ABOUT THE AUTHORS

Christopher K. Mathews is Distinguished Professor Emeritus of Biochemistry at Oregon State University. He earned his B.A. in chemistry from Reed College (1958) and Ph.D. in biochemistry from the University of Washington (1962). He served on the faculties of Yale University and the University of Arizona from 1963 to 1978, when he moved to Oregon State University as chair of the Department of Biochemistry and Biophysics, a position he held until 2002. His major research interest is the enzymology and regulation of DNA precursor metabolism and the intracellular coordination between deoxyribonucleotide synthesis and DNA replication. From 1984 to 1985, Dr. Mathews was an Eleanor Roosevelt International Cancer Fellow at the Karolinska Institute in Stockholm, and in 1994–1995 he held the Tage Erlander Guest Professorship at Stockholm University. Dr. Mathews has published over 175 scientific papers dealing with molecular virology, metabolic regulation, nucleotide enzymology, and biochemical genetics. He is the author of *Bacteriophage Biochemistry* (1971) and coeditor of *Bacteriophage T4* (1983) and *Structural and Organizational Aspects of Metabolic Regulation* (1990). He was a coauthor of the three previous editions of *Biochemistry*. His teaching experience includes undergraduate, graduate, and medical school biochemistry courses.

He has backpacked and floated the mountains and rivers, respectively, of Oregon and the Northwest. As an enthusiastic birder he has served as President of the Audubon Society of Corvallis and is President of the Great Basin Society, which operates the Malheur Field Station.

K. E. van Holde is Distinguished Professor Emeritus of Biophysics and Biochemistry at Oregon State University. He earned his B.A. (1949) and Ph.D. (1952) from the University of Wisconsin. Over many years, Dr. van Holde's major research interest has been the structure of chromatin; his work resulted in the award of an American Cancer Society research professorship in 1977. He has been at Oregon State University since 1967, and was named Distinguished Professor in 1988. He is a member of the National Academy of Sciences and the American Academy of Arts and Sciences, and has received Guggenheim, NSF, and EMBO fellowships. He is the author of over 200 scientific papers and four books in addition to this volume: *Physical Biochemistry* (1971, 1985), *Chromatin* (1988), *Principles of Physical Biochemistry* (1998), and *Oxygen and the Evolution of Life* (2011). He was also coeditor of *The Origins of Life and Evolution* (1981). His teaching experience includes undergraduate and graduate chemistry, biochemistry and biophysics, and the

physiology and molecular biology course at the Marine Biological Laboratory at Woods Hole.

Dean R. Appling is the Lester J. Reed Professor of Biochemistry and Associate Dean for Research and Facilities for the College of Natural Sciences at the University of Texas at Austin, where he has taught and done research for the past 26 years. Dean earned his B.S. in biology from Texas A&M University, and his Ph.D. in biochemistry from Vanderbilt University. The Appling laboratory studies the organization and regulation of metabolic pathways in eukaryotes, focusing on folate-mediated one-carbon metabolism. The lab is particularly interested in understanding how one-carbon metabolism is organized in mitochondria, as these organelles are central players in many human diseases. In addition to coauthoring this book, Dean has published over 60 scientific papers and book chapters.

As much fun as writing a textbook might be, Dean would rather be outdoors. He is an avid fisherman and hiker. Recently, Dean and his wife, Maureen, have become entranced by the birds on the Texas coast. They were introduced to bird-watching by coauthor Chris Mathews and his wife, Kate—an unintended consequence of working on this book!

Spencer J. Anthony-Cahill is a Professor in the Department of Chemistry at Western Washington University (WWU), Bellingham, WA. Spencer earned his B.A. in chemistry from Whitman College, and his Ph.D. in bioorganic chemistry from the University of California, Berkeley. His graduate work, in the lab of Peter Schultz, focused on the biosynthetic incorporation of unnatural amino acids into proteins. Spencer was an NIH postdoctoral fellow in the laboratory of Bill DeGrado (then at DuPont Central Research), where he worked on *de novo* peptide design and the prediction of the tertiary structure of the HLH DNA-binding motif. He then worked for five years as a research scientist in the biotechnology industry, developing recombinant hemoglobin as a treatment for acute blood loss. In 1997, Spencer decided to pursue his long-standing interest in teaching and moved to WWU, where he is today.

Research in the Anthony-Cahill laboratory is directed at the protein engineering of heme proteins. The primary focus is on circular permutation of human β -globin as a means to develop a single-chain hemoglobin with desirable therapeutic properties. The lab is also pursuing the design of self-assembling protein nanowires.

Outside the classroom and laboratory, Spencer is a great fan of the outdoors—especially the North Cascades and southeastern Utah, where he has often backpacked, camped, climbed, and mountain biked. Spencer also holds the rank of 3rd Dan in Aikido, and instructs children and adults at the Kulshan Aikikai Dojo in Bellingham, WA.

PREFACE

A NEW EDITION

What factors might explain the re-emergence of a well-received biochemistry textbook (*Biochemistry*, Third Edition, 2000, by C. K. Mathews, K. E. van Holde, and K. G. Ahern), some 12 years after publication of the previous edition? In a rapidly evolving field like biochemistry, textbooks are typically revised every four or five years to retain their educational value.

Still, biochemistry instructors and students continued to ask when and whether a fourth edition might appear. While Chris Mathews was interested in revising and updating the book, his previous coauthors were unable to commit to a project of this magnitude, and so the search began for a new author team. After a long and careful selection process, two new coauthors joined Chris Mathews: Dr. Dean R. Appling, Lester J. Reed Professor of Biochemistry and Associate Dean for Research and Facilities for the College of Natural Sciences at the University of Texas at Austin, and Dr. Spencer J. Anthony-Cahill, Professor of Chemistry at Western Washington University, Bellingham.

Dean Appling is an enzymologist with interests in regulation and organization of metabolic pathways, with particular emphasis upon folate cofactors and the metabolism of single-carbon units. Much of his work uses NMR and molecular genetics to probe metabolic compartmentation and control. Spencer Anthony-Cahill's chief interest is protein folding and design, with current emphasis upon folding patterns in protein variants that have circularly permuted sequences. Before assuming his present faculty position, Spencer worked for five years in the biotechnology industry, an experience that gives him a valuable perspective in teaching biochemistry. Both Dean and Spencer have used previous editions of *Biochemistry* in their own teaching, so they were well aware of the strengths of this book and areas where fresh attention was needed.

The research interests of the new author team created a natural division of writing responsibilities. Spencer's writing was focused upon biomolecular structure and mechanisms, Dean dealt with metabolism and its control, and Chris put his major effort into genetic biochemistry. However, the project was truly a team effort. Each chapter draft was scrutinized by all three authors, with revisions made by each principal draft author before submission to our editors and outside reviewers. We found our fellow authors to be our strongest critics. And, although Ken van Holde was not actively involved with this edition, he did review some drafts and much of his graceful writing remains in this new edition. We are proud to include him as a coauthor of this new edition.

EVOLUTION OF THE TEXT

Major Changes

In addition to dealing with the vast amount of new information appearing since the publication of the third edition in 2000, this new edition introduces three significant changes. First is more emphasis upon biochemical reaction mechanisms in the enzymes and metabolism chapters. Second is a significant reorganization in the chapters dealing with intermediary metabolism. The coverage of carbohydrate metabolism has been unified, so that we now present glycolysis, gluconeogenesis, glycogen metabolism, and the pentose phosphate pathway in one chapter (Chapter 13). To accomplish this without excessive expansion of the chapter, we moved the section on complex carbohydrate metabolism to Chapter 9; instructors can present this material as part of the metabolism section of the course, if they prefer. Redox thermodynamics has been moved from Chapter 15 (Biological Oxidations) to Chapter 3 (Bioenergetics), where it more properly belongs. The material on interorgan coordination in mammalian metabolism has been split into two chapters—Chapter 18 (Interorgan and Intracellular Coordination of Energy Metabolism in Vertebrates) and Chapter 23 (Signal Transduction).

The third major change is the reorganization of genetic biochemistry in the last major section of the book. As in previous editions, we introduce processes in biological information transfer early, in Chapter 4, with details presented later. In addition, we have integrated prokaryotic and eukaryotic informational metabolism, rather than presenting them in separate chapters, as in previous editions. The four genetic biochemistry chapters in previous editions are now six—Chapters 24 (Genome Organization), 25 (DNA Replication), 26 (Information Restructuring), 27 (Transcription and Its Control), 28 (Protein Synthesis and Processing), and 29 (Control of Gene Expression).

New Topics

A special challenge in writing a new edition after an interval of so many years was incorporating the most important of the many spectacular new developments in molecular life sciences. A partial list of new or significantly revised topics includes:

- Phosphorothioate bonds in DNA (Chapter 4)
- Gene sequence analysis, phylogenetic analysis, proteomic analysis, and amino acid sequencing by mass spectroscopy (Chapter 5)
- New approaches to classifying protein secondary structure, protein structure prediction, and protein folding energy landscapes (Chapter 6)
- Dynamics of myoglobin, roles of heme proteins in nitric oxide physiology, and antibody–drug conjugates as anticancer agents (Chapter 7)
- Biological imaging of complex glycoproteins (Chapter 9)
- Lipid rafts (Chapter 10)
- Organic chemical mechanisms of the common biochemical reaction types (Chapter 12)
- Coordination of energy homeostasis, including mTOR, AMPK, and sirtuins and protein acetylation (Chapter 18)
- Evolution of metabolic pathways (several chapters); regulation of cholesterol metabolism (Chapter 19)
- Ubiquitin and regulated protein turnover (Chapter 20)
- Methyl group metabolism (Chapter 21)
- Pharmacogenetics (Chapter 22)

- A kinase anchoring proteins (Chapter 23)
- Restriction fragment length polymorphisms, single-nucleotide polymorphisms and genome mapping, chromatin structure, and the centromere (Chapter 24)
- Double-strand DNA break repair (Chapter 26)
- Structure and function of RNA polymerases (Chapter 27) and of ribosomes (Chapter 28)
- Apoptosis (Chapter 28)
- The role of Mediator in transcription complexes, DNA methylation and epigenetics, functional significance of histone modifications, RNA interference, and riboswitches (Chapter 29)

Biochemistry Applications

One feature requested by students and instructors alike is practical applications of biochemical knowledge—particularly, applications to the health sciences. Unlike some other textbooks, we prefer to integrate applications with the main text, instead of setting them apart in boxes. We believe that this makes the text flow more smoothly.

New applications discussed in this edition include:

- Influenza virus neuraminidase and the action of Tamiflu (Chapter 9)
- Biofuels (Chapter 13)
- Mitochondrial diseases (Chapter 15)
- Artificial photosynthesis (Chapter 16)
- Diabetes, obesity (Chapter 18)
- Calorie restriction and lifespan extension (Chapter 18)
- Methylentetrahydrofolate reductase variants and disease susceptibility (Chapter 21)
- Chromosomal translocations and targeted cancer drugs (Chapter 23); mapping disease genes (Chapter 24)
- Patterns of oncogene mutations in cancer (Chapter 23)

Keeping What Works Best

Not everything is new in this edition. We have worked hard to retain and improve the best-loved features of previous editions, such as an emphasis upon the physico-chemical concepts upon which biochemical processes and mechanisms are based, and an emphasis upon the experimental nature of biochemistry. This latter emphasis is realized with our continued use of the popular Tools of Biochemistry feature.

TOOLS OF BIOCHEMISTRY

As in past editions, we emphasize the importance of incisive experimental techniques as the engine that drives our increasing understanding of the molecular nature of life processes. This is accomplished through end-of-chapter essays on the most important techniques in biochemistry and molecular biology research. Most of the Tools sections in this edition have been updated or introduced for the first time. New or significantly modified Tools sections include:

- Introduction to Proteomics; Tandem Mass Spectrometry (Chapter 5)
- Nuclear Magnetic Resonance Spectroscopy (Chapter 6)

- *In Vitro* Evolution of Protein Function (Chapter 11)
- Metabolomics (Chapter 12)
- Gene Targeting by Homologous Recombination; Single-Molecule Biochemistry (Chapter 26)
- Microarrays; Chromatin Immunoprecipitation (Chapter 27)

Several Tools sections on manipulating DNA have been combined and moved earlier in the book, to Chapter 4. The Tools section on radioisotopes in Chapter 12 has been considerably shortened. The material on kinetic isotope methods in analysis of enzyme mechanisms has been strengthened in the Tools section in Chapter 11.

END-OF-CHAPTER PROBLEMS

Wherever possible, we have removed problems that emphasize rote learning and retained or added problems that require analytical or quantitative thought to be solved. Several new problems have been added to each chapter. Importantly, we now include complete solutions to each problem, as well as the answers, at the back of the book.

ABOUT THE COVER

The cover illustration depicts the structure of the yeast 80S ribosome at 4.15 Ångstrom resolution, based upon X-ray crystallography. This complex RNA- and protein-containing particle is an enormous molecular machine, which binds the components of protein synthesis—messenger RNA, transfer RNAs containing activated amino acids, and soluble protein factors that aid in all phases of translation—initiation, polypeptide chain elongation, and termination.

Tremendous insight into mechanisms of protein synthesis was gained beginning in 2000, when crystal structures for prokaryotic and archaeal ribosomes were reported. This work was recognized in 2009, with the Nobel Prize in Chemistry to V. Ramakrishnan, T. A. Steitz, and A. Yonath. Although basic processes in translation are similar in all cells, protein synthesis in eukaryotic cells is much more complex than in bacteria, particularly with regard to steps in initiation, where many more soluble protein factors must participate. The eukaryotic ribosome is correspondingly larger and more complex—about 40% larger than the bacterial ribosome, with correspondingly more different proteins and larger RNA components. These factors make solving the eukaryotic ribosome structure an even more formidable problem. This feat was accomplished in several laboratories, beginning in late 2010.

The structure of the yeast ribosome shown here was described by A. Ben-Shem, L. Jenner, G. Yusupova, and M. Yusupov, in *Science* 330:1203–1209 (2010). The image on the cover was created by C. Spiegel and S. Anthony-Cahill, working from atomic coordinates deposited by Ben-Shem and coauthors in the Brookhaven Protein Database (PDB). Color scheme: 40S particle (PDB ID: 3O30): RNA is in orange; proteins are in slate blue; 60S particle (PDB ID: 3O5H): RNA is in raspberry red; proteins are in forest green.

SUPPLEMENTS

For Instructors

Instructor resources are password protected and available for download via the Pearson online catalog at www.pearsonhighered.com. For your convenience, many of these resources are also available on the **Instructor's Resource CD-ROM (IRCD)** (ISBN 978-0-13-279159-5).

- **Test Item File.** The fourth edition features a brand new testbank created by Scott Lefler, Senior Lecturer, Arizona State University, with more than 700 thoughtful questions in editable Word format. The Test Item File can be found on the IRCD or downloaded from the online catalog.
- **PowerPoint® Presentations.** Two sets of PowerPoint® slides are available for the text. The first consists of all the figures and photos in the textbook in PowerPoint® format. The second set, created by Bruce Burnham, Associate Professor of Chemistry, Rider University, consists of PowerPoint® lecture slides that provide an outline to use in a lecture setting, presenting definitions, key concepts, and figures from the textbook. Both sets of PowerPoint® slides can be found on the IRCD or downloaded from the online catalog.
- **Complete Solutions Manual.** As in previous editions, we have created a solutions manual to complement chapter problems in the current edition of our text. The complete solutions manual, prepared by Sara Codding and Tim Rhoads of Oregon State University, contains fully worked solutions for those questions that may benefit from explanations beyond those provided at the back of the book. Instructors can arrange with the publisher to make this material available to students (ISBN 978-0-13-292628-7).
- **CourseSmart for Instructors.** CourseSmart goes beyond traditional expectations, providing instant, online access to the textbooks and course materials you need at a lower cost for students. And even as students save money, you can save time and hassle with a digital eTextbook that allows you to search for the most relevant content at the very moment you need it. Whether it's evaluating textbooks or creating lecture notes to help students with difficult concepts, CourseSmart can make life a little easier. See how when you visit www.coursesmart.com/instructors.
- **Technology Specialists.** Pearson's Technology Specialists work with faculty and campus course designers to ensure that Pearson technology products, assessment tools, and online course materials are tailored to meet your specific needs. This highly qualified team is dedicated to helping schools take full advantage of a wide range of educational resources by assisting in the integration of a variety of instructional materials and media formats. Your local Pearson Education sales representative can provide you with more details on this service program.

For Students

- **The Chemistry Place for Biochemistry, Fourth Edition.** The Chemistry Place is an online tool that provides students with tutorial aids to help them succeed in biochemistry. This Website includes animations of key concepts and processes and self-quizzing created by Scott Napper, Associate Professor, University of Saskatchewan, to allow students to check their understanding of subject matter. TheChemistryPlace also contains our Pearson eText. Please visit the site at www.chemplace.com.
- **Pearson eText** gives students access to the text whenever and wherever they have access to the Internet. eText pages look exactly like the printed text, offering powerful new functionality for students and instructors. Users can create notes, highlight text in different colors, create bookmarks, zoom, click hyperlinked words and phrases to view definitions, and view in single-page or two-page view. Pearson eText allows for quick navigation to key parts of the eText using a table of contents and provides full-text search. The eText may also offer links to associated media files, enabling users to access videos, animations, or other activities as they read the text.

- **CourseSmart for Students.** CourseSmart goes beyond traditional expectations, providing instant, online access to the textbooks and course materials you need at an average savings of 60%. With instant access from any computer and the ability to search your text, you'll find the content you need quickly, no matter where you are. And with online tools like highlighting and note-taking, you can save time and study efficiently. See all the benefits at www.coursesmart.com/students.

ACKNOWLEDGMENTS

Although our names appear as authors on the cover of this book, and we expect to receive most of the credit or criticism resulting therefrom, the book in fact was created by a large team, with many participants whose contributions rivaled ours. To begin, this book would never have come into existence but for the enterprise of Michelle Sartor, now Acting Editor-in-Chief for Humanities and Social Sciences for Pearson Canada. In her former assignment, she became aware of a continuing interest in our book, particularly in Canada. Even though a previous attempt at a fourth edition had aborted, Michelle exercised quiet but effective persistence until the present author team had been assembled. After Michelle's reassignment, Cathleen Sullivan, Executive Editor for Engineering, Science, and Mathematics, took over, and she has held a steady hand on the tiller through calm seas that occasionally, but only briefly, became rough.

Our day-to-day contact through the writing and development phase was John Polanszky, Senior Developmental Editor. We appreciated that he gave us much independence and in general was a calming influence and a source of useful advice. And we credit him with securing some extremely helpful reviewers, whose names are listed separately.

When the writing, reviewing, and revisions were completed, we maintained our valuable contacts with Cathleen and John, but began interacting with a much larger team of dedicated and skilled professionals, particularly Marissa Lok, in-house project manager, and Tracy Duff, project manager at PreMediaGlobal. We exchanged e-mails and phone calls with these ladies nearly every day, and consider them friends, even though we have yet to meet them in person. Signal contributions were made during this phase by Kelly Birch, copy editor; Stephany Craig, proofreader; Heather Jackson, permissions researcher; and Greg Miller, Scott Napper, Mark Jonklaas, Masoud Jelokhani-Niaraki, technical reviewers. Katy Mehrtens, Publishing Services Director, oversaw the efforts at PreMediaGlobal. Julia Jevmenova, Marketing Manager at Pearson Canada, impressed us with her quiet insistence at learning about the substance and content of our book, so that she could become a truly effective advocate.

We owe a great deal to friends and colleagues in science for advice, updated information, and graphics. At the risk of neglecting to recognize all who helped us, the following deserve mention.

Gary Carlton (Arcsine Graphics) produced many of the new figures in Chapters 6–11. Gary's attention to detail and quality yielded spectacular results. Thanks to those researchers who provided new figures for this edition of the text: Shing Ho (Colorado State University), Figures 4A.6 and 26.24; Jack Benner (New England Biolabs), Figure 5D.1; Andy Karplus (Oregon State University), Figures 6.12 and 6.13; Scott Delbecq and Rachel Klevit (University of Washington), Figure 6A.10b; Serge Smirnov (Western Washington University), Figure 6A.12; Vlado Gelev (FBReagents Inc.), Figure 6A.13b; Stephan Grzesiek (University of Basel), Figure 6A.13a; Richard Harris, Figure 6A.14; John Olson (Rice University), Figure 7.6; Marjorie Longo (University of California, Davis), Figure 10.27; Vamsi Mootha (MIT), Figure 12B.3; Adrian Keatinge-Clay (University of Texas at Austin), Figure

17.37B; Rowena Matthews (University of Michigan), Figure 21.12; John Tesmer (University of Michigan), Figure 23.10; Lawrence Loeb (University of Washington), Figure 23.22; Mike O'Donnell (Rockefeller University), Figures 25.25 and 25.34; Whitney Yin (University of Texas at Austin), Figure 25.35; David Josephy (University of Guelph), Figure 26.7; D. G. Vassilyev (University of Alabama at Birmingham), Figure 27.11; Robin Gutell (University of Texas at Austin), Figure 28.19.

P. Clint Spiegel (Western Washington University) rendered the structure of the eukaryotic ribosome that appears on the cover.

Special thanks to several colleagues who generously provided feedback on material in the draft stage, and thereby improved the quality of the final text. Rachel Klevit (University of Washington), Andrew Baldwin (University of Toronto), and Serge Smirnov (Western Washington University) reviewed the material describing optical and NMR spectroscopy in Chapter 6. Tom Brittain (University of Auckland), John Olson (Rice University), and Antony Mathews (Pfizer, Inc.) reviewed the material in Chapter 7 describing the structure and function of globin proteins. Heather Van Epps (Seattle Genetics) provided critical feedback on the sections of Chapter 10 describing excitable membranes. Jack Benner (New England Biolabs) reviewed material in Chapter 5 describing proteomics. Andrew Hanson (University of Florida) provided helpful feedback on the section in Chapter 16 describing photorespiration. John Denu (University of Wisconsin) shared unpublished data and provided helpful feedback on the section in Chapter 18 describing protein acetylation and sirtuins. Jon Huibregtse (University of Texas at Austin) provided helpful feedback on the section in Chapter 20 describing ubiquitin function. Ralph Green (University of California, Davis) provided helpful feedback on the section in Chapter 20 describing vitamin B12 and pernicious anemia. JoAnne Stubbe (MIT) provided helpful feedback on the discussion of ribonucleotide reductase in Chapter 22. John Tesmer (University of Michigan) provided helpful feedback on the section in Chapter 23 describing G protein structure and function. Michael Freitag (Oregon State University) offered valuable information about centromeres, kinetochores, and epigenetics (Chapters 24 and 29).

As always, our most effective critics were our wives—Kate Mathews, Maureen Appling, and Yvonne Anthony-Cahill. Barbara van Holde is greatly missed. But Kate, Maureen, and Yvonne were constant sources of love and support, with occasional pungent advice and criticism. Their patience and enduring support were the most important elements in seeing this project to a timely and satisfying conclusion.

Christopher K. Mathews Dean R. Appling
Spencer J. Anthony-Cahill K. E. van Holde

REVIEWERS

The following reviewers provided valuable feedback on the manuscript at various stages throughout the writing process.

Internal Energy and the State of a System	59
The First Law of Thermodynamics	60
Enthalpy	62

Entropy and the Second Law of Thermodynamics	63	Properties of the Nucleotides	94
The Direction of Processes	63	Stability and Formation of the Phosphodiester Linkage	95
Entropy	63	Primary Structure of Nucleic Acids	97
The Second Law of Thermodynamics	64	The Nature and Significance of Primary Structure	97
Free Energy: The Second Law in Open Systems	65	DNA as the Genetic Substance: Early Evidence	98
An Example of the Interplay of Enthalpy and Entropy: The Transition Between Liquid Water and Ice	65	Secondary and Tertiary Structure of Nucleic Acids	98
The Interplay of Enthalpy and Entropy: A Summary	67	The Double Helix	98
Free Energy and Useful Work	68	Semiconservative Nature of DNA Replication	101
Free Energy and Concentration	68	Alternative Nucleic Acid Structures: B and A Helices	103
Chemical Potential	69	DNA and RNA Molecules in Vivo	106
An Example of How Chemical Potential Is Used: A Close Look at Diffusion Through a Membrane	70	The Biological Functions of Nucleic Acids: A Preview of Molecular Biology	109
Free Energy and Chemical Reactions: Chemical Equilibrium	71	Genetic Information Storage: The Genome	109
The Free Energy Change and the Equilibrium Constant	71	Replication: DNA to DNA	111
Free Energy Calculations: A Biochemical Example	73	Transcription: DNA to RNA	111
Living Cells Are Not at Equilibrium	73	Translation: RNA to Protein	112
High-Energy Phosphate Compounds: Free Energy Sources in Biological Systems	75	Plasticity of Secondary and Tertiary DNA Structure	113
High-Energy Phosphate Compounds as Energy Transducers	75	Changes in Tertiary Structure: A Closer Look at Supercoiling	113
Resonance Stabilization of the Phosphate Products	77	Unconventional Secondary Structures of DNA	115
Additional Hydration of the Hydrolysis Products	77	Stability of Secondary and Tertiary Structure	119
Electrostatic Repulsion Between Charged Products	78	The Helix-to-Random-Coil Transition: Nucleic Acid Denaturation	119
Tautomerization of Product Molecules	78	Superhelical Energy and Changes of DNA Conformation	121
Water, Protons in Buffered Solutions, and the “Biochemical Standard State”	79	Summary	122
Phosphate Transfer Potential	80	References	123
ΔG° for Oxidation/Reduction Reactions	81	Problems	124
Quantitation of Reducing Power: Standard Reduction Potential	81	TOOLS OF BIOCHEMISTRY 4A	
Free Energy Changes from Oxidation–Reduction Reactions	83	An Introduction to X-Ray Diffraction	125
Free Energy Changes Under Standard Conditions	84	TOOLS OF BIOCHEMISTRY 4B	
Calculating Free Energy Changes for Biological Oxidations Under Nonequilibrium Conditions	84	Manipulating DNA	129
Summary	85	CHAPTER 5	
References	86	Introduction to Proteins: The Primary Level of Protein Structure	136
Problems	87	Amino Acids	136
		Structure of the α -Amino Acids	136
		Stereochemistry of the α -Amino Acids	138
		Properties of Amino Acid Side Chains: Classes of α -Amino Acids	142
		Rare Genetically Encoded Amino Acids	144
		Modified Amino Acids	144
		Peptides and the Peptide Bond	144
		Peptides	144
		Polypeptides as Polyampholytes	146
		The Structure of the Peptide Bond	148

CHAPTER 6

The Three-Dimensional Structure of Proteins 177

Secondary Structure: Regular Ways to Fold the Polypeptide Chain	177
Theoretical Descriptions of Regular Polypeptide Structures	177
Describing the Structures: Helices and Sheets	180
Ramachandran Plots	183
Fibrous Proteins: Structural Materials of Cells and Tissues	185
The Keratins	186
Fibroin	187
Collagen	188
Elastin	190
Summary	191
Globular Proteins: Tertiary Structure and Functional Diversity	191
Different Folding for Different Functions	191
Varieties of Globular Protein Structure: Patterns of Folding	192
Factors Determining Secondary and Tertiary Structure	195
The Information for Protein Folding	195
The Thermodynamics of Folding	196
The Role of Disulfide Bonds	200
Dynamics of Globular Protein Structure	201
Kinetics of Protein Folding	201
Chaperones	204
Protein Misfolding and Disease	206
Motions Within Globular Protein Molecules	208

Prediction of Secondary and Tertiary Protein

Structure	209
Prediction of Secondary Structure	209
Tertiary Structure Prediction: Computer Simulation of Folding	210
Quaternary Structure of Proteins	212
Multisubunit Proteins: Homotypic Protein–Protein Interactions	212
Heterotypic Protein–Protein Interactions	215
Summary	215
References	216
Problems	217

CHAPTER 7

Protein Function and Evolution 234

Oxygen Transport: The Roles of Hemoglobin and Myoglobin	235
The Mechanism of Oxygen Binding by Heme Proteins	236
The Oxygen Binding Site	236
Analysis of Oxygen Binding by Myoglobin	238
Oxygen Transport: Hemoglobin	241
Cooperative Binding and Allostery	241
Models for the Allosteric Change in Hemoglobin	245
Changes in Hemoglobin Structure Accompanying Oxygen Binding	246
A Closer Look at the Allosteric Change in Hemoglobin	247
Allosteric Effectors of Hemoglobin	251
Response to pH Changes: The Bohr Effect	252
Carbon Dioxide Transport	252
Response to Chloride Ion at the α -Globin N-Terminus	253
2,3-Bisphosphoglycerate	253
Other Functions of the Heme Globins: Reactions with Nitric Oxide	254
Protein Evolution: Myoglobin and Hemoglobin as Examples	256
The Structure of Eukaryotic Genes: Exons and Introns	256
Mechanisms of Protein Mutation	257
Evolution of the Myoglobin–Hemoglobin Family of Proteins	260

Hemoglobin Variants: Evolution in Progress	262
Variants and Their Inheritance	262
Pathological Effects of Variant Hemoglobins	264
Thalassemias: Effects of Misfunctioning Hemoglobin Genes	265

Immunoglobulins: Variability in Structure Yields Versatility in Binding 266

The Adaptive Immune Response	267
The Structure of Antibodies	269
Generation of Antibody Diversity	272
T Cells and the Cellular Response	272
The Innate Immune Response	274

AIDS and the Immune Response 275

Antibodies and Immunoconjugates as Potential Cancer Treatments 275

Summary 276

Appendix: A Brief Look at Multistate and Dynamic Models of Hemoglobin Allostery 277

References 278

Problems 280

TOOLS OF BIOCHEMISTRY 7A

Immunological Methods	282
-----------------------	-----

CHAPTER 8

Contractile Proteins and Molecular Motors 286

Muscles and Other Actin–Myosin Contractile Systems 287

Actin and Myosin	287
The Structure of Muscle	289
The Mechanism of Contraction: The Sliding Filament Model	290
Regulation of Contraction: The Role of Calcium	293
Energetics and Energy Supplies in Muscle	295
Nonmuscle Actin and Myosin	296

Microtubule Systems for Motility 297

Motions of Cilia and Flagella	299
Intracellular Transport	300

Bacterial Motility: Rotating Proteins 304

Summary 307

References 307

Problems 308

CHAPTER 9

Carbohydrates: Sugars, Saccharides, Glycans 309

Monosaccharides 311

Aldoses and Ketoses	311
Enantiomers	311
Diastereomers	312
Aldose Ring Structures	314

Derivatives of the Monosaccharides 321

Phosphate Esters	321
Alditols	323
Amino Sugars	323
Glycosides	324

Oligosaccharides 324

Oligosaccharide Structures	325
Stability and Formation of the Glycosidic Bond	328

Polysaccharides 329

Storage Polysaccharides	330
Structural Polysaccharides	332
Glycosaminoglycans	334
Bacterial Cell Wall Polysaccharides	336

Glycoproteins 339

N-Linked and O-Linked Glycoproteins	339
Blood Group Antigens	340

Oligosaccharides as Cell Markers 343

Biosynthesis of Glycoconjugates: Amino Sugars 344

Glycoconjugates of Interest 345

O-Linked Oligosaccharides: Blood Group Antigens	346
N-Linked Oligosaccharides: Glycoproteins	347
Microbial Cell Wall Polysaccharides: Peptidoglycan	350

Summary 355

References 356

Problems 357

TOOLS OF BIOCHEMISTRY 9A

Sequencing Oligosaccharides	358
-----------------------------	-----

CHAPTER 10

Lipids, Membranes, and Cellular Transport 359

The Molecular Structure and Behavior of Lipids 359

Fatty Acids	360
Triacylglycerols: Fats	362
Soaps and Detergents	363
Waxes	364

The Lipid Constituents of Biological Membranes 364

Glycerophospholipids	364
Sphingolipids and Glycosphingolipids	367
Glycoglycerolipids	368
Cholesterol	369

The Structure and Properties of Membranes and Membrane Proteins 369

Motion in Membranes	370
The Asymmetry of Membranes	372
Characteristics of Membrane Proteins	373
The Erythrocyte Membrane: An Example of Membrane Structure	375
Insertion of Proteins into Membranes	378
Evolution of the Fluid Mosaic Model of Membrane Structure	380
Lipid Curvature and Protein Function	382

Transport Across Membranes	382
The Thermodynamics of Transport	383
Nonmediated Transport: Diffusion	385
Facilitated Transport: Accelerated Diffusion	386
Active Transport: Transport Against a Concentration Gradient	392
Caveolae and Coated Vesicles	396
Excitable Membranes, Action Potentials, and Neurotransmission	397
The Resting Potential	398
The Action Potential	399
Toxins and Neurotransmission	401
Summary	402
Appendix	402
References	403
Problems	404

TOOLS OF BIOCHEMISTRY 10A

Techniques for the Study of Membranes	406
---------------------------------------	-----

PART 3

Dynamics of Life: Catalysis and Control of Biochemical Reactions	409
---	------------

CHAPTER 11

Enzymes: Biological Catalysts	410
The Role of Enzymes	410
Chemical Reaction Rates and the Effects of Catalysts: A Review	411
Reaction Rates, Rate Constants, and Reaction Order	411
Transition States and Reaction Rates	413
Transition State Theory Applied to Catalysis	416
How Enzymes Act as Catalysts: Principles and Examples	418
General Principles: The Induced Fit Model	418
Lysozyme	422
Serine Proteases	425
The Role of Dynamics in Catalysis	429
The Kinetics of Enzymatic Catalysis	431
Reaction Rate for a Simple Enzyme-Catalyzed Reaction: Michaelis–Menten Kinetics	431
The Significance of K_M , k_{cat} , and k_{cat}/K_M	433
Analysis of Kinetic Data: Testing the Michaelis–Menten Equation	435
Multisubstrate Reactions	436
A Closer Look at Some Complex Reactions	437
Single-Molecule Studies of Enzyme Activity	438
Enzyme Inhibition	440
Reversible Inhibition	440
Irreversible Inhibition	444
Cofactors, Vitamins, and Essential Metals	445
Cofactors and What They Do	446
Metal Ions in Enzymes	448

The Diversity of Enzymatic Function	449
Classification of Protein Enzymes	449
Molecular Engineering of New and Modified Enzymes	449
Nonprotein Biocatalysts: Catalytic Nucleic Acids	449
The Regulation of Enzyme Activity: Allosteric Enzymes	453
Substrate-Level Control	454
Feedback Control	455
Allosteric Enzymes	456
Aspartate Carbamoyltransferase: An Example of an Allosteric Enzyme	457
Covalent Modifications Used to Regulate Enzyme Activity	458
Pancreatic Proteases: Activation by Cleavage	459
A Further Look at Activation by Cleavage: Blood Clotting	462
Summary	463
References	464
Problems	465

TOOLS OF BIOCHEMISTRY 11A

How to Measure the Rates of Enzyme-Catalyzed Reactions	468
--	-----

TOOLS OF BIOCHEMISTRY 11B

Introduction to Protein Engineering of Enzymes	471
--	-----

CHAPTER 12

Chemical Logic of Metabolism	475
A First Look at Metabolism	475
Freeways on the Metabolic Road Map	477
Central Pathways of Energy Metabolism	477
Distinct Pathways for Biosynthesis and Degradation	480
Biochemical Reaction Types	481
Nucleophilic Substitutions	482
Nucleophilic Additions	483
Carbonyl Condensations	483
Eliminations	485
Oxidations and Reductions	485
Some Bioenergetic Considerations	486
Oxidation as a Metabolic Energy Source	486
ATP as a Free Energy Currency	489
Major Metabolic Control Mechanisms	498
Control of Enzyme Levels	498
Control of Enzyme Activity	498
Compartmentation	499
Hormonal Regulation	500
Distributive Control of Metabolism	501
Experimental Analysis of Metabolism	502
Goals of the Study of Metabolism	502
Levels of Organization at Which Metabolism Is Studied	503
Metabolic Probes	505

Summary	506
References	507
Problems	507

TOOLS OF BIOCHEMISTRY 12A

Radioisotopes and the Liquid Scintillation Counter	508
--	-----

TOOLS OF BIOCHEMISTRY 12B

Metabolomics	511

PART 4

Dynamics of Life: Energy, Biosynthesis, and Utilization of Precursors	517
---	-----

CHAPTER 13

Carbohydrate Metabolism: Glycolysis, Gluconeogenesis, Glycogen Metabolism, and the Pentose Phosphate Pathway 518

Glycolysis: An Overview	520
Relation of Glycolysis to Other Pathways	520
Anaerobic and Aerobic Glycolysis	520
The Crucial Early Experiments	522
Strategy of Glycolysis	523
Reactions of Glycolysis	523
Reactions 1–5: The Energy Investment Phase	525
Reactions 6–10: The Energy Generation Phase	529
Metabolic Fates of Pyruvate	535
Lactate Metabolism	535
Isozymes of Lactate Dehydrogenase	536
Ethanol Metabolism	536
Energy and Electron Balance Sheets	539
Gluconeogenesis	540
Physiological Need for Glucose Synthesis in Animals	541
Enzymatic Relationship of Gluconeogenesis to Glycolysis	541
Stoichiometry and Energy Balance of Gluconeogenesis	544
Substrates for Gluconeogenesis	545
Ethanol Consumption and Gluconeogenesis	548
Roles of Extrahepatic Phosphoenolpyruvate Carboxykinase	548
Evolution of Carbohydrate Metabolic Pathways	549
Coordinated Regulation of Glycolysis and Gluconeogenesis	549
The Pasteur Effect	549
Oscillations of Glycolytic Intermediates	550
Reciprocal Regulation of Glycolysis and Gluconeogenesis	551
Regulation at the Phosphofructokinase/Fructose-1,6-Bisphosphatase Substrate Cycle	551

Regulation at the Pyruvate Kinase/Pyruvate Carboxylase + PEPCK Substrate Cycle	555
Regulation at the Hexokinase/Glucose-6-Phosphatase Substrate Cycle	556

Entry of Other Sugars into the Glycolytic Pathway	557
Monosaccharide Metabolism	557
Disaccharide Metabolism	560
Polysaccharide Metabolism	561
Hydrolytic and Phosphorolytic Cleavages	561
Starch and Glycogen Digestion	562
Glycogen Metabolism in Muscle and Liver	562
Glycogen Breakdown	562
Glycogen Biosynthesis	563
Biosynthesis of UDP-Glucose	564
The Glycogen Synthase Reaction	564
Formation of Branches	564
Coordinated Regulation of Glycogen Metabolism	565
Structure of Glycogen Phosphorylase	566
Control of Phosphorylase Activity	567
Proteins in the Glycogenolytic Cascade	568
Nonhormonal Control of Glycogenolysis	569
Control of Glycogen Synthase Activity	570
Congenital Defects of Glycogen Metabolism in Humans	574
Biosynthesis of Other Polysaccharides	575
A Biosynthetic Pathway That Oxidizes Glucose: The Pentose Phosphate Pathway	575
The Oxidative Phase: Generation of Reducing Power as NADPH	576
The Nonoxidative Phase: Alternative Fates of Pentose Phosphates	577
Human Genetic Disorders Involving Pentose Phosphate Pathway Enzymes	581
Summary	584
References	584
Problems	586

TOOLS OF BIOCHEMISTRY 13A

Detecting and Analyzing Protein–Protein Interactions	588
--	-----

CHAPTER 14

Citric Acid Cycle and Glyoxylate Cycle 591

Overview of Pyruvate Oxidation and the Citric Acid Cycle	593
The Three Stages of Respiration	593
Chemical Strategy of the Citric Acid Cycle	594
Discovery of the Citric Acid Cycle	596
Pyruvate Oxidation: A Major Entry Route for Carbon into the Citric Acid Cycle	597
Coenzymes Involved in Pyruvate Oxidation and the Citric Acid Cycle	598

Thiamine Pyrophosphate (TPP)	598	Oxidative Reactions That Drive ATP Synthesis	644
Lipoic Acid (Lipoamide)	598	Mechanism of Oxidative Phosphorylation:	
Flavin Adenine Dinucleotide (FAD)	599	Chemiosmotic Coupling	645
Coenzyme A: Activation of Acyl Groups	601	A Closer Look at Chemiosmotic Coupling: The	
Action of the Pyruvate Dehydrogenase Complex	602	Experimental Evidence	646
The Citric Acid Cycle	604	Complex V: The Enzyme System for ATP Synthesis	649
Step 1: Introduction of Two Carbon Atoms as		Mitochondrial Transport Systems	657
Acetyl-CoA	605	Shuttling Cytoplasmic Reducing Equivalents into	
Step 2: Isomerization of Citrate	605	Mitochondria	659
Step 3: Generation of CO ₂ by an NAD ⁺ -Linked		Energy Yields from Oxidative Metabolism	660
Dehydrogenase	607	The Mitochondrial Genome and Disease	661
Step 4: Generation of a Second CO ₂ by an Oxidative		Mitochondria and Evolution	662
Decarboxylation	608	Oxygen as a Substrate for Other Metabolic Reactions	663
Step 5: A Substrate-Level Phosphorylation	608	Oxidases and Oxygenases	663
Step 6: A Flavin-Dependent Dehydrogenation	609	Cytochrome P450	664
Step 7: Hydration of a Carbon–Carbon Double		Reactive Oxygen Species, Antioxidant Defenses, and	
Bond	610	Human Disease	665
Step 8: A Dehydrogenation That Regenerates		Summary	668
Oxaloacetate	611	References	668
Stoichiometry and Energetics of the Citric Acid Cycle	611	Problems	670
Regulation of Pyruvate Dehydrogenase and the Citric Acid		CHAPTER 16	
 Cycle	612	Photosynthesis	672
Control of Pyruvate Oxidation	612	The Basic Processes of Photosynthesis	673
Control of the Citric Acid Cycle	614	The Chloroplast	675
Organization of the Citric Acid Cycle Enzymes	615	The Light Reactions	677
Evolution of the Citric Acid Cycle	615	Absorption of Light: The Light-Harvesting System	677
Citric Acid Cycle Malfunction as a Cause of Human		Photochemistry in Plants and Algae: Two Photosystems	
Disease	615	in Series	680
Anaplerotic Sequences: The Need to Replace Cycle		An Alternative Light Reaction Mechanism: Cyclic	
 Intermediates	616	Electron Flow	691
Reactions That Replenish Oxaloacetate	616	Reaction Center Complexes in Photosynthetic	
The Malic Enzyme	618	Bacteria	692
Reactions Involving Amino Acids	618	Artificial Photosynthesis	694
Glyoxylate Cycle: An Anabolic Variant of the Citric Acid		The Dark Reactions: The Calvin Cycle	695
 Cycle	620	Stage I: Carbon Dioxide Fixation and Sugar	
 Summary	622	Production	695
 References	623	Stage II: Regeneration of the Acceptor	698
 Problems	624	A Summary of the Light and Dark Reactions in Two-System	
CHAPTER 15		 Photosynthesis	699
Electron Transport, Oxidative Phosphorylation,		The Overall Reaction and the Efficiency	
and Oxygen Metabolism	625	of Photosynthesis	699
The Mitochondrion: Scene of the Action	626	Regulation of Photosynthesis	700
Oxidations and Energy Generation	628	Photorespiration and the C₄ Cycle	701
Free Energy Changes in Biological Oxidations	629	Evolution of Photosynthesis	703
Electron Transport	630	Summary	705
Electron Carriers in the Respiratory Chain	630	References	706
Determining the Sequence of Respiratory Electron		Problems	707
Carriers	632	CHAPTER 17	
Respiratory Complexes	635	Lipid Metabolism I: Fatty Acids,	
Oxidative Phosphorylation	643	Triacylglycerols, and Lipoproteins	708
The P/O Ratio: Efficiency of Oxidative		Utilization and Transport of Fat and Cholesterol	708
Phosphorylation	643		

Fats as Energy Reserves	710
Fat Digestion and Absorption	710
Transport of Fat to Tissues: Lipoproteins	712
Cholesterol Transport and Utilization in Animals	716
Mobilization of Stored Fat	721
Fatty Acid Oxidation	723
Early Experiments	723
Fatty Acid Activation and Transport into Mitochondria	724
The β -Oxidation Pathway	726
Mitochondrial β -Oxidation Involves Multiple Isozymes	728
Energy Yield from Fatty Acid Oxidation	729
Oxidation of Unsaturated Fatty Acids	730
Oxidation of Fatty Acids with Odd-Numbered Carbon Chains	731
Control of Fatty Acid Oxidation	732
Peroxisomal β -Oxidation of Fatty Acids	732
α -Oxidation of Fatty Acids	733
Ketogenesis	733
Fatty Acid Biosynthesis	736
Relationship of Fatty Acid Synthesis to Carbohydrate Metabolism	736
Early Studies of Fatty Acid Synthesis	736
Biosynthesis of Palmitate from Acetyl-CoA	737
Elongation of Fatty Acid Chains	744
Fatty Acid Desaturation	744
Control of Fatty Acid Synthesis	745
Variant Fatty Acid Synthesis Pathways That Lead to Antibiotics	747
Biosynthesis of Triacylglycerols	748
Biochemical Insights into Obesity	750
Summary	750
References	751
Problems	752

CHAPTER 18

Interorgan and Intracellular Coordination of Energy Metabolism in Vertebrates	753
Interdependence of the Major Organs in Vertebrate Fuel Metabolism	753
Fuel Inputs and Outputs	754
Metabolic Division of Labor Among the Major Organs	754
Hormonal Regulation of Fuel Metabolism	757
Actions of the Major Hormones	758
Coordination of Energy Homeostasis	761
Responses to Metabolic Stress: Starvation, Diabetes	768
Starvation	768
Diabetes	770
Summary	773
References	773
Problems	774

CHAPTER 19

Lipid Metabolism II: Membrane Lipids, Steroids, Isoprenoids, and Eicosanoids	775
Metabolism of Glycerophospholipids	775
Biosynthesis of Glycerophospholipids in Bacteria	776
Glycerophospholipid Metabolism in Eukaryotes	781
Metabolism of Sphingolipids	790
Steroid Metabolism	794
Some Structural Considerations	795
Biosynthesis of Cholesterol	795
Bile Acids	803
Steroid Hormones	804
Other Isoprenoid Compounds	808
Lipid-Soluble Vitamins	808
Other Terpenes	811
Eicosanoids: Prostaglandins, Thromboxanes, and Leukotrienes	811
Some Historical Aspects	812
Structure	813
Biosynthesis and Catabolism	813
Biological Actions	815
Summary	817
References	817
Problems	819

CHAPTER 20

Metabolism of Nitrogenous Compounds I: Principles of Biosynthesis, Utilization, and Turnover	820
Utilization of Inorganic Nitrogen: The Nitrogen Cycle	822
Biological Nitrogen Fixation	823
Nitrate Utilization	825
Utilization of Ammonia: Biogenesis of Organic Nitrogen	826
Glutamate Dehydrogenase: Reductive Amination of α -Ketoglutarate	827
Glutamine Synthetase: Generation of Biologically Active Amide Nitrogen	827
Asparagine Synthetase: A Similar Amidation Reaction	831
Carbamoyl Phosphate Synthetase: Generation of an Intermediate for Arginine and Pyrimidine Synthesis	831
The Nitrogen Economy: Aspects of Amino Acid Synthesis and Degradation	832
Metabolic Consequences of the Absence of Nitrogen Storage Compounds	832
Biosynthetic Capacities of Organisms	832
Transamination	833

Protein Turnover	834
Quantitative Features of Protein Turnover	834
Biological Importance of Protein Turnover	835
Intracellular Proteases and Sites of Turnover	836
Chemical Signals for Turnover	837
Amino Acid Degradation and Metabolism of Nitrogenous End Products	840
Common Features of Amino Acid Degradation Pathways	840
Detoxification and Excretion of Ammonia	840
The Krebs–Henseleit Urea Cycle	841
Transport of Ammonia to the Liver	844
Coenzymes Involved in Nitrogen Metabolism	845
Pyridoxal Phosphate	845
Tetrahydrofolate Coenzymes and One-Carbon Metabolism	848
B ₁₂ Coenzymes	853
Summary	858
References	859
Problems	860

CHAPTER 21

Metabolism of Nitrogenous Compounds II: Amino Acids, Porphyrins, and Neurotransmitters 862

Pathways of Amino Acid Degradation	862
Pyruvate Family of Glucogenic Amino Acids	863
Oxaloacetate Family of Glucogenic Amino Acids	865
α -Ketoglutarate Family of Glucogenic Amino Acids	865
Succinyl-CoA Family of Glucogenic Amino Acids	866
Acetoacetate/Acetyl-CoA Family of Ketogenic Amino Acids	870
Amino Acids as Biosynthetic Precursors	874
S-Adenosylmethionine and Biological Methylation	874
S-Adenosylmethionine and Polyamines	880
Other Precursor Functions of Glutamate	882
Nitric Oxide and Creatine Phosphate	883
Tyrosine Utilization in Animals	885
Aromatic Amino Acid Utilization in Plants	887
Porphyrin and Heme Metabolism	889
Biosynthesis of Tetrapyrroles: The Succinate–Glycine Pathway	889
Degradation of Heme in Animals	893
Amino Acids and Their Metabolites as Neurotransmitters and Biological Regulators	895
Biosynthesis of Serotonin and Catecholamines	895
Amino Acid Biosynthesis	897
Synthesis of Glutamate, Aspartate, Alanine, Glutamine, and Asparagine	898
Synthesis of Methionine, Threonine, and Lysine from Aspartate	898
Metabolism of Sulfur-Containing Amino Acids	901
Synthesis of Proline, Ornithine, and Arginine from Glutamate	903

Hydroxyproline and Collagen	905
Synthesis of Serine and Glycine from 3-Phosphoglycerate	906
Synthesis of Valine, Leucine, and Isoleucine from Pyruvate	907
Synthesis of the Aromatic Amino Acids from Glycolytic Intermediates: The Shikimic Acid Pathway	908
Synthesis of Histidine from Glycolytic Intermediates	911

Summary 913

References 913

Problems 915

CHAPTER 22

Nucleotide Metabolism 917

Outlines of Pathways in Nucleotide Metabolism	917
Biosynthetic Routes: De Novo and Salvage Pathways	917
Nucleic Acid Degradation and the Importance of Nucleotide Salvage	918
PRPP: A Central Metabolite in De Novo and Salvage Pathways	920
De Novo Biosynthesis of Purine Nucleotides	920
Early Studies on De Novo Purine Synthesis	920
Purine Synthesis from PRPP to Inosinic Acid	921
Synthesis of ATP and GTP from Inosinic Acid	924
Regulation of De Novo Purine Biosynthesis	925
Utilization of Adenine Nucleotides in Coenzyme Biosynthesis	925
Purine Degradation and Clinical Disorders of Purine Metabolism	926
Formation of Uric Acid	926
Excessive Accumulation of Uric Acid: Gout	927
Salvage of Purines and Lesch–Nyhan Syndrome	929
Unexpected Consequences of Defective Purine Catabolism: Immunodeficiency	929
Pyrimidine Nucleotide Metabolism	931
De Novo Biosynthesis of the Pyrimidine Ring	931
Control of Pyrimidine Biosynthesis in Bacteria	933
Multifunctional Enzymes in Eukaryotic Pyrimidine Synthesis	933
Salvage Synthesis and Pyrimidine Catabolism	934
Glutamine-Dependent Amidotransferases	934
Deoxyribonucleotide Biosynthesis and Metabolism	935
Reduction of Ribonucleotides to Deoxyribonucleotides	936
Biosynthesis of Thymine Deoxyribonucleotides	942
Deoxyuridine Nucleotide Metabolism	943
Salvage Routes to Deoxyribonucleotide Synthesis	944
Thymidylate Synthase: A Target Enzyme for Chemotherapy	945
Flavin-Dependent Thymidylate Synthase: A Novel Route to dTMP	949

Virus-Directed Alterations of Nucleotide Metabolism	950
Biological and Medical Importance of Other Nucleotide Analogs	951

CHAPTER 1

The Scope of Biochemistry

Welcome to the study of **biochemistry**, a branch of science that seeks to describe the structure, organization, and functions of living matter in molecular terms. What are the chemical structures of the components of living matter? How do interactions among these components give rise to organized supramolecular structures, cells, multicellular tissues, and organisms? How does living matter extract energy from its surroundings in order to remain alive? How does an organism store and transmit the information it needs to grow and reproduce? What chemical changes accompany the reproduction, aging, and death of cells and organisms? These are the kinds of questions asked by biochemists, the answers to which provide insight into the chemical nature of life.

Biochemistry can be divided into three principal areas, and that is how this book is arranged: (1) the **structural chemistry** of the components of living matter and relationships of biological function to chemical structure (Chapters 1–11); (2) **metabolism**, the totality of chemical reactions that occur in living matter (Chapters 12–23); and (3) **genetic biochemistry**, the chemistry of processes and substances that store and transmit biological information (Chapters 24–29). This third area is also the province of **molecular genetics**, a field that seeks to understand heredity and the expression of genetic information in molecular terms.

Biochemistry and the Biological Revolution

The biological sciences are undergoing a revolution, and biochemistry is at the heart of that revolution. The revolution began in the mid-twentieth century and received great impetus in 1953, when Watson and Crick proposed the now-familiar double-helical structure for DNA. The revolution continues today, with no letup in the rate at which fundamental knowledge is being revealed about the physics and chemistry of life processes.

The years since the Watson–Crick revelation have seen milestones at intervals of approximately a decade, milestones that help us appreciate how the pace of

Biology was transformed in 1953 when Watson and Crick proposed the double-helical model for DNA structure.

discovery has been maintained and accelerated. Ten years after the seminal Watson–Crick paper, we saw in the early 1960s the elucidation of the genetic code and the discovery of messenger RNA, keys to understanding how genetic information is expressed. Ten years later, the first recombinant DNA molecules were created, opening the door as no other discovery had done, to practical applications of biological information in health, agriculture, forensics, and environmental science. A decade later scientists had learned how to chemically synthesize any nucleic acid fragment and had discovered how to amplify minute amounts of DNA by the polymerase chain reaction, so that any gene could be cloned and subjected to mutagenesis, allowing any desired change to be made in the structure of that gene. After another decade, by the early 1990s, scientists had learned not only how to introduce new genes into the germ line of plants and animals but also how to disrupt or delete any existing gene, allowing analysis of the metabolic function of any gene product. A decade later the nearly complete nucleotide sequence of the human genome was announced— 2.9×10^9 base pairs of DNA, representing more than 20,000 different genes. Shortly afterward the scientific community was rocked by the discovery of genetic regulation by small interfering RNAs. The wealth of information from genomic sequence analysis and gene regulation by RNA continues to transform the biochemical landscape well into the twenty-first century.

During the half century between discovery of the double helix and completion of the human genome sequence, powerful new research techniques in biochemistry and biophysics—X-ray crystallography, mass spectrometry, nuclear magnetic resonance, high-resolution separation techniques, automated protein and nucleic acid sequence determination, techniques for visualizing individual molecules—have fueled the biological revolution. Figure 1.1 gives a timeline for the introduction of these technologies, most of which you will encounter throughout this book.

Our timeline begins with the introduction of radioisotopes as research reagents, at the end of World War II. In the process, the biological sciences have been transformed. It is now clear that biochemistry underlies all of the life sciences, and that understanding any biological process—sensory perception, evolutionary selection, immune mechanisms, energy transformations—demands comprehension of the underlying chemistry and physics. It is also clear that the biology of the twenty-first century involves the gathering, integration, and analysis of enormous sets of data, beginning with the billions of DNA base pairs in the genomes of most animals and plants. A goal of this book is to show how we reached this point—to understand the concepts and principles of biochemistry in terms of the experimental approaches and research technologies upon which those concepts are based and to consider how huge data sets come into existence and are analyzed in the new science called bioinformatics, the quantitative and computational analysis of biological data.

The Roots of Biochemistry

Biochemistry is a young science, although it began well before Watson and Crick's work in 1953. However, much or most of what you will learn by reading this book has been discovered only in the past half-century—since the first shots, so to speak, were fired in the biological revolution. But let us briefly explore the earlier origins of the field.

Biochemistry had its roots as a distinct field of study in the early nineteenth century, with the pioneering work of Friedrich Wöhler. Prior to Wöhler's time it was believed that the substances in living matter were somehow qualitatively different from those in nonliving matter and did not behave according to the known laws of physics and chemistry. In 1828 Wöhler showed that urea, a substance of biological origin, could be synthesized in the laboratory from the inorganic compound ammonium cyanate. As Wöhler phrased it in a letter to a colleague, "I must

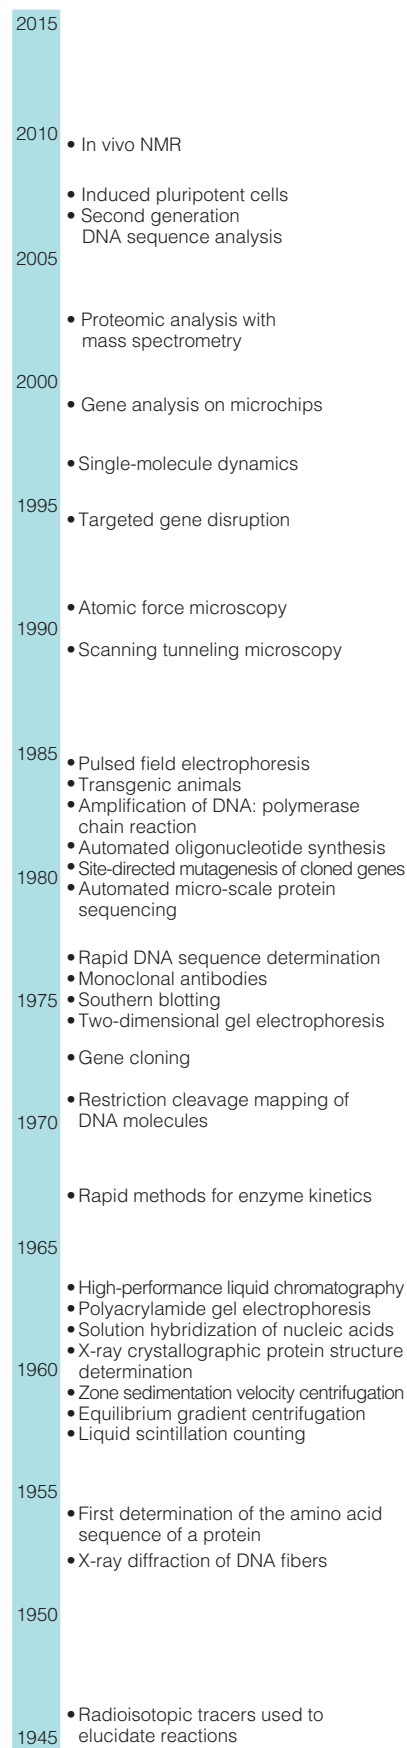

FIGURE 1.1

The recent history of biochemistry as shown by the introduction of new research techniques. The timeline begins with the introduction of radioisotopes as biochemical reagents, immediately following World War II.

Exceedingly powerful new chemical and physical techniques have accelerated the pace at which biological processes have become understood in molecular terms.

Early biochemists had to overcome the view that living matter and nonliving matter were fundamentally different.

tell you that I can prepare urea without requiring a kidney or an animal, either man or dog.” This was a shocking statement in its time, for it breached the presumed barrier between the living and the nonliving.

Even after Wöhler’s demonstration, a pervasive viewpoint called vitalism held that, if not the compounds, at least the reactions of living matter could occur only in living cells. According to this view, biological reactions took place through the action of a mysterious “life force” rather than physical and chemical processes. The vitalist dogma was shattered in 1897, when two German brothers, Eduard and Hans Buchner, found that extracts from broken—and thoroughly dead—yeast cells could carry out the entire process of fermentation of sugar into ethanol. This discovery opened the door to analysis of biochemical reactions and processes **in vitro** (Latin, “in glass”), meaning in a test tube rather than **in vivo**—in living matter. In succeeding decades many other metabolic reactions and reaction pathways were reproduced *in vitro*, allowing identification of reactants and products and of the enzymes, or biological catalysts, that promoted each biochemical reaction.

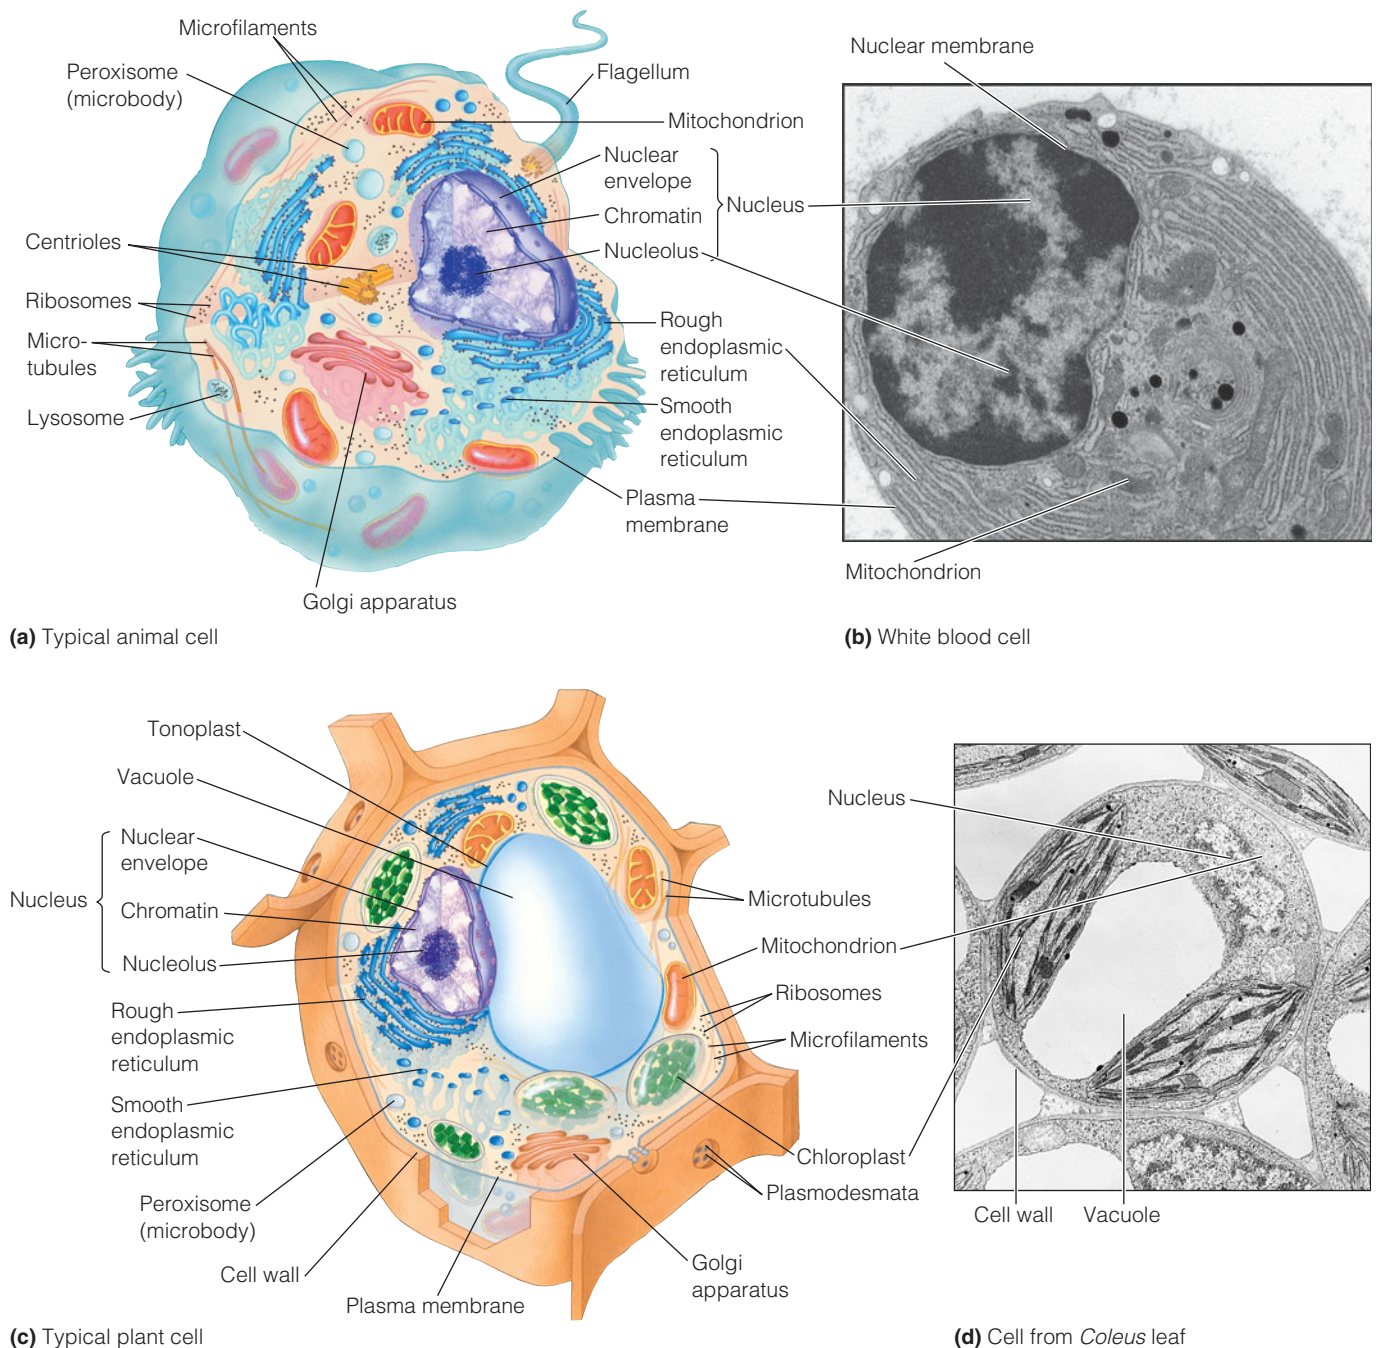

The nature of biological catalysis remained the last refuge of the vitalists, who held that the structures of enzymes (or “ferments”) were far too complex to be described in chemical terms. But in 1926 James B. Sumner showed that the protein urease, an enzyme from jack beans, could be crystallized like any organic compound. Although proteins have large and complex structures, they are just organic compounds, and their structures can be determined by the methods of chemistry and physics. This discovery marked the final fall of vitalism.

In parallel with developments in biochemistry, cell biologists had been continually refining knowledge of cellular structure. Beginning with Robert Hooke’s first observation of cells in the seventeenth century, steady improvements in microscopic techniques led to the understanding that the cell was a complex, multi-compartmented structure (see Figure 1.2). *Chromosomes* were discovered in 1875 by Walter Flemming and identified as genetic elements by 1902. The development of the electron microscope, between about 1930 and 1950, provided a new level of insight into cellular structure. At this point subcellular organelles like *mitochondria* and *chloroplasts* could be studied, and it was realized that specific biochemical processes were localized in these subcellular particles. Figure 1.3 illustrates the parallel developments leading to modern biochemistry and cell biology, and their interweaving with the newer science of genetics.

Although developments in the first half of the twentieth century revealed in broad outline the chemical structures of biological materials, identified the reactions in many metabolic pathways, and localized these reactions within the cell, biochemistry remained an incomplete science. We knew that the uniqueness of an organism is determined by the totality of its chemical reactions. However, we had little understanding of how those reactions are controlled in living tissue or of how the information that regulates those reactions is stored, transmitted when cells divide, and processed when cells differentiate.

The idea of the **gene**, a unit of hereditary information, was first proposed in the mid-nineteenth century by Gregor Mendel, from his studies on the genetics of pea plants. By about 1900, cell biologists realized that genes must be found in chromosomes, which are composed of proteins and nucleic acids. Subsequently, the new science of genetics provided increasingly detailed knowledge of the patterns of inheritance and development. However, until the mid-twentieth century no one had isolated a gene or determined its chemical composition. Nucleic acids had been isolated in 1869 by Friedrich Miescher, but their chemical structures were poorly understood, and in the early 1900s they were thought to be simple substances, fit only for structural roles in the cell. Most biochemists believed that only the proteins were sufficiently complex to carry genetic information.

That belief was incorrect. Experiments in the 1940s and early 1950s proved conclusively that **deoxyribonucleic acid (DNA)** is the bearer of genetic information (see Chapter 4). As noted earlier, 1953 was a landmark year, when Watson

**FIGURE 1.2**

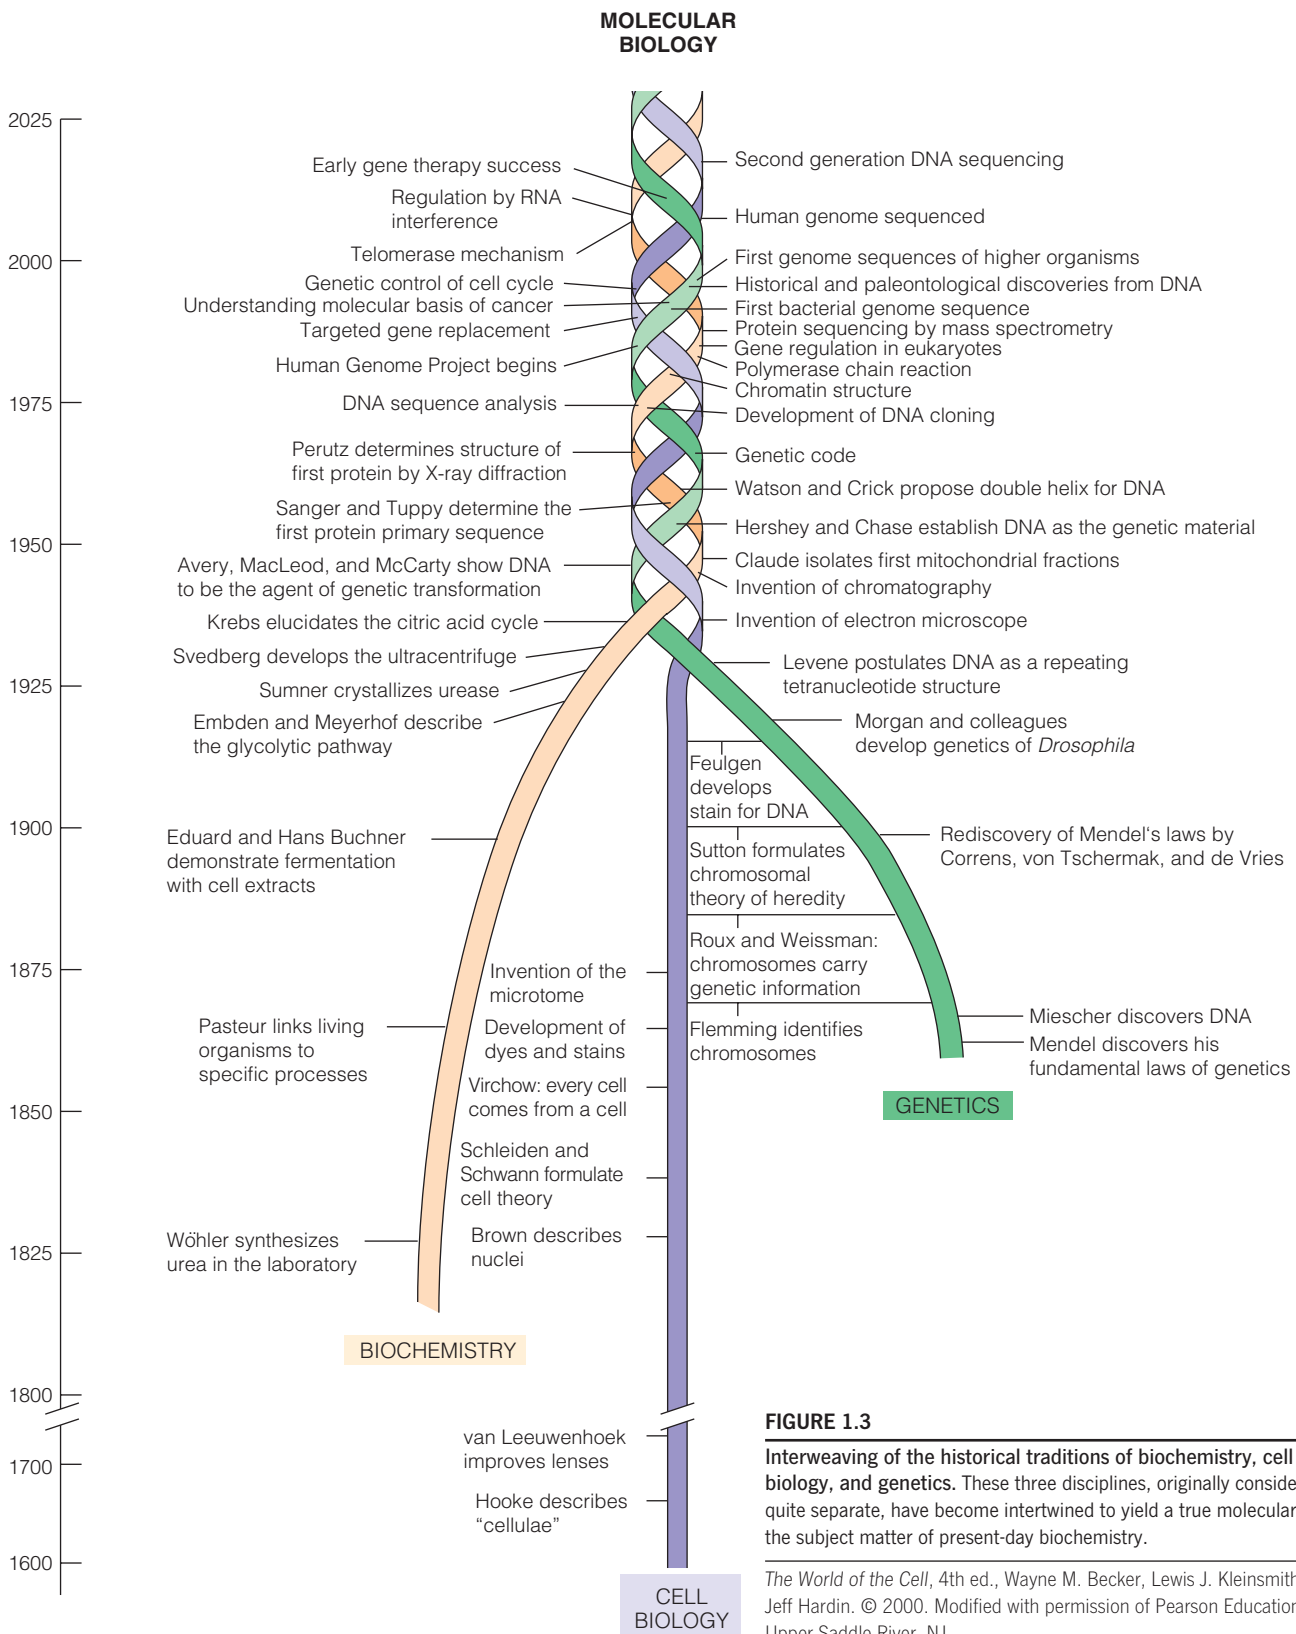

The complexity of cells. Shown in (a) and (c) are schematic diagrams of a typical animal and plant cell, respectively. (b) An electron micrograph of a representative animal cell, a white blood cell. (d) An electron micrograph of a representative plant cell, a thin section of a *Coleus* leaf cell.

and Crick described the double-helical structure of DNA. This concept immediately suggested ways in which information could be encoded in the structure of molecules and transmitted intact from one generation to the next.

At about this point the strands of scientific development shown in Figure 1.3—biochemistry, cell biology, and genetics—became inextricably interwoven, and the new science of molecular biology emerged. The distinction between molecular biology and biochemistry is not always clear because both

• **Molecular biology is a fusion of biochemistry, cell biology, and genetics.**

**FIGURE 1.3**

Interweaving of the historical traditions of biochemistry, cell biology, and genetics. These three disciplines, originally considered quite separate, have become intertwined to yield a true molecular biology, the subject matter of present-day biochemistry.

The World of the Cell, 4th ed., Wayne M. Becker, Lewis J. Kleinsmith, and Jeff Hardin. © 2000. Modified with permission of Pearson Education Inc., Upper Saddle River, NJ.

disciplines take as their ultimate aim the complete definition of life in molecular terms. The term *molecular biology* is often used in a narrower sense, to denote the study of nucleic acid structure and function and the genetic aspects of biochemistry—an area we might more properly call *molecular genetics*. In the early twenty-

first century, however, the distinction between biochemistry and molecular biology has become somewhat artificial because successful scientists in either field must use the approaches of all relevant disciplines, including chemistry, biology, and physics. In fact, three of the most powerful research techniques used by biochemists were developed by physicists: **electron microscopy**, which has revealed remarkable details of cellular structure (see Tools of Biochemistry 1A), and **X-ray diffraction** and **nuclear magnetic resonance**, which have revealed the precise three-dimensional structures of huge biological molecules (see Tools of Biochemistry 4A and 6A).

Biochemistry as a Discipline and an Interdisciplinary Science

Biochemistry draws its major themes from many disciplines—from organic chemistry, which describes the properties of biomolecules; from physical chemistry, which describes thermodynamics, properties of water, and electrical parameters of oxidation-reduction reactions; from biophysics, which applies the techniques of physics to study the structures and functions of biomolecules; from medical science, which increasingly seeks to understand disease states in molecular terms; from nutrition, which has illuminated metabolism by describing the dietary requirements for maintenance of health; from microbiology, which has shown that single-celled organisms and viruses are ideally suited for the elucidation of many metabolic pathways and regulatory mechanisms; from physiology, which investigates life processes at the tissue and organism levels; from cell biology, which describes the metabolic and mechanical division of labor within a cell; and from genetics, which describes mechanisms that give a particular cell or organism its biochemical identity. Biochemistry draws strength from all of these disciplines, and it nourishes them in return; it is truly an interdisciplinary science.

Biochemistry is also a distinct discipline, with its own identity. It is distinctive in its emphasis on the structures and reactions of biomolecules, particularly on enzymes and biological catalysis; on the elucidation of metabolic pathways and their control; and on the principle that life processes can be understood through the laws of physics and chemistry. As you read this book, keep in mind both the uniqueness of biochemistry as a separate discipline and the absolute interdependence between biochemistry and other physical and life sciences.

Biochemistry as a Chemical Science

Though we often describe biochemistry as a life science and relate its developments to the history of biology, it remains first and foremost a chemical science. In order to understand the impact of biochemistry on biology, you must understand the chemical elements of living matter and the complete structures of many biological compounds—amino acids, sugars, lipids, nucleotides, vitamins, and hormones—and their behavior during metabolic reactions. You will need to know the stoichiometry and mechanisms of a large number of reactions. In addition, an understanding of basic thermodynamic principles is essential for learning how plants derive energy from sunlight, how animals derive energy from food, and how biomolecules self-assemble to form complex structures.

All forms of life, from the smallest bacterial cell to a human being, are constructed from the same chemical elements, which in turn make up the same types of molecules. The chemistry of living matter is similar throughout the biological world. Undoubtedly, this continuity in biochemical processes reflects the common evolutionary ancestry of all cells and organisms. Let us begin a preliminary examination of the composition of living matter, starting with the chemical elements.

To understand biochemistry, one must first understand basic chemistry.

The Chemical Elements of Living Matter

Life is a phenomenon of the second generation of stars. This rather strange-sounding statement is based on the fact that life, as we conceive it, can come into being only when certain elements—carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur (C, H, O, N, P, and S)—are abundant. The very early universe was made almost entirely of hydrogen and helium, for only these simplest elements were produced in the condensation of matter following the primeval explosion, or “big bang.” The first generation of stars contained no heavier elements from which to form planets. As these early stars matured over the next seven to eight billion years, they burned their hydrogen and helium in thermonuclear reactions. These reactions produced heavier elements—first carbon, nitrogen, and oxygen and later all the other members of the periodic table. As large stars matured, they became unstable and exploded as novae and supernovae, spreading the heavier elements through the cosmic surroundings. This matter condensed again to form second-generation stars, complete with planetary systems rich in the heavier elements. Our universe, which is now rich in second-generation stars, has an elemental composition compatible with life as we know it.

Why are elements heavier than H and He essential for life? The answer is that life, as we can imagine it, requires large and complex molecular structures. These can be formed only from certain elements and can be stable only under restricted environmental conditions. A universe of hydrogen and helium has no chemistry. Nor is chemistry possible in the heat of stars, where no chemical compounds exist, only elements. In environments as cold as the moon or space, a slow, simple chemistry may occur, but we cannot envision the formation of molecules as complex as proteins or nucleic acids. Only in the temperate environment of an appropriate planet, enriched with elements capable of forming complicated compounds, can life arise.

Few elements are involved in the creation of living matter. Living creatures on the earth are composed primarily of just four—carbon, hydrogen, oxygen, and nitrogen. These elements are also, with the addition of helium and neon, the most abundant elements in the universe. Helium and neon, inert gases, are not equipped for a role in life processes; they do not form stable compounds, and they are readily lost from planetary atmospheres.

The abundance of oxygen and hydrogen in organisms is explained partly by the major role of water in life on earth. We live in a highly aqueous world, and, as we shall see in Chapter 2, the solvent properties of water are indispensable in biochemical processes. The human body, in fact, is about 70% water. The elements C, H, O, and N are important to life because of their strong tendencies to form covalent bonds. In particular, the stability of carbon–carbon bonds and the possibility of forming single, double, or triple bonds give carbon the versatility to be part of an enormous diversity of chemical compounds.

But life is not built on these four elements alone. Many other elements are necessary for terrestrial organisms, as you can see in Table 1.1. A “second tier” of essential elements includes sulfur and phosphorus, which form covalent bonds, and the ions Na^+ , K^+ , Mg^{2+} , Ca^{2+} , and Cl^- . Sulfur is a constituent of nearly all proteins, and phosphorus plays essential roles in energy metabolism and the structure of nucleic acids. Beyond the first two tiers of elements (which correspond roughly to the most abundant elements of the first two rows of the periodic table), we come to those that play quantitatively minor, but often indispensable, roles. As Table 1.1 shows, most of these third- and fourth-tier elements are metals, and some serve as aids to catalysis of biochemical reactions. In succeeding chapters we shall encounter many examples of the importance of these trace elements to life.

Biological Molecules

The complexity of life processes requires that many of the molecules participating in these processes be enormous. Consider, for instance, the DNA molecules released from one human chromosome, as shown in Figure 1.4. The long, looped

Life depends primarily on a few elements (C, H, O, N, S, and P), although many others play essential functions as well.

TABLE 1.1 Elements found in organisms

Element	Comment
First Tier	
Carbon (C)	Most abundant in <i>all</i> organisms
Hydrogen (H)	
Nitrogen (N)	
Oxygen (O)	
Second Tier	
Calcium (Ca)	Much less abundant but found in <i>all</i> organisms
Chlorine (Cl)	
Magnesium (Mg)	
Phosphorus (P)	
Potassium (K)	
Sodium (Na)	
Sulfur (S)	
Third Tier	
Cobalt (Co)	Metals present in small amounts in <i>all</i> organisms and essential to life
Copper (Cu)

**FIGURE 1.4**

The DNA from a single human chromosome. Most of the chromosomal proteins have been removed, leaving only a protein “skeleton” from which enormous loops of DNA emerge. There are just two DNA molecules in this chromosome. The enlargement to the right shows the long DNA fiber in more detail. The fiber is about 2 nm thick.

Reprinted from *Cell* 12:817–828, J. Paulson and U. K. Laemmli, The structure of histone-depleted metaphase chromosomes. © 1977, with permission from Elsevier.

thread you see corresponds to just two huge molecules, each with a molecular mass of about 20 billion daltons (a dalton [Da] is 1/12 the mass of a ^{12}C atom, 1.66×10^{-24} g). Even a simple organism such as the single-celled bacterium *Escherichia coli* contains a DNA molecule with a molecular mass of about 2 billion Da; this molecule is more than one millimeter long. Protein molecules are generally much smaller, but they are still large, with molecular masses ranging from about 10,000 to one million Da. The complexity of these molecules can be seen from the three-dimensional structure of even a fairly small protein. Figure 1.5 illustrates the structure of myoglobin, an oxygen storage protein of muscle, which has a molecular weight of about 16,000 Da.

These giant molecules, or **macromolecules**, constitute a large fraction of the mass of any cell. As we shall see in detail in later chapters, there are good reasons for some biological materials to be so large. DNA molecules, for example, can be thought of as tapes or computer files, from which genetic information is read out in a linear fashion. Because the amount of information needed to specify the structure of a multicellular organism is enormous, these tapes must be extremely long. In fact, the DNA molecules in a single human cell, if stretched end to end, would reach a length of about 2 m. As revealed in the early twenty-first century through the Human Genome Project, the information contained in human DNA could encode about 100,000 proteins, although the actual number of functional genes is far smaller.

The synthesis of such large molecules poses an interesting challenge to the cell. If the cell functioned like an organic chemist carrying out a complex laboratory synthesis bit by bit, millions of different types of reactions would be involved, and thousands of intermediates would accumulate. Instead, cells use a modular approach for constructing large molecules. All such structures are **polymers**, made by joining prefabricated units, or **monomers**. The monomers of a given type of macromolecule are of limited diversity and are linked together, or **polymerized**, by identical mechanisms, each involving **condensation**, or removal of a molecule of water in the joining reaction. A simple example is the carbohydrate **cellulose** (Figure 1.6a), a major constituent of the cell walls of plants. Cellulose is a polymer made by joining thousands of molecules of glucose, a simple sugar; in this polymer all of the chemical linkages between the monomers are identical. Covalent links between glucose units are formed by removing the elements of a water molecule between two adjoining glucose molecules; the portion of a glucose molecule remaining in the chain is called a glucose **residue**. Whereas

Many of the important molecules in cells are enormous. The major biopolymers include the nucleic acids, the proteins, and the polysaccharides. All are polymers, made up of one or more kinds of monomer units.

FIGURE 1.5

The three-dimensional structure of myoglobin. This historic painting, by Irving Geis in collaboration with John Kendrew, portrays as a stick model the first protein whose structure was deduced by X-ray diffraction—sperm whale myoglobin. It depicts, therefore, our first indication of the complexity and specificity of the three-dimensional structure of proteins. Such structures are now routinely displayed by computer graphics.

Cells use a modular approach for constructing large molecules.

all residues in a cellulose chain are identical, the sequences of nucleotides, in nucleic acids, and of amino acids, in proteins, are far more complex.

Because cellulose is a polymer of a simple sugar, or **saccharide**, it is called a **polysaccharide**. This particular polymer is constructed from identical monomeric units, so it is called a **homopolymer**. In contrast, many polysaccharides and all nucleic acids and proteins are **heteropolymers**, polymers constructed from a number of different kinds of monomer units. Nucleic acids (Figure 1.6b) are polymers of four **nucleotides**, so nucleic acids are also called **polynucleotides**. Similarly, proteins (Figure 1.6c) are assembled from combinations of 20 different **amino acids**. Protein chains are called **polypeptides**, a term derived from the **peptide bond** that joins two amino acids together.

FIGURE 1.6

Examples of biological polymers, or biopolymers. **(a)** A carbohydrate. The carbohydrate cellulose is a polymer of β -D-glucose monomers, with a molecule of water split out in each joining reaction. **(b)** A nucleic acid. The nucleic acids, DNA and RNA, are polymers of nucleotides. Part of a DNA molecule is shown, along with one of its monomers, deoxyadenosine monophosphate. **(c)** A polypeptide. Protein chains, or polypeptides, are polymers, assembled from 20 different amino acids. Part of a polypeptide is shown, along with one of its monomers, tyrosine.

Polymers form much of the structural and functional machinery of the cell. Polysaccharides serve both as structural components, such as cellulose, and as reserves of biological energy, such as **starch**, another type of glucose polymer found in plants. The nucleic acids, DNA and RNA, participate in information storage, transmission, and expression. DNA serves principally as a storehouse of genetic information, while the chemically similar **RNA**, or **ribonucleic acid**, is involved in the readout of information stored in DNA. Proteins, which have far more structural diversity than polysaccharides or nucleic acids, perform a more diverse set of biological functions. Some play structural roles, such as keratin in hair and skin or collagen in connective tissue. Others act as transport substances, an outstanding example being hemoglobin, the oxygen-carrying protein of blood. Proteins may transmit information between distant parts of an organism, as do protein **hormones** and the cell surface **receptors** that receive the hormone signals, or they may defend an organism against infection, as do the **antibodies**. Most important of all, proteins function as **enzymes**, catalyzing the thousands of chemical reactions that occur within an individual cell. **RNA polymerase** is an example of an enzyme, catalyzing the DNA-dependent joining of nucleotide molecules to synthesize RNA (see Chapter 27).

In addition to these macromolecules and the many small molecules involved in metabolism and as monomers in macromolecular synthesis, there is one other major class of cellular constituents. The **lipids** are a chemically diverse group of compounds that are classified together because of their hydrocarbon-rich structures, which give them low solubility in the aqueous environment of the cell. This low solubility equips lipids for one of their most important functions—to serve as the major structural element of the **membranes** that surround cells and partition them into various compartments.

Lipids form the major constituents of biological membranes.

Biochemistry as a Biological Science

Distinguishing Characteristics of Living Matter

The chemistry of *life* is what concerns us here. The complex chemical substances and reactions that we have mentioned have their significance as parts of living matter and life processes. To see biochemistry from this perspective, we should begin by asking, what distinguishes living matter from nonliving matter?

Daniel Koshland (see end-of-chapter references) has described seven distinctive attributes, or “pillars of life,” the essential principles on which a living system operates. First is a *program*, or organized plan for constitution and regeneration of an organism. For life on Earth, that program is the information stored in DNA. Second is *improvisation*, the ability of living matter to change the program to assure survival as the surroundings change. The processes of mutation and selection ensure that, as the environment changes (aqueous to terrestrial, for example), organisms can adjust so that survival continues under the new conditions.

The third pillar is *compartmentation*, the ability of an organism to separate itself from the environment (with membranes, for example) so that the chemistry needed to carry out the program, such as enzyme-catalyzed reactions, can occur under favorable conditions of temperature, pH, and concentrations of reactants and products. The smallest organisms contain just one compartment, the interior of a single cell, while larger organisms contain many cells, specialized to carry out different functions, such as sensory perception or movement. In addition, the cells of multicellular organisms contain subcompartments, the organelles that allow for division of labor within the basic functional unit, the cell itself. The fourth pillar is *energy*. Thermodynamics tells us that spontaneous processes occur in the direction of simplicity and randomness. Yet living matter must create complexity in order to sustain the program and the other pillars of life. To do this, cells and organisms carry out reactions that yield energy, such as the oxidation of nutrients,

and they couple some of that energy to energy-requiring reactions that create complexity, such as the synthesis of nucleic acids and proteins or the transmission of nerve impulses. The ultimate source of that energy is the sun, which is used either directly, by photosynthetic plants and bacteria to drive the synthesis of biomolecules, or indirectly, by organisms that consume other organisms and derive their energy from the breakdown of dietary nutrients.

Fifth is *regeneration*, the ability to compensate for the inevitable wear involved in maintaining a physical state far from equilibrium. For example, all of the proteins in a cell are subjected to continuous degradation, either because they suffer environmental damage or because, like digestive enzymes, they undergo degradation as part of their normal function. The ability to continuously replace damaged molecules of this type is a distinguishing characteristic of life. The sixth pillar is *adaptability*, the capacity of an organism to respond to environmental changes. For example, when nutrient stores within an animal are depleted, the animal becomes hungry and seeks food. Adaptability, a property of individual organisms, is distinguished from improvisation, the capacity of populations of organisms to respond to environmental change over a time scale of many generations.

The final pillar is *seclusion*, which means that metabolic processes and pathways must operate in isolation from one another, even though they may take place within the same compartment of a cell. When we digest carbohydrate, a consequence is a rise in intracellular glucose concentration. In liver or muscle that glucose can either be consumed to provide energy or polymerized into glycogen, a glucose polymer, comparable to starch, which is stored for later release when there is an energy demand. Glucose polymerization and the initial steps in breakdown occur within the same cell compartment. Yet intracellular control processes and the specificities of the enzymatic catalysts involved ensure that one of the pathways is favored and the other inhibited, in response to the cell's needs.

Interconnected with all seven pillars of life is the function of semipermeable membranes, which surround cells and intracellular **organelles**, such as mitochondria, maintaining **homeostasis**, a condition in which the chemical composition of a biological system is held constant. Throughout this book we will be concerned with the difference between equilibrium and homeostasis, a non-equilibrium steady state. Cells and organisms maintain constancy of their chemical environment, which may suggest that those systems are at equilibrium. However, the steady-state characteristic of living systems can be maintained only by continuous infusion of energy. A protein molecule at equilibrium will have broken down to amino acids. Proteins in cells, however, are synthesized and maintained in their polymeric state only through the energy-dependent maintenance of a nonequilibrium steady state. As another example, membranes are responsible for maintaining ion concentration gradients. Most cells actively transport potassium inward against a concentration gradient. At equilibrium, the intra- and extracellular potassium concentrations would be equivalent.

How did this remarkable process we call life arise? We do not know, but we do know that it is truly ancient, almost as old as the earth itself. The earth condensed from cosmic dust about 4.5 billion years ago, but recognizable traces of living microbes have been dated to 3.8 billion years, only 700 million years later. It is possible that some of these earliest organisms (or proto-organisms) utilized preformed chemical building blocks. For example, traces of amino acids have been found in meteorites, strong evidence that such substances can be generated **abiotically**, without the involvement of a living system.

Whatever their origin, we know that the earliest organisms must have lived an anaerobic existence, for the earth was devoid of free oxygen. Indeed, it is believed that all of the oxygen now present in the earth's atmosphere is the product of photosynthesis by algae and plants. It probably required 3–4 billion years for the present oxygen level to accumulate. Life has not only occupied this planet, it has rebuilt it.

Life depends on creating and duplicating order in a chaotic environment. This ordering requires energy.

All living creatures are composed of cells.
Most cells are similar in size.

The Unit of Biological Organization: The Cell

A seminal early discovery in biology was Robert Hooke's observation (1665) that plant tissues (in this case, cork) were divided into tiny compartments, which he called *cellulae*, or **cells**. By 1840, improved observations on many tissues led Theodor Schwann to propose that all organisms exist as either single cells or aggregates of cells. That hypothesis is now firmly established.

Furthermore, cells, from whatever organism, are of rather similar size. Most bacterial cells are about 1–2 μm in diameter, and most cells of higher organisms are only about 10- to 20-fold larger, plant cells being somewhat larger than animal cells. There are, to be sure, exceptions: There are very small bacteria (0.2 μm), and there are unusual cells like those in the nervous systems of vertebrates, some of which may be over 1 m long. But compared with the overall range of sizes of natural organisms, most cell sizes are much alike.

In both plants and animals, the size of the cells bears no relationship to the size of the organism. An elephant and a flea have cells of about the same size; the elephant just has more of them. Why is such uniformity in cell size maintained? A clue can be found in the fact that the surface/volume ratio for an object of a given shape depends on its size. For example, a cube 20 μm on a side has a surface-to-volume ratio of 0.3, while 1000 cubes, each 2 μm on a side, have the same total volume, but a surface-to-volume ratio of 3.0, 10 times larger. The ability to exchange substances with its surroundings is crucial for the chemical processes that occur within a cell, meaning that a critical surface-to-volume ratio must be maintained. Evidently, cellular function is sufficiently similar between elephants and fleas, for example, that evolution has selected cells exhibiting similar surface-to-volume ratios.

FIGURE 1.7

Molecular tree of life, based upon ribosomal RNA sequence comparisons. Not all lines of descent are shown. The branch points represent common evolutionary origins, and the distance between two branches represents genetic relatedness. Some lineages represent "environmental sequences," *i.e.*, sequences detected in the environment from which the relevant organisms have not yet been isolated in culture.

Because cells are the universal units of life, let us examine them more closely. Major differences between cell structures define the two great classes of organisms—prokaryotic and eukaryotic. The **prokaryotes**, which are always unicellular, include the true **bacteria** (eubacteria) and an ancient class called **archaea**. Although organisms were originally classified in terms of morphological or structural criteria, current classification is based upon biochemical analysis, primarily DNA nucleotide sequence determination. Figure 1.7 shows the three great branches of life as an evolutionary “tree,” with relationships based upon similarities in ribosomal RNA sequences. The closer together are two branches, the more closely related are organisms in those two branches.

A typical prokaryotic organism is shown schematically in Figure 1.8. Prokaryotic cells are surrounded by a plasma membrane and usually by a rigid cell wall as well. Within the membrane is the **cytoplasm**, which contains the **cytosol**—a semiliquid concentrated solution or gel—and the structures suspended within it. In prokaryotes the cytoplasm is not divided into compartments, and the genetic information is in the form of one or more DNA molecules that exist free in the cytosol. Also suspended in the cytosol are the **ribosomes**, which constitute the molecular machinery for protein synthesis. The surface of a prokaryotic cell may carry **pili**, which aid in attaching the organism to other cells or surfaces, and **flagellae**, which enable it to swim.

All other organisms are called **eukaryotes**. These include the multicellular plants and animals, as well as the unicellular and simple multicellular organisms called protozoans, fungi, and algae. A few of the many differences between eukaryotes and prokaryotes are listed in Table 1.2. Most eukaryotic cells are larger (by 10- to 20- fold) than prokaryotic cells, but they compensate for their large size by being *compartmentalized*. Their specialized functions are carried out in **organelles**—membrane-surrounded structures lying within the surrounding cytoplasm.

The two great classes of organisms have different cell types. Prokaryotic cells are uncompartmented; eukaryotes have membrane-bound organelles.

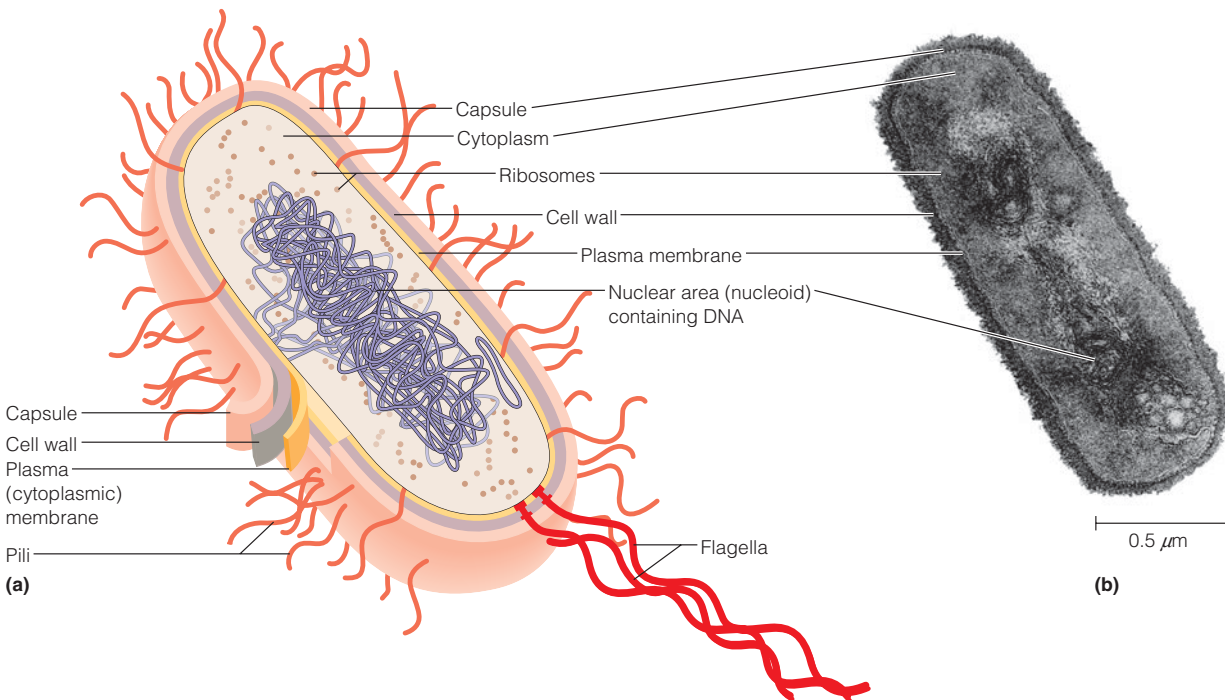

FIGURE 1.8

Prokaryotic cells. (a) Schematic view of a representative bacterial cell. The DNA molecule that constitutes most of the genetic material is coiled up in a region called the nucleoid, which shares the fluid interior of the cell (the cytoplasm) with ribosomes (which synthesize proteins), other particles, and a large variety of dissolved molecules. The cell is bounded by a plasma membrane, outside of which is usually a fairly rigid cell wall. Many bacteria also have a gelatinous outer capsule. Projecting from the surface may be pili, which attach the cell to other cells or surfaces, and one or more flagellae, which enable the cell to swim through a liquid environment. (b) Electron micrograph of a bacterial cell, a thin section of a dividing cell of the bacterium *Bacillus coagulans*. The light areas represent the two nucleoids, and the dark granules are ribosomes.

TABLE 1.2 Comparison of some properties of prokaryotic and eukaryotic cells

	Prokaryotic Cells	Eukaryotic Cells
Size	0.2–5 μm in diameter	Most are 10–50 μm in diameter
Internal compartmentation	No	Yes, with several different kinds of organelles
Containment of DNA	Free in cytoplasm as nucleoid	In nucleus, condensed with proteins into multiple chromosomes
Ploidy ^a	Usually haploid	Almost always diploid or polyploid
Mechanism of cell replication	Simple division following DNA replication	Mitosis in somatic cells, meiosis in gametes ^b

^aThe term *ploidy* refers to the number of copies of the genetic information carried by each cell. Haploid cells have one copy, diploid cells two, and polyploid cells more than two.

^bIn mitosis the diploid state is retained by chromosome duplication. This occurs in most *somatic*, or “body,” cells of organisms. In the cells that produce gametes (sperm or ova) the process of meiosis leads to a haploid state.

The cell can be thought of as a factory, with organelles and compartments specialized to perform different functions.

Schematic views of idealized animal and plant cells were shown earlier in Figure 1.2. Major organelles common to most eukaryotic cells are the **mitochondria**, which specialize in oxidative metabolism; the **endoplasmic reticulum**, a folded membrane structure rich in ribosomes, where much protein synthesis occurs; the **Golgi complex**, membrane-bound chambers that function in secretion and the transport of newly synthesized proteins to their destinations; and the **nucleus**. The nucleus of a eukaryotic cell contains the cell’s genetic information, encoded in DNA that is packaged into **chromosomes**. A portion of this DNA is subpackaged into a dense region within the nucleus called the **nucleolus**. Surrounding the nucleus is a **nuclear envelope**, pierced by pores through which the nucleus and cytoplasm communicate.

There are also organelles specific to plant or animal cells. For example, animal cells contain digestive bodies called **lysosomes**, which are lacking in plants. Plant cells have **chloroplasts**, the sites of photosynthesis; and usually a large, water-filled **vacuole**. Furthermore, whereas most animal cells are surrounded only by a **plasma membrane**, plant cells often have a tough cellulosic **cell wall** outside the membrane. **Basal bodies** act as anchors for cilia or flagellae in cells that have those appendages.

It is useful to think of the cell as a factory, an analogy we shall frequently use in later chapters. Membranes enclose the whole structure and separate different organelles, which can be thought of as departments with specialized functions. The nucleus, for example, is the central administration. It contains in its DNA a library of information for cellular structures and processes, and it issues instructions for proper regulation of the business of the cell. The chloroplasts and mitochondria are power generators (the former being solar, the latter fuel-burning). The cytoplasm is the general work area, where protein machinery carries out the formation of new molecules from imported raw materials. Special molecular channels in the membranes between compartments and between the cell and its surroundings monitor the flow of molecules in appropriate directions. Like factories, cells tend to specialize in function; for example, many of the cells of higher organisms are largely devoted to the production and export of one or a few molecular products. Examples are pancreatic beta cells, which secrete digestive enzymes, and white blood cells, each of which is specialized to synthesize just one of the several million different antibody molecules that can be synthesized by humans as part of the immune response.

Biochemistry as a Biological Science: Form and Function

Function and evolution lie at the heart of biology. Evolution occurs from selection of function. Because biochemistry deals in part with the evolution of proteins and genes, biochemistry is, as we have noted, a biological science. The question of function, however, does not arise in the physical sciences. Function and purpose are irrelevant concepts in the nonliving world. A chemist, for example, explores the relationship between structure and reactivity of molecules by examining the effects

of substitutions on reaction rates and electronic structure. He or she may inquire whether toluene is more reactive than benzene toward nitronium ions (NO_2^+). However, the chemist cannot ask, “What is the function of the methyl group in toluene?” Nor can a geographer ask, “What is the function of the Florida peninsula?” But a biologist may ask why there are species differences in the coloration and pattern of butterfly wings. Similarly, the biochemist can, and does, attempt to explain functional roles of methyl groups; for example, he or she may investigate why methyl groups are introduced into DNA following its replication, or why there are differences in DNA methylation patterns between normal cells and cancer cells.

Or, the biochemist may note that in the biosynthetic pathways to sex hormones, a methyl group is removed from the steroid ring system as an androgen (male sex hormone) is converted to an estrogen (female sex hormone). Because the sex hormones convey different signals in males and females, the methyl group is clearly fulfilling a function.

Therefore, because the biochemist studies living things and he or she deals with functional molecules, in contrast to the chemist, who studies nonliving things and is not concerned with function, biochemists have had to shape their own approach. They use the research techniques of chemistry, but the questions that they seek to answer are unique.

The functioning of each molecule in an organism cannot be properly understood in isolation. Consider an enzyme. Enzymes are proteins, and protein molecules are functionally designed. “Design” here implies the intimate relation of structure to function. Proteins are not random sequences of amino acids. The amino acid sequence dictates the folding of the polypeptide into a particular functional conformation. However, during evolution, the three-dimensional structure is conserved, but not necessarily the linear (one-dimensional) sequence of amino acids.

X-ray crystallography enables us to “see” the exquisite three-dimensional structure of an enzyme. However, X-ray analysis alone cannot show all the events that occur during catalysis. In fact, without prior knowledge that the molecule under study is in fact a catalyst, the crystallographer can only appreciate the beauty of the folded structure. He or she could not identify which crevice holds the substrate or how substrate binding triggers a conformational change, or what adaptations of the enzyme reflect its place in a metabolic pathway in different cell types with varying metabolic needs. In short, the structure of the enzyme assumes its full significance only in relation to its activity, not simply as a catalyst but also as a control device within the functioning of an organism.

Windows on Cellular Function: The Viruses

In analyzing metabolism and the processing of genetic information, biochemists have been aided immeasurably by the **viruses**. Viruses are not cellular and are therefore described as “biological entities” rather than organisms; they are intracellular parasites that can grow only by invading cells. Viruses usually consist of one molecule of nucleic acid (either DNA or RNA) wrapped in an envelope made largely or completely of protein. The envelope is specialized to allow the virus particle to enter particular plant, animal, or bacterial cells. Figure 1.9 shows electron micrographs of several representative viruses.

