in the laboratory and then washed with an acid, the stain remains, or stays fast. *M. tuberculosis* can live in dark places in dried sputum for months, but a few hours in direct sunlight kills it. It is spread by inhalation of the tuberculosis bacilli from respiratory droplets (droplet nuclei) of an infected person.

Once the bacilli enter the lungs, they multiply and begin to disseminate to the lymph nodes and then to other parts of the body. The patient is then infected but may or may not go on to develop clinical (active) disease. During this time the body develops immunity, which keeps the infection under

atypical: a—not + typical—usual

atelectasis: atel—imperfect + ectasis—expansion

control. The immune system surrounds the infected lung area with neutrophils and alveolar macrophages. This process creates a lesion called a tubercle, which seals off the bacteria and prevents spread. The bacteria within the tubercle die or become dormant, and the patient is no longer infectious. If the patient's immune system becomes compromised, however, some of the dormant bacteria can become active again, causing reinfection and active disease. Only 5 to 10 percent of infected individuals in the United States actually develop the disease, and even then it may not occur for many years (Gerontological Issues Box 28–2).

BOX 28-2 GERONTOLOGICAL ISSUES

The reduction in immune system function from aging can decrease the effectiveness of the tuberculosis antibodies in someone who previously had dormant disease. The tuberculosis bacilli can be reactivated, causing active disease.

LEARNING TIPS

If the physician orders "sputum culture for AFB," tuberculosis is suspected. Ask whether isolation precautions should be taken while waiting for culture results.

Etiology

Crowded or poorly ventilated living conditions place people at risk for becoming infected with tuberculosis. Although tuberculosis can infect any age group, the elderly are especially at risk. Elders may have contracted the disease many years before, but it reactivates as the aging process diminishes immune function. Patients with AIDS and chronic alcohol abuse have a very high risk because of their compromised immune function. In the United States, tuberculosis is also prevalent among the urban poor and minority groups.

Before 1985 the incidence of TB was steadily decreasing. Now it is again on the rise, in part because of the prevalence of AIDS, the development of antibiotic-resistant strains of the TB bacillus, and ineffective treatment programs. TB kills 2 million people each year worldwide.¹

Prevention

Clean, well-ventilated living areas are essential to the health of all people. If a hospitalized patient is known or suspected to have tuberculosis, he or she is placed in respiratory isolation to prevent spread to staff or other patients. Special isolation rooms are ventilated to the outside. Staff should wear special high-efficiency filtration masks when in the patient's room. A regular surgical mask is *not* effective against TB. Verify with the institution's infection control department that the masks provided are effective for use with TB patients. If the patient must travel through the hallway for tests or other activities, the patient must wear a

mask. Additional protective barriers, such as gowns, gloves, or goggles, are used when contact with sputum is likely.

A vaccine against tuberculosis is available and is used in areas where TB is prevalent. It is safe, but its effectiveness has been questioned. It is not used routinely in the United States.

Ultimately prevention will come from adequate treatment of patients with TB. A current concern is the development of antibiotic-resistant strains of the tuberculosis bacillus, which develop when patients are noncompliant with drug therapy. When antibiotics are taken intermittently or discontinued early, the more virulent (stronger) bacteria survive and multiply and are resistant to the drugs being used. This drug-resistant bacteria can then be passed on to someone else. It is therefore vital to teach all patients the importance of strict compliance with drug therapy. Patients who are noncompliant with drug therapy must have a visiting nurse or other health professional observe each dose of antibiotic taken. This is called directly observed therapy (DOT). The World Health Organization currently recommends a 6- to 8-month course of treatment, with the first 2 months being directly observed.

Signs and Symptoms

Active tuberculosis is characterized by a chronic productive cough, blood-tinged sputum, and drenching night sweats. A low-grade fever may be present. If effective treatment is not initiated, a downhill course occurs, with pulmonary fibrosis, **hemoptysis**, and progressive weight loss.

Complications

Spread of the tuberculosis bacilli throughout the body can result in pleurisy, pericarditis, peritonitis, meningitis, bone and joint infection, genitourinary or gastrointestinal infection, or infection of many other organs.

Diagnostic Tests

Routine screening for tuberculosis infection is usually done with a purified protein derivative (PPD) skin test. The PPD is injected intradermally; the test is considered positive if a raised area of **induration** occurs within 48 to 72 hours. If there is a red area around the induration, this is not measured. The size of induration that indicates a positive test varies based on the individual's history (Table 28–1). A red area without induration is not considered a positive result. A positive result indicates that a person has been exposed; it does not mean that active TB disease is present.

Some health care institutions use a two-step process for baseline testing of employees and residents. If an individual has a negative test, he or she is retested in 1 to 3 weeks. This is because someone who was exposed many years ago may not react to the first test. The first test acts as a "reminder" to the immune system to react. The second test will then be positive in the person with a past TB infection.

hemoptysis: hem—blood + ptysis—to spit
induration: in—in + durus—hard

TABLE 28-1 CLASSIFYING A TUBERCULIN SKIN TEST REACTION

Size of Induration	Considered Positive For
5 mm or more	<ul style="list-style-type: none"> • People with HIV infection • Close contacts • People who have had TB disease before • People who inject illicit drugs and whose HIV status is unknown
10 mm or more	<ul style="list-style-type: none"> • Foreign-born persons • HIV-negative persons who inject illicit drugs • Low-income groups • People who live in residential facilities • People with certain medical conditions • Children younger than age 4 • People in other groups, as identified by local public health officials

Source: Retrieved August 5, 2002, from Centers for Disease Control and Prevention: Diagnosis of tuberculosis infection and disease. www.phppo.cdc.gov.
HIV = human immunodeficiency virus.

A chest x-ray examination is used as a screening tool in someone with a known positive test. Diagnosis is made based on sputum culture results.

LEARNING TIPS

Some institutions use *Candida* or mumps skin tests along with a PPD skin test. This does not mean the patient is being tested for *Candida* or mumps, because everyone generally reacts to these. Rather, the patient is being tested for **anergy**, or the inability of the immune system to react to an antigen. If the *Candida* or mumps tests produce positive results, the TB results are considered to be reliable.

The *Candida* or mumps test is administered in the same way as the PPD. If more than one test is administered, use an indelible marker to identify which test is which, and clearly document (draw a picture) of where each test was placed. Check institution policy; it may direct where the tests are administered—PPD in the right arm and *Candida* in the left, for example.

Medical Treatment

Treatment consists of specific antibiotic therapy. First-line drugs (Box 28-3) have the fewest adverse effects. However, these drugs can be toxic to the liver and nervous system, as well as having other side effects. Second-line drugs are more toxic and are reserved for cases that do not respond to first-line drug therapy. Generally two or three antibiotics are given simultaneously to allow lower doses of each individual drug and to reduce the incidence of serious side effects. Drugs must be taken for 6 to 8 months or longer. Because of the length of therapy and the incidence of side effects, you must anticipate that compliance may be a problem.

BOX 28-3 Antibiotics Used in Treatment of Tuberculosis

First-line Drugs	Second-line Drugs
Isoniazid	Ethionamide
Rifampin	Kanamycin
Streptomycin	Para-aminosalicylic acid
Ethambutol	Cycloserine
Pyrazinamide	

Nursing Care

Perform thorough respiratory and psychosocial assessments of the patient with TB. The severity of the disease determines the impact on the patient's lifestyle. It is also imperative to determine the patient's knowledge of the disease and treatment and his or her compliance with drug treatment.

Possible nursing diagnoses include impaired gas exchange, ineffective airway clearance, ineffective breathing pattern, anxiety, imbalanced nutrition, risk for infection of patient's contacts, and possible noncompliance with drug therapy or ineffective therapeutic regimen management. Diagnoses should be chosen based on individual patient data.

Nursing interventions for impaired gas exchange, airway clearance, and breathing pattern are found in Nursing Care Plan Box 28-4 for the Patient with a Lower Respiratory Tract Disorder. Anxiety may be reduced by educating the patient in self-care measures and by reassuring the patient that the disease can be controlled by careful compliance with treatment. The patient who is emaciated because of the disease will benefit from a dietitian consultation to provide specific recommendations or supplements. To prevent spread of infection to others, teach the patient to use a tissue to cover the mouth and nose when coughing or sneezing. Tissues should be flushed down the toilet or disposed of carefully in the trash. Teach all family members the importance of careful handwashing, how to manage drug therapy, and when to report side effects. Forewarn the patient that rifampin turns the urine and body fluids red.

A visiting nurse is essential to evaluate the home environment and assess the patient's ability to comply with therapy. If the patient is unable to comply with therapy, measures must be instituted to ensure that medications are taken to protect both the patient and the public. Directly observed therapy at a local health clinic or by a home health nurse may be necessary.

The patient will be followed periodically by the physician for sputum cultures and drug monitoring. Once sputum cultures are negative, the patient is no longer contagious.

The Centers for Disease Control and Prevention has an excellent Web site with lots of information about tuberculosis at www.cdc.gov. Simply type "tuberculosis" into the search window.

BOX 28-4**NURSING CARE PLAN FOR THE PATIENT WITH A LOWER RESPIRATORY TRACT DISORDER**

Note: The three most commonly used nursing diagnoses related to respiratory disorders are presented in the following care plan. This is not a care plan for any one respiratory disorder. Rather, the student should use it as a reference for use when one of the nursing diagnoses applies to the patient, based on a thorough respiratory assessment.

 **Impaired gas exchange related to decreased ventilation or perfusion**

PATIENT OUTCOMES

The patient will experience improved gas exchange, as evidenced by (1) improving arterial blood gases or pulse oximetry and (2) statement of acceptable level of dyspnea.

EVALUATION OF OUTCOMES

(1) Are blood gases or SaO₂ improving? (2) Does patient state that dyspnea is gone or controlled at an acceptable level?

INTERVENTIONS

- Assess lung sounds, respiratory rate and effort, use of accessory muscles.
- Observe skin and mucous membranes for cyanosis.
- Assess degree of dyspnea on a scale of 0 to 10, 0 = no dyspnea, 10 = worst dyspnea.
- Monitor for confusion or changes in mental status.
- Monitor arterial blood gas values and pulse oximetry as ordered.
- Elevate head of bed or help patient to lean on overbed table.
- Position with good lung dependent (“good lung down”).
- Administer supplemental oxygen at ≤ 2 L/min unless ordered otherwise.
- Teach patient relaxation exercises.
- Teach patient diaphragmatic and pursed-lip breathing. (See Chapter 26.)
- Encourage patient to stop smoking if patient is a current smoker.
- For severe dyspnea, ask physician about an order for intravenous morphine sulfate.

RATIONALE

Respiratory rate less than 12 or more than 24 or use of accessory muscles indicates distress. Diminished lung sounds indicate possible poor air movement and impaired gas exchange.

Cyanosis indicates poor oxygenation. Oral mucous membrane cyanosis indicates serious hypoxia.

The patient’s subjective report is the best measure of dyspnea.

Changes in mental status can signal impaired gas exchange.

PaO₂ < 80 mm Hg, PaCO₂ > 45 mm Hg, or SaO₂ < 90 indicate impaired gas exchange.

Upright positioning promotes lung expansion.

This position allows the healthier lung to be better perfused and increases gas exchange.

Supplemental oxygen decreases hypoxia.

Rates more than 2 L/min can depress hypoxic drive.

Relaxation exercises decrease perceived dyspnea.

Breathing exercises promote relaxation and increase CO₂ excretion.

Smoking is damaging to lungs and respiratory function.

Low doses of IV morphine cause vasodilation, which helps relieve pulmonary edema and anxiety.

EVALUATION

Are lung sounds clear and audible? Is respiratory rate 12 to 20 per minute and unlabored?

Are skin and mucous membranes pink?

Is patient’s degree of dyspnea within parameters that are acceptable to patient?

Is patient alert and oriented? If not, could poor gas exchange be the reason?

Are values within patient’s baseline values?

Did change of position relieve some distress?

Is SaO₂ improved in this position?

Is oxygen placed properly on patient? Does it provide relief from dyspnea?

Does patient use relaxation effectively?

Does patient use breathing exercises correctly? Do they help?

Is patient receptive to smoking cessation? Are resources available?

Does morphine provide relief from dyspnea?