Because viruses contain no metabolic machinery of their own, they must use that of the host cell to reproduce. By studying the conditions necessary for virus replication, we can learn how this cellular machinery operates. Viruses thus provide useful windows onto the cellular functions that they co-opt during infection. For example, the smallest DNA-containing viruses replicate their DNA using only host-cell enzymes. Because of their small size, these viral DNA molecules can be isolated and characterized much more easily than the giant DNA molecules in cellular chromosomes. Larger viruses stimulate the formation of new enzymes after infection, with viral genes specifying the structures of these enzymes. Studies of these enzymes have illuminated genetic regulatory mechanisms, and they have identified targets for treating viral diseases, including AIDS, influenza, and herpes virus infections.

Viruses are intracellular parasites that use cellular machinery and energy sources to replicate.

Much of today's biochemistry looks at the cell globally, attempting to understand its functions in terms of the expression of all of the genes in the genome.

Biochemistry and the Information Explosion

As you read this book, you will see that our understanding of biochemistry has taken place by a process involving single molecules and individual reactions. To understand a metabolic pathway, such as the citric acid cycle, which is responsible for oxidation of all nutrients, we must identify all of the intermediate molecules in the pathway, isolate each of the enzymes that catalyzes a reaction in the pathway (there are eight), and characterize each reaction in terms of identifying substrates, products, stoichiometry, and regulation. Ultimately, we would want to learn how each enzyme works, by determining the atomic structure of the enzyme and learning the molecular mechanism of catalysis.

At the same time, we realize that all of the metabolic pathways described in this book represent but a small fraction of the total potential of a cell or organism to carry out chemical reactions in support of its existence and function. The amount of DNA in the 23 pairs of human chromosomes is sufficient to encode 100,000 different proteins, although sequence analysis indicates that far fewer proteins are actually encoded. The ability of scientists to carry out ultra-large-scale DNA sequence analysis has generated biological data on a scale that far exceeds our capacity to integrate it through analysis of individual reactions and pathways. This has given rise to new fields of science that can be considered areas within biochemistry or molecular biology—**bioinformatics**, **genomics**, **proteomics**, and **metabolomics**.

Bioinformatics can be considered as information science applied to biology. Bioinformatics can include mathematical analysis of DNA sequence data, computer simulation of metabolic pathways, or analysis of potential drug targets (enzymes or receptors) for structure-based design of new drugs. Whereas genetics concerns itself with the location, expression, and function of individual genes or small groups of genes, genomics concerns itself with the entire genome, or the totality of genetic information in an organism. This includes not only determining the nucleotide sequence of the whole genome but also assessing the expression and function of each gene, as well as evolutionary relationships among genes in the same genome and with genomes of different organisms. The use of “gene chips,” or microarrays, allows the collection of enormous amounts of data concerning the genes expressed in a given cell or tissue. For this analysis, DNA fragments representing many or most of the genes of an organism are immobilized on a glass slide. Many thousands of DNA fragments, each in a minute amount, are arrayed individually on such a slide. The slide is then incubated with a preparation of total RNA from a cell under conditions where a particular RNA molecule can bind to DNA containing sequences from the gene specifying that RNA (for details see Tools of Biochemistry 27C). The use of fluorescent reagents to monitor binding (see Figure 1.10) allows one to generate a snapshot of the global, or genome-wide, pattern of gene expression within a cell, so that one can ask, for example, how the pattern of gene expression changes as the result of hormonal stimulation of that cell or in the transformation of a normal cell to a cancer cell.

The products of most genes are proteins, which carry out nearly all of the chemistry of a cell, including catalysis of reactions, signaling between cells, and movement of material both inside and outside of cells. A goal of proteomics is to identify all of the proteins present in a given cell, and the amount and function of each protein. The **proteome**, or entire complement of proteins in a cell, can be displayed by two-dimensional gel electrophoresis, as described in Tools of Biochemistry 5D. In this technique, the proteins in a cell are resolved by techniques that separate them on the basis of molecular weight and electric charge. In Figure 1.11 each spot represents one protein, with the size and intensity of each spot determined by the amount of that protein in the cell. The challenge of proteomics is to analyze data like this electrophoretic pattern, such that each protein can be identified and quantitated. Then, as in microarray analysis, one can determine how the proteome changes, for example, in the transformation of a normal cell to a cancer cell, so as to help understand the chemistry of cancer.

FIGURE 1.10

A DNA microchip array. In this experiment, using the MICROMAX detection system, 2 μg of human messenger RNA was annealed with immobilized cDNAs representing 2400 human genes. The cDNAs (complementary DNAs) are DNA copies of individual messenger RNA molecules. Spot intensities and colors indicate the abundance of particular gene-specific mRNAs (for further information see page 1166, Tools of Biochemistry 27A).

FIGURE 1.11

A display of the proteome by two-dimensional gel electrophoresis. An extract containing all of the proteins of a cell or tissue is applied to one corner of a slab of gel-like material, and the proteins are resolved along one edge of the gel by isoelectric focusing (Tools of Biochemistry 2A), which separates proteins on the basis of their relative acidity (horizontally in the figure). The gel is rotated by 90 degrees, and resolution is carried out by denaturing polyacrylamide gel electrophoresis (Tools of Biochemistry 5D), which separates proteins on the basis of molecular weight. The example shown here is part of a study of cadmium toxicity in yeast. Proteins were labeled by growth of yeast in a medium containing ^{35}S , a radioisotope of sulfur. After electrophoresis the gel was placed in contact with photosensitive film. Each protein darkens the film where it was deposited on the gel. The arrows denote proteins whose concentration, as determined by spot intensity, was changed as a result of the cadmium treatment. (a) untreated; (b), (c), and (d), varying cadmium treatment protocols.

The Journal of Biological Chemistry, 276:8469–8474, K. Vido, D. Spector, G. Lagniel, S. Lopez, M. B. Toledano and J. Labarre, A proteome analysis of the cadmium response in *Saccharomyces cerevisiae*. Reprinted with permission. © 2001 The American Society for Biochemistry and Molecular Biology. All rights reserved.

Finally, many of the proteins in a cell are enzymes, and the intracellular rates of enzyme-catalyzed reactions can be estimated by analysis of the intracellular concentrations of the substrates and products of each reaction. A goal of metabolomics is to determine the intracellular concentrations of all small molecules that serve as intermediates in metabolic pathways (see Tools of Biochemistry 12B). Metabolite pool analysis, of course, is at the heart of much of clinical diagnosis. A prime example is the use of cholesterol levels to assess risk of cardiovascular disease. At present there is no single technique that would allow analysis of the metabolome, or complete complement of low-molecular-weight metabolites, but that does represent an important goal of much of contemporary biochemistry. Mass spectrometry is an approach that has the potential to describe the complete metabolome, but formidable challenges remain.

Bioinformatics and the allied fields have the potential to yield enormous amounts of information about the function of cells and organisms. However, effective use of that information requires understanding of the thousands of individual chemical reactions that occur in metabolism, the biological functions of each reaction, and the processes that regulate the expression of genetic information, both as DNA sequences that are read out as RNA and as RNA sequences that are translated into proteins. These latter topics are the focus of this book, but you should be aware that much of the biochemistry of today and tomorrow will integrate this information into a much broader context.

SUMMARY

The aim of the science of biochemistry is to explain life in molecular terms because we now realize that living matter and nonliving matter obey the same fundamental laws of physics and chemistry. Modern biochemistry draws on knowledge from chemistry, cell biology, and genetics and uses techniques adapted from physics. Discoveries in all of these sciences have contributed to the development of a true molecular biology.

Although biochemistry deals with organisms, cells, and cellular components, it is fundamentally a chemical science. The basic chemistry involved is that of carbon, hydrogen, oxygen, nitrogen, phosphorus, and sulfur, but organisms use many other elements in smaller quantities. Many of the important biological substances are giant molecules that are polymers of simpler monomer units. Such biopolymers include polysaccharides, proteins, and nucleic acids. Lipids form the fourth major group of biologically important substances.

The distinguishing feature of living matter is the use of energy to create and duplicate orderly structure. All living organisms are composed of one or more cells, and these cells are quite similar in size. However, the two great classes of organisms, prokaryotes and eukaryotes, have fundamentally different cellular structures: Prokaryotic cells are uncompartmented, lacking the membrane-bound organelles characteristic of eukaryotic cells. Viruses are intracellular parasites, essentially carriers of nucleic acid; to duplicate themselves, they use the reproductive machinery and energy sources of the host cell.

Biochemistry is an experimental science, and the remarkable recent advances in biochemistry are due in large part to the development of powerful new laboratory techniques. Some of these techniques are generating significant information far more rapidly than it can be integrated and understood without recourse to new approaches in information technology.

TOOLS OF BIOCHEMISTRY 1A

MICROSCOPY AT MANY LEVELS

The Light Microscope and Its Limitations

All students of science are familiar with the light microscope (Figure 1A.1), the instrument that made cell biology possible, beginning with Hooke's pioneering microscopic studies. Generations of biologists followed Hooke with steadily improved instruments. But as biology has looked deeper into the details of life, the light microscope has reached its limits.

To understand why these limits exist, consider the **resolution** of a microscope. The resolution (r) is quantitatively defined as the minimum distance between two objects that can just be distinguished as separate. It is given by the equation

$$r = \frac{0.61\lambda}{n \sin \alpha} \quad (1A.1)$$

Here λ is the wavelength of the radiation used, n is the refractive index of the medium between the sample and the objective lens, and α is the **angular aperture** of the objective lens. The quantity $\sin \alpha$ is basically a measure of the radiation-gathering power of the lens system. Resolution depends primarily on wavelength because the objects must be comparable in size to the wavelength in order to perturb the waves sufficiently to convey information.

The angular apertures of the best light microscopes are about 70° , so even if deep blue light of wavelength 450 nm is used and the medium between the sample and the objective lens is air ($n = 1$), we get

$$r = \frac{0.61 \times 450}{1.0 \sin 70^\circ} \sim 300 \text{ nm} = 0.3 \mu\text{m} \quad (1A.2)$$

This value represents the practical limit of resolution for light microscopy. A bit more resolution can be gained by going into the near ultraviolet, but absorption of this light by cellular materials

limits its usefulness. Photographic images can be enlarged, but there is no sense in magnifying an image beyond the point where its resolution is just what the eye can resolve. Because our eyes can resolve images about 0.3–0.6 mm apart, the best light microscopes have a useful maximum magnifying power of about 1000–2000 (magnifying $0.3 \mu\text{m}$ by 2000 gives 0.6 mm). Further magnification of the image does not help—the fuzziness just gets bigger. To make a major advance, it was necessary to use radiation of much shorter wavelength, radiation that we cannot see but that can produce a photographic image. Thus the **electron microscope** was born in the 1930s.

Transmission Electron Microscopy

There are several types of electron microscopes. The first type to be used was the **transmission electron microscope (TEM)**, so called because it detects electrons that have been transmitted through a sample. The transmission electron microscope is compared with the light microscope in Figure 1A.1. An electron beam is emitted from a tungsten filament and accelerated by an electric field. Magnetic lenses focus the beam, as glass lenses focus a beam of light in the conventional microscope. The key to the higher resolution is that electrons, like the photons of light, have both a particle-like and a wavelike nature. A photon or an electron moving with an energy E is characterized by a wavelength where h is Planck's constant ($6.626 \times 10^{34} \text{ J} \cdot \text{s}$) and

$$\lambda = \frac{hc}{E} \quad (1A.3)$$

c is the speed of light ($3 \times 10^8 \text{ m/s}$). When electrons are accelerated by 50,000–100,000 volts between the cathode and the anode, their wavelengths are much shorter than that of visible light—in

**FIGURE 1A.1**

Structure of the optical microscope and the transmission electron microscope. The two images are not to the same scale; the electron microscope is much larger than a conventional light microscope.

fact, less than 1 nm. This wavelength would predict a resolution of better than 1 nm for a transmission electron microscope. Practical considerations give an operational limit of about 2 nm for most instruments. Still, this resolution is about 100 times finer than even the best optical microscope can accomplish; a good transmission electron microscope can usefully magnify to over 100,000 times.

Clear as this advantage may be, transmission electron microscopy has some disadvantages. The electron beam requires that a high vacuum be maintained throughout the instrument, including the sample chamber. This, in turn, means that only completely dried samples can be examined. Although methods for sample fixation and drying have been devised, there is always the possibility of inducing changes in samples as a result of their dehydration. Living structures, of course, cannot be examined.

Some of the methods used to prepare samples for transmission electron microscopy are shown in Figure 1A.2. The electron energies in most transmission microscopes do not allow penetration of thick samples (>100 nm). Thus, cell samples must be fixed, stained, and sliced very thin, by using an **ultramicrotome** (Figure 1A.2a). Particles like viruses and large molecules can be deposited directly on a thin film supported by a copper grid. But the contrast between such a particle and the background is not sufficient, so the sample is usually **negatively stained** (Figure 1A.2b) or **shadowed** (Figure 1A.2c). Other techniques such as *freeze fracturing* and *freeze etching* are discussed in later chapters.

Scanning Electron Microscopy

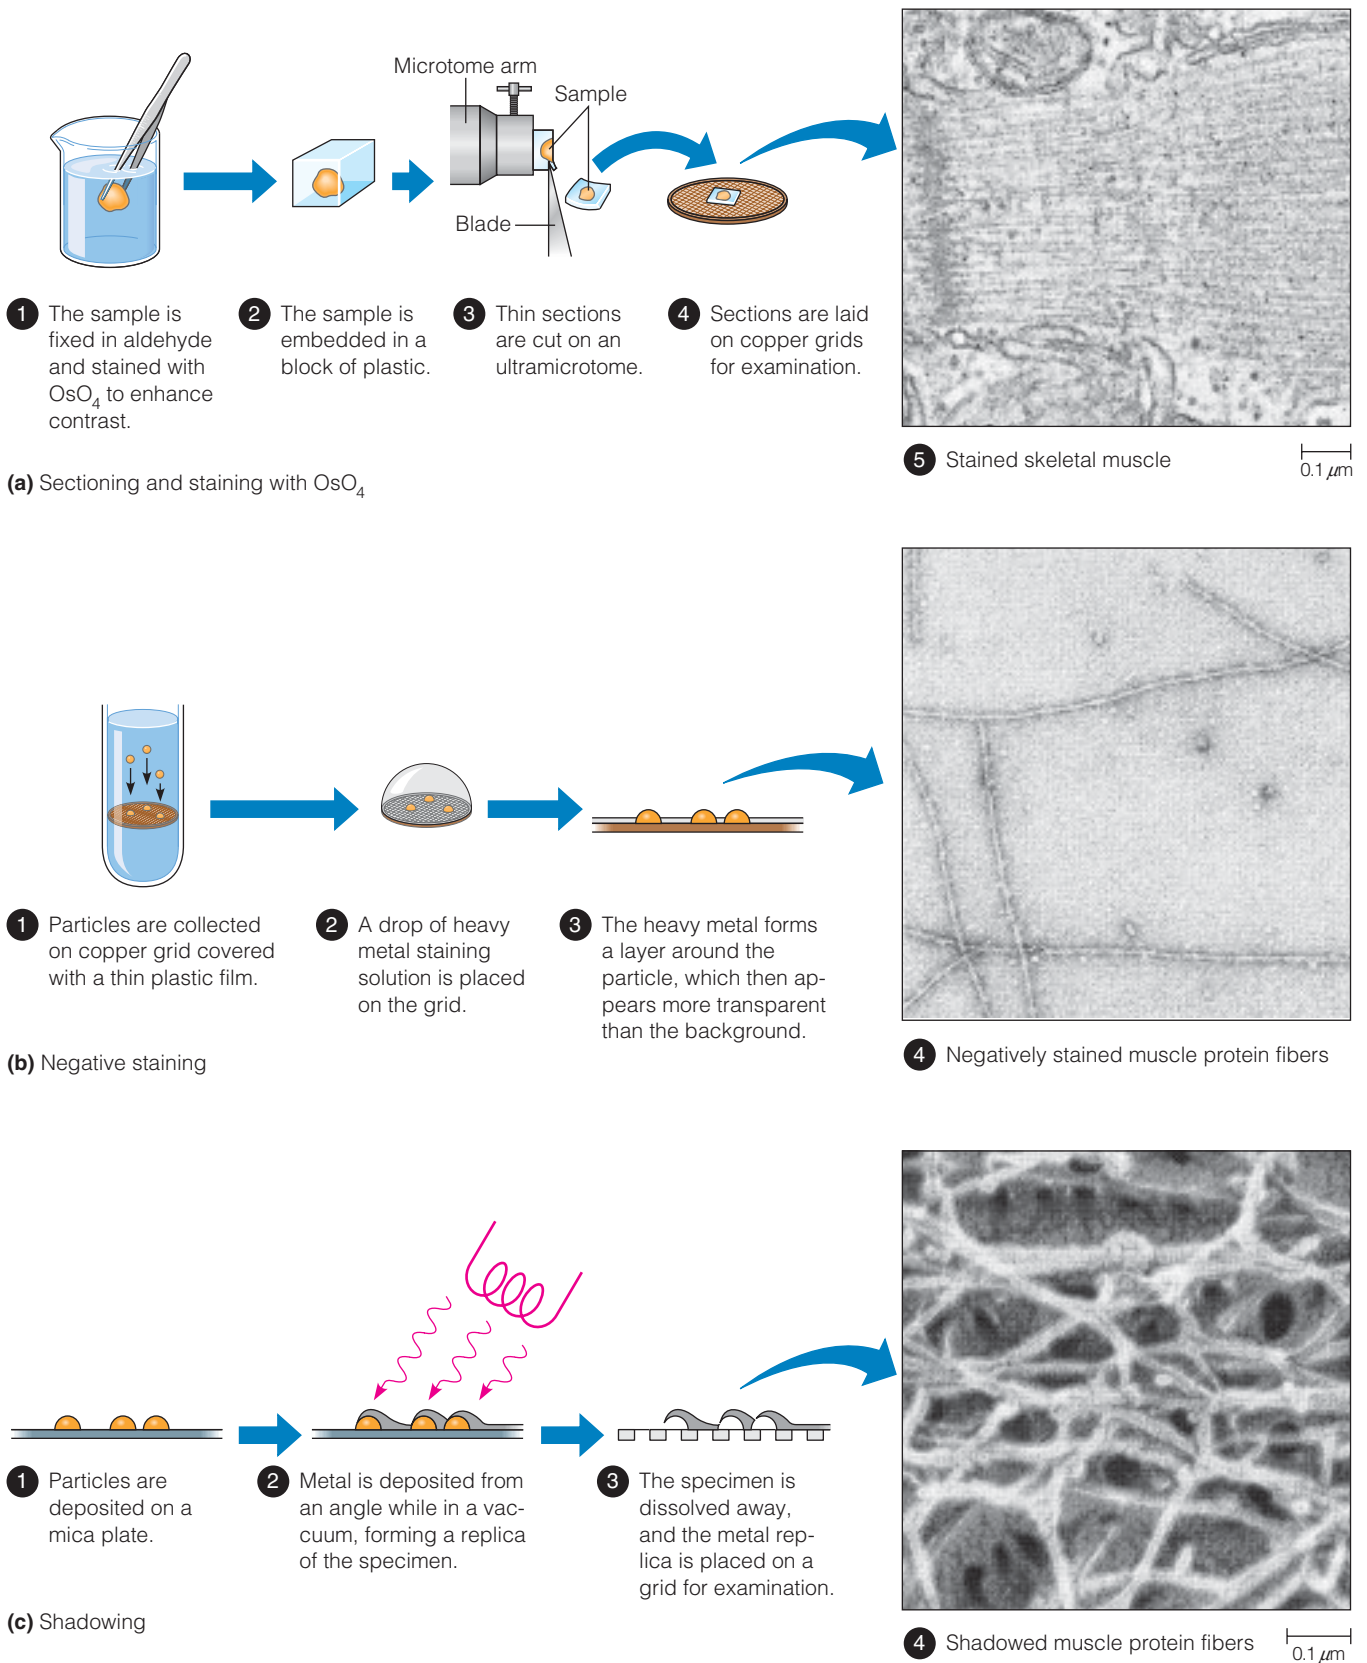

A quite different technique is called **scanning electron microscopy (SEM)**. A schematic diagram of a scanning electron microscope is shown in Figure 1A.3. Here, the electron beam is scanned back and forth across the sample, in a pattern generated by the scan generator and beam deflector, and secondary electrons emitted from the point at which the beam impinges on the

sample surface are picked up by a detector. The image is then displayed on a video screen, whose surface is scanned in register with the scanning of the sample. SEM does not have the resolution of TEM, but it is excellent for obtaining extremely clear views of the surfaces of minute objects, as you can see in Figure 1A.4. Preparation for SEM studies does not require sectioning, but the specimen must be fixed and dried to be stable at high vacuum and is usually coated with a thin layer of gold to aid in emission of secondary electrons.

Another technique should be mentioned: **scanning transmission electron microscopy (STEM)**. In this method the electron beam is scanned over the specimen, as in SEM, but it is detected in transmission. The method has the advantage that unstained, unfixed specimens can sometimes be used. Furthermore, the absorption of electrons of different energies provides information about the composition of different portions of the sample.

Laser Scanning Confocal Microscopy

Aside from the problems of resolution mentioned on page 20, there exists another fundamental limitation to conventional light microscopy for studying internal structure in cells and other biological samples. At high resolution ($\sim 0.3 \mu\text{m}$) the depth of focus of a light microscope is about $3 \mu\text{m}$. Superposition of images of material in this thick slice will obscure detail. To get around this problem, the confocal microscope was developed. As shown in Figure 1A.5, a light beam (preferably from a laser) is focused into a very small volume at the desired level within the sample. Reflected or fluorescent light from this spot is brought back to a detector, through a pinhole that excludes light scattered from other regions. The position of the illuminated spot is scanned back and forth through the sample, always at the same level. The image that is electronically built up in this way represents a very thin, highly resolved “slice” through the sample. It can also be repeated at different levels to build up a three-dimensional image.

**FIGURE 1A.2**

Three methods of preparing samples for transmission electron microscopy.

FIGURE 1A.3

The principle of the scanning electron microscope.

The method is most powerful when fluorescence detection is used, for then specifically labeled structures or substances can be precisely located within a cell. Because the method is relatively nondestructive, it can be used to follow dynamic processes in living cells. It has been employed, for example, to pinpoint the places within a cell nucleus where active replication of DNA is taking place. The rapid development of more versatile and discriminating fluorescent probes is making confocal microscopy a major technique in cellular biochemistry (See Figure 1A.6).

Scanning Tunneling and Atomic Force Microscopy

Recently, a remarkable new kind of microscope has been developed. **Scanning tunneling microscopy** uses a very fine, electrically charged metal tip, which is scanned across the sample. As electrons leak (tunnel) between the tip and the surface supporting the sample, the resistance they encounter varies according to the height of microscopic objects lying on the surface. The resulting fluctuations in current produce a video display of the surface with a resolution comparable to that of an electron microscope. In **atomic force microscopy** (Figure 1A.7), an extremely sharp tip is either dragged or tapped back and forth across the sample, and its up-and-down motion is detected by the deflection of a laser beam reflected off the cantilever which holds the tip. This

**FIGURE 1A.5**

Diagram illustrating the principle of laser scanning confocal microscopy. A laser beam is passed through an x-y scanner, collimated to a small spot by the objective lens, and scanned across the specimen. Fluoresced light is collected by the objective and directed by a dichroic mirror (a mirror that reflects the fluorescent light but not the shorter-wavelength laser light) to a pinhole aperture placed in the conjugate image plane. Light originating from the specimen plane of focus passes through the pinhole to a photomultiplier detector. Light from above or below the specimen focal plane strikes the walls of the aperture and is not transmitted.

motion is greatly amplified to give a contour map of the object. Both of these techniques have the enormous advantage over electron microscopy that wet, even immersed, samples can be studied, and the resolution allows visualization of single macromolecules.

CHAPTER 2

The Matrix of Life: Weak Interactions in an Aqueous Environment

The macromolecules that participate in the structural and functional matrix of life are immense structures held together by strong, covalent bonds. Yet covalent bonding alone cannot begin to describe the complexity of molecular structure in biology. Much weaker interactions are responsible for most of the elegant cellular architecture visible in the electron micrographs of Chapter 1. These are the **noncovalent interactions**, also called *noncovalent forces* or *noncovalent bonds*, between ions, molecules, and parts of molecules.

Consider the macromolecules we discussed in Chapter 1. The linear sequence of the nucleotide residues in a strand of DNA is maintained by covalent bonds. But DNA also has a highly specific three-dimensional structure, which is stabilized by noncovalent interactions between different parts of the molecule. Similarly, every kind of protein is made up of amino acids linked by covalent **peptide bonds**; but each protein is also folded into a specific molecular conformation that is stabilized by noncovalent interactions. Proteins interact with macromolecules, such as other proteins or nucleic acids or lipids, to form still higher levels of organization, ultimately leading to cells, tissues, and whole organisms. All of this complexity is accounted for by a myriad of noncovalent interactions within and between macromolecules.

What makes noncovalent interactions so important in biology and biochemistry? The key is seen in Figure 2.1, which compares noncovalent and covalent bond energies. The *covalent* bonds most important in biology (such as C—C and C—H) have bond energies in the range of 300–400 kJ/mol. Biologically important *noncovalent* bonds are 10 to 100 times weaker. It is their very weakness that makes noncovalent bonds so essential, for it allows them to be continually broken and re-formed in the dynamic molecular interplay that is life. This interplay depends

Noncovalent interactions are critically important determinants of biomolecular structure, stability, and function.

on rapid exchanges of molecular partners, which could not occur if intermolecular forces were so strong as to lock the molecules in conformation and in place.

If we are to understand life at the molecular level, we must know something about noncovalent interactions. Furthermore, we must know how such interactions behave in an aqueous environment, for every cell in every organism on earth is bathed in and permeated by water. This is as true for creatures living in the most arid deserts as for those in the depths of the sea. Water is the major constituent of organisms—70% or more of the total weight, in most cases.

This chapter first describes noncovalent interactions, and then shows that the properties of water have a profound effect on those interactions.

The Nature of Noncovalent Interactions

Molecules and ions can interact noncovalently in a number of different ways, as described in this section and summarized in Figure 2.2. All of these noncovalent interactions are fundamentally electrostatic in nature; thus, they all depend on the forces that electrical charges exert on one another. Table 2.1 lists ranges for the energies of some of the noncovalent interactions prevalent in biomolecules.

Charge–Charge Interactions

The simplest noncovalent interaction is the electrostatic interaction between a pair of charged particles. Such charge–charge interactions are also referred to as ionic bonds or salt bridges. Many of the molecules in cells, including macromolecules like DNA and proteins, carry a net electrical charge. In addition to these molecules, the cell contains an abundance of small ions, both cations like Na^+ , K^+ , and Mg^{2+} and anions like Cl^- and HPO_4^{2-} . All of these charged entities exert forces on one another (see Figure 2.2a). The force between a pair of charges q_1 and q_2 , separated *in a vacuum* by a distance r , is given by **Coulomb's law**:

$$F = k \frac{q_1 q_2}{r^2} \quad (2.1)$$

where k is a constant whose value depends on the units used.* If q_1 and q_2 have the same sign, F is positive, so a positive value corresponds to repulsion. If one charge is $+$ and the other $-$, F is negative, signifying attraction. It is such charge–charge interactions that stabilize a crystal of a salt, like that shown in Figure 2.3.

The biological environment, of course, is not a vacuum. In a cell, charges are always separated by water or by other molecules or parts of molecules. The existence of this **dielectric medium** between charges has the effect of screening them from one another, so that the actual force is always less than that given by Equation 2.1. This screening effect is expressed by inserting a dimensionless number, the **dielectric constant** (ϵ), in Equation 2.1:

$$F = k \frac{q_1 q_2}{\epsilon r^2} \quad (2.2)$$

Every substance that acts as a dielectric medium has a characteristic value of ϵ ; the higher this value, the weaker the force between the separated charges. The dielectric constant of water is high, approximately 80, whereas organic liquids usually have much lower values, in the range of 1 to 10. We shall see presently the reason for the high value of ϵ in water, but its major consequence is that charged

*In the c.g.s. (centimeter–gram–second) system, with charges in electrostatic units, k is unity. In this book we use the SI, or international, system of units. Here q_1 and q_2 are in coulombs (C), r is in meters (m), and $k = 1/(4\pi\epsilon_0)$. The quantity ϵ_0 is the *permittivity of a vacuum* and has the value $8.85 \times 10^{-12} \text{ J}^{-1} \text{ C}^2 \text{ m}^{-1}$, where J is the energy unit joules. F is in newtons (N).

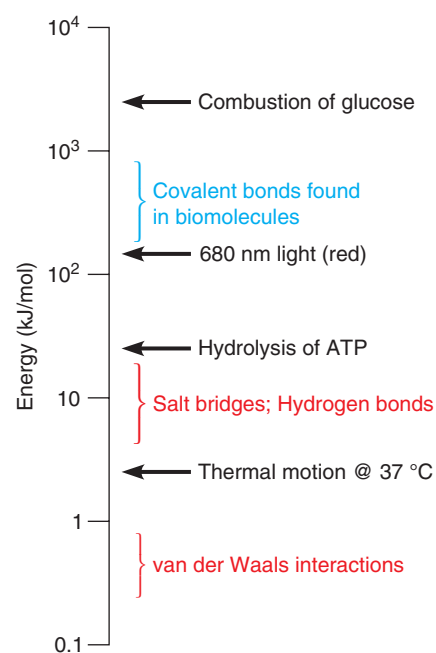

FIGURE 2.1

Covalent and noncovalent bond energies. Energies typical of noncovalent bonds (0.5–20 kJ/mol; red text) are about one to two orders of magnitude weaker than energies of the covalent bonds commonly found in biochemical compounds (150–600 kJ/mol; blue text). The energies available from thermal motion, ATP hydrolysis, red light, and aerobic glucose metabolism are also shown as reference points (discussed in detail in later chapters). Note that values are plotted on a log scale.

Noncovalent interactions always involve electrical charges.

TABLE 2.1 Energies of noncovalent interactions in biomolecules

Type of interaction	Approximate energy (kJ/mol)
Charge–charge	–13 to –17
Charge–dipole (H–bond)	–13 to –21
Dipole–dipole (H–bond)	–2 to –8
van der Waals	–0.4 to –0.8

Values reprinted from *Advances in Protein Chemistry* 39:125–189, S. K. Burley and G. A. Petsko, Weakly polar interactions in proteins. © 1988, with permission from Elsevier.

Type of Interaction	Model	Example	Dependence of Energy on Distance
(a) Charge–charge Longest-range force; nondirectional		$-\text{NH}_3^+$	$1/r$
(b) Charge–dipole Depends on orientation of dipole		$-\text{NH}_3^+$	$1/r^2$
(c) Dipole–dipole Depends on mutual orientation of dipoles			$1/r^3$
(d) Charge–induced dipole Depends on polarizability of molecule in which dipole is induced		$-\text{NH}_3^+$	$1/r^4$
(e) Dipole–induced dipole Depends on polarizability of molecule in which dipole is induced			$1/r^5$
(f) Dispersion (van der Waals) Involves mutual synchronization of fluctuating charges			$1/r^6$
(g) Hydrogen bond Charge attraction + partial covalent bond			Length of bond fixed

FIGURE 2.2

Types of noncovalent interactions. The induced dipole (**d**, **e**) and the dispersion forces (**f**) depend on a distortion of the electron distribution in a nonpolar atom or molecule. The symbols δ^- and δ^+ denote a fraction of an electron or proton charge.

particles interact rather weakly with one another in an aqueous environment unless they are very close together (i.e., within 0.4 to 1.0 nm).

Coulomb's law is an expression of *force*; that is, it is a quantitative description of an interaction. However, every interaction involves a change in *energy*, and because we are concerned with the energy changes in biological processes, we are particularly interested in the **energy of interaction** (E). This is the energy required to separate two charged particles from a distance r to an infinite distance—in other words, to pull them apart working against the electrostatic force. The energy of interaction is given by Equation 2.3, which is similar to Equation 2.2:

$$E = k \frac{q_1 q_2}{\epsilon r} \quad (2.3)$$

As with force, the energy of an oppositely charged pair q_1 and q_2 is always negative, signifying attraction, but E approaches zero as r becomes very large. For charge–charge interactions, the energy of interaction is inversely proportional to the first power of r ; thus, these interactions are relatively strong over greater distances compared to the other noncovalent interactions listed in Figure 2.2. Charge–charge interactions often occur within or between biomolecules—for example, in the attraction between amino and carboxylate groups, as shown in Figure 2.2a. As will be discussed in Chapter 5, charge–charge interactions can play an important role in the purification of a protein from a complex mixture of cellular components.

Permanent and Induced Dipole Interactions

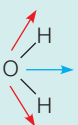

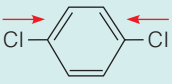

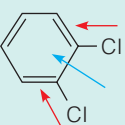

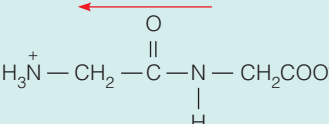

Molecules that carry no *net* charge may nevertheless have an asymmetric internal distribution of charge. For example, the electron distribution of the uncharged carbon monoxide molecule is such that the oxygen end is slightly more negative than the carbon end (Figure 2.4a). Such a molecule is called *polar*, or a **permanent dipole**, and is said to have a **permanent dipole moment** (μ). The dipole moment expresses the magnitude of a molecule's polarity. If a linear molecule like CO has fractional charges δ^+ and δ^- , separated by a distance x , the dipole moment is a vector directed toward δ^+ , whose magnitude is

$$\mu = qx \quad (2.4)$$

where q is the magnitude of the charge (or fractional charge). In molecules with a more complex shape, like water, the dipole moment for the entire molecule is a vector sum of the dipole moments along each polar bond (Figure 2.4b). Water has a significant μ , because electrons are drawn from the hydrogen atoms toward the oxygen atom, due to the much greater electronegativity of the oxygen atom.

Some dipole moment values are given in Table 2.2. Notice the large values for glycine and glycyglycine. At neutral pH, the amino acid glycine exists as the ion $^+\text{NH}_3\text{CH}_2\text{COO}^-$, which has both a positive ammonium group and a negative carboxylate group. Thus, whole electron charges are separated by the length of the molecule, accounting for the large μ . In glycyglycine, which is made by covalently linking two glycine molecules, the dipole moment is nearly twice as large because the charge separation is almost doubled. Molecules with large dipole moments are said to be highly polar.

TABLE 2.2 Dipole moments of some molecules

Molecule	Formula	Dipole Moment (D) ^a
Carbon monoxide		0.12
Carbon dioxide		0
Water		1.83
<i>para</i> -Dichlorobenzene		0
<i>ortho</i> -Dichlorobenzene		2.59
Glycine		16.7
Glycyglycine		28.6

^aThe common units of dipole moment are *debyes*; 1 debye (D) equals $3.34 \times 10^{-30} \text{ C} \cdot \text{m}$.

FIGURE 2.3

Charge–charge interactions in an ionic crystal.

Ionic crystals are held together by charge–charge interactions between positive and negative ions. In a sodium chloride crystal, each sodium ion is surrounded by six chloride ions, and each chloride ion is surrounded by six sodium ions.

Marcel Clemens/Shutterstock.

Some molecules interact because they possess dipole moments.

FIGURE 2.4

Dipolar molecules. (a) Carbon monoxide: the partial negative charge (δ^-) on the oxygen together with corresponding partial positive charge (δ^+) on the carbon produces a dipole moment directed along the O—C axis. (b) Water: the partial negative charge on O together with the partial positive charge on each H produces two moments, μ_1 and μ_2 , directed along the O—H bonds. Their vector sum (μ) represents the net dipole moment of the molecule.

**FIGURE 2.5**

Induced dipoles and dispersion forces. (a) Benzene has neither a net charge nor a permanent dipole moment, but a nearby charge can induce a redistribution of electrons within the benzene ring, producing an induced dipole moment (μ). (b) Planar molecules like benzene have a strong tendency to stack because fluctuations in the electron clouds of the stacked rings interact with one another, producing a dispersion force. (c) Although the molecules approach closely, they do not interpenetrate.

Molecules may attract one another by noncovalent forces but cannot interpenetrate: van der Waals radii determine molecular surfaces.

Note also in Table 2.2 that molecules must possess an appropriate geometry to have dipole moments: compare $\text{C}\equiv\text{O}$ with $\text{O}=\text{C}=\text{O}$, or *o*-dichlorobenzene with *p*-dichlorobenzene. In carbon dioxide and *p*-dichlorobenzene, the dipole vectors are equal in magnitude but oppositely directed so that their effects cancel each other, leaving no net dipole moment.

In the aqueous environment of a cell, a permanent dipole can be attracted by a nearby ion (a *charge–dipole interaction*) or by another permanent dipole (a *dipole–dipole interaction*). These **permanent dipole interactions** are described in Figure 2.2b and c. Unlike the simple charge–charge interactions described earlier, dipole interactions depend on the orientation of the dipoles. Furthermore, they are shorter-range interactions: The energy of a charge–dipole interaction is proportional to $1/r^2$ and that of a dipole–dipole interaction to $1/r^3$. Thus, a pair of permanent dipoles must be quite close together before the interaction becomes strong.

Molecules that do not have permanent dipole moments can become dipolar in the presence of an electric field. The field may be externally imposed, as in a laboratory instrument, or it may be produced by a neighboring charged or dipolar particle. A molecule in which a dipole can be so induced is said to be **polarizable**. Aromatic rings, for example, are very polarizable because the electrons can easily be displaced in the plane of the ring, as shown in Figure 2.5a. Interactions of polarizable molecules are called **induced dipole interactions**. An anion or a cation may induce a dipole in a polarizable molecule and thereby be attracted to it (a *charge–induced dipole interaction*, Figure 2.2d), or a permanent dipole may do the same (a *dipole–induced dipole interaction*, Figure 2.2e). These induced dipole interactions are even shorter range than permanent dipole interactions, with energies of interaction proportional to $1/r^4$ and $1/r^5$, respectively.

Even two molecules that have neither a net charge nor a permanent dipole moment can attract one another if they are close enough (Figure 2.2f). The distribution of electronic charge in a molecule is never static, but fluctuates. When two molecules approach very closely, they synchronize their charge fluctuations so as to give a net attractive force. Such intermolecular forces, which can be thought of as mutual dipole induction, are called **van der Waals**, or **dispersion forces**. Their attractive energy varies as the inverse sixth power of the distance, so van der Waals forces are significant only at very short range. They can become particularly strong when two planar molecules can stack on one another, as shown in Figure 2.5b and c. We shall encounter many examples of such interactions in the internal packing of molecules like proteins and nucleic acids. As discussed in Chapter 6, van der Waals forces are individually weak; but, collectively they make significant contributions to the stability of biomolecules.

Molecular Repulsion at Extremely Close Approach: The van der Waals Radius

When molecules or atoms that do not have covalent bonds between them come so close together that their outer electron orbitals begin to overlap, there is a mutual repulsion. This repulsion increases very steeply as the distance between their centers (r) decreases; it can be approximated as proportional to r^{-12} . If we combine this repulsive energy with one or more of the kinds of attractive energy described previously, we see that the total energy of noncovalent interaction (E) for a pair of atoms, molecules, or ions will vary with distance of their separation (r) in the manner depicted in Figure 2.6. Two points on the graph should be noted. First, there is a minimum in the energy curve, at position r_0 . This minimum corresponds to the most stable distance between the centers of the two particles. If we allow them to approach each other, this is how close they will come. Second, the repulsive potential rises so steeply at shorter distances that it acts as a “wall,” effectively barring approach closer than the distance r_v . This distance defines the

FIGURE 2.6

Noncovalent interaction energy of two approaching particles. The interaction energy of two atoms, molecules, or ions is graphed versus the distance between their centers, r . The total interaction energy (E) at any distance is the sum of the energy of attraction and the energy of repulsion. As the distance between the particles decreases (reading right to left along the x-axis), both the attractive energy (<0) and the repulsive energy (>0) increase, but at different rates. At first the longer-range attraction dominates, but then the repulsive energy increases so rapidly that it acts as a barrier, defining the distance of closest approach (r_v) and the van der Waals radii (R , described by the orange spheres). The position of minimum energy (r_0) is usually very close to r_v .

so-called **van der Waals radius**, R , the effective radius for closest molecular packing. For a pair of identical spherical molecules, $r_v = 2R$; for molecules with van der Waals radii R_1 and R_2 , $r_v = R_1 + R_2$.

Real molecules, of course, are not spherical objects like those depicted in Figure 2.6. Because large biological molecules all have complicated shapes, it is useful to extend the concept of the van der Waals radius to atoms or groups of atoms within a molecule. The values for van der Waals radii given in Table 2.3 represent the distances of closest approach for another atom or group. When we depict complex molecules in a so-called “space filling” manner, we represent each atom by a sphere with its appropriate van der Waals radius (see Figure 2.5c). In this case, the van der Waals radii of the carbon atoms (0.17 nm) mean that the planes of the two stacked rings cannot be closer than 0.34 nm.

Hydrogen Bonds

One specific kind of noncovalent interaction, the **hydrogen bond**, is of the greatest importance in biochemistry. The structure and properties of many biological molecules and of water, the universal biological solvent, are determined largely by this type of bond. A hydrogen bond is an interaction between a covalently bonded hydrogen atom on a *donor* atom (e.g., —O—H or >N—H) and a pair of nonbonded electrons on an *acceptor* atom (e.g., O=C— or N≡), as shown in Figure 2.2g and Figure 2.7. The atom to which hydrogen is covalently bonded is called the *hydrogen-bond donor*, and the atom with the nonbonded electron pair is called the *hydrogen-bond acceptor*. The interaction between the donor and acceptor is typically represented by a dotted line between the acceptor atom and the shared H.

The ability of an atom to function as a hydrogen-bond donor depends greatly on its electronegativity. The more electronegative the donor atom, the more

**FIGURE 2.7**

The hydrogen bond. The figure shows an idealized H bond that might exist, for example, between an alcohol (the donor) and a keto compound (the acceptor). The H bond is represented by a dotted line between the H and the acceptor atom, and a solid line between the H and the donor atom.

Hydrogen bonds are among the strongest, most specific, noncovalent interactions.

negative charge it withdraws from the hydrogen to which it is bonded; thus, the hydrogen becomes more positive and is more strongly attracted to the electron pair of the acceptor. Among the atoms encountered in biological compounds, only O and N have appropriate electronegativities to serve as strong donors. Thus, $\equiv\text{C}-\text{H}$ groups do not form strong hydrogen bonds, but $-\text{O}-\text{H}$ groups do.

The hydrogen bond has features in common with both covalent and noncovalent interactions. In part, it is like a charge–charge interaction between the partial positive charge on H and the negative charge of the electron pair. But it is also true that there is electron sharing (as in a covalent bond) between H and the acceptor. This double character is reflected in the bond length of the hydrogen bond. The distance between the hydrogen atom and the acceptor atom in a hydrogen bond is considerably less than would be expected from their van der Waals radii. For example, the distance between H and O in the bond $\text{>N}-\text{H}\cdots\text{O}=\text{C}<$ is only about 0.19 nm, whereas we would predict about 0.26 nm from the sum of the van der Waals radii given in Table 2.2. On the other hand, a *covalent* H–O bond has a length of only 0.10 nm. The distance between the hydrogen-bond donor and acceptor is about 0.29 nm. The donor–acceptor distances of some particularly strong hydrogen bonds are listed in Table 2.4. Note that these distances are fixed, as they are for covalent (but not for other noncovalent) bonds.

The energy of hydrogen bonds is considerably higher than that of most other noncovalent bonds, in keeping with their partially covalent character (see Figure 2.1). Hydrogen bonds are also like covalent bonds in being highly directional. Computational studies predict that hydrogen bonds are strongest when the angle defined by the donor atom, the shared H atom, and the acceptor atom is 180° (i.e., the three atoms are colinear). The majority of hydrogen bond angles in proteins are within 30° of 180° . The importance of this directionality is seen in the role that hydrogen bonds play in organizing a regular biochemical structure such as the α -helix in proteins (Figure 2.8, discussed in greater detail in Chapter 6). This is but one example of many we shall encounter in which hydrogen bonds stabilize ordered structure in large molecules.

We finish this section by reiterating the important point that the various noncovalent interactions we have described are individually weak, but when many are present within a given macromolecule, or between macromolecules, their energies can sum to an impressive total—often several hundreds of

TABLE 2.4 Major types of hydrogen bonds found in biomolecular interactions

Donor... Acceptor	Distance between Donor and Acceptor (nm)	Comment
$-\text{O}-\text{H}\cdots\text{O}-\text{H}$	0.28 ± 0.01	H bond formed in water
$-\text{O}-\text{H}\cdots\text{O}=\text{C}$	0.28 ± 0.01	Bonding of water to other molecules often involves these
$\text{N}-\text{H}\cdots\text{O}-\text{H}$	0.29 ± 0.01	
$\text{N}-\text{H}\cdots\text{O}=\text{C}$	0.29 ± 0.01	Very important in protein and nucleic acid structures
$\text{N}-\text{H}\cdots\text{N}=\text{C}$	0.31 ± 0.02	
$\text{N}-\text{H}\cdots\text{S}$	0.37	Relatively rare; weaker than above

kilojoules. Thus, such interactions can account for the stability of macromolecular structures. At the same time, the ease with which individual noncovalent bonds can be broken and re-formed gives these structures a dynamic flexibility necessary to their function.

The Role of Water in Biological Processes

The chemical and physical processes of life require that molecules be able to move about, encounter one another, and change partners frequently in the complicated processes of metabolism and synthesis. A fluid environment allows molecular mobility, and water not only is the most abundant fluid on earth, it is also admirably suited to this purpose. To see why, we must examine the properties of water in some detail.

The Structure and Properties of Water

Although we tend to take its properties for granted, water is really a most curious substance. Table 2.5, which contrasts H_2O with other hydrogen-rich compounds of comparable molecular weight, reveals a remarkable fact. These compounds are gases at room temperature and have much lower boiling points than water does. Why is water unique? The answer lies mainly in the strong tendency of water molecules to form hydrogen bonds with other water molecules.

The electron arrangement of a single water molecule is shown in Figure 2.9. Of the six electrons in the outer orbitals of the oxygen atom, two are involved in covalent bonds to the hydrogens. The other four electrons exist in nonbonded pairs, which are excellent hydrogen-bond acceptors. The —OH groups in water are strong hydrogen-bond donors. Thus each water molecule is both a hydrogen-bond donor and a hydrogen-bond acceptor, capable of forming up to *four* hydrogen bonds simultaneously. A sample of water is a dynamic network of H-bonded molecules (Figure 2.10c). The strength of this extensive H-bond network gives water an unusually large heat capacity, and the vaporization of water requires a large amount of energy for a molecule of its size. Both the heat of vaporization and the boiling point of water are therefore unusually high (Table 2.5), and water remains in the liquid state at temperatures characteristic of much of the earth's surface.

The hydrogen bonding between water molecules becomes most regular and clearly defined when water freezes to ice, creating a rigid tetrahedral molecular lattice in which each molecule is H-bonded to four others (Figure 2.10a,b). The lattice structure is only partially dismantled when ice melts, and some long-range order persists even at higher temperatures. On average there are 15% fewer hydrogen bonds in liquid water than in ice (i.e., 3.4 H-bonds per water molecule vs. 4 per ice molecule). The structure of liquid water has been described as “flickering clusters” of hydrogen bonds, with remnants of the ice lattice continually breaking and re-forming as the molecules move about (Figure 2.10c). The rather open

FIGURE 2.8

Hydrogen bonding in biological structure. This example is a portion of a protein in an α -helical conformation. The α helix, a common structural element in proteins, is maintained by $\text{N—H} \cdots \text{O}=\text{C}$ hydrogen bonds between groups in the protein chain. See Chapter 6 for more details on the structure of the α helix.

bond angle = 104.5°

FIGURE 2.9

Hydrogen-bond donors and acceptors in water. The two nonbonded electron pairs on O act as H-bond acceptors and the two O—H bonds act as H-bond donors. The angle between the two O—H bonds is 104.5° ; thus, water has a net dipole moment.

TABLE 2.5 Properties of water compared to some other low-molecular-weight compounds

Compound	Molecular Weight	Melting Point ($^\circ\text{C}$)	Boiling Point ($^\circ\text{C}$)	Heat of Vaporization (kJ/mol)
CH_4	16.04	−182	−164	8.16
NH_3	17.03	−78	−33	23.26
H_2O	18.02	0	+100	40.71
H_2S	34.08	−86	−61	18.66

FIGURE 2.10

Water as a molecular lattice. (a) A space-filling model of the structure of ice, where O atoms are red and H atoms are blue. Ice is a molecular lattice formed by indefinite repetition of a tetrahedral hydrogen-bonding pattern. Each molecule acts as a hydrogen-bond donor to two others and as an acceptor from two others. Because of the length of the hydrogen bonds, the structure is a relatively open one, which accounts for the low density of ice. **(b)** A skeletal model of the ice lattice. **(c)** The structure of liquid water. When ice melts, the regular tetrahedral lattice is broken, but substantial portions of it remain, especially at low temperatures. In liquid water, flickering clusters of molecules are held together by hydrogen bonds that continually break and re-form. In this schematic “motion picture,” successive frames represent changes occurring in picoseconds (10^{-12} s).

Most of the unique properties of water are due to its hydrogen-bonding potential and its polar nature.

structure of the ice lattice accounts for another of water's unusual properties—liquid water is more dense than its solid form because when the lattice breaks down, molecules can move closer together. This seemingly trivial fact is of the utmost importance for life on earth. If water behaved like most substances and became more dense when solid, the ice formed on lake and ocean surfaces each winter would sink to the bottom. There, insulated by the overlying layers, it would have accumulated over the ages, and most of the water on earth would by now have become locked up in ice, leaving little liquid water to support life. It seems doubtful that life could have evolved if liquid water at $0\text{ }^{\circ}\text{C}$ were 9% less dense than it is, for then the ice would sink. Another consequence of this remarkable property of water is that the more dense liquid state is favored over the less dense solid state at high pressures. Thus, even at the high pressures in the depths of the ocean, water remains liquid.

Other unusual properties of water, listed in Table 2.6, are also readily explained in terms of its molecular structure. Relative to most organic liquids, water has a high *viscosity*—a consequence of the interlocked, hydrogen-bonded structure. This cohesiveness also accounts for the high *surface tension* of water. The high dielectric constant of water, mentioned previously, results from its dipolar character. An electric field generated between two ions causes extensive orientation

TABLE 2.6 Important properties of liquid water compared with those of *n*-pentane, a nonpolar, non-hydrogen-bonding liquid^a

Property	Water	<i>n</i> -Pentane
Molecular weight (g/mol)	18.02	72.15

of intervening water dipoles and a significant amount of induced polarization. These oriented dipoles contribute to a counterfield, reducing the effective electrostatic force between the two ions.

Water as a Solvent

The processes of life require a wide variety of ions and molecules to move about in proximity, that is, to be soluble in a common medium. Water serves as the universal intracellular and extracellular medium, thanks primarily to the two properties of water we have discussed: its tendency to form hydrogen bonds and its dipolar character. Substances that can take advantage of these properties so as to readily dissolve in water are called **hydrophilic**, or “water loving.”

Water is an excellent solvent because of its hydrogen-bonding potential and its polar nature.

Hydrophilic Molecules in Aqueous Solution

Molecules with groups capable of forming H bonds tend to hydrogen-bond with water. Thus, water tends to dissolve molecules, such as proteins and nucleic acids, which display on their solvent-accessible surfaces groups that can form H bonds. These include, for example, hydroxyl, carbonyl, and ester groups that are uncharged but polar, as well as charged groups such as amines, carboxylic acids, and phosphate esters. In addition, when molecules that contain internal hydrogen bonds (such as the α helix shown in Figure 2.8) dissolve in water, some or all of their internal H bonds may be in dynamic exchange for H bonds to H₂O (Figure 2.11).

In contrast to most organic liquids, water is an excellent solvent for ionic compounds. Substances like sodium chloride, which exist in the solid state as very stable lattices of ions, dissolve readily in water. The explanation lies in the dipolar nature of the water molecule. The interactions of the negative ends of the water dipoles with cations (e.g., Figure 2.12) and the positive ends with anions in aqueous solution cause the ions to become **hydrated**, that is, surrounded by shells of water molecules called **hydration shells** (Figure 2.12). The propensity of many ionic compounds like NaCl to dissolve in water can be accounted for largely by two factors. First, the formation of hydration shells is energetically favorable. Second, the high dielectric constant of water screens and decreases the electrostatic force between oppositely charged ions that would otherwise pull them back together.

The dipolar nature of the water molecule also contributes to water’s ability to dissolve such nonionic, but polar, organic molecules as phenols, esters, and amides. These molecules often have large dipole moments, and interaction with the water dipole promotes their solubility in water.

Hydrophobic Molecules in Aqueous Solution

The solubility of hydrophilic substances depends on their energetically favorable interaction with water molecules. It is therefore not surprising that

FIGURE 2.11

Exchange of internal hydrogen bonds for water hydrogen bonds. A section of a protein molecule like that in Figure 2.8 is shown here replacing some of its intramolecular hydrogen bonds with hydrogen bonds to solvent water. This dynamic (transient) exchange of H bonds is observed most often at the ends, rather than in the middle, of the helix.

**FIGURE 2.12**

Hydration of ions in solution. A salt crystal is shown dissolving in water. As sodium and chloride ions leave the crystal, the noncovalent interaction between these ions and the dipolar water molecules produces a hydration shell around each ion. The energy released in this interaction helps overcome the charge–charge interactions stabilizing the crystal.

substances like hydrocarbons, which are nonpolar and nonionic and cannot form hydrogen bonds, show only limited solubility in water. Molecules that behave in this way are called **hydrophobic**, or “water fearing.” However, bond energy is not the only factor limiting their solubility. When hydrophobic molecules do dissolve, they are not surrounded by hydration shells such as those formed around hydrophilic substances. Instead, the regular water lattice forms ice-like **clathrate** structures, or “cages,” about nonpolar molecules (Figure 2.13). This ordering of water molecules, which extends well beyond the cage, corresponds to a decrease in the *entropy*, or randomness, of the

mixture (see Chapter 3). The decrease in entropy contributes to the low solubility of hydrophobic substances in water. As is discussed in greater detail in Chapter 3, decreasing entropy is unfavorable thermodynamically; thus, the dissolving of a hydrophobic substance in water is entropically unfavorable. This accounts for the well-known tendency of hydrophobic substances to self-associate, rather than dissolve, in water—we have all seen oil form droplets when we shake it with vinegar. Surrounding two hydrophobic molecules with two *separate* cages requires more ordering of water in clathrates than surrounding both hydrophobes within a *single* cage. Thus, the hydrophobic molecules tend to aggregate because doing so releases some water molecules from the clathrates, thereby increasing the entropy of the system. This phenomenon, called the **hydrophobic effect**, plays an important role in the folding of protein molecules (see Chapter 6) as well as in the self-assembly of lipid bilayers (see Figure 2.15a and Chapter 10).

Amphipathic Molecules in Aqueous Solution

A most interesting and important class of molecules exhibits both hydrophilic and hydrophobic properties simultaneously. Such **amphipathic** substances include fatty acids, lipids, and detergents (Figure 2.14). This class of amphipathic molecules has a “head” group that is strongly hydrophilic, coupled to a hydrophobic “tail”—usually a hydrocarbon. When we attempt to dissolve them in water, these substances form one or more of the structures shown in Figure 2.15a. For example, they may form a **monolayer** on the water surface, with only the head groups immersed. Alternatively, if the mixture is vigorously stirred, **micelles** (spherical structures formed by a single layer of molecules) or **bilayer vesicles** may form. In such cases the hydrocarbon tails of the molecules tend to lie in roughly parallel arrays, which allows them to interact via van der Waals forces.

FIGURE 2.13

One unit of clathrate structure surrounding a hydrophobic molecule (yellow). Oxygen atoms are shown in red. Hydrogens are shown for one pentagon of oxygens. The ordered structure may extend considerably further into the surrounding water.

A simplified representation of an amphipathic lipid molecule

A molecule is “amphipathic” if significant parts of the molecular surface are hydrophilic and other parts of the surface are significantly hydrophobic.

FIGURE 2.14

Amphipathic molecules. These three examples illustrate the dual nature of amphipathic molecules, which have a hydrophilic head group attached to a hydrophobic tail.

(a) Structures formed in water

(b) Vesicle formation

FIGURE 2.15

Interactions of amphipathic molecules with water.

(a) Structures that can occur when amphipathic substances are mixed with water include a monolayer on the water surface, a micelle, and a bilayer vesicle, a hollow sphere with water both inside and out. In each case, the hydrophilic head groups are in contact with the aqueous phase, whereas the hydrophobic tails associate with one another. (b) When phospholipids are mixed with water, the amphipathic molecules aggregate to form films similar to biological membranes. Agitation causes the film to break up into vesicles.

(b) Courtesy of D. W. Deamer and P. B. Armstrong, University of California, Davis.

The polar or ionic head groups are strongly hydrated by the water around them. Most important to biochemistry is the fact that amphipathic molecules are the building blocks of the biological **membrane bilayers** that surround cells and form the partitions between cellular compartments. These bilayers are made primarily from phospholipids, such as that shown in Figure 2.14. Figure 2.15b shows the formation of synthetic membranes from phospholipids. We have much more to say about phospholipids and membranes in Chapter 10.

Ionic Equilibria

Most biochemical reactions occur in an aqueous environment; the exceptions are those that occur within the hydrophobic interiors of membranes. The many substances dissolved in the aqueous cytosol and extracellular body fluids include free ions like K^+ , Cl^- , and Mg^{2+} , as well as molecules and macromolecules carrying ionizable groups. The behavior of all these molecules in biochemical processes depends strongly on their state of ionization. Thus, it is important that we review briefly some aspects of ionic equilibrium, particularly acid–base equilibria and the ionization of water.

Acids and Bases: Proton Donors and Acceptors

A useful definition of acids and bases in aqueous systems is the Brønsted–Lowry definition: that acids are proton donors and bases are proton acceptors. A **strong acid** dissociates almost completely into a proton and a weak conjugate base. For example, HCl dissociates almost completely in water to yield H^+ (actually, hydronium ion, H_3O^+ ; see below) and Cl^- ; thus, the H^+ concentration in the solution is almost exactly equal to the molar concentration of HCl added. Similarly, NaOH is considered a **strong base** because it ionizes entirely, releasing OH^- ion, which is a powerful proton acceptor.

Most of the acidic and basic substances encountered in biochemistry are **weak acids** or **weak bases**, which only partially dissociate. In an aqueous solution of a weak acid there is a measurable equilibrium between the acid and its *conjugate base*, the substance that can accept a proton to re-form the acid. Examples of weak acids and their conjugate bases are given in Table 2.7. Note that these bases do not necessarily contain $—OH$ groups, but they increase the OH^- concentration of a solution by extracting a proton from water.

The weak acids listed in Table 2.7 vary greatly in strength, that is, in their tendency to donate protons. This variation in acid strength is indicated by the range of values of K_a and pK_a , which we will discuss shortly. The stronger the acid, the weaker its conjugate base; in other words, the more strongly an acid tends to donate a proton, the more weakly its conjugate base tends to accept a proton and re-form the acid.

Ionization of Water and the Ion Product

Although water is essentially a neutral molecule, it does have a slight tendency to ionize; in fact, it can act as both a very weak acid and a very weak base. The most correct way to understand this ionization reaction is to note that one water molecule can transfer a proton to another to yield a hydronium ion (H_3O^+) and a hydroxide ion (OH^-) so that water is both the proton donor and the proton acceptor:

This is really an oversimplification because the transferred proton may be associated with different clusters of water molecules to yield species like $H_5O_2^+$ and $H_7O_3^+$. Protons in aqueous solution are very mobile, with the proton hopping from one water molecule to another with a period of about 10^{-15} second.

Many biological molecules are weak acids or weak bases.

TABLE 2.7 Some weak acids and their conjugate bases

Acid (Proton Donor)		Conjugate Base (Proton Acceptor)		pK _a	K _a (M)
HCOOH Formic acid	⇌	HCOO ⁻ Formate ion	+ H ⁺	3.75	1.78 × 10 ⁻⁴

■ Phosphoric acid series ■ Carbonic acid series

*Apparent pK_a and K_a values (see text for explanation).

For the purposes of the following discussion, it suffices to describe the ionization process in a much simpler way,

as long as we remember that a proton *never* exists in aqueous solution as a free ion—it is always associated with one or more water molecules. Whenever we write a reaction involving aqueous H⁺, we are really referring to a *hydrated* proton.

The equilibrium described by the previous equation can be expressed in terms of K_w, the **ion product** of water, which is 10⁻¹⁴ at 25 °C:

$$K_w = \frac{(a_{\text{H}^+})(a_{\text{OH}^-})}{(a_{\text{H}_2\text{O}})} = 10^{-14} \quad (2.6a)$$

As discussed in greater detail in Chapter 3, the proper terms to use in a mass action expression such as K_w are unitless numbers, called “*activities*” (designated by *a*), equal to the effective concentrations of the chemical species. In practice, the distinction between *molar concentration* (i.e., moles of solute per liter of solution, or M) and *activity* is almost always neglected in biochemistry. This approach is appropriate in most biochemical experiments, which are usually conducted in dilute solutions, where activity and molar concentration become nearly equal. The activities of pure liquids and solids have a value of one, and in biochemical reactions the activity of the solvent water is often assumed to have an activity of one. Thus, an alternative expression for the equilibrium shown in Equation 2.5 is

$$K_w \equiv \frac{[\text{H}^+][\text{OH}^-]}{1} = 10^{-14} \quad (2.6b)$$

To correctly evaluate Equation 2.6b we must use unitless values for $[H^+]$ and $[OH^-]$ that are equivalent to their concentrations expressed in units of *molarity* (moles per liter). Throughout this text we will adopt the convention of indicating molar concentration for a solute with square brackets around the symbol for that solute.

Because K_w is a constant, $[H^+]$ and $[OH^-]$ cannot vary independently. If we change either $[H^+]$ or $[OH^-]$ by adding acidic or basic substances to water, the other concentration must change accordingly. A solution with a high $[H^+]$ has a low $[OH^-]$ and vice versa. In pure water to which no acidic or basic substances have been added, all the H^+ and OH^- ions must come from the dissociation of the water itself. Under these circumstances the concentrations of H^+ and OH^- must be equal; thus, at 25 °C

$$[H^+] = [OH^-] = 1 \times 10^{-7} \text{ M} \quad (2.7)$$

and the solution is said to be *neutral*, that is, neither acidic nor basic. However, the ion product depends on temperature, so a neutral solution does not always have $[H^+]$ and $[OH^-]$ of exactly 10^{-7} M. For example, at human body temperature (37 °C) the concentrations of H^+ and OH^- ions in a neutral solution are each 1.6×10^{-7} M.

Most biological reactions occur between pH 6.5 and pH 8.0.

FIGURE 2.16

The pH scale and the physiological pH range.

The pH values of some common substances and body fluids are listed, with NaOH at the basic end of the range shown here and HCl at the acidic end. The pH of most body fluids is in the neutral range, between 6.5 and 8.0, where most physiological processes occur. There are a few exceptions, like gastric juice, which has a pH between 1 and 2.

The pH Scale and the Physiological pH Range

To avoid working with negative powers of 10, we almost always express hydrogen ion concentration in terms of pH, defined as

$$\text{pH} = -\log(a_{H^+}) \cong -\log[H^+] \quad (2.8)$$

The higher the $[H^+]$ of a solution, the lower the pH, so a low pH describes an acid solution. On the other hand, a low $[H^+]$ must be accompanied by a high $[OH^-]$, as indicated by Equation 2.6b, so a high pH describes a basic solution.

A diagrammatic scale of pH values is shown in Figure 2.16, with the values for some well-known solutions indicated. Note that most body fluids have pH values in the range 6.5–8.0, which is often referred to as the **physiological pH range**. Most biochemistry occurs in this region of the scale.

Because of the sensitivity of biochemical processes to even small pH changes, controlling and monitoring pH are essential in most biochemical experiments. The control of pH is achieved by using solutions that are “buffered.” The composition of buffered solutions is described in detail later in this chapter. The pH of a solution is most conveniently measured with glass electrode pH meters. The electrode generates an electrical potential, which depends on the H^+ concentration; this is converted by the instrument into a pH reading.

Weak Acid and Base Equilibria

Many biologically important compounds contain weakly acidic and basic groups. Very large protein molecules, for example, carry on their surfaces both acidic (e.g., carboxylate) and basic (e.g., amino) groups. The response of such groups to changes in pH is often of considerable importance to their function. For example, the catalytic efficiency of many enzymes depends critically on the ionization state of certain groups, so these catalysts are effective only in defined pH ranges (see Chapter 11). We will see that the overall charge on a protein changes as a function of pH; thus, intermolecular recognition events based on complementary charge–charge interactions (e.g., substrate binding to a receptor) are also sensitive to pH. The dissociation equilibria of weak acids and bases can be used to describe the molecular basis for such effects. We begin this discussion by considering a few examples given in Table 2.7.

K_a and pK_a

Each of the reactions shown in Table 2.7 can be written as the dissociation of an acid. This dissociation may take several forms, depending on the substance involved:

Note that in some cases the conjugate base has a negative charge and in other cases it does not, but in *all* cases it has one proton fewer than the acid. For convenience, we will always write such reactions as $\text{HA} \rightleftharpoons \text{H}^+ + \text{A}^-$. The equilibrium constant for the dissociation of a weak acid (often called the **dissociation constant**) is defined as

$$K_a = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]} \quad (2.9)$$

The larger K_a is, the greater is the tendency for the acid to dissociate. Thus, the larger K_a is, the stronger the acid.

The strength of acids is usually expressed in terms of the $\text{p}K_a$ value:

$$\text{p}K_a = -\log K_a \quad (2.10)$$

Because $\text{p}K_a$ is the negative logarithm of K_a , a numerically small value of $\text{p}K_a$ corresponds to a strong acid, and a large value corresponds to a weak acid. Both K_a and $\text{p}K_a$ values are given for the acids listed in Table 2.7.

Some acids, such as the phosphoric and carbonic acids in Table 2.7, are capable of losing more than one proton. These acids are called **polyprotic acids**. The successive dissociations involve separate steps, with separate $\text{p}K_a$ values; thus polyprotic acids exist in several different ionization states.

A Closer Look At $\text{p}K_a$ Values: Factors Affecting Acid Dissociation

The tendency of a particular acid to dissociate results from a specific balance of the factors favoring and opposing dissociation. We can understand some of the factors affecting $\text{p}K_a$ in light of our earlier discussion of the solvent properties of water.

The dissociation of an acid results in hydration of the proton and, in most cases, of the conjugate base as well. Because hydration is energetically favorable and decreases the attraction between the ions, it favors the dissociation of most acids. Exceptions are positively charged acids like NH_4^+ , which dissociate to produce an uncharged conjugate base. In these cases it is the acid that is hydrated and thus stabilized; this is one reason NH_4^+ is such a weak acid.

Opposing the dissociation of an acid is the electrostatic attraction between the proton and a negatively charged conjugate base. This effect can be seen by comparing the successive $\text{p}K_a$ values for phosphoric acid dissociation in Table 2.7. As the charge on the conjugate base rises in going from H_2PO_4^- to PO_4^{3-} , the $\text{p}K_a$ rises as well; HPO_4^{2-} is a very weak acid.

These examples are important, for they show how environmental effects can influence $\text{p}K_a$ values. When we investigate proteins, we will find that the $\text{p}K_a$ values for supposedly identical groups can vary widely, depending on the local molecular environment.

Titration of Weak Acids: The Henderson–Hasselbalch Equation

As will be illustrated throughout this text, the structures and functions of many biomolecules show a strong dependence on pH. As pH changes, so does the level of protonation of acidic and basic groups displayed on the surface of a biomolecule. The important consequence of changing pH is that the *overall charge on the molecule changes*. How does changing the pH of a solution alter the charge on a molecule? We can answer this question by considering the *Henderson–Hasselbalch equation* (Equation 2.12), which is derived by taking the negative logarithm of both sides of Equation 2.9 and rearranging

$$-\log [\text{H}^+] = -\log K_a + \log \frac{[\text{A}^-]}{[\text{HA}]} \quad (2.11)$$

Substituting pH for $-\log [\text{H}^+]$ and $\text{p}K_a$ for $-\log K_a$ gives

$$\text{pH} = \text{p}K_a + \log \frac{[\text{A}^-]}{[\text{HA}]} \quad (2.12)$$

A convenient way to express the strength of an acid is by its $\text{p}K_a$; the lower the $\text{p}K_a$, the stronger the acid.

The Henderson–Hasselbalch equation shows the direct relation between the pH of a solution and the ratio of concentrations of the *deprotonated* form $[A^-]$ to the *protonated* form $[HA]$ of some ionizable group. In the case of a carboxylic acid $[A^-] = [RCOO^-]$ and $[HA] = [RCOOH]$, and in the case of a primary amine base $[A^-] = [RNH_2]$ and $[HA] = [RNH_3^+]$. For example, if we have a buffered solution of formic acid (where the R group = H), Equation 2.12 becomes

$$\text{pH} = \text{p}K_a + \log \frac{[\text{HCOO}^-]}{[\text{HCOOH}]} \quad (2.13)$$

The Henderson–Hasselbalch equation provides a theoretical basis for understanding (1) how the charge on a molecule at a given pH is determined by the ratio of $[A^-]/[HA]$ (see Problem 16b) and (2) how the ratio of $[A^-]/[HA]$ can be used to calculate the pH of a buffered solution made up of some acid HA and its conjugate base A^- (see Problems 9 and 10).

The Henderson–Hasselbalch equation also shows how pH changes during a titration. Suppose we want to titrate a 1 M solution of formic acid with sodium hydroxide. First, we must ask: What is the pH of the solution made by dissolving 1 mol formic acid in sufficient water to make 1 L of solution? This can be calculated from Equation 2.9, if we note that virtually all of the H^+ in such a solution comes from the formic acid, rather than from water, and that dissociation of one formic acid molecule gives one H^+ and one $HCOO^-$ ion. If we denote their molar concentrations by x , then Equation 2.9 becomes

$$K_a = 1.78 \times 10^{-4} = \frac{[H^+][HCOO^-]}{[HCOOH]} = \frac{x^2}{1-x} \quad (2.14)$$

To get an exact answer, we would have to solve this quadratic equation (see Problem 4). For weak acids, however, the quantity x is often much less than the concentration of total acid added (in this case 1 M). As a result, in such cases we can neglect x in the denominator, giving as a good approximation

$$K_a \approx x^2 \quad (2.15)$$

In this example, this yields

$$x = [H^+] = [HCOO^-] = 1.33 \times 10^{-2} \text{ M} \quad (2.16)$$

Note that only about 1% of the acid has dissociated, so our approximation is quite reasonable. It would not be if the acid were more dilute, for then a larger fraction would dissociate.

The preceding calculation tells us that the initial pH is about 1.9. Now, what happens as a solution of NaOH is added to the formic acid solution? As NaOH is added, it dissociates completely into Na^+ and OH^- ; however, the hydroxide ions are in equilibrium with protons according to the relation $K_w = [H^+][OH^-]$, so addition of OH^- reduces the concentration of protons in the solution. According to Le Chatelier's principle, as $[H^+]$ decreases, more formic acid must dissociate to satisfy the equilibrium relationship given by Equation 2.14. This means that the ratio $[HCOO^-]/[HCOOH]$ increases as NaOH is added. Applying the Henderson–Hasselbalch equation (2.13), we see that the pH must also increase continuously as the titration proceeds. At the midpoint of the titration, half of the original formic acid has been neutralized. That means that half is still present in the acid form and half is present as the conjugate base, so $[A^-]/[HA] = 1$. The Henderson–Hasselbalch equation then becomes

$$\text{pH} = \text{p}K_a + \log 1 = \text{p}K_a \quad (2.17)$$

Thus, the pH of a weak acid at the midpoint of its titration curve has the same value as its $\text{p}K_a$. This can be confirmed experimentally, as shown by the titration curves of two acids, formic acid and ammonium ion, in Figure 2.17. The titration curves in Figure 2.17 plot the measured pH against *moles of base added per mole of*

The Henderson–Hasselbalch equation describes the change in pH during titration of a weak acid or a weak base.

FIGURE 2.17

Titration curves of weak acids. The curves for titration of formic acid (HCOOH) and ammonium ion (NH_4^+) show the change in pH as moles of base are added. Note that $\text{pH} = \text{p}K_a$ at the half-titration point of each substance. Most of the titration occurs in a range of about one pH unit on either side of this value. In this range, the change in pH with moles of base added is minimal; thus, this is the best buffering range.

acid originally present. Note that over much of the titration curve the pH lies within one pH unit below or above the pK_a .

It should be emphasized that titration curves are reversible. If we were to take the final solution, at high pH, and begin adding a strong acid like HCl, the same curve would be retraced in the opposite direction.

Buffer Solutions

If we look at Figure 2.17 in a different way, another important point emerges. In the pH range near the pK_a , the pH changes only a little with each increment of base or acid added. In fact, the pH is least changed per increment of acid or base just at the pK_a . This is the principle behind **buffering** of solutions by the use of weak acid–base mixtures, a technique used in virtually every biochemical experiment.

Buffered solutions are able to minimize the change in pH following addition of H^+ or OH^- because the conjugate acid (HA) and conjugate base (A^-) of the buffering compound (commonly called the **buffer** or **buffer salt**) are present in sufficient concentration to combine with the added H^+ or OH^- and neutralize them:

Suppose a biochemist wishes to study a reaction at pH 4.00. The reaction may be one that generates or consumes protons. To prevent the pH from drifting too much during the reaction, the experimenter should use a buffer solution consisting of a nearly equal mixture of a weak acid and its conjugate base. Recall that the Henderson–Hasselbalch equation predicts that an equimolar ratio of A^- to HA is achieved when the pH of the solution equals the pK_a of the buffer. In this example a formic acid–formate buffer would be a good choice because the pK_a of formic acid (3.75) is close to the pH value required for the experiment. An acetic acid–acetate mixture would not be as satisfactory because the pK_a of acetic acid (4.76) is nearly 1 pH unit away. The ratio of formate ion to formic acid required to make a buffered solution with a pH of 4.00 can be calculated from the Henderson–Hasselbalch equation:

$$4.00 = 3.75 + \log \frac{[HCOO^-]}{[HCOOH]} \quad (2.18)$$

To calculate the base/acid ratio, we simply subtract 3.75 from 4.00 and take the antilogarithm of both sides of Equation 2.18:

$$\frac{[HCOO^-]}{[HCOOH]} = 10^{(4.00-3.75)} = 10^{0.25} = 1.78 \quad (2.19)$$

This result shows that at pH = 4.00 there will be a ratio of 1.78 mol of $HCOO^-$ in solution to every 1.00 mol of $HCOOH$ in solution. Such a buffer could be made, for example, by mixing equal volumes of 0.1 M formic acid and 0.178 M sodium formate. Alternatively, a buffer solution could be prepared by titrating a solution of formic acid to pH 4.00 with sodium hydroxide.

Because it is desirable to study many biochemical reactions near physiological pH, there is a particular need for mixtures that buffer the pH in the pH range 6.5–8.0. Of the acid–base pairs listed in Table 2.7, only mixtures of dihydrogen phosphate ion ($H_2PO_4^-$) and hydrogen phosphate ion (HPO_4^{2-}), or possibly carbonic acid (H_2CO_3) and bicarbonate ion (HCO_3^-), would be satisfactory. Phosphate buffers are often used in experiments, but they cannot serve under all circumstances because phosphate is consumed or produced in some biochemical reactions. Furthermore, both phosphate- and carbonate-containing solutions precipitate some ions (e.g., Ca^{2+}) that may be needed in the reaction. Therefore, a number of other naturally occurring and synthetic compounds are employed as buffers in this range. Examples are given in Table 2.8.

Organisms must maintain the pH inside cells and in most bodily fluids within the narrow pH range of about 6.5 to 8.0. For example, the normal pH of human

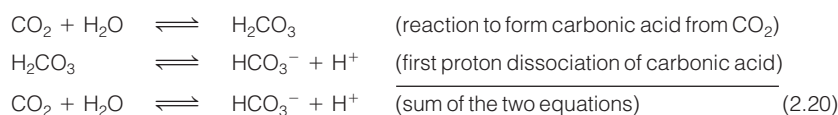

Buffer solutions function because the pH of a weak acid–base solution is least sensitive to added acid or base near the pK_a , where the conjugate acid and conjugate base of the buffer are both present in nearly equimolar concentrations.

TABLE 2.8 Some buffers commonly employed for biochemical studies

Buffer Substance (Acid Form)	Common Name	pK _a
Cacodylic acid	—	6.2
2,2-Bis(hydroxymethyl)2,2',2'' nitrilotriethanol	BISTRIS	6.5
Piperazine- <i>N,N'</i> -bis(2-ethanesulfonic acid)	PIPES	6.8
Imidazole	—	7.0
<i>N'</i> -2-Hydroxyethylpiperazine- <i>N'</i> ,2-ethanesulfonic acid	HEPES	7.6
Tris(hydroxymethyl)aminomethane	Tris	8.3

Organisms use buffer systems to maintain the pH of cells and body fluids in the appropriate range.

blood is 7.4, which is also the pH inside most human cells. We have already mentioned two buffer systems of great importance for biological pH control. The dihydrogen phosphate–hydrogen phosphate system, with a pK_a of 6.86, plays a major role in controlling intracellular pH because phosphate is abundant in cells. In blood, which contains dissolved CO₂ as a waste product of metabolism, the carbonic acid–bicarbonate system provides considerable buffering capacity. Carbonic acid has a pK_a of 3.8; however, because it readily decomposes into water and dissolved CO₂, the concentration of H₂CO₃ in solution is very low. As a consequence, the *apparent* pK_a (designated pK_a') of carbonic acid is 6.3 (this is the value listed in Table 2.7). The relationship between dissolved CO₂ and proton concentration (i.e., pH) can be appreciated by considering the following chemical equations:

Le Chatelier's principle and Equation 2.20 predict that as the concentration of dissolved CO₂ increases, the pH will decrease as a result of increasing H⁺ concentration. We will see in Chapter 7 that a drop in pH in actively respiring tissues results in increased oxygen delivery to these tissues by the oxygen-carrying protein hemoglobin.

From Equation 2.20 we can write an expression that describes the apparent dissociation of carbonic acid to bicarbonate ion and a proton:

$$K_a' = \frac{[\text{H}^+][\text{HCO}_3^-]}{[\text{CO}_2][\text{H}_2\text{O}]} \quad (2.21)$$

The value of the pK_a' for carbonic acid can be derived from the combination of the two relevant equilibrium expressions for the chemical equations that were used to derive Equation 2.20. The first of these is for the equilibrium between dissolved CO₂, water, and H₂CO₃:

The second is for the dissociation of H₂CO₃:

When these two mass action expressions are multiplied they yield Equation 2.21:

$$\begin{aligned}
 \frac{[\text{H}_2\text{CO}_3]}{[\text{CO}_2][\text{H}_2\text{O}]} \times \frac{[\text{H}^+][\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]} &= \frac{[\text{H}^+][\text{HCO}_3^-]}{[\text{CO}_2][\text{H}_2\text{O}]} = K_a' \\
 K_a' &= K_{\text{eq}} \times K_a = 5.1 \times 10^{-7} \text{ and } \text{p}K_a' = -\log(5.1 \times 10^{-7}) = 6.3
 \end{aligned}$$

In addition to phosphate and bicarbonate buffers, proteins play a major role in the control of pH in organisms. As shown in Chapter 5, proteins contain many weakly acidic or basic groups, and some of these have pK_a values near 7.0. The abundance of proteins in cells and body fluids such as blood and lymph contributes to the buffering capacity of these biological solutions.

Molecules with Multiple Ionizing Groups: Ampholytes, Polyampholytes, and Polyelectrolytes

So far, we have considered molecules containing only one or a few weakly acidic or basic groups. But many molecules contain multiple ionizing groups and display more complex behavior during titration.

A molecule that contains groups with both acidic and basic pK_a values is called an **ampholyte**. Consider, for example, glycine: $\text{H}_2\text{N}-\text{CH}_2-\text{COOH}$. Glycine is an α -amino acid, one of a group of important amino acids encountered in Chapter 5 as constituents of proteins. The pK_a values of the α -carboxylate and α -amino groups on glycine are 2.3 and 9.6, respectively. If we dissolved glycine in a very acidic solution (e.g., pH 1.0), both the α -amino group and the α -carboxylate group would be protonated, and the molecule would have a net charge of +1. If the pH was increased (e.g., by adding NaOH), proton dissociation would occur in the following sequence:

Thus, the titration of glycine occurs in two steps as the more acidic α -carboxylate and the less acidic α -amino groups successively lose their protons. Glycine can therefore serve as a good buffer in two quite different pH ranges, as shown in Figure 2.18. In each range we can describe the titration curve by applying the Henderson–Hasselbalch equation to the appropriate ionizing group. At low pH the predominant form of glycine has a net charge of +1; at high pH the predominant form has a net charge of -1. The relative concentrations of the three forms are shown in Figure 2.19, which illustrates the important relationship between pH and overall

FIGURE 2.19

The relative concentrations of the three forms of glycine as a function of pH. The three forms are $\text{H}_3\text{N}^+\text{CH}_2\text{COOH}$, shown in red; $\text{H}_3\text{N}^+\text{CH}_2\text{COO}^-$, black; and $\text{H}_2\text{NCH}_2\text{COO}^-$, blue. The two pK_a values and the isoelectric point (pI) are indicated. As pH increases, the molecule becomes more negatively charged, and as pH decreases, the molecule becomes more positively charged.

FIGURE 2.18

Titration of the ampholyte glycine. Because two groups with quite different pK_a values can be titrated, this is a two-step titration curve. The calculated isoelectric point, pI, is shown.

charge on a molecule: as pH drops, a molecule will become more positively charged, and as pH increases, a molecule will become more negatively charged (see Problem 15).

The situation near neutral pH is an interesting one. In this region, most glycine is in the form $\text{H}_3\text{N}^+-\text{CH}_2-\text{COO}^-$, which has a net charge of zero. An ampholyte in this state, with equal numbers of positive and negative charges, is called a *zwitterion*. However, there is only one point within this pH region where the average charge on glycine is zero. At this pH, called the **isoelectric point (pI)**, most of the glycine molecules are in the zwitterion form, with very small but exactly equal amounts of $\text{H}_3\text{N}^+-\text{CH}_2-\text{COOH}$ and $\text{H}_2\text{N}-\text{CH}_2-\text{COO}^-$ molecules. We can calculate the isoelectric point by applying the Henderson–Hasselbalch equation to both of the ionizing groups. If we call the pH at the isoelectric point pI, we have

$$\text{pI} = \text{p}K_{\text{COOH}} + \log \frac{[\text{H}_3\text{N}^+\text{CH}_2\text{COO}^-]}{[\text{H}_3\text{N}^+\text{CH}_2\text{COOH}]} \quad (2.24)$$

and

$$\text{pI} = \text{p}K_{\text{NH}_3^+} + \log \frac{[\text{H}_2\text{NCH}_2\text{COO}^-]}{[\text{H}_3\text{N}^+\text{CH}_2\text{COO}^-]} \quad (2.25)$$

Adding these equations (remembering that the sum of the logarithms of two quantities is the logarithm of their product) gives

$$2 \text{pI} = \text{p}K_{\text{COOH}} + \text{p}K_{\text{NH}_3^+} + \log \frac{[\text{H}_2\text{NCH}_2\text{COO}^-]}{[\text{H}_3\text{N}^+\text{CH}_2\text{COOH}]} \quad (2.26)$$

But because the definition of pI requires that $[\text{H}_2\text{NCH}_2\text{COO}^-] = [\text{H}_3\text{N}^+\text{CH}_2\text{COOH}]$, the term to the far right is equal to log 1, or zero, so

$$\text{pI} = \frac{\text{p}K_{\text{COOH}} + \text{p}K_{\text{NH}_3^+}}{2} \quad (2.27)$$

The result is simple in this case: For a molecule with only two ionizable groups, the pI is simply the average of the two $\text{p}K_{\text{a}}$ s. If we insert the $\text{p}K_{\text{a}}$ values given previously, we obtain $\text{pI} = 5.95$ for glycine. Actually, as Figure 2.19 shows, glycine will be almost entirely in the zwitterion form from about pH 4 to about pH 8; thus, the average charge on glycine is very close to zero throughout this pH range.

For molecules that have three or more ionizable groups, the pI can be calculated by averaging of the two $\text{p}K_{\text{a}}$ s that describe the ionization of the “isoelectric” species. For example, the amino acid aspartic acid has three ionizable groups with $\text{p}K_{\text{a}}$ s of 2.1 (α -COOH, shown in black below), 3.9 (β -COOH, shown in blue below), and 9.8 (α - NH_3^+). The titration of fully protonated aspartic acid with NaOH occurs in three steps (Figure 2.20), which we can write in the order of increasing $\text{p}K_{\text{a}}$ values for the ionizable groups:

If we sum the charges on each of the four possible ionization states for aspartic acid, we see that one of these, the so-called “isoelectric” species, carries no net charge. As stated above, the two $\text{p}K_{\text{a}}$ s that describe the ionization of the isoelectric species, $\text{p}K_{\alpha\text{COOH}}$ and $\text{p}K_{\beta\text{COOH}}$, have values of 2.1 and 3.9, respectively. Thus, the pI for aspartic acid is

An ampholyte’s isoelectric point, pI, is the pH at which average charge, for all forms of the molecule, is zero. At $\text{pH} < \text{pI}$, a molecule will be positively charged, and at $\text{pH} > \text{pI}$, the molecule will be negatively charged.

FIGURE 2.20

Titration curve of aspartic acid. Because three groups with different $\text{p}K_{\text{a}}$ values can be titrated, this is a three-step process. The predominant species in solution as a function of added hydroxide ion are shown (with titratable protons in red). The buffering regions for the three titratable groups are indicated by the blue dots on the titration curve.

$$pI = \frac{pK_{\alpha\text{COOH}} + pK_{\beta\text{COOH}}}{2} = \frac{(2.1 + 3.9)}{2} = 3.0 \quad (2.28)$$

Careful analysis of the ionization of each functional group at $pH = 3.0$ would show that the α -amino group is fully protonated and therefore carries a full (+1) charge, whereas the two carboxylic acids are *partially* deprotonated; thus, each carries only a partial (−) charge. The sum of these partial (−) charges = −1, which balances the +1 charge on the α -amino group; thus, the net charge on the molecule at $pH = 3$ is zero. For an example of such an analysis, see Problem 16 at the end of this chapter.

Large molecules such as proteins can have *many* acidic and basic groups. Such molecules are called **polyampholytes**. With anything from tens to hundreds of charged groups present, the calculation of pI becomes more complicated. However, as long as the molecule has both positively and negatively charged groups, it always has an isoelectric point, at which the average charge is zero. For example, human hemoglobin has 148 ionizable groups on its surface, and its pI is 6.85. If acidic groups predominate, the pI will be low; if basic groups predominate, the pI will be high. In Chapter 5 we find that this is an important consideration in working with solutions of proteins.

Three important conclusions can be drawn from this discussion of pI . First, when the pH of a protein solution equals the pI for the protein there is no net charge on the protein because the sum of all the negative charges, $\Sigma(-)$, is exactly offset by the sum of all the positive charges, $\Sigma(+)$, or

$$\text{at } pH = pI \quad |\Sigma(-)| = |\Sigma(+)| \quad (2.29)$$

thus, the net charge of the molecule = 0. Second, when the pH is greater than the pI , the molecule carries a net negative charge because the sum of the negative charges dominates the sum of the positive charges:

$$\text{at } pH > pI \quad |\Sigma(-)| > |\Sigma(+)| \quad (2.30)$$

thus, the net charge of the molecule is (−). Third, when the pH is below the pI , the molecule carries a net positive charge because the sum of the negative charges is dominated by the sum of the positive charges:

$$\text{at } pH < pI \quad |\Sigma(-)| < |\Sigma(+)| \quad (2.31)$$

thus, the net charge of the molecule is (+).

This behavior can be understood by considering the chemistry involved. Ionization by H^+ transfer is a *dynamic* process, in which ionizable groups are constantly gaining or losing a proton. Using the Henderson–Hasselbalch equation we can predict, on average, what fraction of these ionizable groups is protonated. As the pH changes, this fraction will also change. For example, protein molecules in aqueous solution become increasingly protonated as the pH decreases. As a consequence, proteins become more positively charged because carboxylic acids, the groups largely responsible for the negative charge density on the surfaces of proteins, become *less negatively charged* in response to a drop in pH , whereas nitrogenous bases (e.g., amines), which are largely responsible for the positive charge density on the surfaces of proteins, become *more positively charged*. A similar logic explains the observation that proteins become more negatively charged as pH increases. Under conditions of increasing pH , the ionizable groups become more deprotonated. Thus, acidic groups become more negatively charged while the basic groups become less positively charged. The effects of pH on the charges of carboxylic acids and amine bases are summarized in Table 2.9.

Significant fluctuations in the charges on proteins will result in loss of function; thus, the concepts summarized in Table 2.9 and Equations 2.29–2.31 not only explain the basis for molecular recognition via charge complementarity but also the critical need to maintain intracellular pH within a narrow range such that charges on molecules remain relatively constant.

TABLE 2.9 Effects of pH on the ionization and charges of amines and carboxylic acids

pH Relative to pK_a	Ratio of $[A^-]$ to $[HA]$	Effect on H^+ Transfer (Ionization)	Net Charge on Group as a Consequence of Ionization
$pH = pK_a$	$[A^-] = [HA]$	A^- is protonated 50% of the time	
Acidic group	$[-COO]^- = [-COOH]$	$-COO^-$ is protonated 50% of the time	net charge = -0.5
Basic group	$[-NH_2] = [-NH_3]^+$	$-NH_2$ is protonated 50% of the time	net charge = $+0.5$
$pH < pK_a$	$[A^-] < [HA]$	A^- is protonated $> 50\%$ of the time	
Acidic group	$[-COO]^- < [-COOH]$	$-COO^-$ is protonated $> 50\%$ of the time	$0 \geq \text{net charge} > -0.5$
Basic group	$[-NH_2] < [-NH_3]^+$	$-NH_2$ is protonated $> 50\%$ of the time	$+1 \geq \text{net charge} > +0.5$
$pH > pK_a$	$[A^-] > [HA]$	A^- is protonated $< 50\%$ of the time	
Acidic group	$[-COO]^- > [-COOH]$	$-COO^-$ is protonated $< 50\%$ of the time	$-1 < \text{net charge} < -0.5$
Basic group	$[-NH_2] > [-NH_3]^+$	$-NH_2$ is protonated $< 50\%$ of the time	$0 \leq \text{net charge} < +0.5$

Although the theory described above can be used to predict a pI value from the amino acid composition of a protein, there are many caveats associated with such predictions. In practice, pI is determined experimentally using the simple method of *electrophoresis*. When an electric field is applied to a solution of charged ampholytes, positively charged molecules migrate toward the cathode and negatively charged ones toward the anode. At its isoelectric point, an ampholyte moves in *neither* direction because it has zero net charge. In the method called **isoelectric focusing**, ampholytes move through a pH gradient, each coming to rest at its own isoelectric point. In this way, the ampholytes are separated and their isoelectric points determined (see Tools of Biochemistry 2A).

Some macromolecules, called **polyelectrolytes**, carry multiples of only positive or only negative charge. Strong polyelectrolytes, like the negatively charged nucleic acids (see Chapter 4), are ionized over a wide pH range. In addition, there are weak polyelectrolytes, like polylysine, a polymer of the amino acid lysine.

When a number of weakly ionizing groups are carried on the same molecule, the pK_a of each group is influenced by the state of ionization of the others. In a molecule like polylysine, the first protons are more easily removed than the last because the strong positive charge on the fully protonated molecule makes deprotonation, and the associated reduction in repulsive charge–charge interactions, more favorable. Conversely, a molecule that develops a strong negative charge as protons are removed gives up the last ones less readily, as reflected in the increasing values of pK_a for successive deprotonations (see entries for H_3PO_4 and H_2CO_3 in Table 2.7).

Polylysine

Interactions Between Macroions in Solution

Large polyelectrolytes such as nucleic acids and polyampholytes such as proteins are classed together as **macroions**. Depending on the solution pH, they may carry a substantial net charge. The electrostatic forces of attraction or repulsion between such charged particles play a major role in determining their behavior in solution.

Solubility of Macroions and pH

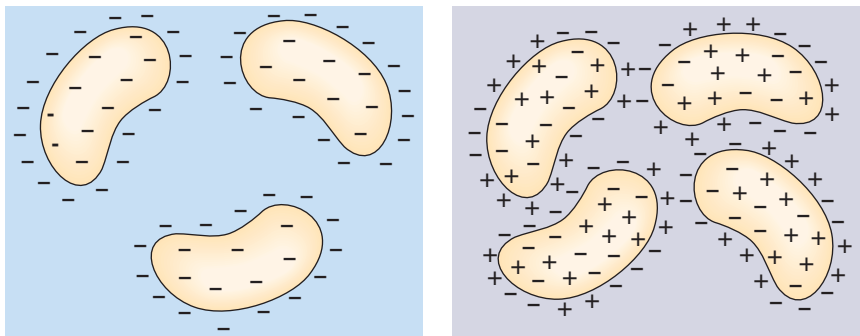

Because macroions of like net charge repel one another, nucleic acid molecules tend to remain separated in solution (Figure 2.21a). For the same reason, proteins tend to be soluble when they have a net charge, that is, at pH values above or below their isoelectric points. On the other hand, if positively and negatively charged macromolecules are mixed, electrostatic attraction makes them tend to associate with one another (Figure 2.21b). Many proteins interact strongly with DNA; most of these turn out to be positively charged. A striking example is found in the chromosomes of higher organisms, in which the negatively charged DNA is

strongly associated with positively charged proteins called *histones* to form the complex called *chromatin* (discussed in Chapter 24).

A more subtle type of electrostatic interaction may cause the molecules of a particular protein to self-associate at the isoelectric pH (Figure 2.22). For example, the common milk protein β -lactoglobulin is a polyampholyte with an isoelectric point of about 5.3. Above or below this pH, the molecules all have either negative or positive charges and repel one another. This protein is therefore very soluble at either acidic or basic pH. At the isoelectric point the net charge is zero, but each molecule still carries surface patches of both positive and negative charge. The charge–charge interactions, together with other kinds of intermolecular interactions such as van der Waals forces, make the molecules tend to clump together and precipitate. Therefore, β -lactoglobulin, like many other proteins, has minimum solubility at its isoelectric point (Figure 2.22d).

The Influence of Small Ions: Ionic Strength

The interactions of macroions are strongly modified by the presence of small ions, such as those from salts dissolved in the same solution. Each macroion collects about it a **counterion atmosphere** enriched in oppositely charged small ions, and this cloud of ions tends to screen the molecules from one another (Figure 2.23a). Obviously, the larger the concentration of small ions present, the more effective this electrostatic screening will be; however, the precise relationship of screening to concentration is rather complex. A quantitative expression of the screening

(a) High pH: protein soluble (deprotonated) (b) Isoelectric point: protein aggregates

(c) Low pH: protein soluble (protonated)

(d) Solubility of β -lactoglobulin

FIGURE 2.22

Dependence of protein solubility on pH. (a) Most proteins are very soluble at high pH, where all of their molecules are negatively charged. (b) At the isoelectric point, where a protein has no net charge, its molecules retain regions of positive and negative charge on their surfaces, resulting in aggregation and precipitation. (c) At low pH the proteins are soluble because of their positive charge. (d) The solubility of β -lactoglobulin with varying pH; the lowest solubility occurs at the isoelectric point.

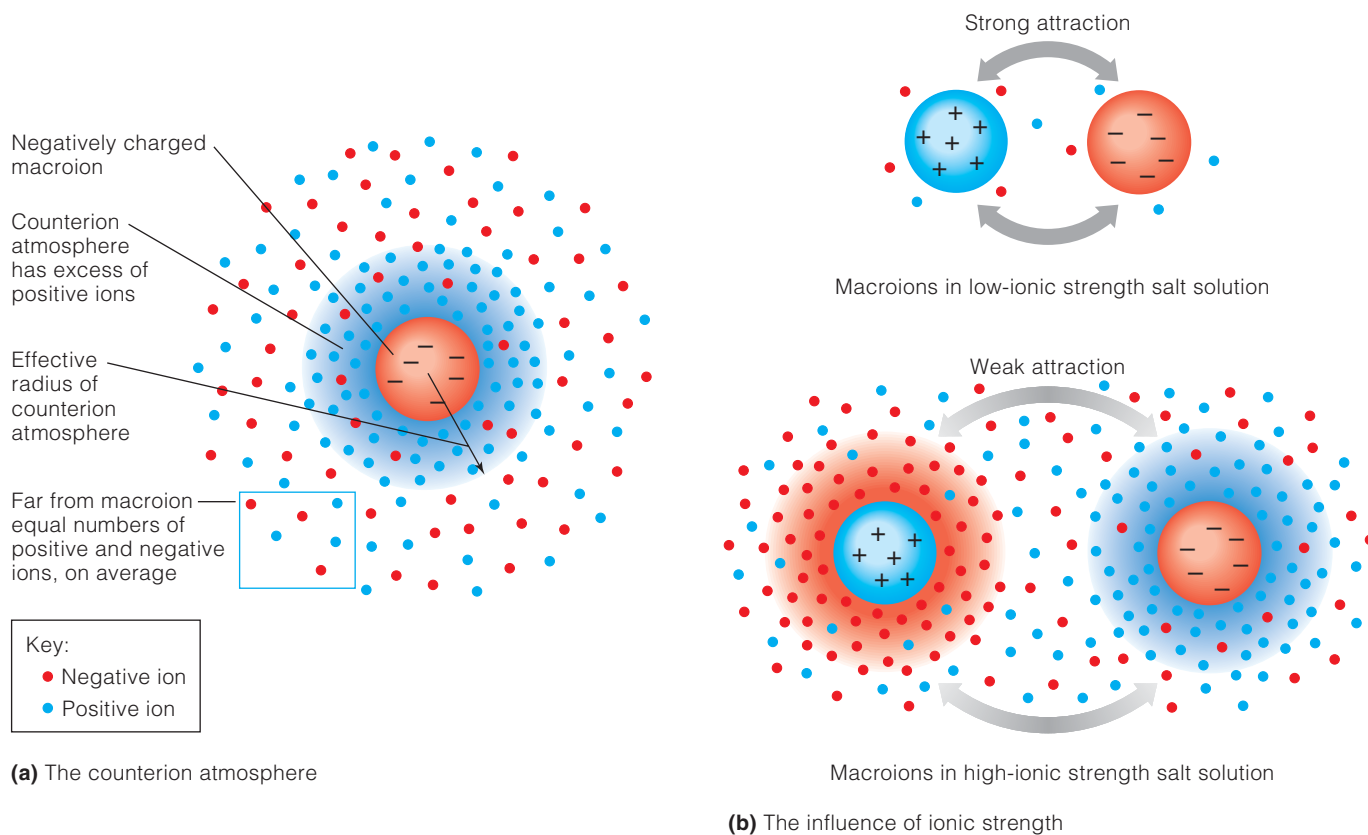

FIGURE 2.21

Electrostatic interactions between macroions.

(a) Repulsion. DNA molecules, with many negative charges, strongly repel one another in solution.

(b) Attraction. If DNA is mixed with a positively charged protein, these molecules have a strong tendency to associate.

Interactions between macroions are greatly influenced by pH and the small ions in the solution.

**FIGURE 2.23**

The influence of small ions on macroion interactions. (a) When a macroion (in this example, negatively charged) is placed in an aqueous salt solution, small ions of the opposite sign tend to cluster about it, forming a counterion atmosphere. There are more cations than anions near the macroion shown here; far away from the macroion, the average concentrations of cations and anions are equal. (b) At low ionic strength, the counterion atmosphere is diffuse and interferes little with the interactions of the macroions. At high ionic strength, the counterion atmosphere is concentrated about the macroions and greatly reduces their interactions.

effect for spherical macroions, proposed by P. Debye and E. Hückel, is stated in terms of an effective radius (r) of the counterion atmosphere. This radius may be taken as a measure of the distance at which two macroions “sense” one another’s presence. According to the Debye–Hückel theory,

$$r = \frac{K}{I^{1/2}} \quad (2.32)$$

where K is a constant that depends on the dielectric constant of the medium and the temperature, and I is a function of the concentration called the **ionic strength**. The ionic strength is defined as follows:

$$I = \frac{1}{2} \sum M_i Z_i^2 \quad (2.33)$$

where the sum is taken over all small ions in the solution. For each ion type, M_i is its molarity and Z_i is its charge. For a 1:1 electrolyte like NaCl we have $Z_{\text{Na}^+} = +1$ and $Z_{\text{Cl}^-} = -1$, and because $M_{\text{Na}^+} = M_{\text{Cl}^-} = M_{\text{NaCl}}$, we find that $I_{\text{NaCl}} = M_{\text{NaCl}}$. Thus, ionic strength equals salt molarity for 1:1 electrolytes, but this is not true if multivalent ions (e.g., Mg^{2+} or SO_4^{2-}) are involved. Multivalent ions make greater individual contributions to the ion atmosphere than do monovalent ions, as reflected in the fact that the *square* of the ion charge is included in calculating the ionic strength. For these electrolytes, $I > M$.

The effects of the ionic strength of the medium on the interaction between charged macroions can be summarized as shown in Figure 2.23b. At very low ionic strength, the counterion atmosphere is highly expanded and diffuse, and screening is ineffective. In such a solution, macroions attract or repel one another strongly. If the ionic strength is increased, the counterion atmosphere shrinks and becomes concentrated about the macroion, and the attractive interactions between positive and negative groups are effectively screened.

The screening effect of the counterion atmosphere helps explain a general observation concerning protein solubility: increasing ionic strength (up to a

point) increases solubility even at the isoelectric point. This effect of putting proteins into solution by increasing the salt concentration is called **salting in**.

Raising the salt concentration to very high levels (several molar, for example) introduces another, opposite effect. In very concentrated salt solutions, much of the water that would normally solvate and help solubilize the protein molecule is bound up in the hydration shells of the numerous salt ions, preventing sufficient hydration of the protein. Thus, at extremely high salt concentration, the solubility of a protein again decreases, an effect called **salting out**. Because different proteins respond differently to these two effects, salting in and salting out can be used to separate proteins in a complex mixture.

The effects of ionic interactions on the behavior of biological macromolecules mean that the biochemist must pay close attention to both ionic strength and pH. In addition to using a buffer to control pH, experimenters will usually add a neutral salt (like NaCl or KCl) to control the ionic strength of a solution. In determining the amount of salt to add, they often try to mimic the ionic strengths of cell and body fluids. Although ionic strengths vary from one cell type or fluid to another, a value of 0.1 to 0.2 M is often appropriate in biochemical experiments.

SUMMARY

The major concepts discussed in this chapter are summarized in two equations: Coulomb's law (Equation 2.1), and the Henderson–Hasselbalch equation (Equation 2.12).

Coulomb's law provides the theoretical foundation for describing the variety of weak, noncovalent interactions that occur among ions, molecules, and parts of molecules in the cell. These interactions, which are 10 to 100 times weaker than most covalent interactions, include charge–charge interactions and the interactions of permanent and induced dipoles. Molecules never interpenetrate because attraction between them is countered by repulsion when their electron orbitals begin to overlap; a molecule's van der Waals radius is half its distance of closest approach to another molecule. The hydrogen bond is a strong noncovalent interaction, and it shares some features (directionality, specificity) with covalent bonds.

Water is the essential milieu of life. Most of the unique properties of water as a substance are accounted for by its polarity and hydrogen bonding, properties that also make it an excellent solvent. Polar, hydrogen-bonding, and ionic substances dissolve easily in water and are called hydrophilic, whereas other compounds dissolve in water to only a limited extent and are called hydrophobic. Amphipathic molecules, which have both polar and nonpolar parts, form distinctive structures such as monolayers, vesicles, and micelles when in contact with water. Such molecules form the membrane bilayers that surround cells and cellular compartments.

The ionization of weak acids and bases is of major importance in biochemistry because it establishes the charges on biomolecules. Most of the important processes occur in the pH range between 6.5 and 8.0, called the physiological pH range. The behavior of weak acids and their conjugate bases is described by the Henderson–Hasselbalch equation, which relates the conjugate base/undissociated acid ratio to pH and pK_a . Titration curves show that the pH change with added acid or base is most gradual in the range near the pK_a of the acid; this is the basis for preparation of buffer solutions.

An ampholyte has both acidic and basic ionizing groups; the molecules can have a net positive, zero, or net negative charge, depending on solution pH. A polyampholyte has many acidic and basic groups. The isoelectric point of an ampholyte or a polyampholyte is the pH at which the average net charge of the molecules is zero. Polyelectrolytes have multiple ionizing groups with a single kind of charge. The behavior of macroions (polyampholytes and polyelectrolytes) in solution depends on pH and on the presence of small ions, which screen the macroions from each other's charges. The magnitude of screening depends on the ionic strength of the solution and is described quantitatively by the Debye–Hückel theory.

PROBLEMS

In this and following chapters, more difficult problems are indicated by an asterisk.

- A chloride ion and a sodium ion are separated by a center–center distance of 0.5 nm. Calculate the interaction energy (the energy required to pull them infinitely far apart) if the medium between them is (a) water and (b) *n*-pentane (see Table 2.6). Express the energy in joules per mole of ion pairs. [Note: The charge on an electron is 1.602×10^{-19} C, Avogadro's number is 6.02×10^{23} molecules/mol.]
- Rank the following in terms of expected dipole moment, and explain your choice:
H₂S, CCl₄, H₃N⁺—CH₂—COO[−], H₃N⁺—CH₂—CH₂—CH₂—COO[−]
- The accompanying graph depicts the interaction energy between two water molecules situated so that their dipole moments are parallel and pointing in the same direction. Sketch an approximate curve for the interaction between two water molecules oriented with *antiparallel* dipole moments.

- (a) Solve the quadratic equation (referred to in Equation 2.14) for the more general case where the total concentration of acid ($A_0 = [\text{HA}] + [\text{A}^-]$) has any value A_0 .
(b) One can avoid solution of the quadratic equation by using a method of successive approximations, starting with $x^2 \approx A_0 K_a$. Explain how this would be done.
- What is the pH of each of the following solutions?
(a) 0.35 M hydrochloric acid
(b) 0.35 M acetic acid
(c) 0.035 M acetic acid
[Note that the approximate method used in Equation 2.15 will not give a good answer at low A_0 .]
- The weak acid HA is 2% ionized (dissociated) in a 0.20 M solution.
(a) What is K_a for this acid?
(b) What is the pH of this solution?
- Calculate the pH values and draw the titration curve for the titration of 500 mL of 0.010 M acetic acid (pK_a 4.76) with 0.010 M KOH.
- What is the pH of the following buffer mixtures?
(a) 100 mL 1 M acetic acid plus 100 mL 0.5 M sodium acetate
(b) 250 mL 0.3 M phosphoric acid plus 250 mL 0.8 M KH₂PO₄
- (a) Suppose you wanted to make a buffer of exactly pH 7.00 using KH₂PO₄ and Na₂HPO₄. If the final solution was 0.1 M in KH₂PO₄, what concentration of Na₂HPO₄ would you need?
(b) Now assume you wish to make a buffer at the same pH, using the same substances, but want the total phosphate molarity ($[\text{HPO}_4^{2-}] + [\text{H}_2\text{PO}_4^-]$) to equal 0.3. What concentrations of the KH₂PO₄ and Na₂HPO₄ would be required?

10. A 500-mL sample of a 0.100 M formate buffer, pH 3.75, is treated with 5 mL of 1.00 M KOH. What is the pH following this addition?
11. You need to make a buffer whose pH is 7.0, and you can choose from the weak acids shown in Table 2.7. Briefly explain your choice.
12. Describe the preparation of 2.00 L of 0.100 M glycine buffer, pH 9.0, from glycine and 1.00 M NaOH. What mass of glycine is required and what volume of 1.00 M NaOH is required? The appropriate pK_a of glycine is 9.6.
13. Carbon dioxide is dissolved in blood (pH 7.4) to form a mixture of carbonic acid and bicarbonate. Neglecting free CO_2 , what fraction will be present as carbonic acid? Would you expect a significant amount of carbonate (CO_3^{2-})?
- *14. The efficiency of a buffer in resisting changes in pH upon addition of base or acid is referred to as the *buffer capacity*. One way to define this quantity, which we shall call B , is $B = dx/dpH$, where x is the number of moles of base added to a weak acid. Note that the Henderson-Hasselbalch equation may be written as

$$\text{pH} = \text{p}K_a + \log \frac{x}{A_0 - x}$$

where A_0 is the total concentration of acid.

- (a) Obtain an expression for B , in terms of A_0 and the fraction of acid titrated f , where $f = x/A_0$. [Hint: It is easiest to determine dpH/dx and take the reciprocal.]
- (b) At what value of f is buffer capacity maximal? (The easiest way to determine this is to make a graph of B versus f .)
- (c) What is the maximal value of B ?
- (d) What is the effect of A_0 on B ?
15. What is the molecular basis for the observation that the overall charge on a protein becomes increasingly positive as pH drops and more negative as pH increases?
- *16. The amino acid *arginine* ionizes according to the scheme below:
- (a) Calculate the isoelectric point of arginine. You can neglect contributions from form I. Why?
- (b) Calculate the average charge on arginine when pH = 9.20 (Hint: find the average charge for each ionizable group and sum these together; see Table 2.8 for some guidance).
- (c) Is the value of average charge you calculated in part (b) reasonable, given the pI you calculated in part (a)? Explain your answer.

Citric acid

18. A student is carrying out a biological preparation that requires 1 M NaCl to maintain an ionic strength of 1.0. The student chooses to use 1.0 M ammonium sulfate instead. Why is this a serious error?

Problems 19 and 20 refer to material presented in *Tools of Biochemistry 2A*.

- *19. What is the optimum pH to separate a mixture of lysine, arginine, and cysteine using electrophoresis? Draw the structures of the three amino acids in the protonation state that would predominate at the pH you have chosen. See Table 5.1 on page 138. For each amino acid, indicate the net charge at the chosen pH as well as the direction of migration and relative mobility in the electric field.

20. Suppose you have two genetic variants of a large protein that differ only in that one contains a histidine (side chain $pK_a = 6.4$) when the other has a valine (uncharged side chain).
- (a) Which would be better for separation: gel electrophoresis or isoelectric focusing? Why?
- (b) What pH would you choose for the separation?

TOOLS OF BIOCHEMISTRY 2A

ELECTROPHORESIS AND ISOELECTRIC FOCUSING

General Principles

When an electric field is applied to a solution, solute molecules with a net positive charge migrate toward the cathode, and molecules with a net negative charge move toward the anode. This migration is called **electrophoresis**. The velocity of the molecules depends on two factors. Driving the motion is the force $q\mathcal{E}$ exerted by the electric field on the particle, where q is the molecule's charge (in coulombs) and \mathcal{E} is the electrical field strength (in volts per meter). Resisting the motion is the frictional force $f\nu$ exerted on the particle by the medium, where ν is the velocity of the particle and f is the **frictional coefficient**, which depends on the size and shape of the molecules. Large or asymmetric molecules encounter more frictional resistance than small or compact ones and consequently have larger frictional coefficients.

When the electric field is turned on, the molecule quickly accelerates to a velocity at which these forces balance and then moves steadily at this rate. The steady velocity is determined by the balance of forces:

$$f\nu = q\mathcal{E} \quad (2A.1)$$

We can rewrite this equation as $\nu/\mathcal{E} = q/f$ in order to express the rate of motion per unit of field strength, ν/\mathcal{E} . This ratio is called the **electrophoretic mobility** (μ) of the molecule:

$$\mu = \frac{\nu}{\mathcal{E}} = \frac{q}{f} = \frac{Ze}{f} \quad (2A.2)$$

On the right-hand side of this equation, we have expressed the charge on the molecule as the product of the unit of electron (or proton) charge (e) times the number of unit charges, Z (a positive or negative integer). Because f depends on molecular size and shape, Equation 2A.1 tells us that the mobility of a molecule depends on its charge and on the molecular dimensions.*

Because ions and macroions differ in both respects, their behavior in an electric field provides a powerful way of separating them. Electrophoretic separation is one of the most widely used methods in biochemistry.

Paper Electrophoresis and Gel Electrophoresis

Although electrophoresis can be carried out free in solution, it is more convenient to use some kind of *supporting medium*. The two most commonly used supporting media, paper and gel, are shown in Figures 2A.1 and 2A.2. **Paper electrophoresis** (Figure 2A.1) can be used for separating mixtures of small charged molecules. A piece of filter paper, moistened with a buffer solution to control the pH, is stretched between two electrode vessels. A drop of the mixture to be analyzed is placed on the paper, and the electric current is turned on. After the molecules have migrated for a sufficient time—usually several hours—the paper is removed, dried, and stained with a dye that colors the substances to be examined. Each kind of charged molecule in the mixture will have migrated a certain distance toward either the anode or the cathode, depending on its charge and dimensions, and will show up as a stained spot on the paper at the new position. Usually the spots can be identified by comparison with a set of standards run on the same paper. If the unknown substances are radioactive, the spots can be cut out and their radioactivity measured by scintillation counting (see Tools of Biochemistry 12A).

Gel electrophoresis (Figure 2A.2) is a technique commonly used with proteins and nucleic acids. A gel containing the appropriate buffer solution is cast as a thin slab between glass plates. Common gel-forming materials are polyacrylamide, a water-soluble, cross-linked polymer, and agarose, a polysaccharide. The

FIGURE 2A.1

Paper electrophoresis.

*Equation 2A.2 is actually an approximation, for it neglects effects of the ion atmosphere. See van Holde, Johnson, and Ho (References) for more detail.

FIGURE 2A.2

Gel electrophoresis.

slab is placed between electrode compartments, with the bottom selected as anode or cathode, depending on whether anions or cations are being separated. A small amount of a solution of each sample is carefully pipetted into one of several precast notches, called “wells”, on top of the gel. Usually glycerol and a water-soluble cationic or anionic “tracking” dye (e.g., bromophenol blue) are added to the sample. The glycerol makes the sample solution dense so that it sinks into the well and does not mix into the buffer solution in the upper electrode chamber. The dye migrates faster than most macroions, so the experimenter is able to follow the progress of the experiment. The current is turned on until the tracking dye band is near the bottom of the slab. The gel is then removed from between the glass plates and is usually stained with a dye that binds to proteins or nucleic acids. At this point, a photograph is taken of the gel for a permanent record. Because the protein or nucleic acid mixture was applied as a narrow band at the top of the gel, components migrating with different mobilities appear as narrow bands on the gel, although the bands may be broadened somewhat by diffusion. Certain techniques (see Tools of Biochemistry References) make it possible to sharpen the bands even further so that individual types of macroions appear as narrow lines on the gel; Figure 2A.3 shows an example of separation of DNA fragments by this method. The *relative mobility* of each component is calculated from the distance it has moved relative to the tracking dye.

Principles of Separation in Gel Electrophoresis

When electrophoresis is carried out in a gel or other supporting medium, the mobility is lower than would be expected from Equation 2A.1 because the gel or other matrix exhibits a molecular sieving effect. This can be seen by graphing mobility as a function of the concentration of the gel-forming material (Figure 2A.4a). A graph of $\log \mu$ versus weight-percent gel composition is usually linear; this is called a **Ferguson plot**. The limiting mobility approached as percent gel approaches zero is called the **free mobility**; it should be given (approximately) by

Equation 2A.1. The steepness of the Ferguson plot depends on the size and shape of the macroion, for it reflects the difficulty the macroion experiences in passing through the molecular mesh of the gel.

As a result of these several factors, different kinds of molecules can exhibit widely different behaviors in gel electrophoresis (Figure 2A.4b). However, certain simple cases are of great importance. Polyelectrolytes like DNA or polylysine have one unit charge on each residue, so each molecule has a charge (Ze) proportional to its molecular length. But the frictional coefficient (f) also increases with molecular length, so to a first approximation, a macroion whose charge is proportional to its length has a *free* mobility almost independent of its size. In a mixture of such molecules, the molecular sieving effect determines the relative mobilities at any given gel concentration (Figure 2A.4c), and the

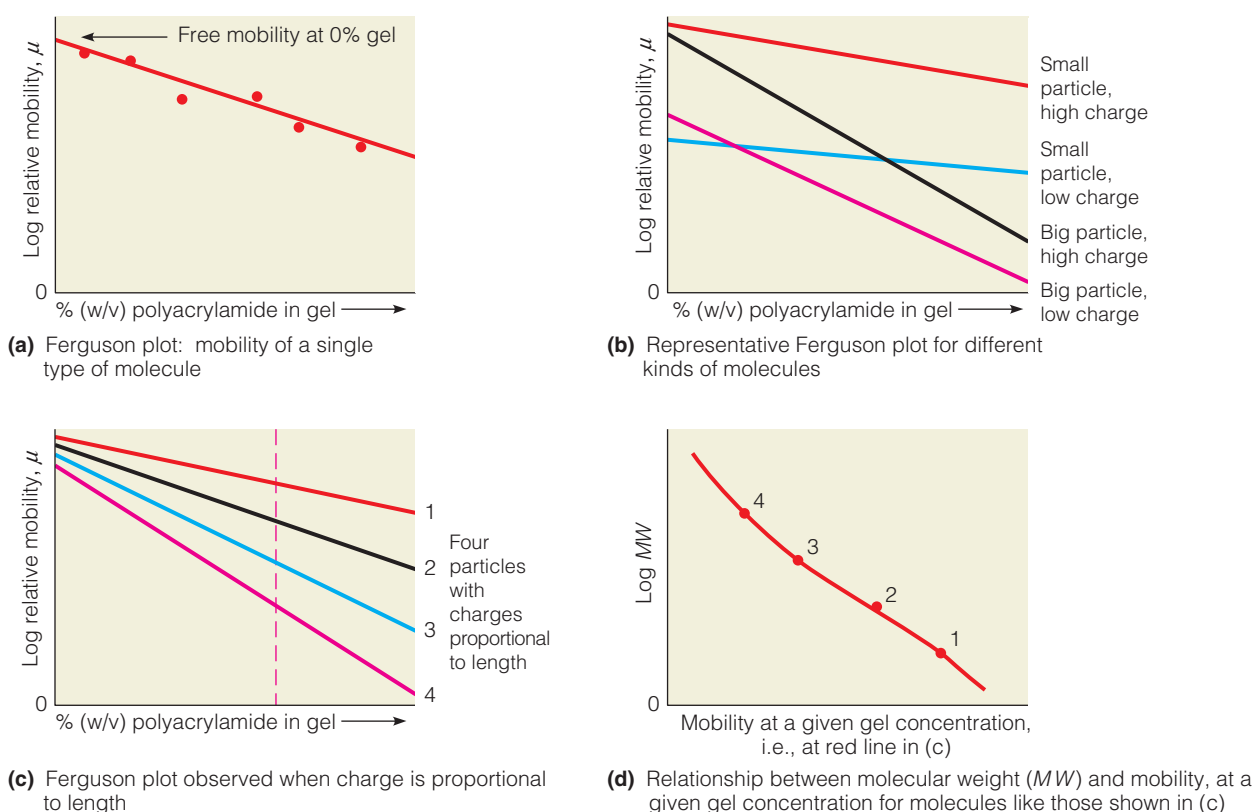

FIGURE 2A.3

Gel showing separation of DNA fragments. Following electrophoretic separation of the different length DNA molecules, the gel is mixed with ethidium bromide, a fluorescent dye that binds DNA (page 1078). The unbound dye is then washed off and the stained DNA molecules are visualized under ultraviolet light.

**FIGURE 2A.4**

Mobility of the particles in gel electrophoresis. The mobility of the particles varies with the concentration of the gel. A Ferguson plot graphs the log of the relative mobility (μ) against the percent gel in the matrix. (a) Ferguson plot for a single type of molecule. Extending the plot to 0% gel gives the theoretical free mobility of the molecule. (b) Ferguson plot for four molecules of different size and charge. Note that free mobilities depend more on charge than on size but the slope depends mainly on size. (c) Ferguson plot for molecules with charges proportional to their lengths. The molecules are numbered in order of increasing length and charge. The free mobilities of such molecules are almost the same, but the longer the molecule, the more it is slowed by increasing gel concentration. (d) Plot of the relationship between molecular weight and mobility. The log of the molecular weight (MW) of the four molecules shown in (c) is plotted against their mobilities at a single gel concentration. When this type of graph is prepared from standards, it can be used to determine the molecular weights of separated molecules.

sieving effect is proportional to molecular length or molecular weight. This means that we can neatly separate molecules of this kind on the basis of *size alone* by gel electrophoresis, as shown in Figure 2A.3. For extended molecules like nucleic acids, the relative mobility is often approximately a linear function of the logarithm of the molecular weight (Figure 2A.4d). Usually, standards of known molecular weight are electrophoresed in one or more lanes on the gel. The molecular weight is then read from a graph like that in Figure 2A.4d prepared from the standards. For proteins, a similar sieving effect is achieved by coating the denatured molecule with the anionic detergent sodium dodecylsulfate (SDS) before electrophoresis. This important technique is discussed further in Tools of Biochemistry 6B.

Isoelectric Focusing

Yet another gel electrophoresis technique allows separation of molecules purely on the basis of their charge characteristics. A polyampholyte will migrate in an electric field like other ions if it has a net positive or negative charge. At its isoelectric point, however, its net charge is zero, and it is attracted to neither the anode nor the cathode. If we use a gel with a stable pH gradient covering a wide pH range, each polyampholyte molecule migrates to the position of its isoelectric point and accumulates there. We can

establish such a gradient by using a mixture of low-molecular-weight ampholytes as the gel buffer. This method of separation, called isoelectric focusing, produces distinct bands of accumulated polyampholytes and can resolve molecules with very small differences in isoelectric point (Figure 2A.5). Because the pH of each portion of the gel is known, isoelectric focusing can also be used to determine the isoelectric point of a particular polyampholyte.

What we have presented here is only a brief overview of a widely applied technique. For further information on gel electrophoresis, consult the references.

Capillary Electrophoresis

The term “capillary electrophoresis” (CE) broadly defines several related techniques that achieve high efficiency separations of ions, including macroions. The techniques all employ narrow-bore capillaries (20–200 μm inner diameter) in which the ions are separated as they migrate from one buffer chamber, past a detector, to a destination buffer chamber (see Figure 2A.6). The equipment required to perform CE is more expensive than, and therefore not as accessible as, that required for gel electrophoresis. In spite of this, for analysis of biomolecules, CE offers many advantages over traditional electrophoresis. The requirement to use low potentials (e.g., 25 V/cm) to avoid heat damage to the sample is a

FIGURE 2A.5

Isoelectric focusing of polyampholytes. A mixture of variants of the polyampholyte hemoglobin is placed on a gel with a pH gradient. When an electric field is applied, each variant protein migrates to its own isoelectric point.

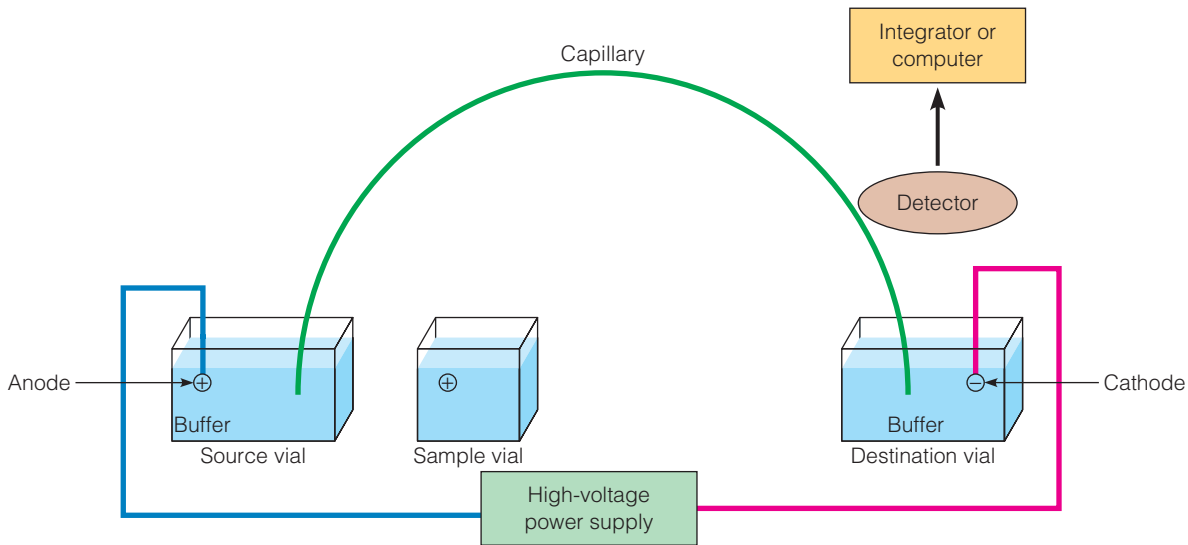

FIGURE 2A.6

A simple capillary electrophoresis experiment. Sample is introduced into the capillary from the sample vial. The capillary end with the sample is then placed in the source vial and high voltage is applied. The sample components will separate as they migrate toward the destination vial.

major limitation to the efficiency of separations achieved by the gel electrophoresis methods described above. Because CE capillaries have a large surface area to volume ratio, heat is efficiently dissipated and much higher potentials can be used (e.g., 500 V/cm). The efficiency of separations is dramatically increased. Analysis times (typically 5–30 minutes) are short, only 10–100 nL of sample is required, and detection is immediate and easily automated. For these reasons, CE has been used as an analytical technique in genomics studies to achieve rapid sequence analysis of large DNA molecules (discussed further in Chapter 4).

The simplest CE experiments use fused silica capillaries filled with an appropriate buffer and the cathode as the destination electrode (see Figure 2A.6). Capillaries with different coatings, as well as gel-filled capillaries, allow for more sophisticated experiments, including isoelectric focusing and SDS polyacrylamide gel CE.

CHAPTER 3

The Energetics of Life

A living cell is a dynamic structure. It grows, it moves, it synthesizes complex macromolecules, and it selectively shuttles substances in and out and between compartments. All of this activity requires energy, so every cell and every organism must obtain energy from its surroundings and expend it as efficiently as possible. Plants gather radiant energy from sunlight; animals use the chemical energy stored in plants or other animals that they consume. The processing of this energy to do the things necessary for a cell or organism to maintain the living state is what much of biochemistry is about. Much of the elegant molecular machinery that exists in every cell is dedicated to this task.

Bioenergetics describes how organisms capture, transform, store, and utilize energy.

Because of the central role of energy in life, it is appropriate that we begin a study of biochemistry with an introduction to **bioenergetics**—the quantitative analysis of how organisms capture, transform, store, and utilize energy. Bioenergetics may be regarded as a special part of the general science of energy transformations, which is called **thermodynamics**. In this chapter we shall review just a bit of that field, focusing attention on fundamental concepts, such as enthalpy, entropy, and free energy, that are important to the biochemist or biologist.

We will introduce in this chapter the basic approaches for determining changes in free energy in biochemical systems. In subsequent chapters these basic approaches will be discussed further in the context of processes such as protein folding, transport of ions across membranes, and extraction of chemical energy from nutrients to make ATP.

Energy, Heat, and Work

A word we shall often use in our discussion is **system**. In this context, a system is any part of the universe that we choose for study. It can be a single bacterial cell, a Petri dish containing nutrient and millions of cells, the whole laboratory in which this dish rests, the earth, or the entire universe. A system must have defined boundaries, but otherwise there are few restrictions. Anything not defined as part of the system

is considered to be the **surroundings**. The system may be *isolated*, and thus unable to exchange energy and matter with its surroundings; it may be *closed*, able to exchange energy but not matter; or it may be *open*, so that both energy and matter can pass between the system and surroundings. For example, our planet displays the essential features of a closed system: Earth can exchange energy (e.g., in the form of electromagnetic radiation) with its surroundings, but except for a few bits of metal (spacecraft and satellites) and some geological samples (meteorites and lunar rocks), material is not exchanged between the planet and its surroundings.

Internal Energy and the State of a System

Any system contains a certain amount of **internal energy**, which we denote by U . It is important for our understanding to be specific as to what this internal energy includes. The system's atoms and molecules have energy of vibration and rotation, and kinetic energy of motion. In addition, we include all of the energy stored in the chemical bonds between atoms and the energy of noncovalent interactions between molecules. We also include any kind of energy that might be changed by chemical or nonnuclear physical processes. We need not include energy stored in the atomic nucleus, for this is unchanged in any chemical or biochemical reaction. The internal energy is a function of the **state** of a system. The thermodynamic state is defined by describing the amounts of all substances present and any two of the following three variables: the temperature (T), the pressure on the system (P), or the volume of the system (V). It is essentially a recipe for producing the system in a defined way. For example, a system composed of 1 mole of O_2 gas in 1 liter at 273 K has a defined state and therefore a definite internal energy value. This value is independent of any past history of the system.

Unless a system is isolated, it can exchange energy with its surroundings and thereby change its internal energy; we define this change as ΔU . For a closed system, this exchange can happen in only two ways. First, **heat** may be transferred to or from the system. Second, the system may do **work** on its surroundings or have work done on it. Work can take many forms. It may include expansion of the system against an external pressure such as expansion of the lungs, electrical work such as that done by a battery or required for the pumping of ions across a membrane, expansion of a surface against surface tension, flexing of a flagellum to propel a protozoan, or lifting of a weight by contraction of a muscle. In all of these examples, a force is exerted against a resistance to produce a displacement, so work is done.

Note that heat and work are not *properties* of the system. They may be thought of as “energy in transit” between the system and its surroundings. Certain conventions have been adopted to describe these ways of exchanging energy:

1. We denote heat by the symbol q . A positive value of q indicates that heat is absorbed by the system from its surroundings. A negative value means that heat flows from the system to its surroundings.
2. We denote work by the symbol w . A positive value of w indicates that work is done by the system on its surroundings. A negative value means that the surroundings do work on the system.

All of this may seem excessively abstract, yet it bears the most direct relationship to the everyday functioning of our bodies. When we ingest a nutrient like glucose, we metabolize it, ultimately oxidizing it to CO_2 and water. A defined energy change (ΔU) is associated with oxidizing a gram of glucose, and some of the released energy is available for our use. We expend a significant portion of this energy as heat (a by-product of mitochondrial metabolism that allows insulated birds and mammals to maintain their normal body temperatures) and the remainder performing various kinds of work. These latter kinds of work include not only the obvious ones, like walking and breathing, but other more subtle kinds—sending impulses along nerves, pumping ions across membranes, and so forth.

The internal energy of a system includes all forms of energy that can be exchanged via simple (nonnuclear) physical processes or chemical reactions.

Energy is conserved. According to the first law of thermodynamics, in a closed system, the internal energy (U) can change only by the exchange of heat or work with the surroundings; however, energy can be converted from one form to another.

FIGURE 3.1

Exchange of heat and work in constant-volume and constant-pressure reactions. A single reaction, oxidation of 1 mole of a fatty acid, is carried out under two sets of conditions. **(a)** The reaction occurs in a sealed vessel, or "bomb." Heat (q) is transferred to the surrounding water bath and is measured by the small increase in temperature of the water. No work is done because the system is at constant volume. **(b)** The reaction vessel is fitted with a piston held at 1 atm pressure. During the reaction, heating of the gas in the vessel causes the piston to be pushed up. However, the reaction results in a decrease in the number of moles of gas, so after the vessel and gas have cooled to the water temperature, the volume of the gas is smaller than the initial volume. Thus, net work is done on the system, and the total amount of heat delivered to the bath is slightly more than in (a).

The First Law of Thermodynamics

Because the internal energy of a closed system can change only by heat or work exchanges with the surroundings, the *change in internal energy* must be given by

$$\Delta U = q - w \quad (3.1)$$

This equation, which holds true for all processes, expresses the **first law of thermodynamics**. This first law is simply a bookkeeping rule, a statement of the conservation of energy. When a physical process or a chemical reaction has occurred, we can total up the incomes and expenditures of energy, and the books must balance. Energy can be gained and released in different ways, but at least in chemical processes, it can neither be created nor destroyed. Consider, for example, some process in which a certain amount of heat is absorbed by a system, while the system does an exactly equivalent amount of work on its surroundings. In this case, both q and w are positive, and $q = w$, so $\Delta U = 0$. This agrees with common sense: If some amount of energy went in as heat and an equal quantity came out as work, then the energy within the system must be unchanged.

Changes in internal energy, as for any function of state, depend only on the initial and final states of a system and are independent of the path; however, the amounts of heat and work exchanged in any process depend very much on the pathway taken between the initial and final states. To make this idea concrete, let us consider a specific chemical reaction—the complete oxidation of 1 mole of a fatty acid, palmitic acid:

The oxidation of palmitic acid is an important biochemical reaction that takes place, in a much more indirect way, in our bodies when we metabolize fats. We shall consider running this reaction in two different ways, as shown in Figure 3.1.

In Figure 3.1a the reaction is carried out by igniting the mixture in a sealed vessel (a “bomb” calorimeter) immersed in a water bath. The reaction, under these conditions, is being carried out at constant volume. We can measure the heat passed from the reaction vessel (the system) to the water bath (the surroundings) by the temperature change in the bath, knowing the mass of water and the heat capacity (per gram) of water. Because the reaction vessel has a fixed volume, no work has been done against the surroundings or by the surroundings; therefore, $w = 0$, and from equation (3.1),

$$\Delta U = q \quad (3.2)$$

The total heat that is transferred from the reaction vessel to the surroundings equals the change in internal energy, and that energy change results mainly from the changes in chemical bonding that occurred during the reaction. The presently accepted unit for heat, work, and energy is the **joule (J)**.^{*} For the above reaction, the value observed for ΔU is -9941.4 kJ/mol . The negative sign indicates that the reaction *releases* energy stored in chemical bonds. The energy within the system *decreased* as this bond energy was transferred as heat to the surroundings.

Now suppose the same reaction is carried out at a constant pressure of 1 atmosphere, as shown in Figure 3.1b. In this case, the system is free to either expand or contract, and it finally contracts by an amount proportional to the decrease in the number of moles of gas, which went from 23 to 16 moles during the reaction. (We neglect the relatively tiny volume of solids and liquids.) The decrease in gas volume means that a certain amount of work has been done by the surroundings on the system. This can be calculated in the following way.

When volume (V) is changed against a constant pressure (P),

$$w = P \Delta V \quad (3.3)$$

To calculate w , we may make an approximation. We assume that the initial and final temperatures of the system are essentially the same (say 25°C , or 298 K) and that the gases are “ideal.” We may then use the ideal gas law, $PV = nRT$. This gives

$$\Delta V = \Delta n \frac{RT}{P} \quad (3.4)$$

where R is the gas constant, T the absolute temperature in kelvin, and Δn the change in number of moles of gas per mole of palmitic acid oxidized. Then, inserting (3.4) in (3.3), we obtain

$$w = \Delta n RT \quad (3.5)$$

Because we would like w in joules per mole, we use $R = 8.315 \text{ J/K} \cdot \text{mol}$ in Equation 3.5, resulting in $w = -17,300 \text{ J/mol}$ (or -17.3 kJ/mol) palmitate.

The heat evolved in this constant-pressure combustion will then be

$$\begin{aligned} q &= \Delta U + w = \Delta U + P \Delta V = \Delta U + \Delta n RT \\ &= (-9941.4 \text{ kJ/mol}) + (-17.3 \text{ kJ/mol}) = -9958.7 \text{ kJ/mol} \end{aligned} \quad (3.6)$$

A slightly greater amount of heat is released to the surroundings under these *constant-pressure* conditions than under the *constant-volume* conditions of

^{*}In the past, biochemists tended to express energy, heat, and work in *calories* or *kilocalories*. However, the International System of Units (SI units) *joules* and *kilojoules* are now replacing these. To convert these units: $1 \text{ cal} = 4.184 \text{ J}$. Similarly, 1 kcal (kilocalorie, or 10^3 calories) $= 4.184 \text{ kJ}$ (kilojoules). A complication arises from the fact that the “calorie” (“C”) referred to in dietetics is really a *kilocalorie*.

The heat evolved in a reaction at constant volume is equal to ΔU .

Figure 3.1a. Under constant-pressure conditions the surroundings can do work on the system and this work (called PV work) reappears as extra heat released from the system to the surroundings (which is required to keep the temperature of the system at a constant value of 298 K).

Although the heat and work exchanged with the surroundings depend on path, it is important to remember that ΔU does not—it depends only on the initial and final states.

Enthalpy

Most chemical reactions in the laboratory and virtually all biochemical processes occur under conditions more nearly approximating constant pressure than constant volume. If we are interested in the heat obtainable by oxidizing palmitic acid in an animal, then the heat evolved at constant pressure is what we want to know. As we showed in Equation 3.6, this heat is not exactly equal to U because of the PV work done; thus, to express the heat change in a constant-pressure reaction, we need another function of state. We define a new quantity, the **enthalpy**, which we give the symbol H :

$$H = U + PV \quad (3.7)$$

Because U and PV are functions of state, H is also a function of state. The change ΔH depends only on the initial and final states of the process for which it is calculated. For reactions at constant pressure, ΔH is defined as follows:

$$\Delta H = \Delta U + P\Delta V \quad (3.8)$$

The value of ΔH is the same as the amount of heat (q) calculated in Equation 3.6. In other words, *when the heat of a reaction is measured at constant pressure, it is ΔH that is determined.*

The energy changes you will find tabulated throughout this book and other books on biochemistry will almost always be given as ΔH values. That is most appropriate, for in vivo these reactions occur under nearly constant-pressure conditions. If a nutritionist wishes to know the energy available from the oxidation of palmitic acid in the body, ΔH is the appropriate quantity.

Measuring changes in energy such as ΔU and ΔH in a calorimeter is of practical use to biochemists and dieticians even though the oxidation of a substance like palmitic acid occurs very differently in the human body than it does in a reaction vessel like that shown in Figure 3.1. The values of ΔU and ΔH for the oxidation of palmitic acid are *exactly* the same in both pathways because a quantity like ΔU or ΔH depends only on the final and initial states. Thus, the calorimeter provides an exact measurement of the energy available to a human from each gram of palmitic acid oxidized completely to CO_2 and H_2O .

The average human requires the expenditure of about 6000 kJ per day (roughly 1500 kcal or 1500 of the “calories” used in dietetics) just to sustain basal metabolic rates. With moderate exercise, this need for metabolic energy may easily double.

Although we have pointed out the distinction between ΔU and ΔH , we should emphasize that for most biochemical reactions the quantitative difference between them is of little consequence. Most of these reactions occur in solution and do not involve the consumption or formation of gases. The volume changes are thus exceedingly small, and $P\Delta V$ is a tiny quantity relative to ΔU or ΔH . Even for the example given, the oxidation of palmitic acid, the difference between ΔH and ΔU is only 0.2%. Thus, we are justified in most cases in thinking of ΔH as a direct measure of the energy change in a process, and we commonly refer to ΔH as the energy change.

The heat evolved in a reaction at constant pressure is equal to the change in enthalpy, ΔH .

The enthalpy change in a reaction is the energy change of most interest to biochemists.

Entropy and the Second Law of Thermodynamics

The Direction of Processes

However useful the first law may be for keeping track of energy changes in processes, it cannot give us one very important piece of information: What is the *favored direction* for a process? The first law cannot answer questions like these:

We place an ice cube in a glass of water at room temperature. It melts. Why doesn't the rest of the water freeze instead?

We place an ice cube in a jar of supercooled water. All the water freezes. Why?

We touch a lit match to a piece of paper. The paper burns to carbon dioxide and water. Why can't we mix carbon dioxide and water to form paper?

One characteristic of such processes is their *irreversibility* under the conditions described above. An ice cube in a glass of room-temperature water at 1 atm will continue to melt—there is no way to turn that process around without major changes in the conditions. But there is a *reversible* way to melt ice—to have it in contact with water at 0 °C and 1 atm. Under these conditions, adding a bit of heat to the glass will result in a small amount of ice melting, whereas removing a little heat will cause a small amount of the water to freeze. A **reversible** process like melting ice at 0 °C is always near a state of **equilibrium**. The defining feature of the equilibrium state is that it is the lowest energy state for a system. As discussed below, lower energy states are favored over those of higher energy; thus, systems tend to adopt states of lower energy. The **irreversible** processes we just described happen when systems are set up far from an equilibrium state. They then drive *toward* a state of equilibrium.

In the jargon of thermodynamics, an irreversible process is often called a “spontaneous” process, but we prefer the word *favorable*. The word *spontaneous* tends to imply, perhaps falsely, that the process is rapid. Thermodynamics has nothing to say about how fast processes will be (this is described by “kinetics”—see Chapter 11), but it does indicate which direction for a process is favored. The *melting* of ice, rather than *freezing*, is favored at 25 °C and 1 atm. Here, the result is intuitive; you would not expect the ice cube to grow, or even remain unmelted, when placed in 25 °C water.

Knowing whether a process is reversible, favorable, or unfavorable is vital to bioenergetics. This information can be expressed most succinctly by the *second law of thermodynamics*, which tells us which processes are thermodynamically favorable. To present the second law, we must consider a new concept—entropy.

Entropy

Why do chemical and physical processes have thermodynamically favored directions? A first guess at an explanation might be that systems simply go toward a lowest-energy state. Water runs downhill, losing energy as it spontaneously falls in the earth's gravitational field; the oxidation of palmitic acid, like the burning of paper, releases energy as heat. Certainly, energy minimization is the key to the favored direction for *some* processes. But such an explanation cannot account for the melting of ice at 25 °C; in fact, energy is *absorbed* in that process. Another, very different factor must be at work, and a simple experiment gives a clear indication of what this factor may be. If we carefully layer pure water on top of a sucrose solution, we will observe as time passes that the solution becomes more and more uniform (Figure 3.2). Eventually the sucrose molecules will be evenly distributed throughout the solution. Though there is practically no energy change, in terms of heat and work, the process is clearly a

Reversible processes occur always near a state of equilibrium; irreversible processes drive toward equilibrium.

FIGURE 3.2

Diffusion as an entropy-driven process. The gradual mixing of a dilute sucrose solution and pure water is the result of random movement of their molecules. We can visualize the increase in entropy if we imagine the volume of the two liquids to be made up of cells, each big enough to hold one sucrose molecule. **(a)** Initially, the sucrose solution is at equilibrium because its N_A molecules are distributed randomly into its N_I cells. **(b)** When a layer of pure water is added without mixing, the system is no longer at equilibrium. It has become more ordered, with all the occupied cells located in one-half of the solution. **(c)** As sucrose and water molecules continue to move randomly, their arrangement becomes less ordered because every cell has an equal chance of being occupied. Eventually, the solution reaches a new equilibrium, with sucrose molecules randomly distributed throughout. The drive toward equilibrium is a consequence of the tendency for entropy to increase. A system would never go spontaneously from state (c) to state (b).

favorable one. We know from experience that the opposite process (self-segregation of the sucrose molecules into a portion of the solution volume) never occurs. What is clearly important here is that *systems of molecules have a natural tendency to randomization*.

The degree of randomness or disorder of a system is measured by a function of state called the **entropy** (S). There are several ways of defining entropy, but the most useful for our applications depends on the fact that a given thermodynamic state may have many *substates* of equal energy. Those substates correspond, for example, to different ways in which molecules can be arranged or distributed within the system (see Figure 3.2). If the thermodynamic state has a number (W) of substates of equal energy, the entropy (S) is defined as

$$S = k_B \ln W \quad (3.9)$$

where k_B is the **Boltzmann constant**, the gas constant R divided by Avogadro's number. A consequence of this definition is that entropy is seen to be a measure of disorder. There will always be many more ways of putting a large number of molecules into a disorderly arrangement than into an orderly one; therefore, the entropy of an ordered state is lower than that of a disordered state of the same system. In fact, the minimal value of entropy (zero) is predicted *only* for a perfect crystal at the absolute zero of temperature (0 K or -273.15°C). The process of diffusion evens out the concentrations in our sucrose solution simply because there are more ways to distribute molecules over a large volume than over a small one. In Figure 3.2 the state shown in panel (c) has more substates of equal energy (i.e., different random arrangements of the sucrose molecules in the cells) than does the state shown in panel (b). We could also say that state (c) has more **degrees of freedom** than state (b); thus, the value of W is greater for state (c). Rotations around bonds increase the degrees of freedom available to a molecule. We will consider the entropy associated with bond rotations when we examine the folding of proteins (Chapter 6). To make the concept of entropy a bit more familiar, consider the examples given in Table 3.1.

The Second Law of Thermodynamics

The preceding example shows that the driving force toward equilibrium for the sucrose solution in Figure 3.2 is just the increase in entropy. This observation can be generalized as the **second law of thermodynamics**. *The entropy of an isolated*

Entropy is a measure of the randomness or disorder in a system.

TABLE 3.1 Examples of low-entropy and high-entropy states

Low Entropy	High Entropy
Ice, at 0°C	Water, at 0°C
A diamond, at 0 K	Carbon vapor, at 1,000,000 K
A protein molecule in its regular, native structure	The same protein molecule in an unfolded, random coil state
A Shakespearean sonnet	A random string of letters
A bank manager's desk	A professor's desk

system will tend to increase to a maximum value. The entropy of such a system will not decrease—sucrose will never “de-diffuse” into a corner of the solution. This simply reflects our commonsense understanding that things, if left alone, will not get more orderly.

Free Energy: The Second Law in Open Systems

The form of the second law as stated in the previous section is not very useful to biologists or biochemists because we never deal with isolated systems. Every biological system (cell, organism, or population, for example) can exchange energy and matter with its environment. Because living systems can exchange energy with their surroundings, both energy *and* entropy changes will take place in many reactions, and both must be of importance in determining the direction of thermodynamically favorable processes. For such systems we need a *function of state that includes both energy and entropy*. There are several such functions, but the one of importance in biochemistry is the **Gibbs free energy** (G) or, as we shall call it, the **free energy**. This function of state combines an enthalpy term, which measures the energy change at constant pressure, and an entropy term, which takes into account the importance of randomization. The Gibbs free energy is defined as

$$G = H - TS \quad (3.10)$$

where T is the absolute temperature measured in kelvin. For a free energy change ΔG in a system at constant temperature and pressure, we can write

$$\Delta G = \Delta H - T\Delta S \quad (3.11)$$

Why is the quantity ΔG called *free* energy? The reason is that ΔG represents the portion of an energy change (ΔH) that is *available*, or *free*, to do **useful work** (that is, work beyond the $P\Delta V$ work of expansion). We can gain an insight into the meaning of free energy by considering the factors that make a process favorable. We said that a decrease in energy (ΔH is negative) and/or an increase in entropy (ΔS is positive) are typical of favorable processes. Either of these conditions will tend to make ΔG negative. In fact, another way to state the second law of thermodynamics—the most important way for our purposes—is this: *The criterion for a favorable process in a nonisolated system, at constant temperature and pressure, is that ΔG be negative.* Conversely, a positive ΔG means that a process is *not favorable*; rather, the *reverse* of that process is favorable.

The importance of quantitating free energy lies in this *predictive* power of ΔG . Given a set of conditions for a process (e.g., temperature, concentrations of reactants and products, pH, etc.), we can calculate the value of ΔG and thereby determine whether or not the process is favorable. Processes accompanied by negative free energy changes are said to be **exergonic**; those for which ΔG is positive are **endergonic**.

Suppose that the ΔH and $T\Delta S$ terms in the free energy equation just balance one another. In this case $\Delta G = 0$, and the process is not favored to go either forward or backward. In fact, the system is at equilibrium. Under these conditions, the process is reversible; that is, it can be displaced in either direction by an infinitesimal push one way or the other. These simple but important rules about free energy changes are summarized in Table 3.2.

An Example of the Interplay of Enthalpy and Entropy: The Transition Between Liquid Water and Ice

To make these ideas more concrete, let us consider in detail a process we mentioned before, the transition between liquid water and ice. This familiar example demonstrates the interplay of enthalpy and entropy in determining the state of a system. In an ice crystal there is a maximum number of hydrogen bonds between the water

The second law of thermodynamics states that the entropy of an isolated system will tend to increase to a maximum value.

The free energy change for a process at constant temperature and pressure is $\Delta G = \Delta H - T\Delta S$.

A thermodynamically favored process tends in the direction that minimizes free energy (results in a negative ΔG); this is one way of stating the second law of thermodynamics.

TABLE 3.2 Free energy rules

If ΔG is ...	The process is ...
Negative	Thermodynamically favorable
Zero	Reversible; at equilibrium
Positive	Thermodynamically unfavorable; the reverse process is favorable

molecules (see Figure 2.10b in Chapter 2). When ice melts, some of these bonds must be broken. The enthalpy difference between ice and water corresponds almost entirely to the energy that must be put into the system to break these hydrogen bonds. As Figure 3.3 shows, the enthalpy change for the transition ice \rightarrow water is positive, as would be expected from the preceding argument.

The entropy change in melting arises primarily because liquid water is a more disordered structure than ice. In an ice crystal, each water molecule has a fixed place in the lattice and binds to its neighbor in the same way as every other water molecule. On the other hand, molecules in liquid water are continually moving, exchanging hydrogen-bond partners as they go (compare Figures 2.10b and 2.10c). Figure 3.3 shows that the entropy change for melting ice to liquid water is a positive quantity, due to the increase in randomness. If we calculate the free energy change ($\Delta G = \Delta H - T\Delta S$) for the ice \rightarrow water transition, we find the following: At low temperatures, ΔH dominates and ΔG is positive. For example, at 263 K (-10°C) we find $\Delta G = +213\text{ J/mol}$. This means that the transition ice \rightarrow water is *not* favorable under these conditions. The opposite transition (water \rightarrow ice) is favorable and therefore irreversible, as we can see from the behavior of supercooled water. If we disturb supercooled water, or add a minute ice crystal to start the process of freezing, the entire sample will freeze. No infinitesimal change we can make will reverse this process.

At a temperature above the melting point of ice, say 283 K ($+10^\circ\text{C}$), an ice cube will irreversibly melt. Again, we would predict this outcome from the data, for if we calculate ΔG at 283 K, we obtain $\Delta G = -225\text{ J/mol}$. The sign of ΔG is now negative because the $T\Delta S$ term dominates when T becomes large enough. At 283 K the process (ice \rightarrow water) is favorable and irreversible.

At the melting temperature, 273 K, the ΔH and $T\Delta S$ terms exactly balance and $\Delta G = 0$. A zero value for ΔG is the condition for equilibrium, and we know that ice and liquid water are in equilibrium at 273 K (0°C). The change is now reversible; when ice and liquid water are together at 273 K, we can melt a bit more ice by adding an infinitesimal amount of heat. Alternatively, we can take a minute amount of heat away from the system and freeze a bit more water. The melting point of a substance is simply the temperature at which the curves for ΔH and $T\Delta S$

FIGURE 3.3

Interplay of enthalpy and entropy in the ice-to-water transition. For the ice-to-water transition, ΔH and ΔS are both positive and approximately constant over a large temperature range. The increase in $T\Delta S$ with increasing temperature means that ΔG decreases from a positive to a negative value. At the melting temperature of ice, 273 K (0°C), the ΔH and $T\Delta S$ curves intersect and ΔG is zero.

intersect; at this temperature, the energetically favored process of freezing is in balance with the entropically favored process of melting. Neither ΔH nor ΔS alone can tell us what will happen, but their combination, expressed as $\Delta H - T\Delta S$, defines exactly which form of water is stable at any temperature.

The Interplay of Enthalpy and Entropy: A Summary

For all chemical and physical processes it is the competition between enthalpy and entropy terms that determines the favorable direction. As Figure 3.4 shows, in some processes the enthalpy change dominates; in others, the entropy change is more important. Furthermore, because ΔS is multiplied by T in Equation 3.11, the favorable direction will depend on the temperature. We have seen one example, the melting of ice, but quite different scenarios are possible depending on the signs of ΔH and ΔS . Table 3.3 lists the possibilities. Note that when ΔH is negative and ΔS is positive, ΔG must always be negative, so the reaction is favorable at all temperatures. The reverse is true when ΔH is positive and ΔS is negative; ΔG is always positive, and the reaction is not favorable at any temperature.

Two matters that frequently cause confusion should be cleared up at this point. First, we must emphasize a point we have mentioned already: The favorability of a process has nothing to do with its rate. Students frequently assume that favorable processes are rapid, but this is not necessarily so. A reaction may have a large negative free energy change but still proceed at a slow rate (for reasons discussed in Chapter 11). A surprising example of this situation is the simple reaction C (diamond) \rightarrow C (graphite). The free energy change for this transformation, at room temperature, is -2.88 kJ/mol; thus, relative to graphite, diamond is unstable. Yet the reaction is imperceptibly slow because it is very difficult for the rigid crystal lattice to change its form. A **catalyst** may increase the rate for some reactions, but the favored direction is always dictated by ΔG and is independent of whether or not the reaction is catalyzed. We will see in Chapter 11 that the protein catalysts called **enzymes** selectively increase the rates for specific *thermodynamically favorable* reactions.

Second, the entropy of an open system can *decrease*. We have just seen that this happens whenever water freezes. More important to biochemists is that decreases in entropy happen all the time in living organisms. An organism takes in nutrients, often in the form of disorganized small molecules, and from them it builds enormous, complex, highly ordered macromolecules like proteins and nucleic acids. From these macromolecules, it constructs elegantly structured cells, tissues, and organs. All of this activity involves a tremendous entropy decrease. The implication of Equation 3.11 is

Favorable processes are not necessarily rapid.

FIGURE 3.4

Contribution of enthalpy and entropy to several favorable processes. Each of these processes has a negative free energy change, but the change is accomplished in different ways. (Note that the arrows in the diagrams are not to scale.) (a) ΔH negative, $-T\Delta S$ negative (because ΔS is positive). When glucose is fermented to ethanol, enthalpy decreases and entropy increases, so both the enthalpy and the entropy changes favor this reaction. (b) ΔH negative, $-T\Delta S$ positive (because ΔS is negative). When ethanol burns, enthalpy and entropy both decrease. The negative ΔH favors this reaction, but the negative ΔS opposes it. (c) ΔH and ΔS both positive. When nitrogen pentoxide decomposes, enthalpy and entropy both increase. The positive ΔH opposes this reaction, but the positive ΔS favors it.

TABLE 3.3 The effect of temperature on ΔG for a process or reaction depends on the signs of ΔH and ΔS .

ΔH	ΔS	Low T	High T
+	+	ΔG positive; not favored	ΔG negative; favored
+	-	ΔG positive; not favored	ΔG positive; not favored
-	+	ΔG negative; favored	ΔG negative; favored
-	-	ΔG negative; favored	ΔG positive; not favored

Life involves a temporary decrease in entropy, paid for by the expenditure of energy.

that entropy can decrease in a favored process, but only if this change is accompanied by a large enthalpy decrease. *Energy must be expended to pay the price of organization.* This exchange really is what life is all about. Living organisms spend energy to overcome entropy. For these life processes to proceed, the *overall* free energy changes in the organism must be negative; thus, life is an irreversible process. An organism that comes to equilibrium with its surroundings is dead.

There is an even deeper philosophical implication of bioenergetics. The universe as a whole is an isolated system. *The entropy of the whole universe must be increasing.* It follows that each of us, as a living organism that locally and temporarily decreases entropy, must produce somewhere in the world around us an increase in entropy. As we metabolize food, for example, we give off heat and increase random molecular motion around us. In a sense, we sustain our lives through the entropic death of the universe.

The folding of proteins is well-described by $\Delta G = \Delta H - T\Delta S$, where ΔH is a measure of the change in bonding interactions and ΔS is a measure of the change in order of the system going from the unfolded state to the folded state.

We will revisit the interplay between enthalpy and entropy in Chapter 6, where protein folding and stability are discussed. The active forms of biomolecules, particularly proteins and RNAs, are generally associated with a well-defined and highly ordered structure. The process whereby a protein goes from an inactive, unstructured (“unfolded”) state to its active, structured (“folded”) state is of central importance in biochemistry and the biotechnology industry. The folding and stability of proteins are related and both are well-described by Equation 3.11, where ΔH is a measure of the change in bonding interactions and ΔS is a measure of the change in order of the system going from one state to the other.

Free Energy and Useful Work

Knowing that ΔG measures the maximum amount of *useful* work that can be obtained from a chemical process is of great importance to biochemistry because useful work includes, for example, the work involved in muscle contraction and cell motility, in transport of ions and molecules, in signal transmission, and in tissue growth.

The free energy change, ΔG , is a measure of the maximum useful work obtainable from any reaction.

Recall that ΔH is the total energy change in a reaction, including the $P\Delta V$ work. The equation $\Delta G = \Delta H - T\Delta S$ indicates that a part of ΔH is always dissipated as heat, as expressed by the $T\Delta S$ term, and is therefore not available to do other things. Whatever the process may be, at least the amount of energy represented by $T\Delta S$ must be unavailable. The remainder, ΔG , is potentially available for other needs, although how much of it is actually used for work depends on the path of the process. The **efficiency** of a biochemical process is defined as the ratio of the work actually accomplished to the theoretical maximum work expected from the change in free energy.

Free Energy and Concentration

The sign of ΔG for a process tells us whether that process, or its reverse, is thermodynamically favorable. The magnitude of ΔG is an indication of how far the process is from equilibrium, and how much useful work may be obtained from it. Clearly, ΔG is a quantity of fundamental importance in determining which processes will or will not occur in a cell, and for what they may be used.

To express these ideas quantitatively we need to answer this question: How does the free energy of a system depend on the concentrations of various components in a mixture? In the next two sections of this chapter we derive an alternative expression for ΔG that allows us to answer that question:

$$\Delta G = \Delta G^\circ + RT \ln Q \quad (3.12)$$

where ΔG° is the **standard free energy change** for a reaction (defined in the next section), R is the gas constant, T is the absolute temperature in kelvin, and Q is the **mass action expression** for the reaction of interest. In essence, Q describes the relative concentrations of the reactants and products. Equation 3.12 allows us to quantify the energy available from a biochemical reaction to do work, and we will use it frequently in the chapters describing metabolic chemistry.

Chemical Potential

The relationship between free energy and the concentrations of components in a mixture can be expressed very simply: If we have a mixture containing a moles of component A, b moles of component B, and so on, we may write

$$G = a\bar{G}_A + b\bar{G}_B + c\bar{G}_C + \dots \quad (3.13)$$

The quantities \bar{G}_A , \bar{G}_B , and so forth are called the **partial molar free energies** or **chemical potentials** of the various components. Each represents the contribution, per mole, of a particular component to the total free energy of the system (in some texts, chemical potential is given the symbol μ). We shall make the approximation, which is usually valid for dilute solutions, that each of the chemical potentials depends only on the concentration of the substance in question. For dilute solutions, \bar{G}_A , \bar{G}_B , etc. turn out to be simple logarithmic functions of the *activities* of the corresponding substance. As described in Chapter 2 (see Equation 2.6a), the **activity** (a) is a dimensionless quantity that measures the effective concentration of a substance, describing its contribution to the free energy of the system. We find

$$\begin{aligned} \bar{G}_A &= G_A^\circ + RT \ln a_A \\ \bar{G}_B &= G_B^\circ + RT \ln a_B \\ &\dots \text{etc.} \end{aligned} \quad (3.14a)$$

For dilute solutions the activity of each solute component can be taken as a number approximately equal to the *molar concentration* of that component. At very low concentration, *activity* and *molar concentration* are numerically the same. This simplifying approximation is satisfactory for almost all biochemical applications. We can then rewrite Equation 3.14a in terms of concentrations:

$$\begin{aligned} \bar{G}_A &= G_A^\circ + RT \ln [A] \\ \bar{G}_B &= G_B^\circ + RT \ln [B] \\ &\dots \text{etc.} \end{aligned} \quad (3.14b)$$

where $[A]$, $[B]$, etc. have (dimensionless) values equal to the molar concentrations of the components. Note what happens when the concentration equals 1 M. The logarithmic term then vanishes (because $\ln 1 = 0$) and, for example, $\bar{G}_A = G_A^\circ$. This shows that G_A° , G_B° , etc. are reference, or standard state, values of the chemical potential. We always express the chemical potentials with respect to a **standard state**. In solutions, the standard state for each *solute* component is 1 M concentration; the standard state for the solvent is pure solvent. In each case, $a = 1$ in the standard state. In the following examples of thermodynamic calculations we will convert concentration terms to activities using the **standard state concentrations** for each component of the system.

The chemical potential of a substance measures the contribution of that substance to the free energy of the system.

The importance of Equations 3.14a-b is that they allow us to apply general thermodynamic principles to practical problems. In particular, they allow us to predict the favored directions for real processes under defined conditions. The calculated value of ΔG , which predicts the favored direction for a biochemical process, is a measure of the difference in free energy between the initial and final states for that process. To calculate the change in any state function (e.g., ΔT , ΔH , ΔS , ΔG , etc.) we subtract the initial value from the final value for that state function; thus, we define ΔG as follows:

$$\Delta G = G_{\text{Final}} - G_{\text{Initial}} \quad (3.15)$$

One biochemical process to which these principles are particularly relevant is diffusion through membranes, a process we shall use as an example here and discuss in much more detail in Chapters 10 and 15.

An Example of How Chemical Potential Is Used: A Close Look at Diffusion Through a Membrane

We know from experience that if a substance can diffuse across a membrane, it will do so in such a direction as to make the concentrations on the two sides equal. Now we will see whether our thermodynamic arguments justify this.

Suppose we have two solutions of substance A separated by a membrane through which A can pass (Figure 3.5). Assume that in region 1 the concentration is initially $[A]_1$ and in region 2 the concentration is $[A]_2$. We must define the direction of transfer for the process to evaluate ΔG . Let us consider transferring some quantity of A from region 1 (the “initial” state of A) to region 2 (the “final” state of A). By the definition of ΔG given in Equation 3.15, the overall free energy change is determined by the difference in molar free energies (or chemical potentials) of A in regions 1 and 2, or

$$\Delta G = G_{A_2} - G_{A_1} \quad (3.16)$$

We expect these molar free energies to be different because the chemical potential for a solute depends on the concentration of that solute (Equation 3.14b). The free energy change for moving A from region 1 to region 2 can be calculated by applying Equations 3.14b and 3.16:

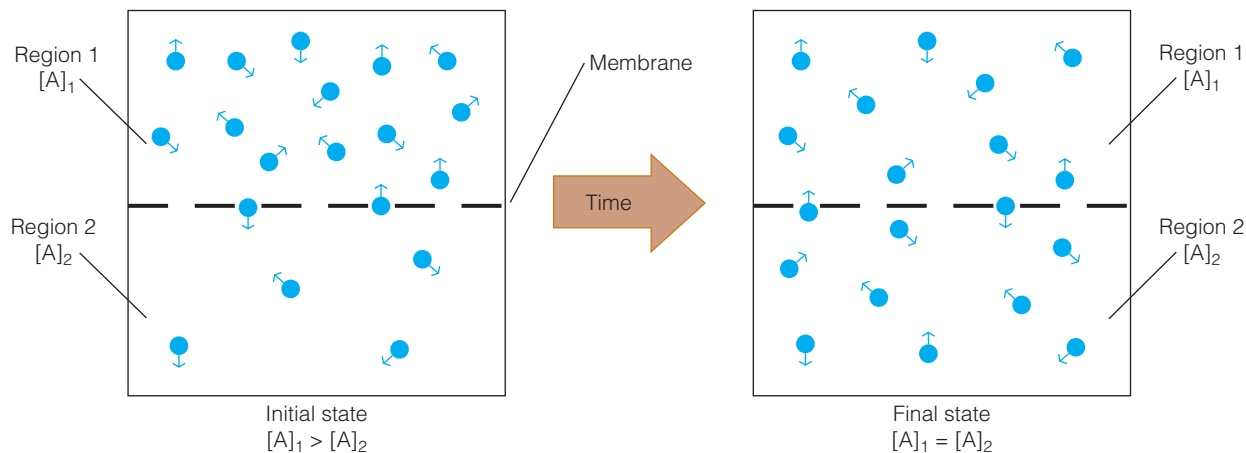

$$G_{A_1} = G_A^\circ + RT \ln[A]_1 \quad (3.17a)$$

$$G_{A_2} = G_A^\circ + RT \ln[A]_2 \quad (3.17b)$$

$$\Delta G = G_{A_2} - G_{A_1} = (G_A^\circ + RT \ln[A]_2) - (G_A^\circ + RT \ln[A]_1) \quad (3.18)$$

FIGURE 3.5

Equilibration across a membrane. Two solutions of A, with concentrations $[A]_1$ and $[A]_2$, are separated by a membrane through which A can pass in either direction. If the initial concentration is higher in region 1, the chemical potential of A will also be higher in that region, and net transport will occur from region 1 to region 2 until equal concentrations (and chemical potentials) are obtained. Blue arrows indicate direction of travel, which is random.

After canceling G_A° terms, Equation 3.18 simplifies to

$$\Delta G = RT \ln \frac{[A]_2}{[A]_1} \quad (3.19)$$

Equation 3.19 predicts the following:

1. If $[A]_2 < [A]_1$, ΔG is negative; thus, transfer from region 1 to region 2 is favorable (this is the situation described in the “initial state” of Figure 3.5).
2. Conversely, for a system where $[A]_2 > [A]_1$, ΔG is positive; thus, transfer from region 1 to region 2 would not be favorable (but transfer in the opposite direction would be favored).
3. If $[A]_2 = [A]_1$, ΔG is zero; thus, there is no net driving force in either direction for the transfer of A. The system is at equilibrium (this is the situation described in the “final state” of Figure 3.5).

From this analysis, we can conclude that if a substance is able to pass through a membrane, the direction of favorable transfer will always be from the region of higher concentration to the region of lower concentration. More generally, we can say that a substance will diffuse from a region where its chemical potential is higher to one where it is lower. Chemical potential plays much the same role for chemical substances that electrical potential does for electrons—it is the driving force. This driving force moves the system from whatever distribution of [A] exists initially, toward the equilibrium state of equal concentrations across the membrane where there is no more driving force because $\Delta G = 0$.

There are cases in which substances pass readily from regions of lower concentration to regions of higher concentration; but, in such circumstances the necessary free energy price is paid by *coupling* the transport process to one or more thermodynamically favorable chemical reactions. Two (or more) reactions are “coupled” when one reaction cannot occur without the other reaction(s) also occurring. We will see throughout this text that the coupling of biochemical reactions is mediated predominantly by enzymes. However, we must show how chemical potential affects ΔG for biochemical reactions before we can explore further the concept of reaction coupling.

Free Energy and Chemical Reactions: Chemical Equilibrium

The Free Energy Change and the Equilibrium Constant

Perhaps the most important use of the chemical potential is to describe quantitatively the free energy changes accompanying chemical reactions under various conditions. We are thereby able to predict the favorable direction for a reaction. Suppose we have a reaction like

Even though the reaction can proceed in either direction, we have written it with C and D on the right, so we call them *products* and A and B *reactants*. We wish to calculate the change in free energy that occurs when a moles of A and b moles of B form c moles of C and d moles of D, each at some given concentration.*

*How do we carry out a reaction while keeping concentrations of both reactants and products constant? Two ways can be imagined. First, the total amounts of reactants and products could be so enormous that reaction of some finite amount of A and B to produce C and D would not appreciably change the concentrations of these species. Alternatively, we could imagine hypothetical processes that would remove products and add reactants so as to keep concentrations unchanged. This often happens in living cells, where the concentrations of metabolites remain within a narrow, nearly constant, concentration range *far from equilibrium values* (this characteristic of the living state is called “homeostasis” and must not be confused with thermodynamic equilibrium).

For any chemical reaction we can equate the reactant state as the “initial state” and the product state as the “final state.” According to Equation 3.15, the free energy change for the reaction must be the free energy of the products minus that of the reactants.

$$\Delta G = G(\text{products}) - G(\text{reactants}) \quad (3.20)$$

By Equation 3.13, we can write these free energies in terms of the chemical potentials of the substances, each multiplied by the number of moles involved. For our example,

$$\Delta G = c\bar{G}_C + d\bar{G}_D - a\bar{G}_A - b\bar{G}_B \quad (3.21)$$

Here we are simply stating that the driving force for the reaction is the total free energy of the products minus that of the reactants.

Now, using Equation 3.14b, we insert the appropriate expressions for \bar{G}_C and so forth in terms of standard concentrations and obtain

$$\Delta G = cG_C^\circ + cRT \ln[C] + dG_D^\circ + dRT \ln[D] - aG_A^\circ - aRT \ln[A] - bG_B^\circ - bRT \ln[B] \quad (3.22a)$$

or

$$\Delta G = cG_C^\circ + dG_D^\circ - aG_A^\circ - bG_B^\circ + RT \ln[C]^c + RT \ln[D]^d - RT \ln[A]^a - RT \ln[B]^b \quad (3.22b)$$

or

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[C]^c [D]^d}{[A]^a [B]^b} \right) \quad (3.23)$$

The free energy change in a chemical reaction depends on the standard state free energy change (ΔG°) and on the activities of reactants and products (described by $RT \ln Q$).

In going from Equation 3.22a to 3.23, we have done two things: grouped the G° terms into ΔG° and made use of rearrangements like: $aRT \ln[A] = RT \ln[A]^a$. The group of G° terms (ΔG°) has a simple meaning; because G° is the free energy per mole of a substance in the standard state (1 M), ΔG° represents the **standard state free energy change** in the reaction. It is the free energy change that would be observed if a moles of A and b moles of B, each at 1 M concentration, formed c moles of C and d moles of D, each at 1 M.

The ratio of products to reactants given inside the parentheses in Equation 3.23 is a *mass action expression*, which can also be represented by the symbol Q :

$$\frac{[C]^c [D]^d}{[A]^a [B]^b} = Q \quad (3.24)$$

If we combine equations 3.23 and 3.24 we get Equation 3.12: $\Delta G = \Delta G^\circ + RT \ln Q$.

The quantity ΔG represents the free energy change when a moles of A (at concentration $[A]$) and b moles of B (at $[B]$) react to produce c moles of C (at $[C]$) and d moles of D (at $[D]$). These concentrations may be anything we want them to be. When all are 1 M, Equation 3.23 reduces to $\Delta G = \Delta G^\circ$. The importance of Equation 3.23 is that it allows us to calculate ΔG under any conditions we wish.

Suppose that the reaction has come to equilibrium. In that case, two things must be true. First, the concentrations in the mass action expression (Equation 3.24) must be equilibrium concentrations. At equilibrium, the factor Q has a value that is identical to the *equilibrium constant* K for the reaction:

$$K = \left(\frac{[C]^c [D]^d}{[A]^a [B]^b} \right)_{\text{eq}} \quad (3.25)$$

Second, if the system is at equilibrium, ΔG must equal zero. In this case, Equation 3.23 reduces to

$$0 = \Delta G^\circ + RT \ln \left(\frac{[C]^c [D]^d}{[A]^a [B]^b} \right)_{\text{eq}} = \Delta G^\circ + RT \ln K \quad (3.26)$$

or

$$-\Delta G^\circ = RT \ln K \quad (3.27)$$

The equilibrium constant K can be calculated from the standard state free energy change ΔG° , and vice versa.

This can be rearranged as

$$K = e^{-\Delta G^\circ/RT} \quad (3.28)$$

Equations 3.27 and 3.28 express an important relationship between the standard free energy change, ΔG° , and the equilibrium constant, K , that we shall use many times. These equations make it possible, for example, to use data from tables of standard state free energy changes to predict equilibrium constants for reactions.

Equation 3.23 may best be thought of in the following way. ΔG° represents a reference value for the free energy change, whereby the intrinsic free energy changes for different reactions can be compared under equivalent circumstances (i.e., 1 M concentrations). The magnitude of this term tells us the equilibrium constant. The (concentration-dependent) $RT \ln Q$ term in Equation 3.23 represents the extra free energy change (+ or -) involved if we were to carry out the reaction at some other, nonequilibrium, set of concentrations. Tabulations of ΔG° values for different reactions are common, but in applying such data to biochemical problems, we must always keep in mind that it is ΔG , as determined by the concentrations of reactants and products found in the cell, rather than ΔG° that determines whether or not a reaction is favorable *in vivo*.

Free Energy Calculations: A Biochemical Example

To illustrate the application of these somewhat abstract ideas, let us consider an example—a very simple but important biochemical reaction, the isomerization of glucose-6-phosphate (G6P) to fructose-6-phosphate (F6P) shown in Figure 3.6:

which may be written more compactly as

This is the second step in the **glycolytic pathway**, which is discussed in Chapter 13. The reaction is clearly endergonic under standard conditions. In other words, the system is not at equilibrium when G6P and F6P are both at 1 M because ΔG° is positive (+1.7 kJ/mol) and the reverse reaction is favored under standard conditions. Therefore, the equilibrium must lie to the left, with a higher concentration of G6P than F6P. We can express this quantitatively by calculating the equilibrium constant using Equation 3.28. Using the given value for ΔG° and assuming a temperature of 25 °C (298 K), we obtain:

$$K = e^{\left(\frac{-\Delta G^\circ}{RT}\right)} = e^{\left(\frac{-\left(\frac{1700 \text{ J}}{\text{mol}}\right)}{\left(\frac{8.315 \text{ J}}{\text{mol}\cdot\text{K}}\right)(298 \text{ K})}\right)} = 0.504 = \left(\frac{[\text{F6P}]}{[\text{G6P}]}\right)_{\text{eq}} \quad (3.29)$$

where $([\text{F6P}]/[\text{G6P}])_{\text{eq}}$ is the equilibrium ratio of the concentration of fructose-6-phosphate to that of glucose-6-phosphate. The fact that $K < 1$ shows that the equilibrium lies to the left, or favors the reactants (in this case, G6P).

Living Cells Are Not at Equilibrium

The concentrations of metabolites for any process in *living* cells are not typically the equilibrium concentrations defined by ΔG° for that process. The state of chemical equilibrium is characteristic of dead cells, not living ones. As stated at the beginning of this chapter, characteristics of the living state include the capture, transformation, storage, and utilization of energy (all of which are discussed in great detail in the following chapters of this textbook). Such processes can only occur when $\Delta G < 0$. In other words, a living organism is not at equilibrium.

Life occurs within relatively narrow ranges of temperature, pH, and concentrations for ions and metabolites. This set of conditions is referred to as **homeostasis** or the **homeostatic condition**. Because the concentrations of certain solutes inside cells remain relatively constant, homeostasis is frequently confused

It is ΔG , as determined by the actual concentrations of reactants and products in the cell, rather than ΔG° that determines whether or not a reaction is favorable *in vivo*.

FIGURE 3.6

Isomerization of glucose-6-phosphate (G6P) to fructose-6-phosphate (F6P).

The homeostatic condition, which is characteristic of living cells, must not be confused with true thermodynamic equilibrium.

with true thermodynamic equilibrium; however, *homeostasis must not be confused with equilibrium!* The critical distinction between the two is that under homeostatic conditions, ΔG for numerous vital processes is < 0 , whereas, at equilibrium, ΔG for any process = 0. In addition, energy is required to maintain homeostasis; hence, the need to capture, transform, and store energy.

We know from Le Chatelier's principle that any system that is not at equilibrium has a driving force ($\Delta G < 0$) to move in the direction that re-establishes the equilibrium state. We can understand the magnitude of these driving forces by comparing equilibrium and nonequilibrium systems. For the reaction

at equilibrium, Le Chatelier's principle predicts that a perturbation of the equilibrium by increasing the concentration of *either* reactant, [A] or [B], would result in an increase in the concentrations of *both* products, [C] and [D], as the system moves back to the equilibrium state. Likewise, if the equilibrium was perturbed by an increase in either [C] or [D], the system would respond by increasing [A] and [B]. We can understand the basis of Le Chatelier's principle using the thermodynamic arguments developed above. Let us reconsider Equation 3.12:

$$\Delta G = \Delta G^\circ + RT \ln Q$$

and substitute $-RT \ln K$ for ΔG° (Equation 3.27) to give:

$$\Delta G = -RT \ln K + RT \ln Q \quad (3.30)$$

For a system at equilibrium $Q = K$, thus

$$\Delta G = -RT \ln K + RT \ln K = 0 \quad (3.31)$$

Because $\Delta G = 0$, there is no driving force in either direction. On the other hand, for a system that is not at equilibrium $Q \neq K$, thus

$$\Delta G = -RT \ln K + RT \ln Q \neq 0 \quad (3.32)$$

In this case, $\Delta G \neq 0$, or, there is a driving force for the reaction, which Le Chatelier predicts will favor the direction that re-establishes equilibrium. We can predict which direction, toward reactants or toward products, will be favored by considering the relative values of K and Q . This is most easily seen if we rearrange Equation 3.30:

$$\Delta G = RT(\ln Q - \ln K) = RT \ln \left(\frac{Q}{K} \right) \quad (3.33)$$

Equation 3.33 predicts that a reaction will proceed as written whenever the ratio $Q/K < 1$ (see Table 3.4). We can imagine two ways that a living cell could maintain $Q/K < 1$. The first is by consuming products as fast as they are formed, such that the homeostatic concentrations of the products are relatively low compared to the reactant concentrations. This is a common strategy employed in multistep metabolic pathways. For example, for the hypothetical pathway

B is the "product" of the first step; but it is also the "reactant" for the second step. The concentration of B in the cell will be low if B is rapidly converted to C. By Le Chatelier's principle, the reaction $A \rightarrow B$ will be driven to the right as a result of removing B from the system. The second way to maintain $Q/K < 1$ is by keeping the concentrations of the "reactant" species relatively high. Again, Le Chatelier's principle predicts that as [A] increases there is a greater tendency to drive the reaction $A \rightarrow B$ to the right. The magnitude and sign of that driving force is succinctly expressed as ΔG and can be readily calculated using Equation 3.23.

In summary, we have described how thermodynamically favored (irreversible) processes are related to equilibrium. Whenever a system is displaced from equilibrium, it will proceed in the direction that moves toward the equilibrium state because the direction leading toward equilibrium will have a $\Delta G < 0$. Because living

TABLE 3.4 Relationships between K , Q , and ΔG for a reaction

Value of Q	Value of ΔG	Favored direction
$< K$	< 0	Forward reaction (formation of products)
$= K$	$= 0$	Neither (system at equilibrium)
$> K$	> 0	Reverse reaction (formation of reactants)

cells are not at equilibrium, most cellular reactions are driven to proceed in either the forward or reverse direction.

We are now prepared to answer a question of fundamental importance in bioenergetics: “How are unfavorable reactions driven forward in living cells?” Thermodynamically unfavorable reactions can be driven by either, or both, of the following strategies:

1. Maintaining $Q < K$
2. Coupling an unfavorable reaction to a highly favorable reaction

The theoretical basis for strategy #1 has been described above. In the following sections we will describe the basis for strategy #2. In later chapters we will illustrate the implementation of these strategies in numerous biochemical reactions. We will see that highly favorable processes such as ion transport across membranes and hydrolysis of **adenosine triphosphate (ATP)** are commonly used to drive unfavorable reactions. The processes of ATP consumption and ATP production feature prominently in biochemistry; thus, we will introduce here the features of ATP (and similar compounds) that make it suitable as the central energy-transduction molecule in cells.

Thermodynamically unfavorable reactions become favorable when $Q < K$, and/or when coupled to strongly favorable (i.e., highly exergonic) reactions.

High-Energy Phosphate Compounds: Free Energy Sources in Biological Systems

Understanding the central role of free energy changes in determining the favorable directions for chemical reactions is of great importance in the study of biochemistry because every biochemical process (e.g., protein folding, metabolic reactions, DNA replication, muscle contraction) must, overall, be a thermodynamically favorable process. Very often, a particular reaction or process that is necessary for life is in itself endergonic. As stated above, such intrinsically unfavorable processes can be made thermodynamically favorable by *coupling* them to strongly favorable reactions. Suppose, for example, we have a reaction that is part of an essential pathway but is endergonic:

At the same time, suppose another process is highly exergonic:

If the cell can manage to *couple* these two reactions, the ΔG° for the overall process will be the algebraic sum of the values of ΔG° for the individual reactions:

Equilibrium for the overall process now lies far to the right; the consequence is that B is now more favorably produced from A.

Coupling of endergonic reactions or processes to exergonic reactions is used not only to drive countless reactions but also to transport materials across membranes, transmit nerve impulses, contract muscles, and carry out other physical changes.

High-Energy Phosphate Compounds as Energy Transducers

Driving an unfavorable process by coupling it to a favorable one requires the availability in cells of compounds (like the hypothetical C in our previous example) that can undergo reactions with large negative free energy changes. Such substances can be thought of as energy transducers in the cell. The most important of these high-energy compounds are certain phosphates, which can undergo hydrolytic release of their phosphate groups in aqueous solution. A number of such compounds and their hydrolysis reactions are shown in Figure 3.7 and Table 3.5. You will encounter

“High-energy” phosphate compounds have very large negative free energies of hydrolysis.

FIGURE 3.7

Hydrolysis reactions for some biochemically important phosphate compounds. The labile phosphate group of each compound is shown in yellow. The more stable reaction product P_i is in gray. A scale of phosphate transfer potential (see text) is shown to the right.

TABLE 3.5 $\Delta G^{\circ'}$ for hydrolysis of some phosphate compounds

Hydrolysis reaction	$\Delta G^{\circ'}$ (kJ/mol)	pH	[Mg ²⁺]
Phosphoenolpyruvate + H ₂ O \longrightarrow pyruvate + P _i	-61.9	7	NS
1,3-Bisphosphoglycerate + H ₂ O \longrightarrow 3-phosphoglycerate + P _i + H ⁺	-49.4	7	NS
Acetyl phosphate + H ₂ O \longrightarrow acetate + P _i + H ⁺	-43.1	7	NS
Creatine phosphate + H ₂ O \longrightarrow creatine + P _i	-43.1	7	NS
ATP + H ₂ O \longrightarrow AMP + PP _i + H ⁺	-45.6	7	NS
ATP + H ₂ O \longrightarrow ADP + P _i + H ⁺	-30.5	7	excess
PP _i + H ₂ O \longrightarrow 2P _i + H ⁺	-33.5	NS	NS
PP _i + H ₂ O \longrightarrow 2P _i + H ⁺	-18.8	NS	0.005
PP _i + H ₂ O \longrightarrow 2P _i + H ⁺	-19.2	7	0.001
Glucose-1-phosphate + H ₂ O \longrightarrow glucose + P _i	-20.9	NS	NS
Glucose-6-phosphate + H ₂ O \longrightarrow glucose + P _i	-13.8	NS	NS

NS = not specified.

W. P. Jencks (1976) Free energies of hydrolysis and decarboxylation in *Handbook of Biochemistry and Molecular Biology*, 3rd ed., G. Fasman ed., CRC Press, Boca Raton, FL.

P. Frey and A. Arabshahi (1995) Standard free energy change for the hydrolysis of the α , β -phosphoanhydride bridge in ATP. *Biochemistry* 34:11307–11310.

all of these important substances in later chapters on metabolism. Some of these substances, like ATP, **phosphoenolpyruvate (PEP)**, **creatine phosphate (CP)**, and **1,3-bisphosphoglycerate (1,3-BPG)**, have large negative standard free energies of hydrolysis. ATP is perhaps the most important of these compounds, and the one you will encounter most often in this book. The structure and hydrolysis reactions of ATP are shown in Figure 3.8. Hydrolysis of ATP to ADP is highly exergonic, with $\Delta G^{\circ'} = -30.5$ kJ/mol (see page 79 for the definition of $\Delta G^{\circ'}$). This value corresponds to an equilibrium constant greater than 10^5 . Such an equilibrium lies so far to the right that ATP hydrolysis can be considered essentially irreversible.

Figure 3.7 also shows that whereas some of these phosphate hydrolysis reactions are truly highly exergonic processes, others are not. For example, hydrolysis of phosphoanhydride (as in ATP, ADP, and pyrophosphate) and mixed anhydride (1,3-BPG) bonds is much more exergonic than is hydrolysis of phosphate esters (AMP, glycerol-1-phosphate). A variety of factors can explain these differences. Those that seem to be most important are described next.

Resonance Stabilization of the Phosphate Products

The **orthophosphate** ion (HPO₄²⁻), which is often abbreviated as **P_i** (inorganic phosphate), is capable of a wide variety of resonance forms. Both the bound proton and the oxygen bonding should be thought of as delocalized, so a more appropriate way to write the structure is as shown in Figure 3.9. The multiple forms, which are of equal energy, contribute to the high entropy of such a resonance structure (see Equation 3.9). Not all of these forms are possible when the phosphate is bound in an ester. Consequently, release of the orthophosphate results in an entropy increase in the system and is therefore favored. Resonance stabilization applies in *all* of the phosphate hydrolysis reactions described in Figure 3.7.

Additional Hydration of the Hydrolysis Products

Release of the phosphate residue from its bonded state allows greater opportunities for hydration, especially when both products are charged. Recall from

FIGURE 3.8

The ATP molecule and its hydrolysis reactions. Throughout this book P represents the tetrahedral orthophosphate group. Hydrolysis of ATP or ADP cleaves a phosphoanhydride bond, whereas hydrolysis of AMP cleaves a phosphate ester bond.

**(a)** Structures of phosphate ion contributing to resonance stabilization**(b)** Hybrid atomic orbitals of tetrahedral phosphate ion**FIGURE 3.9**

Resonance stabilization of orthophosphate, HPO_4^{2-} (P_i). The delocalization of the charge of the orthophosphate ion is depicted here in two ways. **(a)** In this depiction, the four resonance forms of the phosphate ion are shown with the H^+ not assigned permanently to any one of the four oxygen atoms. **(b)** This depiction shows the physical significance of the delocalized $\text{P}=\text{O}$ double bond: the phosphate ion is a tetrahedral structure with four equivalent phosphorus–oxygen bonds.

Chapter 2 that ions are highly hydrated in aqueous solution and that such hydration is an energetically favored state.

Electrostatic Repulsion Between Charged Products

In the hydrolysis of phosphoenolpyruvate, 1,3-bisphosphoglycerate, adenosine triphosphate, and pyrophosphate, both products of hydrolysis carry a negative charge. The repulsion between these ionic products strongly favors the hydrolysis reaction.

Tautomerization of Product Molecules

ΔG° for the hydrolysis of phosphoenol pyruvate, -61.9 kJ/mol, is significantly more favorable than one would predict for the hydrolysis of a simple phosphate ester (e.g., compare to $\Delta G^{\circ}_{\text{hydrolysis}} = -13.8$ kJ/mol for AMP). The explanation for this unexpected reactivity of PEP lies in the structural isomerization, in this case called “tautomerization,” of the pyruvate product that occurs following the release of P_i from PEP. The direct product of phosphate hydrolysis from PEP is the *enol* form of pyruvate, which rapidly tautomerizes to the thermodynamically favored *keto* form:

The equilibrium for this tautomerization lies far toward the keto form ($K_{\text{eq}} \approx 6 \times 10^7$); thus, it is this essentially irreversible isomerization reaction that provides most of the driving force for the overall hydrolysis of PEP to pyruvate and P_i .

Water, Protons in Buffered Solutions, and the “Biochemical Standard State”

In some of the reactions listed in Figure 3.7, a proton is released. Therefore, the hydrogen ion concentration (i.e., the pH) will affect ΔG for the reaction. For the hydrolysis of ATP to ADP:

we can calculate ΔG for the reaction using Equation 3.23:

$$\Delta G = \Delta G^\circ + RT \ln \left(\frac{[\text{ADP}][P_i][\text{H}^+]}{[\text{ATP}][\text{H}_2\text{O}]} \right) \quad (3.34)$$

Because biochemical reactions typically occur in a relatively dilute aqueous solution, buffered near pH 7, it is appropriate to treat the chemical potentials of H_2O and H^+ differently than is done for thermodynamic calculations based on the standard state conditions described previously. In a dilute solution, the activity of the solvent (water) is not significantly changed by reactions that consume or produce H_2O ; thus, for the “biochemical standard state” the *activity* of water is defined as “unity.” For chemical reactions the standard state for solutes is defined as 1 M; however, in living cells the concentration of H^+ is roughly 10^{-7} M, much lower than the standard value of 1 M. It is therefore appropriate to define the chemical potential of H^+ in biochemical reactions relative to the H^+ concentration found in the living state (i.e., 10^{-7} M), rather than the value 1 M defined by the chemical standard state. Recall that when a solute in a dilute solution has a concentration of 1 M, the activity of that solute is unity. For the *biochemical standard state* we define the activity of H^+ to be unity when $[\text{H}^+] = 10^{-7}$ M. We distinguish values of ΔG° that are referenced to the chemical standard state from those referenced to the biochemical standard state by a *superscript prime*: $\Delta G^{\circ'}$. If we assume the activity of $\text{H}_2\text{O} = 1$ and we calculate the activities of the other solutes[†] relative to their

Standard free energy changes for biochemical reactions are defined by $\Delta G^{\circ'}$, where the water concentration is assumed to be constant (thus, the activity of water is defined as unity), and the activity of H^+ is defined as unity when pH = 7.0.

[†]Recall that in the derivation of Equation 3.14a we made the simplifying assumption that the activities of solutes in dilute solutions are not significantly different from the values of molar concentration for each solute. This is not rigorously true; but, it is a common assumption in biochemistry, where the concentrations of solutes are typically well below 1 M. For many reactions described in this text the assumption that activity \cong molar concentration will hold; but, students should be aware that a rigorous calculation of chemical potential requires the use of a more sophisticated definition of activity.

biochemical standard state concentrations, Equation 3.34 can be written as follows:

$$\Delta G = \Delta G^{\circ'} + RT \ln \left(\frac{\frac{[\text{ADP}]}{(1 \text{ M})} \frac{[\text{P}_i]}{(1 \text{ M})} \frac{[\text{H}^+]}{(10^{-7} \text{ M})}}{\frac{[\text{ATP}]}{(1 \text{ M})} (1)} \right) \quad (3.35)$$

In this example Equation 3.35 does not include other factors, such as Mg^{2+} concentration and ionic strength, that can affect significantly the value of ΔG for ATP hydrolysis (as well as many other biochemical reactions; see Table 3.5). In principle, temperature, Mg^{2+} concentration, and ionic strength (“ I ”) must also be specified for a given value of $\Delta G^{\circ'}$. For our purposes it will be sufficient to define the biochemical standard state more simply (i.e., $\text{pH} = 7.0$ and the activity of $\text{H}_2\text{O} = 1$); however, the International Union of Pure and Applied Chemistry has recommended the following set of conditions as a standard for the study of biochemical reactions under approximately “physiological conditions”: Temperature = 37°C (310.15 K), $\text{pH} = 7.0$, $[\text{Mg}^{2+}] = 0.001 \text{ M}$, and $I = 0.25 \text{ M}$.

Equation 3.35 illustrates two key points regarding the calculation of ΔG for the reactions you will encounter throughout this text:

1. $\Delta G^{\circ'}$ is used, signifying the biochemical standard state.
2. The mass action expression Q is unitless. We can strip the units for each concentration term in Q by dividing each term by its proper standard concentration (e.g., 1 M for all solutes except H^+ ; 10^{-7} M for H^+ ; 1 bar for gases, etc.)

The significance of these two points is illustrated in the following example. Let us calculate ΔG for the hydrolysis of ATP at $\text{pH} 7.4$, 25°C , where the concentrations of ATP, ADP, and P_i are, respectively, 5 mM, 0.1 mM, and 35 mM. Under these conditions Equation 3.34 becomes

$$\Delta G = -30.5 \frac{\text{kJ}}{\text{mol}} + \left(0.008315 \frac{\text{kJ}}{\text{mol} \cdot \text{K}} \right) (298 \text{ K}) \ln \left(\frac{\frac{(0.0001 \text{ M})}{(1 \text{ M})} \frac{(0.035 \text{ M})}{(1 \text{ M})} \frac{(10^{-7.4} \text{ M})}{(10^{-7} \text{ M})}}{\frac{(0.005 \text{ M})}{(1 \text{ M})} (1)} \right) \quad (3.36a)$$

or

$$\Delta G = -30.5 \frac{\text{kJ}}{\text{mol}} + \left(2.478 \frac{\text{kJ}}{\text{mol}} \right) \ln \left(\frac{(0.0001)(0.035)(0.398)}{(0.005)} \right) \quad (3.36b)$$

$$\Delta G = -30.5 \frac{\text{kJ}}{\text{mol}} + -20.3 \frac{\text{kJ}}{\text{mol}} = -50.8 \frac{\text{kJ}}{\text{mol}} \quad (3.36c)$$

Note that in Equation 3.36b, the Q term has no units. In addition, the value calculated for ΔG is much more negative (i.e., more favorable) than the standard free energy change $\Delta G^{\circ'}$. This last point underscores the fact that $\Delta G^{\circ'}$ alone is not always a reliable predictor of reaction favorability *in vivo*.

Ultimately it is ΔG and not $\Delta G^{\circ'}$ that determines the driving force for a reaction; however, to evaluate ΔG using Equation 3.23 we must be given, or be able to calculate, $\Delta G^{\circ'}$ for the reaction of interest. Recall that $\Delta G^{\circ'}$ is easily calculated from K_{eq} using Equation 3.27. In the remaining pages of this chapter we will use examples relevant to biochemistry to illustrate two alternative methods for calculating $\Delta G^{\circ'}$.

Phosphate Transfer Potential

There is another useful way in which we can think about the $\Delta G^{\circ'}$ values for hydrolysis of phosphate compounds. As Figure 3.7 shows, these values form a scale of **phosphate transfer potentials**. The potential is defined simply as $-\Delta G^{\circ'}$

The phosphate transfer potential shows which compounds can phosphorylate others under standard conditions.

of hydrolysis; thus, of the compounds listed in Table 3.5, PEP has the highest phosphate transfer potential (61.9 kJ/mol) and glycerol-1-phosphate has the lowest (9.2 kJ/mol). Each compound is capable of driving the phosphorylation of compounds lower on the scale, provided that a suitable coupling mechanism is available. Consider, for example, the following reactions:

Thus, PEP, which has a greater phosphate transfer potential than ATP, is capable of adding a phosphate group to ADP in a thermodynamically favored process. ATP, in turn, can phosphorylate glucose because the phosphate transfer potential of glucose-6-phosphate (G-6-P) lies still farther down the scale:

These examples emphasize how ATP can act as a versatile phosphate transfer agent through coupled reactions. In each case, the coupling is accomplished by having the reactions take place on the surface of a large protein molecule (i.e., an *enzyme*). We shall discuss in Chapter 11 how enzymes both facilitate such coupling and accelerate reactions.

The examples above also show how $\Delta G^{\circ'}$ can be calculated for a reaction of interest by summing the $\Delta G^{\circ'}$ values for two (or more) reactions that, when added together, yield an overall chemical equation that is *identical* to the reaction of interest. Note that when the chemical equation for a reaction is reversed, the sign of $\Delta G^{\circ'}$ is also reversed. For more practice with the calculation of $\Delta G^{\circ'}$ by this method, see Problem 17b at the end of this chapter. Finally, we consider the calculation of $\Delta G^{\circ'}$ for the important class of oxidation/reduction reactions.

$\Delta G^{\circ'}$ for Oxidation/Reduction Reactions

The oxidation of nutrients such as carbohydrates or fats provides cells with substantial free energy for the synthesis of ATP. As we shall see in Chapter 15, the transfer of electrons from nutrients to O_2 releases energy that is stored in the form of a proton gradient across a membrane that, in turn, provides the driving force for the synthesis of ATP in mitochondria. The electron transfer occurs via a series of linked oxidations and reductions, or “redox” reactions. To understand the processes by which metabolic energy is extracted from nutrients, one must understand how to calculate the free energy available from a redox reaction.

Quantitation of Reducing Power: Standard Reduction Potential

Redox chemistry is comparable in many ways to acid–base chemistry, which we discussed in Chapter 2. In an acid–base equilibrium we have an acid (HA) and its conjugate base (A^-), which represent a proton donor and a proton acceptor, respectively.

Similarly, in a redox reaction we have a donor and acceptor of *electrons*.

Free protons and free electrons exist at negligible concentrations in aqueous media, so these equilibrium expressions are merely half-reactions in an overall acid–base or redox reaction scheme. A complete redox reaction must show one reactant as an electron acceptor, which becomes reduced by gaining electrons, and another reactant as an electron donor, which becomes oxidized by losing electrons. One well-known mnemonic for the definitions of **reduction** and **oxidation** is “OIL-RIG”: **O**xidation **I**s **L**oss (of electrons); **R**eduction **I**s **G**ain (of electrons). Of the two reactants in a redox reaction, the electron donor is the **reductant** (or **reducing agent**), which becomes oxidized while transferring electrons to the other reactant, the **oxidant** (or **oxidizing agent**). The general form of a redox reaction is then:

Cu^{1+} is the reductant in this reaction because it is the electron donor. The reductant is thus analogous to the acid in an acid–base equilibrium.

Critical to our understanding of acid–base chemistry is the concept of $\text{p}K_a$, which represents a quantitative measure of the tendency of an acid to lose a proton. In the same sense, our understanding of biological oxidations demands a comparable measure of the tendency of a reductant to lose electrons (or of an oxidant to gain electrons). Such an index is provided by the **standard reduction potential**, or E^0 . In acid–base equilibria we arbitrarily define water, with a $\text{p}K_a$ of 7.0, as neutral. Redox chemistry also employs a reference standard, namely, the *standard hydrogen electrode* in an electrochemical cell.

An electrochemical cell consists of two **half-cells**, each containing an electron donor and its conjugate acceptor (see margin). In the diagram the left-hand beaker constitutes the reference half-cell, a standard hydrogen electrode, with H^+ at 1 M and H_2 at 1 bar (the standard unit of pressure, which is equal to 100 kPa, or ~ 750 torr). The right-hand beaker contains the test half-cell, with the solution containing the test electron donor and its conjugate acceptor, each at 1 M concentration. In this example, the solution contains Fe^{2+} and Fe^{3+} , each at 1 M. The half-cells are connected with an agar salt bridge, which maintains charge neutrality by allowing ions to flow between the cells as electrons move through the completed circuit. A galvanometer placed between the two half-cells measures the **electromotive force**, or **emf**, in volts. Electromotive force is a measure of the potential, or “pressure,” for electrons to flow from one half-cell to the other. The electrons may flow either toward or away from the reference half-cell, depending on whether H_2 or the test electron donor has the greater tendency to lose electrons. Because H_2 loses electrons more readily than Fe^{2+} , the electrons in our example will flow from the reference half-cell to the test half-cell, oxidizing H_2 , reducing Fe^{3+} , and causing the galvanometer to record a positive emf. If the test electron donor loses electrons more readily than H_2 , then electrons flow in the reverse direction, reducing H^+ to H_2 in the reference half-cell and causing a negative emf to be recorded. The stronger oxidant, whether H^+ or the test electron acceptor, will draw electrons away from the other half-cell and become reduced.

By convention, E^0 for the standard hydrogen electrode is set at 0.00 volts. Any redox couple that tends to donate electrons to the standard hydrogen electrode has a negative value of E^0 . A positive E^0 means that electrons from H_2 are flowing toward the test cell and reducing the electron acceptor, or, that the test cell acceptor is oxidizing H_2 . *The higher the value of E^0 for a redox couple, the stronger an oxidant is the electron acceptor of that couple.*

As discussed earlier, standard conditions for biochemists include a pH value of 7.0, a condition far from that seen in the standard hydrogen electrode, which contains H^+ at 1.0 M. Therefore, biochemists use a modified term, $E^{0'}$, which is the standard reduction potential for a half-reaction measured at 10^{-7} M H^+ . These

E^0 is the tendency of a reductant to lose an electron, in the same sense that $\text{p}K_a$ is the tendency of an acid to lose a proton.

The greater the standard reduction potential, the greater the tendency of the oxidized form of a redox couple to attract electrons.

TABLE 3.6 A few standard reduction potentials ($E^{0'}$) of interest in biochemistry

Oxidant	Reductant	n	$E^{0'}$ (V)
$H^+ + e^-$	$\frac{1}{2}H_2$	1	-0.421
$NAD^+ + H^+ + 2e^-$	NADH	2	-0.315
1,3-Bisphosphoglycerate + $2H^+ + 2e^-$	Glyceraldehyde-3-phosphate + P_i	2	-0.290
$FAD + 2H^+ + 2e^-$	FADH ₂	2	-0.219
Acetaldehyde + $2H^+ + 2e^-$	Ethanol	2	-0.197
Pyruvate + $2H^+ + 2e^-$	Lactate	2	-0.185
$Fe^{3+} + e^-$	Fe^{2+}	1	+0.769
$\frac{1}{2}O_2 + 2H^+ + 2e^-$	H_2O	2	+0.815

Note: $E^{0'}$ is the standard reduction potential at pH 7 and 25 °C, n is the number of electrons transferred, and each potential is for the partial reaction written as follows:

The entry for the H^+/H_2 couple ($E^{0'} = -0.421$ V) is not zero because it is measured with $[H^+] = 1$ M in the reference cell (i.e., the standard hydrogen electrode) and $[H^+] = 10^{-7}$ M in the test cell.

are the values used in this book and most other biochemical references. $E^{0'}$ values for a few biochemically important redox pairs are recorded in Table 3.6 (a more complete table of $E^{0'}$ values is given in Chapter 15, page 629). This table is organized with the strongest oxidizing agents listed at the bottom of the “Oxidant” column, and the strongest reducing agents listed at the top of the “Reductant” column. Thus, O_2 in the O_2/H_2O couple is the strongest oxidant, and H_2 in the H^+/H_2 couple is the strongest reducing agent. Another way to express this relationship is to say that H_2O in the O_2/H_2O couple is the weakest reducing agent (just as the strongest acid has the weakest conjugate base). There is very little tendency for water to give up electrons and become oxidized to O_2 , because none of the common biological oxidants has a higher $E^{0'}$ than O_2/H_2O . Photosynthesis, which does oxidize H_2O to O_2 , requires considerable energy in the form of sunlight to accomplish this feat (more about this in Chapter 16). The information in Table 3.6 is useful because the favorable direction of electron flow in a redox reaction is from the reductant in one redox couple to the oxidant in another couple listed lower in the table.

In the next section we illustrate how we use the information in Table 3.6 to calculate $\Delta G^{\circ'}$ and ΔG using examples of reactions involving the important biological electron carrier **nicotinamide adenine dinucleotide**, which is stable in both the oxidized (NAD^+) and reduced (**NADH**) form. We will discuss the structure and function of $NAD^+/NADH$ in greater detail in later chapters.

Free Energy Changes from Oxidation–Reduction Reactions

To recapitulate, the greater the value of $E^{0'}$ for a redox couple, the greater is the tendency for that couple to participate in oxidation of another substrate. We can describe this tendency in quantitative terms because free energy changes are directly related to differences between the reduction potentials listed in Table 3.6:

$$\Delta G^{\circ'} = -nF\Delta E^{0'} = -nF[E^{0'}_{(\text{acceptor})} - E^{0'}_{(\text{donor})}] \quad (3.37)$$

where n is the number of electrons transferred in the half-reactions, F is Faraday’s constant ($96.5 \text{ kJ mol}^{-1}\text{V}^{-1}$), and $\Delta E^{0'}$ is the difference in standard reduction potentials between the two redox couples. Note that $\Delta E^{0'}$ is to ΔE^0 as $\Delta G^{\circ'}$ is to ΔG° ; the “prime” has the same significance in both cases: each reactant and product (except H^+) is at 1M and the reaction is carried out at a pH of 7.0.

Free Energy Changes Under Standard Conditions

As an example, consider the oxidation of ethanol by NAD^+ . This reaction is catalyzed by the enzyme alcohol dehydrogenase:

The two half-reactions given in Table 3.6 are written in the direction of reduction (i.e., as half-reactions for electron acceptors):

Because ethanol becomes oxidized in the reaction, we reverse the second half-reaction to give the desired half-reaction for the electron donor:

Now the overall redox reaction is the sum of half-reactions (a) and (c), in which NAD^+ is the electron acceptor, ethanol is the electron donor, and $\Delta E^{0'}$ is calculated as shown in Equation 3.37:

$$\Delta E^{0'} = E^{0'}_{(\text{acceptor})} - E^{0'}_{(\text{donor})} = (-0.315\text{V}) - (-0.197\text{V}) = -0.118\text{V}$$

The standard free energy change is thus:

$$\Delta G^{0'} = -nF\Delta E^{0'} = -(2)\left(96485 \frac{\text{J}}{\text{mol} \cdot \text{V}}\right)(-0.118\text{V}) = +22.8 \frac{\text{kJ}}{\text{mol}}$$

Note from this example that a negative $\Delta E^{0'}$ value gives a positive $\Delta G^{0'}$ and hence corresponds to a reaction that, under standard conditions, is *not* favorable in the direction written. Note also that if we were to calculate $\Delta G^{0'}$ for the reverse reaction (reduction of acetaldehyde by NADH), $\Delta E^{0'}$ would be +0.118 V, and $\Delta G^{0'}$ would be -22.8 kJ/mol.

Calculating Free Energy Changes for Biological Oxidations Under Nonequilibrium Conditions

The values given in Table 3.6 (and also in Table 15.1, page 629) allow calculation of the biochemical standard state free energy changes. To calculate ΔG for a redox reaction under nonstandard conditions, we must use Equation 3.23. Let us consider the free energy change associated with the transfer of electrons from NADH to O_2 , which is one of the significant energy producing reactions in mitochondria. The overall electron transport process, which actually occurs in several steps, is given by the following equation:

According to Equation 3.23, ΔG for the reaction is given by

$$\Delta G = \Delta G^{0'} + RT \ln \left(\frac{[\text{H}_2\text{O}]^2 [\text{NAD}^+]^2}{[\text{O}_2] [\text{NADH}]^2 [\text{H}^+]^2} \right) \quad (3.38a)$$

Let us assume that inside the mitochondrion the temperature is 37 °C, pH = 8.4, the partial pressure of oxygen is 2 torr, and the concentrations of NAD^+ and NADH are 10 mM and 100 μM , respectively. The value of the $RT \ln Q$ term can be calculated as described previously; however, in this example we will enter the concentration term for oxygen relative to the standard concentration for a gas, which is 1 bar (or 750 torr), rather than as a molar concentration:

$$\Delta G = \Delta G^{0'} + \left(8.315 \frac{\text{J}}{\text{mol} \cdot \text{K}} \right) (310 \text{ K}) \ln \left(\frac{(1)^2 \left(\frac{0.010 \text{ M}}{1 \text{ M}} \right)^2}{\left(\frac{2 \text{ torr}}{750 \text{ torr}} \right) \left(\frac{0.00010 \text{ M}}{1 \text{ M}} \right)^2 \left(\frac{10^{-8.4} \text{ M}}{10^{-7.0} \text{ M}} \right)^2} \right) \quad (3.38b)$$

or

$$\Delta G = \Delta G^{\circ'} + \left(2.58 \frac{\text{kJ}}{\text{mol}}\right) \ln \left(\frac{(1)(10^{-4})}{(2.66 \times 10^{-3})(10^{-8})(1.58 \times 10^{-3})} \right) \quad (3.38c)$$

$$\Delta G = \Delta G^{\circ'} + \left(2.58 \frac{\text{kJ}}{\text{mol}}\right) \ln(2.37 \times 10^9) = \Delta G^{\circ'} + \left(55.6 \frac{\text{kJ}}{\text{mol}}\right) \quad (3.38d)$$

Now we turn our attention to the calculation of $\Delta G^{\circ'}$. Because this is a biochemical redox reaction we can use the information in Table 3.6 and Equation 3.37. Which values of $E^{\circ'}$ should be used to calculate $\Delta E^{\circ'}$ (and thereby $\Delta G^{\circ'}$)? To answer that question we must first identify the relevant “half-reactions.” In this case, the acceptor is O_2 , so we select the half-reaction for the reduction of oxygen to water

The donor is NADH, so we select the half-reaction for the oxidation of NADH to NAD^+

then reverse this half-reaction to show that NADH loses electrons to O_2 :

The half-reactions are adjusted for stoichiometry (such that the e^- terms cancel) and then added together to recreate the overall reaction of interest:

Note that when we adjust stoichiometry (i.e., by multiplying each half-reaction by a factor of 2), we do not make any adjustments to the value of $E^{\circ'}$. The adjustment for changes in stoichiometry is accounted for in the value of n used in Equation 3.37. When we multiply each half reaction by 2 we also double the number of electrons transferred; thus, the value of n is also doubled, and

$$\Delta G^{\circ'} = -nF\Delta E^{\circ'} = -(4) \left(96485 \frac{\text{J}}{\text{mol} \cdot \text{V}}\right) (+1.130\text{V}) = -436.2 \frac{\text{kJ}}{\text{mol}} \quad (3.39)$$

We can now use this value of $\Delta G^{\circ'}$ in Equation 3.38d to calculate ΔG for the reaction

$$\Delta G = \left(-436.2 \frac{\text{kJ}}{\text{mol}}\right) + \left(+55.6 \frac{\text{kJ}}{\text{mol}}\right) = -380.6 \frac{\text{kJ}}{\text{mol}} \quad (3.40)$$

This calculation shows that under the specified conditions, the oxidation of NADH by O_2 is highly favorable. As will be described in greater detail in Chapter 15, a significant portion of this energy is stored in the form of a proton concentration gradient across the inner mitochondrial membrane. The free energy available in the proton gradient (see Equation 3.19) is sufficient to drive the synthesis of ATP from ADP in mitochondria. We will revisit these concepts in Chapter 10 when we discuss membrane transport.

SUMMARY

Bioenergetics is that branch of thermodynamics that deals with energy acquisition, exchange, and utilization in organisms. The internal energy (U) of a system includes all energy that can be exchanged by nonnuclear processes: the energy of motion of atoms and molecules and the energy of chemical bonds and noncovalent interactions. U is

determined by the state of the system and can be changed only by exchange of heat or work with the surroundings ($\Delta U = q - w$). This is the first law of thermodynamics. Under constant-volume conditions, $q = \Delta U$. Under constant-pressure conditions, $q = \Delta U + P\Delta V = \Delta H$, where H denotes the enthalpy ($H = U + PV$). In biochemistry, ΔH is more relevant than ΔU .

Processes may be reversible (near equilibrium) or irreversible (far from equilibrium). The thermodynamically favored direction of a reaction (the direction that leads toward equilibrium) is determined by changes in both the enthalpy (H) and the entropy (S , a measure of randomness). The free energy, $G = H - TS$, takes both into account. The criterion for a favorable process is that the free energy change, $\Delta G = \Delta H - T\Delta S$, be negative (“exergonic”), rather than positive (“endergonic”); this is one statement of the second law of thermodynamics. The ice-to-water transition demonstrates the importance of temperature (T) in determining reaction direction. At the melting point, solid and liquid are in equilibrium ($\Delta G = 0$). The entropy of an open system can decrease, as in freezing of water, but only if the enthalpy decreases. Thus, organisms must constantly expend energy to maintain organization. In every energy transfer, some part of the energy (ΔH) is lost as heat ($T\Delta S$), so ΔG is a measure of the energy that is potentially available for useful work.

To apply thermodynamic relationships in biochemical problems, we use chemical potential, which relates the concentration of each substance to its contribution to the total free energy of the system. From the chemical potential we obtain the equation governing free energy changes in chemical reactions:

$$\Delta G = \Delta G^{\circ'} + RT \ln Q$$

To evaluate the mass action term Q , biochemists commonly use molar concentrations for dilute aqueous solutes, which approximate the *activities* of the solutes in the reaction and are expressed relative to the “biochemical” standard concentrations listed in the text.

There are three common methods for the evaluation of $\Delta G^{\circ'}$:

1. $\Delta G^{\circ'}$ can be calculated from the equilibrium constant, K , using $\Delta G^{\circ'} = -RT \ln K$.
2. $\Delta G^{\circ'}$ can be calculated from tables of standard reduction potentials, $E^{\circ'}$, using $\Delta G^{\circ'} = -nF\Delta E^{\circ'}$.
3. $\Delta G^{\circ'}$ for a reaction of interest can be calculated from the values of $\Delta G^{\circ'}$ for two or more reactions that sum to give the chemical equation of interest.

Reactions that are not thermodynamically favored may nevertheless be driven forward if coupled to reactions that have large negative ΔG values. In living systems, the hydrolysis of certain phosphate compounds is frequently used for this purpose. The phosphate transfer potential ranks these compounds according to their ability to phosphorylate other compounds under standard conditions. ATP, the most important of these compounds, is generated in the energy-producing metabolic pathways and is used to drive many reactions.

REFERENCES

This chapter has presented an abbreviated treatment of thermodynamics. For the student who wishes a more rigorous background in this field and more information about its applications to biochemistry, we recommend the following books:

- Dill, K. A., and S. Bromberg (2010) *Molecular Driving Forces* (2nd ed.). Garland Science, New York. An excellent resource for those desiring a clear and comprehensive presentation of thermodynamic principles.
- Eisenberg, D., and D. Crothers (1979) *Physical Chemistry with Applications to the Life Sciences*. Benjamin/Cummings, Redwood City, Calif. A very fine physical chemistry text, written by two physical biochemists.

Strongly recommended, as it contains many biochemical applications of physical–chemical principles not found in most physical chemistry texts.

PROBLEMS

1. The enthalpy change (heat of fusion, ΔH_f) for the transition ice \rightarrow water at 0 °C and 1 atm pressure is +6.01 kJ/mol. The change in volume when 1 mole of ice is melted is $-1.625 \text{ cm}^3/\text{mol} = -1.625 \times 10^{-6} \text{ m}^3/\text{mol}$. Calculate the difference between ΔH_f and ΔU_f for this process, and express it as a percentage of ΔH_f . [Note: 1 atm = $1.013 \times 10^5 \text{ N/m}^2$ in SI units, where N = newton.]