 **Ineffective airway clearance related to excessive secretions**

PATIENT OUTCOMES

The patient will have improved airway clearance as evidenced by (1) clear breath sounds and (2) ability to cough up secretions.

EVALUATION OF OUTCOMES

(1) Are breath sounds clear? (2) Is patient able to effectively cough up and expectorate secretions?

INTERVENTIONS

- Assess lung sounds q4h and prn.
- Monitor amount, color, and consistency of sputum.
- Encourage oral fluids; use cool steam room humidifier.

RATIONALE

Crackles and wheezes may indicate excess secretions in airways.

Thick, purulent sputum indicates infection and should be reported to the physician.

Hydration decreases viscosity of secretions and aids expectoration.

EVALUATION

Do lung sounds indicate retained secretions?

Does sputum indicate infection?

Is patient able to take oral fluids? Are secretions thin and easily expectorated?

BOX 28-4 NURSING CARE PLAN FOR THE PATIENT WITH A LOWER RESPIRATORY TRACT DISORDER—CONT'D

<ul style="list-style-type: none"> • Turn patient q2h or encourage to ambulate if able. • Encourage patient to cough and deep breathe every hour and prn. • Administer expectorants as ordered. • If patient is unable to cough up secretions, suction per institution policy. • Obtain order for chest physiotherapy or flutter valve if indicated. 	<p>Movement mobilizes secretions.</p> <p>Controlled coughing following deep breaths is more effective.</p> <p>Expectorants help liquefy secretions and trigger the cough reflex.</p> <p>Suctioning is necessary to remove secretions when the patient is unable to cough effectively.</p> <p>Percussion and postural drainage help mobilize secretions.</p>	<p>Is patient mobile?</p> <p>Does patient cough and deep breathe effectively?</p> <p>Are expectorants effective?</p> <p>Is suctioning necessary? Does it help remove secretions?</p> <p>Is chest physiotherapy effective and well tolerated by the patient?</p>
---	---	---

▶ Ineffective breathing pattern related to anxiety or pain

PATIENT OUTCOMES

The patient will maintain an effective breathing pattern as evidenced by (1) respiratory rate between 12 and 20 per minute, even, and unlabored; and (2) arterial blood gas and oxygen saturation results within patient’s normal range.

EVALUATION OF OUTCOMES

(1) Is patient’s respiratory rate within normal limits and unlabored? (2) Does breathing pattern support normal blood gas and SaO₂ values?

INTERVENTIONS

- Assess respiratory rate, depth, and effort q4h and prn.
- Monitor blood gas and oxygen saturation values.
- Determine and treat the cause of ineffective breathing pattern.
- Place patient in Fowler’s or semi-Fowler’s position.
- Teach patient to use diaphragmatic breathing, with a regular 2 second in, 4 second out pattern.

RATIONALE

Respirations less than 12 or more than 20 may indicate an ineffective pattern.

An ineffective breathing pattern will not maintain oxygenation.

Pain or anxiety can cause a patient to change the breathing pattern, and should be treated.

This allows for maximum chest expansion.

Breathing exercises promote relaxation and increase CO₂ excretion.

EVALUATION

Is respiratory pattern ineffective?

Is breathing pattern adversely affecting oxygenation?

Is a contributing factor identifiable and correctable?

Is the patient in a comfortable position that enables the patient to breathe effectively?

Is the patient able to demonstrate an effective breathing pattern?

▶ NURSING PROCESS: THE PATIENT WITH A LOWER RESPIRATORY INFECTION

ASSESSMENT. Question the patient about a history of respiratory disorders, smoking history, and symptoms of the current illness using the WHAT’S UP? format in Chapter 26. Ask about dyspnea, activity tolerance, cough, and sputum presence, including amount, consistency, and color. Whenever possible, observe the sputum. Ask the patient to rate the degree of dyspnea on a scale of 0 to 10. Physical assessment includes vital signs, lung sounds, color of skin and mucous membranes (including presence of cyanosis), use of accessory muscles, and observation of adaptive measures such as positioning to ease respiratory distress.

NURSING DIAGNOSIS. Possible nursing diagnoses include ineffective airway clearance related to increased mucus production, impaired gas exchange related to reduced ventilation, hyperthermia, and activity intolerance related to dyspnea and malaise.

PLANNING. Nursing care is aimed at relieving symptoms and promoting comfort. The airway should be free of secretions, dyspnea and fever should be controlled, and the patient should receive assistance with activities of daily living (ADL) until activity tolerance improves.

IMPLEMENTATION. Oral or intravenous fluids, a room humidifier, expectorants, and reminders to cough and deep breathe every 1 to 2 hours help the patient to raise sputum. Chest physiotherapy may be ordered to help loosen secretions if necessary. Pain control will assist the patient in taking deep breaths and coughing. Suction is used if the patient is unable to cough effectively.

Place the patient in Fowler’s or semi-Fowler’s position to promote lung expansion and reduce dyspnea. Administer oxygen and antibiotics as ordered. Provide acetaminophen as ordered for fever and malaise. Offer assistance with ADLs and allow frequent rest periods until the patient is able to tolerate an increase in activity. (See Nursing Care Plan Box 28-4 for the Patient with a Lower Respiratory Tract Disorder for additional interventions.)

PATIENT EDUCATION. Instruct the patient in use of medications at home and the importance of finishing the antibiotic prescription. Explain the benefit of pacing activities to prevent fatigue and dyspnea and teach measures to prevent recurrence of infection. The patient should also be aware of signs and symptoms to report to the physician.

EVALUATION. If the plan has been effective, dyspnea will be controlled at a level that is acceptable to the patient. The patient will be able to effectively cough up secretions, which will become progressively less purulent. The patient will verbalize correct understanding of medication use at home, and activity tolerance will improve.

CRITICAL THINKING

Jim

Jim is a 36-year-old accountant with bronchiectasis secondary to cystic fibrosis. You enter his room during an episode of uncontrolled coughing and offer him support. You observe his sputum as you dispose of it—a whole Styrofoam coffee cup full of thick, bright yellow sputum; the smell makes you nauseous. Even after coughing, his lungs sound congested from retained secretions. You offer him mouth care before you leave his room.

1. What questions can you ask Jim to assess his cough?
2. What nursing diagnosis is most appropriate for Jim?
3. What nursing care can you provide to enhance secretion removal?
4. You have an order for guaifenesin 300 mg q4h prn. It is supplied as 200 mg per 5 mL. How much will you administer?
5. How would you document this episode of coughing?

Answers at end of chapter.

► RESTRICTIVE DISORDERS

Restrictive disorders are those problems that limit the ability of the patient to expand his or her lungs. These are caused by a decrease in the **compliance** (or elasticity) of the lungs or chest wall.

Pleurisy (Pleuritis)

Pathophysiology

Recall that the visceral and parietal pleura are the membranes that surround the lungs. Between these membranes is a serous fluid that prevents friction as the pleurae slide over each other during respiration. If the membranes become inflamed for any reason, they do not slide as easily. Instead of sliding, one membrane may “catch” on the other, causing it to stretch as the patient attempts to inspire. This causes the characteristic sharp pain on inspiration. The irritation causes an increase in the formation of pleural fluid, which in turn reduces friction and decreases pain.

Etiology

Pleurisy is usually related to another underlying respiratory disorder, such as pneumonia, tuberculosis, tumor, or trauma.

Signs and Symptoms

Pleurisy causes a sharp pain in the chest on inspiration. Pain also occurs during coughing or sneezing. Breathing may be shallow and rapid, because deep breathing increases pain. The patient may also exhibit fever, chills, and an elevated white blood cell count if the cause is infectious. A pleural friction rub is heard on auscultation.

Complications

As pleural membranes become more inflamed, serous fluid production increases, which may result in pleural effusion (see next section). If pleuritic pain is not controlled, patients have difficulty breathing deeply and coughing, which may lead to atelectasis. If infection goes untreated, empyema can result.

Diagnostic Tests

Diagnosis is based on signs and symptoms, including auscultation of a pleural friction rub. A chest x-ray examination and complete blood cell count (CBC) may be done. Additional testing is done to determine the underlying cause.

Medical Treatment

Treatment is aimed at correcting the underlying cause. Narcotics are given to control pain and facilitate deep breathing and coughing. The physician may perform a nerve block, injecting anesthetic near the intercostal nerves to block pain transmission.

Pleural Effusion

Pathophysiology

When excess fluid collects in the pleural space, it is called a pleural effusion. Fluid normally enters the pleural space from surrounding capillaries and is reabsorbed by the lymphatic system. When a pathological condition causes an increase in fluid production or inadequate reabsorption of fluid, excess fluid collects. A normal amount of pleural fluid around each lung is 1 to 15 mL. More than 25 mL of fluid is considered abnormal; as much as several liters of fluid can collect at one time. The effusion can be either transudative, forming a watery fluid from the capillaries, or exudative, with fluid containing white blood cells and protein from an inflammatory process.

Etiology

Like pleurisy, pleural effusion is generally caused by another lung disorder. It is a symptom rather than a disease. Transudative effusions may result from heart failure, liver disorders, or kidney disorders. Exudative effusions more commonly occur with lung cancer, infection, or inflammation.

Signs and Symptoms

Symptoms depend on the amount of fluid in the pleural space. The patient may or may not experience pleuritic pain. Increasing shortness of breath occurs because of the decreasing space for lung expansion. Cough and tachypnea may be present. A dull sound is heard when the affected

area is percussed. Lung sounds are decreased or absent over the effusion, and a friction rub may be auscultated.

Diagnostic Tests

A chest x-ray examination is done to determine whether pleural effusion is present. If a thoracentesis is done, fluid samples are sent to the laboratory for culture and sensitivity and cytological examination. Further tests may be done to determine the cause of the effusion.

Medical Treatment

Bedrest is recommended to enhance spontaneous resolution of the effusion. If symptoms are severe, a therapeutic thoracentesis is done to remove the excess fluid from the pleural space and relieve the patient of dyspnea. See Chapter 26 for how to assist with a thoracentesis. The physician will use x-ray examinations and percussion to determine where to insert the needle to obtain the fluid. If the fluid accumulation is large or recurring, a chest tube might be placed to continuously drain the pleural space. Occasionally talc or another irritating agent will be instilled via the chest tube to cause the pleural membranes to adhere to each other, eliminating the pleural space and preventing future episodes of pleural effusion. Treatment of the underlying cause of the effusion is necessary to prevent recurrence.

Empyema

Empyema is the collection of pus in the pleural space. It is a pleural effusion that is infected. Empyema is usually a complication of pneumonia, tuberculosis, or lung abscess.

Symptoms, diagnosis, medical treatment, and nursing care are the same as the care of the patient with a pleural effusion, with an added emphasis on resolving the infection. A chest tube or surgery may be necessary to drain the area.

Atelectasis

Atelectasis is the collapse of alveoli. It most commonly occurs in postsurgical patients who do not cough and deep breathe effectively, although it can be caused by anything that causes hypoventilation. Areas of the lungs that are not well aerated become plugged with mucus, which prevents inflation of alveoli. As a result, alveoli collapse. Compression of lung tissue from effusion or a tumor can also cause atelectasis. The focus of nursing care is on prevention. Patients should be taught the importance of coughing and deep breathing whenever there is the risk for hypoventilation. Frequent position changes and ambulation are also important.

► NURSING PROCESS: THE PATIENT WITH A RESTRICTIVE DISORDER

ASSESSMENT. Perform a routine respiratory assessment. Monitor lung sounds for friction rub or decreasing breath sounds in any of the lobes. Assess pain level. Promptly report any increase in dyspnea, changes in vital signs or pulse oximetry, or increased white blood cell count or temperature.

NURSING DIAGNOSIS. Most patients experience fear or anxiety when they feel dyspneic. Impaired gas exchange occurs if atelectasis or hypoventilation are present. Risk for infection occurs when there is stasis of pleural fluid. Ineffective breathing pattern is identified when the patient is unable to take a deep breath due to pain on inspiration or buildup of fluid.

PLANNING AND IMPLEMENTATION. Stay with the patient during acute dyspneic episodes and encourage an effective breathing pattern. (See Chapter 26.) Analgesics reduce pain so that the patient will be better able to take deep breaths, though opioids are used cautiously because of their ability to depress respirations. Encourage coughing and deep breathing to help prevent infection and atelectasis. Administer oxygen as ordered. Bedrest is maintained during acute episodes of dyspnea. Encourage fluids unless contraindicated. Instruct the patient to report signs and symptoms of recurrence promptly to the physician. See Chapter 26 for care of the patient undergoing a thoracentesis.

EVALUATION. If interventions have been effective, the patient should report a decrease in dyspnea and anxiety. Pain will be controlled so that the patient is able to take deep breaths and cough effectively, and the patient will be free of signs and symptoms of infection.

► CHRONIC OBSTRUCTIVE PULMONARY DISEASE/CHRONIC AIRFLOW LIMITATION

Pathophysiology

Chronic obstructive pulmonary disease (COPD) is a group of pulmonary disorders characterized by difficulty exhaling because of narrowed or blocked airways. More effort is required to push air out through obstructed airways (Fig. 28–3). **Emphysema**, chronic bronchitis, and asthma are disorders that limit airflow. A patient with COPD often has some degree of both emphysema and chronic bronchitis. Asthma may also be present, but it differs somewhat because the airway constriction in asthma is reversible, whereas the airflow limitation in emphysema and bronchitis is not. Generally either emphysema or bronchitis predominates. COPD may also be referred to as chronic airflow limitation (CAL) or chronic obstructive lung disease (COLD). COPD develops over at least 30 years before symptoms become evident and may be advanced by the time the patient seeks treatment. Box 28–5 summarizes COPD.

Chronic Bronchitis Pathophysiology

Chronic bronchitis is similar to acute bronchitis, with symptoms occurring for at least 3 months out of the year for 2 consecutive years. The bronchial tree becomes inflamed from inhaled irritants, and impaired ciliary function reduces the ability to remove the irritants. The mucous-producing glands in the airways become hypertrophied, producing excessive thick, tenacious mucus, which obstructs airways and

emphysema: to inflate

AIR TRAPPING IN CHRONIC AIRFLOW LIMITATION

A. Air trapping from excess mucous

Air movement
during inspirationAir trapping
during expiration

B. Air trapping from decreased elastic recoil

Normal
inspirationImpaired
expiration

Air trapped due to
decreased elastic recoil of
alveolus and collapsed airway

Figure 28-3 Air trapping in COPD.

traps air (Fig. 28-4). These changes lead to chronic low-grade infection.

Emphysema Pathophysiology

Emphysema affects the alveolar membranes, causing destruction of the alveolar walls and loss of elastic recoil. This also causes damage to adjacent pulmonary capillaries. Because of the loss of elastic recoil, passive expiration is impaired and air is trapped in the alveoli. Reduction in pulmonary capillaries reduces gas exchange. Emphysema can occur primarily in the respiratory bronchioles (centrilobular emphysema), with delayed alveolar damage, or in the respiratory bronchioles and alveoli (panlobular emphysema) (Fig. 28-5).

Etiology

Smoking is the single most important risk factor for COPD. Other factors include passive (secondhand) smoking, air pollution, and exposure to industrial chemicals. Some familial predisposition to chronic bronchitis has been demonstrated. A small number of individuals have an inherited deficiency of the enzyme alpha-antitrypsin (α_1 AT), which causes a predisposition to the development of emphysema.

BOX 28-5 COPD Summary

Signs and Symptoms

Cough, may be productive
Dyspnea
Activity intolerance
Crackles, wheezes, diminished breath sounds
Barrel chest
Use of accessory muscles
Elevated PaCO_2 , decreased PaO_2

Diagnostic Tests

Chest x-ray exam, CT scan
Arterial blood gas analysis (later in disease process)
CBC
Sputum analysis
Pulmonary function studies
 α_1 AT level if deficiency suspected

Therapeutic Management

Smoking cessation
Bronchodilators (PO, NMT, MDI)
Corticosteroids, expectorants
Flu and pneumonia vaccinations
Supplemental oxygen
Breathing exercises
Chest physiotherapy
Pulmonary rehabilitation

MDI = metered dose inhaler; NMT = nebulized mist treatment; PO = by mouth.

Patients with this inherited tendency who also smoke have a very high risk of developing the disease. Children of smoking parents are at higher risk because of secondhand smoke exposure.

Prevention

Prevention is important because no cure for COPD is currently available. Avoidance of smoking and other inhaled irritants is vital, especially in those individuals with parents or siblings with COPD.

Signs and Symptoms

The patient with COPD exhibits prolonged expiration because of obstructed air passages. Hyperinflated lungs caused by air trapping leads to the classic barrel-shaped chest. The patient with chronic bronchitis has a chronic productive cough, shortness of breath, and activity intolerance. Symptoms may initially be worse in the winter months. Crackles and wheezing are often noted on auscultation and may improve after coughing. The most characteristic symptom of emphysema is progressive shortness of breath, accompanied by activity intolerance. Use of accessory muscles is evident. Auscultation reveals diminished breath sounds. Remember that many patients exhibit symptoms of both chronic bronchitis and emphysema.

Arterial blood gases (ABGs) may be checked during an acute exacerbation of COPD and may show an increase in

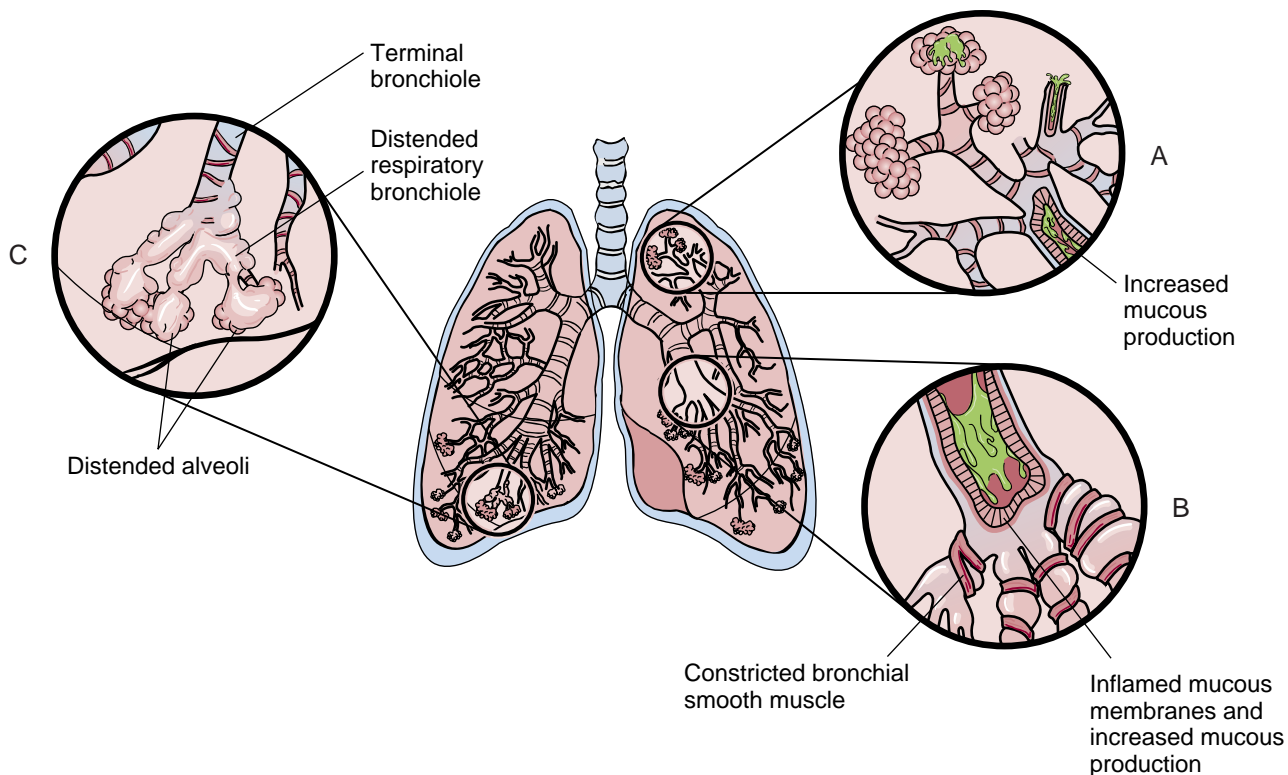

Figure 28-4 (A) Chronic bronchitis. Note inflamed airways and excessive mucus. (B) Asthma. Note narrowed bronchial tubes and swollen mucous membranes. (C) Emphysema. Note distended respiratory bronchioles and alveoli.

PaCO_2 and often a low PaO_2 . The patient develops **polycythemia** in response to reduced oxygenation, which results in a ruddy skin color. Cyanosis may also be present. Right-sided heart failure may develop because the heart has to work harder to pump to the diseased lungs. (See the section on cor pulmonale in Chapter 21.)

In late stages of COPD, patients may lose weight and become malnourished. They have difficulty eating because of severe dyspnea, and the increased work of breathing expends more calories. Chronic hypoxemia causes release of certain chemicals that may also lead to weight loss.

Complications

Some patients with emphysema develop large air spaces within the lung tissue (**bullae**) or adjacent to the pleurae (**blebs**). These are like blisters that can rupture and cause the lung to collapse. In severe COPD, cor pulmonale can develop. Death can result from respiratory infection or respiratory failure.

Diagnostic Tests

Information from a chest x-ray examination, CT scan, blood gas analysis, CBC, sputum analysis, and pulmonary function studies is correlated with the history and physical examination to diagnose COPD. An $\alpha_1\text{AT}$ level is checked if deficiency is suspected.

polycythemia: poly—many + cyt—cells + emia—in the blood

Medical Treatment

The most important treatment measure for COPD is the cessation of smoking. Even late in the disease process, stopping smoking can slow disease progression and prolong life. Exposure to other respiratory contaminants should also be minimized. Hair spray, body powder, and other household aerosols should be avoided.

Oxygen is administered as ordered at a flow rate of 1 to 2 L. Higher flow rates are avoided to prevent suppression of the hypoxic drive. Patients with chronic oxygen saturation levels of less than 88 percent may be placed on home oxygen. A pulmonary rehabilitation program can help the patient increase exercise tolerance. Breathing exercises help improve oxygenation and reduce anxiety. (See Chapter 26.) Bronchodilators and expectorants may be helpful. Table 28-2 lists medications that are used in the treatment of COPD and lower respiratory disorders.

A pneumococcal vaccination and yearly influenza vaccinations are recommended to reduce the risk of respiratory infection. Avoidance of crowds and exposure to people with respiratory infections is advised.

Medications commonly used include adrenergic, anticholinergic, or theophylline bronchodilators; expectorants; and, intermittently, antibiotics. Because the risk for infection is high, the patient is taught to report the onset of purulent sputum as soon as it begins, so treatment can be initiated quickly. Steroids may be used late in the disease to reduce airway inflammation. See Table 28-2 for medications used in the treatment of COPD.