*2. Given the following reactions and their enthalpies:

	ΔH (kJ/mol)
$\text{H}_2(\text{g}) \rightarrow 2\text{H}(\text{g})$	+436
$\text{O}_2(\text{g}) \rightarrow 2\text{O}(\text{g})$	+495
$\text{H}_2(\text{g}) + \frac{1}{2} \text{O}_2(\text{g}) \rightarrow \text{H}_2\text{O}(\text{g})$	-242

(a) Devise a way to calculate ΔH for the reaction

(b) From this, estimate the H—O bond energy.

3. The decomposition of crystalline N_2O_5

is an example of a reaction that is thermodynamically favored even though it absorbs heat. At 25 °C we have the following values for the standard state enthalpy and free energy changes of the reaction:

$$\Delta H^\circ = +109.6 \text{ kJ/mol}$$

$$\Delta G^\circ = -30.5 \text{ kJ/mol}$$

(a) Calculate ΔS° at 25 °C.

(b) Why is the entropy change so favorable for this reaction?

(c) Calculate ΔU° for this reaction at 25 °C.

(d) Why is ΔH° greater than ΔU° ?

4. The oxidation of glucose to CO_2 and water is a major source of energy in aerobic organisms. It is a reaction favored mainly by a large negative enthalpy change.

$$\Delta H^\circ = -2816 \text{ kJ/mol} \quad \Delta S^\circ = +181 \text{ J/mol} \cdot \text{K}$$

(a) At 37 °C, what is the value for ΔG° ?

(b) In the overall reaction of aerobic metabolism of glucose, 32 moles of ATP are produced from ADP for every mole of glucose oxidized. Calculate the standard state free energy change for the overall reaction when glucose oxidation is coupled to the formation of ATP at 37 °C.

(c) What is the efficiency of the process in terms of the percentage of the available free energy change captured in ATP?

*5. The first reaction in glycolysis is the phosphorylation of glucose:

This is a thermodynamically unfavorable process, with $\Delta G^\circ = +13.8 \text{ kJ/mol}$.

(a) In a liver cell at 37 °C the concentrations of both phosphate and glucose are normally maintained at about 5 mM each. What would be the equilibrium concentration of glucose-6-phosphate, according to the above data?

(b) This very low concentration of the desired product would be unfavorable for glycolysis. In fact, the reaction is coupled to ATP hydrolysis to give the overall reaction

What is ΔG° for the coupled reaction?

(c) If, in addition to the constraints on glucose concentration listed previously, we have in the liver cell ATP concentration = 3 mM and ADP concentration = 1 mM, what is the theoretical concentration of glucose-6-phosphate at equilibrium at pH = 7.4 and 37 °C? The answer you will obtain is an absurdly high value for the cell and in fact is never approached in reality. Explain why.

6. In another key reaction in glycolysis, dihydroxyacetone phosphate (DHAP) is isomerized into glyceraldehyde-3-phosphate (GAP):

Because $\Delta G^{\circ'}$ is positive, the equilibrium lies to the left.

(a) Calculate the equilibrium constant, and the equilibrium fraction of GAP from the above, at 37 °C.

(b) In the cell, depletion of GAP makes the reaction proceed. What will ΔG be if the concentration of GAP is always kept at 1/100 of the concentration of DHAP?

7. Assume that some protein molecule, in its folded native state, has *one* favored conformation. But, when it is denatured, it becomes a “random coil,” with many possible conformations.

- (a) What must be the sign of ΔS for the change: native \rightarrow denatured?
 (b) How will the contribution of ΔS for native \rightarrow denatured affect the favorability of the process? What *apparent* requirement does this impose on ΔH if proteins are to be stable structures?

8. When a hydrophobic substance like a hydrocarbon is dissolved in water, a clathrate cage of ordered water molecules is formed about it (see Figure 2.13 in Chapter 2). What do you expect the sign of ΔS to be for this process? Explain your answer.

*9. It is observed that as temperature is increased, most protein molecules go from their defined, folded state into a random-coil, denatured state which exposes more hydrophobic surface area than is exposed in the folded state.

- (a) Given what you have learned so far about ΔH and ΔS , explain why this is reasonable. [Hint: Consider Problem 7.]
 (b) Sometimes, however, proteins denature as temperature is *decreased*. How might this be explained? [Hint: Consider Problem 8.]

*10. Suppose a reaction has ΔH° and ΔS° values independent of temperature. Show from this, and equations given in this chapter, that

$$\ln K = \frac{-\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R}$$

where K is the equilibrium constant. How could you use values of K determined at different temperatures to determine ΔH° for the reaction?

11. The following data give the ion product, K_w (see Equation 2.6b on page 39), for water at various temperatures:

T ($^\circ\text{C}$)	K_w (M^2)
0	1.14×10^{-15}
25	1.00×10^{-14}
30	1.47×10^{-14}
37	2.56×10^{-14}

(a) Using the results from Problem 10, calculate ΔH° for the ionization of water.

(b) Use these data, and the ion product at 25 $^\circ\text{C}$, to calculate ΔS° for water ionization (hint: use the chemical standard state for the activity of water rather than that for the biochemical standard state activity of water).

12. The phosphate transfer potentials for glucose-1-phosphate and glucose-6-phosphate are -20.9 kJ/mol and -13.8 kJ/mol, respectively.

(a) What is the equilibrium constant for this reaction at 25 $^\circ\text{C}$?

(b) If a mixture was prepared containing 1 M glucose-6-phosphate and 1×10^{-3} M glucose-1-phosphate, what would be the thermodynamically favored direction for the reaction?

13. As you exhale each breath, you expel about 0.5 L against a pressure of 1 atm.

- (a) If you breathe about 30 times per minute, how much work do you do in this way each day? (Neglect any work involved in inhaling.)
 (b) Using the ΔG° value for ATP hydrolysis, what is the minimum number of moles of ATP you will utilize per day just in breathing?

14. Undergoing moderate activity, an average person will generate about 350 kJ of heat per hour. Using the heat of combustion of palmitic acid (Equation 3.6) as an approximate value for fatty substances, estimate how many grams of fat would be required per day to sustain this level, if all were burned for heat.

*15. The major difference between a protein molecule in its native state and in its denatured state lies in the number of conformations available. To a first approximation, the native, folded state can be thought to have one conformation. The unfolded state can be estimated to have three possible orientations about each bond between residues.
 (a) For a protein of 100 residues, estimate the entropy change per mole upon denaturation.
 (b) What must be the enthalpy change accompanying denaturation to allow the protein to be half-denatured at 50 $^\circ\text{C}$?
 (c) Will the fraction denatured increase or decrease with increasing temperature?

16. Suppose the concentration of glucose inside a cell is 0.1 mM and the cell is suspended in a glucose solution of 0.01 mM.

(a) What would be the free energy change involved in transporting 10^{-6} mole of glucose from the medium into the cell? Assume $T = 37$ $^\circ\text{C}$.

(b) What would be the free energy change involved in transporting 10^{-6} mole of glucose from the medium into the cell if the intracellular and extracellular concentrations were 1 mM and 10 mM, respectively?

(c) If the processes described in parts (a) and (b) were coupled to ATP hydrolysis, how many moles of ATP would have to be hydrolyzed in order to make *each* process favorable? (Use the standard free energy change for ATP hydrolysis.)

17. For parts (a) and (b) of this problem use the following standard reduction potentials, free energies, and nonequilibrium concentrations of reactants and products:

ATP = 3.10 mM	$P_i = 5.90$ mM	ADP = 220 μM
glucose = 5.10 mM	pyruvate = 62.0 μM	
NAD ⁺ = 350 μM	NADH = 15.0 μM	CO ₂ = 15.0 torr

half reaction	E° (V)
$\text{NAD}^+ + \text{H}^+ + 2e^- \rightarrow \text{NADH}$	-0.315
$2\text{Pyruvate} + 6\text{H}^+ + 4e^- \rightarrow \text{glucose}$	-0.590

(a) Consider the last two steps in the alcoholic fermentation of glucose by brewer's yeast:

Calculate the nonequilibrium concentration of ethanol in yeast cells, if $\Delta G = -38.3$ kJ/mol for this reaction at pH = 7.4 and 37 $^\circ\text{C}$ when the reactants and products are at the concentrations given above.

(b) Consider the degradation of glucose to pyruvate by the glycolytic pathway:

Calculate ΔG for this reaction at pH = 7.4 and 37 $^\circ\text{C}$.

CHAPTER 4

Nucleic Acids

Recall from Chapter 1 the names of the principal organic constituents of cells and organisms—proteins, nucleic acids, carbohydrates, and lipids. Together, they make up a large portion of all living matter. Although they differ in structure, certain design features are held in common. Proteins, nucleic acids, and polysaccharides are all polymers of monomeric constituents, held in linear order by hydrolyzable chemical bonds. Although individual lipid molecules differ in not being polymeric, lipids usually exist as components of giant complexes—membranes and lipoproteins.

The Nature of Nucleic Acids

We begin our treatment of biomolecular architecture with nucleic acids because, with their roles in storage and transmission of biological information, these can be considered the most fundamental of biological molecules. It seems probable that life began its evolution with nucleic acids, for only they, of all biological substances, carry the remarkable potential for self-duplication. The blueprint for an organism is encoded in its nucleic acid, in gigantic molecules like that shown in Figure 1.4 (page 9). Much of an organism's physical development throughout life is programmed in these molecules. The proteins that its cells will make and the functions that they will perform are all recorded on these molecular tapes.

In this chapter, and in the several that follow, we first describe the nucleic acids structurally and then provide a brief introduction to the ways in which they preserve and transmit genetic information. We review events in DNA replication, transcription, and translation, processes that you might have studied previously and which are covered in more detail later in this book. Also, because of the tremendous impact of recombinant DNA techniques upon biomolecular science and technology, some of the most fundamental and informative techniques are briefly presented at the end of this chapter, in Tools of Biochemistry 4B.

The Two Types of Nucleic Acid: DNA and RNA

DNA was discovered in 1869 by Friedrich Miescher, a military surgeon during the Franco-Prussian War. Miescher found quantities of an acidic substance in the pus

FIGURE 4.1

Chemical structures of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA). The ribose-phosphate or deoxyribose-phosphate backbone of each chain is shown in detail. The bases shown schematically here are detailed in Figure 4.2.

from discarded surgical dressings. Because this material was predominantly in the nuclei of the white blood cells that constituted much of this material, he and his student named it (in German) *nukleinsäure*, or nucleic acid. Chemically, nucleic acid was found to consist of organic nitrogenous bases, a pentose sugar, and phosphate. Later, it was recognized that there are two chemical species of nucleic acid, differing in the nature of the sugar component. Miescher discovered **DNA, deoxyribonucleic acid**, and the other major form is **RNA, ribonucleic acid**. As Figure 4.1 shows, each is a polymeric chain in which the monomer units are connected by covalent bonds. Structures of the monomer units of RNA and DNA are shown here:

Both DNA and RNA are polynucleotides. RNA contains the sugar ribose; DNA has deoxyribose.

The nucleic acid bases are of two kinds: the purines, adenine and guanine, and the pyrimidines, cytosine, thymine, and uracil. RNA and DNA use three of the same bases, with uracil being used by RNA, where DNA uses thymine.

In each case the monomer unit contains a five-carbon sugar, **ribose** in RNA and **2-deoxyribose** in DNA (shown in blue in the structures). The carbon atoms are designated by primes ($1'$, $2'$, etc.) to distinguish them from atoms in the bases. The difference between the two sugars lies solely in the $2'$ hydroxyl group on ribose in RNA, which is replaced by hydrogen in DNA. Each successive monomer unit in both nucleic acids is connected by a phosphate group attached to the hydroxyl on carbon $5'$ of one unit and the hydroxyl on carbon $3'$ of the next one. This forms a **phosphodiester link** between two sugar residues (Figure 4.1). The name refers to the fact that hydrolysis of this phosphate diester link yields one acid (phosphoric acid) and two alcoholic sugar hydroxyls. In this way, long nucleic acid chains, containing up to hundreds of millions of units, are built up. The phosphate group is a strong acid, with a pK_a of about 1; this is why DNA and RNA are called nucleic *acids*. Every **residue**, or polymerized monomer unit, in a DNA or an RNA molecule carries a negative charge at physiological pH.

The phosphodiester-linked sugar residues form the backbone of the nucleic acid molecule. By itself, the backbone is a repetitious structure, incapable of encoding information. The importance of the nucleic acids in information storage and transmission derives from their being **heteropolymers**. Each monomer in the chain carries a heterocyclic base, always linked to the $1'$ carbon of the sugar (see Figure 4.1). The structures of the major bases found in nucleic acids are shown in Figure 4.2. There are two types of heterocyclic bases, which are derivatives of **purine** and of **pyrimidine**.

FIGURE 4.2

Purine and pyrimidine bases found in DNA and RNA. DNA always contains the bases A, G, C, T, whereas RNA always contains A, G, C, U. Thymine is simply 5-methyluracil.

DNA has two purine bases, **adenine (A)** and **guanine (G)**, and two pyrimidines, **cytosine (C)** and **thymine (T)**. RNA has three of the same bases, and the fourth, **uracil (U)**, replaces thymine. RNA, particularly the species called **transfer RNA** (page 108), contains several chemically modified bases, which serve in part to stabilize the molecule, as discussed in Chapter 28. Most eukaryotic DNAs contain a small proportion of cytosines methylated at carbon-5. The biological significance of DNA methylation is discussed in Chapter 26. 5-Hydroxymethylcytosine, with $\text{—CH}_2\text{OH}$ replacing —CH_3 (Chapter 22, page 950), has recently been found in some eukaryotic DNAs.

DNA and RNA can each be regarded as a polymer made from four kinds of monomers. The monomers are phosphorylated ribose or deoxyribose molecules with purine or pyrimidine bases attached to their 1' carbons. In purines the attachment is at nitrogen 9, in pyrimidines at nitrogen 1. The bond between the carbon 1' of the sugar and the base nitrogen is referred to as a **glycosidic bond**. These monomers are called **nucleotides**. Each nucleotide can be considered the 5'-monophosphorylated derivative of a sugar-base adduct called a **nucleoside** (Figure 4.3). Thus, these nucleotides are also called *nucleoside 5'-monophosphates*. You have already encountered one of these molecules in Chapter 3: adenosine 5'-monophosphate, or AMP.

FIGURE 4.3

Nucleosides and nucleotides. The ribonucleosides and ribonucleotides are shown here; the deoxyribonucleosides and deoxyribonucleotides are identical, except that they lack the 2'OH, and except that T substitutes for the U found in RNA. Each nucleoside is formed by coupling ribose or deoxyribose to a base. The nucleotides, which can be considered the monomer units of nucleic acids, are the 5'-monophosphates of the nucleosides. Nucleoside phosphates with phosphorylation on other hydroxyl groups exist, but they are not found in nucleic acids. The glycosidic bond linking adenine to ribose is shown for adenosine.

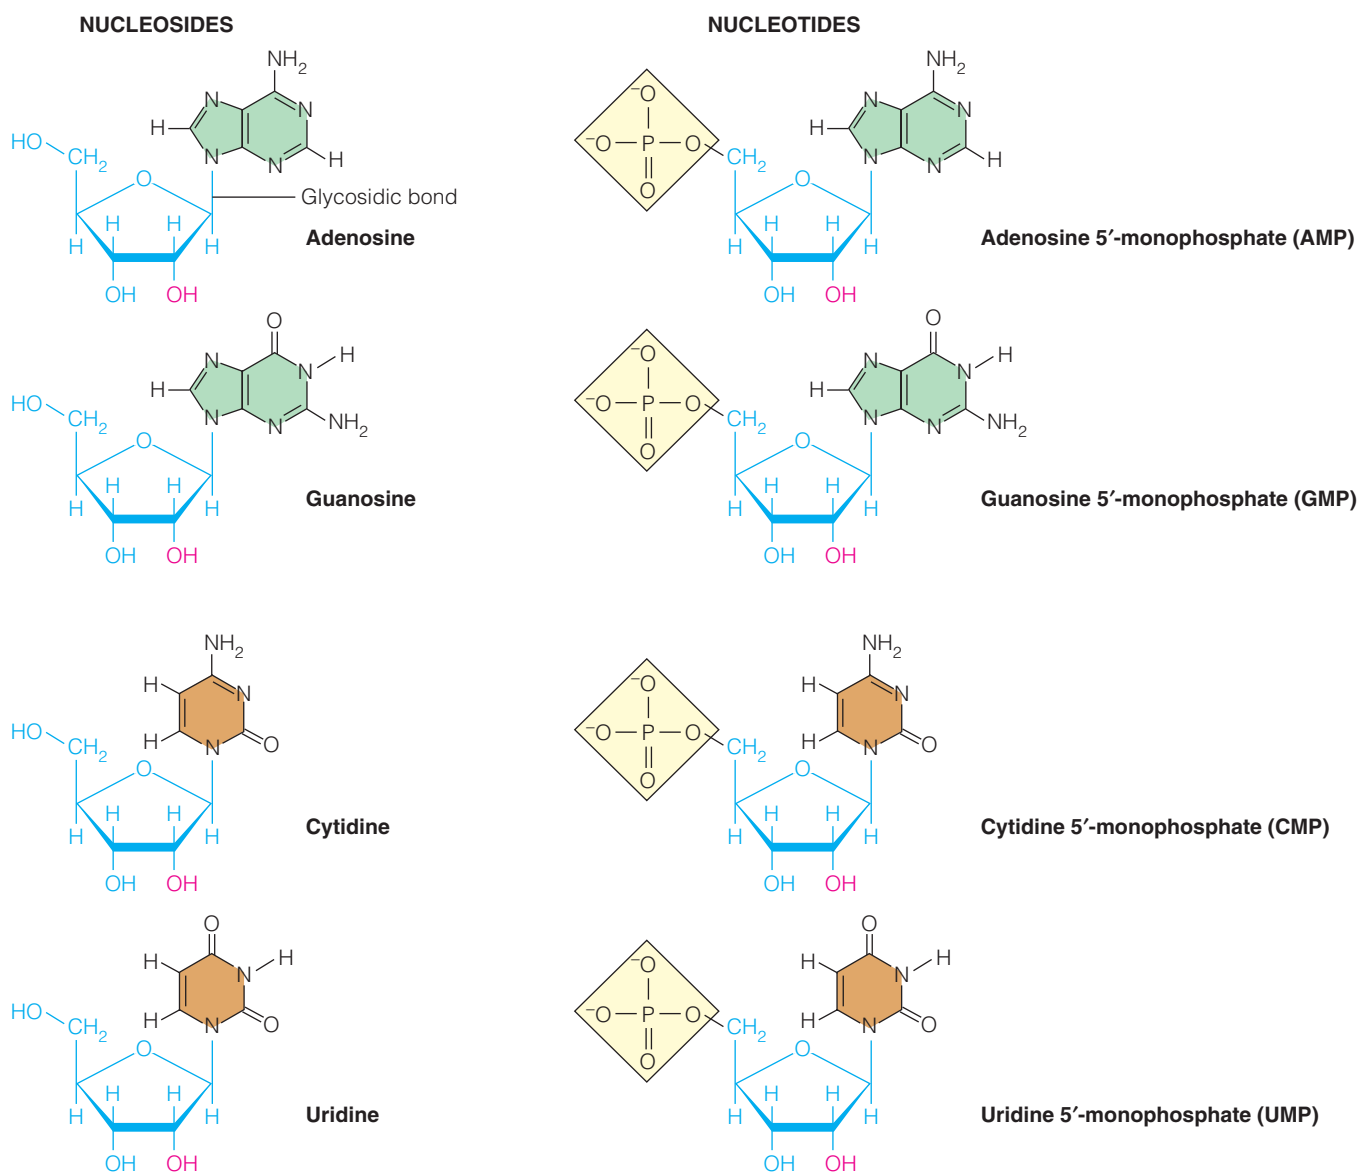

TABLE 4.1 Ionization constants of ribonucleotides expressed as pK_a values

	Phosphate		pK_a	Reaction (as Loss of Proton from)
	Primary Ionization	Secondary Ionization		
	$\text{HO}-\overset{\text{O}}{\parallel}{\text{P}}-\text{R} \rightleftharpoons \text{HO}-\overset{\text{O}}{\parallel}{\text{P}}(\text{O}^-)-\text{R}$	$\text{HO}-\overset{\text{O}}{\parallel}{\text{P}}(\text{O}^-)-\text{R} \rightleftharpoons \text{O}^--\overset{\text{O}}{\parallel}{\text{P}}(\text{O}^-)-\text{R}$		
	pK_{a1}	pK_{a2}		
	+ H^+	+ H^+		
5' AMP	0.9	6.1	3.8	N-1
5' GMP	0.7	6.1	2.4	N-7
			9.4	N-1
5' UMP	1.0	6.4	9.5	N-3
5' CMP	0.8	6.3	4.5	N-3

Because all of the nucleic acids may be regarded as polymers of nucleotides, they are often referred to by the generic name **polynucleotides**. Small polymers, containing only a few residues, are called **oligonucleotides**.

The presence of the 2' hydroxyl groups is of far more than academic interest—it gives RNA a functionality lacking in DNA. As discussed in Chapter 11, Thomas Cech and Sidney Altman, working independently, discovered **ribozymes**, or RNA molecules capable of catalyzing chemical reactions. The 2' hydroxyl groups are critically involved in the catalytic mechanisms. Hence, RNA molecules have the capacity both for information storage and for catalysis. Whether or not this is the reason, many biochemists believe that RNA came into existence earlier than DNA in the primordial environment in which the first living organisms are thought to have evolved. Studies on prebiotic chemistry suggest that ribose was among the earliest organic compounds to be formed. DNA is chemically more stable than RNA, which permits the generation and maintenance of longer genomes. For these reasons, biochemists postulate an initial **RNA world**, which gave way to DNA-based organisms once a mechanism had appeared, allowing conversion of ribose-containing compounds to their deoxyribose-containing counterparts. You should be aware that DNA-based catalysts also exist, but to date these are all laboratory constructs. No “DNAzymes” have yet been found in nature. See Chapter 11 for further discussion of this topic.

FIGURE 4.4

Tautomerization of the bases. The most stable (and therefore common) forms are shown on the left. The less common imino and enol forms, shown on the right, are found in some special base interactions. Still other tautomers (not shown here) are possible.

Properties of the Nucleotides

Nucleotides are strong acids; the primary ionization of the phosphate occurs with a pK_a of approximately 1.0. Both secondary ionization of the phosphate and protonation or deprotonation of the amino groups on the bases within the nucleotides can be observed at pH values close to neutrality (Table 4.1). The bases are also capable of conversion between **tautomeric** forms. Tautomeric forms, or **tautomers**, are structural isomers differing only in the location of their hydrogen atoms and double bonds. The major forms are those shown in Figure 4.2, but G, T, and U can partially isomerize to enol forms, and A and C to imino forms, as shown in Figure 4.4.

As a consequence of the conjugated double-bond systems in the purine and pyrimidine rings, the bases and all of their derivatives (nucleosides, nucleotides, and nucleic acids) absorb light strongly in the ultraviolet region of the spectrum. This absorption depends somewhat on pH because of the ionization reactions in the bases; representative spectra at neutral pH for ribonucleotides are depicted in Figure 4.5. This strong absorbance is often used for quantitative determination of nucleic acids because it allows measurement of nucleic acid concentrations at the microgram/mL level by measurement of light absorption at 260 nm in a spectrophotometer (see Tools of Biochemistry 6A). Ultraviolet light can also have chemically damaging effects on DNA, leading, for example, to skin cancer.

Stability and Formation of the Phosphodiester Linkage

If we compare the structures of the nucleotides shown in Figure 4.3 with the polynucleotide chains depicted in Figure 4.1, we see that, in principle, a polynucleotide could be generated from its nucleotide monomers by elimination of a water molecule between each pair of monomers. That is, we might imagine adding another nucleotide residue to a polynucleotide chain by the dehydration reaction shown in Figure 4.6. However, the free energy change in this hypothetical reaction is quite positive, about +25 kJ/mol; therefore equilibrium lies far to the side of hydrolysis of the phosphodiester bond in the aqueous environment of the cell. Hydrolysis of polynucleotides to nucleotides is the thermodynamically favored process.

We encounter here the first of many examples of the **metastability** of biologically important polymers. Metastable compounds are thermodynamically favored to break down, but do so only very slowly unless the reaction is catalyzed. According to the free energy change involved, polynucleotides should hydrolyze under conditions existing in living cells, but their hydrolysis is exceedingly slow unless catalyzed. This characteristic is of greatest importance, for it ensures that the DNA in cells is sufficiently stable to serve as a useful repository of genetic information. In dehydrated conditions, DNA is so stable that fragments of DNA molecules have been recovered from some ancient fossils. When catalysts *are* present, however, hydrolysis can be exceedingly rapid in aqueous solution. Acid catalysis leads to hydrolysis of the phosphodiester bonds in RNA, yielding a mixture of nucleotides. In both RNA and DNA, the glycosidic bond between the base and the sugar is also hydrolyzed; a mixture of bases, phosphoric acid, and ribose (or deoxyribose) is produced. RNA, but not DNA, is also labile in alkaline solution; treatment with 0.1 M alkali yields a mixture of 2'- and 3'-nucleoside monophosphates. Finally, and most important biologically, enzymes called **nucleases** catalyze the hydrolysis of phosphodiester bonds in both RNA and DNA. Your body is able to break down and utilize polynucleotides in the food you eat because your digestive system contains nucleases. Examples of such enzymes are described in Chapter 22.

The unfavorable thermodynamics of the hypothetical dehydration reaction shown in Figure 4.6 leads us to ask: If polynucleotides cannot be synthesized *in vivo* by the direct elimination of water, how are they actually made? The answer is that their synthesis involves the energy-rich nucleoside or deoxynucleoside *triphosphates*. Although the process as it occurs in cells is quite complex, the basic reaction is simple. Instead of the dehydration reaction of Figure 4.6, what happens in living cells is the reaction shown in Figure 4.7. The nucleoside monophosphate being added to the growing chain is presented as a *nucleoside triphosphate*, like ATP or deoxy ATP (dATP), and pyrophosphate is released in the reaction. We can calculate the free energy change for this reaction by noting that it can be considered the sum of two reactions—hydrolysis of a nucleoside triphosphate and formation of a phosphodiester link by elimination of water:

The coupled reaction is favorable because the *net* ΔG^{o'} is negative. The reaction is further favored because the hydrolysis of the pyrophosphate product (PP_i) to orthophosphate, or inorganic phosphate (P_i), has a ΔG^{o'} = −19 kJ/mol. Thus, the pyrophosphate is readily removed, driving the synthesis reaction even further to the right and yielding an overall ΔG^{o'} of −25 kJ/mol. Polynucleotide synthesis is an example of a principle we emphasized in Chapter 3—the use of favorable reactions to drive thermodynamically unfavorable ones.

It is important to appreciate how the energetics of such processes fit into the overall scheme of life. An organism obtains energy—from photosynthesis, if it is a plant, or from inorganic compounds if it is a chemolithotroph, or in all cases from

FIGURE 4.5

Ultraviolet absorption spectra of ribonucleotides.

The dimensions of the absorption coefficients are $M^{-1}cm^{-1}$. Thus a 10^{-4} solution of UMP would have an absorbance of 0.95 at 260 nm in a 1-cm-thick cuvette. (Absorbance = molar absorptivity \times light path in cm \times molar concentration; see Tools of Biochemistry 6A).

FIGURE 4.6 (left)

Formation of a polynucleotide by a hypothetical dehydration reaction. We might imagine that a polynucleotide could be formed directly from nucleoside monophosphates by removal of water, as shown here, but the dehydration reaction is thermodynamically unfavorable. The reverse reaction, hydrolysis, is favored. Note that in this and subsequent figures we adopt a somewhat more compact way of representing the sugar-phosphate backbone.

**FIGURE 4.7 (right)**

How polynucleotides are actually formed. In this reaction, each monomer is presented as a nucleoside triphosphate to be added to the chain. Cleavage of the nucleoside triphosphate provides the free energy that makes the reaction thermodynamically favorable. The enzymes catalyzing such reactions are called **polymerases**.

metabolism of nutrients—and stores part of this energy by generating ATP, GTP, dATP, dGTP, and similar energy-rich compounds. It uses these compounds in turn as energy sources to drive the synthesis of macromolecules like DNA, RNA, and proteins. This use of triphosphates as the energy currency of the cell is a theme that you will see repeated throughout this book.

Primary Structure of Nucleic Acids

The Nature and Significance of Primary Structure

A closer examination of Figure 4.1 reveals two important features of all polynucleotides:

1. A polynucleotide chain has a *sense* or *directionality*. The phosphodiester linkage between monomer units is between the 3' carbon of one monomer and the 5' carbon of the next. Thus, the two ends of a linear polynucleotide chain are distinguishable. One end normally carries an unreacted phosphate, the other end an unreacted 3' hydroxyl group.
2. A polynucleotide chain has *individuality*, determined by the sequence of its bases—that is, the *nucleotide sequence*. This sequence is called the **primary structure** of that particular nucleic acid.

If we want to describe a particular polynucleotide sequence (either DNA or RNA), it is awkward and unnecessary to draw the molecule in its entirety as in Figure 4.1. Accordingly, some compact conventions have been devised. If we state that we are describing a DNA molecule or an RNA molecule, then most of the structure is understood. We can then abbreviate a small DNA molecule as follows:

This notation shows (1) the sequence of nucleotides, by their letter abbreviations (A, C, G, T); (2) that all phosphodiester links are between 3' hydroxyls and 5' phosphates; and (3) that this particular molecule has a phosphate group at its 5' end and an unreacted hydroxyl at its 3' end. It also tells us it is a DNA sequence, not RNA because it has T, not U.

If all of the phosphodiester bonds can be assumed to link a 3' hydroxyl to a 5' phosphate (as is usually the case), a more compact notation is possible for the same molecule:

The 3' —OH group is understood to be present and unreacted. Were there a phosphate on the 3' end and an unreacted hydroxyl on the 5' end, we would write

Finally, if we are concerned *only* with the sequence of bases in the molecule, as will often be the case, we can write it still more compactly as

Note that the sequence of a polynucleotide chain is usually written, by convention, with the 5' end to the left and the 3' end to the right.

The main importance of primary structure, or sequence, is that *genetic information is stored in the primary structure of DNA*. A *gene* is nothing more than a particular DNA sequence, encoding information in a four-letter language in which each “letter” is one of the bases.

Every naturally occurring polynucleotide has a defined sequence, its primary structure.

The primary structure of DNA encodes genetic information.

DNA as the Genetic Substance: Early Evidence

The search for the substance of which genes are made has a long history. In the late 1800s, shortly after Friedrich Miescher had first isolated DNA from white blood cells, some scientists suspected that DNA might be the genetic material. But subsequent studies showing that DNA contained only four kinds of monomers seemed to deny that it could have such a complicated role. Early researchers thought it more likely that genes were made of proteins, for proteins were beginning to be recognized as extremely complex molecules. For most of the first half of the twentieth century, nucleic acids were considered to be merely some kind of structural material in the cell nucleus.

Between 1944 and 1952 a series of crucial experiments clearly pointed to DNA as the genetic material. In 1944 Oswald Avery, Colin MacLeod, and Maclyn McCarty found that the DNA from pathogenic strains of the bacterium *Pneumococcus* could be transferred into nonpathogenic strains, making them pathogenic (Figure 4.8a). This **transformation** was genetically stable; succeeding generations of bacteria retained the new characteristics. However, it was an elegant experiment by Alfred Hershey and Martha Chase that finally convinced most scientists. Hershey and Chase studied infection of the bacterium *Escherichia coli* by a bacterial virus, the bacteriophage, or phage, T2. Making use of the fact that phage proteins contain sulfur but little phosphorus and that phage DNA contains phosphorus but no sulfur, they labeled T2 bacteriophage with the radioisotopes ^{35}S and ^{32}P (Figure 4.8b). They then showed that when the phage attached to *E. coli*, it was mainly the ^{32}P (and hence the phage DNA) that was transferred into the bacteria. Even if the residual protein part of the bacteriophage was shaken off the bacteria, the inserted DNA alone was sufficient to direct the formation of new bacteriophage.

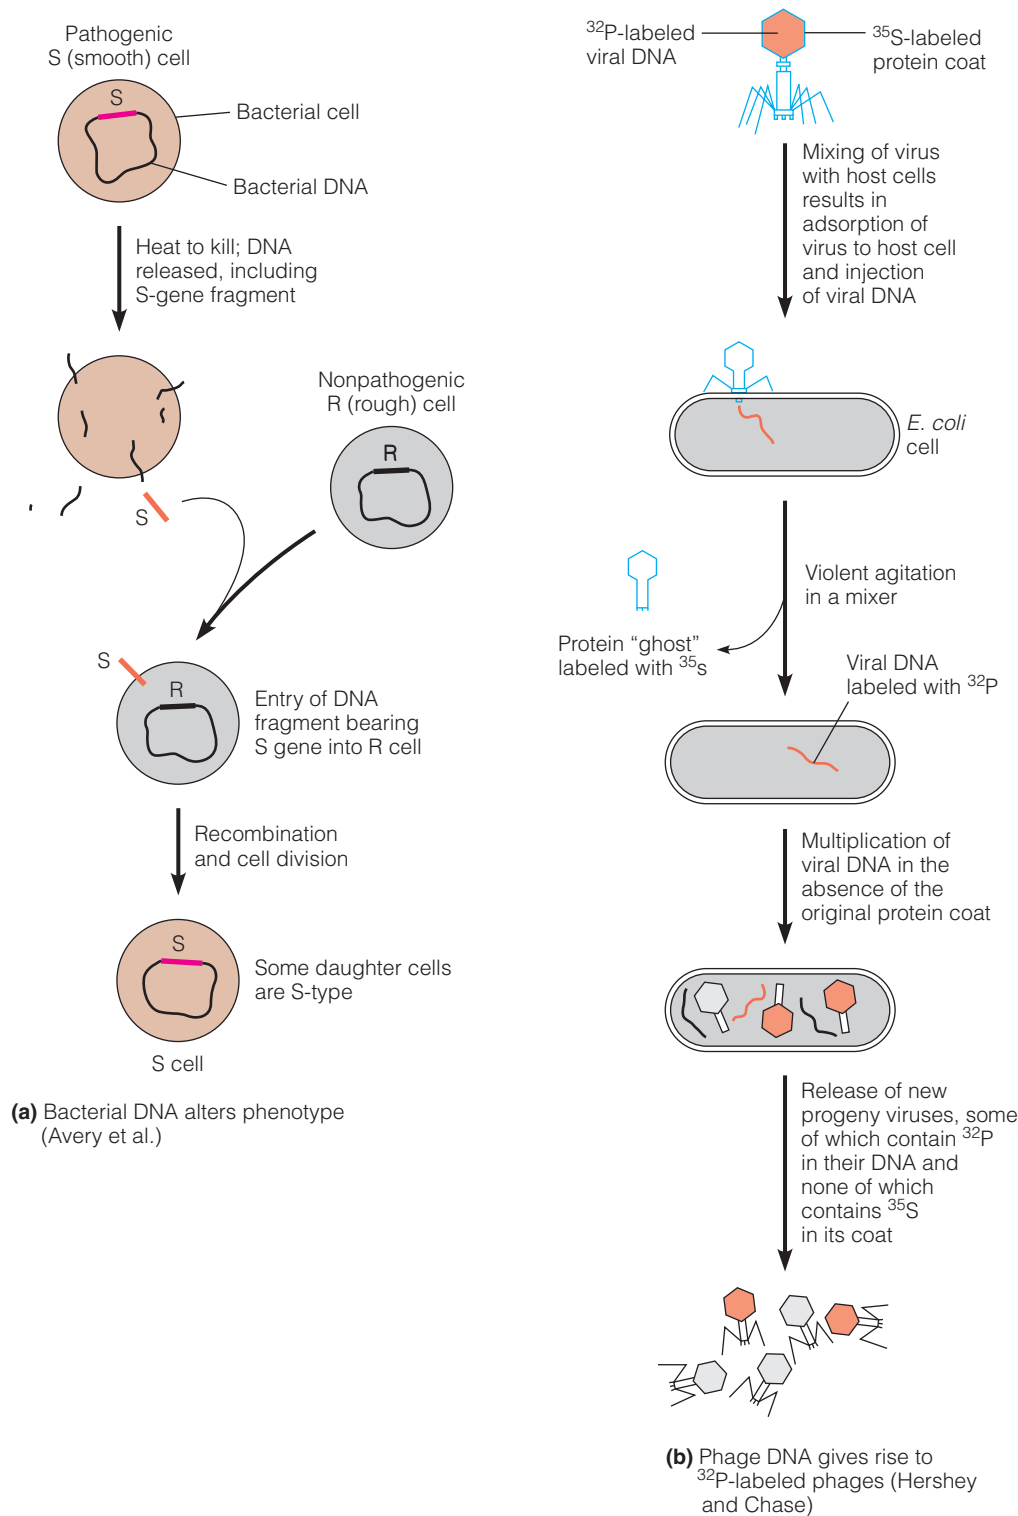

Through these and similar experiments, it was generally recognized by 1952 that DNA must be the genetic substance. But how could it carry the enormous amount of information that a cell needed, how could it transmit that information to the cell, and, above all, how could it be accurately replicated in cell division? The answers to these questions came only after one of the most momentous discoveries in the history of science. In 1953 James Watson and Francis Crick proposed a structure for DNA that opened a whole new world of molecular biology.

Secondary and Tertiary Structure of Nucleic Acids

The Double Helix

Watson and Crick sought answers to the questions posed above in the three-dimensional structure of DNA. For some time, investigators had been studying fibers drawn from concentrated DNA solutions, using the technique of **X-ray diffraction** (see Tools of Biochemistry 4A). Watson and Crick, working at Cambridge University in England, had access to DNA diffraction patterns photographed by Rosalind Franklin, a researcher in the laboratory of Maurice Wilkins at King's College, London. The critical photographs clearly showed that DNA in the fibers must have some kind of regular, repetitive three-dimensional structure. We refer to such regular folding in polymers as *secondary structure*, as distinguished from the primary structure, which, as noted earlier, is simply the sequence of individual nucleotide residues. Watson and Crick were also aware of Erwin Chargaff's data, which showed regularities in DNA base composition (see page 101).

Watson and Crick quickly recognized that the DNA fiber diffraction exhibited a cross pattern typical of a helical secondary structure (Figure 4.9). They noted that because the layer line spacing was one-tenth of the pattern repeat, there must be 10 residues per turn (see Tools of Biochemistry 4A). Data on the density of the fibers suggested that there must be *two* DNA strands in each helical molecule. At that point, only direct scientific deductions had been made from the data. The great leap of intuition made by Watson and Crick was their realization that a two-strand helix

**FIGURE 4.8**

Experiments that showed DNA to be the genetic substance. (a) Avery et al. showed that nonpathogenic pneumococci could be made pathogenic by transfer of DNA from a pathogenic strain. (b) Hershey and Chase showed that it is the transfer of just the viral DNA from a virus to a bacterium that gives rise to new viruses.

could be stabilized by hydrogen bonding between bases on opposite strands if the bases were paired in *one* particular way—the A-T and G-C pairs shown in Figure 4.10. With this pairing, strong hydrogen bonds are formed between the bases. Furthermore, distances between the 1' carbons of the deoxyribose moieties of A-T and of G-C are the same—about 1.1 nm in each case (Figure 4.10a). This pairing arrangement meant that the double helix could be regular in diameter, an impossibility if purines paired with purines or pyrimidines with pyrimidines.

The Watson–Crick model for DNA is a two-strand, antiparallel double helix with 10 base pairs per turn. Pairing is A-T and G-C.

**FIGURE 4.9**

Evidence for the structure of DNA. This photograph, taken by Rosalind Franklin, shows the X-ray diffraction pattern produced by wet DNA fibers. It played a key role in the elucidation of DNA structure. The cross pattern indicates a helical structure, and the strong spots at top and bottom correspond to a helical rise of 0.34 nm. The layer line spacing is one-tenth of the distance from the center to either of these spots, showing that there are 10 base pairs per repeat.

**FIGURE 4.10**

Fundamental elements of structure in the DNA double helix. (a) Base pairing. A-T and G-C are the base pairs in the Watson–Crick model of DNA. This pairing allows the C-1' carbons on the two strands to be exactly the same distance apart for both pairs. (b) Stacking of the base pairs. This view down the helix axis shows how the base pairs stack on one another, with each pair rotated 36° with respect to the next. (c) Distance between the base pairs. A side view of the base pairs shows the 0.34-nm distance between them. This distance is called the rise of the helix.

(a, c) Illustration, Irving Geis. Image from Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Not to be reproduced without permission.

In the Watson–Crick model, the hydrophilic phosphate–deoxyribose backbones of the helix were on the outside, in contact with the aqueous environment, and the base pairs were stacked on one another with their planes perpendicular to the helix axis. Two views of such a structure are shown in Figure 4.10b and c. (The figure shows a recent, refined model, based on better data than Watson and Crick had available: The bases are not exactly perpendicular to the helix axis, and the sugar conformation is slightly different from that proposed by Watson and Crick.) Stacking of the bases, as shown in Figure 4.10b, allows strong interactions between them, probably of van der Waals type; this is usually referred to as “stacking interaction” (see also Figure 2.2, page 28). Each base pair is rotated by 36° , that is, $1/10$ of a 360° rotation with respect to the next, to accommodate 10 base pairs in each turn of the helix (later structural studies showed the number to be closer to 10.5; see page 106). The diffraction pattern showed the repeat distance to be about 3.4 nm, so the helix *rise*, that is, the distance between base pairs, had to be about 0.34 nm (Figure 4.10c). This distance is just twice the van der Waals thickness of a planar ring (see Table 2.2 on page 29), so the bases are closely packed within the helix, as shown in a space-filling model (Figure 4.11).

The model also shows that although the bases are inside, they can be approached through two deep spiral grooves called the *major* and *minor* grooves. The major groove gives more direct access to the bases; the minor groove faces the sugar backbone. Building molecular models of two-strand DNA structures soon convinced Watson and Crick that the DNA strands must run in opposite directions. In other words, the two strands are antiparallel, as indicated in Figure 4.10c. The model Watson and Crick presented was for a right-handed helix, although at that time evidence for the sense (direction of the turn) of the helix was weak. Their guess proved to be correct.

As is often the case with a good theory or model, the Watson–Crick structure also explained other data that had not been understood until then. Erwin Chargaff, who had measured the relative amounts of A, T, G, and C in DNAs from many organisms, had noted the perplexing fact that A and T were almost always present in nearly equal quantities, as were G and C (Table 4.2). If most DNA in cells was double-stranded, with the Watson–Crick base pairing, then *Chargaff’s rule* followed as a natural consequence.

The Watson–Crick model not only explained the structure of DNA and Chargaff’s rule but also carried implications that went to the very heart of biology. Because A always pairs with T, and G always pairs with C, the two strands are *complementary*. If the strands could be separated and new DNA synthesized along each, following the same base-pairing rule, two double-stranded DNA molecules would be obtained, each an *exact* copy of the original (Figure 4.12). This **self-replication** is precisely the property that the genetic material must have: When a cell divides, two complete copies of the genetic information carried in the original cell must be produced. In their 1953 paper announcing the model (see References), Watson and Crick expressed this idea in what may be the most understated scientific prediction ever made: “It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material.”

Semiconservative Nature of DNA Replication

The DNA copying mechanism we have mentioned involves unwinding the two strands of a parental DNA duplex, with each strand serving as template for the synthesis of a new strand, complementary to and wound about that parental strand. Complete replication of a DNA molecule would yield two “daughter” duplexes, each consisting of one-half parental DNA (one strand of the original duplex) and one-half new material. This mode of replication is called **semiconservative** because half of the original material is conserved in each of the two copies (Figure 4.13). It is distinguished from two other possible modes: **conservative**, in which one of the two daughter duplexes is the conserved parental duplex while the other is synthesized *de novo*, and **dispersive**, in which parental material is scattered through the structures of the daughter duplexes.

The complementary, two-strand structure of DNA explains how the genetic material can be replicated.

FIGURE 4.11

A space-filling model of DNA. The DNA molecule as modeled by Watson and Crick is shown here with each atom given its van der Waals radius. This model shows more clearly than Figure 4.10 how closely the bases are packed within the helix. The major and minor grooves are indicated.

^aAmount includes, for some organisms, a few percent of a modified base, 5-methylcytosine.

^bThis bacteriophage has a single-strand DNA, which need not follow Chargaff's rule.

FIGURE 4.12

A model for DNA replication. Each strand acts as a template for a new, complementary strand. When copying is complete, there will be two double-stranded daughter DNA molecules, each identical in sequence to the parent molecule. The actual process is rather complicated (see Chapter 25), but the basic principle is illustrated here.

Meselson and Stahl proved that DNA replicates semiconservatively.

The first experimental test of this model came in 1958, when Matthew Meselson and Franklin Stahl realized that molecules differing in density by very small amounts could be separated from each other by centrifugation in density gradients. In this method, a density gradient is created by centrifuging to equilibrium a concentrated solution of a heavy metal salt like cesium chloride (CsCl). Nucleic acid molecules of different densities suspended in such a gradient will each migrate to the point where the solution density equals its own. This technique allowed Meselson and Stahl to follow the fate of density-labeled DNA through several rounds of replication, with the results shown in Figure 4.14. The density label was applied by growing the bacterium *E. coli* in a medium containing the heavy isotope of nitrogen, ¹⁵N, for many generations, so that DNA achieved a higher density through extensive substitution of ¹⁵N for ¹⁴N in its purine and pyrimidine bases. When isolated and centrifuged to equilibrium at pH 7.0, this DNA formed a single band in a region of the gradient corresponding to a density of 1.724 g/mL (Figure 4.14a, first profile). By contrast, when DNA from bacteria grown in a light medium (containing ¹⁴N) was similarly analyzed, it banded at a density of 1.710 g/mL (Figure 4.14a, second profile). When density-labeled bacteria grown in a heavy

medium were transferred to a light medium, the DNA isolated after one generation of growth banded exclusively at an intermediate density, 1.717 g/mL (Figure 4.14a, third profile). This result is expected if the newly replicated DNA is a *hybrid* molecular species, consisting of one-half parental material and one-half new DNA (synthesized in light medium). If these bacteria were cultured for an additional generation in light medium, two equal-sized bands were seen, one light and one of hybrid density (Figure 4.14a, fourth graph), as expected if the hybrid-density DNA underwent a second round of semiconservative replication.

These results were consistent with the idea that each replicated chromosome contains one parental strand and one daughter strand, but the data did not preclude alternative forms of semiconservative replication, involving the breaking of DNA strands. These models were ruled out by centrifugal analysis of the density-labeled DNAs at pH 12, where DNA strands separate (Figure 4.14b). When centrifuged to equilibrium after bacterial growth in heavy medium followed by one generation in light medium, the DNA formed two bands: one light (equal to that seen on analysis of ^{14}N -grown bacteria) and one heavy (Figure 4.14b, third graph). DNA analyzed after a second round of replication in light medium showed three-fourths light and one-fourth heavy material (Figure 4.14b, fourth graph). The inescapable conclusion was that the replicative hybrid contains one complete strand of parental DNA and one complete strand of newly synthesized DNA.

Alternative Nucleic Acid Structures: B and A Helices

At the time Watson and Crick proposed their model, two quite different X-ray diffraction patterns had already been obtained for DNA, indicating that the molecule can exist in more than one form. The **B form**, which is seen in DNA fibers prepared under conditions of high humidity, is shown in Figures 4.10, 4.11, 4.15a, and 4.15b. Watson and Crick chose to study the B form because they correctly expected it to be the predominant form in the aqueous milieu of the cell. DNA fibers prepared under conditions of low humidity have a different structure, the so-called **A form** (Figure 4.15c and d). Although a B helix is indeed the form of DNA found in cells, the A helix is also important biologically. Double-stranded RNA molecules always form the A structure, and so do **DNA–RNA hybrid molecules**, which are formed by the pairing of one DNA strand with one RNA strand. Thus, two major kinds of secondary structures exist in polynucleotides. As we shall see later in this chapter, a number of other kinds of secondary structures are possible under special circumstances, including the left-handed Z form mentioned in Table 4.3.

As Figure 4.15 and Table 4.3 show, the A and B forms are very different, although both are right-handed helices. In the B helix the bases lie close to the helix axis, which passes between the hydrogen bonds (note the end-on views of the helices in Figure 4.15a and c). In the A helix the bases lie farther to the outside and are strongly tilted with respect to the helix axis. The surfaces of the helices are also different. In the B helix the major and minor grooves are quite distinguishable, whereas in the A helix the two grooves are more nearly equal in width.

All fiber diffraction studies, including those that provided the information just described, suffer from a major limitation. In analyzing fiber patterns, researchers do not directly determine the details of a nucleic acid secondary structure. Instead, they propose models that best account for the positions and intensities of the spots on the diffraction pattern (see Tools of Biochemistry 4A). This approach is necessary because fibers are never perfect crystals, and there is always some ambiguity in the interpretation of their diffraction patterns. Therefore, a major advance was made when R. E. Dickerson and his colleagues succeeded in *crystallizing* a small double-stranded DNA fragment, which had the sequence

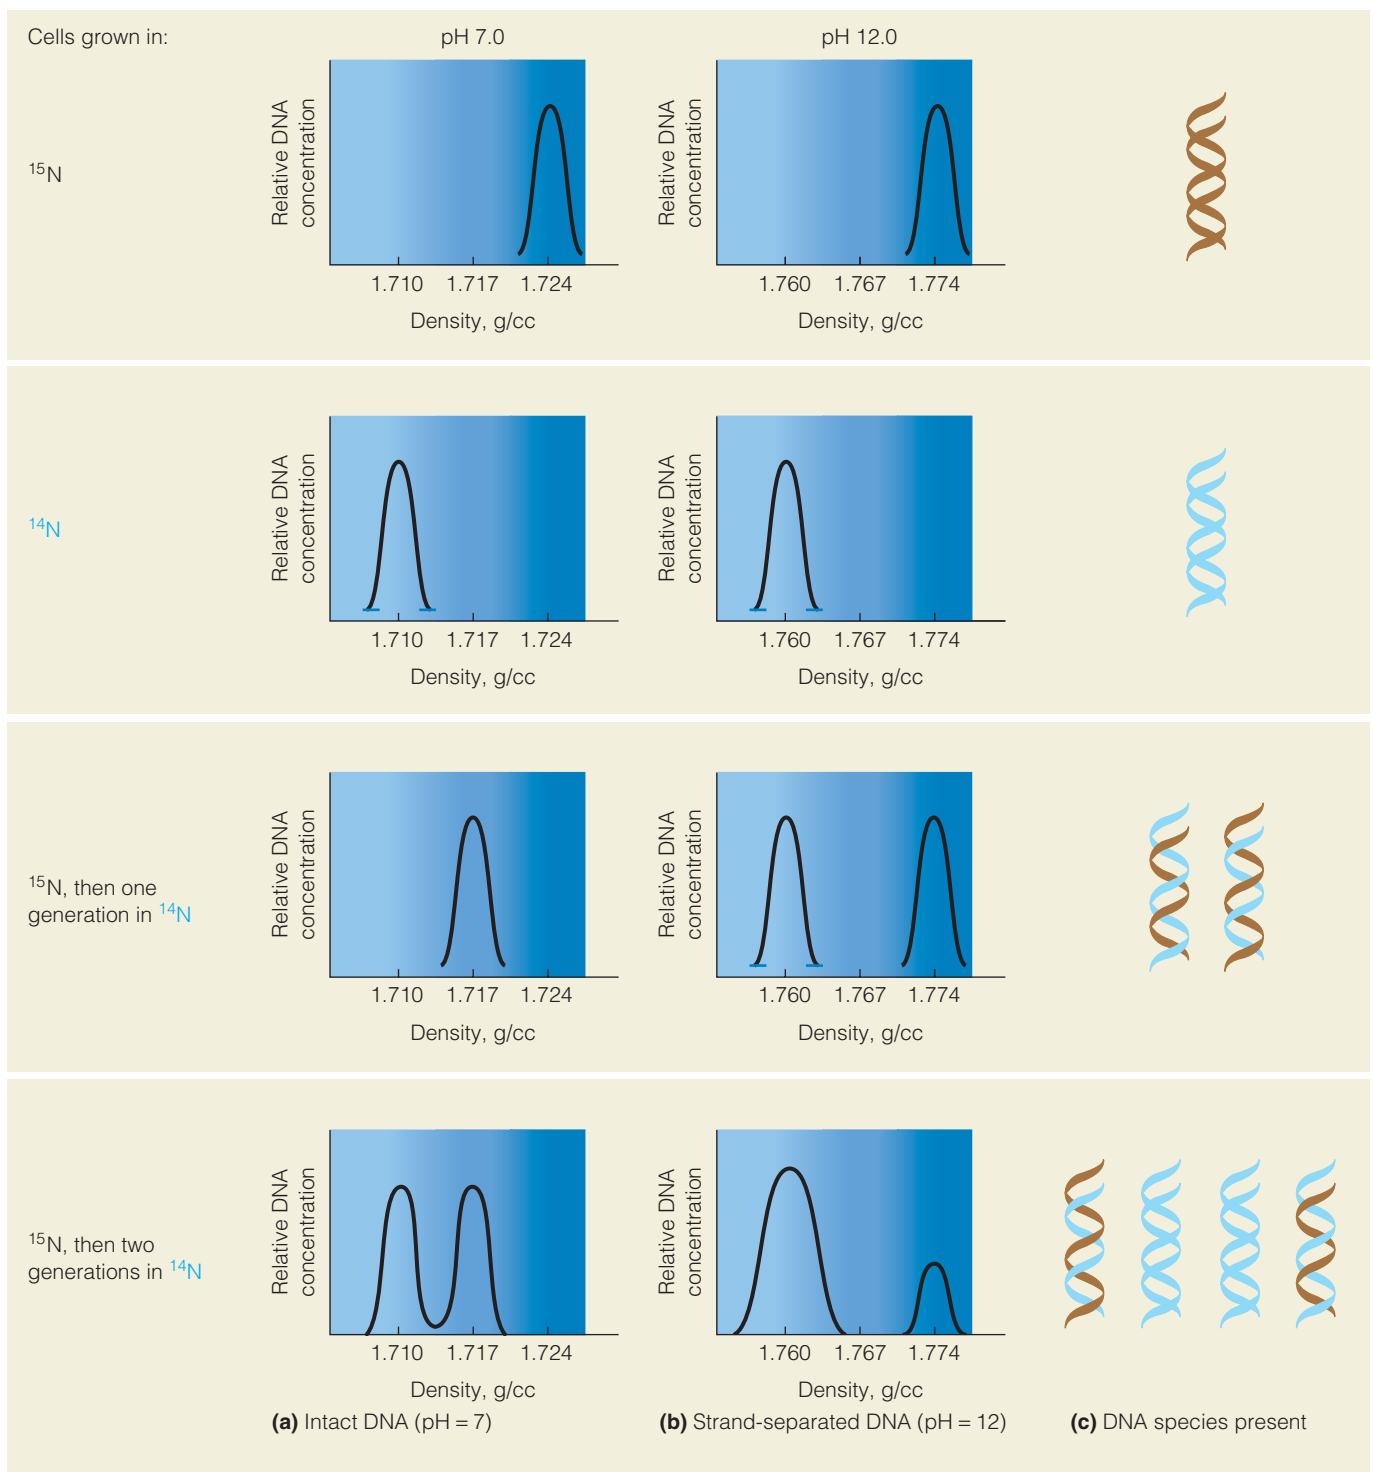

FIGURE 4.13

Three models of DNA replication. Experimental evidence supports the semiconservative model. Brown, parental DNA; blue, new DNA.

The two major forms of polynucleotide secondary structure are called A and B. Most DNA is in the B form; double-stranded RNA and DNA–RNA hybrids are in the A form.

**FIGURE 4.14**

The Meselson–Stahl experiment proves DNA replicates semiconservatively. The banding patterns shown were obtained in density gradients under two pH conditions. At pH 7, the DNA is double-stranded; at pH 12 the strands are separated, and DNA is in the random-coil configuration.

Molecular crystallography of this fragment and other small DNA fragments has given us much more detailed information concerning the secondary structure of polynucleotides. The results of such a study on B-DNA are shown in Figure 4.16. Because the smaller size of this oligonucleotide pair, relative to polymeric DNA, gives it more structural uniformity, we can show DNA molecules with the position of every atom clearly specified.

A first major point emerging from the molecular crystal studies is that the models drawn from the fiber patterns represent oversimplifications of the structures.

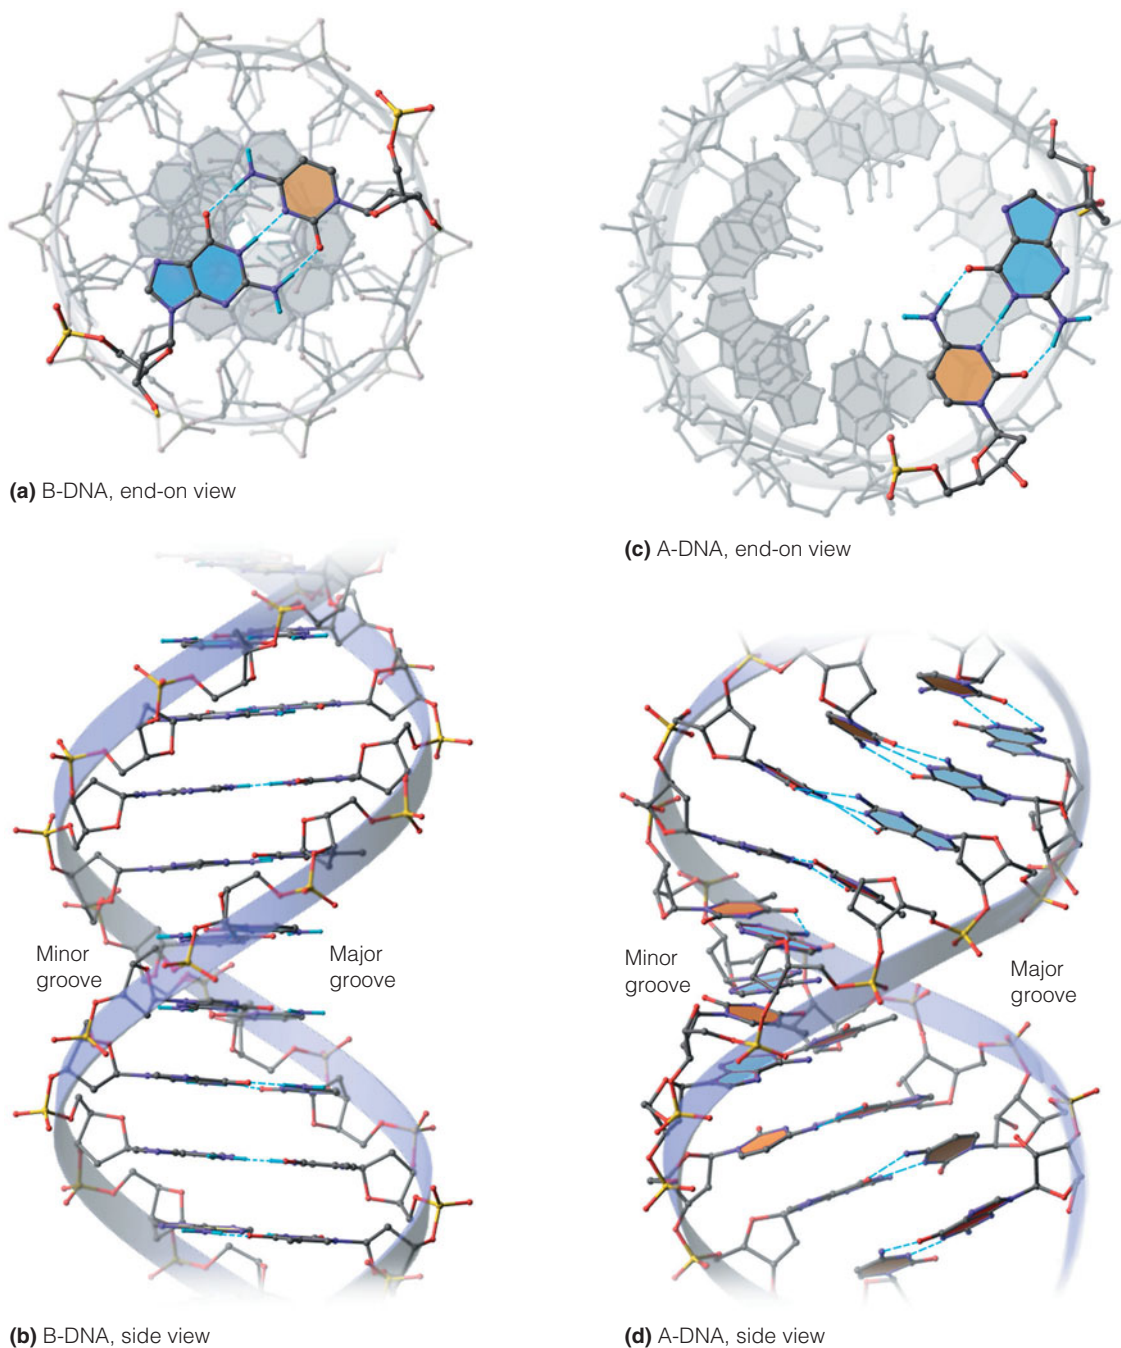

FIGURE 4.15

Comparison of the two major forms of DNA.
 The structures of B-DNA and A-DNA, as deduced from recent fiber diffraction studies, are shown here in both end-on and side views.

TABLE 4.3 Parameters of polynucleotide helices			
	A Form	B Form	Z Form
Direction of helix rotation	Right	Right	Left
Number of residues per turn (n)	11	10	12 (6 dimers)
Rotation per residue ($= 360^\circ/n$)	33°	36°	-60° per dimer; $\sim -30^\circ$ per residue
Rise ^a in helix per residue (h)	0.255 nm	0.34 nm	0.37 nm
Pitch ^a of helix ($= nh$)	2.8 nm	3.4 nm	4.5 nm

^aFor definitions of rise and pitch of a helix, see Tools of Biochemistry 4A.

**FIGURE 4.16**

The structure of B-DNA from studies of molecular crystals. Note the local distortions of the idealized structure shown in Figures 4.11 and 4.15a and b.

Illustration, Irving Geis. Adapted by Richard E. Dickerson. Image from Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Not to be reproduced without permission.

The real structure of B-DNA involves local variations in the angle of rotation between base pairs, the sugar conformation, the tilt of the bases, and even the rise distance. If you examine Figure 4.16 carefully, you can see many distortions from the idealized structures. Nucleic acid secondary structure is not homogeneous. It varies in response to the local sequence and can be changed by interaction with other molecules. The parameters given for various forms of DNA in Table 4.3 should therefore be thought of as *average* values, from which considerable local deviation is possible.

If one closely examines structures like that shown in Figure 4.16, another departure from the original Watson–Crick model becomes apparent. Many DNA molecules are slightly *bent*; that is, the helix axis does not follow a straight line. The degree and directions of bending depend in a complicated way on DNA sequence. They can also be strongly influenced by the interaction of DNA with various protein molecules; we see examples of this in later chapters.

The molecular crystallographic studies also provide a possible explanation of why B-DNA is favored in an aqueous environment. The B form of DNA, but not A-DNA, can accommodate a spine of water molecules lying in the minor groove. The hydrogen bonding between these water molecules and the DNA may confer stability to the B form. According to this hypothesis, when this water is removed (as in fibers at low humidity), the B form becomes less stable than the A form.

Why, then, do double-stranded RNA and DNA–RNA hybrids always adopt the A form? The answer probably lies in the extra hydroxyl group on the ribose in RNA. This hydroxyl interferes sterically in the B form by lying too close to the phosphate and carbon 8 on the adjacent base. Therefore, RNA *cannot* adopt the B form, even under conditions in which hydration might favor it. In DNA, the hydroxyl is replaced by hydrogen, and such steric hindrance does not occur.

DNA and RNA Molecules in Vivo

We have described some of the major features of DNA and RNA. But in what forms do these molecules exist in the living cell? Most of the DNA in most organisms is double-stranded, with the two strands being complementary, although some DNA viruses carry single-stranded DNA molecules (Table 4.4). The proportions of B and A forms of polynucleotides *in vivo* are as you might expect from the conditions under which these conformations are stable. Because cells contain much water, we would expect most of the double-stranded DNA to be in the B form or something much like it. There is evidence that B-DNA dissolved in solution is only a little different in conformation from the B-form seen in fiber preparations, having about 10.5 base pairs per turn instead of the expected 10.0. Double-stranded RNA, as mentioned earlier, always exists in the A form.

The DNA molecules found in organisms vary over an enormous range of sizes. The double-stranded DNA of human mitochondria is only 16,569 base pairs long, while some bacterial *plasmids*, or small extrachromosomal DNA molecules, are much smaller. On the other hand, some DNAs, like those in the chromosomes of eukaryotes, are immense molecules. The DNA from one *Drosophila* (fruit fly) chromosome has a molecular weight of about 4×10^{10} g/mol and would be 2 cm long if fully extended.

Circular DNA and Supercoiling

Another important feature of naturally occurring DNA molecules is illustrated in Figure 4.17a and b: Many of them are *circular*. This means that they do not have free 5' or 3' ends. The circles may be small, as in bacteriophage ϕ X174 DNA (Figure 4.17a), or immense, as in *E. coli* DNA (Figure 4.17b), and they may involve either a single strand or two strands intertwined in a B-form double helix. Not all DNA molecules are circular, however. Figure 4.17c shows the linear DNA of a virus, bacteriophage T2. Human chromosomes also contain giant linear DNA molecules.

Most DNA molecules *in vivo* are double-stranded; many are closed circles. Most double-stranded circular DNA molecules are supercoiled.

TABLE 4.4 Properties of some naturally occurring DNA molecules

Source	Single Strand (SS) or Double Strand (DS)	Circular or Linear	Number of Base Pairs (bp) or Bases (b)	Molecular Mass (Da)	Length ^b	% (G + C)
Simian virus 40 (genome) ^a	DS	Circular	5243 bp	3.293×10^6	1.78 μm	40.80
Bacteriophage ϕX174 (genome)	SS	Circular	5386 b	1.664×10^6	— ^d	44.76
Bacteriophage M13 (genome)	SS	Circular	6407 b	1.977×10^6	— ^d	40.75
Cauliflower mosaic virus (genome)	DS	Circular	8031 bp	4.962×10^6	2.73 μm	40.19
Adenovirus AD-2 (genome)	DS	Linear	35,937 bp	2.221×10^7	12.2 μm	55.20
Epstein–Barr virus (genome)	DS	Circular	172,282 bp	1.065×10^8	58.6 μm	59.94
Bacteriophage T4 (genome)	DS	Linear	168,899 bp	1.062×10^8	57.4 μm	35.30
Bacterium <i>E. coli</i> (genome)	DS	Circular	4,639,221 bp	2.869×10^9	1.57 mm	50.80
Fruit fly (<i>Drosophila melanogaster</i>) (one chromosome) ^c	DS	Linear	$\sim 6.5 \times 10^7$ bp	$\sim 4.3 \times 10^{10}$	~ 2 cm	~ 40

^aThe term *genome* designates the total DNA to specify the genetic information for an organism.

^bCalculated for double-strand DNA of known sequence: $0.34 \text{ nm} \times$ the number of base pairs (assumes B form).

^cThis molecule has not been completely sequenced, so numbers of base pairs, molecular weights, and % (G + C) cannot be given exactly.

^dThe lengths of single-strand DNAs are not well defined; they depend very much on solvent conditions.

(a) Viral single-strand DNA (circular)

(b) Bacterial double-strand DNA (circular)

(c) Bacteriophage double-strand DNA (linear)

FIGURE 4.17

Circular and linear nucleic acid molecules as seen by the electron microscope. (a) The circular single-stranded DNA of the small bacteriophage ϕX174 . (b) The large circular double-stranded DNA of *E. coli*. This molecule exists as a number of supercoiled loops bound to a protein matrix. (c) The single linear double-stranded DNA molecule of bacteriophage T2. The bacteriophage has been lysed, and its DNA has spilled out. One of the two ends is off screen to the lower right. The other is presumably buried in the phage head.

**FIGURE 4.18**

Relaxed and supercoiled DNA molecules. Electron micrograph showing three human mitochondrial DNA molecules. All three are of identical sequence and contain 16,569 bp each. However, the molecule in the center is relaxed, whereas those at top and bottom are tightly supercoiled.

Courtesy of Dr. David A. Clayton.

There is a special aspect to circular DNA molecules that one might not readily expect: Most are **supercoiled**. What this means can be seen by considering the group of molecules shown in Figure 4.18. The figure shows both relaxed and supercoiled forms of mitochondrial DNA molecules. A relaxed circle can lie flat on a plane surface. A supercoiled molecule cannot. In addition to the twist of the DNA strands about one another, a supercoiled molecule has extra twists in the helix axis itself—the helix axis crosses over itself one or more times. Three-dimensional structure, such as supercoiling, that involves a higher-order folding of elements of regular secondary structure is called the **tertiary** structure of a polymer.

Supercoiling is by no means rare. Rather, it is the usual state of closed circular DNA molecules. Most naturally occurring circular DNA molecules have left-handed superhelical twists, but it is possible to form DNA molecules with right-handed superhelicity. By convention, we call right supercoiling **positive** and left supercoiling **negative**.

The DNA molecules shown in Figure 4.18 differ only in their topology, meaning that they can be superimposed only by breaking bonds; therefore, they are called **topoisomers**. Topoisomers can be interconverted *only* by cutting and resealing the DNA. Cells have enzymes capable of doing this. These enzymes are called **topoisomerases**, and they regulate the superhelicity of natural DNA molecules.

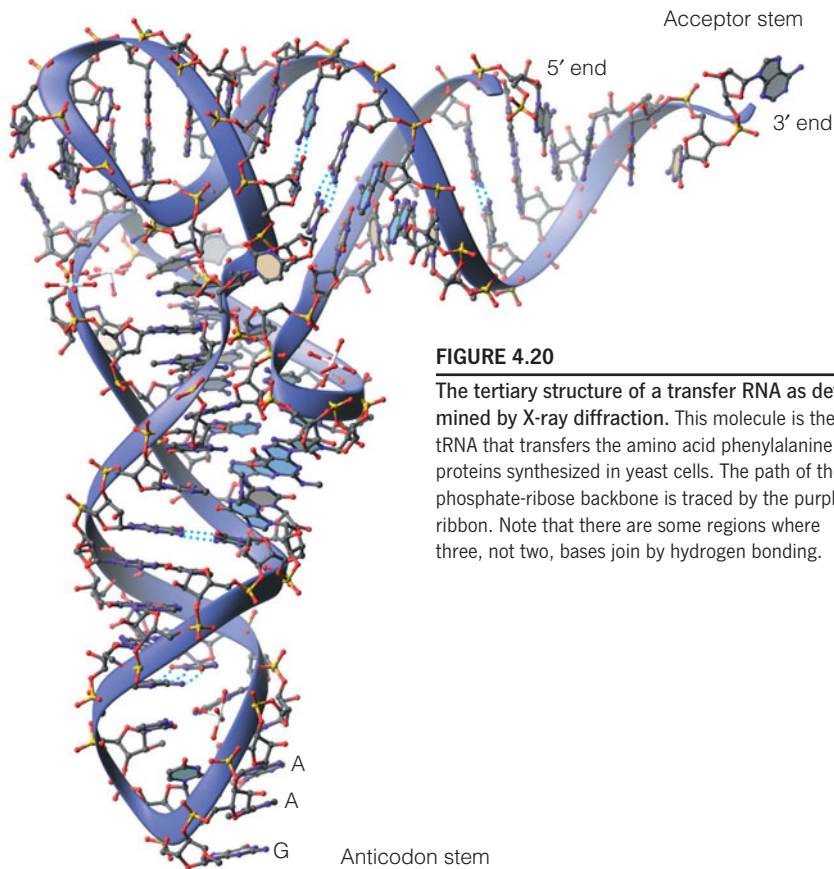

When superhelical turns (either left-handed or right-handed) are introduced into a previously relaxed DNA molecule, the molecule is put under strain. Therefore, energy must be expended to make a DNA molecule supercoiled. Prokaryotic cells like *E. coli* have a special topoisomerase called **DNA gyrase**. This enzyme introduces left-handed superhelical turns in a reaction driven by ATP hydrolysis. Some topoisomerases, which can only relax supercoiled DNA, do not require ATP. We discuss topoisomerases in more detail in Chapter 25. The energy stored in circular DNAs by twisting them into supercoils may have major effects on DNA conformation; we describe such effects later in this chapter after we present a quantitative theory of supercoiling.

Structure of Single-Stranded Polynucleotides

Single-stranded polynucleotides can exhibit a variety of structures, depending on their sequences and the solution conditions. At high temperature or in the presence of denaturing substances, most will be largely in a random coil form, as depicted in Figure 4.19a. Such a structure is characterized by flexibility and freedom of rotation about backbone bonds, which leads to a floppy, constantly changing form. However, under conditions closer to those found in vivo, the stacking interactions will tend to form regions of single-chain, stacked-base helix (Figure 4.19b). Furthermore, most naturally occurring nucleic acid sequences contain regions of self-complementarity between which base pairing is possible. Here the molecule can loop back upon itself to form a double-stranded structure, as diagrammed in Figure 4.19c. A more complex example is given in Figure 4.20, which portrays the structure of a **transfer RNA (tRNA)**, an RNA involved in protein synthesis (see next section). Here we find not only A-type secondary structure from the folding of the chain back on itself but also more complex folding of such helices together. Thus, the tRNA molecule possesses a defined *tertiary* structure, a higher-order folding that gives it a defined shape and internal arrangement necessary for its function. The much larger RNA molecules from ribosomes have similar secondary structure features, but much more complex tertiary structures, as we shall see in Chapter 28.

FIGURE 4.19

Conformations of single-stranded nucleic acids. (a) The random coil structure of denatured single strands. There is flexibility of rotation of residues and no specific structure. (b) Stacked-base structure adopted by non-self-complementary single strands under “native” conditions. Bases stack to pull the chain into a helix, but there is no H-bonding. (c) Hairpin structures formed by self-complementary sequences; the chain folds back on itself to make a stem-loop structure.

**FIGURE 4.20**

The tertiary structure of a transfer RNA as determined by X-ray diffraction. This molecule is the tRNA that transfers the amino acid phenylalanine into proteins synthesized in yeast cells. The path of the phosphate-ribose backbone is traced by the purple ribbon. Note that there are some regions where three, not two, bases join by hydrogen bonding.

The higher-order folding of a biopolymer's secondary structure is called its tertiary structure.

Most DNA molecules found in vivo are left-handed supercoils.

RNA molecules are usually single-stranded, but most have self-complementary regions that form hairpin structures, and some have well-defined tertiary structures.

The Biological Functions of Nucleic Acids: A Preview of Molecular Biology

We have emphasized that the fundamental role of the nucleic acids is the storage and transmission of genetic information, and we will continue to develop this theme throughout the book. In Part V we describe in detail how nucleic acids are passed from parent cell to daughter cell (or from an organism to its descendents) and how they direct biochemical processes, specifically, the synthesis of proteins. In this chapter and the next, we present a preliminary overview of these nucleic acid functions. Even though this may not be your first exposure to these topics, you should gain some further appreciation of the relationships between nucleic acid and protein structures, of evolution at the molecular level, and of our ability to modify microbes, plants, and animals through genetic engineering.

Genetic Information Storage: The Genome

Every organism carries in each of its cells at least one copy of the total genetic information possessed by that organism. This is referred to as the *genome*. Usually, the genomic information is coded in the sequence of double-stranded DNA, but some viruses use single-stranded DNA or even RNA (see Table 4.4). Genomes vary enormously in size; the smallest viruses need only a few thousand bases (b) or base pairs (bp), whereas the human genome consists of about 3×10^9 bp of DNA, distributed in 23 chromosomes. Other organisms have far more (Chapter 24).

Recent years have seen remarkable advances in our ability to determine DNA or RNA sequences. In 1976, Maxam and Gilbert (see References) devised a chemical sequencing method involving selective cleavage at A, T, G, or C residues, followed by separation of the fragments on the basis of fragment length, using gel

electrophoresis. This ingenious technique allowed researchers to begin the exploration of genomic information. The Maxam–Gilbert method has been largely supplanted by a technique that uses enzymes to generate oligonucleotide fragments started and terminated at specific base positions. This method, developed by Fred Sanger, is described in detail in Tools of Biochemistry 4B. Automation of this technique, and development of much faster “high-throughput” methods, has led to the complete genome sequence analysis of hundreds of species, including near-completion of the human genome sequence in 2001, and complete genome sequences for many individual humans within the subsequent few years.

In every organism a significant fraction of the genomic DNA is capable of being transcribed, or “read,” to allow expression of its information in directing synthesis of RNA and protein molecules. Each DNA segment that encodes one protein or one RNA molecule is a gene. The DNA in each cell of every organism contains at least one copy (and sometimes several) of the gene carrying the information to make each protein that the organism requires. In addition, there are genes (often reiterated manyfold) for the many specific functional RNA molecules, such as the transfer RNA (tRNA) shown in Figure 4.20. Like proteins, these RNAs play specific roles as part of the cell’s machinery. (See Table 4.5.) We briefly mention the functions of messenger RNA, ribosomal RNA, and transfer RNA in this chapter, and the more recently discovered micro RNAs and their role in *RNA interference* in Chapter 29.

TABLE 4.5 Properties of some naturally occurring RNA molecules

Source (Organism)	Designation	Function	Size (b or bp)
tRNA (transfer RNA)			
<i>E. coli</i>	tRNA ^{Leu}	Transfers leucine in protein synthesis	87 b
Yeast	tRNA ^{Phe}	Transfers phenylalanine in protein synthesis	76 b
Rat	tRNA ^{Ser}	Transfers serine in protein synthesis	85 b
rRNA (ribosomal RNA)			
<i>E. coli</i>	5S RNA	Part of ribosome structure	120 b
	16S RNA	Part of ribosome structure	1542 b
	23S RNA	Part of ribosome structure	2904 b
mRNA (messenger RNA)			
Chicken	mRNA _{LYS}	Messenger RNA for protein lysozyme	584 b
Rat	mRNA _{SA}	Messenger RNA for protein serum albumin	~2030 b
vRNA (viral RNA)			
Polio virus	Polio RNA	Genome of the virus	7440 b
Cytoplasmic polyhedrosis virus of tussock moth	CPV RNA	Genome of the virus	Ten double-stranded molecules, ~890 to ~5150 bp
miRNA (microRNA), siRNA (small interfering RNA)			
All or most eukaryotes	miRNA, siRNA	Control of gene expression	21–24 b

Replication: DNA to DNA

Replication passes on the genetic information from cell to cell and from generation to generation. The essence of the process is depicted in Figure 4.12—a complementary copy of each strand of duplex DNA is made, usually resulting in two identical copies of the original duplex. The process is highly accurate in copying—making less than 1 error in 10^8 bases—but occasionally mistakes are made. These contribute to the mutations that have allowed the evolution of life to ever more complex forms.

The replication of DNA is accomplished by a complex of enzymes, acting in concert like a finely tuned machine. These enzymes are described in detail in Chapter 25. Each enzyme complex, or **replisome**, centered on a protein called *DNA polymerase*, has multiple functions. As parental DNA strands unwind, forming a *replication fork* (see Figure 4.12), DNA polymerase guides the pairing of incoming deoxyribonucleoside triphosphates, each with its complementary partner on the strand being copied. It then catalyzes the formation of the phosphodiester bond to link this residue to the new growing chain. Thus, each of the parental DNA strands serves as a **template**, specifying the sequence of a daughter strand. DNA polymerase adds nucleotides, one at a time, to the growing daughter strand, which can be considered a **primer** to which nucleotides are added as the daughter DNA strand grows from its 5' end toward its 3' end, as shown in Figure 4.21. In most cases, the enzyme complex also checks, or “proofreads,” the addition before proceeding to add the next residue; proofreading contributes to the high overall accuracy of replication. Because the two DNA strands run in opposite directions, one daughter strand is elongated in the same direction as that of the replication fork while the other is formed in the reverse direction. This and other aspects of DNA replication are discussed in more detail in Chapter 25.

FIGURE 4.21

The DNA polymerase reaction.

DNA polymerase fits a deoxyribonucleoside triphosphate molecule to its complementary nucleotide in the template strand (blue) and catalyzes formation of a phosphodiester link between the incoming nucleotide and the 3'-hydroxyl of the 3'-terminal nucleotide in the growing daughter strand (red), with pyrophosphate being split out.

Transcription: DNA to RNA

Expression of genetic information always involves as a first step the **transcription** of genes into RNA molecules of complementary nucleotide sequence. This production of specific RNA molecules is easy to visualize. Just as a DNA strand can direct replication, it can equally well direct transcription, the formation of a complementary RNA strand (Figure 4.22). Of course, the monomers required in transcription are different from those required in replication. Instead of the

Transcription is the copying of a DNA strand into a complementary RNA molecule.

FIGURE 4.22

The basic principle of transcription. An enzyme (RNA polymerase) travels along a DNA molecule, opening the double strand and making an RNA transcript by adding one ribonucleotide at a time. It copies the oligonucleotide sequence from only one of the two DNA strands. After the enzyme passes, the DNA rewinds.

deoxyribonucleoside triphosphates (dNTPs), the ribonucleoside triphosphates ATP, GTP, CTP, and UTP are needed to make RNA. (Note that U in the new RNA pairs with A in the DNA template.) Another distinction from DNA replication is that only one of the two DNA strands, the **template strand**, is copied. The other strand is called the sense strand, or coding strand. DNA transcription, like DNA replication, requires a special set of enzyme catalysts known as *RNA polymerases*. Transcription is presented in detail in Chapter 27.

Translation: RNA to Protein

Transcription is the central process in producing the many functional RNA molecules of the cell, such as the transfer RNAs or ribosomal RNAs listed in Table 4.5. The synthesis of specific proteins, under the direction of specific genes, is a more complex matter. The problem, as we see in Chapter 5, is that proteins are polymers made from 20 different kinds of amino acid monomers. Because there are only four different nucleotide monomer types in DNA, there cannot be a one-to-one relationship between the sequence of nucleotides in a DNA molecule and the sequence of amino acids in a protein. Rather, the linear sequence of bases that constitutes the protein-coding information is “read” by the cell in blocks of three nucleotide residues, or **codons**, each of which specifies a different amino acid. The set of rules that specifies which nucleic acid codons correspond to which amino acids is known as the **genetic code**. We describe this code in Chapter 5 after we have described the amino acids and the structure of proteins.

In translation, an RNA nucleotide sequence dictates a protein amino acid sequence.

Although the information for all protein sequences is coded in DNA, the production of proteins does not proceed directly from DNA. For the information to be converted from the DNA sequences of the genes into amino acid sequences of proteins, special RNA molecules are needed as intermediates. Complementary copies of the genes to be expressed are transcribed from DNA in the form of **messenger RNA (mRNA)** molecules (see Table 4.5), so called because they carry information from DNA to the protein-synthesizing machinery of the cell. The machinery includes tRNA molecules, special enzymes, and **ribosomes**, which are RNA–protein complexes upon which the assembly of new proteins takes place. This **translation** of RNA information is outlined in Figure 4.23. (We present the main features of translation in Chapter 5 and describe it in detail in Chapter 28.) The flow of genetic information in the cell can be summarized by the simple schematic diagram shown in Figure 4.24.

FIGURE 4.23

The basic principle of translation.

A messenger RNA molecule is bound to a ribosome, and transfer RNA molecules bring amino acids to the ribosome one at a time. Each tRNA identifies the appropriate codon on the mRNA and adds this amino acid to the growing protein chain. The ribosome travels along the mRNA so that the genetic message can be read and translated into a protein.

As we show in the following chapters, proteins are the major structural and functional molecules in most cells. What a cell is like and what it can do depend largely on the proteins it contains. These, in turn, are dictated by the information stored in the cell's DNA, transcribed and processed into mRNA, and expressed by the protein-synthesizing machinery. If we use the analogy of a cell as a factory, the proteins are the working machinery. The master plans for this machinery are stored in a central repository (the DNA of the cell nucleus). Copies of certain plans (mRNAs) are sent out from time to time as new protein machinery or replacements are needed. Those plans find their way to ribosomes where these RNA- and protein-containing particles, in conjunction with transfer RNA molecules, catalyze the template-dependent assembly of proteins. Overlaid on these processes are recently described small RNA molecules, barely 20 nucleotides long, which help regulate the process. These **microRNAs** are discussed further in Chapter 29.

Plasticity of Secondary and Tertiary DNA Structure

In preceding sections we described the B and A forms of DNA, and we briefly mentioned supercoiling of circular DNA. We now recognize that a number of special secondary and tertiary structures exist. Some of these, notably supercoiling, are involved in packing giant DNA molecules into cells. Some depend on the presence of special primary structures, and in some cases they can be stabilized by the presence of supercoiling. To begin, then, we must look more closely into the nature of supercoiled DNA.

Changes in Tertiary Structure: A Closer Look at Supercoiling

In order to get a quantitative feeling for what supercoiling means, examine the "thought experiment" described in Figure 4.25. Consider the linear DNA molecule shown in Figure 4.25a. It contains enough base pairs to make exactly 10 helical turns; we say it has a **twist** (T) = 10.0. Now suppose we took this DNA molecule, laid it flat on a surface, and brought the strand ends together 5' to 3'

FIGURE 4.24

The flow of genetic information in a typical cell. DNA can both replicate and be transcribed into RNA. Messenger RNAs are translated into protein amino acid sequences.

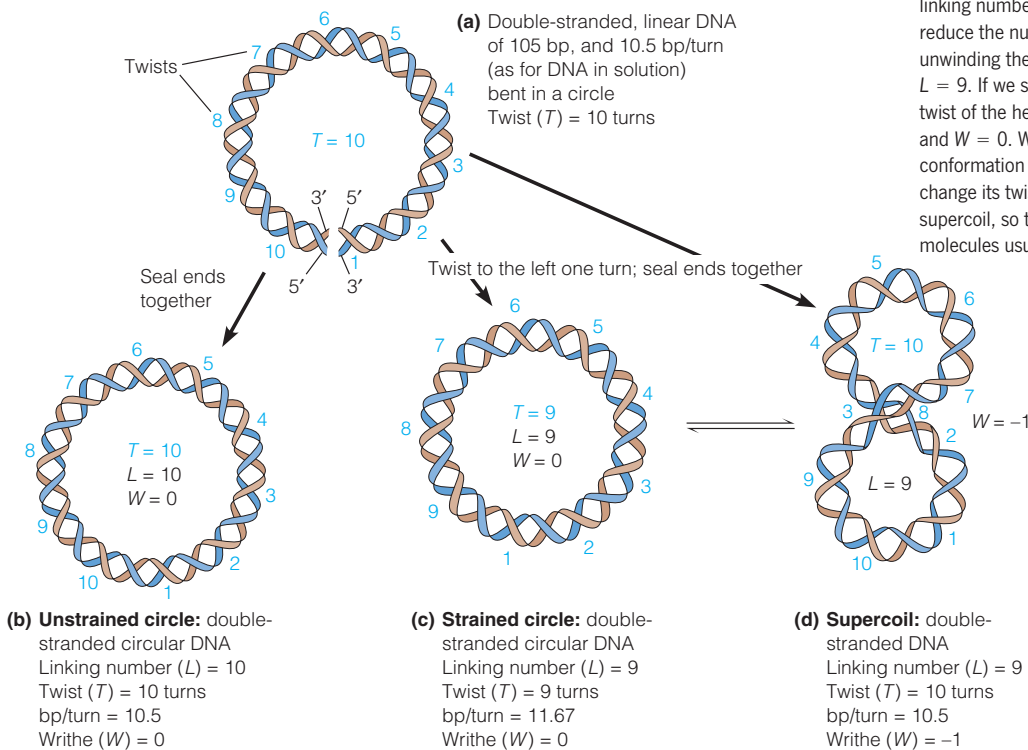

FIGURE 4.25

Forming a DNA supercoil. We can imagine making a linear DNA circular in several ways: **(a)** A linear DNA is laid flat. It has 105 base pairs and 10.5 bp/turn, so there are 10 turns; the twist $T = 10$. **(b)** Because there is an integral number of turns, we can link the 5' and 3' ends together without twisting, to form a relaxed circle that lies flat. The linking number $L = 10$ and the writhe $W = 0$. **(c)** If we reduce the number of turns before joining the ends, by unwinding the DNA one turn, the closed circle will have $L = 9$. If we still require the DNA molecule to lie flat, the twist of the helix must change. We now have $L = 9$, $T = 9$, and $W = 0$. With $T = 9$ in 105 bp, the DNA is forced into a conformation with $105/9 = 11.67$ bp/turn. **(d)** Rather than change its twist, the strained DNA molecule may writhe, or supercoil, so that $L = 9$, $T = 10$, and $W = -1$. Strained molecules usually supercoil rather than change their twist.

(Figure 4.25a). Because the DNA molecule contains just enough base pairs to make 10 complete turns of the helix, the 5' and 3' ends of each strand would be in position to meet one another, and we could covalently join them. (Enzymes called *ligases* carry out this joining.) This connection would make a relaxed circle that could still lie flat on the surface (Figure 4.25b). The covalently closed molecule now has another property—the strands are interlinked 10 times. We say that it has a **linking number** (L) of 10.

Now suppose instead that before joining the ends of this right-handed double helix, we made one turn to the left, unwinding by one turn and thereby reducing the linking number to 9. This change would place a strain on the circular DNA, which could respond in two different ways:

1. The molecule could remain flat on the surface with its twist reduced to 9 ($T = 9$, as shown in Figure 4.25c). The normal 10.5 bp per turn of the helix would then be increased to 11.67. The strain on this DNA molecule is expressed in its “unnatural” twist; it is said to be *underwound*. (If we had added an extra turn to the right instead of left, the circle would also be strained, but it would be *overwound*, with 11 twists and 9.54 bp/turn.)
2. The molecule could restore its original twist ($T = 10$) by wrapping about itself in one negative (left-handed) superhelical turn, as shown in Figure 4.25d. The number of such superhelical turns is called the **writhe** (W); in this case $W = -1$. (If we had added one twist to the right, the molecule could form a positive, or right-hand, writhe with $W = +1$; in the first response, with no supercoiling, $W = 0$.)

When we untwisted one turn and then joined, we produced a molecule in which the two strands were interlinked only 9 times; $L = 9$. The quantity L will remain unchanged no matter how we might distribute the strain of underwinding between twist and writhe. Thus, the two forms found in Figure 4.25c and 4.25d both have $L = 9$. Note that in every case, the linking number is the algebraic sum of T and W :

$$L = T + W \quad (4.1)$$

The linking number is always the algebraic sum of twist and writhe.

The only way in which L can be changed is by cutting, twisting, and rejoining the circular molecule—by means of topoisomerases, for example. When we added the extra twist to the left at the beginning of our experiment, we changed the value of L by -1 ($\Delta L = -1$). The strain imposed by putting L extra turns in the DNA helix distributes itself between a change in twist and a change in writhe: where L is positive or negative, depending on whether the extra twists (T) and superhelical turns (W) are right-handed (positive) or left-handed (negative).

$$\Delta L = \Delta T + \Delta W \quad (4.2)$$

The superhelix density, σ , is a quantitative measure of the intensity of supercoiling.

The superhelicity of DNA molecules is often expressed in terms of the **superhelix density**, $\sigma = \Delta L/L_0$, where L_0 is the linking number for the DNA in the relaxed state. Many naturally occurring DNA molecules have superhelix densities of about 0.06. To get an idea of what this means, consider a hypothetical DNA molecule of 10,500 bp, which is in the solution B form, with 10.5 bp/turn. Then L_0 is 10,500 bp/(10.5 bp/turn), or 1000 turns. Each DNA strand crosses the other 1000 times in the relaxed circle. If the topoisomerase DNA gyrase (see page 1055) twisted the molecule to a superhelical density of -0.06 , then $L = -0.06 L_0$, or $L = -60$. This change could be accommodated, for example, by the helix axis writhing about itself 60 times in a left-handed sense, which would correspond to $\Delta W = -60$, $T = 0$; the molecule would have 60 left-handed superhelical turns. Alternatively, the twist of the molecule could change so that it had 940 turns in 10,000 bp ($T = 940$) or

$10,500/940 = 11.2$ bp/turn. This would correspond to $\Delta W = 0$, $\Delta T = -60$. Although any combination of ΔT and ΔW that sums to -60 could occur, real molecules release strain mainly by writhing into superhelical turns because it is easier to bend long DNA than to untwist it. This explains the contorted structures of the double-stranded circular DNA molecules in Figures 4.17b and 4.18.

Differences in supercoiling can be detected by gel electrophoresis. As described in Tools of Biochemistry 2A, the rate at which a molecule migrates through a gel matrix in an electric field depends on its dimensions; hence the more compact superhelical forms will move faster than the relaxed form. Figure 4.26 shows electrophoretic patterns for supercoiled DNA molecules that are being progressively relaxed by the action of the enzyme topoisomerase. Thus, gel electrophoresis allows us to separate topoisomers of a given DNA.

Unconventional Secondary Structures of DNA

Most of the DNA and RNA in cells can be described as having one of the three secondary structures—random coil (which is really a lack of secondary structure), B form, or A form. But these three do not nearly exhaust the conformational possibilities of these remarkable molecules. In the remainder of this chapter we consider some of the alternative structures that have been recognized in recent years, and we will examine the conditions under which conformational transitions between them take place. We will see that supercoiling often plays a dominant role in these transitions.

Left-Handed DNA (Z-DNA)

Because both the A and B forms of polynucleotide helices are right-handed (see Figure 4.15), the discovery of a left-handed form in 1979 caused considerable surprise. Alexander Rich and his colleagues carried out X-ray diffraction studies of crystals of the small oligodeoxynucleotide

and determined that it is a double-stranded helix with G-C base pairing, as they had expected. However, the data were consistent only with a peculiar *left-handed* structure they called Z-DNA. A model for a long DNA molecule in the Z conformation is shown in Figure 4.27.

In addition to the reverse sense of the helix, Z-DNA exhibits other structural peculiarities. There are, in polynucleotides, two most stable orientations of the bases with respect to their deoxyribose rings. They are called *syn* and *anti*:

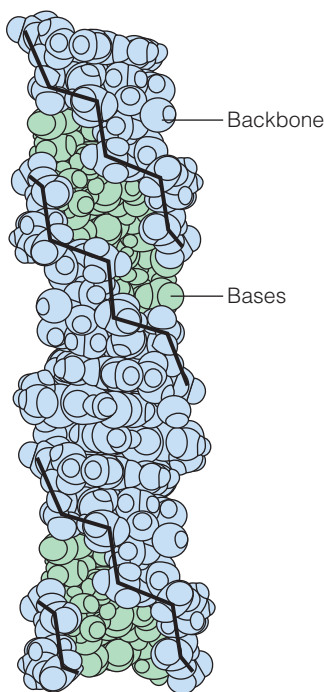

FIGURE 4.26

Gel electrophoresis demonstrating DNA supercoiling. Lane 1: A mixture of relaxed and highly supercoiled DNA. Lanes 2 to 6: The progress of relaxation catalyzed by the enzyme topoisomerase. Samples have been taken at successive times after adding the enzyme. Individual topoisomers are resolved as individual bands on the gel. The highly supercoiled material, which forms a densely packed series of overlapping bands at the bottom, gradually disappears. The DNA species are resolved by electrophoresis in an agarose gel and then visualized by adding the dye ethidium bromide (page 1078) to the gel, a treatment that makes each DNA species fluorescent.

**FIGURE 4.28**

How self-complementarity dictates the tertiary structure of tRNA. A schematic drawing of the tRNA shown in Figure 4.20. X's represent unusual or modified bases (see Chapter 28). The molecule has three hairpin arms resulting from self-complementarity. These arms fold into the tertiary structure of Figure 4.20.

In both A- and B-form polynucleotides, all bases are in the *anti* orientation. In Z-DNA, however, the *pyrimidines* are always *anti*, but the *purines* are always *syn*. Because Z-DNA is most often found in polynucleotides with alternating purines and pyrimidines in each strand (such as that shown earlier), the base orientations will alternate. Parameters for Z-DNA (see Table 4.3, page 105) reflect this characteristic, in that the repeating unit is not one base pair but two base pairs. Furthermore, this alternation gives a zigzag pattern to the phosphates; hence the name Z-DNA (see Figure 4.27).

There is now abundant evidence that Z-DNA exists in living cells. However, the exact role played by Z-DNA *in vivo* is still an open question, partly because of the difficulty of quantitating Z-DNA in living cells. It is perhaps significant that methylation of cytosines on carbon 5, a common modification *in vivo*, favors Z-DNA.

Hairpins and Cruciforms

We have already encountered examples of “hairpin” structures—first in Figure 4.19c and then in the transfer RNA shown in Figure 4.20. In each of these single-stranded molecules, self-complementarity in the base sequence allows the chain to fold back on itself and form a base-paired, antiparallel helix. The schematic structure of a tRNA shown in Figure 4.28 depicts how a particular base sequence accomplishes this folding.

Double hairpins, often called **cruciform** (cross-like) structures, can be formed in some DNA sequences. To form this structure, the sequence must be **palindromic**. As mentioned also on page 129, the word *palindrome* is of literary origin and usually refers to a statement that reads the same backward and forward, such as “Able was I ere I saw Elba.” As used in descriptions of DNA, the word refers to segments of complementary strands that are the exact (or almost exact) reverse of one another. Such a DNA sequence is shown in Figure 4.29, along with the two conformations available to it. In most instances, formation of the cruciform structure leaves a few bases unpaired at the ends of the hairpins. This means that under normal circumstances the cruciform will be less stable than the extended structure. As we shall see later in this chapter, one effect of superhelical strain is to stabilize cruciforms.

Triple Helices and H-DNA

It has long been recognized that certain homopolymers can form **triple** helices. The first to be discovered was the synthetic RNA structure

Later, it was observed that deoxy triplets like $\text{T} \cdot \text{A} \cdot \text{T}$ and $\text{C}^+ \cdot \text{G} \cdot \text{C}$ (where C^+ is a protonated cytosine) can also be formed. Such structures involve, in addition to the normal Watson–Crick base pairing, the *Hoogsteen-type* base pairing shown in Figure 4.30. It is now recognized that many polynucleotide strands, including some of nonrepeating sequence, can enter into such triple helices. An unusual structure that can incorporate a triple helix is shown in Figure 4.31. It is called H-DNA and requires a molecule that has one all-pyrimidine strand (Pyr) and one all-purine strand (Pur). In the example shown, the structure

can exist either in the normal, double-stranded form, or with one strand looped back to form a triple helix (with $\text{C}^+ \cdot \text{G} \cdot \text{C}$ and $\text{G} \cdot \text{A} \cdot \text{G}$ triplets), leaving the other (Pur) strand unpaired. Again, the loss of base pairing should make this structure unstable, except in situations where strain in the DNA molecule favors it.

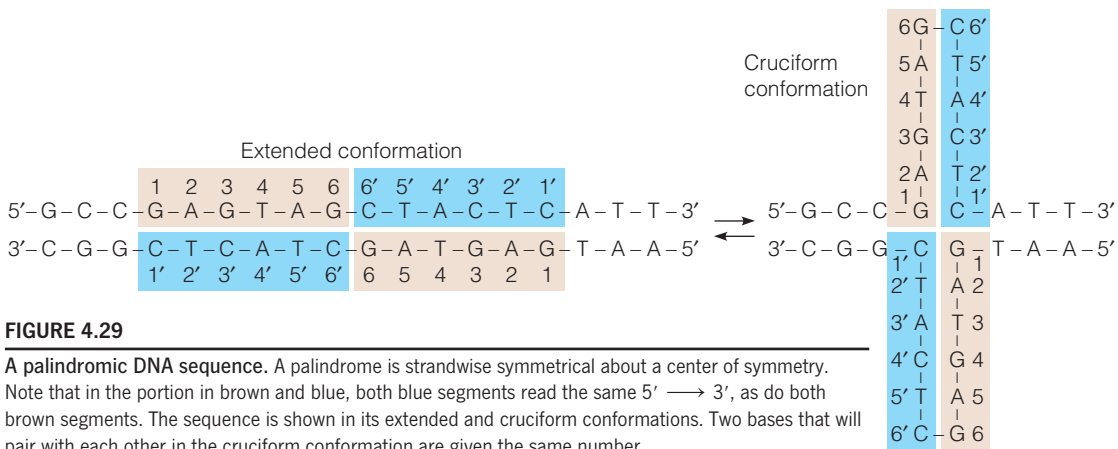

FIGURE 4.29

A palindromic DNA sequence. A palindrome is strandwise symmetrical about a center of symmetry. Note that in the portion in brown and blue, both blue segments read the same 5' → 3', as do both brown segments. The sequence is shown in its extended and cruciform conformations. Two bases that will pair with each other in the cruciform conformation are given the same number.

G-Quadruplexes

As long ago as 1962 David R. Davies realized that four guanine molecules could fit together in a planar hydrogen-bonded structure, and he proposed that such structures might form naturally in guanine-rich sections of DNA. Figure 4.32 shows schematically how four guanines can link to form a **G-quartet** (panel A), and how a single strand of guanine-rich DNA can fold to form a **G-quadruplex** (panel B), in the example shown consisting of three G-quartets. A G-quadruplex structure can form from one DNA strand, as shown, or from as many as four strands. G-quadruplexes actually form in living cells and exist in **telomeres**, special sequences at the ends of linear eukaryotic chromosomes (see Chapter 25). Figure 4.32c shows the likely folding pattern of a human telomere. More recent studies show that G-quadruplexes exist in the transcriptional control sites, or **promoters**, of several biologically important genes, including the **oncogene** cMYC (Chapter 23). Current efforts are aimed at targeting such structures with anticancer drugs.

An Unexpected Primary Structure Modification: DNA Phosphorothioation

All of the unconventional DNA structures described thus far affect secondary and/or tertiary structure, with the phosphodiester link being invariant. Accordingly, there was great surprise in 2007 when Peter Dedon's group at MIT described an enzyme system in bacteria that converts a phosphate group in DNA to a

FIGURE 4.30

Base-pairing in one type of DNA triple helix. Both normal Watson-Crick pairing and the unusual Hoogsteen pairing occur on the same A residue.

FIGURE 4.31

H-DNA. An H-DNA region has one all-purine (blue) and one all-pyrimidine (brown) strand, allowing it to form a triple-stranded helix by doubling back. Some segments contain both purines and pyrimidines (green). **(a)** The nucleotide sequence shown here is one that could give rise to H-DNA. A segment of the purine strand is shown bonded to two different segments of the pyrimidine strand. **(b)** The bonding shown in (a) gives rise to a triple-stranded helix, shown schematically here.

phosphorothioate, as shown in Figure 4.33. The reaction is stereospecific (note that introduction of a sulfur creates an asymmetric center about the phosphorus atom). So far the biological function of this modification is unknown, but it might confer resistance to some foreign invaders, such as bacteriophages, which could degrade unmodified DNA. Recent sequence analysis shows that phosphorothioate nucleotides are clustered in many bacteria, consistent with the idea that phosphorothioation could be part of a restriction-modification system (Chapter 26).

Stability of Secondary and Tertiary Structure

The Helix-to-Random-Coil Transition: Nucleic Acid Denaturation

The major polynucleotide secondary structures (the A and B forms) are relatively stable for RNA and DNA, respectively, under physiological conditions. Yet they must not be *too* stable because important biochemical processes—DNA replication and transcription, for example—require that the double-helix structure be opened up. When it extends over large regions, this loss of secondary structure is called **denaturation** (Figure 4.34). Competing factors create a balance between structured and unstructured forms of nucleic acids.

Two major factors favor dissociation of double helices into randomly coiled single chains. First is the electrostatic repulsion between the chains. At physiological pH, every residue on a DNA or an RNA molecule carries a negative charge on the phosphate group. Even though this charge is partially neutralized by small

FIGURE 4.33

FIGURE 4.34

Denaturation of DNA. (a) When native (double-stranded) DNA is heated above its “melting” temperature, it is denatured (separates into single strands). The two random-coil strands have a higher entropy than the double helix. (b) At low T , ΔG is positive and denaturation of DNA is not favored. As T increases, $-T\Delta S$ overcomes ΔH , making ΔG negative and denaturation favorable. The midpoint of the curve marks the “melting” temperature, T_m , of DNA. (c) Absorption spectra of native and denatured DNA show that native DNA absorbs less light than denatured DNA, with the maximum difference occurring at a wavelength of 260 nm. This **hypochromicity** of double-stranded DNA can be used to distinguish between native and denatured forms. (d) The change in absorbance can be used to follow the denaturation of DNA as temperature increases. An abrupt increase in absorbance, corresponding to the sudden “melting” of DNA, is seen at T_m .

counterions (like K^+ , Na^+ , and Mg^{2+}) present in the medium, a substantial net negative charge remains on each chain in the helix and tends to drive the two chains apart. Therefore, high ionic strength tends to stabilize the double helix.

A more subtle factor favoring denaturation is that the random-coil structure has a higher entropy, resulting from the greater randomness of the denatured form, with its many possible configurations. Consider Equation 3.9 on page 64 ($S = k \ln W$): If a rigid double helix separates into two flexible random coils, the number of configurations accessible to the molecule greatly increases (Figure 4.34a); therefore, the entropy increases. The free energy change in going from a regular two-stranded polynucleotide secondary structure (such as B-form DNA) to individual random-coil strands is given by the usual formula:

$$\Delta G = \Delta H - T\Delta S \quad (\text{helix} \rightleftharpoons \text{random coil}) \quad (4.3)$$

Because ΔS is positive, the term ($T\Delta S$) makes a negative contribution to the free energy change, favoring denaturation.

Thus, two factors favor the helix \rightarrow coil transition: the higher randomness of the random coil ($\Delta S > 0$) and the electrostatic repulsion between chains ($\Delta H_{el} < 0$). If the double-helical structure is to be stable under any conditions, ΔG for the unfolding reaction must be positive. Therefore, we must look for a large contribution from ΔH to compensate for the factors just mentioned. The sources of such a positive ΔH are the hydrogen bonds between the base pairs and van der Waals interactions between stacked bases. In fact, the planar bases stack upon one another in van der Waals contact. Much energy must be expended to break these bonds and interactions, and hence the total ΔH is positive.

Because ΔH and ΔS in Equation 4.3 are both positive, the sign of ΔG will change as T is increased. At low temperature, the term $T\Delta S$ will be less than ΔH ; ΔG will be > 0 , and the helix will be stable. But as the temperature is increased, $T\Delta S$ will become greater than ΔH , and ΔG will become negative. Thus, at higher temperatures the double-stranded structure becomes unstable and will fall apart (Figure 4.34a).

One can follow this denaturation process by observing the absorbance of ultraviolet light of wavelength about 260 nm in a DNA solution. As mentioned on page 94, all nucleotides and nucleic acids absorb light strongly in this wavelength region. When the nucleotides are polymerized into a polynucleotide, and the bases packed into a helical structure, the absorption of light is reduced (Figure 4.34c). This phenomenon, called *hypochromism*, results from close interaction of the light-absorbing purine and pyrimidine rings. If the secondary structure is lost, the absorbance increases and becomes closer to that of a mixture of the free nucleotides. Therefore, raising the temperature of a DNA solution, with accompanying breakdown of the secondary structure, will result in an absorbance change like that shown in Figure 4.34d.

The remarkable feature of this helix-to-random-coil transition is that it is so abrupt. It occurs over a very small temperature range, almost like the melting of ice into water, as described in Chapter 3. Therefore, nucleic acid denaturation is sometimes referred to as a *melting* of the polynucleotide double helix, even though the term is not technically correct. We shall encounter similar abrupt changes in configuration of proteins in Chapter 6. They are always characteristic of what are called **cooperative transitions**. What this term means in the case of DNA or RNA is that a double helix cannot melt bit by bit. If you examine the kinds of structure shown in Figures 4.11 and 4.20, you will see that it would be very difficult for a single base to pop out of the stacked, hydrogen-bonded structure. Rather, the whole structure holds together until it is at the verge of instability and then denatures over a very narrow temperature range.

The “melting temperature” (T_m) of a polynucleotide depends on its $(G + C)/(A + T)$ ratio. Because each G-C base pair forms three hydrogen bonds and each A-T pair only two, ΔH is greater for the melting of GC-rich

AT-rich regions melt more easily than GC-rich regions.

polynucleotides. The greater stacking energy of G-C pairs also contributes to the difference. The value of T_m corresponds to the temperature at which $\Delta G = 0$ (see Figure 4.34b and d). Thus,

$$0 = \Delta H - T_m \Delta S \quad (4.4)$$

or

$$T_m = \frac{\Delta H}{\Delta S} \quad (4.5)$$

On a per-base-pair basis, ΔS is about the same for all polynucleotides, but ΔH depends on base composition, as just described. This is why T_m increases with increasing (G + C) content. Figure 4.35 shows a graph of T_m versus percent (G + C) for a number of naturally occurring DNAs.

DNA denaturation is reversible. For example, when heat-denatured DNA is cooled, DNA duplexes can reform. The rate of cooling must be slow, allowing time for complementary strands to find one another and pair up, or **renature** (also called **annealing**). Similarly, an RNA molecule can form a duplex with a DNA of complementary base sequence, creating a DNA–RNA hybrid, consisting of one strand each of DNA and RNA. DNA–DNA renaturation and DNA–RNA hybridization are at the root of several important research techniques, as we shall see later in this book.

Superhelical Energy and Changes of DNA Conformation

The storage of energy in DNA supercoiling is analogous to the energy required to wind up (supercoil) rubber bands. That is, the first few turns are easy, but the energy required, per turn, increases as the winding gets tighter. In fact, for DNA the amount of free energy stored in supercoiling (ΔG_{sc}) is proportional to the *square* of the superhelical density σ :

$$\Delta G_{sc} = K\sigma^2 \quad (4.6)$$

where K is a constant. Note that ΔG_{sc} is zero when the DNA is relaxed ($\sigma = 0$) and increases with either positive or negative supercoiling. Furthermore, because the square of σ is involved, the energy required to add an extra turn increases as each turn is added, and it becomes about equal to the energy that one ATP can provide when $\sigma = \pm 0.06$. This is at least one reason why superhelix density is limited to about this value in vivo. Highly supercoiled DNA has a lot of stored energy, which can be reduced by *any* process that decreases the superhelix density. For example, suppose we have a circular DNA molecule with negative superhelical turns. If one repeat of the DNA helix (10 base pairs) were to unwind and locally melt, this change would be the equivalent of a ΔT of -1 . Then, to compensate, one negative superhelical turn could be removed ($\Delta W = +1$); that is, some of the writhing has been compensated by local unwinding. Converting a segment of B-DNA to Z-DNA would be even more efficient, requiring less energy. Each 10 bp of DNA that goes from B to Z goes from a twist of $+1$ (one right-handed twist) to approximately -1 (one left-handed twist). This single change amounts to $T = -2$, which would allow relaxation of two negative superhelical turns ($\Delta W = +2$).

Formation of cruciform structures also relaxes superhelical DNA because every base pair put into a cruciform hairpin is essentially removed from superhelical strain. Likewise, H-DNA formation, which leaves part of one strand unpaired, has the same effect.

In other words, imposing high levels of superhelical torsion on a DNA molecule can promote any one of the following changes: local melting, Z-DNA formation, cruciform extension, formation of H-DNA regions, and quite likely

FIGURE 4.35

Effect of base-pair composition on the denaturation temperature of DNA. The graph shows the rise in “melting” temperature of DNA as its percent (G + C) increases.

Data from *Journal of Molecular Biology* (1962) 5:120, J. Marmur and P. Doty.

Energy stored in supercoiled DNA can be used to drive structural transformation.

formation of some other special conformations not yet discovered. Which of these will happen depends on what special sequences are present in the DNA circle under stress. For example:

- The presence of AT-rich regions, which melt more easily than GC-rich regions, may favor local melting.
- Alternate purine/pyrimidine tracts (like \cdots CGCGCG \cdots) favor Z-DNA formation, especially if the Cs are methylated on carbon 5.
- Palindromes allow cruciform extension.
- A segment that is primarily purines in one strand and pyrimidines in the other may permit H-DNA formation.

Superhelical stress is both widespread and controlled in DNA molecules found in cells. As we shall see in later chapters, the special structures described here play diverse roles in the regulation of gene expression. The idea that genes may be turned on and off by changes in supercoiling is an intriguing one.

SUMMARY

There are two kinds of nucleic acids, DNA and RNA. Each is a polynucleotide, a polymer of four kinds of nucleoside 5'-phosphates, connected by links between 3' hydroxyls and 5' phosphates. RNA has the sugar ribose; DNA has deoxyribose. The phosphodiester linkage is inherently unstable, but it hydrolyzes only very slowly in the absence of catalysts. Each naturally occurring nucleic acid has a defined sequence, or primary structure. Early evidence indicated that DNA might be the genetic material, but it was not until Watson and Crick elucidated its two-stranded secondary structure in 1953 that it became obvious how DNA might direct its own replication. The structure they proposed involved specific pairing between A and T and between G and C. The helix is right-handed, with about 10.5 base pairs (bp) per turn in the B form. Such a structure can replicate in a semiconservative manner, as demonstrated by Meselson and Stahl in 1958. Other forms of polynucleotide structures exist, of which the most important is the A form, found in RNA–RNA and DNA–RNA double helices. In vivo, most DNA is double-stranded; some molecules are circular. Most of the circular DNA molecules found in nature are supercoiled. Most RNA is single-stranded, but it may fold back to form hairpins and other well-defined tertiary structures.

The biological functions of nucleic acids may be briefly summarized as follows: DNA contains stored genetic information, which is transcribed into RNA. Some of these RNA molecules act as messengers to direct protein synthesis. The messenger RNA is translated on a ribosome, using the genetic code, to produce proteins. Modern molecular biological techniques allow us to manipulate DNA to make new proteins and modify existing ones.

Supercoiling of DNA can be expressed in terms of twist (T) and writhe (W). These terms are related to the linking number (L) by $L = T + W$. To form superhelical coiling requires the expenditure of ATP energy, using an enzyme called DNA gyrase. Gyrase is one of a class of topoisomerases; others relax supercoiled DNA.

Polynucleotides can form a number of unconventional structures, including left-handed DNA (Z-DNA), cruciforms, in some cases triple helices, and G-quadruplexes. The secondary structures of polynucleotides can be changed in various ways. The helix can “melt,” which involves strand separation. This change is easiest for regions rich in A-T pairs. Energy stored in superhelical DNA may promote local DNA melting or changes to a variety of alternative structures, such as Z-DNA, cruciforms, or a particular triple-helical structure called H-DNA.

PROBLEMS

- A viral DNA is analyzed and found to have the following base composition, in mole percent: A = 32, G = 16, T = 40, C = 12.
 - What can you conclude about the structure of this DNA?
 - What kind of secondary structure do you think it would have?
- Given the following sequence for one strand of a double-stranded oligonucleotide:

5'ACCGTAAGGCTTTAG3'

- Write the sequence for the complementary DNA strand.
 - Suppose you knew that the strand shown above had phosphate on both ends. Using an accepted nomenclature, write the sequence so as to show this.
 - Write the sequence of the RNA complementary to the strand shown above.
- *3. Some naturally occurring polynucleotide sequences are *palindromic*; that is, they are self-complementary about an axis of symmetry. Such a sequence is

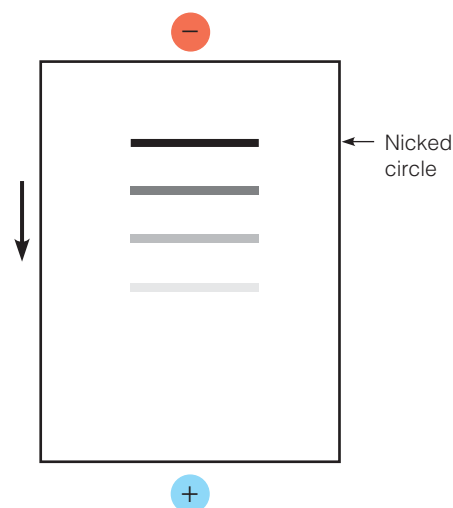

TCAAGTCCATGGACTTGG
AGTTCAGGTACCTGAACC

Show how this structure might form a double hairpin, or cruciform, conformation. Indicate the center of symmetry in the sequence and the bounds of the cruciform.

- The *E. coli* genome has a superhelical density in vivo of about 0.06. Assuming the DNA has 10.5 bp/turn, what is the expected writhing number of the *E. coli* genome?
- Given the following sequence for an RNA molecule, find a secondary structure that will be maximally stable.

GUCCAGCCAUUGCGUUCGCAAUGGC
- The largest of the double-stranded RNA molecules of cytoplasmic polyhedrosis virus contains 5150 bp (see Table 4.5). How long do you expect this molecule to be if extended?
- A circular, double-stranded DNA contains 2100 base pairs. The solution conditions are such that DNA has 10.5 bp/turn.
 - What is L_0 for this DNA?
 - The DNA is found to have 12 left-handed superhelical turns. What is the superhelix density σ ?
- In a supercoiled DNA, a stretch of about 20 base pairs changes from the B form to the Z form. What is the change in (a) T , (b) L , and (c) W ?
- Of the DNA molecules listed in Table 4.4, which would you expect to have the highest and lowest T_m ?
- A scientist isolates the DNA genome from a virus. She attempts to carry out a melting analysis but finds only 10% hypochromicity.
 - Suggest an explanation for the low value.
 - Why do you think she finds *this* much?
- A particular double-stranded DNA has, under the conditions used in Figure 4.32, a melting point of 94 °C. Estimate the base composition (in mole percent) of this DNA.

- A variant of B-form DNA has been reported to exist in the presence of Li^+ ions. This form, called C-DNA, is found by X-ray diffraction to have $9\frac{1}{2}$ base pairs per turn.
 - How many base pairs are contained in one repeat of this structure? How many turns in one repeat?
 - Is C-DNA twisted more or less tightly than B-DNA?
 - Would high superhelix density favor or disfavor C-DNA over B-DNA?
- A closed circular supercoiled DNA is relaxed by treatment with topoisomerase. No matter how much enzyme is used, or how long the experiment is run, the experimenter always finds a gel electrophoresis pattern indicating some DNA with one, two, and three superhelical turns in addition to the relaxed (nicked) circle (see figure). Suggest an explanation for this observation.

- The dye ethidium is a planar molecule that can *intercalate* into double-stranded DNA. This means that it slips between adjacent stacked base pairs. In doing so, it unwinds the DNA helix by about 26° for every ethidium bound.
 - If ethidium were added to relaxed, closed circular DNA, would negative or positive writhing be expected? Explain.
 - What would be the effect on writhing if the DNA were nicked in one strand?
 - It is observed that progressive addition of ethidium to negatively supercoiled DNA has a peculiar effect: First the electrophoretic mobility decreases, but with further addition of ethidium it again increases. Explain.
- Explain why DNA is stable in the presence of alkali (0.3 M KOH), while RNA is quantitatively degraded to 2'- and 3'-nucleoside monophosphates under these conditions.
- Refer to Table 4.1 for the pK_a values for ionization of the four ribonucleoside 5'-monophosphates. Select a pH value at which each of the four nucleotides has a different net charge on the molecule, and predict the direction and relative rate of migration of each nucleotide in an electrophoretic field.

TOOLS OF BIOCHEMISTRY 4A

AN INTRODUCTION TO X-RAY DIFFRACTION

Only a few decades ago, virtually nothing was known about the three-dimensional structures of nucleic acids, proteins, and polysaccharides. Today, largely as a result of the technique of X-ray diffraction, many of these molecules are understood at the atomic level—detail that would have astounded the biochemists of 1950. The method is complicated and it is possible to give only a brief introduction here, describing what is measured and what can be obtained.

When radiation of any kind passes through a regular, repeating structure, *diffraction* is observed. This means that radiation scattered by the repeating elements in the structure shows reinforcement of the scattered waves in certain specific directions and weakening of the waves in other directions. A simple example is given in Figure 4A.1, which shows radiation being scattered from a row of equally spaced atoms. Only in certain directions will the scattered waves be in phase and therefore constructively interfere with (reinforce) one another. In all other directions they will be out of phase and destructively interfere with one another. Thus, a **diffraction pattern** is generated. For the diffraction pattern to be sharp, it is essential that the wavelength of the radiation used be somewhat shorter than the regular spacing between the elements of the structure. This is why X-rays are used in studying molecules, for X-rays typically have a wavelength of only a few tenths of a nanometer. If the regular spacing in the object being studied is large (as in a window screen), we can observe exactly the same phenomenon with visible light, which has a wavelength thousands of times longer than X-rays. We will find that a point source, seen through a window screen, gives a rectangular diffraction pattern of spots.

FIGURE 4A.1

Diffraction from a very simple structure—a row of atoms or molecules.

The rule relating the periodic spacings in object and diffraction pattern is simple: Short spacings in the periodic structure correspond to large spacings in the diffraction pattern, and vice versa. In addition, by determining the relative intensities of different spots, we can tell how matter is distributed within each repeat of the structure.

Fiber Diffraction

We consider first the diffraction from helical molecules, aligned approximately parallel to the axis of a stretched fiber. A helical molecule, like the one shown schematically in Figure 4A.2, is characterized by certain parameters:

The *repeat* (c) of the helix is the distance parallel to the axis in which the structure exactly repeats itself. The repeat contains some integral number (m) of polymer residues. In Figure 4A.2, $m = 4$.

The *pitch* (p) of the helix is the distance parallel to the helix axis in which the helix makes one turn. If there is an integral number of residues per turn (as here), the pitch and repeat are equal.

The *rise* (h) of the helix is the distance parallel to the axis from the level of one residue to the next, so $h = c/m$. If we think of a spiral staircase as an example of a helix, the rise is the height of each step and the pitch is the distance from where one is standing to the corresponding spot directly overhead.

Suppose we wish to investigate a polymer with the helical structure shown in Figure 4A.2. A fiber is pulled from a concentrated solution of the polymer. Stretching the fiber further will produce approximate alignment of the long helical molecules

FIGURE 4A.2

A simple helical molecule.

FIGURE 4A.3

Diffraction from fibers. (a) A fiber in an X-ray beam. (b) The diffraction pattern.

with the fiber axis. The fiber is then placed in an X-ray beam, and a photographic film or comparable detection medium is positioned behind it, as shown in Figure 4A.3a. The diffraction pattern, which consists of spots or short arcs, will look like that in Figure 4A.3b. It can be read as follows: According to the mathematics of diffraction theory, a helix always gives rise to this kind of cross-shaped pattern. Therefore, we know we are dealing with a helical structure. The spots all lie on lines perpendicular to the fiber axis; these are called **layer lines**. The spacing between these lines is inversely proportional to the repeat of the helix, c , which in this case equals the pitch. Note that the cross pattern repeats itself on every fourth layer line. This repetition pattern tells us that there are exactly 4.0 residues per turn in the helix. Thus, the rise in the helix is $c/4$. This is the kind of evidence telling Watson and Crick that B-DNA was a helix with 10 residues per turn.

The information above is given directly by the pattern. To find out exactly how all of the atoms in each residue are arranged in each repeat, a more detailed analysis is necessary. Usually, a model is made using the correct repeat, pitch, and rise. Model making is simplified because we know approximate bond lengths and the angles between many chemical bonds. The model must also be inspected to see that no two atoms approach closer than their van der Waals radii. From such a model, the intensities of the various spots can be predicted. These predictions are compared with the observed intensities, and the model is readjusted until a best fit is obtained. The initial determination of the structure of DNA was done in just this way. As you can see from Figure 4.9, real fiber diffraction patterns are not as neat as the idealized example, mainly because of incomplete alignment of the molecules.

Crystal Diffraction

To study molecular crystals such as those formed by small oligonucleotides, molecules like tRNA, and globular proteins, the experimenter faces a rather different problem from the study of helical fibers and proceeds in a quite different way. A schematic drawing of such a crystal is shown in Figure 4A.4.

FIGURE 4A.4

Schematic drawing of a molecular crystal.

**FIGURE 4A.5**

Diffraction pattern produced by a molecular crystal of a small DNA.

P. S. Ho, Colorado State University.

The repeating unit is now the **unit cell**, which may contain one, two, or more molecules. The unit cell may be thought of as the basic building block of the crystal. Repetition of the unit cell in three dimensions (marked by arrows on the figure) creates the whole crystal. A simple two-dimensional analog of the crystal unit cell is the repeating pattern in wallpaper. No matter how random a wallpaper pattern may seem, if you stare at it long enough, you can always find a unit that, by repetition, fills the entire wall.

Just as in fiber diffraction, passing an X-ray beam through a molecular crystal produces a diffraction pattern. The pattern shown in Figure 4A.5 was obtained from a crystal of a small DNA. Again, the spacing of the spots allows us to determine the repeating distances in the periodic structure—in this case the x , y , and z dimensions of the unit cell labeled a , b , and c in Figure 4A.4. But the important information in crystal diffraction studies is just how the atoms are arranged *within* each unit cell, for that arrangement describes the molecule. Again, this information is contained in the relative intensities of the diffraction spots in a pattern like that shown in Figure 4A.5. But in crystal diffraction, more exact information can be extracted than from a fiber diffraction pattern because the corresponding molecules in each unit cell of the crystal are of the same shape and are oriented in the same way. In fiber diffraction, the helical molecules may all have their long axes pointed in the same direction, but they are rotated randomly about these axes. This difference in exactness of arrangement can be appreciated by comparing the sharpness of the crystal diffraction pattern shown in Figure 4A.5 with the fiber pattern depicted in Figure 4.9.

After obtaining the diffraction pattern from a molecular crystal, the experimenter measures the intensities of a large number of the spots. If the molecule being studied is a small one, it is possible to proceed in much the same manner as with fiber patterns. A structure is guessed at, and expected intensities are calculated and compared with the observed intensities. The structure is refined until the relative intensities of all spots are correctly pre-

dicted. However, such a procedure won't work with a molecule as complex as the tRNA shown in Figure 4.20—there is simply no way to guess such a structure.

Why not proceed directly from spot intensities to the structure? The difficulty is that some of the information contained in the spot intensities is hidden. To greatly simplify a complex problem, we may say that it is as if the quantities that the experimenter needed in order to deduce the structure (which are called **structure factors**) were the square roots of the intensities.* If the intensity has a value of, say, 25, the investigator knows that the number needed is $+5$ or -5 . But which? This sort of quandary is the essence of the *phase problem*, which prevented progress in large-molecule crystallography for many years. One way of solving the problem was discovered in the early 1950s. Suppose a heavy metal atom, such as mercury, can be introduced into some point in the molecule in such a way that the molecule and crystal are otherwise unchanged. This process is called an **isomorphous replacement**. Now suppose the heavy metal contributes a value of $+2$ to the structure factor for the spot we were just discussing. If the original value was $+5$, its new value is $+7$ and its square is 49. If the original value was -5 , the value now becomes 3 and its square is 9. The investigator takes a diffraction photograph of the crystal with the heavy metal inserted. If the new crystal has an intensity of 9 for this spot, the original structure factor must have been -5 , not $+5$. Although an oversimplification, this example gives the essence of the method. Usually multiple isomorphous replacements are necessary to determine the phases of the structure factors.

Given structure factors for all of the spots, the investigator can calculate the positions of all atoms in the unit cell. What is actually calculated is an **electron density** distribution (Figure 4A.6), but this amounts to the same thing, for regions of high electron density are where the atoms are. In the particular view shown in Figure 4A.6, we are looking at a two-dimensional “slice” through the three-dimensional electron density distribution.

It is now appropriate to review the steps that must be taken to determine the three-dimensional structure of a macromolecule from crystal diffraction studies:

1. Obtain satisfactory crystals. This step is often the hardest part of the procedure, for the crystals must be of good quality and at least a few tenths of a millimeter in minimum dimension. Crystals that are too small will not give sharp diffraction patterns. Getting macromolecules to crystallize well is still more of an art than a science.
2. Record the diffraction pattern from the crystal, and measure the intensities of many of the spots.
3. Find some way to make isomorphous replacements in the molecule. Usually two or more replacements are required.

*For the more mathematically sophisticated reader, we note that the structure factors are usually complex numbers and can thus be represented as vectors in the complex plane. What are determined from the intensities are their *amplitudes*, but what is not known are their *phases*.

**FIGURE 4A.6**

Part of an electron density map derived from the DNA crystal diffraction pattern in Figure 4A.5.

P. S. Ho, Colorado State University.

4. Repeat steps 1 and 2 for each isomorphous derivative.
5. Calculate structure factors and, from them, the electron density distribution. These calculations are usually done on a large computer.

In most cases, the investigator will first carry through this analysis with a relatively small number of spots. This procedure will give a *low-resolution* structure. If all is going well, more spots will be measured and the calculations refined to give higher resolution. With the best crystals, it is now possible to obtain resolutions of about 1 Å. This resolution is sufficient to identify individual groups and even some atoms and to show how they interact with one another. The detail in the phenolic ring of a protein side chain revealed at different resolutions is shown in Figure 4A.7.

Most of the detailed three-dimensional structures of biological macromolecules shown in this book have been determined by X-ray diffraction studies of crystals. At present, tens of thousands of such structures are known. This knowledge represents an enormous amount of labor in many laboratories, but the results allow us to understand macromolecular function at a level that would have been unbelievable only a short time ago.

TOOLS OF BIOCHEMISTRY 4B

MANIPULATING DNA

The biological sciences have been revolutionized by laboratory techniques that allow the researcher to isolate any desired gene, amplify the gene for determination of its nucleotide sequence, express the gene at a high level for production and analysis of its protein product, and introduce any desired mutation into the gene, either for analysis of structure–function relationships within the protein or to create some desirable property, such as increased stability. In addition, a modified gene can be introduced into the genome of a living organism for determination of its metabolic function. The key discoveries, made in the 1970s and early 1980s, spawned a large biotechnology industry, which has created hundreds of new drugs and genetically modified organisms, such as drought-resistant crop plants. Because these methods have taught us so much about the structure and function of the proteins and enzymes we will be discussing in the next several chapters, we introduce some of the benchmark techniques here, even though much of the genetic biochemistry upon which they are based is presented later in this book. Within this family of **recombinant DNA** techniques we present here outlines of (1) gene cloning, (2) chemical synthesis of oligonucleotides for use as primers, (3) DNA sequence analysis, and (4) site-directed mutagenesis. A fifth technique, **polymerase chain reaction** (PCR), which allows amplification of any DNA sequence, starting from minute amounts of material, is presented in Chapter 24 (Tools of Biochemistry 24A).

Gene Cloning

In 1973, Stanley Cohen and Herbert Boyer realized that two recent developments had set the stage for them to **clone**, or isolate, a single gene. In classical biology a clone is a population of organisms that are genetically homogeneous because they were derived from a single ancestor. For example, all of the bacterial cells in a colony represent a clone because they were derived from a single cell that was deposited at that location on a Petri plate.

The first of the developments leading to cloning of single genes was the characterization of **plasmids** as small circular DNA molecules capable of independent replication within bacterial cells. Clinical resistance to antibiotics is often caused by mutations in genes carried on plasmid DNA molecules. For example, resistance to penicillin results from a plasmid-encoded enzyme called β -lactamase (page 353), which cleaves penicillin to an inactive derivative. The second development was the discovery of a class of bacterial enzymes called **restriction endonucleases** and, more important, the fact that many of these enzymes catalyze cleavage of DNA at specific sites (Chapter 26). For example, the enzyme **EcoRI** cleaves DNA whenever it recognizes the sequence

A sequence of this type is a *palindrome* (see page 116), a message that reads the same in both directions. This sequence is sym-

metrical, meaning that the two strands have identical sequences running in opposite directions. The enzyme cuts between G and A on both strands. Thus, each of the cleavage products has a short (four-base) single-stranded end, 3' . . . TTAA 5' (see Figure 4B.1). What this means is that any two DNA molecules that have been cut by *EcoRI* can rejoin end-to-end when **annealed**, or subjected to DNA renaturation conditions, by base-pairing between the two 5'-terminated AATT sequences, also called “cohesive ends” or “sticky ends.” Once this pairing has occurred, an enzyme called **DNA ligase** (Figure 4B.1 and page 1047) can form a covalent bond in the openings between the 3'-terminal G and the 5'-terminal A. If the two DNA sequences being rejoined come from different sources, the product is called a recombinant DNA molecule, after the fact that genetic recombination in vivo involves cutting and rejoining DNA from different chromosomes (Chapter 26).

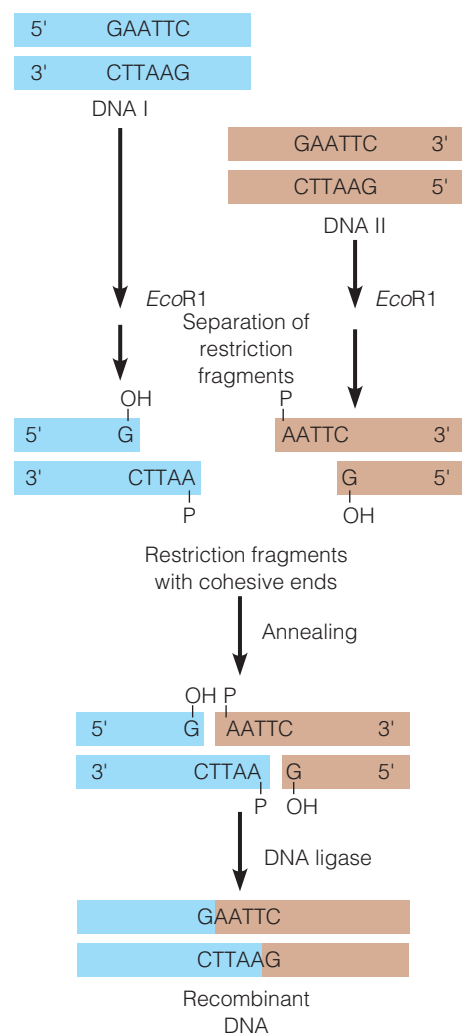

FIGURE 4B.1

Creation of recombinant DNA molecules in vitro.

Cohen and Boyer also devised a technique for high-frequency *transformation*, so that recombinant DNA molecules could be introduced into living bacterial cells. This originally involved treating bacteria with calcium chloride followed by heat shock, but this has been supplanted by more efficient methods, notably *electropo-*

FIGURE 4B.2

Cloning a fragment of DNA into a plasmid vector and introducing the recombinant molecule into bacteria.

ration (application of an electric charge). The **vector** is a DNA molecule into which the gene to be cloned is inserted. As schematized in Figure 4B.2, the vector is a plasmid (small circular DNA) containing a gene that specifies resistance to a particular antibiotic, such as ampicillin. The plasmid contains just one site for cleavage by the restriction enzyme to be used. Both the plasmid and a DNA molecule or chromosome containing the gene of interest are cleaved with the same restriction enzyme, such as *EcoRI*. Annealing, or renaturation, followed by enzymatic ligation, yields recombinant DNA molecules in which the gene of interest has been spliced into the vector. Note that the vector need not be a plasmid. Any DNA capable of independent replication within a cell, such as a virus genome, can serve as a vector.

After annealing and ligation, the DNA, containing a mixture of recombinant and nonrecombinant DNAs, is introduced into recipient bacteria by transformation. Any transformed bacteria can be identified by plating in the presence of ampicillin. Only those bacteria that have been transformed will grow because they now contain the antibiotic resistance gene. The investigator must then carry out additional experiments to establish that a particular transformed cell contains the gene being cloned. A variety of methods are available, including additional antibiotic-resistance screens, DNA-DNA renaturation reactions, or analysis of expression of the cloned gene with an antibody or activity assay.

Figure 4B.3 shows the structure of pBR322, a plasmid engineered for gene cloning in 1977 and still in occasional use

FIGURE 4B.3

pBR322, one of the earliest cloning vectors. Some of the restriction sites are shown, as well as the direction of transcription of the ampicillin and tetracycline resistance genes. The bottom diagram shows the effect of cloning a novel sequence into the *HindIII* site.

today. This small recombinant DNA molecule, 4632 base pairs in length, contains two antibiotic resistance genes, one for ampicillin resistance (*amp^R*) and one for tetracycline resistance (*tet^R*). Note that each of these genes contains restriction cleavage sites within its sequence. A site for the restriction enzyme *Hind*III lies within the *tet^R* sequence. Hence, if this site is used for cloning, the *tet^R* gene is split and, therefore, inactive. Because the *amp^R* gene is intact, all bacteria that have acquired a plasmid, whether recombinant or not, can be selected on the basis of their resistance to ampicillin. But now, recombinant plasmids can be identified because these bacteria are sensitive to tetracycline as well as ampicillin-resistant, whereas bacteria that acquired the original plasmid, without an insert, are resistant to both drugs.

Many variations have been devised on this original approach. Blunt-ended DNA molecules, containing no sticky ends, can now be cloned. Many cloning vectors have been devised, usually as recombinant DNA molecules themselves. One such vector, bacteriophage M13, is particularly useful because the recombinant DNA can be isolated as a single-stranded molecule, readily amenable to DNA sequence analysis (page 1039). Particularly widely used are expression vectors, in which signals to regulate and activate high-level expression of the cloned gene are built into the vector. Other modifications include sequences that aid in purification of the recombinant protein (see Figure 5A.1). In the biotechnology industry, techniques such as these led to the introduction as early as 1982 of human insulin as a recombinant gene product, used for diabetes treatment. Other recombinant proteins later approved for clinical use include blood-clotting factors, clot-dissolving enzymes used to treat heart attack victims, pituitary growth hormone, and interferons.

Automated Oligonucleotide Synthesis

In 1976 the British biochemist Fred Sanger introduced **dideoxy DNA sequencing**, the rapid DNA sequence analysis that led to completion of the 3 billion-base-pair human genome sequence in 2001. In 1978 the Canadian biochemist Michael Smith devised a method for site-directed mutagenesis, which allows an investigator to introduce any desired mutation into a cloned gene. Both researchers received the Nobel Prize for their contributions.

Both dideoxy DNA sequencing and site-directed mutagenesis depend upon the availability of oligodeoxyribonucleotide molecules of precisely known sequence to serve as primers in DNA polymerase-catalyzed reactions. The oligonucleotide synthesis process most widely used at present is the **phosphoramidite** method. This method is popular because it can be carried out in automated fashion, with the oligonucleotide linked to a solid support as nucleotides are added one at a time.

The method is illustrated in Figure 4B.4. Intermediates in this chemical synthesis are nucleoside 3' phosphoramidites, with the phosphorus in the reactive trivalent form. The process begins with attachment of the 3' hydroxyl of the first nucleotide to a silica matrix. The 5'-hydroxyl group is protected with a dimethyl-

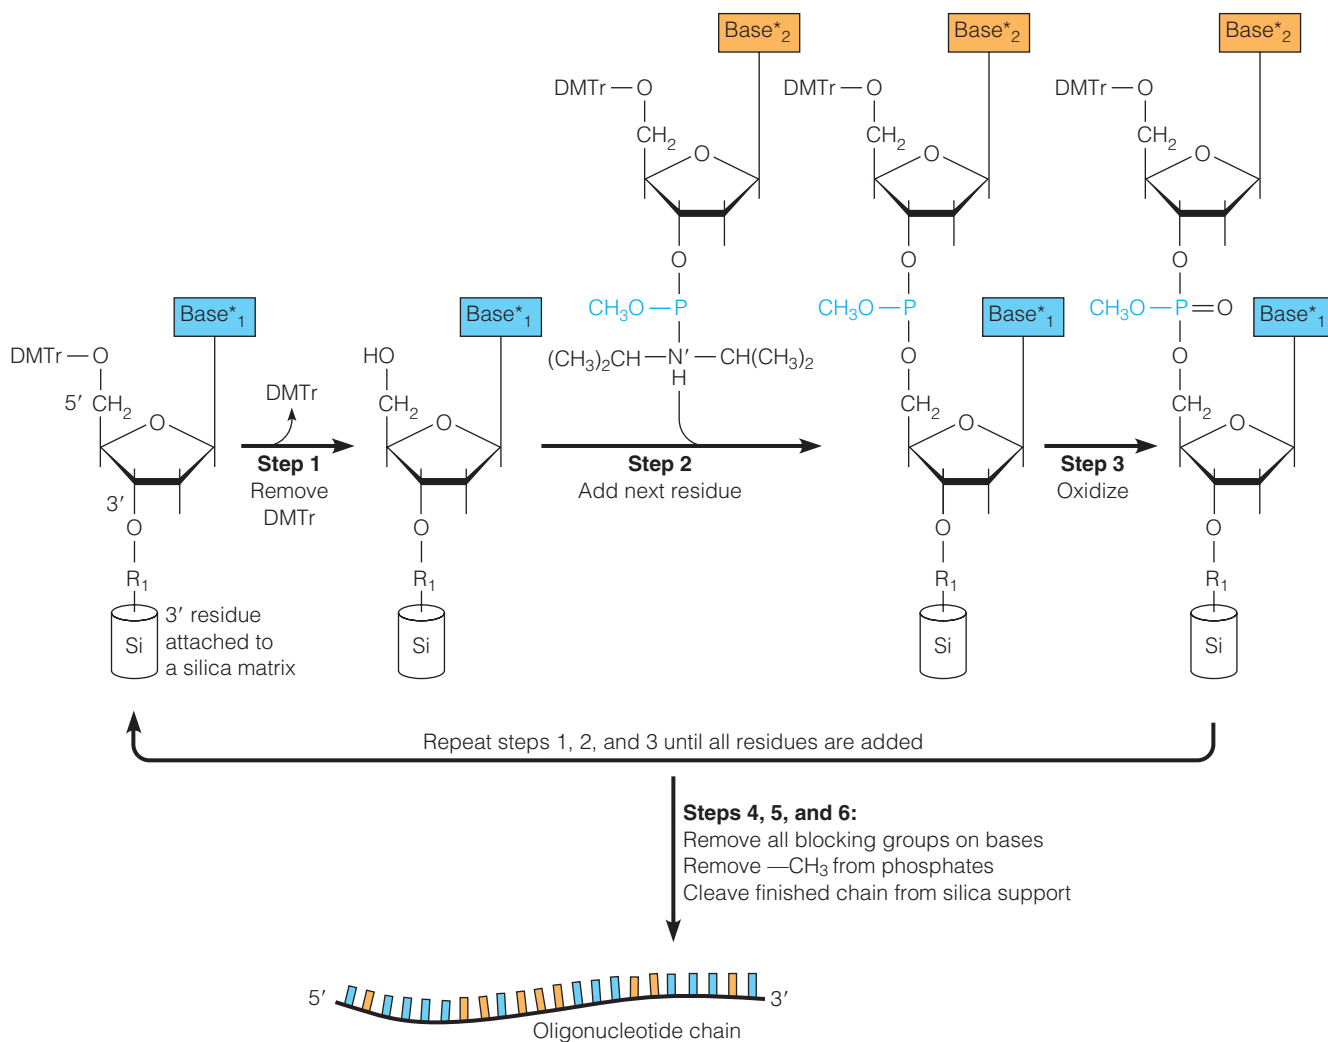

trityl (DMTr) blocking group. Amino groups on the purine or pyrimidine base are also protected. The next nucleotide is introduced as the blocked derivative, with a phosphoramidite group on position 3'. Tetrazole is present, leading to protonation of the diisopropylamine moiety on the incoming nucleotide and facilitating its loss upon reaction with the unprotected 5'-hydroxyl. Oxidation with iodine converts the trivalent phosphorus to a phosphotriester. This process is repeated in stepwise fashion until up to 150 nucleotides have been added in a precisely determined sequence. Finally, the blocking groups are removed, and the finished chain is removed from the solid support, followed by chromatographic purification if necessary. Each step proceeds with about 98% efficiency, meaning that a 20-mer, containing 20 nucleotide residues, can be produced at about 80% final yield. Note that the phosphoramidite synthetic method proceeds from the 3' end of the polymer toward the 5' end, whereas the enzymatic synthesis of DNA by DNA polymerase proceeds in the opposite direction.

Because of the ease with which oligonucleotides of defined sequence can be synthesized, and because of the regularity of DNA secondary structure, scientists have devised numerous methods for creating defined DNA-based nanostructures. Figure 4B.5 illustrates one example. In this example synthetic oligonucleotides were designed to fold into the form of a perfect tetrahedron. By means such as these, synthetic DNAs have been used to form structures with possible applications in nanotechnology, including gears, tubes, and even mechanical devices.

Dideoxynucleotide Sequence Analysis

On page 110 we mentioned the Maxam-Gilbert method for DNA-sequence analysis, which involves treating DNA with reagents that cleave at specific nucleotides, yielding a population of molecules that can be resolved on the basis of molecular weight by gel electrophoresis. The enzymatic method introduced by Sanger similarly involves electrophoretic analysis of DNA fragments terminated at specific nucleotides, but Sanger's method allows analysis of longer stretches of DNA, and it lends itself more readily to automation. The method, as originally carried out, uses bacteriophage M13 as a cloning vector for the DNA sequence being analyzed. M13 DNA, as isolated from virus particles, is circular and single-stranded. However, the molecule replicates through a two-stranded intermediate form, called the replicative form, or RF. With introduction of useful restriction cleavage sites, M13 RF becomes a cloning vector comparable to pBR322. As shown in Figure 4B.6, the DNA fragment to be analyzed is cloned into M13 RF. After ligation the recombinant DNA is introduced into *E. coli* by transformation, and the infected cells are incubated and allowed to produce phage particles. The phage particles are purified, and DNA is isolated from each, as single-stranded DNA containing the sequence for analysis.

Isolated single-stranded circular DNA from phage genomes carrying the desired insert becomes the template for four DNA polymerase-catalyzed reactions. The primer is an oligonucleotide that is complementary to an M13 sequence lying just to the

*Reactive groups on all bases are blocked by chemical reagents

3' side of the insert. Extension of this primer by DNA polymerase copies the insert. The polymerase reactions are run in the presence of deoxyribonucleoside triphosphate analogs, the 2',3'-**dideoxyribonucleoside triphosphates** (ddNTPs), which serve as inhibitors of chain extension because they lack 3' hydroxyl termini. The dideoxy analog (ddATP) of deoxyadenosine triphosphate is shown here.

FIGURE 4B.4

Solid-phase synthesis of oligonucleotides by the phosphoramidite method.

To generate a series of A-terminated fragments, the DNA polymerase reactions are run in the presence of equal concentrations of dATP, dCTP, dGTP, and dTTP, plus 1/10th that concentration of ddATP. When T is in the template strand, DNA polymerase occasionally inserts ddAMP instead of dAMP. When that happens, DNA replication stops and the fragment is released from the enzyme. Thus, a series of fragments of varying lengths accumulates, with a common 5' end (the primer) and variable 3' ends, and with each 3' end identifying a T residue in the insert sequence that is being analyzed. Similarly, sites terminated by C, G, and T are identified simply by running polymerase reactions with the other three dideoxy analogs, one at a time. Inclusion of a radioactive nucleotide in the polymerization mixture and gel electrophoresis followed by radioautography yields four “sequencing ladders,” as shown in Figure 4B.6. Each band in the radioautographic image of the electrophoretic gel identifies one of the four bases at that site.

**FIGURE 4B.5**

Design and synthesis of a three-dimensional DNA nanostructure, in this case a DNA tetrahedron. (a) Design of four synthetic oligonucleotides with complementary base sequences indicated by matching colors. The four oligonucleotides were annealed, by heating and slow-cooling, followed by ligation—treatment with an enzyme (Chapter 25) that creates covalent bonds between the DNA ends. (b) Two images of a space-filling representation of a tetrahedron with three 30-nucleotide sides (A, B, and C) and three 20-nucleotide sides (D, E, and F).

As noted above, M13 vectors were originally used because they permitted DNA synthesis on single-stranded templates. Modifications of polymerase chain reaction (Tools of Biochemistry 24A) now permit the preparation of single-stranded DNA molecules for sequencing without the need for M13-based vectors.

Sanger sequencing is now done automatically. Each ddNTP is derivatized with a fluorescent dye, each of a different color. Thus, each fragment has a distinct color based upon the identity of the ddNTP that terminated the sequencing reaction. This allows all four reaction mixtures to be resolved in one lane of a sequencing gel, permitting analysis of far more DNA in one sequencing operation. The gel is scanned fluorometrically, and a computer reads the DNA sequence directly from the resulting pattern of differently colored peaks (Figure 4B.7).

Further refinements of this method have greatly increased its “throughput,” or the amount of sequencing information derived from one operation. These methods yielded complete genomic sequences for several bacteria in the mid-1990s, and the near-completion of the human genome sequence in 2001. Since then, further modifications have yielded several approaches that greatly expand the speed and accuracy of DNA sequencing operations. Several of the most prominent of these “second-generation” sequencing technologies are described in articles cited at the end of this section. As detailed later in this book, enormous amounts of information about health and disease, biological individuality, and evolutionary relationships have come from these developments.

Site-directed Mutagenesis

Analysis of the function of a protein involves altering the structure of the protein and then determining whether and how the biological function of the protein has been altered. Two methods have been used classically. One is to alter certain residues chemically by treatment with protein-modifying reagents. The approach lacks specificity because all residues of a given amino acid may be altered, not just the one or two of special interest. Another approach is to mutagenize an organism with ultraviolet light, ionizing radiation, or a chemical mutagen and then select for surviving organisms containing the mutation of interest, followed by isolation of the mutant protein. The problem with this approach is the difficulty in targeting the action of the mutagen to a specific region of the gene of interest, typically the catalytic site of an enzyme or a region involved in regulatory interactions with DNA or with other proteins.

Once it became possible to clone the gene encoding a protein of interest, it became possible to systematically alter the gene at specific sites to generate virtually any desired mutation, a technique known as **site-directed mutagenesis**. Introduction of the cloned mutant gene into a host cell, followed by its expression, could then yield the mutant protein for study of its altered function.

The most powerful and widely used method for site-directed mutagenesis, conceived by Michael Smith, allows the introduction of practically any mutation at any site, including single-base substitutions, short deletions, or insertions. The approach, illustrated in Figure 4B.8, requires that the gene first be cloned into a single-stranded vector, such as phage M13, as discussed for DNA sequence analysis. Next an oligodeoxynucleotide, about 20 nucleotides long, is synthesized that is complementary in sequence to the cloned gene at the site of the desired mutation, *except in the center of the sequence*.

Here the oligonucleotide sequence contains one or two deliberate mistakes—either single nucleotides that do not pair with the template or insertions or gaps of a few nucleotides. Upon annealing to the cloned gene, these alterations create either non-Watson-Crick base pairs or bases that have no partners and therefore form a “looping out.” The correctly matched bases on both sides of the mismatch cause it to remain annealed, despite the mismatch. DNA polymerases are then used to synthesize around the circular vector from this primer, followed by enzymatic ligation to create a closed circular duplex. After introduction of this circular molecule into bacteria by transformation, both strands replicate and yield phage. In principle, 50% of the phage should contain the desired mutation within the inserted sequence. In practice, that percentage is considerably less, but it can be increased by various techniques (see reference by Kunkel et al.). In any event, the mutant gene is then cleaved out of the modified phage genome by restriction nuclease treatment, and it can be recloned into an expression vector for large-scale preparation and subsequent isolation of the mutant protein.

Although single-stranded DNA phages, such as M13, were originally used to prepare templates for site-directed mutagenesis, such molecules are now readily prepared by polymerase

chain reaction (PCR; Tools of Biochemistry 24A), and that has made an already relatively straightforward technique even simpler.

CHAPTER 5

Introduction to Proteins: The Primary Level of Protein Structure

We have seen that one class of biopolymers, the nucleic acids, stores and transmits the genetic information of the cell. Much of that information is expressed in another class of biopolymers, the **proteins**. Proteins play an enormous variety of roles: Some carry out the transport and storage of small molecules; others make up a large part of the structural framework of cells and tissues. Muscle contraction, the immune response, and blood clotting are all mediated by proteins. An important class of proteins is the **enzymes**—the catalysts that promote the tremendous variety of reactions that are required to support the living state. Each type of cell in every organism has several thousand kinds of proteins to serve these many functions.

In keeping with the multiplicity of their functions, proteins are extremely complex molecules. This complexity is illustrated in Figure 5.1, which depicts the molecular structure of myoglobin, a relatively small protein that functions primarily in oxygen binding and storage in animal tissues. In this and the following three chapters, we analyze in detail the structures and functions of a handful of proteins, including myoglobin. We will see that although there are general features of protein structure shared by most proteins, each protein has a distinct structure that is optimally suited to its function. Protein structures may appear at first glance to be hopelessly complex; however, there is an elegant and readily comprehensible logic to protein structure, which we will describe here and in Chapter 6. We begin with a description of the simple “building blocks” that are found in all proteins: the amino acids.

Amino Acids

Structure of the α -Amino Acids

All proteins are polymers, and the monomers that combine to make them are **α -amino acids**. A general representation of an α -amino acid is shown in Figure 5.2a. The amino group is attached to the α -carbon, the carbon next to the carboxylic acid group; hence the name α -amino acid. To the α -carbon of every amino acid are also

Protein function is determined by protein structure, which, in turn, is determined by the structures and properties of the various amino acids which make up the protein.

FIGURE 5.1

The three-dimensional structure of the globular protein **myoglobin**. This molecular model was generated from the X-ray crystal structure determined by H. C. Watson and J. C. Kendrew (PDB ID: 1MBN), and it shows the heavy atoms (i.e., non-hydrogen atoms) in sperm whale myoglobin. The amino acid atoms are shown as sticks, where carbon atoms are gray, oxygen atoms are red, nitrogen atoms are blue, and sulfur atoms are yellow. The heme atoms are shown in a space-filling display that represents the van der Waals surface of each atom. The orange sphere in the center of the heme is the Fe^{2+} ion that binds a molecule of oxygen (the oxygen-binding site is obscured by the heme). The orientation of the protein in this figure is the same as that shown in the painting by Irving Geis in Chapter 1 (Figure 1.5).

attached a *hydrogen atom* and a *side chain* (“R” group). Different α -amino acids are distinguished by their different side chains. We can write the general structure for an α -amino acid as shown in Figure 5.2a. This representation, although chemically correct, ignores the conditions *in vivo*. As pointed out in Chapter 2, most biochemistry occurs in the physiological pH range near neutrality. The pK_a 's of the carboxylic acid and amino groups of the α -amino acids are about 2 and 10, respectively. Therefore, near neutral pH the carboxylic acid group will have lost a proton, and the amino group will have picked up a proton, to yield the **zwitterion** form shown in Figure 5.2b. This is the form in which we will customarily write amino acid structures.

Twenty different kinds of amino acids are commonly incorporated into proteins during the process of translation (see Figure 4.23 page 112). The complete structures

FIGURE 5.2

The structure of an α -amino acid. (a) A general representation of a nonionized α -amino acid showing the carboxylic acid group, the α -amino group, and a hydrogen bonded to the α -carbon, as well as the side chain (R group) that gives the amino acid its unique properties. (b) An amino acid shown as a zwitterion at neutral pH. Under physiological conditions, amino acids exist as zwitterions in which the α -carboxylic acid group has lost a proton and the α -amino group has gained one. Note that the negative charge on the α -carboxylate is delocalized over the two oxygen atoms. The stereochemistry shown in this figure is that for the α -amino acids found in biosynthetic proteins.

of these amino acids are shown in Figure 5.3 and other important data are given in Table 5.1. At least two additional amino acids, selenocysteine and pyrrolysine, are encoded genetically and incorporated into proteins; however, they are found in a relatively small number of proteins. For the purposes of this introductory discussion we will focus our attention on the twenty common amino acids shown in Figure 5.3.

Stereochemistry of the α -Amino Acids

The asymmetry of biomolecules plays a critical role in determining their structures and functions; thus, familiarity with the basic stereochemistry of amino acids is necessary for an understanding of the biochemistry of proteins.

The four groups shown in Figure 5.2a are bonded to the central α -carbon in a tetrahedral arrangement, as is predicted for an sp^3 hybridized carbon atom. In Figure 5.2 the projection of these groups around the α -carbon (C_α) is represented as follows: The lines represent bonds in the plane of the page, the solid wedges represent bonds projecting forward from the page, and the dashed wedges represent bonds projecting behind the page. When a carbon atom has four different substituents attached to it, it is said to be **chiral**, or a **stereocenter**, or, preferably, an **asymmetric carbon**. In Figure 5.3, the stereochemistry of the amino acids is shown by a convention known as the **Fischer projection**. In a Fischer projection the bonds are all represented as solid lines, where the horizontal bonds project forward from the page and the vertical bonds project behind the page. To help you visualize the Fischer projection convention, we have drawn in Figure 5.4 the general structure of an amino acid in a ball-and-stick rendering as well as a Fischer projection that includes solid and dashed wedges. Note that the spatial orientation of the four groups bound to the C_α is the same in Figures 5.2, 5.3, and 5.4.

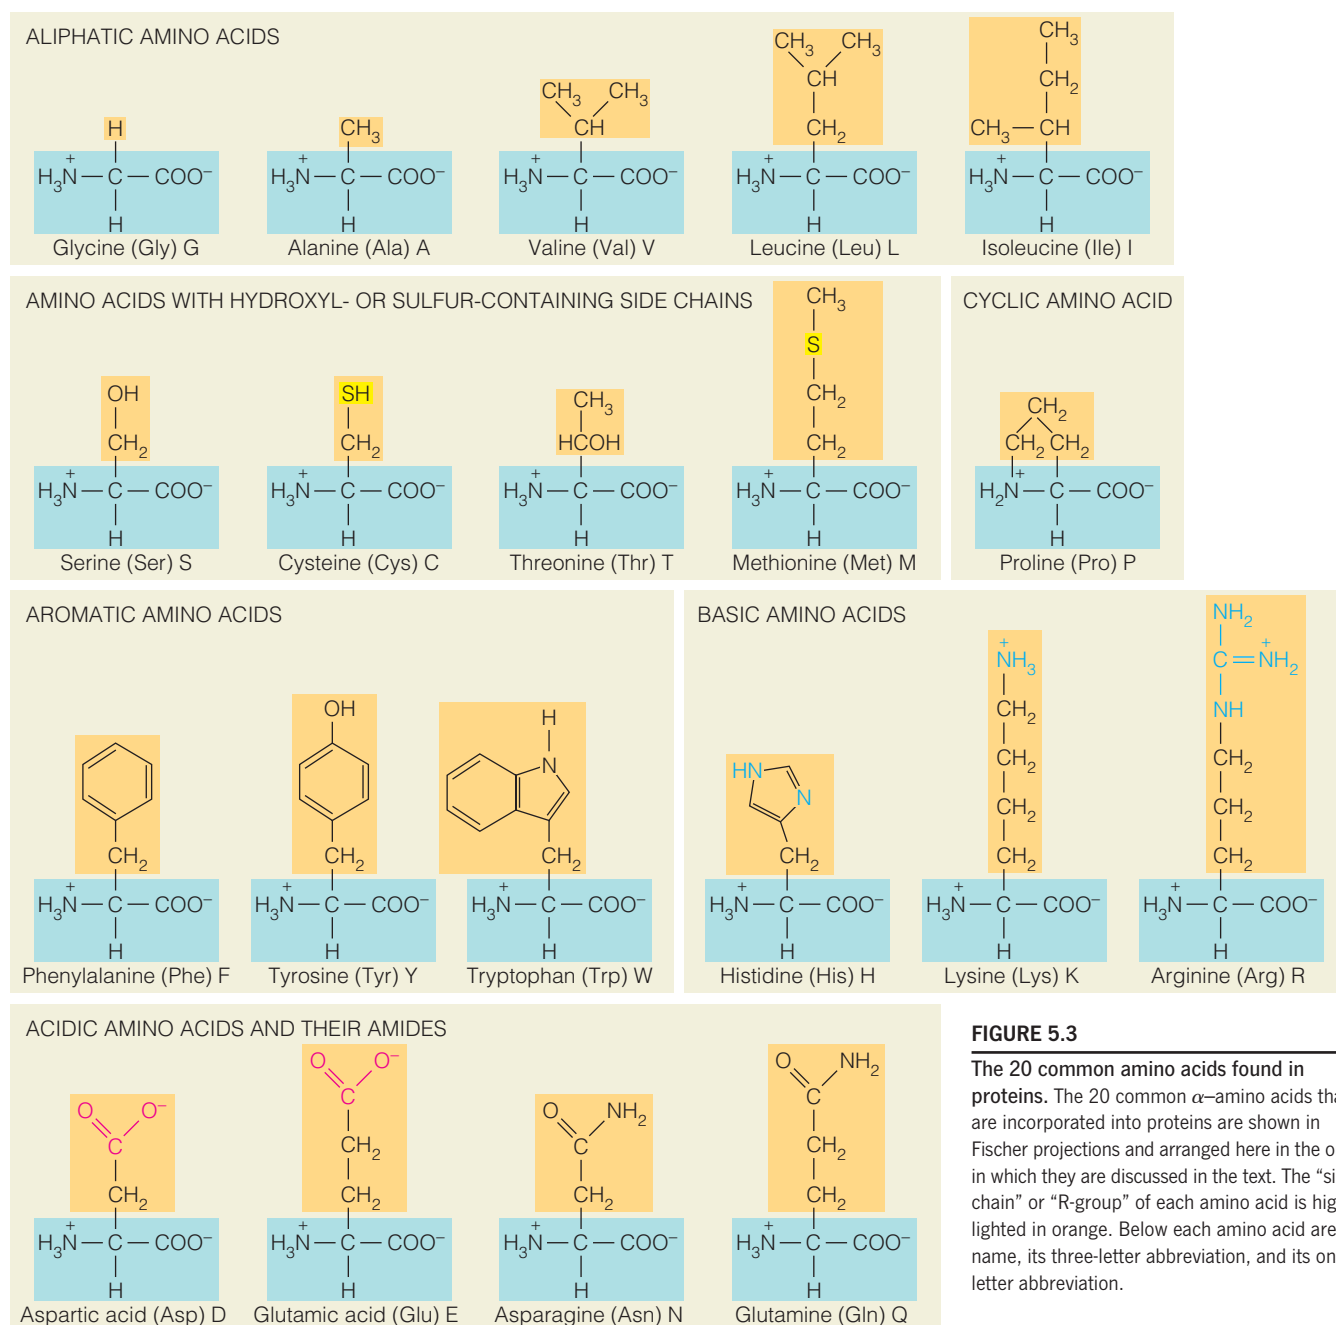

FIGURE 5.3

The 20 common amino acids found in proteins. The 20 common α -amino acids that are incorporated into proteins are shown in Fischer projections and arranged here in the order in which they are discussed in the text. The "side chain" or "R-group" of each amino acid is highlighted in orange. Below each amino acid is its name, its three-letter abbreviation, and its one-letter abbreviation.

If a molecule contains one asymmetric carbon, two distinguishable **stereoisomers** exist; these are nonsuperimposable mirror images of one another, or **enantiomers**, as shown in Figure 5.5. The stereoisomers of **alanine** shown in Figure 5.5 are called the L and D enantiomers.* The L and D enantiomers can be distinguished from one another experimentally because their solutions rotate plane polarized light in opposite directions. For this reason, enantiomers are sometimes called **optical isomers**. All amino acids except glycine can exist in D and L forms because in each case the α -carbon is asymmetric. Glycine is the sole exception because two of

*Those who are familiar with modern organic chemistry will know that there are two commonly used systems for distinguishing stereoisomers—the older D-L system and the newer, more comprehensive R-S system (Cahn-Ingold-Prelog system). Both are discussed in more detail in Chapter 9.

Proteins are polymers of α -amino acids. There are 20 common α -amino acids that are the major building blocks of proteins.

All α -amino acids except glycine contain an asymmetric α -carbon, thus both L and D enantiomers are possible. However, in the vast majority of proteins, only the L-enantiomers are found.

(a) α -Amino acid

(b) Representation of an amino acid in Fischer projection

FIGURE 5.4

Three-dimensional representations of α -amino acids. (a) This ball-and-stick model shows the three-dimensional arrangement of the atoms. The α -carbon is asymmetric, with tetrahedral bonding. (b) In a Fischer projection (left) the horizontal bonds are projecting toward the viewer and the vertical bonds are projecting away from the viewer. This orientation of bonds in the Fischer projection is represented on the right by solid and dashed wedges.

the four groups bonded to the α -carbon are the same (i.e., there are two H atoms), eliminating the asymmetry.

Chemical analysis of naturally occurring proteins shows that *nearly all of the amino acids found in proteins are of the L form*. Random mixtures of D- and L-amino acids could not reproducibly form protein structures as well-defined as the structure of myoglobin shown in Figure 5.1. Cell viability depends on protein function, and protein function depends on the ability of a protein to adopt a well-defined *active* structure; thus, the need for cells to produce many structurally identical copies of a given protein is absolute. For this reason, nature uses only L-amino acids in protein biosynthesis. How the absolute preference for the L-isomer over the D-isomer evolved is puzzling. Indeed, we shall find that each of the three major classes of biological macromolecules exhibits a strong preference for one stereoisomer class or the other. Most naturally occurring polysaccharides prefer D-sugars, as do DNA and RNA. It may be that productive interaction between these substances was established early in the evolution of life; but, why was a particular set of enantiomers chosen at all? It is hard to see how L-amino acids have any inherent selective advantage over the D-isomers for biological function. Indeed, D-amino acids exist in nature, and some play important biochemical roles (some examples are given in Table 5.2), but they are rarely found in proteins.

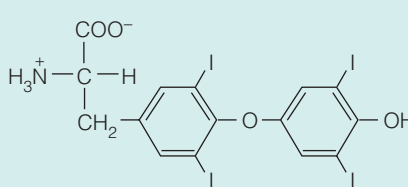

Many scientists have attempted to provide explanations for this “handedness preference” in biology. Most point to an intrinsic asymmetry in the behavior of subnuclear particles, a kind of asymmetry that gives electrons emitted in β decay a preferential left-hand spin. Such influences are very weak but might, in a competition between primitive organisms using L- or D-proteins, give a slight advantage to one or the other. After billions of generations, even a small advantage can become overwhelming.

Using peptide synthesis methods described in Tools of Biochemistry 5C, it is possible to chemically synthesize proteins using all D-amino acids. These structures are the mirror images of the corresponding natural proteins. One such D-protein synthesized in the laboratory of Stephen Kent is the mirror image of a protease (a protein-cleaving enzyme) from the human immunodeficiency virus, HIV (see References). Whereas its natural L-counterpart cleaves natural L-proteins, this synthetic enzyme will cleave only those containing D-amino acids. The results of this experiment suggest that life would be possible for cells that made proteins from only D-amino acids rather than L-amino acids.

**FIGURE 5.5**

Stereoisomers of α -amino acids. (a) L-alanine and its enantiomer D-alanine are shown as ball-and-stick models. The alanine side chain is $-\text{CH}_3$. The two models are mirror images, which are not superimposable. The plane of mirror symmetry is represented by the vertical dashed line (red). (b) The same two enantiomers in a Fischer projection.

TABLE 5.2 Some biologically important amino acids not typically found in proteins

Name	Formula	Biochemical Source, Function
β -Alanine	$\text{H}_3\text{N}^+ - \text{CH}_2 - \text{CH}_2 - \text{COO}^-$	Found in the vitamin pantothenic acid and in some important natural peptides
D-Alanine	$\begin{array}{c} \text{COO}^- \\ \\ \text{H} - \text{C} - \text{NH}_3^+ \\ \\ \text{CH}_3 \end{array}$	In polypeptides in some bacterial cell walls
γ -Aminobutyric acid	$\text{H}_3\text{N}^+ - \text{CH}_2 - \text{CH}_2 - \text{CH}_2 - \text{COO}^-$	Brain, other animal tissues; functions as neurotransmitter
D-Glutamic acid	$\begin{array}{c} \text{COO}^- \\ \\ \text{H} - \text{C} - \text{NH}_3^+ \\ \\ \text{CH}_2 \\ \\ \text{CH}_2 - \text{COO}^- \end{array}$	In polypeptides in some bacterial cell walls
L-Homocysteine	$\begin{array}{c} \text{COO}^- \\ \\ \text{H}_3\text{N}^+ - \text{C} - \text{H} \\ \\ \text{CH}_2 - \text{CH}_2\text{SH} \end{array}$	Many tissues; precursor for methionine biosynthesis
L-Ornithine	$\begin{array}{c} \text{COO}^- \\ \\ \text{H}_3\text{N}^+ - \text{C} - \text{H} \\ \\ \text{CH}_2 - \text{CH}_2 - \text{CH}_2\text{NH}_3^+ \end{array}$	Many tissues; an intermediate in arginine synthesis
Sarcosine	$\text{CH}_3 - \text{N} - \text{CH}_2 - \text{COO}^-$ H	Many tissues; intermediate in amino acid synthesis
L-Thyroxine		Thyroid gland; is thyroid hormone (I = iodine)

Reza Ghadiri and coworkers have shown that a homochiral 32-residue peptide (i.e., composed of either all L- or all D-amino acids) *preferentially* catalyzes replication of homochiral products from a racemic mixture of peptide fragments. These experiments do not explain why L-amino acids are preferred over D-amino acids; but, they show that once the preference is established, there is a natural tendency to amplify homochiral sequences (in this case the sequences containing only L-amino acids).

The preference for L-amino acids in natural proteins has two important consequences, which we will discuss further in subsequent chapters:

1. The surface of any given protein, which is where the interesting biochemistry occurs, is asymmetric. This asymmetry is the basis for the highly specific molecular recognition of binding targets by proteins.
2. The stereochemistry of the amino acids plays an important role in the formation of so-called “secondary structure” (i.e., α helices and β strands) and thereby the overall structure of proteins.

The stereochemistry of the amino acids plays an important role in the formation of the structure of proteins.

Properties of Amino Acid Side Chains: Classes of α -Amino Acids

The 20 common amino acids contain, in their 20 different side chains, a remarkable collection of chemical groups. It is this diversity of the side chains that allows proteins to exhibit such a great variety of structures and properties. If we examine Figure 5.3, it becomes evident that there are several different classes of side chains, distinguished by their dominant chemical features. These features include hydrophobicity or hydrophilicity, polar or nonpolar character, and the presence or absence of ionizable groups. Many ways have been proposed to group the amino acids into classes, but none is wholly satisfactory. We shall discuss the amino acids in the order shown in Figure 5.3, which proceeds from the simplest to the more complex.

The variety of side chains on amino acids allows proteins enormous versatility in structure and function.

Amino Acids with Aliphatic Side Chains

Glycine, alanine, valine, leucine, and isoleucine have aliphatic side chains. As we progress from left to right along the top row of Figure 5.3, the R group becomes more extended and more hydrophobic. Isoleucine, for example, has a much greater tendency to transfer from water to a hydrocarbon solvent than does alanine. The more hydrophobic amino acids such as isoleucine are usually found *within the core* of a protein molecule, where they are shielded from water. **Proline**, which has a secondary α -amino group, is difficult to fit into any category. It is the only amino acid in this group in which the side chain forms a covalent bond with the α -amino group. The proline side chain has a primarily aliphatic character; however, it is frequently found on the *surfaces* of proteins due to its unique structural constraints. The rigid ring of proline is well-suited to those sites in a protein structure where the protein must fold back on itself (so-called “turns”).

Amino Acids with Hydroxyl- or Sulfur-Containing Side Chains

In this category we can place **serine, cysteine, threonine, methionine, and tyrosine**. Although methionine and tyrosine are fairly hydrophobic, these amino acids, because of their more polar side chains, display more hydrophilic character than their aliphatic analogs. As we will see in Chapter 11, the —OH group of serine and the —SH group of cysteine are good nucleophiles and often play key roles in enzyme activity. Cysteine is noteworthy in two additional respects. First, the side chain can ionize at moderately high pH:

Second, oxidation of two cysteine side chains yields a **disulfide bond**:

The product of this oxidation is given the name **cystine**. We do not list it among the 20 amino acids because cystine is always formed by oxidation of two cysteine side chains and is not coded for by DNA. Such disulfide bonds often play an important role in stabilizing the structure of a protein.

Aromatic Amino Acids

Three amino acids, **phenylalanine**, **tyrosine**, and **tryptophan**, carry aromatic side chains. Phenylalanine, together with the aliphatic amino acids valine, leucine, and isoleucine, is one of the most hydrophobic amino acids. Tyrosine and tryptophan have some hydrophobic character as well, but it is tempered by the polar groups in their side chains. In addition, tyrosine can ionize at high pH:

The aromatic amino acids, like most highly conjugated compounds, absorb light in the near-ultraviolet region of the spectrum (Figure 5.6). This characteristic is frequently used for the detection and/or quantitation of proteins, by measuring absorption at 280 nm.

Basic Amino Acids

Histidine, **lysine**, and **arginine** carry basic groups in their side chains. They are represented in Figure 5.3 in the form that predominates at pH 7. Histidine is the least basic of the three, and as its titration curve (Figure 5.7) shows, the imidazole ring in the side chain of the free amino acid loses its proton at about pH 6 (pK_a values for the side chains of free amino acids are given in Table 5.1.). When histidine is incorporated into proteins, the pK_a typically ranges from 6.5–7.4 (Table 5.3). The value of pK_a for an ionizable side chain is sensitive to the proximity of other charged groups. In the folded structures of proteins the local electrostatic environment can perturb the pK_a of an ionizable side chain by \pm three pH units. Because the histidine side chain has a pK_a near physiological pH, it often plays a role in enzymatic catalysis involving proton transfer. Lysine and arginine are more basic amino acids, and as their pK_a values indicate (Tables 5.1 and 5.3), their side chains are almost always positively charged under physiological conditions. The guanidino group of arginine is a particularly strong base due to the resonance stabilization of the protonated side chain.

The basic amino acids are strongly polar, and as a consequence they are usually found on the exterior surfaces of proteins, where they can be hydrated by the surrounding aqueous environment.

Acidic Amino Acids and Their Amides

Aspartic acid and **glutamic acid** typically carry negative charges at pH 7; they are depicted in the anionic forms in Figure 5.3. The titration curve of aspartic acid is shown in Figure 2.20 (page 46). The pK_a values of the acidic amino acids are so low (see Table 5.3) that even when the amino acids are incorporated into proteins, the negative charge on the side chain is typically retained under physiological conditions. Hence, these amino acid residues are often referred to as **aspartate** and **glutamate** (i.e., the conjugate bases rather than the acids).

FIGURE 5.6

Absorption spectra of the aromatic amino acids in the near-ultraviolet region. Tryptophan (red; $\lambda_{\text{max}} = 278$ nm) and tyrosine (blue; $\lambda_{\text{max}} = 274$ nm) account for most of the UV absorbance by proteins in the region around 280 nm. Phenylalanine (black; $\lambda_{\text{max}} = 258$ nm) does not absorb at 280 nm. Note that the absorptivity scale is logarithmic. Compared with nucleic acids, amino acids absorb only weakly in the UV; see Figure 4.5 for comparison.

FIGURE 5.7

Titration curve of histidine. The dots correspond to pK_a values, and the forms predominating at different pH values are shown. Ionizable hydrogens are shown in red. It is presumed that the starting solution was adjusted to pH < 2 by addition of H^+ to the dissolved amino acid. See also Figure 2.20 (page 46) for the titration curve of aspartic acid.

TABLE 5.3 Typical ranges observed for pK_a values of groups in proteins

Group Type	Typical pK_a Range ^a
α -Carboxyl	3.5–4.0
Side chain carboxyls of aspartic and glutamic acids	4.0–4.8
Imidazole (histidine)	6.5–7.4
Cysteine (—SH)	8.5–9.0
Phenolic (tyrosine)	9.5–10.5
α -Amino	8.0–9.0
Side chain amino (lysine)	9.8–10.4
Guanidinyl (arginine)	~12

^aValues outside these ranges are observed. For example, side chain carboxyls have been reported with pK_a values as high as 7.3.

Nonpolar amino acids are typically found in the interiors of soluble proteins, whereas polar and charged amino acids are typically found on the surfaces of proteins.

FIGURE 5.8

Structures of selenocysteine and pyrrolysine.

The selenium atom in selenocysteine and the 4-methyl-pyrroline-5-carboxylic acid in pyrrolysine are highlighted in red.

Sometimes amino acid side chains are modified after incorporation into a protein—a process called “post-translational modification.”

Oligopeptides and polypeptides are formed by polymerization of amino acids. All proteins are polypeptides.

Companions to aspartic and glutamic acids are their amides, **asparagine** and **glutamine**. Unlike their acidic analogs, asparagine and glutamine have *uncharged* polar side chains. Like the basic and acidic amino acids, they are hydrophilic and tend to be on the surface of a protein molecule, in contact with the surrounding water.

Rare Genetically Encoded Amino Acids

We have considered the 20 common amino acids that are coded for in DNA and are incorporated directly into proteins by ribosomal synthesis. There are two other amino acids encoded in gene sequences: selenocysteine, which is widely distributed but found in few proteins, and pyrrolysine, which is restricted to a few archaea and eubacteria. Selenocysteine (“Sec”) and pyrrolysine (“Pyl”) are sometimes referred to, respectively, as the 21st and 22nd amino acids (Figure 5.8). Selenocysteine is a structural analog of cysteine in which the sulfur atom is replaced by a selenium atom. In prokaryotes selenoproteins are typically involved in catabolic processes, whereas in eukaryotes the roughly 25 selenoproteins characterized to-date appear to be anabolic and/or anti-oxidant catalysts. Pyrrolysine is a derivative of lysine in which a 4-methyl-pyrroline-5-carboxylic acid forms an amide bond with the ϵ -amino group of the lysine side chain. Pyrrolysine is found in the active sites of several archaeal enzymes involved in the catabolism of methylamine.

Modified Amino Acids

The repertoire of side chain groups in proteins can be expanded beyond the 20 canonical structures described above by the chemical modification of certain amino acids after they are assembled into proteins. The structures of four such *post-translationally modified amino acids* are depicted below, with the modifying group shown in red.

We shall consider these again when we encounter specific proteins in which such modification has occurred.

The amino acids found in proteins are by no means the only ones to occur in living organisms. Many other amino acids play important roles in metabolism. A partial list is given in Table 5.2. Note that not all of them are α -amino acids, or the L-enantiomers. We shall encounter all of the amino acids in this table in later chapters.

Peptides and the Peptide Bond

Peptides

Amino acids can be covalently linked together by formation of an **amide bond** between the α -carboxylic acid group on one amino acid and the α -amino group on another. This bond is often referred to as a **peptide bond**, and the products formed by such a linkage are called **peptides**. The formation of a peptide bond between glycine and alanine is shown in Figures 5.9 and 5.10. The product in this case is called a **dipeptide** because two amino acids have been combined. As illustrated in Figure 5.10, the reaction can be viewed as a simple elimination of a

FIGURE 5.9

Formation of a dipeptide. Here the dipeptide glycylalanine (Gly–Ala) is depicted as being formed by removal of a water molecule as glycine is linked to alanine (See Figure 5.10).

water molecule between the carboxylic acid of one amino acid and the amino group of the other. Note that amide bond formation leaves an H_3N^+ group available on one end of the dipeptide and a —COO^- group on the other; thus, the reaction could in principle be continued by adding, for example, glutamic acid to one end and lysine to the other to yield the **tetrapeptide** shown in Figure 5.11. As each amino acid is added to the chain, another molecule of water must be eliminated. The portion of each amino acid remaining in the chain is called an **amino acid residue**. When specifying an amino acid residue in a peptide, the suffix **–yl** may be used to replace **–ine** or **–ate** in the name of the amino acid (e.g., glycy l for glycine, aspartyl for aspartate; tryptophanyl and cysteinyl are exceptions to this general rule). Thus, the *alanyl residue* in the tetrapeptide in Figure 5.11 is

In the structure of a peptide we distinguish the side chains (i.e., the R groups in Figure 5.3) from the **main chain** (or **peptide backbone**), which is composed of the atoms that make up the peptide bonds: the $\alpha\text{-NH}$, the C_α , and the $\alpha\text{-C=O}$ groups of each amino acid residue in the peptide. The N-terminal amino group and C-terminal carboxylate are also part of the main chain.

Chains containing only a few amino acid residues (like a tetrapeptide) are collectively referred to as **oligopeptides**. If the chain is longer ($> \sim 15\text{--}20$ residues), it is called a **polypeptide**. Polypeptides greater than ~ 50 residues are generally referred to as **proteins** (note that most globular proteins contain 250–600 amino acid residues). As shown in Figure 5.11, most oligopeptides and polypeptides retain an unreacted amino group at one end (called the **amino terminus** or **N-terminus**) and an unreacted carboxylic acid group at the other end (the **carboxyl terminus** or **C-terminus**). Exceptions are certain small cyclic oligopeptides, in which the N- and C-termini have been linked covalently. In addition, many proteins have N-termini blocked by

FIGURE 5.10

Elimination of water during the formation of a peptide bond. The formation of a peptide bond between glycine and alanine is shown. Step 1 involves attack of the deprotonated amino group on the carboxylic acid to form a tetrahedral intermediate. Step 2 shows proton transfer to the leaving group (H_2O , shown in green). Step 3 shows collapse of the tetrahedral intermediate and elimination of water to yield the planar amide bond. The newly formed peptide bond is highlighted in blue.

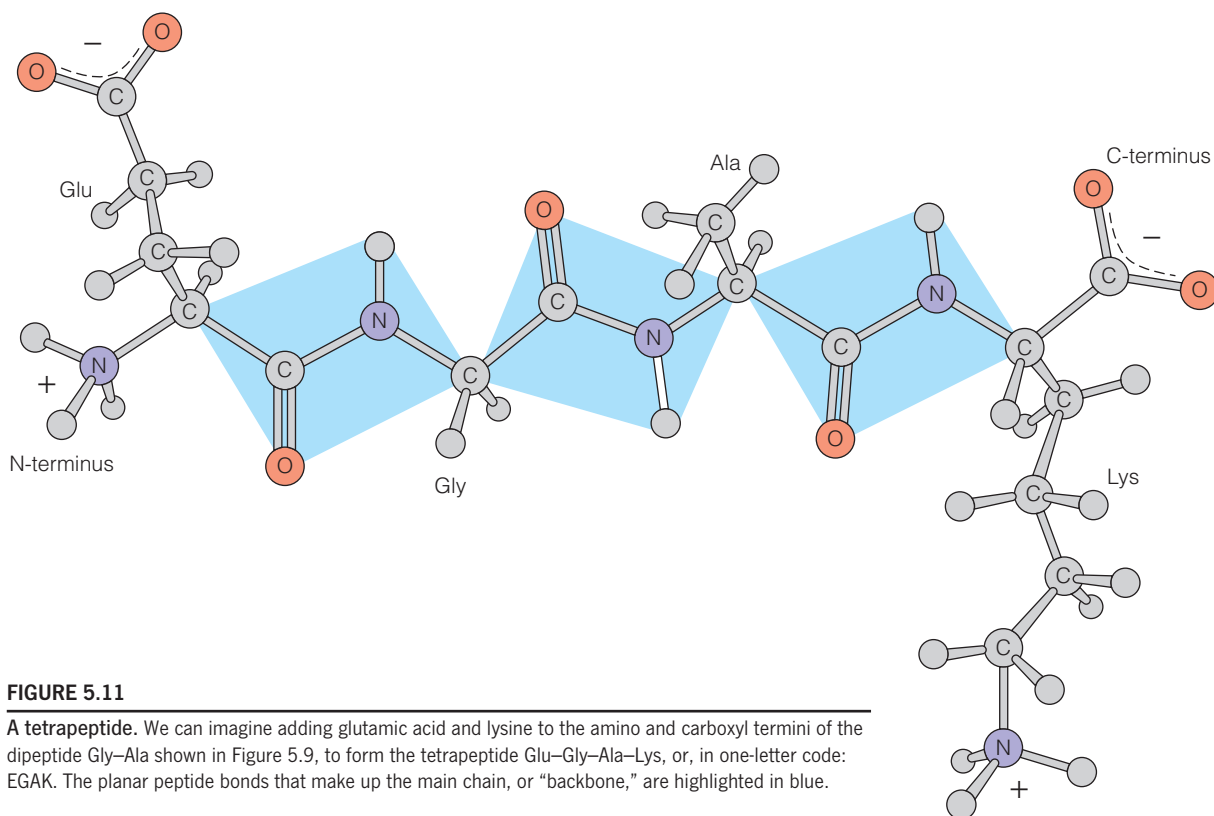

FIGURE 5.11

A tetrapeptide. We can imagine adding glutamic acid and lysine to the amino and carboxyl termini of the dipeptide Gly–Ala shown in Figure 5.9, to form the tetrapeptide Glu–Gly–Ala–Lys, or, in one-letter code: EGAK. The planar peptide bonds that make up the main chain, or “backbone,” are highlighted in blue.

N-formyl or *N*-acetyl groups, and a few have C-terminal carboxylates that have been modified to amides (Figure 5.12).

In writing the sequence of an oligopeptide or polypeptide, it would be awkward to spell out all the amino acid residue names. Therefore, biochemists usually write such sequences in terms of either the three-letter abbreviations or the one-letter abbreviations given in Figure 5.3. For example, the oligopeptide shown in Figure 5.11 could be written as either

Glu–Gly–Ala–Lys

or

EGAK

Note that the convention is to *always* write the N-terminal residue to the left and the C-terminal residue to the right. Because amino acids are asymmetric and there is only one free N-terminal amino group (and one free C-terminal carboxylate), the sequence EGAK \neq KAGE.

Polypeptides as Polyampholytes

In addition to the free amino group at the N-terminus and the free carboxylate group at the C-terminus, polypeptides usually contain some amino acids that have ionizable groups on their side chains. These various groups have a wide range of pK_a values, as shown in Table 5.3, but are all weakly acidic or basic groups; thus, polypeptides are excellent examples of the polyampholytes described in Chapter 2. As stated above, amino acid side chains display a range of pK_a values in different proteins due to differences in the local electrostatic environment around a given amino acid. For example, an aspartic acid side chain near another negatively charged group (i.e., Glu or another Asp) will likely have a higher pK_a value than an aspartic acid near a positively charged group (i.e., Lys, His, or Arg). This topic will be explored in more detail in Chapters 7, 11, and 15.

FIGURE 5.12

Groups that may block N- or C-termini in proteins. Blocking of the N-terminus by a formyl or acetyl group is more common than modification of the C-terminus to an amide.

The kind of behavior that is seen during the titration of an oligopeptide or a polypeptide is exemplified by the tetrapeptide (Glu-Gly-Ala-Lys) in Figure 5.11. We can imagine starting with the tetrapeptide in a very acidic solution with $\text{pH} = 0$. At this pH , which is below the pK_a of any of the groups present, all of the ionizable residues will be in their protonated forms:

As predicted from the information in Table 2.9 (page 48), all amino groups will be positively charged, and each carboxyl will have zero charge; thus, the tetrapeptide has an overall charge of $+2$ at this pH .

If we now imagine raising the pH of the solution (e.g., by titrating with NaOH), the various ionizable groups will lose protons at pH values in the vicinity of their pK_a values. The progress of this titration is shown in Figure 5.13. As the pH of the solution increases, more groups become deprotonated; thus, the net positive charge decreases and passes through zero at the isoelectric point (see Figure 2.19, page 45). As more base is added, the molecule becomes increasingly negatively charged, ultimately reaching a net charge of -2 at very high pH .

We will find the effects of changing pH on the overall charge on a protein to be of considerable importance in biochemistry. For example, even a small shift in pH can alter the constellation of charges displayed on the surface, or in the active site, of a protein and will thereby significantly affect its stability and/or functional properties. Also, the solubility of many proteins is minimal at the isoelectric point because the molecules no longer repel one another when their net charge is zero (see Figure 2.22, page 49). Finally, the fact that different proteins and oligopeptides have different net charges at a given pH is often used to advantage in their separation, either by electrophoresis (see Tools of Biochemistry 2A) or by ion-exchange chromatography (see Tools of Biochemistry 5A).

Amino acids, peptides, and proteins are ampholytes; each has an isoelectric point.

FIGURE 5.13

Polyampholytic behavior of a tetrapeptide. This titration curve for the tetrapeptide Glu-Gly-Ala-Lys (Figure 5.11) shows the major forms present at several pH values. The tetrapeptide is shown schematically here in blue (see inset, which indicates locations of N- and C-termini, as well as locations of side chains), and ionizable groups that may be charged are indicated by $+$, $-$, or \cdot , depending on whether they carry a positive, negative, or zero charge at a given pH . Net charges for the different ionization states of the tetrapeptide are shown in red.

The Structure of the Peptide Bond

Now let us examine the nature of the peptide bond that is formed between covalently linked amino acids. In the dipeptide of Figure 5.9 (Gly–Ala), the blue-shaded portion contains the peptide bond. This substituted amide bond, which is found between every pair of residues in a protein, has properties that are important for defining the structures of proteins. For example, almost invariably the amide carbonyl (C=O) and amide N—H bonds are nearly parallel; in fact, the six atoms shown in the blue rectangle in Figure 5.14 are usually coplanar. There is little twisting possible around the peptide bond because the C—N bond has a substantial fraction of double-bond character. The peptide bond can be considered a resonance hybrid of two forms:

A schematic depiction of the electron density about the peptide bond is shown in Figure 5.14a, and bond lengths and angles are given in Figure 5.14b.

X-ray crystallography data of proteins shows that the group of atoms about the peptide bond exist in two possible configurations, *trans* and *cis*, which are related by rotation around the C_{CO}—N bond (blue):

trans

cis

The peptide bond is nearly planar, and the *trans* form is favored.

FIGURE 5.14

Structure of the peptide bond. (a) Delocalization of the π -electron orbitals over the three atoms O—C—N accounts for the partial double-bond character of the C—N bond. **(b)** The presently accepted values for bond angles and lengths are shown here. Bond lengths are in nanometers (nm). The six atoms shown in (a) and those in the blue rectangle in (b) are nearly coplanar.

(a) Partial double-bond character of peptide bond

(b) Bond angles and lengths

In fact, the *trans* form is usually favored because in the *cis* configuration the R groups on adjacent α -carbons can sterically interfere. The major exception is the bond in the sequence X—Pro, where X is any other amino acid. In this bond the *cis* configuration is sometimes allowed, although the *trans* configuration is still favored by about 4:1.

Stability and Formation of the Peptide Bond

Figure 5.10 implies that a peptide bond could be formed by the elimination of a water molecule between two amino acids. In fact, in an aqueous environment this process is not thermodynamically favored. The free energy change for peptide bond formation at room temperature in aqueous solution is about +10 kJ/mol; therefore, the favored reaction under these conditions is the *hydrolysis* of the peptide bond:

with equilibrium lying well to the right. However, the uncatalyzed reaction is exceedingly slow at physiological pH and temperature. Like polynucleotides, polypeptides are metastable, hydrolyzing rapidly only under extreme conditions or when catalysts are present.

Peptide hydrolysis can be achieved in several ways. A general method, which cleaves all peptide bonds, is boiling in strong mineral acid (usually 6 M HCl). More specific cleavage is provided by **proteolytic enzymes** or **proteases**. Many such enzymes exhibit specificity as to which peptide bonds they will cleave; a number of them are listed in Table 5.4. Some of these enzymes are secreted into the digestive tracts of animals, where they catalyze the initial breakdown of proteins to smaller peptides, which are then further digested to amino acids by other enzymes. Others, such as papain, are found in certain plant tissues. The existence of several proteolytic enzymes with different sequence specificities is of great utility to the biochemist, as they allow the cleavage of polypeptides in well-defined ways. A nonenzymatic reaction that cleaves a specific peptide bond uses the reagent cyanogen bromide ($\text{BrC}\equiv\text{N}$). Cyanogen bromide specifically cleaves the peptide bond at the carboxyl side of methionine residues (Figure 5.15). We will see later how these specific cleavage reactions can aid in determining the sequence of residues in a protein.

As with polynucleotides, the thermodynamic instability of polypeptides raises the question of how they can be synthesized in the aqueous medium of the cell. You may already have guessed the answer—that coupling of the unfavorable synthetic

The peptide bond is metastable. Peptide bonds hydrolyze in aqueous solution when a catalyst is present.

Peptides can be cleaved at specific sites by proteolytic enzymes or by treatment with chemical agents such as cyanogen bromide.

TABLE 5.4 The sequence specificities of some proteolytic enzymes

Enzyme	Preferred Site ^a	Source
Trypsin	$R_1 = \text{Lys, Arg}$	From digestive systems of animals, many other sources
Chymotrypsin	$R_1 = \text{Tyr, Trp, Phe, Leu}$	Same as trypsin
Thrombin	$R_1 = \text{Arg}$	From blood; involved in coagulation
V-8 protease	$R_1 = \text{Asp, Glu}$	From <i>Staphylococcus aureus</i>
Prolyl endopeptidase	$R_1 = \text{Pro}$	Lamb kidney, other tissues
Subtilisin	Very little specificity	From various bacilli
Carboxypeptidase A	$R_2 = \text{C-terminal amino acid}$	From digestive systems of animals
Thermolysin	$R_2 = \text{Leu, Val, Ile, Met}$	From <i>Bacillus thermoproteolyticus</i>

^aThe residues indicated are those next to which cleavage is most likely. Note that in some cases preference is determined by the residue on the N-terminal side of the cleaved bond (R_1) and sometimes by the residue to the C-terminal side (R_2). Generally, proteases do not cleave where proline is on the other side of the bond. Even prolyl endopeptidase will not cleave if $R_2 = \text{Pro}$.

FIGURE 5.15

The cyanogen bromide reaction. This reaction specifically cleaves the peptide bond to the carboxyl side of methionine in any polypeptide and converts the Met residue to homoserine lactone. The cleavage sites are indicated by ▲.

reaction to the hydrolysis of high-energy phosphate compounds is required. In fact, every amino acid must be activated by an ATP-driven reaction before it can be incorporated into proteins. We shall give a brief outline of the process later in this chapter.

Proteins: Polypeptides of Defined Sequence

Every protein has a unique, defined amino acid sequence—its primary structure.

Proteins are polypeptides of defined sequence. Every protein has a defined number and order of amino acid residues. As with the nucleic acids, this sequence is referred to as the *primary structure* of the protein. In later chapters we shall see that it is this fundamental level of structure upon which higher levels of structural organization are based.

Figure 5.16 shows the primary structure of sperm whale *myoglobin*, the protein whose three-dimensional structure is shown in Figure 5.1. Also listed is the primary structure of human myoglobin, the protein that serves the same O₂ binding function in humans. The two sequences are aligned to show the maximum amino acid similarity between them. Two points are immediately obvious from

FIGURE 5.16

The amino acid sequences of sperm whale myoglobin and human myoglobin. Single-letter abbreviations are used here for the amino acids; numbering of the amino acids starts at the N-terminus. Of the 153 amino acid residues, 128 (84%) are identical in humans and whales. If we include the 13 conservative substitutions (e.g., isoleucine for leucine), the two proteins are 92% similar.

Key:

- Identical amino acids
- Conservative substitutions
- Nonconservative substitutions

examination of these sequences. First, proteins are *long* polypeptides. Sperm whale myoglobin contains 153 amino acids, as does human myoglobin; yet, these are among the smaller proteins. Some proteins have sequences extending for many hundreds or even thousands of amino acid residues. Second, although the two myoglobin sequences are similar, they are not identical. Their similarity is sufficient for each to serve the same biochemical function; therefore, we call each a *myoglobin*. But they are not quite the same, for many millions of years have passed since sperm whales and humans had a common ancestor. Proteins evolve, and they evolve by changes in their amino acid sequences. Some of these are called **conservative** changes; they conserve the chemical properties and/or size of the side chain (Asp for Glu, for example). Other, **nonconservative** changes (Asp for Ala, for example) may have more serious consequences. It must be noted that structural context is of great importance in determining the effects of changing the identity of an amino acid at a given position in the sequence of the protein. If the amino acid side chain is in the interior of the protein, even a “conservative” substitution could have dramatic consequences for the stability and/or function of the protein. A solvent exposed site in the protein may tolerate many side chain substitutions with little effect on the structure or function of the protein.

We must also emphasize the uniqueness of a given protein in a particular species of organism. Every sample of sperm whale myoglobin, taken from any sperm whale, has the same amino acid sequence (unless, by rare chance, a sample is taken from a whale that carries a mutated myoglobin gene).

Biochemists have come to understand the complex structure of the myoglobin molecule bit by bit, by analyzing successively higher levels of complexity in the protein structure. To begin any such study of a protein, it is necessary to prepare the protein in a pure form, free of contamination by other proteins or other cellular substances. Methods for doing this are described in Tools of Biochemistry 5A. Historically, the next step after purifying a protein would be to determine its amino acid composition, that is, the relative amounts of the different amino acids in the protein, and then the sequence of the amino acids in the polypeptide chain. These steps have been superseded by the routine mass determination of purified proteins by mass spectrometry. Modern mass spectrometers can also be used to determine the amino acid sequence of a purified protein. These procedures are described in Tools of Biochemistry 5B at the end of this chapter.

A complication arises in the sequence determination if the protein being studied contains more than one polypeptide chain. These chains may be held together by noncovalent interactions, as in the protein *hemoglobin*, which is made up of four myoglobin-like chains (see Chapter 7). Alternatively, chain connection can be by covalent bonds such as disulfide bonds. An example of such a protein is the hormone **insulin** (Figure 5.17). Tools of Biochemistry 6B describes methods for detecting such multichain proteins and how to separate them.

Although direct sequencing of purified proteins provided much of the early protein sequence information, biochemists are more and more turning to gene sequencing for such information. As described in Chapter 4, the primary structure of every protein is dictated by a particular gene. Because we now know the code that relates DNA sequence to protein sequence, determination of the

Some proteins contain two or more polypeptide chains held together by noncovalent or covalent bonds.

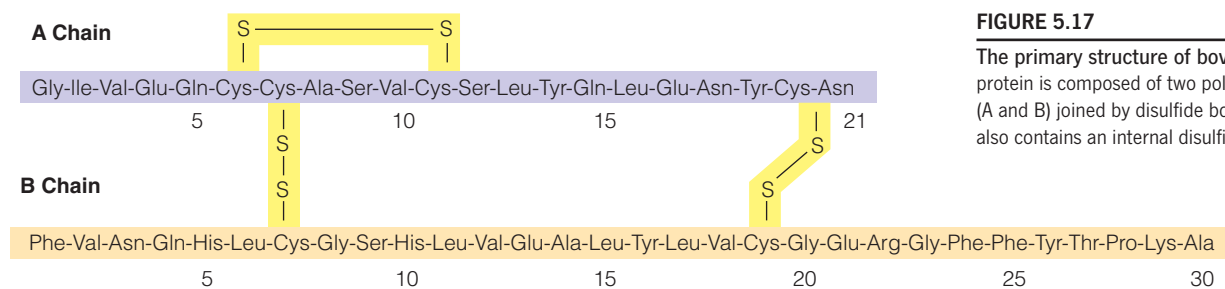

FIGURE 5.17

The primary structure of bovine insulin. This protein is composed of two polypeptide chains (A and B) joined by disulfide bonds. The A chain also contains an internal disulfide bond.

nucleotide sequence of a gene (or more often, the sequence of the messenger RNA transcribed from that gene) allows us to translate the nucleic acid sequence into the corresponding protein sequence. It should be kept in mind, however, that gene sequencing tells us only the sequence *as synthesized*. As we will see, there are often post-translational modifications of the polypeptide chain that are not revealed in this way and can be found only by analysis of the purified protein.

The techniques for identifying protein-encoding sequences in the genome and for retrieving, cloning, and sequencing the genes are discussed in Part V of this text (see also Tools of Biochemistry 4B).

From Gene to Protein

The Genetic Code

In Chapter 4 we stated that the DNA sequences of genes are transcribed into messenger RNA molecules, which are in turn translated into proteins. But there are only four kinds of nucleotides in DNA, each of which transcribes to a particular nucleotide in RNA, and there are 20 kinds of amino acids. Obviously, a 1:1 correspondence between nucleotide and amino acid is impossible. In fact, triplets of nucleotides (**codons**) are used to code for each amino acid, allowing 4^3 , or 64, different combinations. This number is more than enough to code for 20 amino acids, so most amino acids have multiple codons. We can consider the information shown in Figure 5.18 to be the “standard” genetic code because nearly all terrestrial organisms use the same codons to translate their genomes into proteins. The few exceptions are scattered through the biological kingdoms. We discuss these and other details of the genetic code in Chapter 28.

Figure 5.18 depicts the genetic code in terms of the mRNA triplets that correspond to the different amino acid residues. Three triplets—UAA, UAG, and UGA—

The genetic code specifies RNA triplets that correspond to each amino acid residue.

FIGURE 5.18

The genetic code. The table is arranged so that users can quickly find any amino acid from the three bases of the mRNA codon (written in the 5' → 3' direction). For example, to find the amino acid corresponding to the codon 5' AUC 3', we look first in the A row, then in the U column, and finally in the C space, to find the amino acid to be Ile.

typically do not code for any amino acids but serve as “stop” signals to end translation at the C-terminus of the chain. In rare cases the codon UGA codes for selenocysteine and UAG codes for pyrrolysine. The codon AUG, which normally codes for methionine, also serves as a translation “start” signal that directs the placement of *N*-formylmethionine (in prokaryotes and eukaryotic organelles, see Figure 5.19) or methionine (in eukaryotes) at the N-terminal position. The implication is that all prokaryotic proteins should start with *N*-formylmethionine (“fMet”), and most eukaryotic proteins with methionine. Often this is true, though in many cases the N-terminal residue or even several residues are cleaved off in the cell by specific proteases during, or immediately after, translation. Figure 5.20 shows the relationship between DNA, mRNA, and polypeptide sequences for the N-terminal portion of human myoglobin. In this case the N-terminal methionine is removed.

Post-translational Processing of Proteins

When a polypeptide chain is released from a ribosome following translation, its synthesis is not necessarily finished. It must fold into its correct three-dimensional structure, and in some cases disulfide bonds must form. Certain amino acid residues may be acted upon by enzymes in the cell to produce, for example, the kinds of modifications shown on page 144.

Many proteins are further modified by specific proteolytic cleavage, which shortens the chain length. A remarkable example is found in the synthesis of insulin (Figure 5.21). We have encountered insulin as a two-chain protein held together by disulfide bonds (Figure 5.17). Insulin is actually synthesized as a single, much longer polypeptide chain, called **preproinsulin** (Figure 5.21, step 1). The residues at the N-terminus of the molecule (the exact number varies with the species) serve as a “signal peptide” (also called a **leader sequence**) to aid the transport of the preproinsulin molecule across the hydrophobic cell membranes. This transport is essential, for insulin is one of a class of proteins that function outside the cells in which they are synthesized. The leader sequence is then cut off by a specific protease, leaving **proinsulin** (step 2). Proinsulin folds into a specific three-dimensional structure, which helps it form the correct disulfide bonds (step 3). The connecting sequence between the A chain and the B chain is then cut out by further protease action, yielding the finished insulin molecule (step 4). This achieves an important physiological advantage. Because proinsulin is not an active hormone, it can be produced and stored in tissues at high concentrations where such high levels of active insulin would be toxic. The proinsulin can be quickly converted to insulin by proteolysis to allow for rapid secretion of active insulin when needed by the body.

The primary structure of a protein molecule is a sequence of *information*. The amino acid side chains can be thought of as words in a long sentence. These words

Translation of mRNA into protein sequence begins with an AUG codon, which encodes Met in eukaryotes and fMet in prokaryotes and eukaryotic organelles.

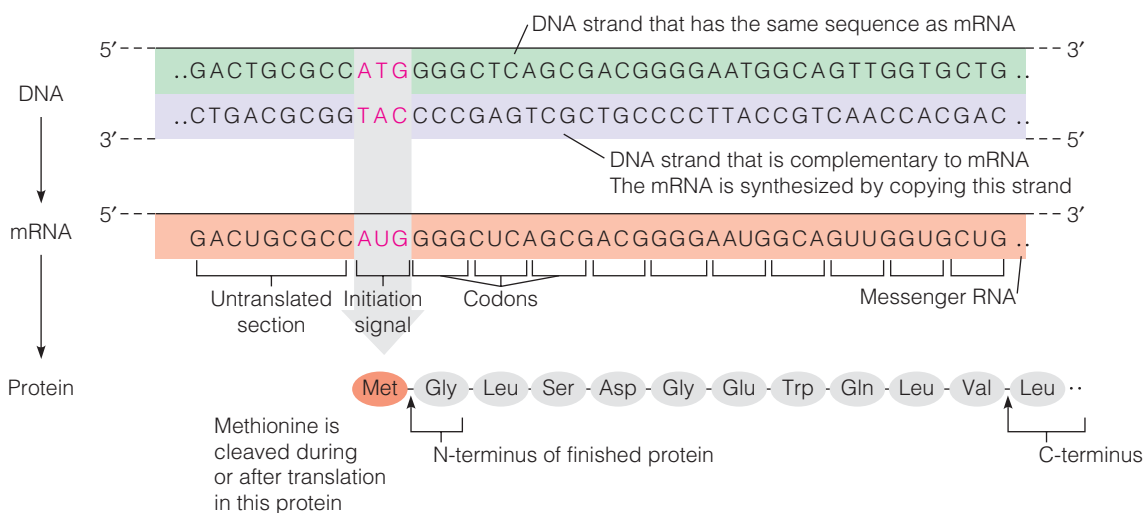

FIGURE 5.19

N-Formylmethionine. This amino acid residue initiates prokaryotic translation as well as in eukaryotic organelles. It is coded by AUG when that triplet appears at the start of a gene encoding a protein.

After being translated from mRNA, a protein may be modified in many ways—including cleavage of specific peptide bonds.

FIGURE 5.20

Relationships of DNA to mRNA to polypeptide chain. These relationships are shown for the first twelve residues of human myoglobin. Note that the DNA strand that is transcribed is the strand complementary to the final mRNA message.

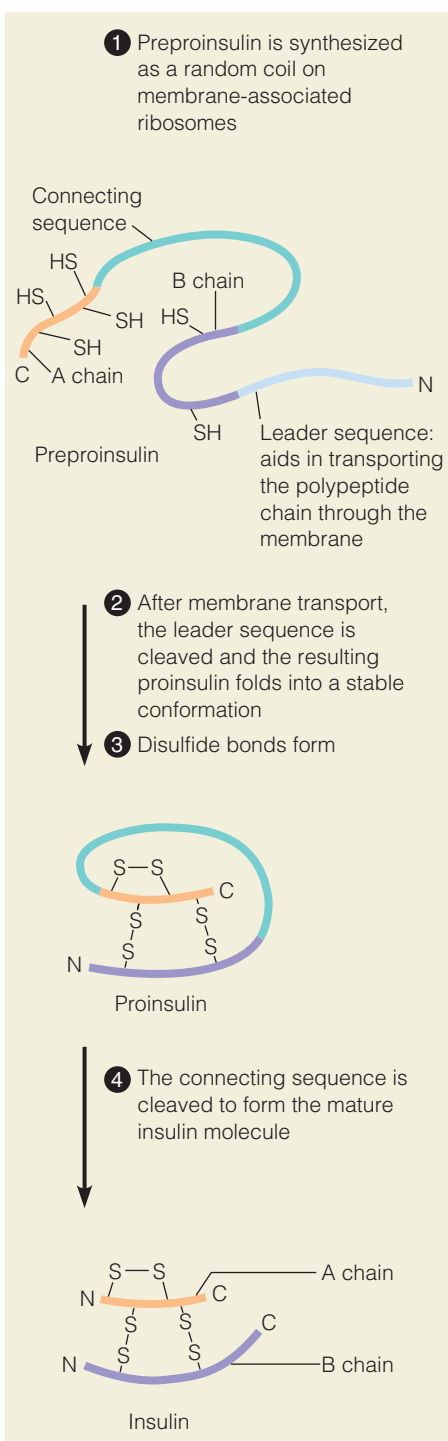

FIGURE 5.21

Structure of preproinsulin and its conversion to insulin.

have been translated from another language, the language of nucleic acid sequences stored in the genes and copied into messenger RNA. After translation, the sentence has been edited, with certain words modified and others deleted in the post-translational processing. In the next chapter we shall see that the information contained in the “sentence” of a protein sequence dictates how that protein folds in three dimensions. This folding, in turn, determines the function of the protein—how it interacts with small molecules and ions, with other proteins, and with substances like nucleic acids, carbohydrates, and lipids. The information expressed in protein sequences plays a primary role in determining how cells and organisms function.

From Gene Sequence to Protein Function

The development of **systems biology** has created a revolution in the molecular biosciences. The impact of systems biology on biochemistry will be described in much greater detail in later chapters of this textbook; however, we briefly introduce the topic here because vast amounts of protein primary structure information have been generated as a result of the genomics projects that have spurred the rapid growth of systems biology.

Historically, biochemistry has been a discipline in which the functions and/or structures of highly purified macromolecules are studied in isolation. Systems biology is directed at understanding the functions of biomolecules in the context of intact cells where, for example, several thousand different proteins, nucleic acids, and smaller molecules can potentially interact with, and thereby affect, cellular processes. Systems biology is a relatively new discipline that has grown out of the development of recent technologies. Mapping cellular interaction networks is a complex task that relies on large-scale computation resources for information management, as well as on laboratory instruments and techniques for generating large amounts of data.

To map possible interactions between biomolecules in a cell it is necessary to know what molecules are present in the cell. For this reason one of the earliest goals of systems biology was the sequencing of an entire genome for an organism. In 1995 a team led by J. Craig Venter at the Institute for Genome Research sequenced the first genome of a free-living organism, *Haemophilus influenzae* (1.8 million base pairs), and in 2001 two large teams, one led by Venter (then at a privately held company) and the other by Francis Collins (at the National Institutes of Health), jointly announced the draft sequence of the human genome (3 billion base pairs). The sequencing of the human genome is considered to be one of the most significant achievements in science. Since then, an exponential growth in genome sequencing has occurred. As of December 2011, complete sequences for 3334 microbial and 320 eukaryotic genomes had been reported.

Nearly all DNA sequences are deposited in public databases such as GenBank, and there are several web-based tools that researchers can use to search these databases (some of these are cited in the references at the end of this chapter). In addition, the Protein Data Bank (PDB) is a repository of protein and nucleic acid structures.[†] Throughout this text you will see representations of biomolecular structures that have been generated from the data in the PDB. The exponential growth of gene sequence information has had a profound effect on many areas of biochemistry. One such area is the prediction of protein function from translated gene sequences.

Because the technology to determine DNA sequence has developed to the point where entire genomes can be determined in a relatively short period of time,

[†]As of December 2011, there were more than 77,000 structures of biomolecules deposited in the PDB and over 132 billion nucleotide bases from more than 144 million individual sequences (obtained from more than 300,000 different organisms) deposited in GenBank (about 11 million of the sequences in GenBank are of human origin).

there is tremendous interest in identifying how much of a given genome encodes functional properties. For example, how much of the human genome encodes metabolic function, or tissue differentiation and growth, or cell signaling?

To attempt to answer these questions researchers can translate putative gene sequences into protein sequences, and then search protein sequence databases to find similar sequences. In most cases proteins with similar amino acid sequence possess similar structural and functional properties (e.g., the two myoglobins in Figure 5.16); thus, it is reasonable to use sequence similarity to propose functional properties for an uncharacterized protein.

What does it mean for two proteins to have “similar” amino acid sequence? We must first distinguish **sequence identity** from **sequence similarity**. In this context “identity” refers to those parts of the amino acid sequence that are an exact match (e.g., the amino acids highlighted in blue in Figure 5.16). The definition of “similarity” is less clear cut; but, as discussed earlier in this chapter, is based on the classification of the chemical properties of the side chains such as hydrophobicity, polarity, and charge. The classification of some amino acids is ambiguous because they possess more than one of these properties. Consider lysine, which has a charged amino group at the end of four hydrophobic methylene groups; thus, in one context lysine might be best characterized as hydrophobic and in a different context it would be considered charged.

Once a definition of “similarity” has been adopted, how is sequence similarity assessed? Sequence similarity is based on finding the best **alignment** of the sequences that are to be compared. For example, one can imagine a process in which two (or more) sequences are aligned and an amino acid similarity score for the alignment is calculated based on some scoring rubric (e.g., a “high” score for a perfect amino acid match, a “medium” score for a chemically similar amino acid, and a “low” score for a chemically dissimilar amino acid). The registry of the alignment is then changed and the similarity score is once again calculated. This iterative process continues until the alignment is found that gives the highest similarity score. For example, the alignment of the two myoglobin sequences in Figure 5.16 shows the maximum value for sequence similarity. This example is rather straightforward given the high degree of similarity between these two sequences. In many cases it is necessary to allow gaps in the alignment to get the best overall alignment score.

The alignment optimization process occurs many times during a protein database search. The output of such a search is a listing of several proteins from the database that are best matches based on a statistical analysis of sequence similarity. One widely used protocol for conducting database searches is the Basic Local Alignment Search Tool (BLAST). The suite of BLAST programs can be used to find the best alignment between the sequences of any two proteins, or more commonly, between the sequence of a “new” protein and sequences of proteins in several public databases. The results of a BLAST search can be used to infer potential function for an uncharacterized protein sequence; however, any proposed function must be validated experimentally.

To summarize, given a newly discovered gene sequence it is possible to make a best guess as to the function of the gene product based on a search of protein sequence databases using BLAST. The BLAST search generates sequence alignments and returns those alignments with the statistically significant sequence similarity scores. Similarities in sequence appear to be correlated with similarities in function and structure. As a rule of thumb, if two aligned protein sequences share at least 25% amino acid sequence identity they will have similar structure and, very likely, similar function. An example of a BLAST alignment between human myoglobin and human α globin is shown in Figure 5.22. The use of sequence information obtained from gene sequencing (Tools of Biochemistry 4B) or direct sequencing of proteins (Tools of Biochemistry 5B) to identify a protein is described further in Tools of Biochemistry 5D: A Brief Introduction to Proteomics.

The degree of similarity between protein sequences is determined from a procedure called “alignment.”

Primary sequence analysis can be used to predict protein function because similarities in aligned sequences are correlated with similarities in protein function and structure.