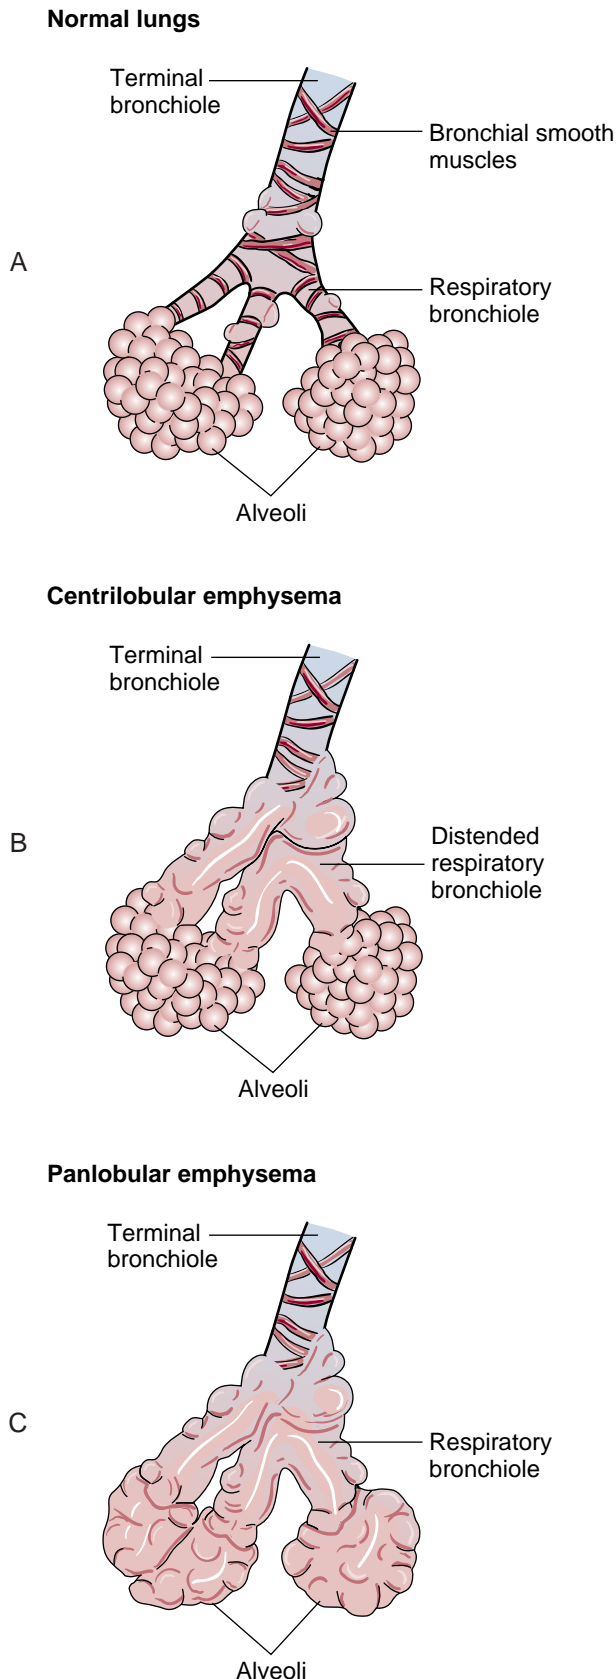

Figure 28-5 Types of emphysema. (A) Normal lungs. (B) Centrilobular emphysema. (C) Panlobular emphysema.

Good hydration and a cool mist humidifier help keep secretions loose. Chest physiotherapy may be used to help the patient remove excessive secretions. Nebulized mist treatments and metered dose inhalers are commonly used to administer bronchodilators. A dietitian consultation is helpful for the patient who is unable to maintain a desirable weight. Pulmonary rehabilitation programs can help the patient increase exercise tolerance and maintain a sense of well-being.

A newer treatment for emphysema is the surgical removal of some of the diseased lung tissue (called lung volume reduction surgery, or LVRS). This increases the space available for good lung tissue to expand, reducing dyspnea and increasing exercise tolerance. This is a high-risk procedure, but it has allowed some patients to return to a more normal activity level. Another new treatment is replacement of α_1 AT. Research is ongoing to determine if either of these treatments will alter long-term outcomes of the disease. Lung transplant may be an option in some patients. Check the American Lung Association Web site for more information at www.lungusa.org.

▶ ASTHMA

The incidence of asthma is on the rise. Nearly 12 million people in the United States have asthma. It is more prevalent in African-Americans than in whites. Nearly 5000 people die from asthma each year. Asthma deaths are more prevalent in lower socioeconomic groups, presumably because of lack of compliance with treatment regimens. With careful monitoring and treatment, however, patients with asthma can control their symptoms and lead normal lives.

Pathophysiology and Etiology

Asthma is characterized by inflammation of the mucosal lining of the bronchial tree and spasm of the bronchial smooth muscles (**bronchospasm**). This causes narrowed airways and air trapping. (See Fig. 28-4.) Symptoms are intermittent and reversible, with periods of normal airway function. About 50 percent of asthmatics develop the disorder in childhood, but contrary to popular belief, most children do not outgrow asthma. Instead, symptoms just diminish, often returning later in life.

The tendency to develop asthma is inherited. Some sources classify asthma as either allergic or idiosyncratic (unexpected). Allergic asthma is triggered by allergens such as pollen, foods, medications, animal dander, air pollution, molds, or dust mites. It is commonly seasonal. Individuals who developed asthma as children tend to have allergic asthma. Idiosyncratic asthma is generally diagnosed in adults and is related to environmental or other nonallergic factors, such as environmental irritants, smoking, and respiratory or sinus infection. Emotional upset and exercise can also trigger symptoms in some persons with asthma. Asthma frequently complicates chronic bronchitis or emphysema.

A newer finding is asthma caused by gastroesophageal reflux disease (GERD). It is believed that stomach acid may

bronchospasm: broncho—airway + spasm—convulsion, narrowing

TABLE 28-2 SELECTED MEDICATIONS USED FOR LOWER RESPIRATORY TRACT DISORDERS

Drug Class and Examples	Route	Action	Side Effects and Nursing Implications
Glucocorticoids			
Methylprednisolone (Medrol, Solumedrol)	PO IV	Potent anti-inflammatory agents, reduce inflammation in airways	Cushingoid side effects with prolonged use: moon face, sodium and water retention, buffalo hump, osteoporosis, hyperglycemia. May be given IV, PO, or inhaled. Inhaled route causes fewer side effects. Never discontinue abruptly.
Prednisone	PO		
Triamcinolone acetonide (Azmacort)	Inhaled		
Beclomethasone (Vanceril, Beclovent)	Inhaled		
Fluticasone (Flovent)	Inhaled		
Bronchodilators			
<i>Adrenergic</i>			
Albuterol (Ventolin, Proventil)	PO, Inhaled	Stimulate beta receptors to dilate bronchioles	Adrenergic agents cause increased heart rate, tremor, anxiety. Use with care in patients with cardiac disease. Overuse can cause rebound bronchospasm. Serevent is long acting, used bid only.
Metaproterenol (Alupent, Metaprel)	PO, Inhaled		
Pirbuterol (Maxair)	Inhaled		
Salmeterol (Serevent)	Inhaled		
<i>Anticholinergic</i>			
Ipratropium (Atrovent)	Inhaled	Blocks parasympathetic response, causing bronchodilation	
<i>Methylxanthines</i>			
Theophylline (Theovent, Theolair, Uniphyll)	PO	Relax bronchial smooth muscle to dilate airways	Most common side effects are tremor, anxiety, tachycardia, nausea, vomiting. Therapeutic theophylline level 5–15 µg/mL.
Aminophylline	PO, IV		
Combination Agents			
Albuterol and ipratropium (Combivent)	Inhaled		
Fluticasone and Salmeterol (Advair)			
Mast Cell Stabilizers			
Cromolyn sodium (Intal)	Inhaled	Stabilize mast cells to reduce histamine release	Few side effects. Effective for allergic asthma. May be used prophylactically before exercise or allergen exposure.
Nedocromyl (Tilade)			
Expectorants			
Guaifenesin (Robitussin, Humabid)	PO	Liquefy secretions and stimulate cough	Few side effects. Encourage fluids.
Antileukotrienes			
Zafirlukast (Accolate)	PO	Inhibit leukotriene synthesis or activity, a mediator of inflammation in asthma	No serious side effects. Possible elevation of liver enzymes.
Montelukast (Singulair)			
Zileuron (Zyflo)			
Antitussives			
Codeine	PO	Suppress cough reflex	Related to opioids; may be sedating at high doses. Avoid giving to patient who has secretions that need to be expectorated.
Dextromethorphan (DM suffix in cough preparations)			

NOTE: This table is an overview. A drug guide should be consulted for complete administration guidelines.

PO = by mouth.

reflux into the esophagus and then be aspirated, triggering asthma. This occurs especially at night. GERD and its treatment are discussed in Chapter 30.

Prevention

Although asthma cannot be prevented, individual episodes can be. It is important that the patient identify triggers of asthma symptoms and avoid them whenever possible. Compliance with prophylactic and maintenance therapy is also important.

Signs and Symptoms

Asthma symptoms are intermittent and are often referred to as “attacks,” which may last from minutes to days. The pa-

tient complains of chest tightness, dyspnea, and difficulty moving air in and out of the lungs. Once initial symptoms are controlled, airways may remain hypersensitive and prone to asthma symptoms for many weeks.

On examination, you will note an increased respiratory rate as the patient attempts to compensate for narrowed airways. Inspiratory and expiratory wheezing is heard because of turbulent airflow through swollen airways with thick secretions and may sometimes be audible even without a stethoscope. Air is trapped in the lungs, and expiration is prolonged. A cough is common and may produce thick, clear sputum. Use of accessory muscles to breathe is a sign that the attack is severe and warrants immediate attention.

Be aware that an absence of audible wheezing may not signal improvement but rather may be an ominous sign that the patient is moving very little air. If wheezing is not heard, use of accessory muscles and peak expiratory flow rate values must be carefully evaluated. Once treatment begins to be effective and the patient is moving more air, wheezing may become audible.

Complications

Status asthmaticus occurs if bronchospasm is not controlled and symptoms are prolonged. As the patient increases the respiratory rate to compensate for narrowed airways, a lot of carbon dioxide is blown off and respiratory alkalosis occurs. If the attack is not resolved and the patient begins to tire, the patient will no longer be able to compensate and PaCO_2 will rise, resulting in respiratory acidosis. This can lead to respiratory failure and death if untreated.

Diagnostic Tests

Diagnosis is based on the patient's report of symptoms, physical examination, and pulmonary function studies. Peak expiratory flow rate is reduced. Arterial blood gases may initially show decreased PaCO_2 . Late in the course of an attack, PaO_2 decreases and PaCO_2 increases. Allergy skin testing and increased serum IgE and eosinophil levels indicate allergic involvement and may help determine treatment.

Medical Treatment

MONITORING. Some patients monitor their peak expiratory flow rate (PEFR) at home (Fig. 28–6). This is a measure of the amount of air the patient can blow into a peak flowmeter from fully inflated lungs and is measured in liters per minute. The patient determines his or her normal PEFR during symptom-free times. If the PEFR begins to fall below the patient's personal norm, treatment that has been predetermined with the health care provider should be initiated. Readings can be charted to keep track of progress (Fig. 28–7). Often PEFR results indicate the onset of asthma before the patient experiences any symptoms (Home Health Hints).

HOME HEALTH HINTS

- When a patient is using oxygen by nasal cannula, the area around the ears can become irritated or excoriated. A small sponge-type hair roller can be placed around the tubing to protect the ears.
- When a home health patient has a metered dose inhaler (MDI), the nurse should not assume he or she is using it correctly. The patient should be observed using it. (Review procedure in Chapter 26.)
- When a patient requires more than one MDI, the canisters can be numbered in the order they are to be taken.
- To tell if an inhaler is empty, put the canister in a bowl of water. A full canister will sink and an empty canister will float.
- To help the COPD patient conserve energy, he or she can be encouraged to sit on a stool when cooking at the stove or doing dishes. Personal care activities should be spaced throughout the day (shampoo, bath, etc.).
- If the COPD patient is tempted to adjust his or her own oxygen flow rate, equipment suppliers can put on a locking flowmeter. Increasing flow rate can reduce hypoxic drive and cause hypoventilation.
- Nebulizer parts should be cleaned three times a week or every other day, using warm soapy water in a common home disinfectant solution for 30 minutes.

Figure 28-7 Peak flow chart. The green zone is 80 to 100 percent of the patient’s normal peak flow rate. The yellow zone is 50 to 80 percent of normal. The red zone is less than 50 percent of normal. The patient works with the physician to determine which actions to take when readings fall in the yellow or red zones.

AVOIDANCE OF TRIGGERS. The patient is instructed to identify and avoid asthma triggers. If triggers cannot be avoided, the patient can use bronchodilator or mast cell inhibitor metered dose inhalers (MDIs) as prescribed before exposure. MDIs can be especially useful before exercise. Animal dander and foods that cause symptoms are best avoided when possible. Eliminating carpets and curtains in bedrooms, using vinyl mattress and pillow covers, and installing a portable or central air filter can reduce dust mite exposure. Maintenance of indoor humidity between 40 and 50 percent can reduce mold growth. If cold air triggers symptoms, the patient should keep his or her nose and mouth covered when outside in cold weather. Smoking and exposure to secondary smoke are strongly discouraged.

Aspirin and nonsteroidal anti-inflammatory drugs can cause asthma symptoms in some individuals. Beta-blocking medications (propranolol, metoprolol), used commonly for hypertension, block beta receptors in the lungs, preventing the sympathetic nervous system from promoting bronchodilation. These drugs should be avoided if they make symptoms worse.

MEDICATIONS. Medications for asthma treatment may be continuous or intermittent, depending on the chronicity of symptoms. See Table 28–2 for a summary of medications

used in the treatment of lower respiratory disorders. For patients with only occasional symptoms, adrenergic bronchodilators such as albuterol (Proventil, Ventolin) may be administered via MDI when symptoms occur or before exercise or other events that trigger asthma.

If the patient needs to use an adrenergic MDI more than three times a week, a mast cell inhibitor such as cromolyn sodium (Intal) or nedocromil sodium (Tilade) MDI or an inhaled steroid (Azmacort, Beclovent) may be added. Steroids delivered via metered dose inhalers have become popular and effective therapy in recent years. Because they are used topically, side effects are minimal. Instruct the patient that mast cell inhibitors and steroids must be used regularly to prevent symptoms and will not provide immediate symptom relief during an acute attack. Some patients use mast cell inhibitors 10 to 15 minutes before exposure to allergens or exercise to reduce symptoms.

LEARNING TIPS

If both bronchodilator and corticosteroid inhalers are used at the same time, instruct the patient to use the bronchodilator first. This opens the airways and allows the corticosteroid to be better distributed in the lungs.

If inhaled medications do not control symptoms, or if the patient has nocturnal symptoms, oral theophylline bronchodilators such as Theovent or Theo-Dur may be added. Alternatively, antileukotrienes may be tried; these are in a newer class of bronchodilators that have fewer side effects than theophylline. Immunotherapy (allergy shots) may be used for some patients with allergic asthma.

An acute asthma attack may be treated with an inhaled (nebulized) or subcutaneous adrenergic bronchodilator or intravenous aminophylline. Intravenous or oral corticosteroids (methylprednisolone, prednisone) are potent anti-inflammatory agents that are useful in an acute episode but are avoided for long-term therapy if possible because of their cushingoid side effects. (See the section on Cushing's syndrome in Chapter 37.) Corticosteroids must be tapered before discontinuing, to prevent withdrawal symptoms. (See the section on Addisonian crisis in Chapter 37.)

Oxygen is not often necessary, because many patients hyperventilate. If the attack is prolonged and the patient becomes cyanotic or PaO₂ levels begin to fall, oxygen therapy will be used.

LEARNING TIPS

Instruct the patient to contact the health care provider if the patient is using more than two adrenergic MDI canisters per month. This has been associated with an increased risk of death.

► CYSTIC FIBROSIS

In the past, cystic fibrosis (CF) was thought to be just a childhood disease, because most affected children did not survive past puberty. However, with new treatments, patients with CF are living longer and more productive lives. Some CF patients now marry, have careers, and live well into their thirties.

Pathophysiology

CF is a disorder of the exocrine glands that affects primarily the lungs, gastrointestinal (GI) tract, and sweat glands. The disease varies in severity; some patients have no GI involvement. Abnormal sodium and chloride transport across cell membranes, causing thick, tenacious secretions, is responsible for many of the characteristic symptoms. Thick, sticky respiratory secretions that are difficult to remove cause airway obstruction, resulting in frequent respiratory infections.

Similar abnormalities in the pancreas cause blocked ducts and retained digestive enzymes. These retained enzymes digest and destroy the exocrine pancreas. The absence of digestive enzymes in the intestines causes malabsorption of essential nutrients; frequent foul-smelling, fatty stools; and excess flatus.

Patients with CF secrete sweat that is high in sodium and chloride, because these electrolytes are not reabsorbed as they pass through the sweat ducts.

Etiology

CF is a genetic disorder. Both parents must be carriers of the defective gene for CF to be present in a child. Patients who marry are counseled on the risk of potential offspring having the disease.

Signs and Symptoms

Symptoms usually first appear in infancy or childhood, although a few individuals are not diagnosed until adulthood. Respiratory symptoms are often the first visible manifestation of the disease and range from chronic sinusitis to production of thick, tenacious sputum. Patients with CF are at risk for frequent respiratory infections, manifested by an increase in cough and purulent sputum. Finger clubbing is common. Late in the disease, hemoptysis may occur related to damaged blood vessels within the lungs. Over time, bouts of infection become more frequent, with eventual loss of lung function and respiratory failure. Antibiotic-resistant bacteria are a threat to life in these individuals.

Frequent foul-smelling stools result from the lack of enzymes in the small intestine. Inability to absorb fat-soluble vitamins and poor appetite due to respiratory disease result in malnutrition. Bowel obstruction, cirrhosis, cholecystitis, and cholelithiasis are associated findings.

Chronic disease causes delayed sexual maturation in both males and females, and infertility is common.

Complications

Patients with CF are at risk for a variety of complications, including bronchiectasis, pneumothorax, cor pulmonale, and respiratory failure. Bowel obstructions can occur as a result of thick mucus binding with poorly digested fecal matter. Diabetes from pancreatic islet cell involvement may be present late in the disease. Death is usually the result of pulmonary complications.

Diagnostic Tests

Because so many different gene mutations can occur in CF, genetic testing is not helpful at this time. The standard diagnostic test is the sweat chloride test. If respiratory symptoms are accompanied by excessive amounts of sodium chloride in sweat, CF is diagnosed. The reader may recall public health campaigns that advised parents to kiss their babies and report any salty taste to their physicians.

Medical Treatment

Because there is no cure for CF, treatment is aimed at relieving symptoms. Removal of thick sputum is promoted with hydration, use of the Flutter mucous clearance device, and chest physiotherapy up to four times a day. Regular exercise also helps mobilize secretions. A hot shower may be an easy occasional alternative to loosen secretions. Nebulized mist treatments using saline or mucolytic medications may be used before chest physiotherapy. Medications to decrease the viscosity of secretions have not yet been entirely successful, but new drugs are constantly being tested. Inhaled bronchodilators are sometimes useful. High doses of

ibuprofen (Motrin) may slow lung deterioration. Breathing exercises, incentive spirometry, and effective coughing techniques are also helpful. Lung transplant is a potentially promising treatment.

Prevention of infection is vital to slowing progression of lung damage. Antibiotics must be administered as soon as signs of infection occur. Prophylactic antibiotic therapy may be used. Some patients use home intravenous antibiotic therapy. Antibiotic-resistant infections are a deadly threat to the CF patient.

Pancreatic enzyme replacement (Pancrease, Viokase) helps reduce symptoms related to malabsorption and improve nutritional status. An increase in calorie requirements necessitates a high-calorie, nutrient-dense diet. For more information, visit the Cystic Fibrosis Foundation at www.cff.org.

Nursing Care

Nursing care of respiratory system problems in the patient with CF is similar to care of the patient with COPD. However, be sure to remember the special needs of the adolescent patient with this chronic, debilitating disease. Not only are normal physical growth and development delayed, but psychosocial development is also affected by repeated hospitalizations and the necessity of routine daily medication and treatments.

► NURSING PROCESS: THE PATIENT WITH COPD/CAL

ASSESSMENT. Perform a complete respiratory assessment as presented in Chapter 26. Frequency of assessment is dictated by the severity of the patient's condition. Note level of consciousness; poor gas exchange causes confusion and lethargy. Observe skin and mucous membranes for cyanosis. Auscultate lung sounds for adventitious sounds. Monitor cough and color and amount of sputum. Note exercise tolerance, and measure degree of dyspnea on a scale of 0 to 10. Monitor oxygen saturation or arterial blood gases. Careful documentation of findings allows you to monitor and report trends in the patient's progress.

NURSING DIAGNOSIS. A number of nursing diagnoses are appropriate for the patient with COPD. As always, choose diagnoses based on defining characteristics and the patient's individual assessment findings. Impaired gas exchange caused by poor ventilation or damaged alveoli is common and can be easily identified when dyspnea is accompanied by abnormal ABGs. Ineffective airway clearance related to copious thick secretions is also a common occurrence, especially in patients with chronic bronchitis and cystic fibrosis. Ineffective breathing pattern may occur related to anxiety. Activity intolerance related to hypoxia is often present. Related diagnoses may include imbalanced nutrition: less than requirements related to dyspnea and poor appetite, and anxiety related to dyspnea. See Nursing Care Plan Box 28–4 for the Patient with a Lower Respiratory Disorder.

PLANNING. To increase patient acceptance of the plan of care, the patient must be involved in identifying goals. The

airway should remain clear of secretions. Anxiety should be manageable. Dyspnea should be controlled to allow the patient to maintain his or her desired activity level, within appropriate limitations. Nutrition status should be stable.

IMPLEMENTATION

Impaired Gas Exchange, Ineffective Airway Clearance, Ineffective Breathing Pattern. Gas exchange, airway clearance, and breathing pattern are priority problems for most respiratory patients. Interventions for these diagnoses are presented in Nursing Care Plan Box 28–4 for the Patient with a Lower Respiratory Tract Disorder.

Activity Intolerance. Encourage the patient to rest between activities. Even talking or eating can cause dyspnea in a patient with end-stage disease. A bedside commode prevents unnecessary trips to the bathroom. A shower chair and handheld showerhead conserve energy while bathing. If the patient is able to ambulate, a portable oxygen source should be used. The patient should be allowed to sleep without interruptions at night as much as possible. Most patients sleep with the head of the bed elevated; a reclining chair may be used at home. Activity level is slowly increased if the patient is able. Referral to a pulmonary rehabilitation program can help increase exercise tolerance.

Altered Nutrition. The cause of altered nutrition must first be identified. If the patient is too dyspneic to eat, scheduling rest periods and nebulized mist treatments or MDI administration before meals may be helpful. A poor appetite can be improved by creating a pleasant eating environment; providing smaller, more frequent meals of the patient's favorite foods; or encouraging family members to bring food from home for the hospitalized patient. Liquid supplements may be necessary to maintain weight. A specialized supplement such as Pulmocare provides less carbon dioxide when metabolized and may be used for patients with respiratory disease (Nutrition Notes Box 28–6).

Anxiety. Remain with the patient who is acutely anxious. A calm voice reminding the patient to breathe slowly in through the nose and out through pursed lips can be very helpful. Relaxation exercises, learned during times when anxiety is minimal, may be used at this time. Some patients learn to fold their arms just below the ribcage. They then push into their belly while exhaling to help push out trapped air and release pressure during inhalation. Antianxiety medications are given as ordered. Intravenous morphine helps acute dyspnea and anxiety, but it is usually reserved for patients with end-stage disease.

PATIENT EDUCATION. The patient must be aware of the contributing factors to the disease and eliminate them if at all possible. The patient who is a smoker should not simply be told to quit smoking; he or she should be referred to a smoking cessation program and be provided with medication, nicotine patches, or other resources and support as necessary to quit. (See Chapter 26.) Techniques for effective breathing and anxiety control should also be taught.

BOX 28-6

Nutrition Notes

Optimizing Nutrition in Patients with Respiratory Disease

Many factors affect nutrition in a patient with respiratory disease. For example, patients commonly have an inadequate food intake because of anorexia, shortness of breath, or gastrointestinal (GI) distress or a combination of these problems.

Caloric requirements are commonly increased in patients with pulmonary disease. The caloric cost of breathing ranges from 36 to 72 calories each day in normal people, but it increases to 430 to 720 calories each day in patients with chronic obstructive pulmonary disease (COPD). Both decreased food intake and increased energy requirements may contribute to the weight loss commonly seen in these patients. When caloric intake is decreased, the body begins to break down muscle stores, including the respiratory muscles.

The GI distress common in these patients may be related to malnutrition of the GI tract. Malnutrition and the resulting decrease in antibody production lower the patient's resistance to infection. Also, the malnourished patient's lungs produce less pulmonary phospholipid, a fatlike substance that assists in lubricating lung tissue and helps to protect the lungs from inhaled pathogens.

Improved nutritional status has been associated with an increased ability to wean patients from respirators or ventilators. To some extent, all the respiratory muscles atrophy from inactivity when a machine does the work for the patient. Nutrition support improves the likelihood of successful weaning in patients on artificial respiration.