FIGURE 5.22

BLAST alignment between human myoglobin and human α globin sequences. The sequence of myoglobin is above that for the α globin, and between them are shown identical amino acids (blue) and those that are considered similar (green “+”). Gaps in the alignment are shown by red text and red dashes. In this alignment there is 25% sequence identity, suggesting a high degree of structural similarity between the proteins. The significance of the alignment is given by the “Expect” value, which is a measure of the likelihood that the alignment is due to chance. The lower this value, the more significant is the alignment.

Protein Sequence Homology

Protein sequence similarity is also used to map evolutionary relationships between organisms. Two organisms that have a common evolutionary ancestry are likely to have gene sequences, and therefore protein sequences, that are related. Protein sequences are classified as “homologous” in cases where any sequence similarity is thought to be the result of a common evolutionary ancestry. Note that sequence similarity can also arise without common ancestry via convergent evolution (e.g., two proteins may have evolved independently to bind to the same peptide sequence found on a particular transcription factor). Two such protein sequences would be *similar* but not *homologous*; hence, “sequence similarity,” which is based on sequence alignment, is distinct from “sequence homology,” which is used only to indicate an evolutionary relationship between two sequences.

For organisms that have a common ancestor, a greater degree of protein sequence homology indicates a closer evolutionary relationship; whereas a lesser degree of homology indicates greater divergence. Figure 5.23a shows an alignment of sequences for cytochromes *c* from 27 different organisms. In this figure the hydrophobic (gray), positively charged (blue), negatively charged (red), and polar uncharged (green and magenta) amino acids are highlighted to illustrate the clustering of these similar amino acid properties in this alignment. Figure 5.23b shows a phylogenetic tree for the sequences, where branches show points of proposed evolutionary divergence based on differences in the amino acid sequences of the aligned proteins. The construction of such trees involves complex analyses of gene mutation rates and polymorphism within populations—topics beyond the scope of this introduction to protein sequence analysis. The important point for this discussion is that protein sequence analysis can be used to propose evolutionary relationships between organisms, such as those shown in Figure 5.23b.

Finally, when several homologous protein sequences are aligned, one can determine the so-called **consensus sequence**. A common representation of the consensus sequence lists the amino acid that is most frequently found at a given position in the sequence; however, this representation can be an oversimplification. If a certain amino acid is found at a specific position in 80% of the aligned sequences, that means that 20%, a significant percentage, of the sequences do not have that amino acid at that position. A more information-rich representation is the **sequence logo** in which the relative size of the one-letter code is correlated with the relative frequency of an amino acid at a given position. Figure 5.24 shows a sequence logo for an alignment of 412 sequences of proteins from the

Protein sequence analysis can be used to propose evolutionary relationships between organisms.

FIGURE 5.23

Sequence alignment and a phylogenetic tree for cytochromes *c* from different organisms. **(a)** Alignment of cytochrome *c* sequences from 27 organisms, where hydrophobic amino acids are highlighted in gray, basic amino acids in blue, acidic amino acids in red, and polar uncharged amino acids in green (except for Asn and Gln, which are magenta). **(b)** A phylogenetic tree for the sequences shown in (a). Branches indicate points of evolutionary divergence based on differences in the amino acid sequences of the aligned proteins. Both the alignment and the phylogenetic tree were created using CLUSTALW2 and CINEMA (both available via the ExPASy Website; see References).

cytochrome *c* family, where the amino acid found most frequently at any position is shown at the top of each column.

The sequence logo shows better the degree of **amino acid conservation** within the aligned sequences. If only one amino acid is found at a given position within an alignment of homologous proteins, that amino acid is said to be absolutely “conserved” (e.g., cysteine at position 17 and histidine at position 18 in Figure 5.24). An amino acid type can also be conserved at a given position. For example, only leucine, valine, isoleucine, and methionine are found at position 80 in the 412 aligned cytochrome *c* sequences; thus, hydrophobic amino acids are conserved at this position. As we will discuss further in Chapter 6, the most highly conserved amino acids tend to be those that serve a critical structural and/or functional role in the protein.

FIGURE 5.24

Sequence logo from the alignment of 412 sequences from the cytochrome *c* family. The amino acid found most frequently at a given position is shown on top and the relative size of the one letter code is correlated with the relative frequency of that amino acid in that position. The sequence logo was generated using the WEBLOGO program from data available in the Prosite database (matrix alignment #51007; see the ExPASy Website).

SUMMARY

Proteins are polymers of L- α -amino acids. Twenty common amino acids and two rare amino acids are coded for in genes and incorporated into proteins by the process of translation. Other, less common, amino acid structures are found in nature (e.g., in bacterial cell walls, antibiotics, and venoms). The variety of side chains—hydrophilic, hydrophobic, acidic, basic, or neutral—allows much functional complexity in proteins. Additional variation is made possible by post-translational modification of some amino acids. The presence of both positive and negative charges on side chains makes proteins polyampholytes.

Oligopeptides and polypeptides are produced by polymerization of amino acids via peptide bond formation. The peptide bond is nearly planar, and the *trans* form is favored. This bond is metastable and can be readily hydrolyzed in the presence of catalysts. The unique, defined sequence of amino acids in each protein constitutes its primary structure, dictated by its gene. Some proteins contain more than one polypeptide chain, held together by either covalent (disulfide) or noncovalent bonds. Proteins are synthesized in the cell by an ATP-dependent process called translation. The genetic code is made up of a standard set of codons of three nucleotides, each of which specifies a particular amino acid. Specific “start” and “stop” triplets in the genetic code specify the chain length for a particular protein.

Even after translation has been completed, the protein molecule can be further covalently modified, either by cleavage of particular portions or by modification of certain amino acid side chains.

Genome sequencing has generated vast amounts of gene sequence information. The functions of most of these genes are unknown; however, sequence similarity analysis can be used to predict the function, and in some cases the structure, of a gene product.

PROBLEMS

Note that some of these problems refer to information presented in the Tools of Biochemistry 5A-D.

- Using the data in Table 5.1, calculate the *average* amino acid residue weight in a protein of typical composition. This is a useful number to know for approximate calculations.
- The melanocyte-stimulating peptide hormone α -melanotropin has the following sequence:

Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val

- Write the sequence using the one-letter abbreviations.
 - Calculate the molecular weight of α -melanotropin, using data in Table 5.1.
- *3. (a) Sketch the titration curve you would expect for α -melanotropin (Problem 2). Assume the pK_a s of the N- and C-termini are, respectively, 7.9 and 3.8. For side chains, assume the pK_a values given in Table 5.1.
- Calculate to 3 decimal places the charge on α -melanotropin at pH values of 11, 5, and 1.
 - Calculate the isoelectric point of α -melanotropin.

For parts (b) and (c) of this problem refer to the logic used to solve Problem 2.16. You may find a spreadsheet useful to solve part (c).

- What peptides are expected to be produced when α -melanotropin (Problem 2) is cleaved by (a) trypsin, (b) cyanogen bromide, and (c) thermolysin? (Refer to Table 5.4.)
- There is another melanocyte-stimulating hormone called β -melanotropin. Cleavage of β -melanotropin with trypsin produces the following peptides plus free aspartic acid.

WGSPPK DSGPYK MEHFR

If you assume maximum sequence similarity between α -melanotropin and β -melanotropin, what must be the sequence of the latter?

- Given the following peptide

SEPIMAPVEYPK

- Estimate the net charge at pH 7 and at pH 12. Assume the pK_a values given in Table 5.1.
 - How many peptides would result if this peptide were treated with (1) cyanogen bromide, (2) trypsin, and (3) chymotrypsin?
 - Suggest a method for separating the peptides produced by chymotrypsin treatment.
- *7. A mutant form of polypeptide hormone angiotensin II has the amino acid *composition*

(Asp, Arg, Ile, Met, Phe, Pro, Tyr, Val)

The following observations are made:

- Trypsin yields a dipeptide containing Asp and Arg, and a hexapeptide with all the rest.
- Cyanogen bromide cleavage yields a dipeptide containing Phe and Pro, and a hexapeptide containing all the others.
- Chymotrypsin cleaves the hormone into two tetrapeptides, of composition
(Asp, Arg, Tyr, Val) and (Ile, Met, Phe, Pro)
- The dipeptide of composition (Pro, Phe) cannot be cleaved by either chymotrypsin or carboxypeptidase.

What is the sequence of angiotensin II?

- A protein has been sequenced after cleavage of disulfide bonds. The protein is known to contain 3 Cys residues, located as shown below. Only one of the Cys has a free —SH group and the other two are involved in an —S—S— bond.

The only methionine and the only aromatic amino acid (Phe) in this protein are in the positions indicated. Cleavage of the *intact* protein (i.e., with disulfide bonds intact) by either cyanogen bromide or chymotrypsin does *not* break the protein into two peptides. Where is the —S—S— bond (AB, BC, or AC)?

- Apamine* is a small protein toxin present in the venom of the honeybee. It has the sequence

CNCKAPETALCARRCQQH

- It is known that apamine does not react with iodoacetate (see page 169). How many disulfide bonds are present?
 - Suppose trypsin cleavage gave two peptides. Where is(are) the S—S bond(s)?
- (a) Write a possible sequence for an mRNA segment coding for apamine.
(b) Do you think apamine is synthesized in the form shown in Problem 9, or is it more likely a product of proteolytic cleavage of a larger peptide? Explain.
 - Assume the following portion of an mRNA. Find a start signal, and write the amino acid sequence that is coded for.
5'—GCCAUGUUUCCGAGUUAUCCCAAAGAUAAAAAGAG—3'
 - A researcher has isolated an oligopeptide of unknown sequence and unknown amino acid composition. All attempts to sequence it by Edman degradation fail; the reaction just will not go.
(a) Suggest two quite different possible explanations for the problem.
(b) Suggest an experiment that will at least distinguish between these two.
 - Suppose you had separated the A and B chains of insulin by disulfide reduction. What chromatographic method should allow the isolation of pure A and B chains? Explain your choice of separation method.
 - Sickle cell disease is caused by a so-called “point mutation” in the human β -globin gene. A point mutation is the result of a single base substitution in the DNA encoding a gene. The sickle cell mutation results in substitution of Val for Glu at position 6 in the β -globin protein.
(a) Using the information in Figure 5.18 explain how a point mutation could change a codon for Glu to a codon for Val.
(b) Do you expect the pI for the sickle cell β -globin to be higher or lower than the pI for wild-type β -globin? Explain.
 - You have discovered a novel protein that has a pI = 5.5. To study the functional properties of this new protein, your research group has made a mutant that contains two amino acid changes: a surface phenylalanine residue in the normal protein has been replaced by histidine (side chain pK_a = 6.1), and a surface glutamine has been replaced by glutamic acid (side chain pK_a = 6.0). Is the pI of the mutant protein predicted to be *greater than*, *less than*, or *the same as* the pI of normal protein? Support your answer with the appropriate calculation.

TOOLS OF BIOCHEMISTRY 5A

PROTEIN EXPRESSION AND PURIFICATION

Much of the information presented in this text was gained through the study of highly purified protein molecules. To determine the structure and/or functional properties of a specific protein it is necessary to separate that protein from the other biomolecules in the cell (lipids, nucleic acids, saccharides) and, of course, all other proteins. In a typical cell the protein of interest is usually a minor component; thus, the isolation of that protein from such a complex mixture presents a challenge. Modern methods of gene expression and protein purification have simplified the problem by increasing the concentration of the desired protein within the cell and exploiting specific interactions between the protein and materials used in the purification process.

Recombinant Protein Expression

To begin, let's consider the problem of protein concentration. A typical enzyme may represent only 0.01% of the soluble protein in a cell. Thus, a 10,000-fold enrichment is necessary to purify that protein to homogeneity. If recombinant DNA technology (see Tools of Biochemistry 4B) can increase the intracellular abundance of that protein to 1%, then only a 100-fold enrichment is required; if to 10%, then a 10-fold enrichment will suffice. Historically, proteins were purified from natural sources, such as animal or plant tissues. The first proteins to be studied in detail were those with high abundance in particular tissues (e.g., hemoglobin in red blood cells). For proteins that are present in low concentration in their natural tissues, it is necessary to harvest large amounts of the tissue to isolate a useful amount of the desired protein. This unfortunate scenario was a fact of life for biochemists for many years until the tools of "recombinant protein expression" were developed and widely adopted in the late 1970s and early 1980s. Recombinant protein expression allows researchers to produce proteins of interest at relatively high concentrations within cells and also enables the production of so-called **site-directed mutants**, which are protein variants with designed amino acid sequence alterations (see Tools of Biochemistry 4B). Frequently, the mutant proteins exhibit changes in structure, function, and/or stability relative to the "wild-type" (i.e., naturally occurring) protein; thus, the mutants are of great scientific interest. Another important feature of recombinant technology is the ability to express a wide variety of foreign proteins in host cells. For example, many proteins of animal or plant origin have been successfully expressed in *Escherichia coli* cells. Because *E. coli* can be easily programmed to produce foreign proteins and they grow quickly compared to most plants and animals, *E. coli* cells can be viewed as convenient "factories" for protein production; however, *E. coli* cells are limited in the types of post-translational modifications they carry out. It is usually necessary to express proteins in eukaryotic systems if some post-translational modification (e.g., glycosylation) is required for activity.

Recombinant protein expression technology is based on the observation that the amino acid sequence for a protein is determined by the sequence of the DNA in the gene that encodes that protein, as described in Chapters 4 and 5 (see Figures 4.23, page 112, and 5.18, page 152). In theory, any protein sequence can be expressed in a cell that contains a copy of the gene encoding that protein. *E. coli* can be made to take up small circular DNA molecules, called "expression vectors," that are on the order of 2–10 kilobases in length. An expression vector is a modified form of a natural extrachromosomal DNA, such as a plasmid, which is capable of autonomous replication in a bacterial cell. Recombinant DNA technology allows a researcher to cut open that plasmid at a desired site and splice in a gene encoding the protein of interest. As shown in Figure 5A.1, the gene encoding the wild-type or mutant protein to be expressed is within each vector, along with a gene encoding a so-called **selection marker**. The selection marker is usually a protein that confers resistance to an antibiotic that is included in the cell growth medium; thus, only those cells that have taken up the vector, and are thereby capable of expressing the desired protein, will survive in the growth medium. With many tens to hundreds of copies of the vector in each cell, production of the desired protein is maximized. Using this approach, even those proteins that occur in low intracellular concentrations in nature can be produced in sufficient yield to allow biochemical characterization and/or commercial production.

FIGURE 5A.1

Schematic representation of a generic protein expression vector. The circle represents the double-stranded DNA sequence for the entire vector. The box marked "ori" is the "origin of replication", which determines how many copies of the vector will be made in the cell. The arrows represent locations of protein genes in the vector DNA sequence. This vector will express two proteins: the recombinant protein of interest (red arrow, in this case, myoglobin) and a so-called selection marker (green arrow).

The Purification Process

Although recombinant technology can increase the concentration of a specific protein inside the cell, the problem of separating the desired protein from all the other cellular components remains. The sequence of steps taken to purify a given protein will be unique to that protein because proteins vary in chemical properties; however, many features of the purification process are common. For example, most purification steps begin with lysis, or rupture, of the cells. Cell lysis can be achieved by sonic disruption (“sonication”), mechanical rupture using a homogenizer, or by enzymatic digestion of the cell wall. This is followed by centrifugation to remove unbroken cells and insoluble cell parts (e.g., membranes) to yield an extract, called the “cell lysate,” which contains the soluble proteins and other biomolecules in a cell. The desired protein is then purified from the other proteins in the lysate by one or more of the following commonly used steps: (1) affinity chromatography, (2) ion exchange chromatography, or (3) size exclusion chromatography. As illustrated in Figure 5A.2, purification of the desired protein by chromatography is the result of differential interactions between the various proteins in the mixture loaded onto the chromatography column and the matrix within the column. In general, the more strongly some protein interacts with the matrix, the later it will elute from the column. Proteins are generally detected by UV absorbance at 280 nm, or 220 nm, as they elute from the column.

Affinity Chromatography

Affinity chromatography relies upon selective adsorption of a protein to a natural or synthetic ligand, typically a substrate or inhibitor, which is immobilized by covalent attachment to an inert solid support. The support that displays the bound ligand is called the “affinity matrix.” The interactions between the desired protein

FIGURE 5A.2

The principle of column chromatography.

and the affinity matrix are expected to be highly specific; thus, most of the contaminants in the mixture will not interact with the affinity matrix, whereas the desired protein is expected to bind tightly. As shown in Figure 5A.3, when a complex mixture flows through the affinity matrix the desired protein will bind tightly and remain bound until most contaminants are washed through the column. The bound protein can then be eluted using a variety of methods that preserve the structure and activity of the protein. In some exceptional cases the elution methods require extreme conditions to disrupt the bonds between the protein and the matrix, including denaturation of the protein.

Specific, complementary, noncovalent interactions are the basis for much interesting biological chemistry, including antibody binding, enzyme-substrate recognition, enzymatic catalysis, gene regulation, cell signaling, and muscle contraction, just to name a

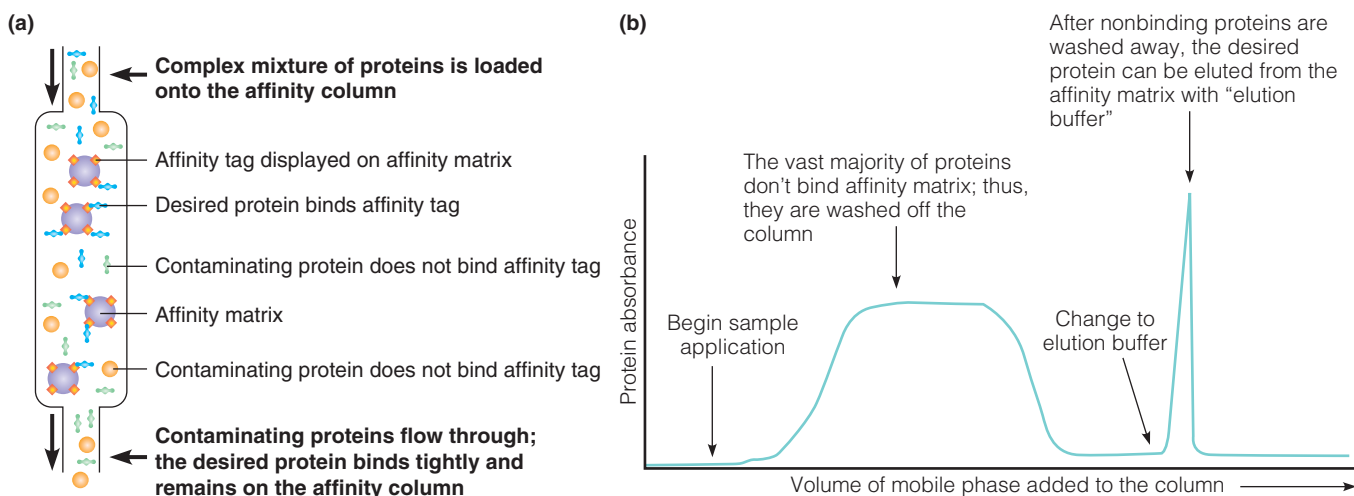

FIGURE 5A.3

(a) A simplified view of affinity chromatography. Specific binding of the desired protein (blue shapes) to the affinity matrix is shown. The contaminating proteins (green shapes, beige circles) wash through the column without binding, resulting in a significant purification of the desired protein. The bound protein can then be eluted by any one of several methods discussed in the text. (b) A schematic representation of an affinity chromatogram. The proteins that don’t bind the affinity matrix are washed off and elute early, giving rise to a large protein absorbance. After the contaminants are washed off, the desired protein is eluted, giving a smaller protein absorbance.

few examples. Early in the development of affinity purification methods, many investigators immobilized the natural binding targets (“ligands”) for a protein on a solid chromatography support to take advantage of such specific binding interactions. A related technique, called “immunoaffinity” chromatography, takes advantage of the high binding specificity of antibodies for their ligands. Antibodies raised against a given protein can be covalently attached to a solid support to make an affinity matrix that binds selectively and reversibly to that protein. Although immunoaffinity columns are efficient, the costs and time required to produce the antibodies are significant; thus, this method has largely given way to faster and less expensive techniques.

One of the most prevalent affinity methods, immobilized metal affinity chromatography (IMAC), takes advantage of the strong interactions between a Ni^{2+} , Zn^{2+} , or Co^{2+} ion and a string of six sequential histidine residues. The amino acid sequence $(\text{His})_6$ is called a “hexahistidine-tag,” (or “His-tag”) and it is quite rare in nature; thus, few naturally occurring proteins will bind to the IMAC matrix. Using recombinant DNA technology, the His-tag can be appended to the gene encoding the desired protein, as shown in Figure 5A.4. When this protein is expressed it will include the His-tag sequence and therefore it will bind tightly to the IMAC matrix. The bound protein can be eluted from the IMAC column with a buffer containing imidazole (an analog of the His side chain), or a low pH buffer (which protonates the His side chains and reduces metal ion binding), or with a buffer containing the metal chelator EDTA. EDTA effectively removes the metal ion from the column and thereby disrupts the bonding interactions between the protein and the affinity matrix.

The His-tag affinity method described above is used extensively to produce purified proteins for biochemical characterization. This example illustrates the power of recombinant technol-

FIGURE 5A.4

Insertion of a protein gene into one of several commercially available expression vectors results in addition of the affinity “His-tag” (i.e., a sequence of six His residues) to the protein sequence.

ogy not only for increasing protein concentration in cells, but also for improving the protein-purification process. One possible limitation to this method is that the resulting protein sequence carries some modification compared to the wild-type, in this case, an extra six histidine amino acids.

Affinity chromatography is so efficient that in many cases no further purification steps are required; however, further steps may be required to achieve separation of the desired protein from those contaminants that are closely related (e.g., proteins that differ by post-translational modifications).

Ion Exchange Chromatography (IEC)

Ion-exchange chromatography is used to separate molecules on the basis of their electrical charge. The strength of interaction between a protein molecule and an ion exchange matrix depends on (1) the charge density on the protein and (2) the ionic strength of the mobile phase, which is always a buffered solution. The charge density on the protein is modulated by altering the pH of the solution (see Chapter 2). Recall that the overall charge on a protein is zero when the pH of a protein solution is equal to the isoelectric point (pI) for the protein, and that as the pH of a protein solution increases, the charge on the protein molecules becomes increasingly negative. Conversely, as the pH of the solution decreases, the charge on the protein molecules becomes increasingly positive. This behavior is a consequence of the fact that the ionizable groups on the surface of a protein are either carboxylic acids or amines (see Problem 15 in Chapter 2).

There are two main types of ion exchange matrices: (1) *anion* exchangers such as diethylaminoethyl (DEAE) cellulose and quaternary ammonium (“Q”) resins, which carry a positive charge and therefore bind to negatively charged proteins, and (2) *cation* exchangers such as carboxymethyl (CM) cellulose and sulfonic acid (“S”) resins, which carry a negative charge and bind to positively charged proteins. DEAE and CM exchangers are considered “weak” ion exchangers because they carry functional groups that can lose their charges at $\text{pH} > \sim 10$ (DEAE) or $\text{pH} < \sim 4$ (CM). The “Q” and “S” resins are effectively always charged in aqueous buffers; thus, they are considered “strong” ion exchangers. It is critical to match the IEC resin and buffer to the pI of the protein of interest. For example, a protein will bind to a column of DEAE-cellulose when the pH of the mobile phase is above the pI for that protein, but will not bind the column if buffer $\text{pH} < \text{pI}$.

Elution of a protein bound to an IEC matrix can be achieved by changing the pH of the mobile phase such that the charge on the

protein is reduced, thereby weakening its binding to the support and/or increasing the ionic strength of the mobile phase (e.g., by addition of some salt to the elution buffer). Soluble ions compete for binding to the charged functional groups on the matrix. As the concentration of soluble ions increases, the ions will out-compete, and thereby displace, the protein from the matrix.

In summary, IEC allows for separation of proteins based on differences in charge density. The theoretical basis for this separation technique was presented in Chapter 2 and includes the following concepts: (1) relative strengths of electrostatic interactions, as described by Coulomb's law, (2) the isoelectric point or pI for a given protein, and (3) modulation of charge density on a protein as a function of pH, as described by the Henderson–Hasselbalch equation.

Size Exclusion Chromatography (SEC)

Size exclusion chromatography, which is also known as “**gel filtration chromatography**,” differs from the two methods above in that noncovalent interactions between the protein and support are negligible. As shown in Figure 5A.5, SEC separates proteins on the basis of apparent size, or “hydrodynamic radius.” The apparent size of a protein molecule is approximately correlated with the length of the protein amino acid sequence. This rule of thumb assumes, to a first approximation, that soluble folded proteins behave as spheres. The distinguishing feature of the SEC stationary phase is the porous structure of the matrix (Figure 5A.5b). These matrices are generally spherical beads with pores in the surface of the bead that are on a size scale close to that of protein molecules. Different SEC matrices have larger or smaller sized pores in the beads.

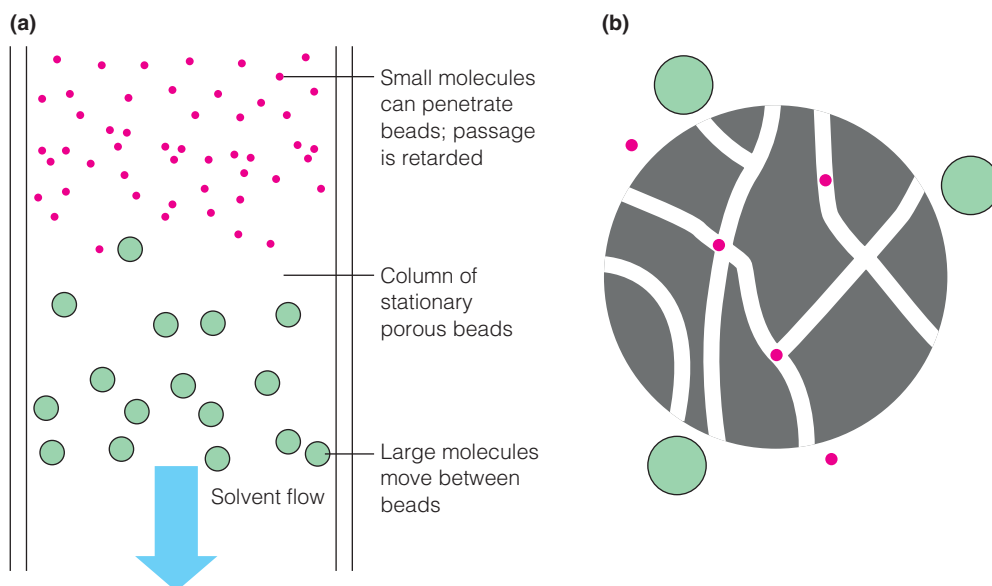

The principles at work in SEC are diffusion by Brownian motion and “excluded volume.” The total volume in an SEC column includes the volume of the porous beads and the volume of the mobile phase, which is in the space between the beads and also inside the beads. The volume of buffer solution required to elute a protein from the column depends on what fraction of the column

volume that protein can occupy: the more volume the protein can occupy, the more buffer will be needed to elute the protein, and the later it will elute from the column. The size of the pores in the beads determines which proteins can occupy volume inside the bead and which proteins cannot. Because smaller proteins are more likely to diffuse into the interior of a bead, they will occupy more of the total column volume than a large protein, which can only occupy the volume between—but not inside—the beads. In other words, larger proteins are “excluded” from the volume found inside the beads, and, consequently, larger proteins elute from an SEC column earlier than smaller proteins. Note that this order of elution by size is the reverse of the order of migration in an SDS-PAGE experiment (see Tools of Biochemistry 2A).

SEC works best as a purification technique when the differences in size between the desired protein and the contaminants are a factor of two or greater; thus, for SEC to be effective the complexity of the protein mixture must be relatively low. For this reason SEC is often the last step of a purification process. In addition, SEC is a convenient way to “desalt” or change the buffer composition of a protein solution because the salts that make up a buffer are low molecular weight and elute well after the desired protein. For example, it is convenient to run affinity columns and IEC columns in nonvolatile buffers such as phosphate-buffered saline (PBS); however, nonvolatile buffers are not compatible with lyophilization (freeze-drying) and many mass spectrometry techniques. Mass spectrometry is a powerful tool for protein analysis and is often used to confirm the identity of a purified protein (see Tools of Biochemistry 5B). To prepare a protein for lyophilization or mass spectrometry, an SEC column is equilibrated with a mobile phase that uses a volatile buffer, such as ammonium acetate. As a protein, which is loaded onto the SEC column in PBS, moves through the column it becomes separated from the phosphate buffer salts and is surrounded instead by the ammonium acetate buffer solution. In this way a “buffer exchange” from PBS to ammonium acetate occurs, and the protein is now ready for lyophilization and/or mass spectrometric analysis.

FIGURE 5A.5

The principle of size-exclusion chromatography. **(a)** As a mixture of proteins flows down the column, the smaller proteins are retarded; thus, the larger proteins elute first. **(b)** A close-up of an SEC bead (gray). Proteins larger (green) than the pores in the beads flow around the beads; but, the smaller proteins (red) can enter the pores in the beads, resulting in retarded mobility through the column.

Example: Purification of a Recombinant Myoglobin Mutant

Figure 5A.6 illustrates a scheme for the purification of a mutant form of the eukaryotic muscle protein myoglobin expressed in *E. coli* bacteria. This particular mutant includes a 16 amino acid insertion into the protein sequence. Following the period of protein production in bacterial cells, the cells are lysed so that the contents of the cytoplasm are released into a buffered solution. The soluble material can then be separated from the insoluble material (e.g., membranes, precipitated protein aggregates) by centrifugation. The resulting supernatant is a complex mixture of nucleic acids and proteins, as shown in Lane 1 of Figure 5A.7. An efficient purification scheme will significantly reduce the complexity of the mixture in the early steps of the process; thus, affinity chromatography is a good choice for the first chromatography step. In this case an IMAC purification step achieves significant purification of the mutant myoglobin, as shown in Lane 2 of Figure 5A.7. After IMAC, all the remaining contaminants appear to be of higher molecular weight than the mutant myoglobin; thus, SEC can be

FIGURE 5A.6

Flow chart for the purification of recombinant myoglobin.

FIGURE 5A.7

The myoglobin mutant is purified to greater than 95% homogeneity by a two-column procedure. A Coomassie-stained 15% SDS-PAGE gel is shown. Lane 1: *E. coli* lysate (after centrifugation). Lane 2: IMAC purified proteins; the prominent band is the desired myoglobin mutant. Lane 3: 2 μg of the mutant myoglobin after SEC. Lane 4: 10 μg of the mutant myoglobin after SEC. Lane 5: SEC-purified wild-type myoglobin. Lane 6: Protein molecular weight markers.

TOOLS OF BIOCHEMISTRY 5B

MASS, SEQUENCE, AND AMINO ACID ANALYSES OF PURIFIED PROTEINS

Mass Determination

Once a protein has been purified, how does a researcher convince her/himself that the correct target protein has been obtained in a purified form? The first indication comes typically from an SDS-PAGE gel (see Tools of Biochemistry 2A and Figure 5A.7), which shows (1) the purity of the protein and (2) an approximate molecular weight estimated by comparing the migration of the target protein in the gel to protein molecular weight standards. For example, the molecular weight of the mutant myoglobin shown in Figure 5A.7 is predicted to be 18,232 Da based on the amino acid sequence of the translated gene. Figure 5A.7 shows that the mutant protein migrates between 14 and 22 kDa as would be expected. The purified protein appears to have the correct mass by SDS-PAGE; however, this is not a high resolution technique. The actual mass could differ from the expected mass by several hundred daltons and still appear reasonably close to the expected mass by SDS-PAGE. Mass spectrometry (MS) provides the most accurate mass measurements of large biomolecules. For this reason it is desirable to obtain high resolution mass data via MS to confirm that the protein has no unexpected post-translational modifications (e.g., proteolytic cleavage and/or covalent modifications).

Protein MS has become an indispensable analytical tool since ionization techniques compatible with protein analysis were developed in the late 1980s. The application of MS to significant problems in biochemistry continues to grow as the technology improves. We will present more advanced MS techniques in later chapters; here we will focus on the application of MS to accurate protein mass determination and peptide sequencing.

Figure 5B.1 shows a simplified diagram of a mass spectrometer that contains a single mass analyzer, sufficient for the routine determination of accurate protein masses using **electrospray ionization** (ESI) or **matrix-assisted laser desorption/ionization** (MALDI) techniques. In ESI, a fine mist of protein solution is accelerated toward a mass analyzer. By the time the mist reaches the analyzer most of the solvent has evaporated, leaving protein molecules with a varying number of charges to be separated in the mass analyzer. The detector records the ratio of mass to charge (m/z , where m = mass and z = charge). The ESI-MS mass spectrum is a collection of peaks with different m/z ratios, where m is constant and z varies (Figure 5B.1 top). In the MALDI technique, the protein is imbedded in a large excess (~10,000-fold) of some matrix that absorbs UV light. When a laser pulse hits the matrix, it absorbs the energy of the laser light

FIGURE 5B.1

Electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) mass spectrometry techniques. See the text for a description of these techniques.

and is vaporized. The vaporized matrix carries intact protein molecules into the gas phase and toward the mass analyzer. The MALDI-MS spectrum shows m/z for predominantly the parent ion (Figure 5B.1 bottom).

Sequence Determination

An accurate protein mass is usually sufficient to confirm the identity of a known protein; however, if an unknown protein is the target of some purification scheme, the mass alone is not typically sufficient to identify the protein. In this case, sequence information is also desirable. If the function of the protein is also unknown, the sequence will allow potential identification of the function by similarity searching.

There are several ways in which the amino acid sequence can be determined. As mentioned on page 154, determination of the gene sequence is one of the easiest methods. Indeed, as the entire genomes of many organisms have been determined, we have amino acid sequence information for hundreds of thousands of proteins, many of them of still unknown function. Protein sequences translated from cloned genes do not provide us with information concerning modification of amino acids or the existence of intramolecular cross-links such as disulfide bonds. To find these, we must sequence the protein itself. Here we present two methods for obtaining peptide sequences: tandem MS, which was developed in the mid-1980s and is now the method of choice for most labs, and Edman sequencing, which was developed 20 years earlier by Pehr Edman and is still in use today.

We will present the procedure for Edman sequencing first because there is much useful protein chemistry involved, and the logic for reconstructing the overall protein sequence is the same for both the Edman and tandem MS methods.

The Edman method is based on the stepwise removal of amino acids from the N-terminus of a peptide by a series of chemical reactions called the “Edman degradation” (Figure 5B.2). The compound phenylisothiocyanate (PITC) is reacted in alkali with the N-terminal amino group to yield a phenylthiocarbonyl (PTC) derivative of the peptide (Figure 5B.2, step 1). This derivative is then treated with a strong anhydrous acid, which results in cleavage of the peptide bond between residues 1 and 2 (step 2). The derivative of the N-terminal residue then rearranges to yield a phenylthiohydantoin (PTH) derivative of the amino acid (step 3). Two important things have been accomplished: (1) the N-terminal residue has been marked with an identifiable label, and (2) the rest of the polypeptide has not been destroyed; it has simply been shortened by one residue. The whole sequence of reactions can now be repeated and the second residue determined. By continued repetition, a long polypeptide can be “read,” starting from the N-terminal end. This procedure can be performed automatically with an instrument known as a sequenator, which is able to carry out the entire set of reactions shown in Figure 5B.2 over and over again. The sequenator will accumulate in a separate tube the PTH derivative of each amino acid residue in the polypeptide, starting with the N-terminal residue and proceeding for as many cycles as the operator desires or precision allows. The PTH

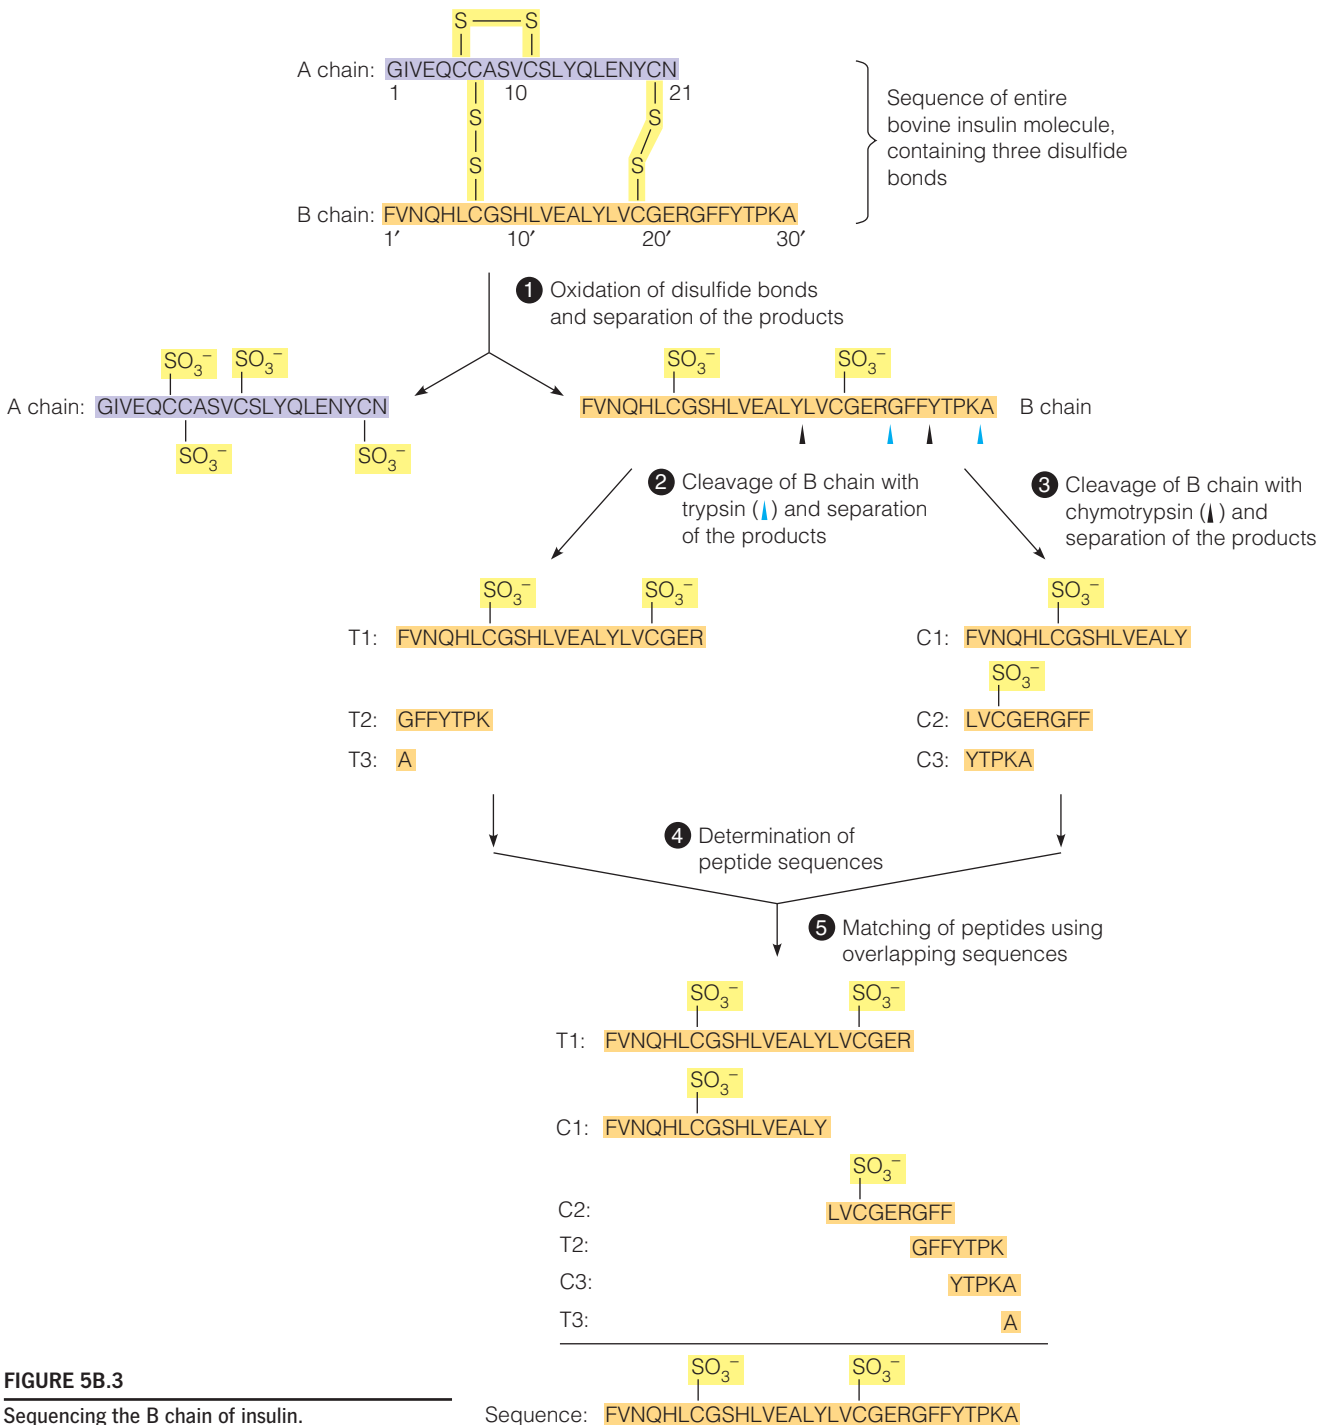

FIGURE 5B.2

The Edman degradation.

derivatives are then identified by high-performance liquid chromatography (HPLC) and/or MS.

In practice, 30–40 residues can be read reliably by Edman sequencing; thus, it is necessary to fragment longer proteins and then sequence the smaller peptides obtained from the fragmentation reaction. Fragmentation is achieved using proteases such as those listed in Table 5.4 and/or cyanogen bromide. Once this first set of fragments has been sequenced, a second fragmentation is carried out using a protease with a different specificity such that a second set of peptides is obtained that overlaps the set obtained in the first fragmentation. We will use the sequencing of bovine insulin as an example to illustrate this process. This choice is appropriate because it was the first protein ever sequenced, by Frederick Sanger and his coworkers in the early 1950s (work for which Sanger won his *first* Nobel Prize). The example is also more complicated than most because we must deal with two covalently

**FIGURE 5B.3**

Sequencing the B chain of insulin.

connected chains and locate disulfide bonds. The steps of the procedure are outlined in Figure 5B.3.

The researcher intending to sequence a protein by Edman degradation must first make sure that the material is pure. The protein can be separated from other proteins by some combination of the methods described in Tools of Biochemistry 5A and checked for purity by means of electrophoresis and/or isoelectric focusing. Next, it must be determined whether the material contains more than one polypeptide chain because, in some cases disulfide bridges

covalently bond chains together. SDS-PAGE in the presence and absence of reducing agents can answer this question (see Tools of Biochemistry 6B). In the insulin example, there are two chains, A and B, as shown in Figure 5B.3. These chains must be separated and sequenced individually because the Edman degradation would release two sets of PTH derivatives simultaneously if the peptides were not separated. To break disulfide bonds and thus separate the chains, several reactions are available. Descriptions of two common procedures follow.

Performic acid oxidation is the technique used in Figure 5B.3, step 1. The strong oxidizing agent performic acid will *irreversibly* react with cystine to yield cysteic acid residues:

Reduction with β -mercaptoethanol is a milder, and *reversible*, technique.

Reduction leaves free sulfhydryl groups, often positioned so that reoxidation to re-form the disulfide bond is likely. Therefore, the sulfhydryls are usually blocked to prevent this. A common blocking reagent is iodoacetate:

If either of these methods is carried out with insulin, the intact protein is cleaved into A and B chains. These chains can then be separated by chromatographic methods.

Before Edman sequencing of the individual chains is started, their amino acid composition is usually determined (see below). This determination may point to unusual compositions and thus warn the operator of potential problems. Furthermore, composition data will serve as a check on the sequencing results because the sequence determined must be consistent with the amino acid composition.

In bovine insulin, the A and B chains are so short that modern instrumentation could sequence either in one sequenator run; however, to demonstrate the methods needed for larger proteins, we assume that the investigator must cleave the insulin chains into shorter polypeptides (this was indeed the case in Sanger's pioneering sequencing studies on insulin). Suppose the insulin B chain is to be sequenced. A first step would be to cleave separate aliquots of the chain with two or more of the specific cleavage reagents described in Table 5.4. Trypsin and chymotrypsin, for instance, would yield the sets of peptides shown in steps 2 and 3, respectively, of Figure 5B.3. The individual peptides would then be isolated from each of the two mixtures, using, for example, ion-exchange chromatography, and their sequences could be determined (Figure 5B.3, step 4).

Suppose each of the peptides shown in Figure 5B.3 has been sequenced (step 4). Although the tryptic peptides alone cover the whole sequence, they are not sufficient to allow us to write down the sequence of the insulin B chain because we do not know the order in which they appear in the intact chain. To overcome this problem we also have the chymotryptic peptides, which overlap the tryptic peptides; therefore, all ambiguity is removed. Only one arrangement of the whole chain is consistent with the sequences of these two sets of peptides, as can be seen by matching overlapping sequences (step 5).

Finally, a complete characterization of the covalent structure of a protein requires that the positions of any disulfide bonds be located. In preparation for sequencing, these bonds would have been destroyed, but the positions of all cysteines, some of which *might* have been involved in bonding, would have been determined. How can we determine which cysteines are linked via disulfide bonds in the native protein?

To determine the arrangement of disulfide bonds, the experimenter again starts with the native protein—insulin in the example shown in Figure 5B.4. Reaction with radioactively labeled iodoacetate marks any free cysteine residues, and fragmentation of the protein into the same peptides used in sequencing allows the positions of these nonbonded cysteines to be identified (step 1). Then samples of the intact protein are cut with various cleavage reagents but now without first cleaving disulfide bonds (steps 2 and 3). Some peptides, which are connected by these bonds, are attached to one another. These can then be isolated and their disulfide bonds cleaved to map the location of each disulfide-bonded cysteine in the protein.

Mass spectrometry can also be used to obtain peptide-sequence information. To do this the mass spectrometer must have a collision cell and two mass analyzers rather than the single mass analyzer shown in Figure 5B.1. Figure 5B.5 shows a schematic diagram of a tandem mass spectrometer (MS-MS) capable of peptide sequencing, where the two mass analyzers are labeled “quadrupole analyzer” and “time-of-flight analyzer.” The role of each mass analyzer will be described below.

As in Edman sequencing, MS-MS sequencing works best on smaller peptide fragments. The fragments can be generated

FIGURE 5B.4

Locating the disulfide bonds in insulin.

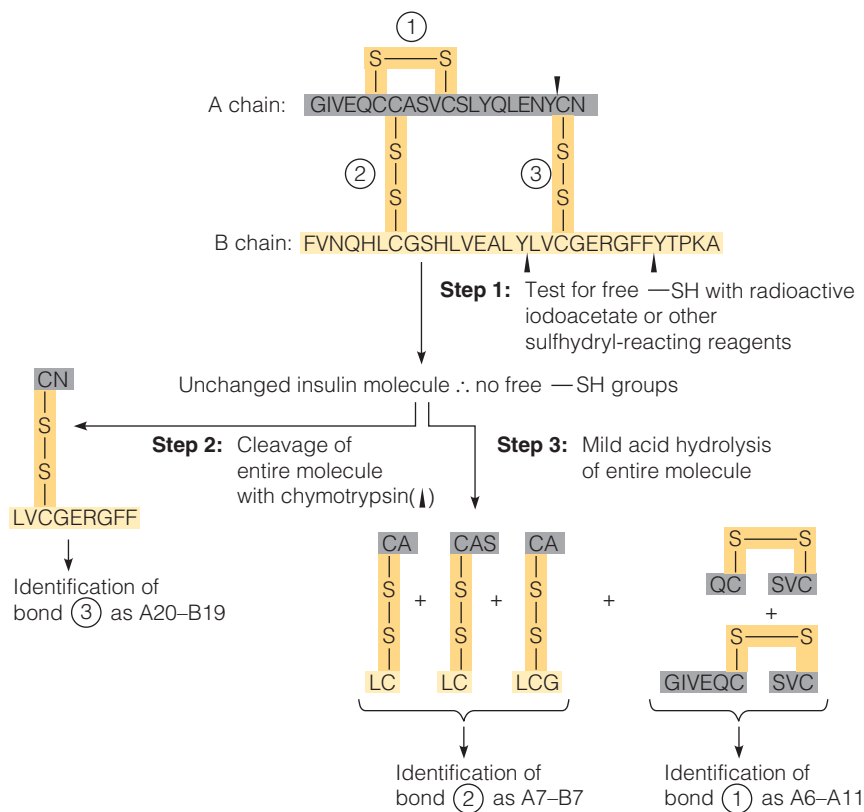

FIGURE 5B.5

Peptide sequencing by MS-MS.

using proteases, or in the spectrometer itself. Let us consider the case in which the fragments are generated using a protease and then introduced into the MS-MS instrument using electrospray. Electrospray is advantageous for sequencing because the fragments tend to have multiple charges distributed along their lengths. Recall that the mass detector records m/z ; thus, without a charge the fragment is not detectable. As depicted in Figure 5B.5 the mixture of peptide fragments is introduced by electrospray into the first mass analyzer (the quadrupole analyzer). The quadrupole analyzer can be tuned to select a specific fragment (i.e., a specific m/z range) for introduction into the collision cell. In the course of the analysis each fragment in turn will be directed from the quadrupole analyzer into the collision cell.

In the collision cell the selected fragment is fragmented further by collisions with argon atoms. To a large extent the fragmentations in the collision cell result in cleavage of the peptide backbone as shown in Figure 5B.6, where cleavage of the first peptide bond gives two subfragments: the N-terminal subfragment that includes the residue R_1 , and the C-terminal subfragment that includes residues R_2 – R_4 . By convention, the N-terminal subfragments are called “ b ions” and the C-terminal subfragments are called “ y ions.”

FIGURE 5B.6

Principal ions generated by low energy collision-induced dissociation. The wavy red lines indicate sites of peptide bond cleavage in the collision cell (see Figure 5B.5).

In the collision cell two series of subfragments are generated simultaneously—a series of b ions and the corresponding set of y ions. Within each series the masses of the ions differ from one another by the mass of a single amino acid residue (i.e., in Figure 5B.6 the masses of b_2 and b_3 differ by the mass of residue R_3). The m/z ratio for each ion is determined in the time-of-flight analyzer and recorded to generate a complex spectrum with peaks for each

ion. Because the masses for amino acid residues are known (see Table 5.1), the amino acids present in each fragment can be reliably identified. Modern MS-MS instruments include software that can rapidly identify fragmentation patterns consistent with a specific amino acid sequence. This process is repeated until every fragment that enters the quadrupole analyzer is sequenced (a matter of a few minutes), thereby generating a set of peptide sequences for the protein. To find the order of the peptides a second MS-MS analysis is performed on a series of different fragments generated by a different protease (or CNBr, etc.).

Both MS-MS and Edman sequencing are used to determine peptide sequences and each has its set of strengths and weaknesses. Edman sequencing requires a few micrograms (10^{-6} g) of purified protein. It gives nearly complete sequence coverage; however, if the N-terminus of the intact protein is modified, the Edman degradation is blocked. This problem is somewhat ameliorated by fragmentation methods that generate unmodified N-termini for each fragment. MS-MS methods are very sensitive; thus, only picograms (10^{-12} g) of protein are needed. Also, separation of chains or fragments is not required because the MS-MS method achieves fragment separation in the mass spectrometer; thus, the MS-MS method is rapid. MS-MS does not usually give complete sequence coverage because some amino acid sequences are difficult to ionize; however, 70–80% sequence coverage is typical (recall that only ions can be detected in the MS instrument—if a peptide carries no charge it will not be detected).

We have described how the entire amino acid sequence, or primary structure, of a protein can be determined. Such analyses have been carried out on several thousand different proteins in the years since Sanger first determined the sequence of insulin. Today it is rare that an entire protein sequence would be determined using these methods because the sequencing of genes is much more rapid (and frequently precedes the isolation of the protein of interest); however, MS-MS is often used to determine a portion of the sequence of an unknown protein. With a sequence of only 6–10 amino acids one can often identify a protein by searching databases of protein sequences. This use of protein sequence information is the basis for the field of **proteomics**, which we discuss briefly in Tools of Biochemistry 5D.

Amino Acid Analysis

Finally, we turn our attention to the determination of the amino acid composition (or “amino acid analysis”) of a purified protein. Given recent developments in gene sequencing and mass spectrometry of proteins, the determination of the amino acid composition of a protein is no longer a common analytical procedure; however, it remains a standard method for the accurate quantitation of protein in an analytical sample.

Amino acid analysis (AAA) involves three basic steps:

1. *Hydrolysis* of the protein to its constituent amino acids.
2. *Separation* of the amino acids in the mixture.
3. *Quantitation* of the individual amino acids.

A small sample of the protein is first purified, perhaps by some combination of the methods described in Tools of Biochemistry 5A. The purified protein is dissolved in 6 M HCl, and the solution

is sealed in an evacuated ampoule. It is then heated at 105–110 °C for about 24 hours. Under these conditions, the metastable peptide bonds between the residues are completely hydrolyzed.

The hydrolyzed sample is then separated into the constituent amino acids on a cation-exchange column. The kinds of resin typically used are sulfonated polystyrenes:

Such a resin separates amino acids in two ways. First, because it is negatively charged, it tends to pass acidic amino acids first and retain basic ones. The pH of the eluting buffer is increased during elution to facilitate this separation. Second, the hydrophobic nature of the polystyrene itself tends to hold up the more hydrophobic amino acids such as leucine and phenylalanine. An example of such an analysis is shown in Figure 5B.7. Note the order of appearance of the amino acids, proceeding from the more acidic to the more basic. Modern amino acid analyzers are completely automated and carry out both the chromatographic separation of the amino acids and their quantitation.

There are many methods for detection and quantitation of the amino acids eluting from the column; but, fluorescence is commonly used due to its sensitivity. For example, the amino acids may be reacted with *o*-phthalaldehyde to yield a fluorescent complex:

Such detection techniques easily give sensitivity to the picomole (pmol, or 10^{-12} mol) range. Microelectrophoresis systems and fluorescence detection have extended this sensitivity to the *attomole* (amol, or 10^{-18} mol) range. This amount corresponds to only a few thousand molecules. Indeed, amino acid analysis techniques have proceeded to the point that the amount of protein contained in one spot in two-dimensional gel electrophoresis (see Figure 1.11, page 19) can be analyzed easily.

Of course, these procedures are not as simple and trouble free as the foregoing discussion might imply. Some amino acids give problems in reaction with the compounds used for detection; proline in particular because it is a secondary amino acid, often reacts

FIGURE 5B.7

Analysis of a protein hydrolysate on a single-column amino acid analyzer. The chromatogram shows the order of elution of hydrolyzed amino acids on a polystyrene column. Free amino acids are detected by absorbance at 220 nm.

slowly or not at all. Furthermore, some amino acids tend to be partially destroyed during the severe hydrolysis. Tryptophan is troublesome in this respect and must be determined by hydrolysis with base and detection by ultraviolet absorbance (see Figure 5.6). Serine, threonine, and tyrosine also tend to be degraded during long hydrolysis. To a considerable extent, these difficulties can be circumvented either by carrying out protective reactions first or by measuring the apparent content of the amino acid at different hydrolysis times and extrapolating to zero hydrolysis time. Asparagine and glutamine are invariably hydrolyzed to aspartic and glutamic acids, so that the total content of these acids observed includes the amides. This reaction, as well as the other degradation reactions mentioned above, can be avoided by using an enzymatic hydrolysis, with a mixture of proteolytic enzymes, in place of the acid hydrolysis. However, this method also has its drawbacks because it is sometimes difficult to achieve complete hydrolysis and the enzymes themselves must be removed before analysis. Despite

such complications, amino acid analysis, using automated analyzers, has become a routine operation in protein characterization.

TOOLS OF BIOCHEMISTRY 5C

HOW TO SYNTHESIZE A POLYPEPTIDE

Chemical synthesis of peptides of defined sequence is of great importance in medicine and molecular biology. Some synthetic hormones can be made with non-natural amino acids that make them more stable *in vivo*, and therefore better therapeutics. Synthetic peptides can be used to elicit antibodies against portions of specific proteins; such antibodies are useful in studying the interaction of proteins with other molecules.

To synthesize a peptide of defined sequence, several criteria must be met:

1. It should be possible to add amino acids one at a time, preferably in an automated reactor.
2. Because of peptide-bond metastability, the amino acids must be activated in some way such that peptide-bond formation is both favorable and efficient (>98% per cycle).
3. To avoid side reactions, all reactive groups (in this case good nucleophiles) must be protected (i.e., blocked from reacting) other than the carboxyl and amino groups that are meant to form the desired peptide bond.
4. The protecting groups used for side chain groups must be stable for the entire synthesis; but, the protecting group for the α -amino group must be removed selectively for each cycle of peptide bond formation.

There are two common synthetic schemes used to make peptides. The solid-phase peptide synthesis (SPPS) chemistry developed by Bruce Merrifield (and recognized by the Nobel Prize) uses the *t*-butyloxycarbonyl (Boc) group to protect the α -amino group. A second popular scheme uses the 9-fluorenylmethoxycarbonyl (Fmoc) group to protect the α -amino group. Both schemes are amenable to automated solid-phase synthesis and are still widely used. In some cases, one scheme will give a better yield for a given sequence than another, so most labs that synthesize peptides have machines for both Boc and Fmoc methods.

A simplified scheme based on the Merrifield solid-phase chemistry is shown in Figure 5C.1. The advantage of the solid-phase method is that the growing peptide chain remains attached to a solid matrix (called the “SPPS resin”) until the last step of the synthesis; thus, during each step, excess reactants and contaminants can be washed away. To begin the synthesis, the C-terminal amino acid of the desired peptide sequence is covalently attached to a bead of SPPS resin, with its α -amino group exposed. A series of three steps is then carried out to complete a cycle of peptide-bond formation. These steps include: (1) deprotonation of the α -amino group to make it a better nucleophile; (2) activation of the carboxylic acid group of the next amino acid in the desired sequence, followed by covalent addition of the activated amino acid to the growing peptide chain; and (3) deprotection of the new N-terminal α -amino group. The new peptide bond is formed in step 2. Steps 1–3 are repeated until the desired sequence has been synthesized. Finally, the N-terminal α -amino group and all the protected side chains are deprotected, and the peptide is cleaved from the resin.

A brief description of each step in a peptide-bond synthesis cycle follows. The amino acid to be added to the growing peptide bound to the resin has a free carboxylic acid group, a Boc-protected α -amino group and, if necessary, a protected side chain group. The carboxylic acid is converted in situ to a more reactive carboxylic ester by reaction with a carbodiimide reagent (step 2). The coupling reaction yields a new peptide bond and a peptide, longer by one amino acid, that has a Boc-protected α -amino group. The Boc protecting group is removed selectively using trifluoroacetic acid (step 3), and the next activated residue is then added (repeats steps 1–3). Note that the last residue added is the

N-terminal residue. All reactions are carried out automatically, with the growing chains attached to the resin. In the final step, HF is added to remove any side-chain protecting groups and simultaneously cleave the peptide from the resin.

Using these methods, peptides of 50 residues in length can be routinely synthesized in good yield. Expert laboratories can make chains of roughly 150 amino acids. Merrifield, for example, synthesized an active enzyme (ribonuclease) of 124 residues, and Stephen Kent and coworkers have made small proteins of 140–160 amino acids. There are also methods for condensing a synthetic peptide with a sequence derived from an intact biosynthetic protein. In this way non-natural amino acids can be incorporated into larger proteins. A description of these methods, called “native chemical ligation” and “expressed protein ligation,” is beyond the scope of this discussion. The interested reader can find more details in the citations given at the end of this section.

FIGURE 5C.1

Reactions in solid-phase peptide synthesis. Individual steps are described in the text.

Spatially Organized Combinatorial Peptide Arrays

Frequently, it is necessary to test simultaneously a large number of different peptides for some kind of biological activity. One might want to know, for example, which member(s) of a large family of similar oligopeptides is(are) the antigen(s) reacting with a specific antibody. Formerly, this was an extremely laborious process, involving perhaps hundreds of separate syntheses.

Using techniques borrowed from photolithography and inkjet printing, it is now possible to prepare microscopic, two-dimensional arrays containing many combinations of peptides grown on a solid surface. The photolithographic technique is illustrated in Figure 5C.2. The amino acids to be used are each blocked on the N-terminus with a photolabile protecting group and carry activated carboxyl groups. First, one class of amino acids (in this case Leu) is reacted with a surface coated with amino groups. The whole surface is then illuminated, which removes the protective groups. A second activated amino acid can then be added to each chain. In this example, after four rounds, the peptide GGFL has been grown on each site. To generate sequence diversity, a rectangular mask is placed over the surface, so that only half the squares in a checkerboard pattern are illuminated. This allows coupling Tyr residues in the illuminated portion. The other portion is then illuminated and coupled with Pro. Thus, in this example, a simple checkerboard pattern is obtained, with PGGFL and YGGFL alternating. Figure 5C.3 shows the reaction of a fluorescent antibody reactive to YGGFL on such a surface. The example shown is simple: much more complex patterns can easily be generated by use of overlapping masks, allowing thousands of different peptides to be generated, in a prescribed pattern, on one surface.

Using a different synthetic strategy, protein microarrays with greater than 10,000 different proteins immobilized on a single glass slide have been developed for the rapid detection of protein–protein interactions and the determination of intracellular protein expression levels. These “protein chips” are created by

FIGURE 5C.3

Three-dimensional representation of the checkerboard array of YGGFL and PGGFL. Fluorescence intensity data were converted into spike heights that are proportional to the number of counts detected from 2.5-mm square pixels. The spikes are also color coded.

depositing a few nanoliters of a protein solution at a precise location on the slide. Each spot on such a slide can be a different protein. The proteins in these microarrays are capable of interacting with other proteins and smaller molecules such as drug candidates and enzyme substrates; thus, this technology allows for direct measurement of protein–protein and protein–ligand interactions.

TOOLS OF BIOCHEMISTRY 5D

A BRIEF INTRODUCTION TO PROTEOMICS

The complement of proteins present in a given cell make up the so-called **proteome** of that cell. As mentioned in Chapter 1, **proteomics** is the field of study that attempts to understand the complex relationships between proteins and cell function through global analysis of the proteome rather than investigating the properties of purified protein in isolation. Proteomics includes, among other things, efforts to understand how protein expression and/or post-translational modification levels change in cells, and the consequences of such changes. For example, how does the proteome of a normal pancreatic cell differ from the proteome of a cancerous pancreatic cell? How might a researcher begin to address this question since every cell has the potential to express many thousands of different proteins at any given time? The protein chips described in Tools of Biochemistry 5C offer one method for obtaining such information; but, there are other methods which are more commonly used.

A proteomics experiment can, for example, rapidly identify differences in the levels of cellular expression, or post-translational modification (e.g., phosphorylation) between the proteomes of normal and diseased cells. The key is to correctly identify the affected proteins. The best technique for achieving this is mass spectrometry (see Tools of Biochemistry 5B). Once the affected proteins have been identified, the putative role of the protein in the disease can be researched.

A typical proteomics experiment includes the following steps: (1) separation and isolation of proteins, or protein fragments, from cells or an organism; (2) identification by MS-MS sequencing (Figures 5B.5 and 5B.6) of a particular protein within the complex mixture; and (3) database searching to identify the target protein, and its putative function. In practice, 2-D electrophoresis can be used to separate peptides (see Figure 1.11, page 19) as well as to identify potential protein targets for proteomic analysis. However, the extraction of peptides from 2-D gels is laborious, and direct analysis of complex peptide mixtures

using tandem mass spectrometry is preferred for large-scale proteomic analyses.

A basic proteomics experiment is illustrated in Figure 5D.1. A complex mixture of proteins is digested—in this case with the protease trypsin. This mixture gives rise to a complex mixture of peptides that can be separated, for example, by HPLC (see Tools of Biochemistry 5B). Here, the HPLC effluent is injected directly into a mass spectrometer. The complexity of this peptide mixture is represented by the many peaks in the total ion current (TIC) mass spectrum [Panel (a)]. If a very complex sample (e.g., a cellular extract) is the starting material for this experiment, it is likely that each of the peaks in the TIC mass spectrum will contain several peptides; however, these peptides can be separated within the mass spectrometer based on differences in mass-to-charge ratio between the peptides. The separated peptides are shown in a much less complex “parent ion” mass spectrum [Panel (b)]. Each parent ion can be analyzed by MS-MS to yield amino acid sequence (see Figures 5B.5 and 5B.6). Panel (c) of Figure 5D.1 shows the MS-MS spectrum of one of the parent ions from the mass spectrum in Panel (b). The experimentally determined amino acid sequence is then used as input to search a protein sequence database. In the example here, the sequence of the peptide is a fragment of bovine serum albumin.

MS-MS is compatible with the analysis of complex peptide mixtures because only one peptide fragment from the mixture is selected for sequencing by the mass analyzer. Thus, it is still possible to make a positive identification of a protein from complex mixtures of many proteins. In theory, all the proteins in the mixture can be identified, assuming the sequences are listed in some database.

Mass spectrometry is particularly suited to the detection of post-translational modifications. A common modification is protein phosphorylation, which confers changes in both mass and charge on the phosphorylated protein. The presence of some enzymatic activity can also be detected by mass analysis by

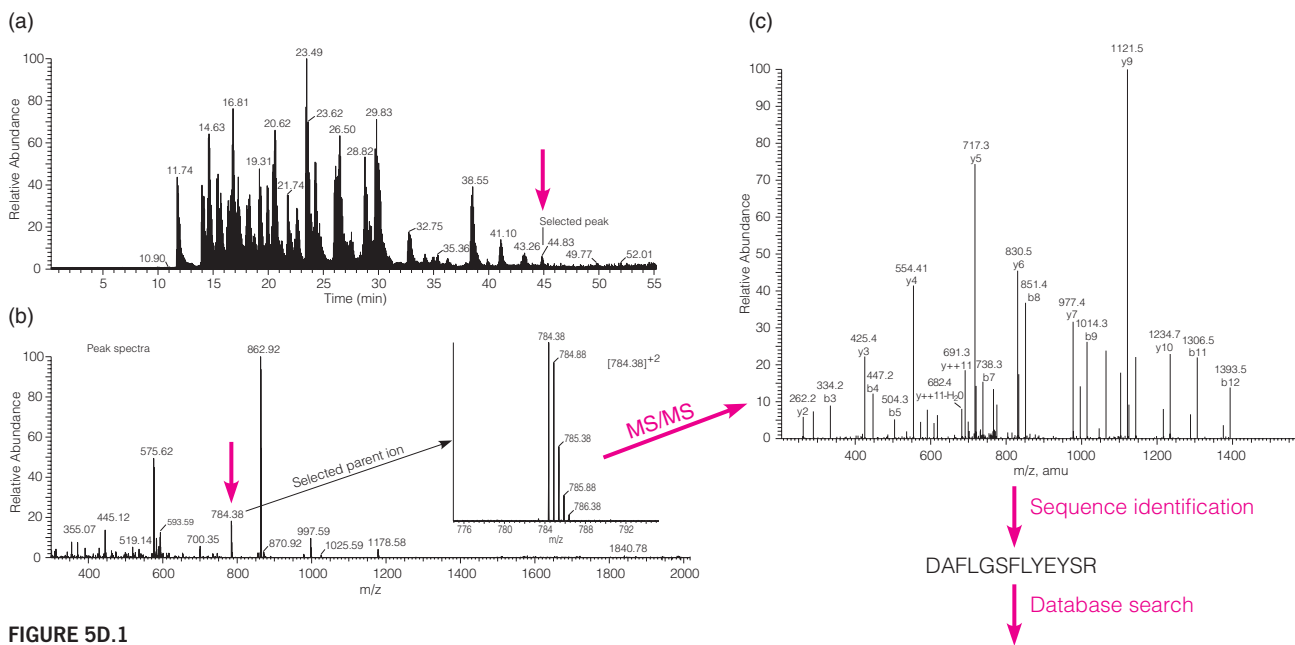

FIGURE 5D.1

Identification of a protein of interest using proteomics methods.

adding a chemical labeling reagent that is either covalently attached to some substrate by the target enzyme, or is converted to a lower molecular weight product. These types of proteomics experiments have been used to detect metabolic disorders in newborns (see citations).

There are many challenges to proteomic analysis. For example, the proteins present at low levels in a cell lysate can be difficult to detect. In some eukaryotic cells, the concentration differences between the most- and least-abundant proteins can be 10^6 -fold, and many proteins that are interesting targets (e.g., for drug development) are low-abundance proteins. For these reasons a fractionation step prior to mass analysis may be included to either remove highly-expressed proteins and/or increase the concentrations of low-level proteins.

CHAPTER 6

The Three-Dimensional Structure of Proteins

In Chapter 5 we introduced the concept of protein primary structure. We emphasized that this first level of organization, the amino acid sequence, is dictated by the DNA sequence of the gene for the particular protein. However, nearly all proteins exhibit higher levels of structural organization as well. It is the three-dimensional structure of each protein that specifies its function in a particular biological process.

Figure 5.1 (page 137) shows a well-defined spatial location for every heavy atom within the protein sperm whale myoglobin. Figure 6.1 depicts another representation of the three-dimensional conformation of the myoglobin molecule, and illustrates that there exist two distinguishable levels of three-dimensional folding of the polypeptide chain. First, the chain appears to be locally coiled into regions of helical structure. Such local *regular* folding is called the **secondary structure** of the molecule. The helically coiled regions themselves are, in turn, folded into a specific compact structure for the entire polypeptide chain. We call this further level of folding the **tertiary structure** of the molecule. Later in this chapter we shall find that some proteins consist of several folded polypeptide chains, arranged in a regular manner. This arrangement we designate as the **quaternary** level of organization.

This chapter is devoted to an examination of the levels of protein structure, how folded proteins are stabilized, the mechanisms by which protein folding is thought to occur, and emerging computational methods for predicting tertiary structure from primary sequence.

Secondary Structure: Regular Ways to Fold the Polypeptide Chain

Theoretical Descriptions of Regular Polypeptide Structures

Our understanding of the protein secondary structure had its origins in the remarkable work of Linus Pauling, one of the greatest chemists of the twentieth century. As early as the 1930s, he had begun X-ray diffraction studies of amino

Protein molecules have four levels of structural organization: primary (sequence), secondary (local folding), tertiary (overall folding), and quaternary (subunit association).

FIGURE 6.1

Three-dimensional folding of the protein myoglobin. This “cartoon” rendering was generated from the X-ray crystal structure determined by H. C. Watson and J. C. Kendrew (PDB ID: 1MBN), and it shows the polypeptide main chain as helices connected by thick lines. Side chains are shown as thin lines. Individual helical regions are color-coded, with the peptide N-terminus shown in blue and the C-terminus shown in red. This protein binds a heme group (shown in space-filling display). The orientation of the protein in this figure is the same as that shown in Figure 5.1.

acids and small peptides, with the aim of eventually analyzing protein structure. In the early 1950s, Pauling and his collaborators used these data together with remarkable scientific intuition to begin a systematic analysis of the possible regular conformations of the polypeptide chain. They postulated several principles that any such structure must obey:

1. The bond lengths and bond angles should be distorted as little as possible from those found through X-ray diffraction studies of amino acids and peptides, as shown in Figure 5.14b (page 148).
2. No two atoms should approach one another more closely than is allowed by their van der Waals radii.
3. The amide group must remain planar and in the *trans* configuration, as shown in Figure 5.14b. (This feature had been recognized in the earlier X-ray diffraction studies of small peptides.) Consequently, rotation is possible only about the two bonds adjacent to the α -carbon in each amino acid residue, as shown in Figure 6.2.
4. Some kind of noncovalent bonding is necessary to stabilize a regular folding. The most obvious possibility is hydrogen bonding between amide protons and carbonyl oxygens:

Such a concept was familiar to Pauling, who had had much to do with the development of the idea of H-bonds. In summary, the preferred conformations must be those that allow a maximum amount of hydrogen bonding, yet satisfy criteria 1–3.

Of the several possible secondary structures for polypeptides, the most frequently observed are the α helix and the β sheet.

α Helices and β Sheets

Working mainly with molecular models, Pauling and his associates were able to arrive at a small number of regular conformations that satisfied all of these criteria. Some were helical structures formed by a single polypeptide chain, and some were sheet-like structures formed by adjacent chains. The two structures they proposed as most likely—the right-handed α helix, and the β sheet—are shown in Figure 6.3a and b. These two structures are, in fact, the most commonly observed secondary structures in proteins. Figure 6.3c shows the so-called 3_{10} helix, which is observed in some proteins but is not as common as the α helix. All of the protein secondary structures shown in Figure 6.3 satisfy the criteria listed earlier. In particular, in each structure the peptide group is planar, and every amide proton and every carbonyl oxygen (except a few near the ends of helices) is involved in hydrogen bonding. The arrangement of the main chain H-bonds in the α helix along the helical axis orients the amide N—H and C=O such that the dipole moments for each of these polar bonds align and gives rise to a **helical dipole moment** (also called a “macro-dipole”). In effect, the

FIGURE 6.2

Rotation around the bonds in a polypeptide backbone. Two adjacent amide planes are shown in light green. Rotation is allowed only about the $\text{N}_{\text{amide}} - \text{C}_{\alpha}$ and $\text{C}_{\alpha} - \text{C}_{\text{carbonyl}}$ bonds. The angles of rotation about these bonds are defined as ϕ (phi) and ψ (psi), respectively, with directions defined as positive rotation as shown by the arrows; positive rotation is clockwise as seen from the α -carbon. The extended conformation of the chain shown here corresponds to $\phi = +180^\circ$, $\psi = +180^\circ$.

FIGURE 6.3

The right-handed α helix, β sheet, and 3_{10} helix.

The right-handed α helix and β sheet are the two most frequently observed regular secondary structures of polypeptides. **(a)** In the α helix the hydrogen bonds (red dotted lines) are within a single polypeptide chain and are almost parallel to the helix axis. The alignment of amide bonds in the helix gives rise to a helical macrodipole moment shown by the red arrow (see Figure 2.4, page 29). The N-terminal end of the helix has partial (+) charge character and the C-terminal end has partial (–) charge character. **(b)** In the β sheet, the hydrogen bonds are between adjacent chains, of which only two are shown here. In this structure, the hydrogen bonds are nearly perpendicular to the chains. **(c)** The 3_{10} helix is found in proteins, but is less common than the α helix.

Illustration, Irving Geis. Image from Irving Geis Collection/Howard Hughes Medical Institute. Rights owned by HHMI. Not to be reproduced without permission.

N-terminus of the helix has partial (+) charge character and the C-terminus has partial (–) charge character as shown by the red arrow in Figure 6.3.

Amphiphilic Helices and Sheets

In an α helix the side chains are pointing away from the center of the helix (Figure 6.4). In a β sheet, a network of main chain H-bonds connects the β strands. If we consider the H-bonded main chains to be a “sheet,” the side chains are located on opposite faces of this sheet, as shown in the right-hand panels of Figure 6.4. Side chains of similar polarity are frequently clustered together to form extended hydrophilic or hydrophobic surfaces, or “faces,” on one side of a helix or sheet. Secondary structures that display a predominantly hydrophobic face opposite a predominantly hydrophilic face are said to be “**amphiphilic**” (or “**amphipathic**”). Many α helices and β sheets have this characteristic because it allows two or more secondary structures to associate via contacts between the hydrophobic surfaces, while projecting the hydrophilic surfaces toward the aqueous solvent. An amphiphilic α helix will have side chains of similar polarity every 3–4 residues, whereas a β strand in an amphiphilic β sheet will have alternating polar and nonpolar side chains. These distinct patterns of side chain polarity are the basis for many secondary structure prediction algorithms (discussed below).

An amphiphilic α helix will have side chains of similar polarity every 3–4 residues, whereas a β strand in an amphiphilic β sheet will have alternating polar and nonpolar side chains.

FIGURE 6.4

The positions of side chains in the α helix and β sheet. An idealized right-handed α helix and a two-stranded β sheet are shown with the main chain atoms colored gray/red/blue and side chain atoms colored green, red, blue, yellow. In the α helix the side chains radiate away from the center of the helix (lower left panel). In the β sheet the side chains are located on opposite faces of the sheet defined by the H-bonded main chain amides. This is shown in the upper right panel, looking at the main chain strands from the side (one strand is hidden behind the other), and the lower right panel, looking down the main chains of both strands.

Describing the Structures: Helices and Sheets

In Tools of Biochemistry 4A, we listed the distances that define a molecular helix: the crystallographic repeat (c), the pitch (p), and the rise (h). We also pointed out that helices may be either right-handed or left-handed and may contain either an integral number of residues per turn or a nonintegral number. We call the number of residues per turn n . Some idealized helices with integral values of n are illustrated schematically in Figure 6.5. Note that as the number of residues per turn decreases, the structure changes progressively from a broad helix to a flat ribbon ($n = 2$). Not all of these proposed helical structures are found in polypeptides. For example, the single-chain $n = 2$ structure shown in Figure 6.5 has not yet been observed in proteins.

One of Pauling's major insights was to recognize that polypeptide helices are not required to have an integral number of residues per turn. For example, the α helix repeats after exactly 18 residues, which amounts to 5 turns. It has, therefore, 3.6 residues per turn. Because the pitch of a helix is given by $p = nh$, we have for the α helix, with a rise of 0.15 nm/residue, $p = (3.6 \text{ res/turn}) \times (0.15 \text{ nm/res}) = 0.54 \text{ nm/turn}$. Parameters for the secondary structures shown in Figures 6.3 and 6.4 are listed in Table 6.1.

FIGURE 6.5

Idealized helices. These hypothetical structures show the effect of varying the number (n) of polypeptide residues per turn of a helix. The white balls represent α -carbon atoms. In each case the pitch (p) is indicated, and for $n = 2$ the rise (h) is also shown. The $n = 4$ and $n = 3$ helices are right-handed, the $n = -3$ helix is left-handed, and $n = 2$ (a flat ribbon) has no handedness. The right-handed α helix (not shown here), with $n = 3.6$, is intermediate between the $n = 3$ and $n = 4$ structures.

When you examine the model for the α helix (Figure 6.3a), you will note that a given carbonyl oxygen, on residue i , is hydrogen-bonded to the amido proton that is four residues removed in the direction of the C-terminus (i.e., on residue $i + 4$). Thus, if we include the hydrogen bond, a loop of 13 atoms is formed. Figure 6.6 shows this schematically for the α and 3_{10} helices. Each helix type has a different number of atoms in such a hydrogen-bonded loop. We shall call this number N . Rather than using the parameters n , h , and p , an alternative way to describe a polypeptide helix is to combine n and N in the shorthand n_N . The 3_{10} helix fits this description; it has exactly 3.0 residues per turn and a 10-member hydrogen-bonded loop. The α helix could also be called a 3.6_{13} helix.

Because hydrogen bonds tend to be linear, the atoms $N-H \cdots O$ in polypeptide helices should lie on a straight line. Figure 6.3 shows that this requirement is approximately satisfied for the 3_{10} and α helices. On the other hand, it is very difficult to make helices with only two residues per turn *and* linear hydrogen bonds between residues in the same chain; thus, the only $n = 2$ structure that is found in proteins is *not* the flat ribbon shown in Figure 6.5 but the β sheet structure shown in Figure 6.3b.

A β sheet is composed of two or more **β strands**. Each residue in the strand is rotated by 180° with respect to the preceding one, which makes each β strand an $n = 2$ “helix.” If the chains are also folded in the pleated fashion shown in Figure 6.3b, hydrogen bonds can occur *between* adjacent β strands. Forming inter-chain bonds allows correct bond angles with minimal strain when $n = 2$. There are two ways in which β strands can be oriented in a β sheet. The β sheet shown in Figure 6.3b shows two β strands arranged such that the N-terminus to C-terminus orientations of the two strands are in opposite directions. Such an arrangement of strands is called “antiparallel,” whereas the arrangement with both strands oriented in the same direction is called “parallel” (see Figure 6.7). The hydrogen bonds between antiparallel strands are linear, whereas those between parallel strands are not.

In addition to the helices and sheets described above, there is one more regularly repeating conformation that is commonly observed in protein structures—the so-called **polyproline II helix**. This particular conformation was not predicted on theoretical grounds because it does not satisfy Pauling’s requirement for H-bonding. Nevertheless, it is a common motif in protein structures. Unlike the α and 3_{10} helices, this structure does not have stabilizing H-bonds between mainchain groups, and it is left-handed. Roughly a third of the amino acid residues found in this conformation are prolines, leading to the designation “polyproline II helix”; however, glycine is often found in this conformation, as are, albeit to a much lesser extent, several other amino acids. Because this conformation is not restricted to proline residues, we will refer to this secondary structure motif by the more general term “polypeptide II helix” (Figure 6.8).

TABLE 6.1 Parameters of some polypeptide secondary structures

Structure Type	Residues/Turn	Rise (h) per residue	Pitch (p)
β Strand (antiparallel)	2.0	0.34 nm	0.68 nm
β Strand (parallel)	2.0	0.32 nm	0.64 nm
α helix	3.6	0.15 nm	0.54 nm
3_{10} helix	3.0	0.20 nm	0.60 nm
Polypeptide II helix (“polyproline II helix”)	3.0	0.47 nm	0.94 nm

FIGURE 6.6

Hydrogen bonding patterns for the α and 3_{10} helices. The structures are represented in a diagrammatic way to simplify counting the atoms in each H-bonded loop. For example, there are 13 atoms in the H-bonded loop corresponding to the α (3.6_{13}) helix. The significance of the π helix is discussed later in this chapter.

(b) Parallel

FIGURE 6.7

β Sheets. (a) An antiparallel arrangement of β strands. (b) A parallel arrangement of β strands. Only main chain atoms are shown (side chains omitted for clarity); H-bonds between strands are represented by dashed lines.

FIGURE 6.8

The polypeptide II helix. A polyproline sequence is shown; however, polyglycine also adopts this conformation. The left-handed helical twist is indicated by the curved gray arrow.

To close this section we describe a conformation called the π helix. The π helix is also known as an “ α bulge” or “ α aneurism” or “ π bulge.” It is widespread, as it is found in $\sim 15\%$ of protein sequences in the Protein Data Bank, although it is infrequent, as it typically occurs only once in any given sequence. Most ($\sim 85\%$) π helix conformations appear to be the result of a mutation event that results in the insertion of an amino acid into an α helix (Figure 6.9). This disrupts the normal H-bonding in the α helix, and two or more residues form H-bonds with the $i + 5$ residue, rather than the $i + 4$ residue (see Figure 6.6), creating a bulge in the helical structure. The short stretch of π helix shown in Figure 6.9 is typical of π helices found in most proteins—most are only one turn in length, and extended π helices of greater than two turns are not observed in proteins. For this reason, we will not consider the π helix as a regular repeating conformation. Nevertheless, the π helix is noteworthy because the inserted amino acid frequently confers some new functional properties on the resulting protein; thus, it is a potential marker for tracing the evolution of protein function.

We have described the common secondary structural motifs found in proteins and some of the reasons we should expect to see these structures based on consideration of (1) the planarity of the amide bond and (2) steric restrictions to rotation

FIGURE 6.9

The π helix conformation. On the left, a main-chain rendering of the C-terminal α helix from *Staphylococcus aureus* nuclease is shown (PDB ID: 1EYD). The amino acid sequence of this helix is shown below in one-letter code. The site of Gly insertion is underlined. On the right, the analogous helix from a Gly insertion mutant is shown (PDB ID: 1STY). The inserted Gly is highlighted in green and the adjacent four residues that adopt the π helix conformation are highlighted in magenta. Note that the inserted Gly carbonyl does not form an intrahelical H-bond.

around the angles ϕ and ψ . We have also described two ways to specify the regular repeating unit of the motif—by n_N , or by listing the parameters in Table 6.1. Yet another way to describe the regular repeat of a secondary structural motif is to specify the values of the angles ϕ and ψ . As illustrated in Figure 6.10a, some combinations of ϕ and ψ (e.g., $\phi = 0^\circ$ and $\psi = 0^\circ$) are not allowed due to steric crowding. These steric constraints on peptide conformation can be appreciated by considering space-filling models for helices and sheets. For example, as shown in Figure 6.10b, the main chain atoms in the α helix are closely packed, with R groups projecting away from the helical axis. The combinations of ϕ and ψ angles that are most favorable (or “allowed”)—because they relieve steric crowding—are shown in a systematic description of polypeptide backbone conformation called a **Ramachandran plot**.

Ramachandran Plots

As is shown in Figure 6.2, each residue in a polypeptide chain has two backbone bonds about which rotation is permitted. The angles of rotation about these bonds, defined as ϕ and ψ , describe the backbone conformation of any particular residue in any protein. To make the definition meaningful, we must specify what we mean by a positive direction of rotation and the zero-angle conformation of each. The conventions chosen for directions of positive rotation about ϕ and ψ are given by the arrows in Figure 6.2—that is, clockwise when looking in either direction from the α -carbon. The conformation shown in that figure corresponds to $\phi = +180^\circ$ and $\psi = +180^\circ$, the fully extended form of the polypeptide chain.

With these conventions, the backbone conformation of any particular residue in a protein can be described by a point on a map (Figure 6.11) with coordinates ϕ and ψ . Such maps are called Ramachandran plots, after the biochemist G. N. Ramachandran, who first made extensive use of them. For any regular

FIGURE 6.10

Steric interactions determine peptide conformation. (a) A sterically nonallowed conformation. The conformation $\phi = 0^\circ$, $\psi = 0^\circ$ is not allowed in any polypeptide chain because of the steric crowding between the carbonyl oxygen and amido proton. (b) The atoms in a helix are closely packed. Here, a segment of an α helix in sperm whale myoglobin (the longer green helix in Figure 6.1; PDB ID: 1MBN) is shown as a space-filling model.

FIGURE 6.11

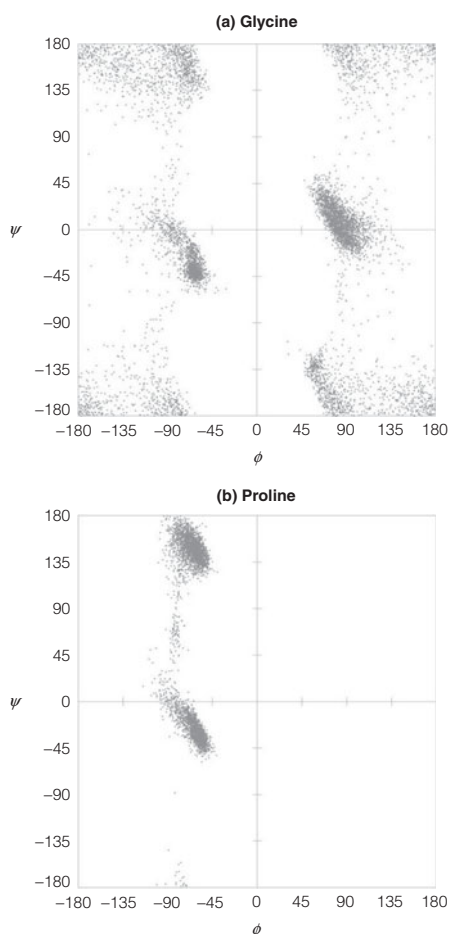

A Ramachandran plot for poly-L-alanine. A map of this type can be used to describe the backbone conformation of any polypeptide residue as well as the secondary structures of proteins. The coordinates are the values of the bond angles ϕ and ψ , defined as in Figure 6.2. The white areas correspond to sterically allowed conformations for poly-L-alanine (i.e., a peptide consisting of only L-Ala residues). The colored lines running across the graph correspond to various values of n (residues per turn); the line bisecting the graph corresponds to $n = 2$. The helix is right-handed when n is positive (pink and red regions), left-handed when n is negative (blue regions). The circles with the following symbols correspond to the secondary structures discussed in the text: α_R , right-handed α helix; 3, 3_{10} helix; β , β sheet; P_{II} , polypeptide II helix; α_L , left-handed α helix.

TABLE 6.2 Ranges of allowed ϕ and ψ angles for some polypeptide secondary structures

Structure Type	Φ	Ψ
β strand	-150° to -100°	$+120^\circ$ to $+160^\circ$
α helix	-70° to -60°	-50° to -40°
3_{10} helix	-70° to -60°	-30° to -10°
Polypeptide II helix ("polyproline II helix")	-80° to -60°	$+130^\circ$ to $+160^\circ$

Data from *Protein Science* 18:1321–1325 (2009), S. A. Hollingsworth, D. S. Berkholtz, and P. A. Karplus, On the occurrence of linear groups in proteins.

Many secondary structural motifs, defined by regular repeats of ϕ and ψ angles, can be imagined; but, only a few are sterically allowed. The Ramachandran plot illustrates which combinations of ϕ and ψ angles are allowed.

**FIGURE 6.12**

Ramachandran plots for glycine and proline. The data shown are for glycine and proline residues found in high-resolution X-ray crystal structures of proteins. The favorable combinations of the bond angles ϕ and ψ are shown by the darker regions. Glycine has the greatest number of allowed ϕ , ψ angle combinations, whereas proline has the fewest.

Plots courtesy of S. A. Hollingsworth and P. A. Karplus, Oregon State University.

repeating secondary structure (e.g., α helix, β sheet, etc.), all the residues that are part of the structure are in nearly equivalent conformations and have nearly equivalent ϕ and ψ angles; thus, the points on a Ramachandran plot that correspond to those residues will cluster within a narrow range of sterically allowed ϕ and ψ angles for a given secondary structure. Table 6.2 lists the ranges of ϕ and ψ angles that correspond to the various helices and β sheets described above.

One of the most useful features of Ramachandran plots is that they allow us to describe very simply which structures are sterically possible and which are not. For many of the conceivable combinations of ϕ and ψ values, some atoms in the chain would approach closer than their van der Waals radii would allow (an example is shown in Figure 6.10). Such conformations are unfavorable because they are sterically crowded. Ramachandran and other researchers have examined the entire map surface, using models and computers to determine which conformations are actually allowed. The allowed ϕ , ψ combinations for poly-L-alanine correspond to the white regions in Figure 6.11. Clearly, only a small fraction of the conceivable conformations is actually favorable. All of the regular secondary structures we have discussed fall within or very close to these regions.

Although Figure 6.11 shows the left-handed α helix lying on the edge of an allowed region, it is, in fact, not nearly as favored as the right-handed form. This difference is a consequence of the fact that all amino acids in proteins are of the L-form. With L-amino acids, steric interference between the side chains and the backbone of the helix is less with a right-handed helix than with a left-handed helix. This principle can be understood from a careful inspection of Figure 6.3a. Note that each R group is approximately *trans* to the adjacent carbonyl oxygen. If the amino acid were D instead of L, the orientation would be *cis*, with more likelihood of steric crowding. Recall from Chapter 5 that chemists have synthesized proteins with all D-amino acids. These proteins have, as expected, left-handed α helices. The importance of such side-chain effects depends on the bulkiness of the side chain. The map shown in Figure 6.11 was drawn with the assumption that all residues are L-alanine (that is, all have CH_3 side chains). If bulkier side chains were considered, the “allowed” region would shrink. Conversely, glycine, with its $-\text{H}$ side chain, allows more conformations, as shown in Figure 6.12a. Proline has fewer combinations of allowed ϕ and ψ angles due to restricted rotation around ϕ (Figure 6.12b).

The foregoing analysis of protein structure is based on a relatively simple consideration of probable steric interactions. How does it compare with observations of actual protein structures? In this case, the correspondence between theory and observation is remarkably good. Figure 6.13 shows a plot of ϕ , ψ pairs for 30,692 residues found in 209 different polypeptide chains for which high resolution (≤ 0.12 nm) X-ray crystallography data exist. As is evident in this figure, the majority of the observed ϕ , ψ pairs (gray dots in Figure 6.13) cluster in the regions of the Ramachandran plot that are predicted to give the most favorable combinations of ϕ and ψ (white spaces in Figure 6.11). Those residues that are classified by H-bonding patterns and geometry to be helix or sheet are identified by color in Figure 6.13 and illustrate the range of ϕ and ψ values that correspond to each of the secondary structure types discussed above (see Table 6.2).

Most of the points on this Ramachandran plot fall close to the right-hand α helix or the β sheet positions; but, they do not correspond exactly to these points, testifying to the existence of distortions of these structures in folded proteins, and to the existence of regions of structure different from either β sheet or α helix. Although most of the points fall in “allowed” regions, a few lie in “nonallowed” regions. These are mainly glycines, for which a much wider range of ϕ and ψ angles is allowed because the side chain is so small (Figure 6.12a).

Historically, the ideal and observed values of ϕ and ψ angles for parallel and antiparallel β sheets have been listed as distinct. That distinction is no longer apparent in the high-resolution structural data shown in Figure 6.13. Because the observed ϕ and ψ angles for these two β structure types overlap significantly (due to distortion of ideal angles in actual protein structures), we have chosen to list in Table 6.2 a single range of values that describes both parallel and antiparallel β sheet conformations.

Our discussion so far provides a background for understanding the basics of protein structure. It is now time to consider some specific cases. We begin with the observation that two major classes of proteins exist. These are called *fibrous* and *globular* proteins and are distinguished by major structural differences. Let us first consider the fibrous proteins.

Fibrous Proteins: Structural Materials of Cells and Tissues

Fibrous proteins are distinguished from globular proteins by their filamentous, or elongated, form. Most of them play structural roles in animal cells and tissues—they hold things together. Fibrous proteins include the major proteins of skin and connective tissue and of animal fibers like hair and silk. The amino acid sequence of each of these proteins favors a particular kind of secondary structure, which confers on each protein a particular set of appropriate mechanical properties. Table 6.3 lists

FIGURE 6.13

Observed values of ϕ and ψ from protein structural data. ϕ , ψ pairs for 30,692 residues observed in high resolution (≤ 0.12 nm) crystal structures of proteins are shown (gray dots). Different colors highlight those residues defined to be right-handed α helix (cyan), right-handed 3_{10} helix (purple), β strand (blue), and left-handed polypeptide II helix (orange). The median values of ϕ and ψ for each secondary structure type are (ϕ , ψ): α helix (-63 , -43), 3_{10} helix (-62 , -22), β strand (-116 , $+129$), and polypeptide II helix (-65 , $+145$). See also Table 6.2.

Fibrous proteins are elongated molecules with well-defined secondary structures. They usually play structural roles in the cell.

α -Keratin is built on a coiled-coil α -helical structure.

the amino acid composition of four examples of fibrous proteins: α -keratin, fibroin, collagen, and elastin. Compared to the typical distributions of the 20 amino acids in globular proteins (see “All proteins” column in Table 6.3) each of these fibrous proteins is significantly enriched in 3–4 particular amino acids, which stabilize the extended secondary structures typical of the fibrous proteins.

The Keratins

Two important classes of proteins that have similar amino acid sequences and biological function are called α - and β -keratins. The **α -keratins** are the major proteins of hair and fingernails and comprise a major fraction of animal skin. The α -keratins are members of a broad group of **intermediate filament proteins**, which play important structural roles in the nuclei, cytoplasm, and surfaces of many cell types. All of the intermediate filament proteins are predominantly α -helical in structure; in fact, it was the characteristic X-ray diffraction pattern of α -keratin that Pauling and his colleagues sought to explain by their α helix model.

The structure of a typical α -keratin, that of hair, is depicted in Figure 6.14. The individual molecules contain long sequences—over 300 residues in length—that are wholly α -helical. Pairs of these right-handed helices twist about one another in a left-handed **coiled-coil** structure. This pairing of α helices appears to be a consequence of a peculiarity of the amino acid sequence of α -keratin. Every third or fourth amino acid has a nonpolar, hydrophobic side chain. Because the α helix has 3.6 residues/turn, this means there is a strip of contiguous hydrophobic surface area along one face of each helical chain (the hydrophobic surface area makes a shallow spiral around the helix because 4.0 does not exactly equal 3.6). As we noted in Chapter 2, hydrophobic surfaces tend to associate in aqueous

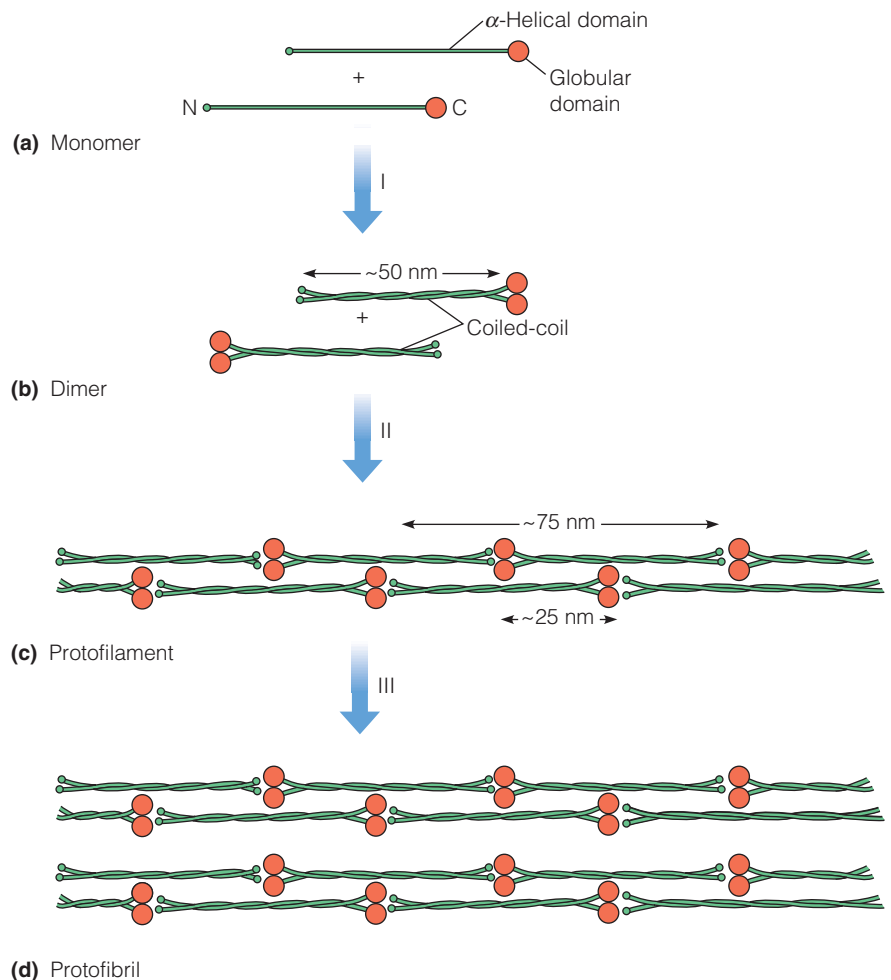

FIGURE 6.14

Proposed structure for keratin-type intermediate filaments. Two monomers **(a)** pair via a parallel coiled-coil to form the 50-nm-long dimer **(b)**. These then associate to form first a 4-strand protofilament **(c)** and then an 8-strand protofibril **(d)**. The regular spacing of 25 nm along the fibers is accounted for by the overlap.

medium; thus, two α -keratin helices are noncovalently bonded by hydrophobic interactions between the entwined helices.

In intermediate filaments, pairs of coiled coils themselves tend to associate into a four-chain protofilament (Figure 6.14c), and two of these in turn pack together to form a protofibril (Figure 6.14d). The details of these higher levels of association are still unclear. Such twisted cables can be very stretchy and flexible, but in different tissues α -keratin is hardened, to differing degrees, by the introduction of disulfide cross-links within the several levels of fiber structure (note that α -keratin has an unusually high content of cysteine—see Table 6.3). Fingernails have many cross-links in their α -keratin, whereas hair has relatively few. The process of introducing a “permanent wave” into human hair involves reduction of these disulfide bonds, rearrangement of the fibers, and reoxidation to “set” the tight curls thus introduced.

The β -keratins, as their name implies, contain much more β -sheet structure. Indeed, they represented the second major structural class described by Pauling and his coworkers. The β -keratins are found mostly in birds and reptiles, in structures like feathers and scales.

Fibroin

The β -sheet structure is most elegantly utilized in the fibers spun by silkworms and spiders. Silkworm fibroin (Figure 6.15) contains long regions of antiparallel β sheet, with the polypeptide chains running parallel to the fiber axis. The β -sheet regions comprise almost exclusively multiple repetitions of the sequence

In silkworm fibroin almost every other residue is Gly, which is usually followed by Ala or Ser residues. In other species, the residues following the Gly residues are different, leading to differences in physical properties. This alternating pattern of residues allows the sheets to fit together and pack on top of one another in the manner shown in Figure 6.15. This arrangement of sheets results in a fiber that is strong and relatively inextensible because the covalently bonded chains are stretched to nearly their maximum possible length. Yet the fibers are very flexible because bonding between the sheets involves only the weak van der Waals interactions between the side chains, which provide little resistance to bending.

Not all of the fibroin protein is in β sheets. As the amino acid composition in Table 6.3 shows, fibroin contains small amounts of other, bulky amino acids like valine and tyrosine, which would not fit into the structure shown. These are carried in compact folded regions that periodically interrupt the β -sheet segments,

Fibroin is a β sheet protein. Almost half of its residues are glycine.

FIGURE 6.15

The structure of silk fibroin. (a) A three-dimensional view of the stacked β sheets of fibroin, with the side chains shown in color. The region shown contains only alanine and glycine residues. (b) Interdigitation of alanine or serine side chains and glycine side chains in fibroin. The plane of the section is perpendicular to the folded sheets.

and they probably account for the amount of stretchiness that silk fibers have. In fact, different species of silkworms produce fibroins with different extents of such non- β -sheet structure and corresponding differences in elasticity. The overall fibroin structure is a beautiful example of a protein molecule that has evolved to perform a particular function—to provide a tough, yet flexible, fiber for the silkworm's cocoon or the spider's web.

Collagen

Collagen fibers are built from triple helices of polypeptides rich in glycine and proline.

Because it performs such a wide variety of functions, **collagen** is the most abundant single protein in most vertebrates. In large animals, it may make up a third of the total protein mass. Collagen fibers form the *matrix* material in bone, on which the mineral constituents precipitate; these fibers constitute the major portion of tendons; and a network of collagen fibers is an important constituent of skin. Basically, collagen holds most animals together.

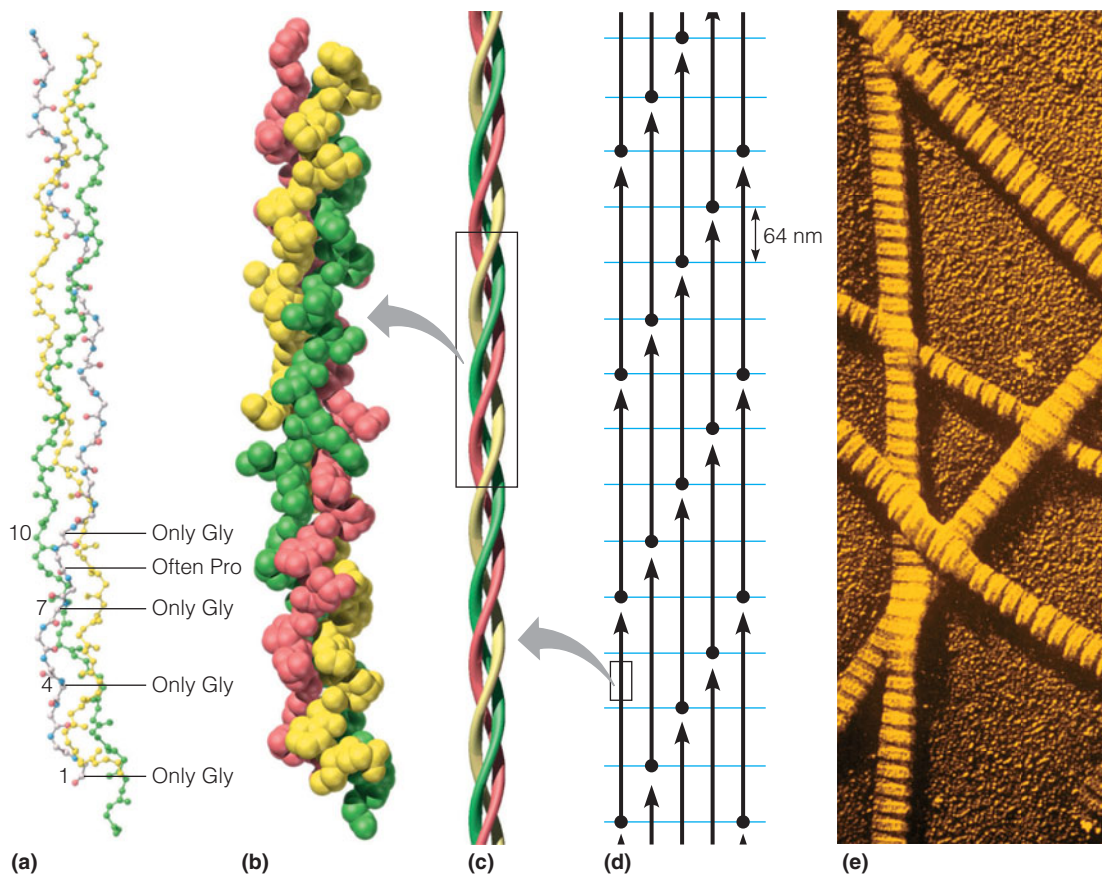

FIGURE 6.16

The structure of collagen fibers. The protein collagen is made up of tropocollagen molecules packed together to form fibers. The tropocollagen molecule is a triple helix. **(a)** and **(b)** Stick and space-filling views of the tropocollagen triple helix. **(c)** A lower magnification model emphasizes the interwoven triple-helical secondary structure. **(d)** Tropocollagen triple helices align side by side in a staggered fashion to form the collagen fiber. This regular arrangement leads to periodic pattern of bands separated by 64 nm (blue lines) **(e)** An electron micrograph of collagen shows the crisscrossing of fibers, with the 64 nm periodic pattern clearly visible in each.

(e) J. Gross, Biozentrum/Science Photo Library.

Collagen Structure

The basic unit of the collagen fiber is the **tropocollagen** molecule, a *triple helix* of three polypeptide chains, each about 1000 residues in length. This triple helical structure, shown in Figure 6.16a and b, is unique to collagen. The individual chains are *left-handed* helices, with about 3.3 residues/turn. Three of these chains wrap around one another in a right-handed sense, with hydrogen bonds extending between the chains. Examination of the model reveals that every third residue, which must lie near the center of the triple helix, can be *only* glycine (see Figure 6.16a, and Table 6.3). Any side chain other than —H would be too bulky. Formation of the individual helices of the collagen type is also favored by the presence of proline or hydroxyproline in the tropocollagen molecule. A repetitive motif in the sequence is of the form Gly–X–Y, where X is often proline and Y is

proline or hydroxyproline (see Table 6.3). However, other residues are often tolerated in these positions. Like silk fibroin, collagen is a good example of how a particular kind of repetitive sequence dictates a particular structure. In order to properly serve the multiple functions it does, collagen exists in a larger number of genetic variants in higher organisms.

Collagen is also unusual in its widespread modification of proline to hydroxyproline. Most of the hydrogen bonds between chains in the triple helix are from amide protons to carbonyl oxygens, but the —OH groups of hydroxyproline also seem to participate in stabilizing the structure. Hydroxylation of lysine residues in collagen also occurs, but is much less frequent. It plays a different role, serving to form attachment sites for polysaccharides.

The enzymes that catalyze the hydroxylations of proline and lysine residues in collagen require **vitamin C**, L-ascorbic acid (see Figure 21.33, page 906). A symptom of extreme vitamin C deficiency, called **scurvy**, is the weakening of collagen fibers caused by the failure to hydroxylate these side chains, which results in reduced H-bonding between chains. Consequences are as might be expected: Lesions develop in skin and gums, and blood vessels weaken. The condition quickly improves with administration of vitamin C.

The individual tropocollagen molecules pack together in a collagen fiber in a specific way (Figure 6.16c). Each molecule is about 300 nm long and overlaps its neighbor by about 64 nm, producing the characteristic banded appearance of the fibers shown in Figure 6.16e. This structure contributes remarkable strength: Collagen fibers in tendons have a strength comparable to that of hard-drawn copper wire.

Part of the toughness of collagen is due to the cross-linking of tropocollagen molecules to one another via a reaction involving lysine side chains. Some of the lysine side chains are oxidized to aldehyde derivatives, which can then react with either a lysine residue, or with one another via an aldol condensation and dehydration, to produce a cross-link:

This process continues through life, and the accumulating cross-links make the collagen steadily less elastic and more brittle. As a result, bones and tendons in older individuals are more easily snapped, and the skin loses much of its elasticity. Many of the signs we associate with aging are consequences of this simple cross-linking process.

Collagen Synthesis

As you will have judged by now, collagen is a protein that undergoes extensive modification. Indeed, it can be considered an almost complete example of the post-translational modification pathways we discussed at the end of Chapter 5. The tropocollagen triple helix that ends up cross-linked into an extracellular collagen fiber is very different from the molecule that is first synthesized on a ribosome. The steps in this transformation are shown in Figure 6.17, which begins with translation (step 1). The newly translated polypeptide is hydroxylated (step 2), and then sugars are attached to some of the newly hydroxylated lysine side chains (step 3) to yield **procollagen** (step 4). Procollagen contains almost 1500 residues, of which about 500 are in N-terminal and C-terminal regions that do not have the typical collagen fiber sequence described earlier. Three molecules of procollagen wrap their central regions into a triple helix, while the N- and C-terminal regions fold into globular protein structures. The procollagen triplexes are then exported into the extracellular space (step 5), at which point the N- and C-terminal regions

(2S,4R)-4-hydroxyproline

(2S,5R)-5-hydroxylysine

Scurvy is caused by failure to hydroxylate prolines and lysines in collagen.

Collagen undergoes extensive post-translational modification.

FIGURE 6.17

Biosynthesis and assembly of collagen. The process can be visualized in several steps. Steps 1–4 occur in the endoplasmic reticulum and cytosol of collagen-synthesizing cells; steps 6 and 7 occur in the extracellular region. Gal = galactose, Glc = glucose.

are cleaved off by specific proteases, leaving only the tropocollagen triple helix, about 1000 residues long (step 6). These molecules then assemble into the staggered arrays shown in Figure 6.16d. Finally, cross-linking cements the molecules together into a tough collagen fiber.

Elastin

Collagen is found in tissues where strength or toughness is required, but some tissues, such as ligaments and arterial blood vessels, need highly elastic fibers. Such tissues contain large amounts of the fibrous protein **elastin**.

The protein elastin forms elastic fibers found in ligaments and blood vessels.

The polypeptide chain of elastin is rich in glycine, alanine, and valine and is very flexible and easily extended. In fact, its conformation probably approximates that of a **random coil**, with little secondary structure at all. However, the sequence also contains lysine side chains, which can be involved in cross-links. These cross-links prevent the elastin fibers from being extended indefinitely, causing the fibers to snap back when tension is removed. Exactly the same principle accounts for the elasticity of vulcanized rubber, the flexible chains of which are also held by cross-links. The cross-links in elastin are rather different from those in collagen, for they are designed to hold several chains together. Four lysine side chains can be combined to yield a **desmosine** cross-link as shown in the margin. Because four separate chains are connected, only a small amount of such cross-linking is needed to convert elastin fibers into a highly interconnected, rubbery network.

Summary

This brief overview of a few of the structural proteins brings out several points. First, proteins can evolve to serve an almost infinite diversity of functions. Second, the structural fibrous proteins do this by taking advantage of the propensities of particular repetitive sequences of amino acid residues to favor one kind of secondary structure or another. Finally, post-translational modification of proteins, including cross-linking, is an important adjunct in tailoring a protein to its function. We say more about the cellular sites for such modification in Chapter 28 when we consider the whole process of protein synthesis in detail.

These few examples do not exhaust the list of structural proteins. There are other important ones, such as actin and myosin of muscle and tubulin in microtubules. But these proteins are constructed in a quite different way and are discussed in Chapter 8.

Globular Proteins: Tertiary Structure and Functional Diversity

Different Folding for Different Functions

Abundant and essential as the structural proteins may be in any organism, they constitute only a small fraction of the *kinds* of proteins an organism possesses. Most of the chemical work of the cell—the synthesizing, transporting, and metabolizing—is carried out with the aid of an enormous class of **globular proteins**. These proteins are so named because their polypeptide chains are folded into compact structures very unlike the extended, filamentous forms of the fibrous proteins. Myoglobin (see Figure 6.1) is a typical globular protein. A glance at its three-dimensional structure, when compared with that of, say, collagen, immediately reveals this qualitative difference.

We now know a great deal about the structural details of many globular proteins, largely through the use of X-ray diffraction methods (see Tools of Biochemistry 4A) and **nuclear magnetic resonance spectroscopy** (NMR, see Tools of Biochemistry 6A). Both of these methods provide structural information with atomic-level details.

Within the protein molecule, the polypeptide chain is often locally folded into one or another of the kinds of secondary structure (α helix, β sheet, and so forth) that we have already discussed. But to make the structure globular and compact, these regions must themselves be folded on one another. This folding is referred to as the **tertiary structure** of the protein; it is this folding that gives the molecule its overall three-dimensional shape. The distinction between secondary and tertiary structures can be clearly seen in the structure of myoglobin, as shown in Figure 6.1. About 70% of the myoglobin chain is α helical, and the eight helices in myoglobin pack against one another to form a compact molecule. A pocket within this structure holds a **prosthetic group**, the heme. Many globular proteins carry prosthetic groups—small molecules that may be noncovalently or covalently bonded to the protein and enable the protein to fulfill special functions. In this case, the noncovalently bound heme group carries the oxygen-binding site of myoglobin (discussed in Chapter 7).

Globular proteins not only possess secondary structures but also are folded into compact tertiary structures.

FIGURE 6.18

The tertiary structure of BPTI. Bovine pancreatic trypsin inhibitor, or BPTI, binds to trypsin and prevents it from catalyzing peptide hydrolysis. BPTI contains only 58 amino acid residues and is one of the most completely studied of all proteins. **(a)** A “stick” model, showing atomic positions (excluding H atoms) from X-ray diffraction (PDB ID: 4PTI). C atoms are green, N atoms are blue, O atoms are red, and S atoms are yellow. **(b)** A “cartoon” model of the backbone. There are short α helices (cyan), near the termini of the molecule, as well as a two-stranded antiparallel β sheet (red). The positions of the three disulfides are shown by yellow sticks. **(c)** A “surface” model, showing the solvent-accessible surface of the molecule. Atom coloring is the same as in panel (a).

To show the great structural variation among globular proteins, let us consider another example. Figure 6.18 depicts one of the smallest and simplest globular proteins—bovine pancreatic trypsin inhibitor (BPTI). This protein, synthesized in the cow pancreas, is one of a number of proteins whose sole function is to bind to and inhibit proteolytic enzymes like trypsin. It is important to health, as it prevents damage to the pancreas if trypsin is activated prematurely. We shall use it repeatedly as an example of a globular protein because it is relatively simple and, as a consequence, it has been studied in great detail.

BPTI is depicted in three ways in Figure 6.18. A stick model showing the positions of all atoms (except hydrogens), which have been determined to high resolution by X-ray diffraction, is given in Figure 6.18a. Figure 6.18b shows a cartoon model of the main chain. In this model you can easily trace the path of the polypeptide backbone and can clearly see both α helix and β sheet structures present in this molecule; also shown are the positions of the three disulfide bonds in BPTI. Finally, Figure 6.18c depicts the surface of the molecule, illustrating the important point that globular proteins are tightly packed structures and are often, as their name implies, rather globular in shape.

Comparing Figure 6.18 with Figure 6.1, you can see that the structure of BPTI is wholly different from that of myoglobin. Whereas myoglobin is mostly α helix, BPTI has both helix and sheet regions, connected by bends in the chain. The important point is this: Every globular protein has a characteristic tertiary structure, made up of secondary structure elements (helices, β sheets, nonregular regions) folded in a specific way. As we examine proteins, we will find that each such conformation is suited to the particular functional role that the protein plays.

Varieties of Globular Protein Structure: Patterns of Folding

At first glance, it might seem that there would be an almost infinite number of ways in which globular proteins could fold. If we examine every possible detail of folding, this is true. Yet when a large number of the known structures is examined, certain common motifs and principles emerge. The first principle is that many proteins are made up of more than one domain. A **domain** is a compact, locally folded region of tertiary structure. Domains are interconnected by the polypeptide strand that runs through the whole molecule. Multiple domains are especially common in the larger globular proteins, whereas very small proteins like BPTI tend to be single folded domains. As we shall see in later sections, different domains often perform differing functions, and a given domain type can sometimes be recognized in several different proteins.

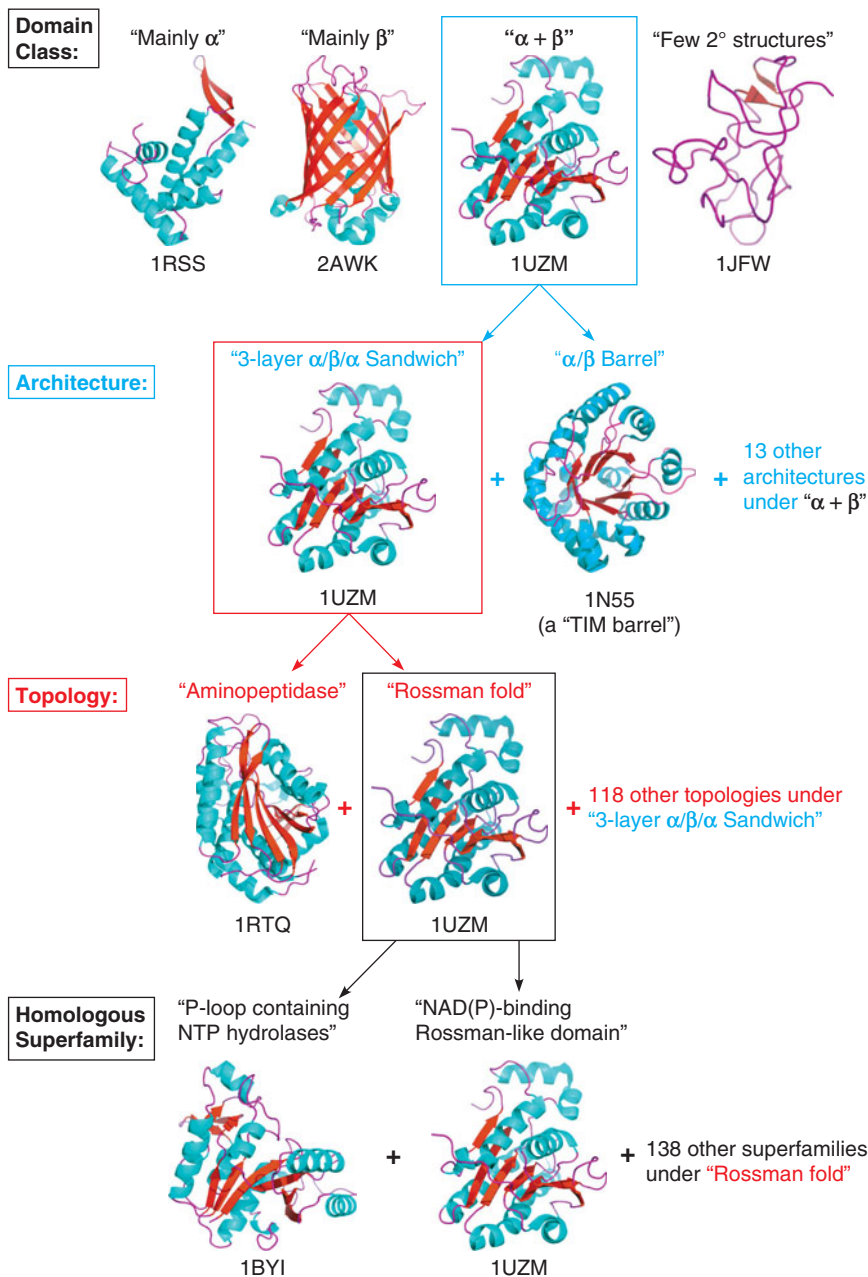

Among the domain varieties, several hundred distinct structural motifs have been classified and organized into searchable online databases (see References). These databases allow identification of potential functional and evolutionary relationships among proteins that share similar structural domains.

A protein “domain” is a compact, locally folded region of tertiary structure. Smaller proteins typically contain a single domain. Larger proteins may contain several domains.

To illustrate the immense structural variation in globular proteins, we can consider the ~1,300 distinct domain structures, which are used to classify ~130,000 protein domain entries in the CATH (Class, Architecture, Topology, and “Homologous superfamily”) database. Figure 6.19 shows seven distinct domain folds, and there are over 1,200 others cataloged in CATH. However, this immense variation can be distilled down to four basic folding patterns in globular proteins: those that are built about a packing of α helices, those that are constructed on a framework of β sheets, those that include both helices and sheets, and those that contain little helix or sheet structure.

In the CATH classification system, “Class” refers to one of four categories based on the prevalent 2° structure in the domain fold (top row Figure 6.19). If we look more closely at the “ $\alpha + \beta$ ” class, we would find 15 different general shapes, or “architectures,” for domain folds that include α helix and β sheet structure. Two of these architectures, “3-layer $\alpha/\beta/\alpha$ sandwich” and “ α/β barrel” are shown in the second row of Figure 6.19. In the context of protein structure, **topology** refers to the order in which

The majority of globular protein structures can be broadly classified as: “mainly α ,” “mainly β ,” and “ $\alpha + \beta$.” A small number of globular proteins has little α or β secondary structure.

FIGURE 6.19

Structural diversity in globular protein domains. See text for a more detailed description of this figure. Top row: Representatives of the four main classes of domain structure are shown in cartoon rendering with α helices in cyan, β strands in red, and connecting loops in magenta. Second row: two representatives of the 15 architectures within the “ $\alpha + \beta$ ” class. Third row: two representatives of the 120 topologies found in the “3-layer $\alpha/\beta/\alpha$ sandwich” architecture. Fourth row: two representatives of the 140 homologous superfamilies found in the “Rossmann fold” topology. PDB IDs: Ribosomal protein S7 (1RSS); green fluorescent protein (2AWK); β -ketoacyl ACP reductase (1UZM); HIV1 transactivator protein (1JFW); triosephosphate isomerase (1N55); leucyl aminopeptidase (1RTQ); dethiobiotin synthase (1BYI).

the 2° structural features are connected in the protein amino acid sequence. For example, in different proteins, two α helices and one β strand might be linked “helix-helix-strand” or “helix-strand-helix” or “strand-helix-helix.” Each of these represents a different topology for these three secondary structural elements. Row three of Figure 6.19 shows two examples of the 120 different topologies for the “3-layer $\alpha/\beta/\alpha$ sandwich” architecture: “amino peptidase” and the “Rossman fold.” The **Rossman fold** is a common domain structure for an important class of enzymes that bind a **nicotinamide adenine dinucleotide** (NAD) cofactor (see page 446). There are 140 distinct “superfamilies” of proteins that include a Rossman fold topology. The proteins within each superfamily appear to be homologous (i.e., they have a common evolutionary ancestor). There are 3078 different domain entries within the “NAD(P)-binding Rossman-like domain” superfamily (~2% of total entries in the CATH database), and one of these is the structure shown in Figure 6.19 (1UZM). In summary, the CATH designation for this domain is: “ $\alpha + \beta$ ” \rightarrow “3-layer $\alpha/\beta/\alpha$ sandwich” \rightarrow “Rossman fold” \rightarrow “NAD(P)-binding Rossman-like domain”.

Studying the details of domain structural variation can be overwhelming; however, it is in these structural details that we find a deeper understanding of protein function. Fortunately for students of biochemistry, the analysis of the structures of thousands of globular proteins has led to the formulation of a few general rules governing tertiary folding:

- *All globular proteins have a defined inside and outside.* If we examine the amino acid sequences of globular proteins, we find no particular distribution pattern of hydrophobic or hydrophilic residues (Figure 6.20a). But when we look at the positions of the amino acids in the three-dimensional structure, we invariably find that tertiary structure causes hydrophobic residues to be packed mostly on the inside (Figure 6.20b), whereas the hydrophilic residues are on the surface, in contact with water (Figure 6.20c).
- *β sheets are usually twisted, or wrapped into barrel structures.* Examples can be seen in Figure 6.19 (e.g., 1RTQ). It is probable that the structure of silk fibroin is not exactly planar, as depicted in Figure 6.15, but slightly twisted.
- *The polypeptide chain can turn corners in a number of ways, to go from one β segment or α helix to the next.* One kind of compact turn is called a β turn (Figure 6.21). There are several varieties of β turn, each able to accomplish a

FIGURE 6.20

The distribution of hydrophilic and hydrophobic residues in globular proteins. **(a)** The amino acid sequence of sperm whale myoglobin. Hydrophobic (green), hydrophilic (red), and ambivalent (black) residues appear to be scattered throughout the sequence. The two His residues in blue play a special role in heme and oxygen binding—see Chapter 7. **(b)** The three-dimensional structure of the same protein. Note how the hydrophobic side chains (shown in green) cluster about the hydrophobic heme cofactor (orange with iron ion in gray) and on the inside of the molecule. **(c)** In this view of the myoglobin structure the hydrophilic side chains are shown in red. Note how they tend to lie on the solvent-exposed surface of the protein.

complete reversal of the polypeptide chain direction in only four residues; in each case the carbonyl of residue i hydrogen-bonds to the amide hydrogen of residue $i + 3$. In the even tighter γ turn, bonding is to residue $i + 2$ (Figure 6.22). Proline often plays a role in turns, as in Figure 6.22, and also as a breaker of α helices because this residue cannot be easily accommodated in the helix. Bends and turns most often occur at the surface of proteins.

- *Not all parts of globular proteins can be conveniently classified as helix, β sheet, or turns.* Examination of Figure 6.19, for example, reveals many strangely contorted loops and folds in the chains (the regions shown in magenta). These have sometimes been referred to as “random coil” regions, but this term is a misnomer because such sections of the chain are not flexible in the same way that a true random coil is (see page 108). Rather, X-ray diffraction and NMR data indicate that such regions do, in fact, possess a well-defined fold. We might call these *irregularly structured regions*. Several proteins also have intrinsically unstructured regions, a feature that is particularly important in a class of signaling proteins that bind to several different targets.

In some proteins the folding is dominated by the need to bind a prosthetic group. Myoglobin is an example (Figure 6.20). Although myoglobin might be roughly described as an α helix bundle, the tertiary structure of this protein has been distorted to form a hydrophobic pocket about the heme group.

Factors Determining Secondary and Tertiary Structure

The Information for Protein Folding

What ultimately determines the complex mixture of secondary and tertiary folding that characterizes each globular protein? Much evidence indicates that *most of the information for determining the three-dimensional structure of a protein is carried in the amino acid sequence of that protein*. This can be demonstrated by experiments in which the *native*, or folded, three-dimensional structure is perturbed by changing the environmental conditions. If we raise the temperature sufficiently, or make the pH extremely acidic or alkaline, or add to the solvent certain kinds of organic molecules, such as alcohols or urea, the protein structure will unfold (Figure 6.23). As with nucleic acids, this process is called **denaturation** because the natural structure of the protein has been lost, along with many of its specific functional properties. In diagrams such as Figure 6.23a, the unfolded chain is often drawn as a *random coil*, with freedom of rotation about bonds in both the polypeptide backbone and the side chains. Much recent evidence suggests that this is a gross oversimplification. In many cases the unfolded state for a protein is a dynamic ensemble of largely unstructured, extended conformations; however, even in the “unfolded” state, regions of structure may persist.

In the classic experiment by Chris Anfinsen depicted in Figure 6.23a, and recognized with the Nobel Prize in 1972, the enzyme ribonuclease A (RNase A) was denatured by addition of urea, and the four native disulfide bonds were reduced by addition of β -mercaptoethanol (BME). RNase A catalyzes the hydrolysis of ribonucleic acids. When RNase A is denatured, its tertiary and secondary structures are lost, and it can no longer catalyze RNA cleavage. The denaturation process can be tracked by various physical measurements, as shown in Figure 6.23b. Remarkably, the total disruption of RNase A structure was shown by Anfinsen to be reversible. If the urea is removed by dialysis, the reduced RNase A will spontaneously refold into its native structure. Oxidation of the refolded protein in air restores the native disulfide bonds and full enzymatic activity. Oxidation of urea-denatured RNase A, followed by removal of the urea, yields a mixture of protein molecules with randomly formed disulfide bonds. This mixture has ~1% of the original enzymatic activity, suggesting that molecules with native disulfide bonds account for ~1% mixture. Random formation of four

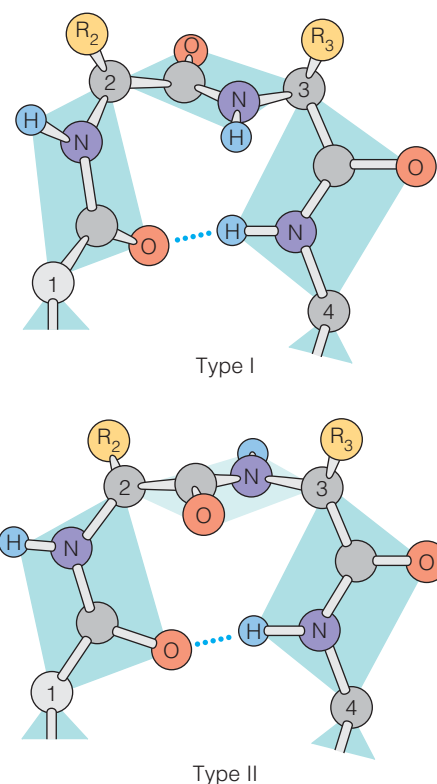

FIGURE 6.21

Examples of β turns. Each of these turn types allows an abrupt change in polypeptide chain direction. In the type II turn, residue 3 is usually glycine, presumably because a bulky R group would clash with the carbonyl oxygen of residue 2.

Amino acid sequence (primary structure) determines secondary and tertiary structure.

FIGURE 6.22

A γ turn. Only one residue is out of the hydrogen-bonding sequence. In this case it is a proline, which cannot act as an H-bond donor in any case. Note that no H atom is bonded to the α -amino group of the proline (the H that appears to be bonded to the α -N atom is, in fact, bonded to the δ -carbon of the proline side chain).

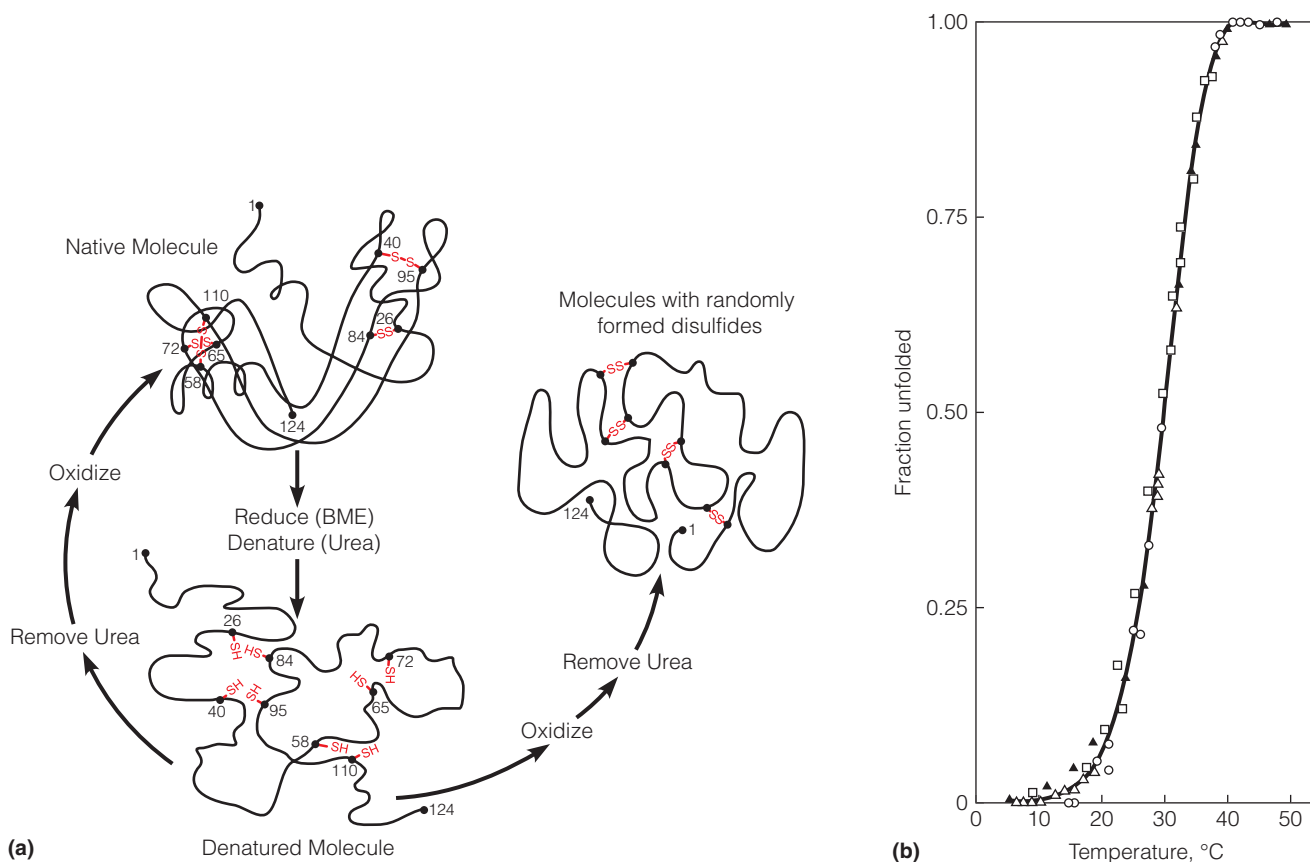

FIGURE 6.23

The denaturation and refolding of ribonuclease A.

(a) This schematic drawing depicts the classic RNase A refolding experiment of Anfinsen. See text for details.

(b) Thermal denaturation of RNase A monitored by various physical methods. Differences between the native and denatured conformations can be detected by several of the spectroscopic methods discussed in Tools of Biochemistry 6A. This graph shows the fraction of protein that is denatured, as measured by the increase in solution viscosity (□), change in optical rotation at 365 nm (○), or change in UV absorbance at 287 nm (△). All three techniques indicate the same fraction unfolding as a function of increasing temperature.

Measurements of a second denaturation after cooling (▲) produce the same curve, showing that the process is reversible with a melting temperature (T_m ; see Tools of Biochemistry 5C) of 29.0 °C. The experiments were conducted at pH 2.1, ionic strength 0.019 M. Under physiological conditions, RNase A is much more stable, not denaturing until about 70–80 °C.

disulfides from eight cysteines predicts 105 possible different combinations—one of which is the set of native disulfide bonds ($1/105 \approx 1\%$).

Anfinsen's work showed that a protein can self-assemble into its functional conformation, and it needs no information to guide it other than that contained in its sequence. The same phenomenon has been observed experimentally for many other proteins; thus, we might expect a newly synthesized polypeptide in a cell to spontaneously fold into the proper active conformation. As we shall see later in this chapter, the actual process in vivo is more complicated. To avoid misfolding or aggregation, some proteins interact with cellular machinery that guides the folding process. Nonetheless, the basic principle of self-assembly of secondary and tertiary structure seems to be the general rule.

The Thermodynamics of Folding

The folding of a globular protein is clearly a thermodynamically favorable process under physiological conditions. In other words, the overall free energy change for folding must be negative. But this negative free energy change is achieved by a balance of several thermodynamic factors, which we will now describe.

Conformational Entropy

The folding process, which involves going from a multitude of “random-coil” conformations to a *single* folded structure[†], involves a decrease in randomness and thus a decrease in entropy. This change is termed the **conformational entropy** of folding.

random coil (higher entropy) \longrightarrow folded protein (lower entropy)

[†]For the sake of simplicity we will present an idealized case for which there is a single well-defined native state conformation. Because most proteins require some conformational flexibility to perform their function, it is more proper to acknowledge that the native state comprises a limited number of well-defined conformations with similar values of free energy. In any event, the entropy of the native state ensemble of conformations is much less than that of the denatured state ensemble.

The free energy equation, $\Delta G = \Delta H - T\Delta S$, shows that this negative ΔS makes a *positive* contribution to ΔG . In other words, the conformational entropy change works *against* folding. To seek the explanation for an overall negative ΔG , we must seek features of protein folding that yield either a large negative ΔH or some other *increase* in entropy on folding. Both can be found.

The major source for a negative ΔH is energetically favorable interactions between groups within the folded molecule. These include many of the noncovalent interactions described in Chapter 2.

Charge–Charge Interactions

Charge–charge interactions can occur between positively and negatively charged side chain groups. For example, a lysine side chain ϵ -amino group may be placed close to the γ -carboxyl group of some glutamic acid residue. At neutral pH, one group will be charged positively and the other negatively, so an electrostatic attractive force exists between them. We could say that such a pair forms a kind of salt within the protein molecule; consequently, such interactions are sometimes called **salt bridges**. These ionic bonds are broken if the protein is taken to pH values high enough or low enough that either side chain loses its charge. This loss of salt bridges is a partial explanation for acid or base denaturation of proteins. The mutual repulsion between pairs of the numerous similarly charged groups that are present in proteins in very acidic or basic solutions contributes further to the instability of the folded structure under these conditions.

Internal Hydrogen Bonds

Many of the amino acid side chains carry groups that are either good hydrogen bond donors or good acceptors. Examples are the hydroxyl groups of serine or threonine, the amino groups and carbonyl oxygens of asparagine or glutamine, and the ring nitrogens in histidine. Furthermore, if amide protons or carbonyls in the polypeptide backbone are not involved in secondary structure formation, they are potential candidates for interaction with side chain groups. A network of several types of internal hydrogen bonds is seen in the portion of the molecule of the enzyme lysozyme shown in Figure 6.24. As we have seen before, hydrogen bonds are relatively weak in aqueous solution, but their large number can add a considerable contribution to stability.

van der Waals Interactions

As discussed in Chapter 3, the weak induced dipole-induced dipole interactions between nonpolar groups can also make significant contributions to protein stability because in the folded protein these groups are densely packed and thus make a large number of van der Waals contacts. Detailed analyses of native protein structures show that the nonpolar interior of a globular protein is indeed very tightly packed, allowing maximum contact between nonpolar side chain atoms.

The contribution of any of these interactions to the negative enthalpy of folding is diminished by the fact that when a protein molecule folds from an expanded and highly solvated random coil, it has to give up some favorable interactions with water. As we pointed out in Chapter 2, an unfolded α helical peptide forms hydrogen bonds with water instead of forming internal bonds. It is not clear by how much this exchange modifies the overall value of ΔH ; however, we do know that a substantial energy difference in favor of the unfolded state would result if internal H-bonds were *not* formed when H-bond acceptors or donors were buried by folding.

The change in enthalpy for folding, $\Delta H_{U \rightarrow F}$, is dominated by the differences in noncovalent bonding interactions between the unfolded and folded states:

$$\Delta H_{U \rightarrow F} = H_{\text{folded}} - H_{\text{unfolded}} \quad (6.1)$$

The decrease in conformational entropy when a protein folds disfavors folding. This is compensated in part by energy stabilization through internal noncovalent bonding.

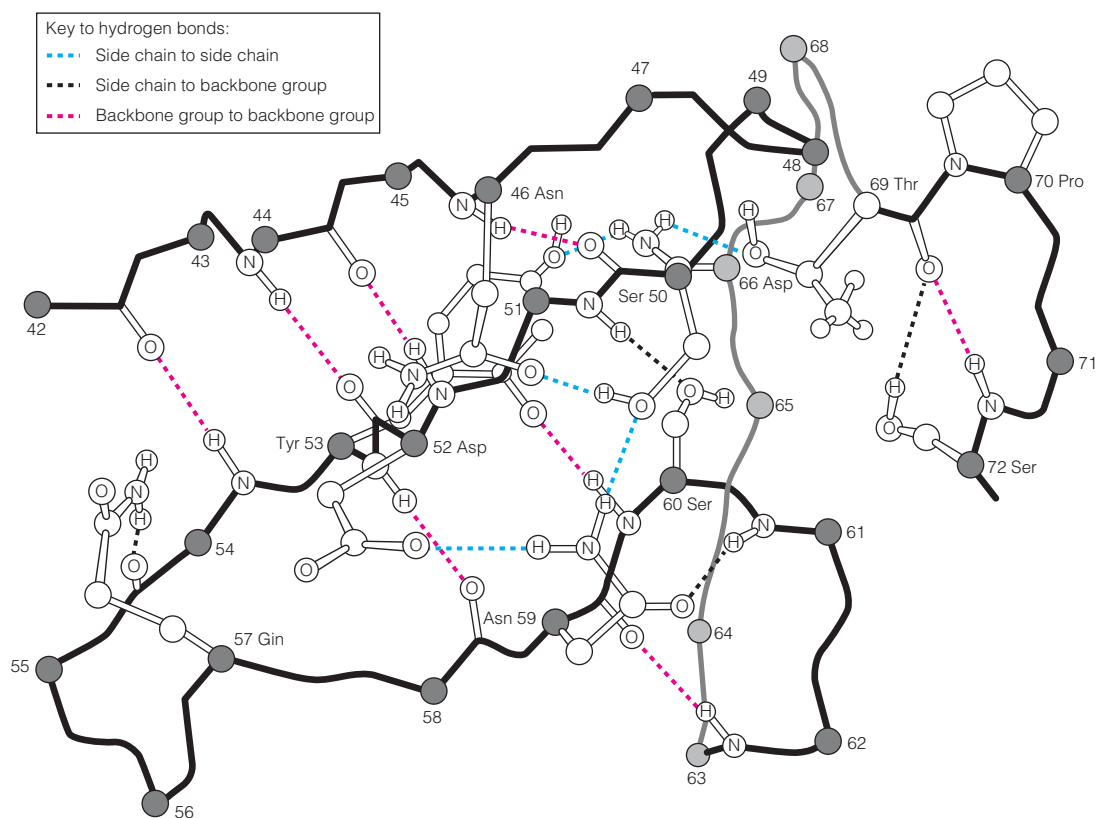

FIGURE 6.24

Details of hydrogen bonding in a typical protein. A network of hydrogen bonds within the enzyme lysozyme is illustrated. Three kinds of H bonds are distinguished: bonds between side chain groups, bonds between backbone groups, and bonds between a side chain group and a backbone amide hydrogen or carbonyl oxygen.

TABLE 6.4 Thermodynamic parameters for folding of some globular proteins at 25 °C in aqueous solution

Protein	ΔG (kJ/mol)	ΔH (kJ/mol)	ΔS (kJ/K·mol)
Ribonuclease	-46	-280	-0.79
Chymotrypsin	-55	-270	-0.72
Lysozyme	-62	-220	-0.53
Cytochrome <i>c</i>	-44	-52	-0.027
Myoglobin	-50	0	+0.17

Note: Data adapted from *Journal of Molecular Biology* (1974) 86:665–684, P. L. Privalov and N. N. Khechinashvili, A thermodynamic approach to the problem of stabilization of globular protein structure: A calorimetric study. Each data set has been taken at the pH value where the protein is maximally stable; all are near physiological pH. Data are for the folding reaction: Denatured (unfolded) \rightleftharpoons native (folded).

where the unfolded state is characterized by noncovalent interactions between the extended protein chain and solvent water molecules and the folded state includes many fewer interactions with solvent and many more intramolecular interactions instead. Typically the only new *covalent* bonds that form upon folding are disulfide bonds (note, however, that most proteins do not contain disulfide bonds). Formation of disulfides will contribute to ΔH ; however, as discussed below, the entropic effects of disulfides on protein stability are likely more significant than are their enthalpic effects.

Each individual interaction can contribute only a small amount (at most only a few kilojoules per mole) to the overall negative enthalpy of interaction. But the sum of the contributions of many interactions can yield significant stabilization to the folded structure. Examples of the total enthalpy changes for folding are given for some representative proteins in Table 6.4. In many cases, a favorable energy contribution from the sum of intramolecular interactions more than compensates for the unfavorable entropy of folding.

The Hydrophobic Effect

Yet another factor makes a major contribution to the thermodynamic stability of many globular proteins. Recall from Chapter 2 that hydrophobic substances in contact with solvent water cause the water molecules to form clathrate, or cage-like, structures around them. This ordering corresponds to a loss of randomness in the solvent; thus, the entropy of the solvent is decreased. Suppose a protein contains, in its amino acid sequence, a substantial number of residues with hydrophobic side chains (for example, leucine, isoleucine, and phenylalanine). When the polypeptide chain is in an unfolded form, these residues are in contact with water and cause ordering of the surrounding water structure into clathrates. When the chain folds into a globular structure, the hydrophobic residues become buried within the molecule (see Figure 6.20b), and the water molecules that were ordered around the solvent-exposed hydrophobic surfaces in the protein denatured state

are now released, gaining freedom of motion. Thus, the randomness of the solvent is increased by internalizing hydrophobic groups via folding.

Recall that the *overall* change in entropy is the sum of the change in entropy for the system (in this case the polypeptide chain) *and* the change in entropy of the surroundings (in this case the solvent water molecules):

$$\Delta S_{\text{universe}} = \Delta S_{\text{system}} + \Delta S_{\text{surroundings}} \quad (6.2a)$$

$$\Delta S_{U \rightarrow F} = \Delta S_{\text{protein}} + \Delta S_{\text{solvent}} \quad (6.2b)$$

In equation 6.2b, $\Delta S_{\text{protein}}$ is the conformational entropy change for folding, which is *negative*; however, this unfavorable entropy change is offset by the favorable entropy increase for the solvent ($\Delta S_{\text{solvent}}$). In summary, the burial of hydrophobic surface area in the solvent-inaccessible core of the protein acts to stabilize the folded state by making the value of $\Delta S_{U \rightarrow F}$ more positive.

The term *hydrophobic bonding* has sometimes been used to describe the stabilization resulting from the burial of hydrophobic groups, but this term is a misnomer. The stabilization is not primarily the result of bonds forming between hydrophobic groups, although van der Waals interactions surely do make favorable enthalpic interactions upon folding. Rather, the folded protein is stabilized by a solvent entropy effect. The more appropriate term to describe this source of protein stabilization is **the hydrophobic effect**. Examples of the importance of the hydrophobic effect can be seen in Table 6.4. The very small negative ΔS for cytochrome *c* and the positive value for myoglobin are a consequence of the hydrophobic effect in these proteins. Indeed, the stability of myoglobin comes mainly from the hydrophobic effect.

Different amino acid residues make larger or smaller contributions to the hydrophobic effect. Studies of the transfer of amino acids from water to organic solvents, as well as theoretical considerations, have led to the construction of various **hydrophobicity scales**. Two examples are shown in Table 6.5. The two scales, based on somewhat different premises, are similar but not identical. Nevertheless, such scales can be used to predict the importance of the hydrophobic effect in stabilizing any particular protein. In Chapter 10 we shall see how they can also be used to predict which portions of a protein will insert into a lipid membrane.

In summary, the stability of the folded structure of a globular protein depends on the interplay of three factors:

1. The unfavorable conformational entropy change, which favors the unfolded state
2. The favorable enthalpy contribution arising from intramolecular interactions
3. The favorable entropy change arising from the burying of hydrophobic groups within the molecule

Thus, factor 1 works against folding, whereas factors 2 and 3 favor folding. A picture of the way these components might contribute to the free energy of folding for some protein is shown in Figure 6.25. In different proteins, the contributions to the stability of the folded protein from enthalpic interactions and the hydrophobic effect differ (see Table 6.4), but the overall consequence is the same: Some particular folded structure corresponds to a free energy minimum for the polypeptide under physiological conditions. This is why the protein folds spontaneously. Methods for determining thermodynamic parameters for protein stability are described in Tools of Biochemistry 6C.

Examination of the data in Table 6.4 reveals another important aspect of protein stabilization. Proteins are relatively unstable molecules. The free energy difference between the native and denatured states is modest—typically, 20–60 kJ/mol. The relatively small ΔG corresponding to the folding reaction is usually the difference between large ΔH and $T\Delta S$ terms. These large values arise because a protein (or protein domain) on the order of 150–200 residues tends to fold in a

The burying of hydrophobic groups within a folded protein molecule produces a stabilizing entropy increase known as the hydrophobic effect.

FIGURE 6.25

Contributions to the free energy of folding of globular proteins. The conformational entropy change works against folding, but the enthalpy of internal interactions and the entropy change from the hydrophobic effect favor folding. Summing these three quantities makes the total free energy of folding negative (favorable); thus, the folded structure is stable.

predominantly *cooperative* manner with few intermediate structures; thus, many folding interactions within a molecule form or break in concert. As a consequence of this cooperativity, the thermal denaturation of a protein usually occurs over a narrow temperature range, as is shown in Figure 6.23b.

The Role of Disulfide Bonds

Once folding has occurred, the three-dimensional structure is in some cases further stabilized by the formation of disulfide bonds between cysteine residues. An extreme example of this bonding is found in the bovine pancreatic trypsin inhibitor (BPTI) protein, depicted in Figure 6.18. With three —S—S— bridges in 58 residues, this molecule is one of the most stable proteins known. Pioneering work on the role of disulfide bond formation in the folding of a protein was carried out on BPTI in the lab of Thomas Creighton. The BPTI is quite inert to unfolding reagents like urea and exhibits thermal denaturation below 100 °C only in very acidic solutions; the half-point for reversible denaturation is about 80 °C at pH 2.1 (Figure 6.26). However, if only *one* of the disulfide bonds (that between cysteine residues 14 and 38—the uppermost disulfide bond shown in Figure 6.18b) has been reduced and carboxymethylated, the midpoint is decreased to 59 °C. When all the disulfide bonds in BPTI are reduced, the protein is unfolded at room temperature; yet, upon reoxidation of the sulfhydryls, native protein with the three correct disulfide pairings is efficiently formed. This re-formation is not what would be expected by chance. Suppose a BPTI molecule has been reduced, yielding 6 cysteine residues, and we now randomly reoxidize the —SH groups. The first —SH group to pick a partner will have 5 choices, the second group 3, and the last only 1, so there are $5 \times 3 \times 1$, or 15, equally probable combinations. Thus, we would expect only about 7% of reduced BPTI to refold to the correct native state *by chance*. Many studies of this and other proteins (e.g., RNase A) containing disulfide bonds indicate that correct pairing is regained in almost 100% of the molecules if sufficient time is allowed. This finding must mean that it is the preferred folding of the protein that places the —SH groups in position for correct pairing. The corollary of this statement is that the disulfide bonds are not themselves essential for correct refolding. They do, however, contribute to the stability of the structure once it is folded.

A molecule containing disulfide bonds has a smaller number of conformations available in the unfolded state than does a comparable protein without the bonds. This dramatic reduction in conformational entropy for the unfolded state results in an increased free energy for the disulfide-bonded unfolded state, relative to the unfolded state in the absence of disulfide bonds (Figure 6.27). In contrast, the conformational entropy of the folded state is not significantly perturbed by the presence or absence of disulfide bonds because the folded state has much lower conformational entropy than does the unfolded state. These differential effects on conformational entropy result in a larger difference in the free energies of the folded and unfolded states for the disulfide-bonded protein. The net result is to make $\Delta G_{F \rightarrow U}$ more *unfavorable* for a protein containing disulfide bonds than it would be in the absence of the disulfide bonds.

Some folded proteins are stabilized by internal disulfide bonds, in addition to noncovalent forces.

FIGURE 6.26

Thermal denaturation of BPTI. The percent denaturation as a function of temperature at pH 2.1 is indicated for the native protein and for the protein in which the Cys 14–Cys 38 disulfide bond has been reduced and carboxymethylated.

Data from *European Journal of Biochemistry* (1971) 23:401–411 J. P. Vincent, R. Chicheportiche, and M. Lazdunski, The conformational properties of the basic pancreatic trypsin-inhibitor.

Figure 6.27 illustrates the concept that a larger free energy difference between the folded and unfolded states corresponds to a more stable protein. Thus, one can imagine two ways to increase protein stability: (1) stabilize the folded state (i.e., make G_F more negative), or (2) destabilize the unfolded state (i.e., make G_U more positive). The major effect of disulfide bond formation is to dramatically reduce the conformational entropy of the unfolded state, which destabilizes the unfolded state relative to the folded state.

The apparent advantage of disulfide-bond formation raises a question: Why don't *most* proteins have disulfide bonds? In fact, such bonds are relatively rare and are found primarily in proteins that are exported from cells, such as ribonuclease, BPTI, and insulin. One explanation is that the environment inside most cells is reducing and tends to keep sulfhydryl groups in the reduced state. External environments, for the most part, are oxidizing and stabilize —S—S— bridges.

A powerful method for studying the sources of protein structural stabilization has been developed from recombinant DNA techniques. Because the genes for proteins can be cloned and expressed in bacterial carriers (see Tools of Biochemistry 5A), it is possible to make specific changes at desired positions. This method of **site-directed mutagenesis** (see Tools of Biochemistry 4B) allows us to test the effect of changing one or more amino acid residues on protein folding and stability. The method has already been used, for example, to delete specific disulfide bonds in BPTI by replacing cysteines with serines or alanines, then measuring the effect of removing a disulfide bond on the stability of the mutant protein. Conversely, site-directed mutagenesis has been used to introduce into proteins appropriately placed cysteine residues to promote the formation of one (or more) new disulfide bonds in the folded structure. For example, in work from the lab of Brian Matthews, the X-ray crystal structure of the enzyme bacteriophage T4 **lysozyme** was used to guide the selection of three sites in that protein for the introduction of new disulfides. The introduction of one new disulfide increased the thermal stability of T4 lysozyme by 11 °C, and when all three disulfides were introduced the thermal stability increased by 23 °C compared to the enzyme lacking disulfide bonds.

Dynamics of Globular Protein Structure

The structural and thermodynamic descriptions we have developed so far tend to give too static a picture of globular proteins. The models of folded proteins produced from structural studies often give the impression of a rigid structure. Likewise, the thermodynamic analysis of folding concentrates on the initial (unfolded) and final (folded) states; but, it is now recognized that globular proteins fold via complex *kinetic* pathways and that even the folded structure, once attained, is a dynamic structure. The following section explores some of these dynamic aspects of globular proteins.

Kinetics of Protein Folding

The folding of globular proteins from their denatured conformations is a remarkably rapid process, often complete in less than a second. This observation has been of profound interest to biochemists, for at first glance, the attainment of the well-defined structure typical of globular proteins would seem to be very difficult. This point of view was dramatically expressed in “Levinthal’s paradox,” first enunciated by Cyrus Levinthal in 1968: A rough estimate would say that about 10^{50} conformations are possible for a polypeptide chain such as RNase A (124 residues). Even if the molecule could try a new conformation every 10^{-13} second, it would still take about 10^{30} years to try a significant fraction of them! Yet RNase A is experimentally observed to fold, *in vitro*, in about 1 minute. Clearly, something is wrong with such a calculation.

Levinthal’s paradox assumes that folding is a random process; thus, a protein must sample a vast number of *possible* conformations to find the desired native

FIGURE 6.27

The effect of disulfide bonds on protein stability. The free energies of the folded and unfolded states of a protein are shown schematically for the case of a protein with (dashed red lines) or without (unbroken black lines) disulfide bonds. The presence of disulfide bonds destabilizes (i.e., raises the free energy of) the unfolded state more than the folded state due to greater restriction of conformational entropy in the unfolded state. This results in a larger difference in the free energies of the folded and unfolded states for the disulfide-bonded protein; thus, the presence of disulfide bonds makes unfolding *less favorable* ($\Delta G_{F \rightarrow U}$ becomes more positive, or more “uphill”).

FIGURE 6.28

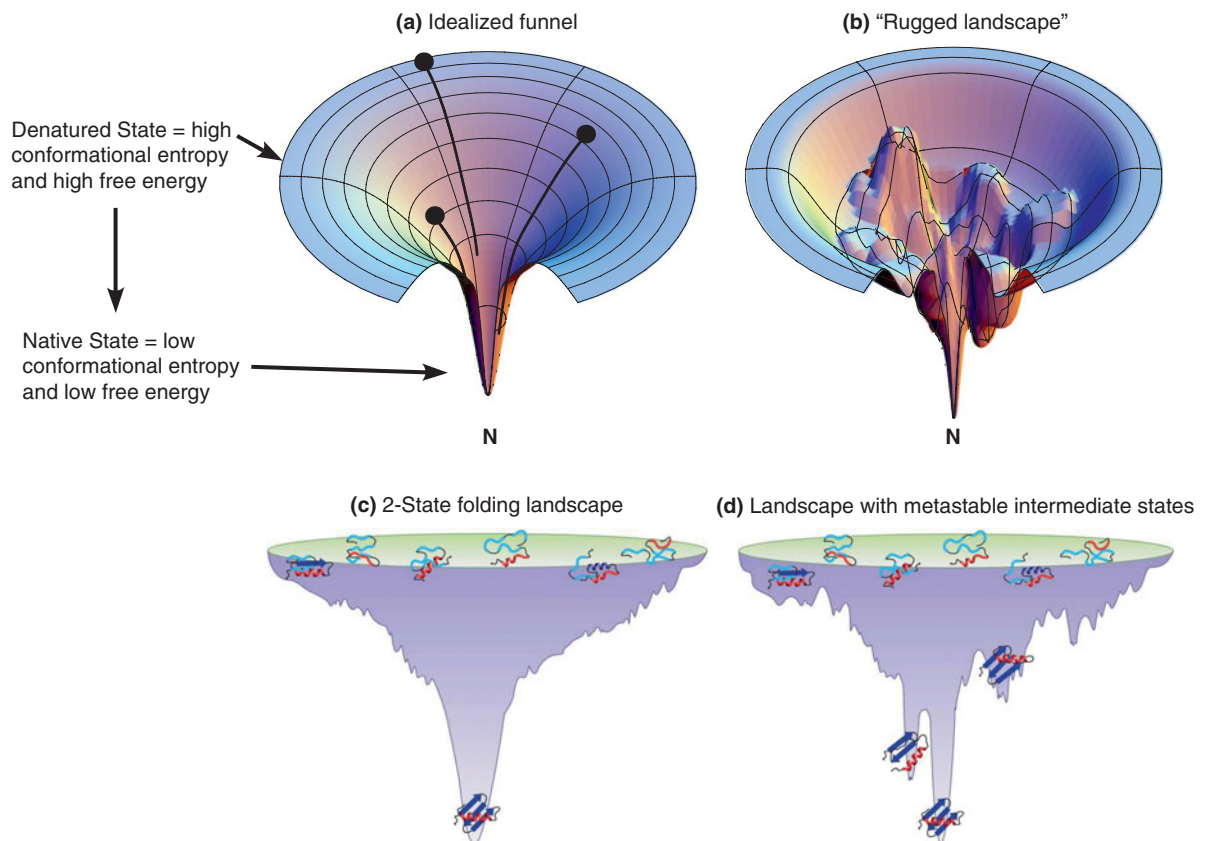

A simplified representation of the folding pathway for a protein. “U” indicates the unfolded or denatured state, “F” the folded or native state, and “I” “on-pathway” intermediate states. Off-pathway states include aggregates and other non-native states that may be kinetic or thermodynamic “dead-ends”; thus, the paths to these states are generally shown as irreversible. In fact, not all pathways leading to such states are irreversible.

conformation. Years of experimental and theoretical studies have shown that protein folding is not a completely random search through a vast conformational space. Rapid kinetic studies, using a variety of physical techniques to monitor different aspects of protein structure, show that folding takes place through a series of intermediate states. One particularly well-studied intermediate is the so-called **molten globule**. The molten globule is a compact, partially folded intermediate state that has native-like secondary structure and backbone folding topology, but lacks the defined tertiary structure interactions of the native state. These observations led initially to the classical “pathway” model of folding, depicted in a simplified fashion in Figure 6.28.

The “Energy Landscape” Model of Protein Folding

Several proteins are known to fold via well-characterized intermediate states as shown in Figure 6.28, yet this simple model of protein folding is not sufficient to resolve Levinthal’s paradox. That can only be achieved if the number of conformational states that the protein samples during folding is significantly restricted. The so-called **energy landscape**, or **folding funnel** model, described by José Onuchic and Peter Wolynes, explains how conformational restriction can be achieved during folding. Imagine that the energetics of folding is described by a funnel-shaped landscape (Figure 6.29) for which the width of the funnel corresponds to the number of conformational states and the depth of the funnel corresponds to free energy. As a protein molecule follows a “downhill” (i.e., thermodynamically favorable) trajectory

**FIGURE 6.29**

Protein folding energy landscapes. For all folding funnels shown, the widest part of the funnel corresponds to the denatured state and the deepest and narrowest part of the funnel corresponds to the native state. **(a)** Highly idealized energy landscape for which all trajectories lead to productive folding to the native state. **(b)** A more “rugged” energy landscape. Here, many different paths are possible, some of which lead “downhill” with no local energy minima, and give rapid folding. Others may lead to conformations corresponding to local energy minima, which may slow folding. These conformations represent stable intermediate states along the folding pathway. **(c)** A relatively smooth energy landscape with no significant energy barriers between the denatured and native states. This landscape describes so-called two-state folding because the only significantly populated states are the denatured and native states. **(d)** A more rugged energy landscape showing local minima for metastable intermediate states. This landscape describes a multistate folding process.

on the energy landscape, the funnel becomes narrower and the number of conformations accessible to the protein decreases. According to this model, any one molecule need sample only an infinitesimal fraction of the total conformations possible, and thereby, Levinthal's paradox is averted.

The classical pathway model and the folding funnel are compatible if we consider the U and I states in Figure 6.28 to be made up of ensembles of conformations, rather than unique conformations. Recent studies have shown that, in some cases, the F state is also an ensemble of closely related conformations.

The folding of several small proteins has been studied in great detail, and much experimental evidence suggests the energy landscape model is robust. Some of the earliest events in protein folding are “nucleation” of secondary structure (typically α helix; see Problem 6.18) and “hydrophobic collapse.” Nucleation events are critical because it is much more difficult to initiate an α helix, for example, than to extend it (note that at least four residues must fold properly to make the first stabilizing H bond). Hydrophobic collapse is driven by the hydrophobic effect and typically involves several highly hydrophobic sidechains (see Table 6.5) rapidly associating to create a desolvated hydrophobic core. Whether secondary structure nucleation or hydrophobic collapse (or both) is the first event in protein folding, the formation of *any* partially folded structure imposes significant constraints on the conformational entropy of the peptide chain, as indicated by the landscape model. This model proposes that there is not just one but *many* possible paths from the denatured state to the folded state, and each path leads downhill in energy. It is now recognized that nucleation may start at a number of points and that all of these partially folded structures will be “funneled” toward the final state along trajectories that minimize the energy of the peptide.

Intermediate and Off-Pathway States in Protein Folding

On the folding trajectory toward the “global” free energy minimum, there may be “local” energy minima corresponding to metastable intermediates, just as in the classical pathway model. There is also evidence for “off-pathway” states—those in which some key element is incorrectly folded. Such states also correspond to local free energy minima in the funnel and may temporarily, or permanently, trap the protein. As described below, cells contain specialized proteins, and protein complexes, to assist incorrectly folded proteins to find their proper conformations.

One of the most common of folding errors results from the incorrect *cis–trans* isomerization of the amide bond adjacent to a proline residue:

Unlike other peptide bonds in proteins, for which the *trans* isomer is highly favored (by a factor of about 1000), proline residues favor the *trans* form in the preceding peptide bond by a factor of only about 4. Therefore, there is a significant chance that the conformationally incorrect *cis* isomer will form first. Conversion to the *trans* configuration may involve a significant chain rearrangement and hence may be slow *in vitro*. Cells have an enzyme, called **prolyl isomerase** (or peptideprolyl isomerase, or PPIase), to catalyze this *cis–trans* isomerization, and thus speed *in vivo* folding.

Similarly, for proteins containing disulfide bonds, some disulfide bonds that are not found in the native structure may be formed in intermediate stages of the folding process. The protein can utilize a number of alternative pathways to fold; but, it ultimately finds both its proper tertiary structure and the correct set of

Protein folding can be rapid but seems to involve well-defined intermediate states.

The molten globule is a compact, partially folded intermediate state that has native-like secondary structure and backbone folding topology, but lacks the defined tertiary structure interactions of the native state.

In the “energy landscape” model, the trajectory of protein folding is “downhill”—it proceeds with a decrease in free energy.

Folding can be delayed by trapping of molecules in “off-pathway” states.

disulfide bonds. This process is aided *in vivo* by catalysis of —S—S— bond rearrangement by the enzyme **protein disulfide isomerase** (or PDI). If a non-native disulfide forms during folding in the endoplasmic reticulum of eukaryotes (or the periplasmic space in prokaryotes), PDI will reduce the incorrect disulfide and thereby allow the protein to continue folding toward its native structure.

Backbone Topology and Contact Order

Two factors appear to play dominant roles in determining the rate of protein folding. The first is size. In general, smaller proteins fold faster than larger ones, although the presence of multiple disulfide bonds (e.g., as in BPTI) can slow folding significantly. The second factor is backbone topology, or the arrangement of the peptide main chain in 3-D space. Figure 6.30 shows two different main chain topologies, one for two mainly β proteins (6.30a and b) and another for two $\alpha + \beta$ proteins (6.30c and d). Any given topology will define a set of local interactions (i.e., those that occur between residues that are close in sequence) and nonlocal interactions (i.e., those that occur between residues that are far apart in the primary sequence). The relative percent of nonlocal interactions is reflected in the **contact order** for a protein. Contact order is calculated as the average sequence separation between residues that physically contact in the native state, divided by the total number of residues in the sequence. This somewhat abstract idea is illustrated graphically in Figure 6.30e. A protein in which the N- and C-termini are in contact will have a relatively high contact order because the termini represent the maximum possible separation in sequence. Of interest to the current discussion is the observation of the remarkable correlation between contact order and folding rate (k_f in Figure 6.30f). As contact order, or the number of nonlocal interactions, *increases*, the folding rate *decreases*. Note that the values of folding rates in Figure 6.30f span a million-fold range. Another general trend from data like those in Figure 6.30f is that all-helical proteins tend to fold faster than all β -sheet proteins.

Proteins with lower contact order tend to fold faster than those with high contact order.

Protein folding and assembly *in vivo* is sometimes aided by chaperone proteins.

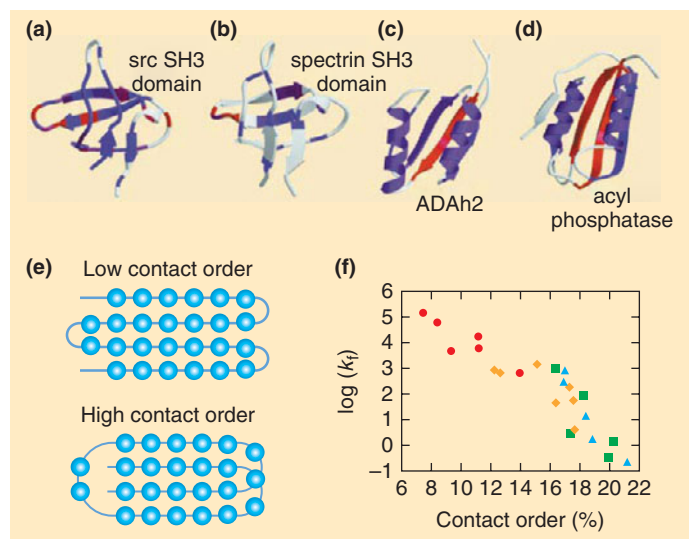

Chaperones

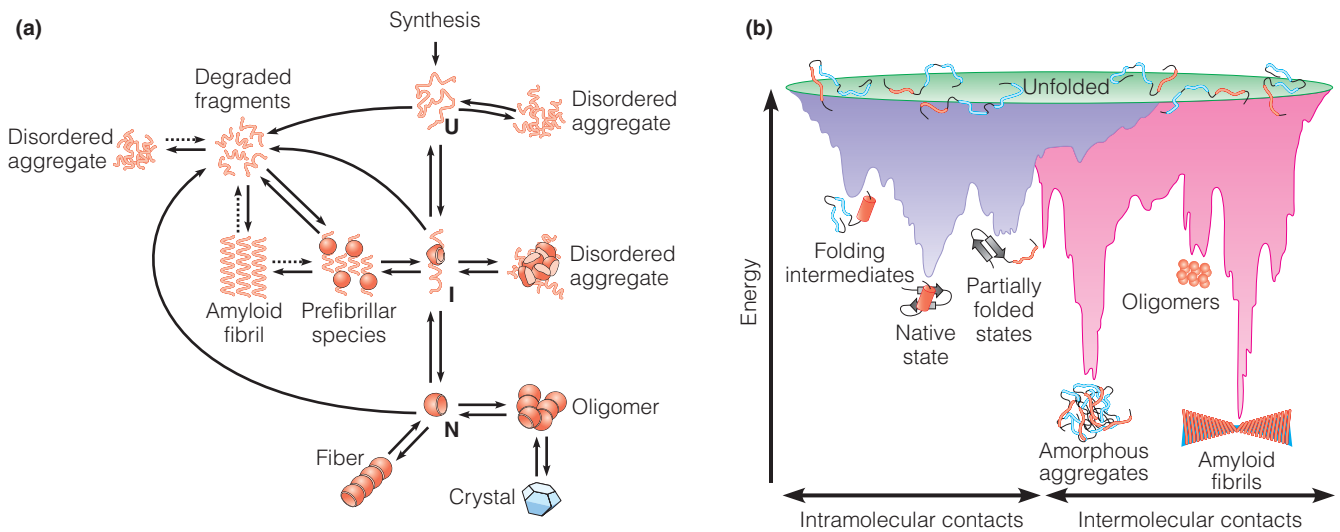

The fact that a protein can, by itself, find its proper folded state *in vitro* does not necessarily mean that the same events occur *in vivo*. We have already noted two of the catalytic aids to folding that are present in cells, the enzymes that accelerate the *cis-trans* isomerization at proline residues, and those that catalyze disulfide bond rearrangement; however, some proteins require the action of specialized proteins called **molecular chaperones** to achieve proper folding. As the name implies, the function of these chaperones is to keep the newly formed protein out of trouble. Trouble, in this case, means either improper folding or aggregation.

FIGURE 6.30

Protein topology and folding rates. Panels (a) and (b) show two proteins with very different primary sequences but similar topologies. Likewise for panels (c) and (d). The two SH3 domains fold with similar rates, as do ADAh2 and acyl phosphatase, suggesting that protein topology is an important factor in determining the rate of protein folding. (e) Examples of low and high contact order (see text). (f) Correlation of folding rate to contact order. Proteins with higher contact orders tend to fold with slower rates. Data are shown for all-helical proteins (red circles), all-sheet proteins (green squares), and proteins containing both helix and sheet (orange diamonds and blue triangles). The blue triangles correspond to those proteins that are structurally similar to acyl phosphatase (Panel (d)).

Improper folding may correspond to being trapped in a deep local minimum on the energy landscape (see Figure 6.31). Aggregation is often a danger because the protein, released from the ribosome in an unfolded state, will have hydrophobic groups exposed. These can form *intermolecular* hydrophobic contacts with other polypeptide strands and thereby lead to aggregation.

A molecular chaperone can be defined as an accessory protein that binds to and stabilizes a non-native protein against aggregation and/or helps it achieve folding to its native structure; but, is not part of the final functional structure of the correctly folded protein. A number of chaperone systems have been discovered, and we discuss their variety in Chapter 28, where we describe in detail the processing that proteins receive in different cell types. For now, we consider, as an example, the best studied of all chaperones: the GroEL-ES complex from *E. coli*. The structure of this enormous and remarkable complex (see Figure 6.32) consists of two basic portions—GroEL and GroES. GroEL is made of two rings each consisting of seven protein molecules, or “subunits.” The center of each ring is an open cavity, accessible to the solvent at the ends. Either cavity can be “capped” with GroES, a seven-membered ring of smaller protein subunits. Such double-ringed chaperone complexes are also known as **chaperonins**.

The cavity in the GroEL-GroES complex provides a favorable environment in which non-native protein chains of up to ~60 kDa can fold properly. The chaperonin does not stipulate the folding pattern; that is determined by the protein sequence. However, insulation from the environment prevents aggregation or misfolding. The folding cycle experienced by a protein molecule is schematically shown in Figure 6.32e. The unfolded protein enters into an open form of the GroEL ring lined with hydrophobic residues. Subsequent to ATP and then GroES binding, the enclosed cavity changes conformation, presenting a hydrophilic, negatively charged surface. This releases the protein from the walls of the cavity, whereupon it folds and is then released from the chaperonin. Note that ATP is required, presumably to drive the process in one direction.

Why are chaperones needed in cells? First, the intracellular environment is very crowded. The total concentration of proteins and other macromolecules inside cells is on the order of 300–400 grams per liter, or roughly 1000 times more concentrated than is typical for *in vitro* studies of folding. Intermolecular interactions are more likely to occur in such a concentrated intracellular “stew”; thus, aggregation of misfolded or incompletely folded proteins is problematic *in vivo*. Second, chaperones play a critical role in protecting cellular proteins during times of stress. In fact, many chaperones were discovered during studies of the heat shock response. When the temperature inside cells is raised by a few degrees

Celsius, so-called **heat shock proteins** (Hsp proteins) are produced by cells. For example, GroEL is also known as Hsp60. We now know that the Hsp proteins are preventing irreversible denaturation of cellular proteins. Once the temperature is restored to normal, any temperature-sensitive proteins can be refolded; thus, the viability of the cell is preserved through the action of molecular chaperones. Finally, it has been suggested that chaperones provide a critical mechanism for cells to survive mutations that might render a protein less stable and/or more susceptible to misfolding.

Understanding the mechanisms of protein folding and how folding occurs in cells is of profound importance given the number of diseases associated with protein misfolding. In addition, with the vast amount of protein sequence information available from genomics studies, the prediction of protein tertiary structure from sequence remains an outstanding challenge in molecular biology and biophysics.

Protein Misfolding and Disease

A broad range of diseases is associated with protein misfolding. A few misfolding diseases, such as cystic fibrosis, are the consequence of mutations that reduce the stability of a critical protein, thereby leading to its misfolding and subsequent clearance by cellular quality control processes (e.g., via the **proteasome**, which is discussed in Chapter 20). However, most human misfolding diseases are associated with the formation of highly ordered protein aggregates called **amyloid fibrils** or **amyloid plaques**. Proteins that misfold to form amyloid structures are said to be “amyloidogenic.” Table 6.6 lists a few examples of amyloidogenic proteins associated with human disease states.

TABLE 6.6 Examples of amyloid-related human diseases

Disease	Associated Protein
Alzheimer's disease	Amyloid β or " $A\beta$ " peptide
Parkinson's disease	α -Synuclein
Spongiform encephalopathies (e.g., Creutzfeldt-Jakob disease; kuru; etc.)	prion protein
Amyotrophic lateral sclerosis (Lou Gehrig's disease)	Superoxide dismutase I
Huntington's disease	Huntingtin with polyQ tracts
Cataract	γ -Crystallins
Type II diabetes	Islet amyloid polypeptide (IAPP)
Injection-localized amyloidosis	Insulin

Although some proteins, or fragments thereof, are predisposed to form amyloid fibrils under physiological conditions, many other proteins can be induced to form amyloid structures under extreme conditions (e.g., high or low pH, elevated temperature, etc.). This observation led Chris Dobson to propose the hypothesis that the amyloid structure is a generic low-energy conformation accessible to all peptides. A corollary to this hypothesis is that the folding pathways of soluble proteins have evolved to avoid amyloid formation, even though amyloid may be the most thermodynamically stable conformation for proteins (see Figure 6.31b).

Amyloid fibrils are characterized by highly organized arrays of β structure. Figure 6.33a shows two electron microscopy images of insulin amyloid fibrils. These fibrils are formed from a right-handed helix of four "protofibrils" (Figure 6.33b). Each protofibril, in turn, is formed from a highly ordered array of parallel β sheets separated by roughly 1.0 nm (Figure 6.33c). This so-called **cross- β** structure is a characteristic of amyloids. Studies on amyloidogenic peptides indicate the amyloid formation under physiological conditions is slow; however, protofibrils and fibrils form rapidly once the cross- β structure is nucleated.

The structure of amyloid and its mechanism of formation have been studied extensively in the hope of finding therapeutic interventions for misfolding

Protein misfolding is the basis for several diseases, including Alzheimer's disease and Parkinson's disease.

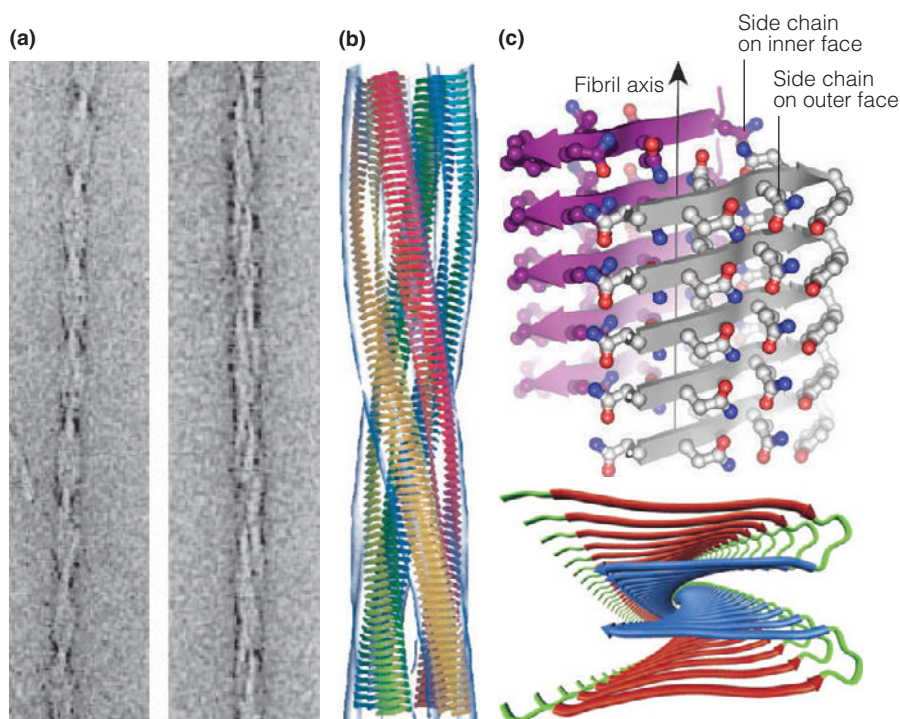

FIGURE 6.33

Amyloid fibril structure. (a) Electron micrographs of amyloid fibrils of insulin. (b) A model of insulin amyloid fibrils fitted to electron density data from cryo-electron microscopy. Four protofibrils wind together to form a right-handed helix. (c) The cross- β structure of the protofibril. The top figure shows the X-ray crystal structure of protofibrils formed from the GNNQY peptide from the yeast prion protein Sup35. The bottom figure shows a model of the protofibril formed from residues 1–40 of the $A\beta$ peptide. Solid-state NMR data were used to derive this model.

diseases. The formation of amyloid fibrils (Figure 6.33a) is thought to occur from non-native conformations of proteins such as folding intermediates or disordered aggregate states (Figure 6.31a). Recent experiments suggest that the amyloid fibrils *per se* are not responsible for causing disease; rather, it appears that the toxic species may be the prefibrillar or disordered aggregates that are precursors to amyloid formation. In some cases, increasing the intracellular concentration of chaperones reduces formation of these pre-fibrillar aggregates and reduces the toxicity associated with protein misfolding. Similar effects have been observed for low molecular weight compounds that can bind to, and thereby stabilize, the native structures of amyloidogenic proteins (see Tools of Biochemistry 6C).

Among the amyloidogenic proteins, **prions** are remarkable. Until very recently, virtually all researchers believed that the only ways in which diseases could be transmitted from one organism to another were via viruses or microorganisms. However, there is now evidence that a class of diseases is transmitted by a protein and nothing more. The most notorious of these diseases is *bovine spongiform encephalopathy*, or “mad cow disease,” but they also include *scrapie* in sheep and certain neuropathologies in humans (see entries in Table 6.6). The infectious agent has been termed *prion*, and the protein believed to be responsible is called *prion-related protein*, or *PrP*. The PrP is normally present in many animals (including humans) in a nonpathological form called PrP^c (*prion-related protein cellular*). Under certain circumstances PrP^c can change conformation to a different structure called PrP^{sc}, or *prion-related protein scrapie*. It is this form, in which the intrinsically disordered N-terminal portion of PrP appears to at least partially fold into a β sheet, that wreaks havoc with the nervous system. Even more remarkable is the fact that ingesting PrP^{sc} can induce conversion of PrP^c in the recipient to PrP^{sc}; thus the condition is transmitted. How this conversion is catalyzed is unknown, but it strongly suggests that PrP^{sc} represents an especially stable off-path folding of the type hypothesized in the preceding section. All known prion diseases are untreatable and fatal. In 1997 Stanley Prusiner was awarded the Nobel Prize in Physiology or Medicine for his work in defining the relationship of PrP to these diseases.

Motions Within Globular Protein Molecules

Globular proteins are not static but continually undergo a wide variety of internal motions.

Much evidence, particularly from NMR studies, indicates that various kinds of motions are continually occurring within folded protein molecules. A protein molecule undergoes continued, rapid fluctuations in its energy, as a consequence of interactions with its environment. The resulting motions can be roughly grouped into three classes, as shown in Table 6.7. Class 1 motions occur even within protein molecules in crystals and account, in part, for the limits of resolution obtainable in X-ray diffraction studies. The larger, slower motions in classes 2 and 3 are more likely to occur in solution. Some of them, like the opening and closing of clefts in molecules, are thought to be involved in the catalytic functions of enzymes. As we shall see in later chapters, how long it takes for a protein to bind or release a small molecule may depend on the time required for the protein to open or close a cleft. Similarly, the protein channels that pass molecules and ions through membranes

TABLE 6.7 Motions in protein molecules

Class	Type of Motion	Approximate Range	
		Amplitude (nm)	Time (s)
1	Vibrations and oscillations of individual atoms and groups	0.2	10^{-15} – 10^{-12}
2	Concerted motions of structural elements, like α helices and groups of residues	0.2–1	10^{-12} – 10^{-8}
3	Motions of whole domains; opening and closing of clefts	1–10	$\geq 10^{-8}$

rapidly change from open to closed states. It seems likely that the dynamic behavior of proteins is at least as important in their function as are the static details of their structure. In fact, an emerging area of protein research is the characterization of so-called intrinsically unstructured proteins. This class of proteins possesses significant regions of sequence that are highly dynamic and remain unstructured until one of several possible partner proteins is bound.

Prediction of Secondary and Tertiary Protein Structure

Can protein structure be predicted? In one sense, the answer to this question must surely be yes. We know that the molecular information necessary to determine the secondary and tertiary structures is carried in the amino acid sequence itself; thus, the gene “predicts” the structure. The implication of this fact is that if we fully understood the rules of folding, we could describe the entire three-dimensional conformation of any protein, starting with nothing more than a knowledge of its sequence. This kind of prediction cannot yet be done completely. We can predict secondary structure fairly reliably. Prediction of tertiary folding is a much more complicated problem; however, significant progress in this area has been made in recent years.

Prediction of Secondary Structure

Although a number of approaches have been applied to the problem of predicting secondary structure, the most successful method is entirely empirical. From analysis of the *known* structures of a number of proteins, tables have been compiled to show the relative frequency (P_α, P_β, P_t) with which a particular kind of amino acid residue lies in α helices, β sheets, or turns. An example of such a compilation is given in Table 6.8. From these data, certain clear distinctions can be

Protein secondary structure can now be predicted with good accuracy. The *de novo* prediction of more complex tertiary structure is not yet as accurate.

Prediction of the secondary structure of BPTI. The sequence on the left shows the secondary structural elements predicted by P. Y. Chou and G. D. Fasman for bovine pancreatic trypsin inhibitor. The sequence on the right shows the results of X-ray diffraction studies of the same protein. The exceptionally good agreement found between the predicted and observed structures is somewhat better for BPTI than for most proteins.

made. For example, Ala, Leu, Met, and Glu are all strong helix formers; Gly and Pro do not favor helices. Similarly, Ile, Val, and Phe are strong β sheet formers, whereas Pro does not fit well into β sheets. Gly is frequently found in β turns, whereas Val is not. We have already mentioned that Pro tends to lie in turns. Why other residues are generally found in one structure or another is not so clear. Various rules have been proposed to use P values to predict structures; those developed in the 1970s by P. Y. Chou and G. D. Fasman were used to predict the secondary structure of BPTI from its sequence (Figure 6.34).

In addition to P values, patterns of side chain polarity are used to predict secondary structure. A stretch of alternating polar and nonpolar residues is diagnostic for a β strand that is part of an amphiphilic β sheet. Similarly, a pattern of side chains with similar polarity every 3–4 residues indicates amphiphilic α helix.

The structures predicted by applying these guidelines often agree fairly well, although never exactly, with secondary structures determined experimentally (Figure 6.34). Differences are most frequently found in definition of the precise location of the ends of α and β regions.

As the amount of structural data stored in public databases grows, so too does the sophistication of the computational methods used to make structural predictions from sequence data. As of 2007 the accuracy of the best predictions was ~80% (up from ~70% just a few years previously). Today, many different algorithms exist online to make rapid predictions of secondary structure from amino acid or gene sequence information (see the References section at the end of this chapter).

Tertiary Structure Prediction: Computer Simulation of Folding

The prediction of tertiary structure has proved much more difficult, probably because the higher-order folding depends so critically on specific noncovalent interactions, often between residues far removed from one another in the sequence. In spite of the difficulty of the problem, recent efforts in *de novo* structure prediction have met with spectacular success. Figure 6.35 shows the results of two recent *de novo* predictions that were achieved at high resolution *before* the X-ray crystal structures for the protein sequences were released publicly. The close agreement between the predicted structures and the crystal structures is remarkable, and bodes well for the future of *de novo* structure prediction from amino acid sequence.

The prediction of tertiary structure from amino acid sequence is fundamentally a problem in energy minimization requiring sophisticated computation. The underlying assumption is that the native functional conformation for a polypeptide is the conformation with the lowest value of free energy.* Thus, during folding, proteins are seeking a global free energy minimum. To understand the process, let us consider the oversimplified case of a computer simulation in which a random-coil chain is allowed to undergo a very large number of small permutations in its conformation, through rotation about individual bonds. For each conformation generated by the computer, the total energy of all noncovalent interactions is calculated using a table of parameters called a “force field,” or “potential function.” The values of total energy for each conformation are then compared, and the conformation with the lowest energy is considered to be a better candidate for the

*This is a reasonable assumption for most proteins; however, there are a few notable exceptions (e.g., see: D. Baker, J. L. Sohl, and D. Agard, *Nature* (1992) 356:263–265), and more are likely to be discovered in the future.

FIGURE 6.35

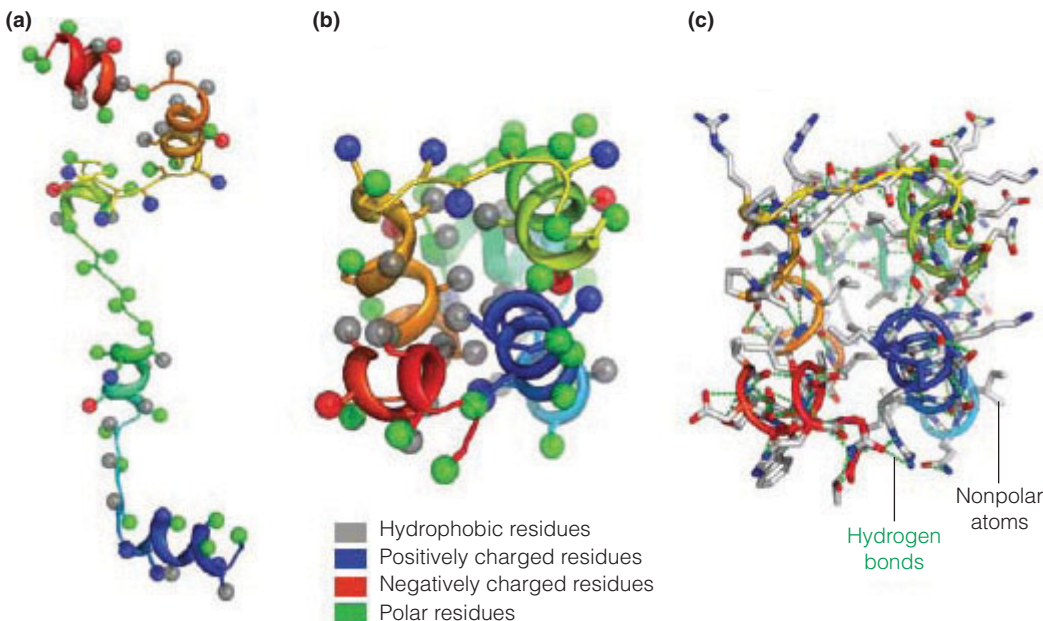

Comparison of *de novo* predictions to X-ray crystal structures. native structure. This process may be repeated for up to a million conformations before the computation converges on a single lowest energy conformation.

These methods have two basic requirements. The first is a potential function that calculates energies with good accuracy. Most of the current potential functions are based on quantum mechanics and make certain simplifying assumptions about solvent interactions. The second requirement is a tractable method for sampling the vast number of possible conformations that ensures the true global minimum is ultimately found, rather than some local minimum on the energy landscape. A simple random search through all possible conformations is an impossible task; it is, in essence, confronting the Levinthal paradox with a computer. The massive computational power required for such a random search simply does not exist. Somehow, a search for the true energy minimum must be more directed.

Many researchers have devised elegant solutions to this problem. For the purposes of our discussion we will focus on only two of these. The first is the use of empirically derived folding “fragments,” or short structural motifs, employed by the Rosetta suite of algorithms, developed in the lab of David Baker. Rosetta has not only been used to successfully predict structure *de novo*, it has also been successfully applied to *de novo* protein-design problems. Rosetta first matches local regions of amino acid sequence to a library of structural fragments derived from high-resolution crystal structures (see Figure 6.36a). In essence, Rosetta assigns the most likely local secondary structure based on sequence homology to proteins with known structures (see Tools of Biochemistry 5D). These assembled structural fragments are then packed together in ways that give low-energy conformations. For this part of the calculation Rosetta doesn’t consider atomic detail for the side chains; rather, a simpler classification in terms of polarity and charge is used (Figure 6.36b). Finally, the side chains are added back to the simulation, and the conformation with the

Experimental data from NMR and cryo-electron microscopy can be used to improve the successful prediction of protein tertiary structure by computational methods.

...TPPVQAAYQKVVAGVANA...

FIGURE 6.37

The four levels of protein structure. This summary of the structural levels of protein uses the hemoglobin molecule (PDB ID: 2HHB), a tetramer of myoglobin-like chains, as an example.

Association of polypeptide chains to form specific multisubunit structures is the quaternary level of protein organization.

lowest calculated energy is sought, as described in the preceding paragraphs (Figure 6.36c). This entire process is repeated, starting from many hundred assembled secondary structure fragments, until Rosetta converges on a final low-energy conformation, which is calculated using a potential function that accounts for the energies associated with the hydrophobic effect (i.e., burial of hydrophobic side chains), close packing of interior groups in the final structure (i.e., maximizing van der Waals contacts), and intramolecular H-bond formation (i.e., no unsatisfied H-bond donors or acceptors for buried groups). In summary, Rosetta solves the conformational search problem by making educated guesses for local structure, thereby dramatically restricting the number of possible conformations that must be sampled.

A second approach, which shows great promise, is the use of experimental data to restrict the conformational search. NMR chemical-shift data (which report on local amino acid conformation and the chemical environment of an atom; see Tools of Biochemistry 6A), information from chemical modification studies (which can be used to identify solvent-accessible side chains), and cryo-electron microscopy data (which provide constraints on backbone topology) have all been used to augment computational structure prediction. Such approaches are likely to further improve the success of de novo prediction. The need for reliable methods of de novo structure prediction is tremendous, given the fact that structures are known for only 1% of all known protein sequences.

Quaternary Structure of Proteins

In Chapter 5 and in this chapter, we have explored increasingly complex levels of protein structure, from primary to secondary to tertiary (Figure 6.37a–c). Functional protein organization can reach at least one more level—**quaternary structure** (Figure 6.37d). Many proteins exist in the cell (and in solution, under physiological conditions) as specific complexes of two or more folded polypeptide chains, or *subunits*. Methods for determining whether or not a protein is composed of multiple subunits are described in Tools of Biochemistry 6B. Such quaternary organization can be of two kinds—association between identical or nearly identical polypeptide chains (**homotypic**) or interactions between subunits of very different structures (**heterotypic**). In either case, *multisubunit proteins* are formed.

Multisubunit Proteins: Homotypic Protein–Protein Interactions

The interactions between the folded polypeptide chains in multisubunit proteins are of the same kinds that stabilize tertiary structure—salt bridges, hydrogen bonding, van der Waals forces, the hydrophobic effect, and sometimes disulfide bonding. These interactions provide the energy to stabilize the multisubunit structure.

Each polypeptide chain is an asymmetric unit in the complex, but the overall quaternary structure may exhibit a wide variety of symmetries, depending on the geometry of the interactions. For purposes of illustration, we shall use an asymmetric object familiar to everyone—a right shoe. Think of this shoe as a polypeptide chain folded into a compact three-dimensional form. We can stick shoes together in many ways. If the interacting surfaces (A and B) were at toe and heel, a linear complex could form:

Because the two interacting groups lie in entirely different regions of the subunit, we would call this interaction **heterologous**. Heterologous interactions must be specially oriented to give a truly linear complex. More often, the interaction is such that each unit is twisted through some angle with respect to the preceding one. This twisting gives rise to a helical structure. Figure 6.38a shows an arrangement of shoes

FIGURE 6.38

Symmetries of protein quaternary structures. Although composed of asymmetric polypeptides, proteins adopt many symmetrical patterns in forming quaternary structures. In this figure, a right shoe represents the asymmetric structural unit. **(a)** A helix formed by rotation of each unit by $360/n$ degrees with respect to the preceding one. Such rotation produces an n -unit-per-turn helix of indefinite length. **(b)** A dimer with C_2 symmetry: one 2-fold axis. **(c)** A trimer with C_3 symmetry: one 3-fold axis. **(d)** A tetramer with C_4 symmetry: one 4-fold axis. **(e)** A tetramer with D_2 symmetry: three 2-fold axes. **(f)** A 24-mer exhibiting cubic symmetry. This structure has 4-fold, 3-fold, and 2-fold axes. **(g)** An icosahedral 60-mer, the kind of structure found in the protein coat of a number of viruses. This structure has 5-fold, 3-fold, and 2-fold axes. **(h)** An octamer with D_4 symmetry: one 4-fold axis and two 2-fold axes.

that forms a right helix with n units per turn. The top of the toe of each shoe is attached to the sole of the toe of the next, with a rotation of $360/n$ degrees. Two biological examples, both of **helical symmetry**, are shown in Figure 6.39: the helix of the muscle protein actin and the helical coat of tobacco mosaic virus. Note that both linear and helical arrays are potentially capable of indefinite growth by addition of more subunits. Actin filaments can be thousands of units in length.

Most assemblies of protein subunits are based not on helical symmetry but on one of the classes of **point-group symmetry** (Figure 6.38b–h). The classes of point-group symmetry involve a defined number of subunits arranged about one or more **axes of symmetry**. An n -fold axis of symmetry corresponds to rotation of each subunit by $360/n$ degrees with respect to its neighbor; thus, a 2-fold axis corresponds to 180° rotation. The simplest kinds of point-group symmetry are the cyclic symmetries C_n , shown in Figure 6.38b–d. These rings of subunits involve heterologous interactions where $n = 3$ or greater.

A special situation of great importance arises when two subunits are related to one another by a 2-fold axis (also called a **dyad axis**) to give C_2 symmetry. That is, each subunit is rotated by 180° about this axis with respect to the other:

(This arrangement is visualized in three dimensions in Figure 6.38b.) Imagine that there are interacting groups at A and B. For example, A could be a hydrogen-bond donor, B an acceptor. Note that in this case the 2-fold symmetry means that

Two general classes of symmetry—helical and point-group—characterize most quaternary structures.

FIGURE 6.39

Two helical proteins. Beside each electron micrograph is a diagrammatic representation of the helical aggregate structure. **(a)** Actin. **(b)** Tobacco mosaic virus. In the virus, protein subunits form a helical array about a helically coiled RNA (red).

two identical interactions occur, symmetrically placed about the dyad axis. Such a symmetric interaction is called **isologous**, as opposed to the asymmetric heterologous interaction. Isologous interactions will be found whenever 2-fold axes are present. Dimers are the most common of all quaternary structures, and they are almost always bound together in this way. An example is shown in Figure 6.40. Further isologous interactions can easily give rise to more complex quaternary structures of higher symmetry. An example is **dihedral** symmetry (Figure 6.38e), the most common structure for tetrameric proteins. It has three mutually perpendicular 2-fold axes and, therefore, involves three pairs of isologous interactions. In fact, any D_n symmetry can be generated by isologous interactions alone.

Other, more complex point-group symmetries exist in some protein quaternary structures; examples are shown in Figure 6.38f and g. Note that the more complex structures involve both 2-fold axes and axes with $n > 2$. Such molecules exhibit both isologous and heterologous interactions. Most important is that molecules exhibiting any of the point-group symmetries are always constrained to a definite number of subunits. Most multisubunit proteins exhibit this kind of association geometry, rather than the linear or helical aggregation that can lead to indefinite growth. This is why most protein molecules, even if they contain multiple subunits, have a well-defined size, shape, and mass.

Two exceptions to this simple characterization of possible structures must be noted. First, although most dimers have 2-fold symmetry and isologous binding, it is possible to construct dimers in which the binding is heterologous but indefinite association is still sterically blocked. Such dimers do not have 2-fold symmetry (Figure 6.41). A second complication is encountered whenever more than one type of polypeptide chain is incorporated into a specific multisubunit structure. In such cases the symmetry is reduced from the level you might expect from the total number of polypeptide chains because two or more different chains will now form one asymmetric unit. We consider one such example, *hemoglobin*, in Chapter 7.

Note that each level of protein structure is built on the lower levels, as summarized in Figure 6.37. Tertiary structure can be thought of as a folding of elements of secondary structure, and quaternary structure is established by combining folded subunits. All of this higher-level structuring is dictated by primary structure and

All higher levels of structure of a protein are dictated by its genes.

FIGURE 6.40

The prealbumin dimer. In the prealbumin dimer the two monomers combine to form a complete β sandwich, or flattened β barrel. The dimer has 2-fold symmetry about an axis perpendicular to the paper. The isologous interactions are mostly hydrogen bonds between specific β sheet strands: F to F' and H to H'. Prealbumin can also form a tetramer from two of these dimers by a second set of isologous interactions.

Rerat, Structure of human plasma prealbumin at 2.5 Å resolution: A preliminary report on the polypeptide chain conformation, quaternary structure and thyroxine binding. © 1974, with permission from Elsevier.

ultimately by the gene. This understanding of the relationship between protein structure and gene sequence is one of the most important ideas in molecular biology.

Heterotypic Protein–Protein Interactions

The preceding section has centered on the association of identical or near-identical protein subunits. However, the range of protein–protein interactions is much greater; specific associations between entirely different protein molecules are common. Sometimes these associations lead to organized structures containing a dozen or more different subunit types. The interactions that form these assemblies are of the same kind we described earlier—noncovalent forces at complementary protein surfaces.

Complementary interactions also determine the specific interactions between a protein, or protein complex, and its target. A simple example involves BPTI, a protein we have described in detail in this chapter. Bovine pancreatic trypsin inhibitor is so named because it forms a tight, specific complex with the enzyme trypsin, thereby inhibiting trypsin proteolytic activity in the pancreas. Figure 6.42 shows that the two protein surfaces fit one another closely.

Computational methods like those described earlier in this chapter can predict such complementary protein–protein interactions with good success. For example, the computational “docking” of BPTI with trypsin closely matches the actual structure of the complex as determined by X-ray diffraction. The accuracy of such predictions suggests that it may be easier to predict protein–protein interactions (including protein quaternary structure interactions) than it is to predict tertiary structure.

SUMMARY

Protein molecules typically have several levels of organization. The first, or primary, level is the amino acid sequence, dictated by the gene. This sequence in turn dictates local folding (secondary structure), global folding (tertiary structure), and organization into multisubunit structures (quaternary structure).

Of many conceivable secondary structures, only a limited number are sterically allowed and can be stabilized by hydrogen bonds. These include the α helix, the β sheet, and the 3_{10} helix. There are also specific structures that allow a polypeptide chain to make sharp turns. Ramachandran diagrams provide a way to visualize the possibilities, and describe various secondary structures in terms of allowed ϕ and ψ angles.

Proteins can be grouped into two broad categories—fibrous and globular. Fibrous proteins are elongated, usually of regular secondary structure, and perform structural roles in the cell and organism. Important examples include the keratins (α helix), the fibroins (β sheet), collagen (triple helix), and elastin (cross-linked random coils). Globular proteins have more complex tertiary structures and fold into compact shapes that often contain defined domains. Several classes of folding motifs have been recognized, such as α helix bundles, twisted β sheets, and β barrels.

A number of factors determine globular protein stability—conformational entropy, enthalpy from internal noncovalent bonding, the hydrophobic effect, and disulfide bonds. The folding of many globular proteins occurs spontaneously and rapidly under “native” conditions. In the cell, proteins called chaperones help prevent formation of incorrectly folded structures or undesired intermolecular interactions leading to aggregation. Even when folded, globular proteins are dynamic structures undergoing several kinds of internal motions. Protein secondary structure can be predicted with good accuracy, but prediction of tertiary structure, although improving, remains challenging.

Many (perhaps most) globular proteins exist and function as multisubunit assemblies forming a quaternary level of structure. A few of these proteins are elongated structures with helical symmetry; most have a small number of subunits (often 2, 4, or 6) and exhibit point-group symmetry. All of the levels of protein structure are determined by the gene sequence.

FIGURE 6.41

A dimer without symmetry. This schematic picture shows how two subunits can associate by heterologous interactions and still not yield an indefinite chain. The interaction sites (A, B, C, D) are blocked from reaction with more monomers by the close fit of the surfaces.

FIGURE 6.42

Interaction of BPTI with trypsin. The BPTI molecule (green, red, and blue) fits snugly onto the surface of the trypsin molecule (slate blue), blocking the active site of trypsin. The orientation of the BPTI is the same as that in Figure 6.18. PDB ID:2RA3.

PROBLEMS

- Polyglycine, a simple polypeptide, can form a helix with $\phi = -80^\circ$, $\psi = +150^\circ$. From the Ramachandran plot (see Figure 6.11), describe this helix with respect to (a) handedness and (b) number of residues per turn.
- Certain polypeptide sequences that show a pronounced tendency to dimerize in an antiparallel coiled-coil structure exhibit an exact repetition of leucine every 7 residues. If you also know that the α helix is distorted somewhat from its usual 3.6 residues/turn in coiled coils, propose a mechanism for the dimerization. What does this suggest that the residue/turn value might be in a coiled coil?
- A schematic structure of the subunit of hemerythrin (an oxygen-binding protein from invertebrate animals) is shown below.
 - It has been found that in some of the α -helical regions of hemerythrin, about every third or fourth amino acid residue is a hydrophobic one. Suggest a structural reason for this finding.
 - What would be the effect of a mutation that placed a proline residue at point A in the structure?

- In the protein *adenylate kinase*, the C-terminal region is α -helical, with the sequence

Val–Asp–Asp–**Val**–**Phe**–Ser–Gln–**Val**–Cys–Thr–His–**Leu**–Asp–Thr–**Leu**–Lys–

The hydrophobic residues in this sequence are presented in boldface type. Suggest a possible reason for the periodicity in their spacing.

- Although the bond energy for the hydrogen bond in a vacuum is estimated to be about 20 kJ/mol, we find that each hydrogen bond in a folded protein contributes much less—probably less than 5 kJ/mol—to the enthalpy of protein stabilization. Suggest an explanation for this difference.
- Consider a small protein containing 101 amino acid residues. The protein will have 200 bonds about which rotation can occur. Assume that three orientations are possible about each of these bonds.
 - Based on these assumptions, about how many *random-coil* conformations will be possible for this protein?
 - The estimate obtained in (a) is surely too large. Give one reason why.
- Based on a more conservative answer to Problem 6 (2.7×10^{92} conformations), estimate the conformational entropy change on folding a mole of this protein into a native structure with only one conformation.
 - If the protein folds *entirely* into α helix with H bonds as the only source of enthalpy of stabilization, and each mole of H bonds contributes -5 kJ/mol to the enthalpy, estimate $\Delta H_{\text{folding}}$. Note that you cannot form 4 H bonds at one end.
 - From your answers to (a) and (b), estimate $\Delta G_{\text{folding}}$ for this protein at 25 °C. Is the folded form of the protein stable at 25 °C?
- The following sequence is part of a globular protein. Using Table 6.8 and the Chou–Fasman rules, predict the secondary structure in this region.

... RRPVVLMAACLRPVVFITYGDGGTYHWHYH ...
- A protein is found to be a tetramer of identical subunits. Name two symmetries possible for such a molecule. What kinds of interactions (isologous or heterologous) would stabilize each?
 - Suppose a tetramer, like hemoglobin, consists of two each of two types of chains, α and β . What is the highest symmetry now possible?

- *10. Under physiological conditions, the protein hemerythrin exists as an octamer of eight chains of the kind shown in Problem 3.
- Name two symmetries possible for this molecule.
 - Which do you think is more likely? Explain.
 - For the more likely symmetry, what kinds of interactions (isologous, heterologous, or both) would you expect? Why?
- *11. A researcher studies the thermal denaturation of hemerythrin by two methods: (1) Using circular dichroism, which measures the α helix content (see Tools of Biochemistry 6A) and (2) using differential scanning calorimetry (see Tools of Biochemistry 6C). She observes a considerably larger ΔH by calorimetry than she finds using circular dichroism. Suggest a reason for this.
12. The peptide hormone *vasopressin* is used in the regulation of saltwater balance in many vertebrates. Porcine (pig) vasopressin has the sequence Asp-Tyr-Phe-Glu-Asn-Cys-Pro-Lys-Gly
- Using the data in Figure 5.6 and Table 5.1, estimate the extinction coefficient ϵ (in units of cm^2/mg) for vasopressin, using radiation with $\lambda = 280 \text{ nm}$.
 - A solution of vasopressin is placed in a 0.5-cm-thick cuvette. Its absorbance at 280 nm is found to be 1.3. What is the concentration of vasopressin, in mg/cm^3 ? (See Tools of Biochemistry 6A.)
 - What fraction of the incident light is passed through the cuvette in (b)? (See Tools of Biochemistry 6A.)
- *13. A protein gives, under conditions of buffer composition, pH, and temperature that are close to physiological conditions, a molecular weight by sedimentation equilibrium measurements of $140,000 \text{ g}/\text{mol}$. When the same protein is studied by SDS gel electrophoresis in the absence or presence of the reducing agent β -mercaptoethanol (BME), the patterns seen, respectively, in lanes A and B are observed. Lane C contains standards of molecular weight indicated. From these data, describe the native protein, in terms of the kinds of subunits present, the stoichiometry of subunits, and the kinds of bonding (covalent, noncovalent) existing between subunits. (See Tools of Biochemistry 6B.)

- *14. A protein gives a single band on SDS gel electrophoresis, as shown in lanes 1 and 2 below. There is little if any effect from adding

β -mercaptoethanol (BME) in the gel; if anything, the protein runs a little bit slower. When treated with the proteolytic enzyme thrombin (see Chapter 5) and electrophoresis in the absence of BME, the protein migrates a bit more rapidly (lane 3). But if BME is present, two much more rapidly migrating bands are found (lane 4). Explain these results in terms of a model for the protein.

15. It has been postulated that the normal (noninfectious) form of prion differs from the infectious form only in secondary/tertiary structure.
- How might you show that changes in secondary structure occur?
 - If this model is correct, what are the implications for structural prediction schemes?
16. Below are shown two views of the backbone representation of the Myc-Max complex binding to DNA (PDB ID: 1NPK). Myc and Max are members of the basic helix-loop-helix (bHLH) class of DNA-binding proteins (see Chapter 29). Myc (red) and Max (blue) associate via a coiled-coil interaction and bind DNA as a dimer.

- Are the helices bound to the DNA likely to be amphiphilic? Explain.
 - Where do you predict the N- and C-termini are located for Max?
17. Do you expect a Pro \rightarrow Gly mutation in a surface-loop region of a globular protein to be stabilizing or destabilizing? Assume the mutant folds to a native-like conformation. Explain your answer in terms of the predicted *enthalpic* and *entropic* effects of the mutation on the ΔG for protein folding compared to ΔG of folding for the wild-type protein.
18. Rank the following in terms of predicted rates: the nucleation of an α helix; the nucleation of a *parallel* β sheet; the nucleation of an *antiparallel* β sheet. Justify your predictions.

TOOLS OF BIOCHEMISTRY 6A

SPECTROSCOPIC METHODS FOR STUDYING MACROMOLECULAR CONFORMATION IN SOLUTION

X-ray diffraction (see Tools of Biochemistry 4A) is a very powerful method for determining the details of the three-dimensional structure of globular proteins and other biopolymers; however, this technique has the fundamental limitation that it can be employed only when the molecules are crystallized, and crystallization is not always easy or even possible. For example, proteins containing significant regions of sequence that are intrinsically unstructured are notoriously difficult to crystallize. Furthermore, X-ray diffraction cannot easily be used to study conformational changes in response to changes in the molecules' environment. Other methods, however, allow us to study molecules in the solution state. A number of these methods can be grouped in the category of **spectroscopic techniques**.

Absorption Spectroscopy

Proteins, carbohydrates, and nucleic acids are complex molecules and can absorb electromagnetic radiation over a wide spectral range; however, the basic principles of such absorption phenomena can be explained in terms of the simplest kind of molecule, a diatomic molecule.

When two atoms interact to form a molecule, the potential energy curve for the lowest-energy electronic state (the **ground state**) will look like the lower curve in Figure 6A.1a. **Excited electronic states** will have similar curves for energy vs. interatomic distance, but at higher energies. For each electronic state of the molecule, there will be a series of allowed **vibrational states**, with energy levels indicated by horizontal lines in the figure. The basics of molecular absorption spectroscopy can be understood by two simple rules: (1) Transitions are possible only between allowed energy states of the molecule (energy levels are **quantized**), and (2) the energy (ΔE) that is absorbed, or emitted, in any transition between allowed states determines the wavelength (λ) of the radiation that is absorbed, or released, to accomplish that transition. The energy in a **quantum** (or **photon**) of radiation is inversely proportional to λ

$$E_{\text{final state}} - E_{\text{initial state}} = \Delta E = \frac{hc}{\lambda} \quad (6A.1)$$

Here h is Planck's constant (6.626×10^{-34} J s), and c is the velocity of light in a vacuum (2.998×10^8 m s $^{-1}$). According to equation 6A.1, transitions with smaller energy differences between

(a)

(b)

FIGURE 6A.1

The principles of absorption spectroscopy.

(a) Electronic and vibrational transitions in a diatomic molecule.

(b) The electromagnetic spectrum.

states correspond to absorption (or release) of longer wavelength radiation, and transitions with larger energy differences correspond to absorption (or release) of shorter wavelength radiation. This relationship is in accord with Figure 6A.1b, which indicates that the high-energy transitions between electronic states of a molecule lead to absorption in the visible or ultraviolet region of the spectrum, whereas the low-energy transitions between different vibrational energy levels correspond to absorption of infrared energy.

Complex biopolymers like proteins and nucleic acids can undergo many kinds of molecular vibrations and oscillations. **Infrared spectroscopy** can therefore provide direct information concerning macromolecular structure. For example, the exact positions of infrared bands corresponding to vibrations in the polypeptide backbone are sensitive to the conformational state of the protein backbone (α helix, β sheet, and so forth). Thus, studies in this region of the spectrum are often used to investigate the secondary structural features in protein molecules.

Most biopolymers do not absorb visible light to a significant extent. Some proteins are colored, but they invariably contain prosthetic groups (such as the heme in myoglobin) or metal ions (such as copper) that confer the visible absorption. Blood and red meat owe their color to the heme groups carried by hemoglobin, myoglobin, and other heme proteins. Such absorption can often be exploited to investigate changes in the molecular environment of the prosthetic group. An example is the use of absorption spectroscopy in the visible spectrum to follow the oxygenation of myoglobin or hemoglobin (see page 238 in Chapter 7). The most common uses of spectroscopic techniques in biochemistry involve **ultraviolet spectroscopy**. In the ultraviolet region both proteins and nucleic acids absorb strongly (Figure 6A.2). The strongest protein absorbances are found in two wavelength ranges within the ultraviolet region, at approximately 280 and 220 nm. In the range 270–290 nm, we see absorbance by the aromatic side chains of phenylalanine, tyrosine, and tryptophan. Because this region of the spectrum is easy to study, absorbance at 280 nm is used routinely to measure protein concentrations. The second region of strong absorbance in the protein spectrum lies in the range 180–220 nm. Absorbance at such wavelengths arises from electronic transitions in the polypeptide backbone itself and is therefore sensitive to the backbone conformation.