Many patients with COPD have carbon dioxide retention and oxygen depletion. The medical goal for these patients is to decrease the level of carbon dioxide in their blood. Because fat calories produce less carbon dioxide when metabolized than carbohydrate calories, a diet with as much as 50 percent of the calories from fat may be prescribed. Several companies produce complete nutritional supplements with higher fat content formulated for patients with respiratory disease. Medical opinion is not unanimous on this issue because some evidence has related a high fat intake to immunosuppression in some patients.

NURSING INTERVENTIONS. Many respiratory patients are breathless and lack the energy to eat. Offer small frequent feedings of nutrient-dense foods. Select foods that require little or no chewing. To lessen abdominal pressure on the diaphragm, discourage gaseous foods.

EVALUATION. If interventions have been effective, the airway will be clear of secretions. The patient will be able to manage anxiety symptoms and complete ADLs or other desired activity without dyspnea. The patient's intake should be adequate to maintain a stable weight. If any of the patient's goals have not been met, the plan of care should be revised.

Rehabilitation of the Patient with COPD

Many institutions now have pulmonary rehabilitation departments. These programs help patients learn effective breathing techniques and how to slowly increase their exercise tolerance. You can request this referral when appropriate.

CRITICAL THINKING

Mr. Franklin

Mr. Franklin is admitted to the respiratory unit with exacerbated COPD. He has a history of emphysema and now has an acute infection complicating his disease. His lung sounds are very diminished, and he is short of breath at rest, even on 4 L of oxygen per nasal cannula. You walk into his room when he puts on his call light and find him sitting on the bedside commode with a look of panic in his eyes. He is gasping for breath, his color is gray, and his respiratory rate is 36 per minute.

1. What do you do first?
2. What can you teach Mr. Franklin to prevent an acute dyspneic episode in the future?
3. How will you document this episode?

Answers at end of chapter.

PULMONARY VASCULAR DISORDERS

Pulmonary Embolism

Pathophysiology

An **embolism** is a foreign object that travels through the bloodstream. It may be a blood clot, air, or fat. A pulmonary embolism (PE), sometimes called pulmonary thromboembolism (PTE), is usually a blood clot that has traveled into a pulmonary artery. Resulting obstruction of blood flow causes a ventilation-perfusion mismatch, which in this case means that an area of the lung is well ventilated with air but has no blood flow, or perfusion. Because reduced or no blood supply is available to pick up the oxygen in the affected portion of the lung, it becomes pulmonary "dead space," causing seriously impaired gas exchange.

Occasionally damage occurs to a portion of the lung because of lack of oxygen. This is called lung infarction, and it is not common because oxygen is delivered to lung tissue not only from the pulmonary arteries but also via the bronchial arteries and the airways.

Etiology

Most pulmonary emboli originate in the deep veins of the lower extremities (deep vein thrombosis, or DVT). Some risk factors of DVT, and therefore PE, include surgical procedures done under general anesthesia, heart failure, fractures of the lower extremities, bedrest, obesity, and a previous history of DVT or PE. Less common causes of PE include fat emboli from compound fractures, amniotic fluid embolism during labor and delivery, and air embolism from entry of air into the bloodstream.

Prevention

Prevention of thrombi in the deep veins of the legs is the most important factor in the prevention of a pulmonary embolism. Regular ambulation is advised if the patient is able. If a patient is at risk for DVT or PE, low-dose heparin, enoxaparin, warfarin (Coumadin), or intermittent compression stockings are used to prevent thrombus formation. If a

DVT is diagnosed, prompt treatment is essential to prevent a PE.

Signs and Symptoms

The most common symptom of PE is a sudden onset of dyspnea for no apparent reason. The patient may be gasping for breath and may appear anxious. Tachycardia, tachypnea, and cough may be present. Auscultation may reveal crackles or a friction rub. If lung infarction has occurred, hemoptysis and pleuritic chest pain may also be present. Some patients have no symptoms at all. Be alert to the presence of risk factors and obtain immediate assistance if the cause of dyspnea might be PE. Death can occur if treatment is not quick and effective.

Complications

High blood pressure within the pulmonary circulation (pulmonary hypertension) may result from arterial occlusion and lead to right ventricular failure. This occurs because the right ventricle is unable to push blood into the occluded artery. As a result, the contraction becomes weak, cardiac output falls, and the patient becomes hypotensive.

Diagnostic Tests

A spiral CT scan is a new and fast type of CT scan that is noninvasive and can diagnose PE quickly. If this is not available, a lung scan (ventilation-perfusion scan) is done to assess the degree of ventilation of lung tissue and the areas of blood perfusion. If an area is well ventilated but poorly perfused (i.e., a mismatch), PE is suspected.

A pulmonary angiogram can outline the pulmonary vessels with a radiopaque dye injected via a cardiac catheter. This can show where blood flow is diminished or absent, suggesting an embolism.

Chest x-ray examination, electrocardiogram (ECG), arterial blood gas analysis, or magnetic resonance imaging (MRI) may also be done. However, many of these show changes only in the presence of a very large embolism or infarction.

Medical Treatment

The body naturally dissolves clots in 7 to 10 days. However, if the embolism is large, a thrombolytic agent might be used. These agents, such as streptokinase, urokinase, and tissue plasminogen activator (t-PA), dissolve clots and are very effective. However, they must be used within 4 to 6 hours of the clot's occurrence and are associated with a risk for hemorrhage.

If a thrombolytic agent is not used, treatment is aimed at preventing extension of the clot and the formation of additional clots. Heparin, a potent anticoagulant medication, is administered via continuous intravenous infusion. Sometimes an intermittent IV or subcutaneous route is used. Heparin is never given intramuscularly because of the risk of hematoma development. Clotting studies (partial thromboplastin time [PTT] or thrombin clotting time [TCT]) are monitored and maintained at 1.5 to 2 times the control

value. Sometimes heparin therapy is initiated even before a diagnosis of PE is made. It is believed that it is safer to begin therapy and then stop if PE is not confirmed than to wait until all test results are available.

Oxygen is administered as ordered. Intubation and mechanical ventilation may be required in some cases.

Warfarin sodium, an oral anticoagulant, is used for approximately 12 weeks following the embolism to prevent recurrence. It can also be used for long-term prevention of repeated clots in patients who have risk factors that cannot be resolved. Warfarin therapy can be initiated 2 to 3 days after the initiation of heparin therapy. Because it has a slow onset of action, it may require several days for the full anticoagulant effect to occur. The patient will be on both anticoagulants for a time. Warfarin therapy is monitored regularly with prothrombin times or international normalized ratios (INRs). See Box 28–7 for education topics for patients on anticoagulant therapy.

If clots are a recurring problem, a filter may be placed into the inferior vena cava via the jugular or femoral vein. One filter that is commonly used is the Greenfield filter, which filters out clots traveling from the lower extremities toward the heart and lungs.

In patients with life-threatening symptoms, a surgical embolectomy can be performed. This is a rare procedure that is reserved for emergency situations.

Nursing Care

ASSESSMENT. The patient is assessed for respiratory distress, including respiratory rate and effort, cyanosis, confusion, and subjective feelings of dyspnea and anxiety. Lung sounds are auscultated. Sputum color and amount are noted. Arterial blood gases and oxygen saturation are mon-

BOX 28-7 Education for Clients Receiving Anticoagulant Therapy

Anticoagulants prolong the time it takes blood to clot, so it is important to prevent injury and to recognize and report signs of bleeding to the physician.

To Prevent Injury

- Wear shoes or slippers; avoid going barefoot.
- Use an electric razor to shave.
- Use a soft toothbrush.

Signs of Bleeding to Report to Physician

- Easy bruising
- Nosebleeds
- Bleeding that does not stop
- Blood in urine
- Blood in sputum
- Blood in stools or black stools

Additional Instructions

- Avoid use of aspirin because it further prolongs clotting time.
- Have your lab work done as prescribed by your physician to monitor your clotting time and medication dosage.

itored. Heart sounds and peripheral edema are monitored for signs of heart failure. Contributing factors, such as calf pain, are assessed.

NURSING DIAGNOSIS. The priority nursing diagnosis for a patient with a pulmonary embolism is impaired gas exchange. Because of the impaired perfusion of the affected area of the lung, oxygen and carbon dioxide exchange are limited. Anxiety occurs related to dyspnea. Risk for injury related to anticoagulant therapy is a concern once treatment is initiated.

PLANNING AND IMPLEMENTATION

Impaired gas exchange. Administer oxygen as ordered. Bedrest is maintained to decrease oxygen demand. Assisting the patient with turning, coughing, and deep breathing further facilitates gas exchange.

Anxiety. Stay with the patient during acute episodes of dyspnea. Answer the patient's questions, and provide information about pulmonary embolism and its treatment at a level appropriate to the patient's need and tolerance because knowledge may help decrease anxiety. Administer antianxiety agents as ordered.

Risk for injury. Monitor coagulation studies and report results to the physician. Protect the patient from injury, so that excessive bleeding does not occur. Encourage the patient to wear shoes or slippers when ambulating. A soft toothbrush and an electric razor are used. Instruct the patient to report any signs of bleeding, such as hematuria or easy bruising. (See Box 28–7.)

EVALUATION. The patient should state that dyspnea and anxiety are controlled, and verbalize understanding of anticoagulant therapy and precautions.

Pulmonary Hypertension *Pathophysiology and Etiology*

Primary pulmonary hypertension occurs when the arteries that carry deoxygenated blood from the heart to the lungs become narrowed as a result of changes in the vascular smooth muscle. The result is elevated pressure in the pulmonary arteries, causing the right ventricle to work harder to push blood into them. Eventually the right ventricle fails. The reason for these vascular changes is not known. Primary pulmonary hypertension is more common in women between ages 20 and 40 and has a hereditary tendency.

Secondary pulmonary hypertension results from other disorders, such as coronary artery disease or mitral valve disease, both of which increase pressures in the left side of the heart. The pulmonary arterial pressure then rises to push blood into the left heart. Capillary destruction related to alveolar damage in COPD can also lead to secondary pulmonary hypertension. Right ventricular failure eventually occurs as the heart works to push blood against high pulmonary arterial pressures.

Signs and Symptoms

The most common symptoms include dyspnea and fatigue, which worsen over time. Crackles and decreased breath sounds are heard on auscultation. Cyanosis and **tachypnea** (rapid respiratory rate) are noted. If heart failure is present, peripheral edema and distended jugular veins are seen. Angina may result from right ventricular ischemia. Death usually occurs within 2 to 3 years of diagnosis, unless a lung or heart-lung transplant is done.

Diagnostic Tests

Arterial blood gases commonly show hypoxemia and hypocapnia. Cardiac catheterization can be done to determine high pulmonary arterial pressures. An ECG may show right ventricular hypertrophy. A chest x-ray examination, pulmonary function tests, lung scan, and pulmonary angiogram may be done to determine underlying causes in secondary pulmonary hypertension.

Treatment

No cure is available for pulmonary hypertension, except for lung or heart-lung transplant. In secondary pulmonary hypertension, the underlying disorder is treated. Supportive care includes a low-sodium diet and diuretics to reduce blood volume (and therefore pressure), oxygen, and cardiac monitoring. Vasodilators such as calcium channel blockers may be beneficial in some patients to reduce pulmonary artery pressure. Warfarin may be used to prevent clotting. A newer therapy is IV administration of prostacyclin, a vasodilator that may reverse some of the vascular changes but has many serious side effects. Nursing care is collaborative and focuses primarily on patient assessment. Fowler's or high Fowler's position may help reduce dyspnea, and bedrest and comfort measures are helpful in treating fatigue and anxiety.

► TRAUMA Pneumothorax

The term **pneumothorax** literally means "air in the chest" and is used to describe conditions in which air has entered the pleural space outside the lungs. If the pneumothorax occurs without an associated injury, it is called a spontaneous pneumothorax. A secondary spontaneous pneumothorax may occur due to underlying lung disease. Traumatic pneumothorax may result from a penetrating chest injury.

Pathophysiology and Etiology

Recall that the pleural cavity has visceral and parietal pleurae. These membranes normally are separated only by a thin layer of pleural fluid. Each time a breath is taken in, the diaphragm descends, creating negative pressure in the thorax.

tachypnea: tachy—rapid + pnea—breathing
pneumothorax: pneumo—air + thorax—chest

This negative pressure pulls air into the lungs via the nose and mouth. If either the visceral pleura or the chest wall and parietal pleura is perforated, air enters the pleural space, negative pressure is lost, and the lung on the affected side collapses (Fig. 28–8). Each time the patient takes a breath, the temporary increase in negative pressure draws air into the pleural space via the perforation. During expiration, air may or may not be able to escape through the perforation.

SPONTANEOUS PNEUMOTHORAX. If no injury is present, the pneumothorax is considered spontaneous. This occurs mostly in tall, thin individuals and in smokers. Patients who have had one spontaneous pneumothorax are at greater risk for a recurrence. Patients with underlying lung disease (especially emphysema) may have blisterlike defects in lung tissue, called bullae or blebs, that can rupture, allowing air into the pleural space. Weakened lung tissue from lung cancer can also lead to pneumothorax.

TRAUMATIC PNEUMOTHORAX. Penetrating trauma to the chest wall and parietal pleura allows air to enter the pleural space. This can occur as a result of a knife or gunshot wound or from protruding broken ribs.

OPEN PNEUMOTHORAX. If air can enter and escape through the opening in the pleural space, it is considered an open pneumothorax.

CLOSED PNEUMOTHORAX. If air collects in the space and is unable to escape, a closed pneumothorax exists.

TENSION PNEUMOTHORAX. If a pneumothorax is closed, air, and therefore tension, builds up in the pleural space. As tension increases, pressure is placed on the heart and great vessels, pushing them away from the affected side of the chest. This is called a mediastinal shift. When the heart and vessels are compressed, venous return to the heart is impaired, resulting in reduced cardiac output and symptoms of shock. Tension pneumothorax is often related to the high pressures present with mechanical ventilation. It is a medical emergency.

HEMOTHORAX. The term **hemothorax** refers to the presence of blood in the pleural space. This can occur with or without accompanying pneumothorax (hemopneumothorax) and is often the result of traumatic injury. Other causes include lung cancer, pulmonary embolism, and anticoagulant use.

Signs and Symptoms

Sudden dyspnea, chest pain, tachypnea, restlessness, and anxiety occur with pneumothorax. On examination, asymmetrical chest expansion on inspiration may be noted. Breath sounds may be absent or diminished on the affected side. In a “sucking” chest wound, air can be heard as it enters and leaves the wound.

hemothorax: hem—blood + thorax—chest

Figure 28–8 Types of pneumothorax. (A) Spontaneous pneumothorax. (B) Traumatic pneumothorax. (C) Tension pneumothorax with mediastinal shift.

If tension pneumothorax develops, the patient becomes hypoxemic and hypotensive as well. The trachea may deviate to the unaffected side. Heart sounds may be muffled. Bradycardia and shock occur if emergency intervention is not provided.

Diagnostic Tests

History, physical examination, and chest x-ray examination are used to diagnose pneumothorax. Chest x-ray examinations are repeated to monitor the resolution of the pneumothorax with treatment. Arterial blood gases and oxygen saturation are monitored throughout the course of treatment.

Medical Treatment

A small pneumothorax may absorb with no treatment other than rest, or the trapped air may be removed with a small-bore needle inserted into the pleural space. Chest tubes connected to a water seal drainage system are used to remove larger amounts of air or blood from the pleural space. See Chapter 26 for complete information about chest drainage. A Heimlich valve is another option, used for some patients who are treated at home. This is a small rubber tube that is attached to the chest tube instead of the water seal drainage system. The tube opens to allow air to escape, but then collapses during inspiration to prevent reentry of air into the pleural space. Some injuries require surgical repair before the pneumothorax can be resolved.

If the pneumothorax is recurrent, other treatments can be used to prevent additional episodes. Sterile talc or certain antibiotics (such as tetracycline) can be injected into the pleural space via thoracentesis, irritating the pleural membranes and making them stick together. This is called **pleurodesis**, or sclerosis, and prevents recurrent pneumothorax. Pleurodesis is painful; prepare the patient with an analgesic before the procedure.

Nursing Care

Nursing care of the patient with a pneumothorax involves close monitoring of the condition. A frequent and thorough assessment should be done, including level of consciousness, skin and mucous membrane color, vital signs, respiratory rate and depth, and presence of dyspnea, chest pain, restlessness, or anxiety. Regular auscultation of lung sounds provides information about reinflation of the affected lung. Any signs of increasing or tension pneumothorax are reported to the physician immediately. See Chapter 26 for care of the patient with a chest tube and water seal drainage system.

Rib Fractures

Etiology and Signs and Symptoms

Chest trauma is often accompanied by fractured ribs. Uncontrolled coughing, especially in the presence of osteoporosis or cancer can also fracture ribs. The fourth through ninth ribs are the most commonly affected. Broken ribs can be very painful, and often prevent the patient from breathing deeply or coughing effectively, which can result in atelectasis or pneumonia. Displaced ribs can also damage lung tissue, causing pneumothorax.

pleurodesis: pleur—pleural membrane + desis—binding

Treatment

In the past, elastic rib belts were used to stabilize the ribs while healing took place. These are no longer used because it further restricts deep breathing. Pain control is the most important treatment. Keeping the patient comfortable allows coughing and deep breathing, which in turn prevents complications such as pneumonia and atelectasis. If traditional pain control measures are ineffective, intercostal nerve blocks may be used. Ribs generally heal in about 6 weeks.

Flail Chest

Pathophysiology and Etiology

When multiple ribs are fractured, the structural support of the chest is impaired. As a result, the affected part of the chest collapses with inspiration and bulges with expiration. This is called **paradoxical respiration**, which is ineffective in ventilating the lungs and results in hypoxia.

Signs and Symptoms

The patient with a flail chest exhibits chest movement that is opposite to that usually seen with respiration. The patient is dyspneic, anxious, tachypneic, and tachycardic.

Treatment

The patient is given supplemental oxygen. Intubation and mechanical ventilation may be necessary. If lung damage has occurred, chest tubes may be necessary for reinflation.

► **NURSING PROCESS: THE PATIENT WITH CHEST TRAUMA**

The following nursing process is based on the stabilized patient. For emergency care of the patient with chest trauma, see Chapter 12.

ASSESSMENT. When caring for the patient following chest trauma, it is important to monitor respiratory status. Any sign of worsening status should be reported to the physician immediately, such as a change in vital signs or lung sounds; change in respiratory rate; increase in dyspnea, chest pain, pallor, or cyanosis; development of tracheal deviation; or new onset of anxiety. If a chest wound is present, it is cared for and closely monitored. Additional assessment may be necessary depending on the type of injury sustained.

NURSING DIAGNOSIS. Nursing diagnoses for the patient with chest trauma may include impaired gas exchange, acute pain, ineffective breathing pattern, and anxiety. Additional diagnoses may be appropriate depending on the individual patient's assessment.

PLANNING AND IMPLEMENTATION. Gas exchange is maintained with supplemental oxygen. Mechanical ventilation may be necessary. Position the patient for comfort and maximum chest expansion and encourage him or her to take deep breaths. Control pain with analgesics, so the patient is able to breathe deeply. Remember that narcotics depress respirations, so respiratory rate is carefully monitored. Splinting

the chest for coughing may also be helpful to reduce pain. Additional care is necessary if the patient has chest tubes.

EVALUATION. Are pain, anxiety, and dyspnea controlled? Is the respiratory rate within normal limits? Are vital signs stable? Frequent evaluation is essential, so that failure to progress can be reported to the physician.

► RESPIRATORY FAILURE

Acute Respiratory Failure

Pathophysiology

Acute respiratory failure is diagnosed when the patient is unable to maintain adequate blood gas values. Hypoxemia may result from inadequate ventilation (air movement in and out of lungs) or poor oxygenation (adequate ventilation but inability to get the oxygen into the blood and therefore the cells). Some patients with chronic respiratory disease have adapted to impaired gas exchange. In these patients a drop in PaO₂ of 10 to 15 mm Hg is considered acute failure.

Etiology

An acute respiratory infection in a patient with chronic airway obstruction is often the precipitating factor in acute respiratory failure. Other causes include central nervous system disorders that affect breathing, such as a stroke or myasthenia gravis, inhalation of toxic substances, and aspiration.

Prevention

Avoidance of respiratory infections in patients with chronic respiratory disease is important. Patients should be instructed to notify their physician immediately if sputum becomes purulent so treatment can be initiated.

Sedatives and narcotics should be used carefully or avoided in patients with chronic respiratory disease, because these are respiratory depressants and can precipitate failure.

Signs and Symptoms

The patient with impending respiratory failure may become restless, confused, agitated, or sleepy. Arterial blood gases show decreasing PaO₂ and pH and increasing PaCO₂.

Diagnostic Tests

Arterial blood gas analysis is important in determining the presence of respiratory failure. A drop in PaO₂ of 10 to 15 mm Hg or a pH of less than 7.30 with associated elevated PaCO₂ indicates respiratory failure. Sputum cultures or chest x-ray examinations may be used to determine the cause and guide treatment. Pulse oximetry is used to continuously monitor oxygen saturation.

Medical Treatment

Carefully assess the patient and report significant findings to the physician immediately. It is easy to mistakenly treat symptoms of agitation or confusion with sedatives, which will speed the onset of respiratory failure. Oxygen therapy via nasal cannula or mask is provided at a flow rate of 1 to 2 L to prevent interference with the hypoxic drive. Anti-

otics or other treatments are ordered to correct the underlying cause of the failure. Aminophylline and beta-adrenergic bronchodilators are used to dilate the bronchioles, promoting ventilation and secretion removal. The patient is instructed to cough and deep breathe if able. Suctioning is indicated if the patient is unable to cough effectively. Mechanical ventilation may be required.

Acute Respiratory Distress Syndrome

Acute respiratory distress syndrome (ARDS), also called adult respiratory distress syndrome, is a group of disorders that has diverse causes but similar pathophysiology, symptoms, and treatment. It is called ARDS to differentiate it from neonatal respiratory distress syndrome.

Pathophysiology and Etiology

The most common cause of ARDS is sepsis. Other causes include pneumonia, trauma, shock, narcotic overdose, inhalation of irritants, burns, pancreatitis, and aspiration, among others. Each of these causes begins a chain of events leading to alveolocapillary damage and noncardiac pulmonary edema (pulmonary edema that is not caused by heart failure). ARDS usually affects patients without a previous history of lung disease.

The alveolocapillary membranes become inflamed and damaged either by direct contact with an inhaled irritant or by chemical mediators that are released when systemic injury occurs. The membranes become leaky, so that proteins, blood cells, and fluid move from the capillaries into the interstitial space and then into the alveoli. Surfactant, a substance that reduces surface tension in the alveoli, is reduced. Alveoli collapse (atelectasis) and fibrotic changes take place. These changes cause the lungs to become stiff, or less compliant, making the patient work very hard to inspire. Blood supply to the alveoli may be adequate, but collapsed, wet alveoli are unable to oxygenate it. In other areas of the lungs, vasoconstriction reduces the ability of the vessels to pick up oxygen from functioning alveoli. Tired respiratory muscles, in combination with edema and atelectasis, reduce gas exchange and result in hypoxia. As the condition progresses, atelectasis and edema worsen and the lungs may hemorrhage. A chest x-ray examination appears white because of the excessive fluid in the lungs. These changes explain some of the older names for what is now known as ARDS: wet lung, white lung, shock lung, and stiff lung.

Prevention

Early recognition and treatment of underlying disorders is important in prevention of ARDS. Good nursing care can help reduce aspiration and some types of pneumonia.

Signs and Symptoms

Initially the patient may experience dyspnea and an increase in respiratory rate. Respiratory alkalosis results from hyperventilation. Fine inspiratory crackles may be auscultated. As the condition worsens, breathing becomes more rapid and labored and the patient becomes cyanotic. The

patient is no longer able to oxygenate the blood and get rid of carbon dioxide, and respiratory acidosis occurs. Oxygen therapy does not reverse the hypoxemia. If ARDS is not reversed, eventually hypoxemia leads to decreased cardiac output and death.

Complications

Complications that can result from ARDS include heart failure, pneumothorax related to mechanical ventilation, infection, and disseminated intravascular coagulation (DIC). The death rate for ARDS in the past was 100 percent. With newer treatments, it is now between 50 and 60 percent. Most patients who survive ARDS recover completely.

Diagnostic Tests

Diagnosis is made based on history of a causative injury, physical examination, chest x-ray examination, and blood gas analysis. An ECG is done to rule out a cardiac-related cause.

Medical Treatment

The patient with ARDS is cared for in an intensive care unit. Treatment begins with oxygen therapy that is adjusted based on repeated ABG results. Intubation and mechanical ventilation is necessary in most cases, with the use of positive end-expiratory pressure (PEEP) to keep the airways open. Diuretics may be used to reduce pulmonary edema, but care must be taken to prevent fluid depletion. A pulmonary artery catheter may be used to monitor hemodynamic status. If infection is the underlying cause, antibiotics are administered. Parenteral nutrition may be given to maintain nutritional status while the patient is acutely ill. Positioning the patient with the less involved lung in the dependent position (“good lung down”) allows the better lung to be well perfused with blood and may increase PaO₂. Prone positioning has also been shown to increase oxygenation in patients with ARDS.

► NURSING PROCESS: THE PATIENT EXPERIENCING RESPIRATORY FAILURE

ASSESSMENT. Assess the patient’s degree of dyspnea on a scale of 0 to 10 if the patient is able to participate. Respiratory rate, effort, and use of accessory muscles is noted. Arterial blood gases and oxygen saturation values are monitored as ordered. The presence of cyanosis is noted.

Mental status, including restlessness, confusion, and level of consciousness, is also assessed, because reduced oxygenation can produce central nervous system (CNS) symptoms. Symptoms of the underlying cause of respiratory failure are monitored. If the cause is infectious, sputum amount and color, temperature, and white blood cell counts are monitored.

All assessment findings should be compared with earlier data. Even subtle changes in the assessment findings can be significant and should be reported.

NURSING DIAGNOSIS. Possible diagnoses include impaired gas exchange, ineffective airway clearance, and inef-

fective breathing pattern. Related diagnoses include activity intolerance, anxiety, disturbed thought processes, and self-care deficit.

PLANNING AND IMPLEMENTATION. The patient is positioned to maximize oxygenation; this might be semi-Fowler’s, good lung down, prone positioning, or a combination of these. Relaxation exercises may help reduce anxiety and relieve dyspnea. Breathing exercises may be helpful if the patient is able to cooperate. Bedrest is important to reduce the demand for oxygen. Because any movement can trigger an increase in dyspnea, help position the patient in bed and anticipate needs to prevent unnecessary exertion by the patient. Meals and treatments should be spaced to allow the patient time to rest. It is often helpful to provide nebulized mist treatments (NMTs) or MDI therapy before meals, so that the patient is able to eat without excessive dyspnea. Oxygen therapy is maintained as ordered. Fluids (if not contraindicated) and coughing and deep breathing help remove secretions. Suctioning may be ordered if necessary.

LEARNING TIPS

The good lung down position can help increase oxygenation in patients with lung disease. Gravity results in more blood in the dependent lung, where it can receive oxygen from the healthier lung tissue. If both lungs are diseased, the right lung down position may be beneficial, because the right lung has a larger surface area.²

EVALUATION. If interventions have been effective, the patient will state that dyspnea is controlled. Mental status will be normal for the patient. Airways will be kept clear at all times, and the patient’s respiratory rate will be regular and within normal limits.

► LUNG CANCER

Lung cancer is the leading cause of cancer death in the United States. An estimated 169,500 new cases were predicted for the United States in 2001. About 28 percent of cancer deaths are from lung cancer. The 5-year survival rate for all lung cancers is 14 percent. This rate increases to 49 percent if lung cancer is diagnosed and treated early.³ The incidence of lung cancer among men is decreasing, whereas it is on the rise in women; this is thought to be related to an increase in the number of women who smoke.

Pathophysiology

Lung cancers originate in the respiratory tract epithelium; most originate in the lining of the bronchi (Fig. 28–9). The four major types of lung cancer are identified by the type of cells that are affected. These include small cell lung cancer (SCLC), large cell carcinoma, adenocarcinoma, and squamous cell carcinoma. The latter three types are classified as non-small cell lung cancer (NSCLC).

About 20 percent of lung cancers are SCLC, sometimes called oat cell carcinoma. SCLC grows rapidly and often

Figure 28-9 Lung cancer. The black arrow marks the tumor site. (Photograph courtesy Dinesh Patel, MD, Medical Oncology, Internal Medicine, Zanesville, Ohio.)

has metastasized by the time of diagnosis. It is usually caused by smoking and is most often found centrally, near the bronchi. The patient with small cell carcinoma has a poor prognosis, with survival time averaging only 9 to 10 months.

Large cell carcinoma is a rapidly growing cancer that can occur anywhere in the lungs. It metastasizes early in the disease, so these patients also have a poor prognosis. It accounts for about 10 percent of lung cancers.

Adenocarcinoma occurs more often in women, and most often in the peripheral lung fields. It accounts for about 40 percent of lung cancers. It is slow growing but often is not diagnosed until metastasis has occurred. It is less closely linked with smoking. Prognosis may be better than other lung cancer types.

About 30 percent of lung cancers are squamous cell carcinomas. These usually originate near the bronchi and metastasize late in the disease. They are associated with a history of smoking. The prognosis for individuals with squamous cell carcinoma may also be better than for some other lung cancers.

Etiology

The most common cause of lung cancer is tobacco smoke. Cigarettes contain chemicals that cause DNA to mutate, creating changes in cells and development of tumors. Smokers have an approximately 13 times greater risk for developing lung cancer than nonsmokers. If a patient stops smoking, the risk of lung cancer decreases significantly. Unfortunately, even with all this information, 25 percent of adults in the United States continue to smoke and teen smoking is on the rise.⁴

Environmental tobacco smoke (ETS) has also been shown to cause lung cancer. A recent study by the American Cancer Society showed that women who were married to smokers but who had never smoked themselves were 20 percent more likely to die of lung cancer.⁵ Other factors that contribute to increased lung cancer risk are exposure to asbestos, radon, or arsenic; air pollution; diesel exhaust; and

radiation. Genetic predisposition and a diet poor in vitamins A, C, and E may also be factors.

Prevention

The single most important way to prevent lung cancer is to reduce smoking. Many programs educate schoolchildren about the dangers of smoking. Smoking cessation programs are available for people who desire to quit. Contact your local American Cancer Society chapter for smoking cessation programs that can be recommended to patients. See Chapter 26 for more information on smoking cessation.

Signs and Symptoms

Manifestations of lung cancer depend on the location of the tumor. Commonly, patients exhibit a cough with sputum production. These symptoms may be ignored by the patient because they are also associated with smoking. Repeated respiratory infections may occur, producing thick, purulent sputum. Sputum may become bloody (hemoptysis). The patient may experience dyspnea. If the airway becomes obstructed by the tumor, wheezing or stridor may be heard. Late signs include chest pain, weight loss, anemia, and anorexia.

Complications

PLEURAL EFFUSION. Fifty percent of patients with lung cancer develop pleural effusion. Pleural fluid collects in the pleural space as a result of irritation or obstruction of lymphatic or venous drainage by the tumor.

SUPERIOR VENA CAVA SYNDROME. If the tumor obstructs the superior vena cava, blood flow is interrupted, causing distention of the jugular veins and swelling of the chest, face, and neck. Diuretics may help relieve the fluid buildup. Radiation may be used to shrink the obstruction.

ECTOPIC HORMONE PRODUCTION. Some lung cancers produce **ectopic** hormones that mimic the body's own hormones. Ectopic production of antidiuretic hormone (ADH) can produce syndrome of inappropriate ADH production (SAIDH), which is associated with fluid retention. Ectopic production of adrenocorticotrophic hormone (ACTH) can cause Cushing's syndrome. These disorders are discussed in Chapter 37.

ATELECTASIS AND PNEUMONIA. Atelectasis occurs when tumor growth prevents ventilation of areas of the lung. Patients with lung cancer also have a greater risk for pneumonia.

METASTASIS. Common sites of lung cancer metastasis include the brain, bones, opposite lung, liver, adrenal gland, and lymph nodes.

Diagnostic Tests

A complete medical history and physical examination are done to look for symptoms and risk factors for lung cancer. A chest x-ray examination is done to identify a mass. How-

ectopic: displaced

ever, all tumors may not show up on a radiograph. A CT scan and lung scan may be done to provide more specific information about the size and location of a tumor. Sputum is analyzed for abnormal cells. Brain and bone scans are done to find metastatic lesions.

Diagnosis is confirmed with a biopsy of the lesion. A biopsy specimen may be obtained via bronchoscopy, percutaneous biopsy (a needle through the skin guided by radiograph), or mediastinoscopy (use of an endoscope into the mediastinum to look for changes in mediastinal lymph nodes).

Medical and Surgical Treatment

Tumors are staged based on the tumor-node-metastasis (TNM) staging system. (See Chapter 10.) Staging helps determine appropriate treatment (Table 28-3). If NSCLC is localized and in an early stage, it may be cured with surgical removal of the tumor. This can be accomplished with a segmental or wedge resection, which removes only the affected lung segment. A **lobectomy** (removal of a lobe) or

TABLE 28-3 STAGES OF LUNG CANCER

Cancer Type	Stage	Characteristics
Non-small cell lung cancer	I	No metastasis to lymph nodes. Atelectasis or pneumonia may be present.
	II	Cancer has spread to local lymph nodes.
	III	Cancer has invaded chest wall and usually has spread to lymph nodes.
	IV	Tumor has metastasized to distant organs and lymph nodes.
Small cell lung cancer	Limited	Cancer is limited to one side of the chest.
	Extensive	Cancer cells are found outside one side of the chest or in pleural fluid.

removal of an entire lung may be done in more advanced cases (Fig. 28-10). Surgery is contraindicated if the cancer has spread to the other lung or has metastasized to distant areas.

lobectomy: lobe—lobe (of lung) + ectomy—excision

Figure 28-10 Types of surgeries for lung cancer. (A) Wedge resection. (B) Segmental. (C) Lobectomy. (D) Pneumonectomy.

Chemotherapy is the treatment of choice in SCLC, because usually it has metastasized and may be widespread by the time of diagnosis. Radiation may be used in combination with chemotherapy. Surgery is not indicated. The goal of treatment is not cure but rather palliation of symptoms.

Radiation may be used to shrink the tumor to reduce symptoms in patients who are unable to undergo surgery. Both radiation and chemotherapy may be used before or after surgery as **adjuvant** treatments. For more information about lung cancer, visit the American Cancer Society Web site at www.cancer.org.

► NURSING PROCESS: THE PATIENT WITH LUNG CANCER

ASSESSMENT. Perform a complete biopsychosocial assessment of the patient with lung cancer. Assess and document respiratory rate and depth, skin and mucous membrane color, lung sounds, cough, and sputum amount and character. Ask the patient to rate the degree of pain and dyspnea on appropriate scales. Ask about appetite and weight loss, as well as symptoms of other complications. Note activity tolerance and fatigue.

In addition, the patient may be grieving about his or her illness and impending death. Assessment of the patient's coping strategies and support systems will help you plan care for psychosocial needs. When you recall the prognosis for patients with some types of lung cancer, the need to consider planning for terminal care becomes obvious (Ethical Consideration Box 28–8). The presence of a living will or durable power of attorney should be noted.

NURSING DIAGNOSIS. Possible diagnoses that may be experienced by the patient with lung cancer include impaired gas exchange, ineffective airway clearance, imbalanced nutrition: less than body requirements, pain, constipation related to opioid use, anticipatory grieving, and activity intolerance, among others.

PLANNING. A plan is formulated that will help the patient control episodes of dyspnea, maintain a clear airway, reduce anorexia and maintain body weight, promote comfort, and maintain regular bowel habits. Patients who have a terminal condition are assisted in coping with their impending death.

IMPLEMENTATION. The experience of dyspnea related to impaired gas exchange is frightening to patients and their families. Home oxygen therapy may be necessary. Positioning, relaxation, and breathing exercises can help reduce dyspnea and feelings of panic. Antianxiety drugs or morphine may also be helpful. Resting between activities reduces the demand for oxygen. Encourage the patient to avoid smoking and exposure to secondary smoke.