Spectroscopic measurements of protein concentration use a **spectrophotometer**, in which a cuvette with a light path of length l

FIGURE 6A.2

The near-ultraviolet absorbance spectra of a typical protein and of DNA. Absorbance at 280 nm is commonly used to measure protein concentrations, whereas absorbance at 260 nm is more sensitive for nucleic acids.

containing a solution of the protein is placed in a beam of monochromatic radiation of intensity I_0 (Figure 6A.3). The intensity of the emerging beam will be decreased to a value I because the solution absorbs some of the radiation. The **absorbance** at wavelength λ is defined as $A_\lambda = \log(I_0/I)$ and is related to l and the concentration c by the **Beer-Lambert law**:

$$A = \epsilon_\lambda l c \quad (6A.2)$$

Here ϵ_λ is the **extinction coefficient** (or **molar absorptivity**) at wavelength λ for the particular substance being studied (see Problem 12). The dimensions of ϵ_λ depend on the concentration units employed. When protein concentration is measured in molarity (M) and l in cm, then ϵ_λ must have the dimensions $\text{M}^{-1}\text{cm}^{-1}$, because A is a dimensionless quantity. Note that the molar absorptivities of the aromatic amino acids differ in the order: Trp > Tyr \gg Phe (see Figure 5.6, page 143. Note that Cys also absorbs at 280 nm, albeit 10-fold less than Tyr).

Once the molar absorptivity for a particular protein has been determined (for example, by measuring the absorbance of a solution containing a known mass of the protein), the concentration of any other solution of that protein can be calculated from a simple absorbance measurement, using Equation 6A.2. The same method is routinely used with nucleic acids, but in that case a wavelength of 260 nm is usually employed because nucleic acids absorb most strongly in that spectral region.

FIGURE 6A.3

Measurement of light absorption with a spectrophotometer.

Fluorescence

In most cases, molecules raised to an excited electronic state by absorption of radiant energy return, or “relax,” to the ground state by **radiationless transfer** of the excitation energy to surrounding molecules. In short, the energy of relaxation most often is manifested as heat rather than an emitted photon. As shown in Figure 6A.4a, an excited state molecule can lose a small part of its energy of excitation by radiationless transfer (yellow arrow) and will lose the larger part in the form of an emitted photon (red arrow). This gives rise to the phenomenon called **fluorescence**. Because, as Figure 6A.4a shows, the quantum of energy re-emitted as fluorescence is always of lower energy than the quantum that was initially absorbed (blue arrow), the wavelength of the emitted light will be longer than the wavelength of the light used for excitation. The **fluorescence emission spectrum** of tyrosine is contrasted with its absorbance (or **excitation**) spectrum in Figure 6A.4b. In proteins, tyrosine and tryptophan are the major fluorescent groups. The local environment of these residues can greatly modify the intensity and wavelength of maximum fluorescence (the so-called λ_{max}). For example, the fluorescence λ_{max} shifts to shorter wavelength (a “blue-shift”) and the intensity of the fluorescence signal increases as the polarity of the solvent surrounding a tryptophan residue decreases. Tryptophan residues buried in the hydrophobic cores of proteins can have values for λ_{max} that are blue-shifted by 10 to 20 nm compared to tryptophans in solvent-accessible locations; thus, fluorescence spectroscopy of tryptophan can be used to monitor changes in protein conformation, such as the transition from a folded to a denatured state.

Further, excitation of fluorescence by plane polarized light (see the next section) provides a way of studying the dynamics of protein structure. If the excited residues are able to move or rotate appreciably between the excitation and emission events, the fluorescence will be depolarized to some extent. Measurement of the extent of this depolarization provides a measure of group or molecule rotational mobility.

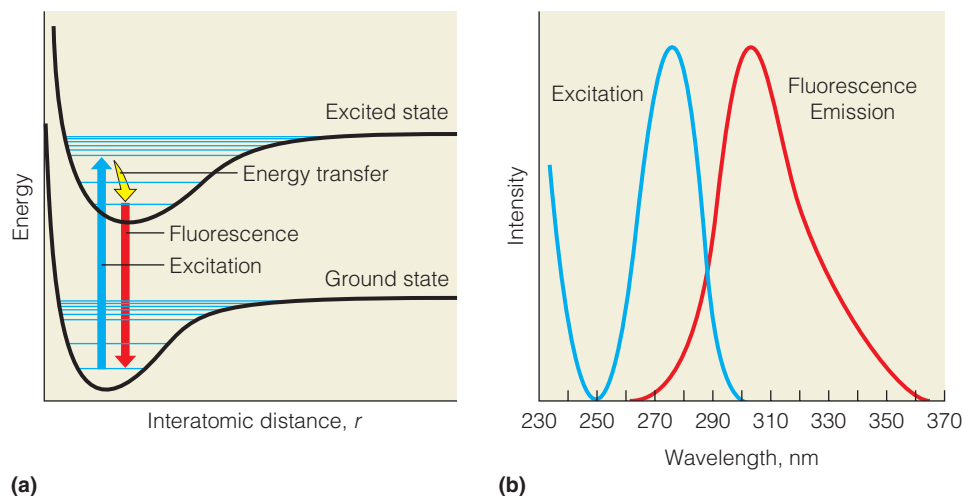

FIGURE 6A.4

Fluorescence. (a) The principle of fluorescence. (b) Excitation and fluorescence-emission spectra of tyrosine (note: the y-axes for excitation and emission are different).

FIGURE 6A.5

Fifteen different fluorescent proteins, each with a distinct fluorescence spectrum, are shown. The emission spectra of some of these proteins are shown in Figure 6A.6.

Roger Tsien Lab/Composite by Paul Steinbach.

Because fluorescence spectroscopy is a technique that can detect a small number of fluorescent molecules, it has become widely used as a tool for precisely locating proteins in cells or subcellular organelles. Confocal microscopy (see Tools of Biochemistry 1A) allows such location, if the protein can be specifically labeled. Sometimes this can be done by covalently attaching fluorescent dyes, but this is challenging *in vivo*. A powerful new technique uses a highly fluorescent protein found in some jellyfish, called **green fluorescent protein** (GFP, Figure 6A.5). The intense fluorescence is due to an unusual chromophore, generated by oxidation of the amino acid sequence Ser-Tyr-Gly. GFP is used most effectively as a **fusion protein**; the gene for GFP is fused to the gene for the protein being studied, and the fused product is expressed in the organism of interest. In many cases the fusion protein functions and localizes like the native protein, and provides a brilliant marker in microscopy. Several variants of GFP have been developed that absorb and fluoresce across the visible spectrum (Figure 6A.5 and 6A.6). The impact of fluorescent-protein fusion technology on our understanding of the timing and location within cells of gene expression, protein movement, and changes in pH and/or Ca^{2+} levels was recognized by the 2008 Nobel Prize in Chemistry, shared by Osamu Shimomura, Martin Chalfie, and Roger Tsien.

Förster Resonance Energy Transfer (FRET)

Using fluorescent fusion proteins it is possible to detect protein–protein interactions or protein conformational change by **Förster resonance energy transfer (FRET)**. In FRET an excited fluorescent “donor” transfers energy to a nearby ground-state “acceptor” in a nonradiative process. The donor returns to its ground state without fluorescence, but the excited acceptor can now emit the excess energy received from the donor by fluorescence. In effect, excitation of the *donor* results in fluorescence emission by the *acceptor* at a wavelength that is longer than the emission λ_{\max} of the donor (Figure 6A.7). The energy transfer in FRET is achieved via

FIGURE 6A.6

Fluorescence emission spectra of several fluorescent proteins.

The emission λ_{\max} (nm) is listed above each peak. The spectra were generated from data available at: <http://www.tsienlab.ucsd.edu/Documents/REF-FluorophoreSpectra.xls>.

FIGURE 6A.7

Förster resonance energy transfer (FRET). FRET is a nonradiative transfer of energy from an excited donor to a nearby ground-state acceptor. Excitation (dotted lines) and emission (solid lines) spectra are shown for cyan fluorescent protein (CFP) and yellow fluorescent protein (YFP). Note the extensive overlap between the emission spectrum of CFP and the excitation spectrum of YFP.

long-range dipole–dipole interactions between the donor and acceptor; thus, the efficiency of FRET depends on the distance between the donor and acceptor as well as the overlap between the emission and excitation spectra, respectively, of the donor and acceptor. The efficiency of FRET depends on $1/r^6$, where r is the distance between the donor and acceptor, which must be closer than 10 nm. A commonly used donor/acceptor pair is cyan fluorescent protein (CFP; the donor) with yellow fluorescent protein (YFP; the acceptor). FRET can be used to detect interactions in whole cells between proteins fused to CFP or YFP (Figure 6A.8a).

Using a “sensor” protein labeled at its termini with an appropriate donor/acceptor pair, FRET can also monitor, *in vivo*, changes in Ca^{2+} or H^{+} ion concentrations, or the presence of some protein ligand. In the absence of the ligand or ion there is no FRET between the donor and acceptor. Upon binding the ligand, the protein sensor undergoes a conformational change that brings the donor and acceptor in proximity and FRET is observed (Figure 6A.8b).

Circular Dichroism

Although visible absorption spectroscopy and fluorescence are useful for monitoring significant changes in protein tertiary conformation due to local or global unfolding, such measurements are difficult to interpret directly in terms of changes in secondary structure. For this purpose, infrared spectroscopy (see above) and techniques involving polarized light are more informative.

Light can be polarized in various ways. Most familiar is **plane polarization** (Figure 6A.9a, top), in which the oscillating electric

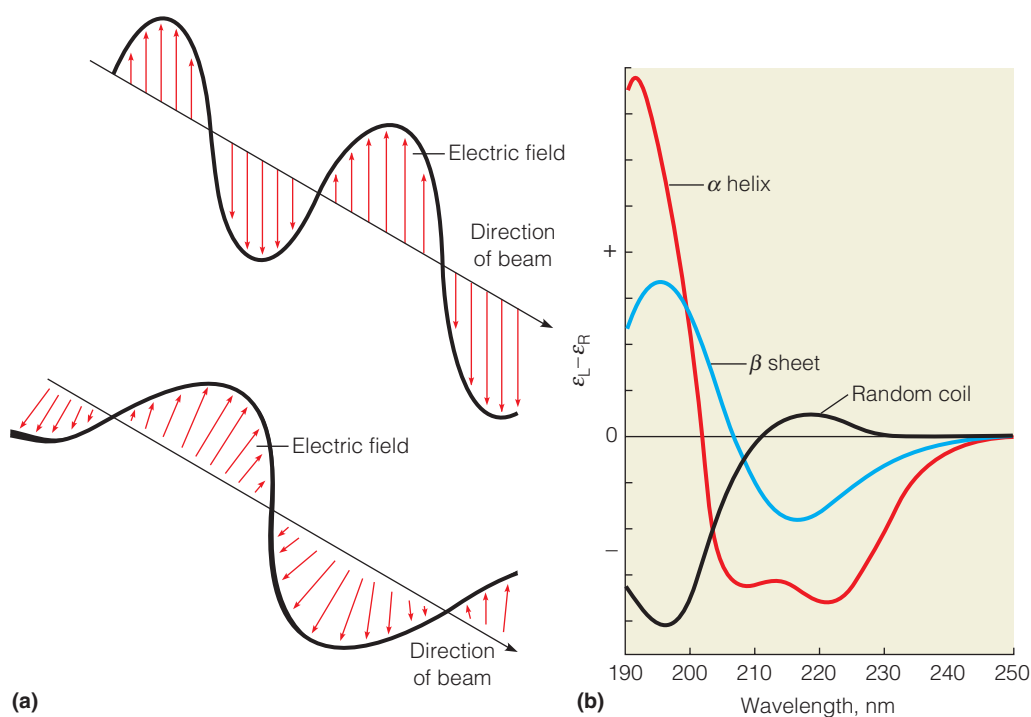

FIGURE 6A.8

Using FRET to measure protein–protein interactions, or protein conformational change.

FIGURE 6A.9

Circular dichroism. (a) Polarization of light. Above: Plane polarized light, in which the amplitude of the electric field oscillates in a single plane. Below: In circularly polarized light, the oscillation of the electric field follows a helical path around the axis describing the direction of the beam. (b) Circular dichroism spectra for polypeptides in various conformations. Here the y-axis records differences in molar absorptivity (ϵ) between left- and right-circularly polarized light.

field of the radiation has a fixed orientation in a single plane. In contrast, *unpolarized* light consists of waves vibrating in *all* planes perpendicular to the direction of travel. Less familiar, but equally important, is **circular polarization**, in which the direction of polarization *rotates* with the frequency of the radiation (Figure 6A.9a, bottom). If you observe a circularly polarized beam coming toward you, the electric field can be rotating in either a clockwise or counterclockwise direction; thus, as the light moves toward you, the oscillation of the electric field describes a right-handed or a left-handed helix. The former is called *right circularly polarized light*, the latter *left circularly polarized light*.

Most of the molecules studied by biochemists are asymmetric—for example, L- and D-amino acids, right- and left-handed protein helices, and right- and left-handed nucleic acid helices. Such molecules exhibit a preference for the absorption of either left or right circularly polarized light. For example, a right circularly polarized beam interacts differently with a right-handed α helix than does a left circularly polarized beam. This difference in absorption, called **circular dichroism**, is defined as

$$\Delta A = \frac{A_L - A_R}{A} \quad (6A.3)$$

where A_L is the absorbance for left circularly polarized light, A_R is the corresponding quantity for right circular polarization, and A is the absorbance for unpolarized light. Because ΔA can be either positive or negative, a **circular dichroism spectrum** (or **CD spectrum**) is unlike a normal absorption spectrum in that both (+) and (−) values are allowed.

Figure 6A.9b shows CD spectra for polypeptides in the α helix, β sheet, and random-coil conformations. The three spectra in the figure are very different, so circular dichroism is a sensitive technique for following conformational changes of proteins in

solution. For example, if a protein is denatured so that its native structure, containing α helix and β sheet regions, is transformed into an unfolded, random-coil structure, this transformation will be reflected in a dramatic change in its CD spectrum.

Circular dichroism can also be used to estimate the content of α helix and β sheet in native proteins. The contributions of these different secondary structures to the circular dichroism at different wavelengths are known, so we may attempt to match an observed spectrum for a protein by a linear combination of such contributions. This kind of analysis frequently turns out to agree with the secondary structure composition as determined by X-ray crystallography and NMR studies, and it has given support to the idea that the structures of globular proteins observed in crystals are preserved when the crystals are dissolved in buffer solutions at physiological pH.

Although circular dichroism is an extremely useful technique for monitoring global changes in protein or nucleic acid structures, it is not a high-resolution one. That is, it cannot provide insight into biomolecular structure at the level of atomic detail.

Two methods that can provide the details of structure at the atom level are X-ray crystallography (introduced in Tools of Biochemistry 4A) and **nuclear magnetic resonance spectroscopy** (NMR; described in the next section). The influence of these two structure-determination methods on the field of biochemistry is profound. Our detailed understanding of the functions of biomolecules is enhanced by, and in some cases based on, the knowledge of the high-resolution structures obtained by these methods. The first report of an X-ray crystal structure of a protein (myoglobin), published in 1958 by Nobel laureate John Kendrew and coworkers, established crystallography as the standard technique for the determination of high-resolution structures. As of 2011,

more than 12 X-ray crystallographers had received Nobel prizes for their significant achievements in the determination of protein and/or nucleic acid structures. The first structure of a protein determined by NMR methods (proteinase inhibitor IIa) was published in 1985 by Kurt Wüthrich and coworkers. It took some time for NMR to become widely accepted as a reliable method for high-resolution structure determination. However, that is no longer in doubt, and in 2002 Wüthrich was awarded the Nobel Prize for his contributions to the development of NMR methods for the determination of protein structures in solution. The recent development of powerful methods for the analysis of protein structure, dynamics, and function by NMR justifies a brief introduction to some of the basic experiments in this important field.

Nuclear Magnetic Resonance Spectroscopy (NMR)

General Principles: One-Dimensional NMR

The nuclei of certain elemental isotopes have a property referred to as **spin**, which makes these nuclei behave like microscopic magnets. A limited number of isotopes have this property; some that are particularly useful to biochemists are listed in Table 6A.1. The most useful nuclei for NMR have spin states of $-\frac{1}{2}$ or $+\frac{1}{2}$. If an external magnetic field is applied to a sample containing such nuclei, the different nuclear spin states will align with or against the magnetic field and therefore have different energies. As Figure 6A.10a shows, the difference in energy (ΔE) between these two spin states increases as the strength of the external magnetic field increases. For most NMR spectrometers, a pulse of radio frequency (RF) radiation can change the orientation of the nuclear spin (or “magnetization”) in the external field, a phenomenon called nuclear magnetic resonance. Such reorientation of the nuclear magnetization is analogous to the “excited” electronic states described above. Whereas the techniques of absorption spectroscopy described above record the wavelengths of light absorbed during “allowed” *electronic* transitions, NMR spectroscopy records the frequencies of RF radiation that are absorbed when the spin states of different nuclei in a molecule become reoriented in the external field.

The energy of a nuclear spin in a magnetic field is very sensitive to the chemical environment surrounding the atom in question. The chemical environment of a nucleus is defined by factors such as the polarity, hydrophobicity, and charge state of the surroundings. For example, due to differences in chemical environments, different hydrogen nuclei in a compound will reach resonance at different field strengths. These differences are recorded in the **NMR spectrum** and are expressed in terms of **chemical shifts** (δ) defined with respect to a reference material:

$$\delta = \frac{B_{\text{ref}} - B}{B_{\text{ref}}} \quad (6A.4)$$

Here B is the field strength at which the nucleus in question reaches resonance, and B_{ref} is that for a reference nucleus. The differences between B_{ref} and B are quite small, and this fact is reflected in the units for chemical shift, which are *parts per million* or ppm. A common reference compound for protein NMR is 4,4-dimethyl-4-silapentane-1-sulfonic acid (DSS), which has a strong ^1H resonance for its nine methyl protons. This resonance is assigned the value of 0 ppm. The electronic absorption spectra described earlier in this section are obtained by plotting signal intensity vs. wavelength. Similarly, an NMR spectrum is obtained by plotting signal intensity (for each resonance) vs. chemical shift. For example, a ^1H NMR spectrum will record a peak (or “line”) for every ^1H nucleus in the molecule.

As illustrated in Figure 6A.10b, the ^1H NMR spectrum of a protein is extremely complex, containing many peaks because even relatively small proteins have several hundred protons with many overlapping resonances (e.g., human ubiquitin, with only 76 amino acid residues, contains >600 protons). Most of the ^1H resonances for aliphatic side chains occur between 0.5 and 5 ppm, whereas the backbone amide proton resonances generally occur between 6.5–10 ppm, and aromatic side chain resonances occur between 6–8 ppm. In cases where specific ^1H resonances in a protein can be identified, it becomes possible to monitor changes in the chemical environment of a specific amino acid residue. An example of such an experiment is given in Figure 6A.11, which uses NMR to generate titration curves of individual histidine residues

TABLE 6A.1 Nuclei most often used in biochemical NMR experiments

Isotope	Spin	Natural Abundance ^a (%)	Relative Sensitivity ^b	Applications
^1H	$\frac{1}{2}$	99.98	(1.000)	Almost every kind of biochemical study
^2H	1	0.02	0.0096	Studies of selectively deuterated compounds; structure determination of proteins >20 kDa
^{13}C	$\frac{1}{2}$	1.11	0.0159	Multidimensional NMR; residue assignment
^{15}N	$\frac{1}{2}$	0.37	0.0104	Multidimensional NMR; residue assignment; protein backbone dynamics
^{19}F	$\frac{1}{2}$	100.00	0.834	Substituted for H (e.g., ^{19}F -Tyr) to probe local structure
^{31}P	$\frac{1}{2}$	100.00	0.0664	Studies of nucleic acids and phosphorylated compounds

^aThe number represents the percentage of this isotope in the naturally occurring mix of isotopes of each element. Isotopes with figures that are close to 100% can be studied directly in the naturally occurring biopolymers. Rare isotopes, such as ^2H (deuterium), ^{13}C , and ^{15}N usually must be artificially enriched in the biomolecules to be studied. This is achieved by including one or more of these isotopes in the medium used to grow the organism containing the molecule of interest (usually a recombinant protein).

^bIndicates the sensitivity (relative to ^1H) of conventional NMR instruments to each isotope, when that isotope has been enriched to 100%. Low values mean that the experiment will be more difficult or time-consuming.

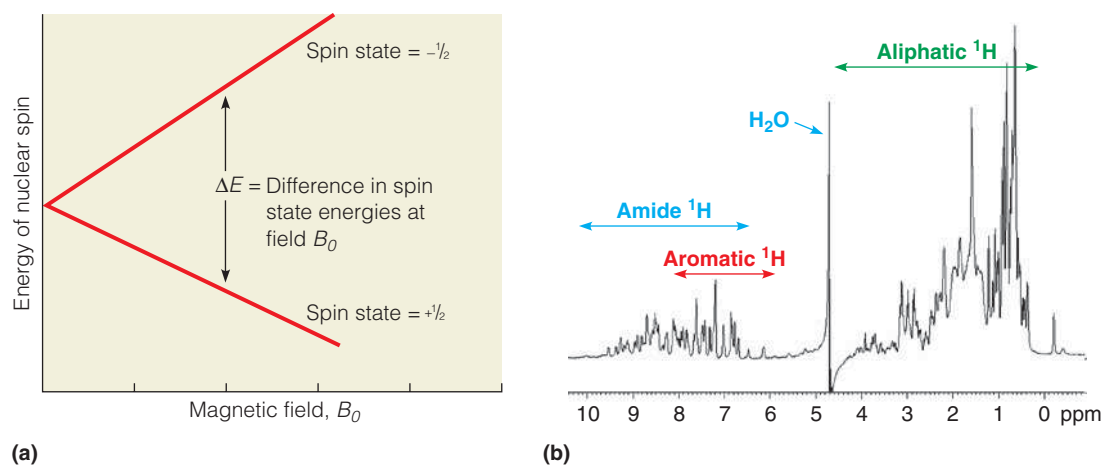

FIGURE 6A.10

in the protein ribonuclease A. The figure also graphically illustrates a principle described in Chapter 5: Individual side chains of a given amino acid type can show quite different pK_a values because of their different chemical environments within the protein molecule.

Changes in chemical shift are also correlated with conformational changes in protein structure; thus, NMR can be used to monitor dynamic motions of proteins, such as those that occur upon local or global unfolding of the polypeptide.

With modern NMR instruments, it is possible to resolve resonances for many of the ^1H nuclei in proteins as large as 30 kDa using **multidimensional techniques** (discussed below). Structure determination by solution phase NMR for proteins larger than 50 kDa is challenging. This is the major limitation on structure determination by NMR compared to X-ray crystallography; however, NMR is the more powerful technique for studying dynamic processes in solution.

Multidimensional NMR Spectroscopy

The spectrum shown in Figure 6A.10b is also known as a *one-dimensional*, or 1-D, NMR spectrum. Such 1-D data can tell us much about the behavior of individual atoms in a protein; however, the true power of NMR lies in more sophisticated *multidimensional* experiments. Discussion of the details of multidimensional NMR is beyond the scope of this basic introduction. The interested reader can find more on NMR theory in the references cited at the end of this section. Here, we present an overview of the application of multidimensional NMR to the determination of protein structure.

Multidimensional NMR techniques exploit the fact that spins on different nuclei interact or “couple” with one another either *through bonds* or *through space*. Using multiple pulses of RF energy to re-orient nuclear spins and transfer magnetization from one nucleus to its coupled partner(s), it is possible to perturb the spin of one nucleus and detect its effect on the spin states of other nuclei. Importantly, such experiments correlate the chemical shifts of the coupled nuclei, such that a detailed network of spin–spin interactions can be mapped out. It is this information that leads to the solution of the 3-D structure of the molecule under investigation. Two critical sets of data are needed to solve the 3-D structure of a protein using NMR methods: (1) A set of chemical shift

FIGURE 6A.11

Titration of the four histidine residues in ribonuclease A by NMR. The y-axis is the ^1H chemical shift and each curve follows the titration of an individual histidine group, as detected by the NMR chemical shift of a ^1H bound to either one of the two C atoms in the imidazole ring (red H atoms on ring). The labels such as H12 and H48 indicate the positions of the histidines in the primary sequence. The two histidines with lowest pK_a values (H12 and H119) are involved directly in the catalytic process.

assignments that correlate specific backbone amide ^1H and side chain ^1H resonances to at least 85% of the amino acid sequence of the protein, and (2) several hundred to thousands of distance measurements between coupled ^1H nuclei for which chemical shift assignments have been made. The chemical shift assignments are obtained from multidimensional **correlation spectroscopy** (COSY) experiments that determine through-bond coupling, and the distance measurements are obtained from the determination of through-space couplings by **nuclear Overhauser effect spectroscopy** (NOESY).

The methods used to make chemical shift assignments typically require proteins that have been enriched in the NMR-active nuclei ^{15}N and ^{13}C , which are present in low natural abundance

(see Table 6A.1). Such isotopically labeled proteins are obtained by expressing recombinant proteins in bacteria grown in medium containing, for example, $[^{15}\text{N}]\text{-NH}_4\text{Cl}$ and $[^{13}\text{C}]\text{-glucose}$ such that all the N and C atoms in the protein are labeled. Such labeling is required to resolve resonances that overlap in one dimension by projecting them in a second (or third) dimension whereby the overlap is reduced.

With ^{15}N -labeled protein a 2-D NMR experiment called $^1\text{H}/^{15}\text{N}$ **heteronuclear single quantum coherence** (or **HSQC**) can be used to resolve resonances for every backbone amide N-H group in a protein (Figure 6A.12). In this experiment, magnetization is transferred from the ^1H nucleus to the ^{15}N nucleus, then back to the original ^1H nucleus. Each magnetization transfer step records the chemical shift of the receiving nucleus and thereby establishes a “dimension” in which these data can be plotted (in this case there are two dimensions—one corresponding to the ^1H chemical shift of the amide N-H, and the other corresponding to the ^{15}N chemical shift of the same N-H group). Just as 2-D electrophoresis of proteins achieves greater resolution of individual proteins in a large mixture of proteins (see Figure 1.12), this 2-D NMR spectrum achieves greater resolution of the multitude of protein amide resonances because each individual spot or 2-D peak corresponds to the amide group of an individual amino acid residue in the protein. $^1\text{H}/^{15}\text{N}$ -HSQC spectra display a useful chemical shift “fingerprint” for a protein; however, more information is needed to fully assign the ^1H resonances in the protein. This information is gathered using some combination of standard 3-D (or even up to 6-D) experiments in which magnetization is transferred through bonds from an amide ^1H to the amide ^{15}N to an adjacent backbone ^{13}C , and so on. At each step in this process the ^1H or ^{15}N or ^{13}C chemical shifts are recorded such that the

covalent, *through-bond*, connections between backbone atoms in the primary sequence can be established. In essence, the NMR spectroscopist uses multidimensional methods to “walk” along the covalently bonded spin systems in the peptide backbone (and some side chains) and assign specific resonances to their corresponding amino acid residues in the protein sequence.

With these assignments in hand, the *through-space* ^1H spin couplings can then be determined using NOESY experiments, which depend on the fact that two protons closer than about 0.5 nm will have coupled spins *even if they are not closely bonded in the primary structure*. The strength of the NOE signal is proportional to the inverse sixth power of the distance between the coupled ^1H nuclei; thus, NOESY shows only those protons which are in close proximity in the three-dimensional structure of the protein. A typical protein NOESY spectrum is shown in Figure 6A.13a, where the ^1H chemical shifts are plotted along each axis and the spots on the diagonal (from upper right to lower left) correspond to the peaks in the 1-D ^1H NMR spectrum. The spots off this diagonal are called **crosspeaks**, and they represent the through-space interactions between two protons that have different chemical shifts. When combined with chemical shift assignments and bond constraints (i.e., “allowed” ϕ and ψ angles), such NOESY crosspeaks provide critical information that allows the calculation of accurate models for the 3-D structures of proteins in solution.

To illustrate this process, let us consider Figure 6A.13b, where each yellow sphere represents a proton in ubiquitin. The red lines in Figure 6A.13c represent the predicted NOE interactions between all the protons that are within 0.5 nm of each other. This set of red lines, which represents a set of distance constraints between the protons, can be used to locate each proton in 3-D space. The crosspeaks in the NOESY spectrum provide the experimental data that

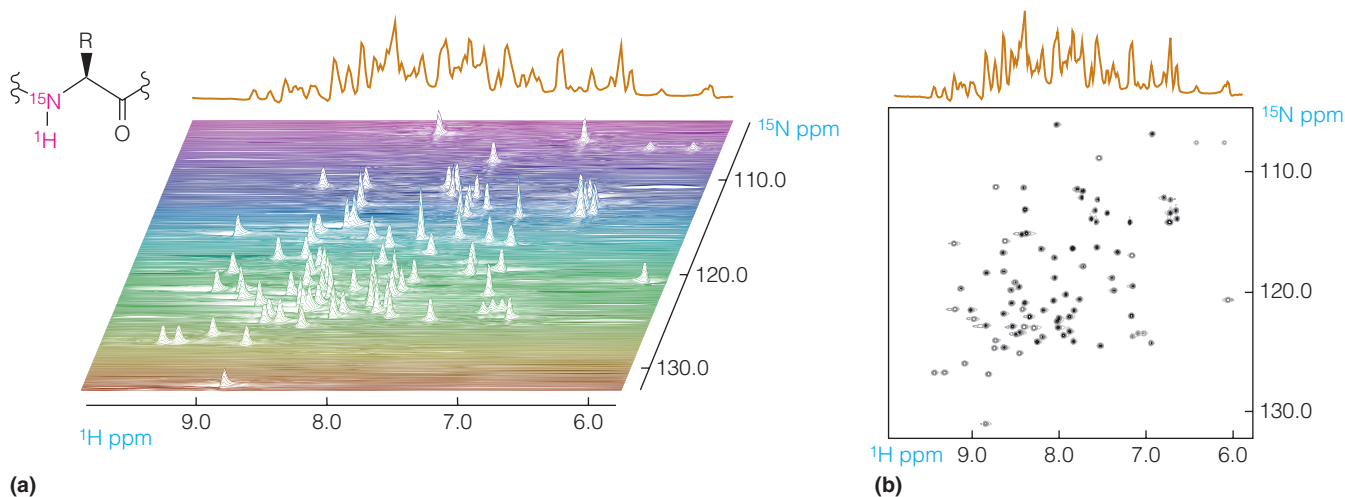

FIGURE 6A.12

$^1\text{H}/^{15}\text{N}$ HSQC spectra of human ubiquitin. The peaks shown are for ^1H nuclei bonded to ^{15}N nuclei (upper left corner). **(a)** The 1-D ^1H spectrum of ubiquitin (brown) and chemical shifts (bottom) for the amide proton region are shown along the x-axes. The ^{15}N chemical shifts for the amide nitrogen region are shown along the rightmost y-axis. Each trace shows a ^1H spectrum taken at a specific ^{15}N resonance. The sum of all the traces is the 1-D ^1H spectrum shown in brown at the top of the panel. This image was prepared with MestRe Nova software. **(b)** $^1\text{H}/^{15}\text{N}$ HSQC spectrum of ubiquitin. This is the common way to plot such spectra. Each spot in the HSQC spectrum corresponds to a single amide N-H group with a characteristic combination of ^1H and ^{15}N chemical shifts (i.e., unique x and y coordinates in the spectrum). The HSQC spectrum resolves the overlapping resonances in the 1-D ^1H spectrum by plotting them in a second dimension (in this case the second dimension is the ^{15}N chemical shift for each amide N-H group). Plots were generated from data available at <http://www.biochem.ucl.ac.uk/bsm/nmr/ubq/> (see R. Harris and P. C. Driscoll [2007] The ubiquitin NMR resource, in *Modern NMR Spectroscopy in Education*, D. Rovnyak and R. A. Stockland eds., ACS Symposium Series vol. 969, pp. 114–127).

UBIQUITIN 2D NOESY

**FIGURE 6A.13**

Detection of through-space spin-spin coupling by NOESY. **(a)** A NOESY spectrum for human ubiquitin showing the 1-D ^1H spectrum along the diagonal and the off-diagonal crosspeaks. **(b)** A model showing the locations of ^1H nuclei (yellow spheres) in ubiquitin. **(c)** The same model shown in (b) with all the predicted NOE interactions for nuclei closer than ~ 0.5 nm indicated by red lines. In theory, the NOESY spectrum would show a crosspeak for each red line, and the intensity of each crosspeak would be correlated with the distance between the nuclei.

Panel (a) courtesy of Stephan Grzesiek, University of Basel; Panels (b) and (c) courtesy of Vlado Gelev, fbreagents.com, Cambridge MA.

are used to define this network of distance constraints. In other words, each NOE crosspeak in Figure 6A.13a corresponds to one of the red lines in Figure 6A.13c. In practice, not all of the red lines in Figure 6A.13c are needed to fix the locations of the protons in our model protein, but ~ 10 NOE crosspeaks are required for *each residue* to solve the structure at high resolution.

The NMR data are used to perform a computer-based molecular dynamics simulation (see Figures 6.35 and 6.36) that provides multiple structural models, each of which must satisfy the distance constraints obtained from the NOESY experiments, as well as other tests for “reasonableness.” For example, a reasonable structural model can’t have several highly unfavorable ϕ and ψ angles, or expose large hydrophobic surfaces to solvent.

Recent work has shown it is possible to accurately determine the angles ϕ and ψ from NMR chemical-shift data alone. Thus, ϕ and ψ angles can be mapped to specific residues, allowing the

solution of a low-resolution backbone structure for a protein without NOESY data. For a high-resolution structure, NOESY data are still needed, but the combination of chemical shift assignments and correlated ϕ and ψ data allows a rapid determination of protein backbone structure.

Whereas a structural model derived from X-ray crystallography shows a single best fit to the X-ray data, NMR data typically yield several very similar structures that all fit the data equally well. A set of NMR structures for human ubiquitin is shown in Figure 6A.14. The NMR data emphasize the dynamic nature of protein structures in solution because the more mobile regions of the protein are less constrained in these models (i.e., fewer NOE crosspeaks are detected for more mobile protons). To a first approximation, this means that the group of reasonable structures derived from the molecular dynamics simulation will overlap most in the regions of the protein structure that are least dynamic and show greater

**FIGURE 6A.14**

NMR solution structure of human ubiquitin. In each panel, 20 structural models derived from NMR data are superimposed. Left: All atoms except H are shown. Middle: A backbone rendering showing the excellent overlap of the peptide chain in the helical and sheet regions. The C-terminus (top) is more dynamic. Right: A cartoon rendering.

Data for this figure provided courtesy of R. Harris. See R. Harris and P. C. Driscoll (2007) The ubiquitin NMR resource, in *Modern NMR Spectroscopy in Education*, D. Rovnyak and R. A. Stockland eds., ACS Symposium Series vol. 969, pp. 114–127.

divergence in those regions that are probably more dynamic. Such conclusions should be verified by other NMR experiments (not described here) that can *directly* measure protein dynamics.

This introduction to the methods of structure determination by NMR has only scratched the surface of describing applications of this versatile tool for the study of protein structure, dynamics, and ligand binding. More detail is given in the references listed below.

TOOLS OF BIOCHEMISTRY 6B

DETERMINING MOLECULAR MASSES AND THE NUMBER OF SUBUNITS IN A PROTEIN MOLECULE

When a new protein has been identified and purified, three questions immediately arise:

1. Does the protein exist under physiological conditions as a single polypeptide chain, or is it made up of multiple subunits?
2. If the functional protein has more than one subunit, are the subunits identical, or are there several kinds?
3. If the functional protein has more than one subunit, are the subunits covalently linked by disulfide bonds or not?

The answers to these questions can usually be obtained by first determining the **molecular mass** (sometimes called the “molecular weight”), M_w , of the protein under native conditions (i.e., in a buffer that approximates the relevant physiological pH and ionic strength) and then subjecting it to conditions under which dissociation into subunits should occur. If subunits are held together by noncovalent interactions, changing the solvent environment will often promote dissociation. For example, the pH might be raised or lowered well outside the physiological range. Alternatively, non-native (i.e., denaturing) solvents like concentrated solutions of urea

or guanidine hydrochloride (GnHCl) might be used. These compounds, which are excellent hydrogen-bond formers, disrupt the regular water structure. For this reason they are also called **chaotropic** (“chaos-forming”) agents. Disruption of the regular water structure decreases the hydrophobic effect and thereby promotes the unfolding and dissociation of protein molecules. Detergents like sodium dodecyl sulfate (SDS), which form micelle-like structures (see Figure 2.15) about individual polypeptide chains, are even more effective at unfolding proteins. By determining the molecular masses of the dissociated subunits under non-native solvent conditions and comparing them with the native M_w , we can tell how many subunits are present in the native protein.

Determining the Molecular Mass of the Native Structure

To determine the molecular masses of proteins in their physiological states, several techniques are available. Recall from Tools of Biochemistry 5A that size exclusion chromatography (SEC) separates proteins in a mixture based on differences in hydrodynamic

radius. The hydrodynamic radius is related to the M_W ; thus, SEC can be used to estimate the native M_W of a protein. The shape of the protein (i.e., rod-like vs. spherical) has a significant impact on hydrodynamic radius and this can skew SEC data. Nevertheless, SEC provides a simple means to estimate, with reasonable accuracy, the M_W of a protein under native conditions. This is done by making a calibration curve of $\log M_W$ vs. retention time for a series of protein standards of known M_W .

A more exact, but less commonly available, way to measure M_W uses the technique of **sedimentation equilibrium**. If a protein solution is sedimented for many hours at low rotor speed in an analytical ultracentrifuge, an equilibrium will be established between the tendency of the molecules to sediment and their tendency to diffuse back into the solution. Details of sedimentation equilibrium and other physical techniques that can be used to determine the molecular masses of native proteins are given in van Holde et al. (see References).

Mass spectrometry (see Tools of Biochemistry 5B) is routinely employed to determine masses of protein subunits with great accuracy. In most cases it is possible to obtain masses for each subunit of a multisubunit complex following the isolation of the native complex by SEC. More recently, it has been reported that quaternary structural features of large protein complexes (e.g., chaperonins) can be maintained in the gas phase and are therefore amenable to mass spectrometric analysis. Work in the lab of Carol Robinson has recently demonstrated that it is possible to use these techniques to identify proteins associated in complexes of >1 MDa ($1 \text{ MDa} = 10^6 \text{ g/mol}$), as well as to monitor dynamic processes such as subunit association in real time.

Determining the Number and Approximate Masses of Subunits: SDS Gel Electrophoresis

Once the native M_W has been determined, the easiest way to estimate the molecular masses of the subunits is to use gel electrophoresis in the presence of SDS. Under these conditions, quaternary, tertiary, and secondary structures of proteins are all broken down. The chain is unfolded and coated by SDS molecules. The numerous negative charges carried by the many SDS molecules bound noncovalently to the protein make the intrinsic charge carried by the protein insignificant. The folded polypeptide chain is therefore transformed into an elongated object, the length and charge of which are each proportional to the number of amino acid residues in the chain (and hence the polypeptide M_W). As pointed out in Tools of Biochemistry 2A and 5A, such particles will migrate in gel electrophoresis with relative mobilities depending only on their lengths. This phenomenon is demonstrated by the graph shown in Figure 6B.1. If electrophoresis of an unknown protein chain is carried out on the same gel as such a set of standards, the M_W of the unknown can be measured by interpolation using a graph like Figure 6B.1.

In investigating the subunits of a protein by this technique, it is advisable to do two experiments: one in the presence of a disulfide-bond-reducing agent like β -mercaptoethanol ($\text{HSCH}_2\text{CH}_2\text{OH}$, see page 169) and one in its absence. This will distinguish between subunits that are bonded by —S—S— bridges and those that are held together only by noncovalent forces. If a single band is found on each of these SDS gels, corresponding to the M_W of the native protein, we

FIGURE 6B.1

SDS gel electrophoresis. The graph plots $\log M_W$ versus relative electrophoretic mobility for a series of proteins dissolved in a solution containing the detergent SDS. The resulting curve is used to interpolate data for an unknown protein.

may conclude that the protein exists under physiological conditions as a single polypeptide chain. If the band or bands observed are of much lower molecular mass, a multisubunit structure is indicated. Even though the M_W values obtained from gel electrophoresis may be approximate, they should be sufficiently accurate for a good guess as to the number of subunits (see Problem 13).

Assuming that multiple subunits are indicated, is there only one kind or are there several? More than one band on the SDS gel is a clear indication of multiple types of subunits. But finding only one band does not prove that subunits are identical. There may, in fact, be several kinds of subunits with distinct amino acid sequences but nearly identical molecular masses; these different subunits usually cannot be resolved on SDS gels. To be satisfied that only one type of chain is present, the researcher must turn to other methods. Again, mass spectrometry is the method of choice for such determinations.

TOOLS OF BIOCHEMISTRY 6C

DETERMINING THE STABILITY OF PROTEINS

Our knowledge of the relative strengths of the noncovalent forces that stabilize protein structure has come largely from the determination of thermodynamic parameters for proteins that display apparent **two-state folding**. For such proteins the transition between the folded and unfolded states is highly cooperative (see Figure 6.23b); thus, no intermediates are detectable, and the unfolding process is described as

Because the covalent structure of the protein doesn't change upon folding or unfolding, protein unfolding is treated as a *phase transition*—such as the conversion of ice to liquid water, or liquid water to steam. For these processes the chemical identity of the molecule in question is not changed; rather, noncovalent interactions are formed, or broken, during the transition from one phase (e.g., “folded state”) to the other (e.g., “unfolded state”).

Here we present basic introductions to the theories behind two common methods to measure thermodynamic stabilities of proteins: differential scanning calorimetry and chemical denaturation. In both cases we will assume the two-state model applies.

Differential Scanning Calorimetry

To extract values for ΔH and ΔS , such as those reported in Table 6.4, the amount of heat required to unfold a protein must be accurately measured. Such measurements can be made in a **differential scanning calorimeter** (DSC) operating at constant pressure. Recall from page 62 of Chapter 3 that heat transferred at constant pressure corresponds to ΔH ; thus, a DSC allows the direct determination of ΔH for protein unfolding.

Figure 6C.1 shows the basic features of a DSC. A buffered solution of protein is placed in the “sample” cell, and the buffer alone is placed in the “reference” cell. The initial temperature of the cells is below the denaturation temperature of the protein (also called the **transition temperature** or **melting temperature**, T_m). The temperature of both cells is then raised in a controlled fashion—generally at a rate of 0.5 to 2.0 °C per minute until the final temperature is above the T_m of the protein. As the protein unfolds, it will absorb the heat required to complete the phase transition from the native to the denatured state (Equation 6C.1). The absorption of excess heat by the protein as it denatures will require that more heat is added to the sample cell to keep it at the same temperature as the reference cell. The DSC records the difference in heat absorbed by the buffered protein solution vs. the buffer alone. This excess absorbed heat is manifested as a change in *heat capacity at constant pressure*, C_p , as a function of temperature. Figure 6C.2 shows an idealized plot of C_p vs. temperature for protein denaturation, called a “thermogram.”

The thermogram provides several key pieces of information. Here we focus upon three. The first of these is the peak value of

FIGURE 6C.1
Schematic diagram of a differential scanning calorimeter.

C_p , which corresponds to the T_m of the protein. For a protein that unfolds in a two-state fashion, T_m represents the temperature at which the free energies of the native and denatured states are equal; thus, at T_m

$$\Delta G_{F \rightarrow U} = G_U - G_F = 0 \quad (6C.2)$$

and

$$\Delta G_{F \rightarrow U} = \Delta H_{F \rightarrow U} - T_m \Delta S_{F \rightarrow U} = 0 \quad (6C.3)$$

or

$$\Delta H_{F \rightarrow U} = T_m \Delta S_{F \rightarrow U} \quad (6C.4)$$

The second piece of key information is the value of $\Delta H_{F \rightarrow U}$, which corresponds to the area under the C_p vs. temperature curve in the transition region. To determine the enthalpy change for the unfolding transition alone, we must subtract out the contributions to C_p from the heat capacities of the native ($C_{p,f}$) and denatured ($C_{p,u}$) states in the transition region. In practice, this correction is

FIGURE 6C.2

An idealized DSC thermogram of protein denaturation. C_p is plotted as a solid black line. The pre-transition baseline, $C_{p,f}$ is the constant-pressure heat capacity of the native (folded) state; the post-transition baseline, $C_{p,u}$ is the constant-pressure heat capacity of the denatured (unfolded) state; $\Delta C_p = C_{p,u} - C_{p,f}$; T_m is the transition temperature; $\Delta H_{F \rightarrow U}$, shown in blue shading, is the area under the curve in the transition region corrected for differences in $C_{p,f}$ and $C_{p,u}$.

made by the data analysis software provided with the DSC; however, it requires that sufficient data are recorded for pre- and post-transition baselines, such that these baselines can be properly evaluated in the transition region. With the value of $\Delta H_{F \rightarrow U}$ in hand, we can calculate $\Delta S_{F \rightarrow U}$ using Equation 6C.4 and T_m .

You will notice that the data in Table 6.4 report values of ΔG , ΔH , and ΔS for folding at the reference temperature of 25 °C. Because most intracellular proteins are stably folded at 37 °C, how can stability parameters at 25 °C be determined? This is done by taking the temperature dependence of ΔH and ΔS into account. Recall from the thermodynamics of phase changes:

$$\Delta H_T = \Delta H_{T_m} + \Delta C_p(T - T_m) \quad (6C.5)$$

$$\Delta S_T = \Delta S_{T_m} + \Delta C_p \ln\left(\frac{T}{T_m}\right) \quad (6C.6)$$

$$\Delta G_T = \Delta H_T - T\Delta S_T \quad (6C.7)$$

where ΔH_{T_m} and ΔS_{T_m} are, respectively, the enthalpy change and entropy change at T_m , and T is any desired value of temperature, such as 298 K (25 °C). Thus, we can calculate values of ΔH , ΔS , and ΔG at any temperature if we have ΔH_{T_m} (which is the same as $\Delta H_{F \rightarrow U}$), T_m , and ΔC_p .

As shown in Figure 6C.2, ΔC_p is the third bit of critical information provided by the DSC experiment; thus, DSC provides all the information we need to derive the thermodynamic parameters that allow comparisons of protein stability to be made.

The foregoing treatment assumes two-state unfolding behavior *and* reversibility. In other words, can the original folded state be recovered after the thermally unfolded protein is cooled and allowed to refold? For a true two-state unfolding process one ought to get the same thermogram for a second (or third) DSC trial following cooling of the sample cell. This is an important control in DSC because a protein may undergo irreversible chemical modification (e.g., thermal deamidation of Asn or Gln side chains)

FIGURE 6C.3

Circular dichroism (CD) spectra of native and chemically denatured myoglobin. The CD spectrum of native state sperm whale myoglobin (sw Mb) in pH 7.0 buffer is shown as solid black squares. The red data show the CD spectrum of denatured sw Mb in buffered 8 M urea (note: urea absorbs strongly below 210 nm). The vertical dashed line shows the difference in the CD signal at 222 nm, which can be used to distinguish between the folded and unfolded states.

or aggregation at the higher temperatures required to get a good post-transition baseline. Evidence for either of these events precludes application of the simple two-state model described above.

It is possible to use DSC to derive thermodynamic parameters for proteins that display more complex unfolding behavior; however, the discussion of such methods is beyond the scope of this introduction (see the References cited below).

Chemical Denaturation Methods

An alternative method for comparing relative stabilities between different proteins is the method of linear extrapolation from chemical denaturation data. This is a widely used method because it uses reagents and equipment that are available in most protein chemistry labs. It is used to calculate $\Delta G_{F \rightarrow U}^\circ$ (note: this is for the process of *unfolding*); however, it gives no information about the enthalpy and entropy changes, as does DSC.

The method is based on the observation that increasing concentrations of chaotropes (i.e., chemical denaturants) such as urea and guanidine hydrochloride (GnHCl) perturb the equilibrium of Equation 6C.1 toward the unfolded state. Given any of the spectroscopic methods discussed in Tools of Biochemistry 6A that can distinguish the folded from the unfolded state (e.g., see Figure 6C.3), it is possible to determine the equilibrium constant for the protein unfolding as a function of denaturant concentration.

Assuming two-state unfolding, the equilibrium constant, K_{eq} , for protein unfolding is

$$K_{eq} = \left(\frac{[U]}{[F]}\right) \quad (6C.8)$$

and it can be shown that

$$K_{eq} = \left(\frac{A_F - A_{obs}}{A_{obs} - A_U}\right) \quad (6C.9)$$

where A_F is the spectroscopic signal of the native state; A_U is the spectroscopic signal of the denatured state; and A_{obs} is the spectroscopic signal of the protein sample (the derivation of Equation 6C.9 is given in the References cited below). These values of K_{eq} can then be used to calculate values of $\Delta G^\circ_{F \rightarrow U}$ for each sample of protein solution containing denaturant:

$$\Delta G^\circ_{F \rightarrow U} = -RT \ln K_{\text{eq}} \quad (6C.10)$$

In practice, one needs 15–20 protein solutions where each sample contains the same concentration of protein but a different concentration of denaturant. The spectroscopic signal of each sample is then recorded and plotted as a function of the denaturant concentration (open triangles in Figure 6C.4). In the past, the data points in the transition region would be converted to values of $\Delta G^\circ_{F \rightarrow U}$ and then used to *extrapolate* a value of $\Delta G^\circ_{F \rightarrow U}$ at zero

FIGURE 6C.4

Circular dichroism at 222 nm for samples of mutant sperm whale myoglobin in buffered urea solutions. The open triangles show CD signal at 222 nm. The red line shows the slope of the pre-transition baseline, corresponding to the CD signal for the mutant in the native state. The blue line shows the slope of the post-transition baseline, corresponding to the CD signal for the mutant in the denatured state. The solid black line is a nonlinear curve fit of a two-state unfolding model to the data. From the curve fit, a value of $\Delta G^\circ_{\text{H}_2\text{O}}$ is obtained.

denaturant concentration. This step is the source of the method's name (linear extrapolation). The value of $\Delta G^\circ_{F \rightarrow U}$ at zero denaturant is more commonly referred to as $\Delta G^\circ_{\text{H}_2\text{O}}$. With the availability of software packages that perform nonlinear curve fitting, it is now possible to fit an equation for two-state unfolding directly to the spectroscopic data (solid black line in Figure 6C.4). Such curve-fitting procedures give the value of $\Delta G^\circ_{\text{H}_2\text{O}}$ without the need for tedious calculations and extrapolation; however, it is important to have sufficient pre- and post-transition data to adequately constrain the curve-fitting with reliable values of A_F and A_U .

Using this procedure it is relatively straightforward to compare the stabilities of two or more proteins. The concentration of denaturant at the midpoint of the transition (C_m) is a crude, but quite useful, indicator of relative stabilities. The curve fitting that gives $\Delta G^\circ_{\text{H}_2\text{O}}$ also yields C_m . More stable proteins have more positive values of $\Delta G^\circ_{\text{H}_2\text{O}}$ and also tend to have higher values of C_m . In other words, it generally takes higher concentrations of denaturant to unfold more-stable proteins (Figure 6C.5).

As with DSC, it is important to perform controls that support use of the two-state model. A common control with chemical denaturation studies is to perform multiple trials using different spectroscopic techniques. Frequently, complementary techniques such as CD (which measures secondary structure) and fluorescence (which measures tertiary structure, i.e., packing of Trp and Tyr residues) are used. If folding is cooperative and two-state, secondary and tertiary structures should denature in concert, and the denaturation curves obtained by different spectroscopic techniques will superimpose. An example of this is shown in Figure 6C.5 for the unfolding of wild-type myoglobin monitored by CD at 222 nm (monitors α helix content) and heme absorbance at 409 nm (monitors tertiary folding around heme group). The superposition of the two data sets is consistent with, but doesn't prove, two-state behavior. If the data did not superimpose, the existence of intermediate states would be implied and application of the two-state model would not be warranted.

Chemical denaturation has also been used to screen for compounds that stabilize protein native structure. The Ala 4 to Val (A4V) mutant of superoxide dismutase (SOD1) is linked to familial amyotrophic lateral sclerosis (ALS; see Table 6.6), and predisposes SOD1 to form amyloid fibrils. Several potential drug candidates were screened for ability to stabilize the A4V mutant of SOD1 using chemical denaturation (Figure 6C.6). Fifteen compounds were found to stabilize the native state dimer and

(a)

(b)

reduce aggregation *in vitro*. These compounds will therefore serve as lead structures in the search for drugs that could be of therapeutic value in treating familial ALS. An alternative view, based upon the finding that mutant and wild-type SODs can hybridize to form a toxic enzyme, is that the goal of therapy should be to destabilize the mutant enzyme, so that it can be degraded and removed from the cell.

CHAPTER 7

Protein Function and Evolution

With an understanding of the complex, folded structures of globular proteins, we can look more closely at how such structures are related to the molecules' functions and how they may have evolved to fulfill those functions. In this chapter we will use as examples two groups of proteins whose main functions are binding other molecules: the globins and immunoglobulins.

We will start with **myoglobin** (abbreviated **Mb**) and its molecular relative **hemoglobin** (**Hb**), members of a family of proteins collectively termed **globins**. We have chosen these examples for a number of reasons. First, the hemoglobins and myoglobins play vital roles in one of the most important aspects of animal metabolism—the acquisition and utilization of molecular oxygen (O_2). As described in detail in Chapter 15, the most efficient energy-generating mechanisms in animal cells require O_2 for the oxidation of nutrients; therefore, proteins that transport O_2 to respiring cells are essential for any higher organism. Myoglobin is an O_2 binding protein found primarily within the muscle tissue of animal species; hemoglobin is used for oxygen transport in all vertebrates and some invertebrates. Second, hemoglobin plays a role in removing CO_2 from tissues. CO_2 is a major product of metabolite oxidation and must be continually removed and exhaled. The role of hemoglobin in O_2 and CO_2 transport is schematically illustrated in Figure 7.1. Because O_2 binding and CO_2 removal must be carefully regulated to meet tissue needs, these examples illustrate regulation of protein function. Third, the close structural relationship between hemoglobin and myoglobin yields important insights into evolution of protein function. Finally, the structure, function, and evolution of the globin family have been studied more than for any other

FIGURE 7.1

Role of the globins in oxygen transport and storage. Vertebrate animals use hemoglobin and myoglobin to provide their tissues with a continuous O_2 supply. Hemoglobin transports O_2 from the lungs or gills to the respiring tissues, where it is used for aerobic metabolism in the mitochondria. Inside cells, dissolved O_2 diffuses freely or is bound to myoglobin, which aids transport of O_2 to the mitochondria. Myoglobin can also store O_2 for later use (as in deep-diving mammals). CO_2 produced by oxidative processes in the tissues is carried back to the lungs or gills by hemoglobin and released.

group of proteins. The study of hemoglobin has played a significant role in defining the early history of biochemistry and molecular biology. Indeed, the properties of hemoglobin have been investigated extensively because the protein was successfully crystallized in the first half of the nineteenth century.

Whereas the hemoglobins and myoglobins bind to a few specific molecules reversibly (described below), the **immunoglobulins** (or **antibody** molecules) are protein structures that can be produced in a multitude of variations, and each variant binds with exquisite specificity, and essentially nonreversibly, to a unique target. Our primary defenses against infectious disease depend on the ability of immunoglobulins to recognize and bind to “foreign” molecules (i.e., of “nonself” origin) as part of the **immune response**.

Structure–function relationships for another diverse and important group of proteins, the **enzymes**, are discussed in Chapter 11.

Oxygen Transport: The Roles of Hemoglobin and Myoglobin

Hemoglobin and myoglobin are proteins that have evolved to carry out the specialized function of O_2 transport in animals. Any animal larger than a few millimeters in diameter faces a serious problem in carrying out **aerobic** (oxygen-requiring) metabolism. It must ensure a steady supply of O_2 to cells throughout its body and remove metabolic waste products such as CO_2 . These gases will diffuse through tissues; but transport by diffusion becomes very slow if appreciable distances must be crossed. Insects solve the problem by having **tracheae**, tubular networks that lead from the body surface down into the tissues. They have, in effect, increased their body surface area to the extent that diffusion is practicable. This mechanism works because insects are small. (Alternatively, we might conclude that insects are small because they rely on this mechanism for obtaining O_2 .*)

Almost all other animals pick up O_2 in lungs or gills and pump it in the blood through arteries to the tissues (see Figure 7.1). Carbon dioxide is returned in the venous blood and released in the lungs or gills. In some primitive organisms, the gases are simply dissolved in the blood, but this mechanism is very inefficient because O_2 has low solubility in plasma (plasma is the liquid portion of the blood). Much plasma must be pumped, at great metabolic expense, to deliver even a little dissolved O_2 . Evolution of all higher organisms has been accompanied by the development of **oxygen transport proteins**, which allow the blood to carry a 100-fold higher concentration of O_2 than would be permitted by solubility of the gas alone. Oxygen transport proteins may be either dissolved in the blood (as in some invertebrates) or concentrated in specialized cells, like the human **erythrocytes** (red blood cells) shown in Figure 7.2. In all vertebrates the O_2 transport protein is hemoglobin, a protein that can bind O_2 in lungs or gills and deliver it to other tissues.

Once the O_2 is transported to the tissues, it must be released for utilization. Some tissues, such as skeletal and heart muscle, have high energy demands and require rapid transport of O_2 from hemoglobin in the circulation to mitochondria (where ATP is produced) inside respiring cells. The relatively high concentration (~2 mg/g of human muscle tissue) of myoglobin in all mammalian skeletal muscle is thought to facilitate diffusion of O_2 in cells so it reaches mitochondria efficiently. In deep-diving mammals the concentration of myoglobin in skeletal muscle is 10–30 times higher than that of terrestrial mammals. Thus, myoglobin also acts as an O_2 storage molecule, providing a substantial reserve of O_2 to

All but the smallest animals need a protein—hemoglobin in vertebrates—to transport O_2 from gills or lungs to tissues.

FIGURE 7.2

Human erythrocytes. Arrows point to red blood cells, or erythrocytes, shown moving in a capillary. Each erythrocyte contains about 300 million hemoglobin molecules.

© Ed Reschke/Peter Arnold/Getty Images.

*This hypothesis raises an intriguing problem: How do we explain the giant dragonflies of the Carboniferous period, which had wingspans up to 2 feet? Was the O_2 content of the atmosphere higher then (about 300 million years ago), or did they use some other mechanism for O_2 uptake? Recent evidence suggests that the first explanation may be correct.

FIGURE 7.3

Comparison of myoglobin and hemoglobin. These drawings illustrate the backbone structures of the two oxygen-binding molecules as revealed by X-ray crystallography. Each of the four chains in hemoglobin has a folded structure similar to that of myoglobin, and each carries a heme (shown in red). Hemoglobin contains two identical α chains and two identical β chains. The letters A–H indicate α -helical regions. The α and β chains are very similar but have distinct primary structures and folds (note that the α chain does not have a “d” helix).

FIGURE 7.4

The structures of protoporphyrin IX and heme. (a) The protoporphyrin IX is the tetrapyrrole portion of the heme molecule. (b) Heme, which is protoporphyrin IX complexed with Fe(II), is the prosthetic group of hemoglobin and myoglobin. Because of resonance delocalization of the electrons in the porphyrin ring, all N–Fe bonds within the heme are equivalent.

support the demand for ATP production while the animal is submerged. In larger whales this can be 30 minutes or longer! As is described later in this chapter, recent studies have shown that myoglobin and hemoglobin play other important physiological roles beyond O_2 transport and storage.

Myoglobin and hemoglobin are built on a common structural motif, as shown in Figure 7.3. In myoglobin, a single polypeptide chain is folded about a prosthetic group, the **heme** (Figure 7.4), which contains the O_2 binding site. Hemoglobin is a tetrameric protein, made up of four polypeptide chains each of which binds a heme group, and closely resembles myoglobin in structure. We begin the discussion of how these structures serve the function of O_2 transport from lungs to mitochondria with a description of O_2 binding in myoglobin.

The Mechanism of Oxygen Binding by Heme Proteins

An oxygen storage or transport molecule must be able to bind O_2 reversibly and protect it from reaction with any other substance that can reduce O_2 , thereby rendering it useless for ATP production in mitochondria. How do the globins achieve this? To answer this question we must consider how the peptide and the prosthetic group interact. The peptide portion of any protein without its prosthetic group bound is called the **apoprotein**, whereas with its prosthetic group bound, it is called a **holoprotein**.^{*} The apoglobins are unable to bind O_2 themselves; however, certain transition metals in their lower oxidation states—particularly Fe(II) and Cu(I)—have a strong tendency to bind O_2 . The globin proteins have evolved such that Fe(II) is bound to the proteins to produce a site at which O_2 binds reversibly.

The Oxygen Binding Site

Various iron-containing proteins can hold Fe(II) in a number of possible ways. Throughout the myoglobin–hemoglobin family, the iron is chelated by a tetrapyrrole ring system called **protoporphyrin IX** (Figure 7.4a), one of a large class of **porphyrin** compounds. We will encounter other porphyrins in chlorophyll (Chapter 16), the cytochrome proteins (Chapter 15), and some natural pigments. Like most compounds with large conjugated ring systems, the porphyrins are strongly colored. The iron-porphyrin in the globin accounts for the red color of blood and meat, and the magnesium-porphyrin in chlorophyll is responsible for the green color of plants.

^{*}For enzymes the corresponding terms are “apoenzyme” (without prosthetic group) and “holoenzyme” (prosthetic group present).

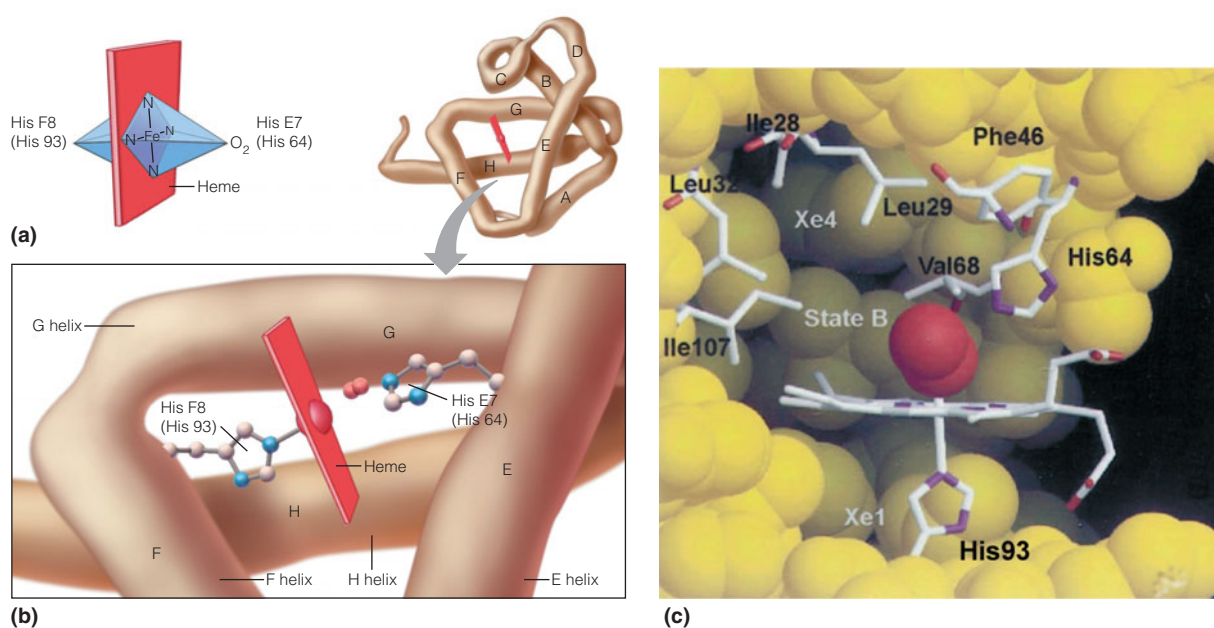

FIGURE 7.5

The geometry of iron coordination in oxymyoglobin. (a) The octahedral coordination of the iron ion. The iron and the four nitrogens from protoporphyrin IX lie nearly in a plane. A histidine (F8, or His 93) occupies one of the axial positions, and O_2 the other. (b) Schematic drawing of the heme pocket, showing the proximal (F8; His93) and distal (E7; His64) histidine side chains. (c) The crystal structure of the ligand-binding site in sperm whale oxymyoglobin (PDB ID: 2MGM). Amino acids in the O_2 binding pocket are shown as stick models and labeled. The heme group and the proximal histidine (His93) are also rendered as stick models, with O_2 in red (spacefilling model). The rest of the protein is drawn as a space-filling model in yellow. Here the D helix and the CD corner have been deleted to show the ligand-binding site. Residues Phe46 (or CD1) and Val68 (or E11) are highly conserved (Phe46 is invariant), and both make critical contributions to the binding affinity between the heme and the heme pocket. The sites labeled Xe1 and Xe4 indicate hydrophobic cavities that can be occupied by Xenon under pressure and apparently define channels for ligand entry and exit (see Figure 7.8).

(c) Courtesy of Dr. Jeffrey Nichols.

The complex of protoporphyrin IX with Fe(II) is called heme (Figure 7.4b). This prosthetic group is bound in a hydrophobic crevice in the myoglobin or hemoglobin molecule (see Figure 7.3). The binding of oxygen to heme is illustrated in Figure 7.5, which shows the oxygenated form of myoglobin. Ferrous iron (Fe^{2+}) is normally octahedrally coordinated, which means it should have six **ligands**, or binding groups, attached to it. As shown in Figure 7.5a, the nitrogen atoms of the porphyrin ring account for only four of these ligands. Two remaining coordination sites are available, and they lie along an axis perpendicular to the plane of the heme. In both the deoxygenated and the oxygenated forms of myoglobin, one of these remaining coordination sites is occupied by the ϵ -nitrogen of histidine residue number 93 (see margin). The eight helical segments in the globins are designated A through H (as shown in Figure 7.3), and residue 93 is located in the F helix (Figure 7.5b). Using a nomenclature that allows for meaningful comparisons between the homologous sequences of different globins, this residue is called histidine F8 (it is the eighth residue in the F helix). Because it is in direct contact with the Fe^{2+} , it is also called the **proximal histidine**. In **deoxymyoglobin**, the remaining coordination site, on the other side of the iron, is unoccupied. When oxygen is bound, making **oxymyoglobin**, the O_2 molecule occupies this site.

The $Fe-O_2$ bond is highly polar due to the good orbital overlap between d orbitals on the Fe^{2+} and the π^* molecular orbital of the electronegative O_2 . This backbonding increases the electron density on the O_2 and gives the formal $Fe(II)-O_2$ complex some $Fe(III)-O_2^-$ character. Stabilization of this $Fe(III)-O_2^-$ -like structure is achieved by a hydrogen bond between the bound O_2 and another important His residue located in the O_2 binding pocket—the so-called **distal histidine** (His 64, or E7; see Figure 7.5c). The H-bond between His E7 and O_2 selectively increases the affinity of Mb for O_2 vs. CO, which doesn't make a similar bond to His E7. Even so, CO binds ~200 times more tightly to Mb than does O_2 ; however, without the E7 H-bond, that ratio would be ~6000:1 in favor of CO. Thus, the distal histidine plays a critical role in promoting O_2 binding over other ligands.

A similar mode of oxygen binding, with histidines at the homologous F8 and E7 positions, is found in each subunit of hemoglobin.

Normally, an O_2 molecule in such close contact with a ferrous ion would oxidize the latter to the ferric [$Fe(III)$] state. The heme alone does not protect the iron because heme dissolved free in solution is readily oxidized by O_2 . However, in the hydrophobic (and anhydrous) environment provided by the heme-binding

The ϵ -tautomer of histidine

Coordination of Fe(II) in a porphyrin (heme) within a hydrophobic globin pocket allows reversible O_2 binding without iron oxidation.

cleft of the myoglobin or hemoglobin molecule, the iron is not easily oxidized; thus, when the O_2 is released, the iron remains in the ferrous state, able to bind another O_2 . The distal histidine also plays a role by inhibiting this autooxidation reaction, which is acid-catalyzed. The globins provide environments for ferrous heme in which the first step of an oxidation reaction (the binding of oxygen) is permitted, but the final step (oxidation) is blocked.

In fact, the ferrous heme in myoglobin and hemoglobin can become oxidized to the ferric (Fe^{3+}) state, to form **metmyoglobin** or, respectively, **methemoglobin**. The met-globins do not bind O_2 ; a water molecule occupies the O_2 binding site instead. For this reason red blood cells contain enzymes that can reduce the Fe^{3+} in methemoglobin to Fe^{2+} and thereby restore its O_2 -binding activity.

Although myoglobin and hemoglobin are ideally adapted to reversibly bind an O_2 molecule, they also bind other diatomic gases such as carbon monoxide (CO) and nitric oxide (NO). The toxicity of CO is due to its ability to block respiration by binding tightly to the Fe^{2+} -hemes in globins as well as those in other critical respiratory proteins called **cytochromes**. Nitric oxide also inhibits respiratory proteins (primarily **cytochrome-c oxidase**; discussed in Chapter 15), and is released by macrophages to destroy invading organisms as part of the immune response. At low levels, NO is also a cell-signaling molecule. The interaction of the globins and NO are discussed later in this chapter.

Analysis of Oxygen Binding by Myoglobin

The binding of O_2 by myoglobin must meet certain physiological requirements. As Figure 7.1 shows, myoglobin located inside muscle cells binds O_2 , which diffuses into cells from hemoglobin circulating in capillaries, then delivers the O_2 to the mitochondria. To understand these functions on a quantitative basis, we must examine how the binding of a ligand like O_2 depends on its concentration in the surroundings.

First, a way to measure the concentration of dissolved O_2 is needed. According to Henry's law, the concentration of any gas dissolved in a fluid is proportional to the *partial pressure* of that gas above the fluid. Therefore, we can conveniently regulate (and measure) the concentration of dissolved O_2 by regulating the partial pressure of O_2 above the myoglobin solution being studied. In fact, we can express O_2 concentration as this partial pressure: P_{O_2} .

To study ligand binding, we must have a way of measuring the fraction of myoglobin molecules carrying O_2 . When myoglobin or hemoglobin are oxygenated they change colors (the absorption spectrum changes due to alteration of the electronic structure of the heme iron—see Tools of Biochemistry 6A). This allows a spectrophotometric determination of the fraction of binding sites that are oxygenated (Figure 7.6). The results of such analysis, using myoglobin in solution

FIGURE 7.6

Changes in the visible spectrum of hemoglobin. Spectra for hemoglobin in the deoxygenated state (blue trace) and the O_2 -bound state (red trace) are shown. Hemoglobin in the deoxygenated state is a venous purple, whereas completely oxy-Hb is bright red. As more O_2 binds to Hb, the visible spectrum shifts from the blue to the red trace (several spectra for partially bound Hb are shown). Thus, the ligand-binding behavior of the globins is easily monitored by visible spectroscopy (see Tools of Biochemistry 6A) due to the distinctive spectral differences between the various forms of the globins.

at neutral pH, are shown in Figure 7.7. Such a graph is called a *binding curve* because it describes how the fraction of the myoglobin sites that have O₂ bound to them (Y_{O_2}) depends on the concentration of free O₂ (P_{O_2}).

We can describe the binding of a ligand (in this case: O₂) to myoglobin by the following reaction

and ligand dissociation by

where k_{on} and k_{off} are the rate constants for binding and dissociation, respectively. Thus, reversible ligand binding is described by the following equilibrium

and

$$K_d = \frac{[\text{Mb}][\text{O}_2]}{[\text{MbO}_2]} \quad (7.3)$$

where the equilibrium constant K_d is called a **dissociation constant**. The quantities in brackets denote the *activities* (see Chapter 3) of oxymyoglobin [MbO₂], deoxymyoglobin [Mb], and free oxygen [O₂]. The fraction of myoglobin sites occupied is defined as follows:

$$Y_{O_2} = \frac{\text{sites occupied}}{\text{total sites available}}$$

Each myoglobin molecule has only one site, so the total number of potentially available sites is proportional to the total concentration of myoglobin species = [MbO₂] + [Mb]. Therefore,

$$Y_{O_2} = \frac{[\text{MbO}_2]}{[\text{Mb}] + [\text{MbO}_2]} = \frac{\frac{[\text{Mb}][\text{O}_2]}{K_d}}{[\text{Mb}] + \frac{[\text{Mb}][\text{O}_2]}{K_d}} \quad (7.4)$$

where we have used [MbO₂] = [Mb][O₂]/ K_d from equation (7.3) to obtain the expression on the right. The concentration of deoxymyoglobin, [Mb], can be factored out of the numerator and denominator to give

$$Y_{O_2} = \frac{\frac{[\text{O}_2]}{K_d}}{1 + \frac{[\text{O}_2]}{K_d}} = \frac{[\text{O}_2]}{K_d + [\text{O}_2]} \quad (7.5)$$

Equation 7.5 shows that K_d describes the oxygen concentration at which half the Mb molecules have O₂ bound. You can check this relationship by setting $Y_{O_2} = 1/2$ in Equation 7.5. Because oxygen concentration is proportional to oxygen partial pressure, Equation 7.5 can also be written as

$$Y_{O_2} = \frac{P_{O_2}}{P_{50} + P_{O_2}} \quad (7.6)$$

where P_{50} is the oxygen partial pressure required for 50% O₂ saturation. The value of P_{50} is an indicator of the relative binding affinity for a ligand. In the case of myoglobin, when $P_{O_2} = P_{50}$, [Mb] = [MbO₂]. For a myoglobin with high O₂-binding affinity, half-saturation occurs at *low* P_{O_2} ; thus, the value of P_{50} is *low*. For a myoglobin which has a low O₂-binding affinity, half-saturation would occur at *high* P_{O_2} ; thus, the value of P_{50} would be *high*.

We see that Equation 7.6 describes the *hyperbolic* binding curve shown in Figure 7.7; Y_{O_2} starts at zero at $P_{O_2} = 0$ and approaches 1 as P_{O_2} increases. The P_{50}

FIGURE 7.7

Oxygen-binding curve for myoglobin. The free oxygen concentration is expressed as P_{O_2} , the partial pressure of oxygen. The proportion of myoglobin binding sites that are occupied is expressed as a fraction (Y_{O_2} , on the left) or as percent saturation (on the right). As P_{O_2} becomes large, 100% saturation is approached asymptotically, as described by Equation 7.6. The value of P_{50} , the partial pressure of oxygen at 50% saturation, is indicated on the graph (magenta arrow). The dashed blue lines show that at P_{O_2} of 30 mm Hg, Mb would be >90% saturated with O₂ (blue arrow on y-axis).

P_{50} is an indicator of the relative binding affinity of a globin for a ligand: For a globin with higher O₂-binding affinity, the value of P_{50} is lower. For a globin with lower O₂-binding affinity, the value of P_{50} is higher.

Binding of a ligand (like O_2) to a single site on a protein (like Mb) is described by a hyperbolic binding curve.

for myoglobin is very low (3–4 mm Hg), signifying that myoglobin has a high affinity for O_2 . This characteristic is appropriate for a protein that must extract O_2 from the blood in capillaries. At the P_{O_2} existing in the arterial capillaries (about 30 mm Hg), the myoglobin in adjacent tissues would be nearly saturated (blue arrow in Figure 7.7). When cells are metabolically active, their internal P_{O_2} falls to much lower levels (3–18 mm Hg). Under these conditions, myoglobin will release its O_2 .

The myoglobin molecule must not only provide the heme a protein environment suitable for the reversible binding of O_2 , it must also ensure that the O_2 -binding affinity (which is indicated by the value of P_{50}) is of the right magnitude to balance the requirements for both uptake and release of O_2 . We can gain some insight into how this ideal binding affinity is achieved if we recall that the O_2 dissociation constant, K_d , is an equilibrium constant and therefore must be the ratio of two rate constants, k_{on} for the *association reaction* and k_{off} for the *dissociation reaction*. Recall that at equilibrium, where the rates of ligand binding and release are equal, $k_{on}[Mb][O_2] = k_{off}[MbO_2]$ and

$$K_d = \frac{[Mb][O_2]}{[MbO_2]} = \frac{k_{off}}{k_{on}} \quad (7.7)$$

Thus, the oxygen affinity can be controlled at the molecular level by regulating the rates of binding or release.

Rapid kinetic studies of several myoglobin mutants, performed in the laboratory of John Olson, have revealed that the binding of O_2 is mediated in large part by the distal histidine. The imidazole side chain acts both as a gate, between the solvent environment and the heme iron, as well as a hydrogen-bonding discriminator for certain ligands. As described above, the ϵ -NH tautomer of the distal histidine can H-bond to an O_2 bound at the heme in myoglobin (and the α and β subunits of hemoglobin). Recent kinetic and high-resolution structural studies have shown that in Mb, this H-bond has a strength of ~ 15 kJ/mol, whereas in the subunits of hemoglobin it is somewhat weaker, at ~ 8 kJ/mol. To investigate further the role of the distal His in ligand binding and release, CO-myoglobin was studied. X-ray crystallography data collected after photolytic cleavage of the Fe-CO bond in CO-myoglobin reveal that the distal histidine undergoes relatively large movements within 100 ps ($1\text{ ps} = 10^{-12}$ seconds) after ligand photolysis (Figure 7.8a). This finding is consistent with its role as the “gate.” Computer simulations also suggest that the major route in ligand dissociation from the protein is through a narrow tunnel, gated by the distal histidine. However, as shown in Figure 7.8c, ligands can also exit the protein at other sites—some of them quite distant from the heme-binding pocket! In fact, the ligand may spend some time

FIGURE 7.8

Dynamics of CO release by myoglobin. (a) Time-resolved X-ray diffraction data comparing the positions of atoms before (magenta) and 100 ps after (green) photolysis of the L29F mutant of Mb-CO (PDB ID: 2GOV). Where there is overlap the electron densities are shown in white. 100 ps after photolysis the CO appears to be located about 0.2 nm from the heme iron (green density inside the yellow circle numbered 1). The largest displacements (yellow arrows) in Mb are for side chains in the distal pocket: His64 and Phe29. (b) As in (a), but 3.16 μ s after photolysis (PDB ID: 2G14). At this point the CO can be detected on the proximal side of the heme (within yellow circles labeled 4 and 5), and the distal pocket side chains have adopted positions similar to those in the deoxy-state. (c) Computational modeling of ligand migration pathways in Mb are shown in blue. The major pathways are near the heme (labeled 1-5) and the minor pathways are on the opposite side of the protein (labeled 6-9). Significant internal motions of the protein are required for a bound ligand to dissociate via the minor pathways.

rattling in its protein cage—and perhaps rebinding at the heme iron—before it escapes to the solvent. This process is an explicit example of a principle set forth in the preceding chapter—the dynamic internal motions of globular protein molecules play important roles in the functions of proteins.

In summary, we observe in myoglobin a molecular structure that has been selected through evolution to produce an optimized environment for the binding *and* release of oxygen under physiological conditions of relatively low P_{O_2} . Recent evidence suggests that myoglobin plays another critical role in animal physiology, namely, protection from toxic levels of NO (nitric oxide) in cells. We will return to this topic later in the chapter, after we complete the discussion of O_2 transport.

Oxygen Transport: Hemoglobin

All higher animals contain some kind of an oxygen transport protein. In vertebrates and some invertebrates this protein is hemoglobin. Nearly all hemoglobins are found to be multisubunit proteins, in contrast to the single-subunit myoglobins. Why should this be so? Investigating this question reveals new aspects of globin protein function.

Hemoglobin is not the only oxygen-binding protein used by animals. Most mollusks and some arthropods have a quite different protein, hemocyanin, which contains copper at the O_2 -binding site. Still other invertebrates use an unrelated iron-containing protein called hemerythrin. Even the hemoglobins among the invertebrates are diverse in structure, ranging in size from dimers to complexes with 180 subunits (Figure 7.9). This diversity shows that the same function can often be arrived at by several independent evolutionary routes. In the following discussion we will focus on the tetrameric $\alpha_2\beta_2$ hemoglobin of higher vertebrates shown in Figure 7.3.

Cooperative Binding and Allostery

Consider the considerable demands placed on an O_2 transport protein. It must bind O_2 efficiently at the partial pressure found in lungs or gills (approximately 100 mm Hg) and then release a significant fraction of the O_2 to tissues. At rest,

Dynamic motions of myoglobin facilitate ligand binding and release.

Myoglobin has evolved to bind and release O_2 under conditions of relatively low oxygen concentration.

Higher animals use O_2 -binding proteins to transport oxygen from lungs or gills to respiring tissues where it is needed to support metabolism.

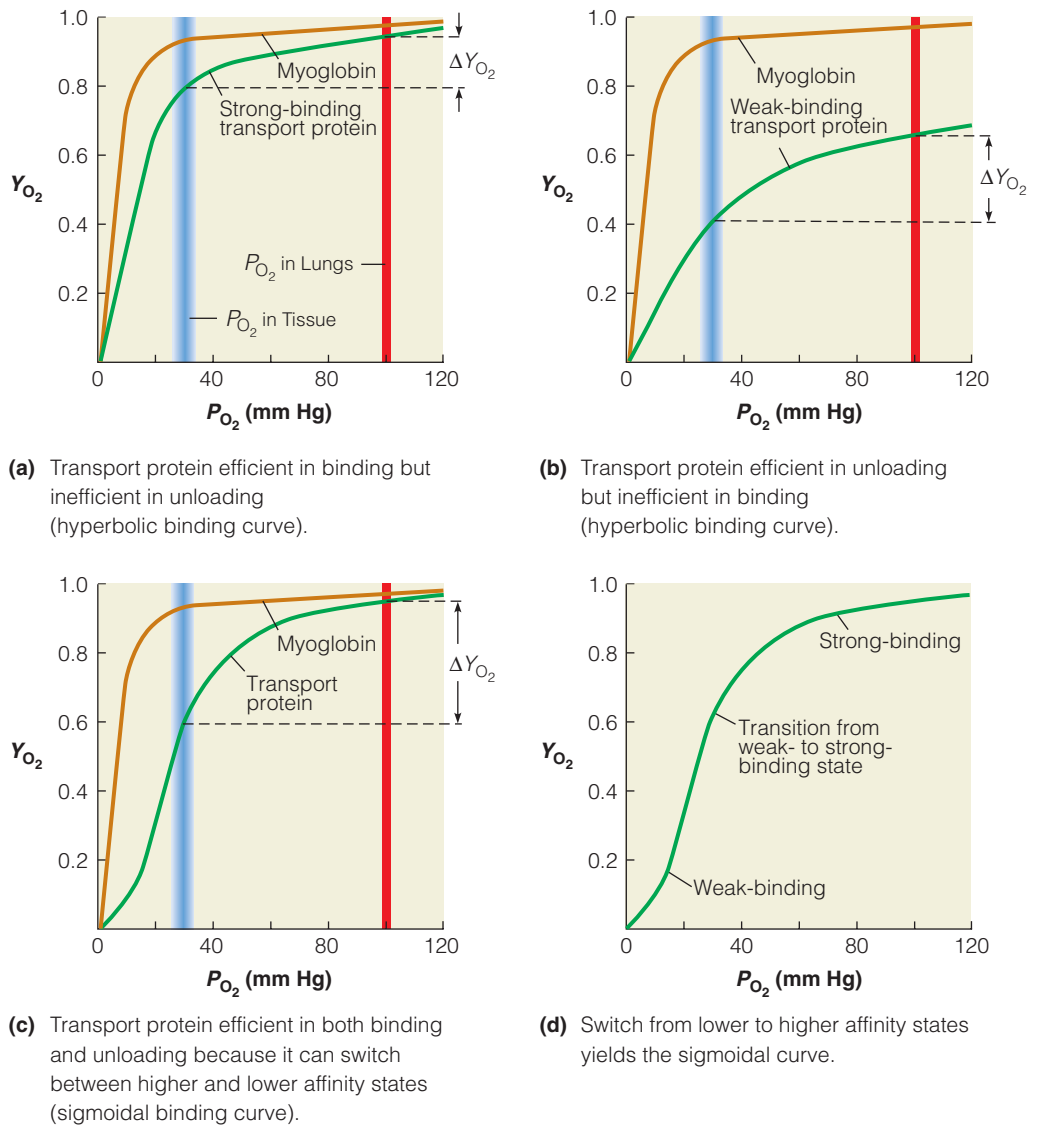

the P_{O_2} in capillaries is about 30 mm Hg and the difference in fractional saturation between the lungs and capillaries, ΔY_{O_2} , is roughly 0.4. Under conditions of extreme metabolic demand for O_2 (such as chasing prey or flight from predators), P_{O_2} can drop to 10 mm Hg and ΔY_{O_2} is roughly 0.85. In other words, to achieve optimum O_2 delivery to tissues, an ideal oxygen transport protein would be nearly saturated at 100 mm Hg, deliver sufficient O_2 to tissues at rest, yet maintain a significant O_2 reserve for periods of high demand. If the transport protein had a hyperbolic binding curve like that of myoglobin, such behavior would be impossible to achieve. With such a binding curve, the protein would be inefficient in supporting either basal or extreme metabolism. The advantages of enhanced aerobic capacity translate to greater survival for both predators and prey and provide the selective pressure for the evolution of optimized O_2 transporters.

This problem has been solved through the evolution of O_2 transport proteins, such as hemoglobin, that have the *sigmoidal* binding curve shown in Figure 7.10c. A sigmoidal curve is very efficient because it allows nearly full saturation of the protein in the lungs or gills, as well as optimal release in the capillaries. You can understand how such a curve can be possible by examining Figure 7.10d. At low oxygen pressures hemoglobin binds O_2 with low affinity;

Efficiency in O_2 transport is achieved by cooperative binding in multisite proteins, described by a sigmoidal binding curve.

FIGURE 7.10

Cooperative vs. noncooperative O_2 -binding curves. These graphs show why an O_2 transport protein such as hemoglobin is more efficient if it switches cooperatively between lower and higher affinity states. The vertical blue and red bars represent P_{O_2} in capillaries and lungs, respectively. The difference in O_2 saturation of Hb in lungs vs. capillaries (ΔY_{O_2}) is represented by the gap between horizontal dashed lines. **(a)** If the transport protein were noncooperative and had a high O_2 affinity, ensuring saturation in the lungs, transfer of O_2 to myoglobin in the tissues would be inefficient. In this case ΔY_{O_2} is very small. **(b)** If a noncooperative transport protein had a lower O_2 affinity, it would efficiently transfer O_2 to myoglobin in tissues; but, it would not be saturated in the lungs. In this case ΔY_{O_2} is somewhat greater than it is for the high affinity noncooperative Hb. **(c)** A transport protein that binds efficiently in the lungs and unloads efficiently in the tissues requires a sigmoidal binding curve, and delivers the largest fraction of its bound O_2 (i.e., it has the largest value of ΔY_{O_2}). **(d)** The sigmoidal binding curve represents the transport protein's switch from a lower affinity state at low oxygen pressures to a higher affinity state at high oxygen pressures.

but, as more oxygen is bound, the affinity for oxygen becomes greater. This behavior must mean that a *cooperative interaction* exists among O₂-binding sites. Ligand binding to the first empty site somehow increases the O₂-binding affinity of the remaining sites, thus promoting complete saturation of the protein with O₂. We can also express this idea the other way around, by saying that dissociation of one O₂ from the protein makes it easier for the remaining O₂ to dissociate, thus promoting the fully deoxygenated state. This behavior requires some kind of intramolecular communication between the binding sites. A single-subunit protein, such as myoglobin, cannot achieve this sort of modulation of ligand-binding affinity; however, such communication *is* possible between the subunits of a multisubunit protein, such as hemoglobin. Thus, the answer to the question “Why are hemoglobins multisubunit proteins?” lies in the evolutionary advantages conferred by cooperative switching between high- and low-affinity states.

Vertebrate hemoglobin has evolved from the *monomeric* structure of myoglobin into the *tetrameric* structure shown in Figure 7.3. Hemoglobin can bind four O₂ molecules—one in each of the four subunits. Although each of the subunits has primary, secondary, and tertiary structures similar to those of myoglobin, the amino acid side chains in hemoglobin also provide other necessary interactions—salt bridges, hydrogen bonds, and hydrophobic interactions—to stabilize a particular quaternary structure.

The functional difference between hemoglobin and myoglobin lies in the cooperativity exhibited by the ligand-binding sites in hemoglobin. This cooperativity is possible because the oxygenation state (filled or empty) of one site can be communicated to another.

As described later in this chapter, there is a structural basis for the cooperative ligand binding in hemoglobin: the lower-affinity state has a protein conformation that is distinct from that of the higher-affinity state. When binding curves are represented as in Figure 7.10c or 7.10d, the important parameters that describe the ligand binding (i.e., the difference in binding affinities of the conformational states and the degree of interaction between sites) are not obvious. A rearrangement of Equation 7.6 provides a simple method to derive some of these parameters from ligand-binding data. If we calculate the quantity $Y_{O_2}/(1 - Y_{O_2})$, we obtain

$$\frac{Y_{O_2}}{1 - Y_{O_2}} = \frac{P_{O_2}}{P_{50}} \tag{7.8}$$

Or, taking logarithms of both sides,

$$\log\left(\frac{Y_{O_2}}{1 - Y_{O_2}}\right) = \log P_{O_2} - \log P_{50} \tag{7.9}$$

Graphing $\log [Y_{O_2}/(1 - Y_{O_2})]$ versus $\log P_{O_2}$ produces what is called a **Hill plot** (Figure 7.11), after Archibald Hill, who proposed in 1910 that the binding of O₂ by hemoglobin could be empirically described by the function

$$Y_{O_2} = \frac{P_{O_2}^h}{P_{50}^h + P_{O_2}^h} \tag{7.10}$$

This gives the general form of the **Hill equation**:

$$\log\left(\frac{Y_{O_2}}{1 - Y_{O_2}}\right) = h \log P_{O_2} - h \log P_{50} \tag{7.11}$$

In the original analysis made by Hill (Equations 7.10 and 7.11), he gave no special physical meaning to the parameter *h*, which is called the **Hill coefficient**. We now know that, in fact, *h* is related to the number of ligand-binding sites (*n*) and the energy of their interaction, such that the value of *h* approaches the value *n*

Cooperativity in binding requires communication between binding sites.

FIGURE 7.11

Hill plots of oxygen binding for myoglobin and hemoglobin under physiological conditions. The circles show the P₅₀ of each protein and binding state. The plot for myoglobin, which binds oxygen noncooperatively, is a solid black line with a slope of 1. The plot for hemoglobin (in green), which binds cooperatively, shows the switch from a lower-affinity state (larger P₅₀; blue circle) to a higher-affinity state (smaller P₅₀; red circle) and has a Hill coefficient of about 3. Values of the ligand binding affinities are derived from extrapolation of the upper and lower arms of the binding curve to the x-axis at $\log [Y_{O_2}/(1 - Y_{O_2})] = 0$. The Hill coefficient *h* is determined by the slope at half-saturation (the green circle in the figure).

as the interaction between sites increases. Note that in the case of myoglobin, $h = 1$, and the Hill plot (Figure 7.11, black curve) yields a straight line as predicted by Equation 7.11. The Hill plot for hemoglobin does not yield a straight line as predicted by Equation 7.11—so the model doesn't fit the data. In 1925, Gilbert Adair published a more rigorous treatment of cooperative ligand binding to hemoglobin that allows for *sequential* binding of ligand with affinities for each site that are not equal and which generally increase as more sites are bound.

In spite of its limitations, the Hill equation is still widely used to analyze ligand binding to hemoglobin because it fits the data in the transition region well, and it yields values for parameters that can be used to compare the ligand binding behaviors of different hemoglobins (e.g., comparing normal to mutant hemoglobin). As shown in Figure 7.11, these parameters are derived from the Hill plot and include the value of P_{50} , estimates of P_{50} for the lower and higher affinity states, and a qualitative description of the degree of cooperativity in terms of the Hill coefficient.

On a Hill plot, the distinction between cooperative and noncooperative systems is clear. As predicted by the Hill equation, the Hill plot for noncooperative binding yields a straight line, with a slope = 1. Now consider the Hill plot for a cooperative ligand-binding protein such as hemoglobin. In this case, the binding curve is sigmoidal rather than linear. When deoxyhemoglobin binds the first O_2 molecule (at low P_{O_2}), its Hill plot has a slope $\cong 1$ and describes binding to the lower-affinity state (characterized by a larger P_{50} value). As progressively more O_2 binds, the curve switches over to approach another, parallel, straight line that describes binding to the higher-affinity state (which has a lower value of P_{50}). For both cooperative and noncooperative systems, the Hill plot gives the value of h as the slope at $\log[Y_{O_2}/(1 - Y_{O_2})] = 0$. Four cases may be considered for a molecule with n binding sites:

A Hill plot can distinguish cooperative ligand binding from noncooperative binding. For cooperative binding, the value of the Hill coefficient is greater than one. For noncooperative binding, the Hill coefficient is equal to one.

1. $h = 1$: There is no interaction between the sites; thus, the molecule binds ligands noncooperatively (e.g., as for myoglobin in Figure 7.11). This situation may also be observed for a multisite protein if the binding sites do not interact with one another.
2. $1 < h < n$: There is interaction between the sites. This situation is the usual one for a protein that binds ligands with so-called positive cooperativity, as depicted for hemoglobin in Figure 7.11. The Hill coefficient must be greater than unity for the curve to switch over from the lower-affinity line to the higher-affinity line.
3. $h = n$: The energy of interaction between sites approaches infinity. In this hypothetical situation the molecule is wholly, or *infinitely*, cooperative. In such a situation, only wholly unliganded and wholly liganded molecules would be present at any point in the binding process. This represents the upper limit on cooperativity and is not observed in real proteins. For example, the Hill coefficient measured under physiological conditions for hemoglobin ($n = 4$) is ~ 3 .
4. $h < 1$: In this case, ligand binding at one site *reduces* binding affinity at other binding sites and is called “negative cooperativity.” This situation is also predicted when a protein contains noninteracting sites with different binding affinities; thus, well-documented examples of true negative cooperativity are rare.

The cooperative binding of oxygen by hemoglobin is one example of what is referred to as an **allosteric** effect. In allosteric binding, the uptake of one ligand by a protein influences the affinities of remaining unfilled binding sites. The ligands may be of the same kind, as in the case of O_2 binding to hemoglobin, or they may be different. As discussed in Chapter 11, allostery is also an important mechanism for regulating the activity of enzymes.

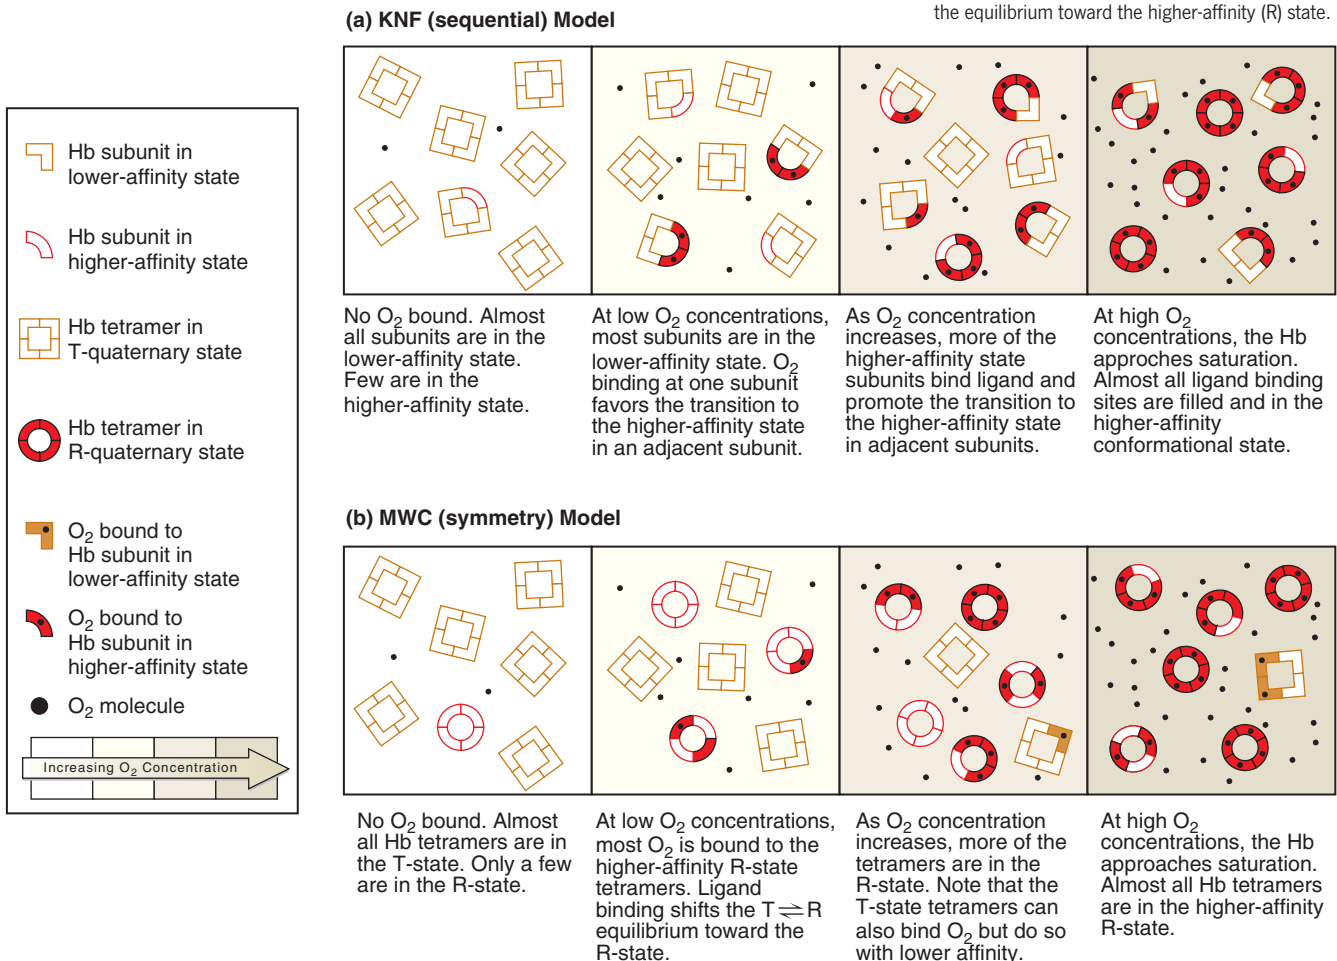

Models for the Allosteric Change in Hemoglobin

How do allosteric transitions from lower-affinity binding states to higher-affinity binding states actually occur? A number of theories have been developed to describe the allosteric transitions in hemoglobin. These can be grouped into four classes.

1. *Sequential models:* The prototype for such models is one proposed by Gilbert Adair in 1925, then further developed in 1966 by Koshland, Nemethy, and Filmer (KNF; Figure 7.12a). The Adair-KNF model assumes that the subunits can change their tertiary conformation one at a time in response to the binding of oxygen. Positive cooperativity arises because the binding of O₂ in one subunit favors the higher-affinity conformational state in adjacent subunits whose sites are not yet filled. Thus, as oxygenation progresses, almost all the sites adopt the higher-affinity conformation. Such models are characterized by the existence of molecules containing subunits in both high-affinity and low-affinity conformational states.
2. *Concerted, or Symmetry, models:* At the opposite extreme lies the theory of Monod, Wyman, and Changeux published in 1965 (MWC; Figure 7.12b). According to the MWC model, the hemoglobin tetramer exists in an equilibrium between two distinct quaternary conformations. In the deoxy state, all subunits in each molecule are in the lower-affinity conformation (also called the T state), and in the oxy state, all are in the higher-affinity conformation (also called the R state). The symbols T and R stand for “tense” and “relaxed”; the significance of this will be seen in the next section. An

FIGURE 7.12

Two classical models for the cooperative ligand binding by hemoglobin. (a) The Koshland, Nemethy, and Filmer (KNF) model. As each subunit binds a ligand, it promotes a change in an adjacent subunit to the higher-affinity conformation. (b) The Monod, Wyman, and Changeux (MWC) model. The entire molecule has two different quaternary states—tense (T) and relaxed (R)—which are in equilibrium. Binding of ligands shifts the equilibrium toward the higher-affinity (R) state.

Hemoglobin switches between conformational states with lower and higher O₂-binding affinities. In the O₂-rich environment of the lungs or gills the higher-affinity state is favored, and oxygen binds to hemoglobin. In the O₂-poor environment of respiring tissues the lower-affinity state is favored, and oxygen is released from hemoglobin.

Vertebrate hemoglobins are tetramers ($\alpha_2\beta_2$) made up of two kinds of myoglobin-like chains.

equilibrium between these states is presumed to exist, and ligand binding shifts that equilibrium toward the R state. The shift is a *concerted* one so that molecules with some subunits in the T state and some in the R state are specifically excluded. Historically, this has been the most widely accepted model for allostery in hemoglobin.

3. *Multistate models*: It has become clear since the early 1990s that neither the KNF nor the MWC model completely explains the allosteric behavior of proteins, including hemoglobin. Consequently, more complex models have been devised, though most retain some elements of the KNF and/or MWC models.
4. *Dynamics models*: A completely different proposal for allostery attributes changes in functional properties to changes in the dynamic behavior of proteins, rather than conformational changes *per se*.

Multistate and dynamic models of hemoglobin allostery are discussed further in the Appendix at the end of this chapter.

Changes in Hemoglobin Structure Accompanying Oxygen Binding

To understand the different models for allosteric behavior in hemoglobin, it is necessary to examine the protein structure in more detail. The hemoglobins of higher vertebrates are made up of two types of subunits, referred to as α and β . The primary structures of human hemoglobins are compared with that of sperm whale myoglobin in Figure 7.13. As you can see, the human α and β sequences have 44% amino acid identity to one another and 18% identity to the sequence of whale myoglobin. Essential residues, like the proximal and distal histidines (F8 and E7, respectively), are strictly conserved, and those critical to the tertiary structure appear to be conserved as well, for the hemoglobin subunits and myoglobin all have very similar tertiary structures. As a rule of thumb, sequences with greater than 30% amino acid identity are predicted to have the same tertiary structure. The hemoglobin molecule contains two copies of each type of subunit, so the whole molecule can be described as an $\alpha_2\beta_2$ tetramer. The subunits are placed in a roughly tetrahedral arrangement as shown schematically in Figure 7.3. When hemoglobin is dissolved in mildly denaturing solutions, it dissociates into $\alpha\beta$ dimers, suggesting that the strongest subunit contacts are between α and β chains, rather than α - α or β - β . In other words, the molecule can be thought of as a dimer of $\alpha\beta$ dimers. Figure 7.3 also shows that the hemes, with their O₂ binding sites, are all close to the surface but *not* close to one another. Therefore, we cannot seek the source of cooperative binding in anything as simple as direct heme-heme interaction.

General features of the protein conformational changes that occur upon ligand binding/release can be seen in Figure 7.14, which illustrates two views of the crystal structural differences between the deoxygenated state and the fully oxygenated hemoglobin molecule. Early X-ray diffraction studies suggested that these differences arise primarily as a result of changes in the quaternary structure, accompanied by much smaller tertiary structure changes. One $\alpha\beta$ dimer pair rotates 15 degrees and slides with respect to the other, as seen in Figure 7.14a. Upon O₂ binding, this movement brings the β subunits closer

FIGURE 7.13

Comparison of sequences of myoglobin and the α and β subunits of hemoglobin. The aligned sequences are those of whale myoglobin and the two human hemoglobin subunits. Gaps (indicated by dashes) have been inserted where necessary to provide maximum alignment of the sequences; the residue numbers to the left of the chains are for the myoglobin sequence. A residue critical to the functioning of these proteins is indicated to the right of the sequences; F8 and E7 are the proximal and distal histidines, respectively (see Figure 7.5). Brown indicates the residues that are identical in all three sequences, and purple the residues identical in both hemoglobin sequences.

together and narrows a central cavity in the molecule, as can be seen in Figure 7.14b. To a first approximation, then, we can regard the hemoglobin molecule as having two quaternary states, one characteristic of the lower-affinity deoxy conformation (the T state) and the other favored by the higher-affinity oxy conformation (the R state).

The MWC view of hemoglobin allostery interprets the Hill plot shown in Figure 7.11 in terms of a *concerted* shift between these two protein quaternary conformations. Wholly deoxygenated hemoglobin molecules are predominantly in the T state conformation, so O₂ binding initially occurs along the line corresponding to the lower-affinity state. The key feature of the MWC model is that the switch between T and R states occurs over a narrow O₂ concentration range, where oxygenation favors transition to the higher-affinity R state. The remaining unliganded sites are in hemoglobin molecules that have predominantly the R-state conformation; thus, the binding curve switches to the line for the higher-affinity state. This leaves, however, many important questions unanswered. What triggers the change? Which models, if any, suffice to explain the results?

A Closer Look at the Allosteric Change in Hemoglobin

A stereochemical, nonquantitative mechanism to explain the cooperativity in oxygen binding was proposed in 1970 by M. F. Perutz, founder of the Laboratory of Molecular Biology at Cambridge University, a pioneer in the field of protein X-ray crystallography and Nobel laureate. Perutz and his colleagues solved crystal structures of both the deoxy and the oxy states of hemoglobin and then used these structures as the basis for a model of allostery in hemoglobin. Given the symmetries of the deoxy-hemoglobin and oxy-hemoglobin structures, it was reasonable for Perutz to describe his stereochemical model of hemoglobin allostery in terms of the symmetric MWC model. In the MWC model, the more reactive (i.e., higher affinity) conformation is called the *relaxed* (R) state and the less reactive (lower affinity) quaternary conformation is the *tense* (T) state. Before we present the Perutz model of allostery, let us consider some of the important differences between the T and R crystal structures.

The transition from the deoxy to the oxy conformation involves significant changes in the subunit–subunit interactions. Some understanding of this process can be gained from a closer study of Figure 7.14b. Note the region, to the lower left, where the β_2 subunit interacts with the α_1 chain. In the deoxy form, the C-terminus of β_2 (residue 146) lies atop the C helix of α_1 (residues 36–42) and is held in this position by a network of hydrogen bonds and salt bridges. His 97 in the FG corner of β_2 is pushed against the CD corner of α_1 , between Thr 41 and Pro 44. In the oxy form, rotation and sliding of the subunits pulls the C-termini of β chains away from α contacts (Figure 7.14b). The salt bridges and hydrogen bonds holding the C-terminus in the deoxy state (see Figure 7.15) are broken, and His 97 of β_2 now lies between Thr 38 and Thr 41 of α_1 . Because of the symmetry of the structure, an exactly equivalent set of changes occurs at the $\alpha_2\beta_1$ interface. The molecule “switches” into a new set of interactions in the oxy state whereby a number of strong interactions in the deoxy state must be broken.

Figure 7.15 shows more details of the key salt bridge interactions that are broken going from the T state to the R state conformation. In the T state each of the β -globin C-termini (His146) makes two salt bridges: an inter-subunit interaction between the His146 C-terminal $-\text{COO}^-$ and the $-\text{NH}_3^+$ side chain of Lys40 on a nearby α -globin, and an intra-subunit interaction between the *protonated* His146 side chain and the $-\text{COO}^-$ of Asp94. The latter interaction plays a major role in stabilizing the T state under conditions of low pH, where protonation of the His146 side chain is favored (see the *Bohr Effect* below). In the T state each α -globin C-terminus (Arg141) is involved in four critical inter-subunit interactions.

R-state hemoglobin has a higher O₂-binding affinity (lower P_{50}). T-state hemoglobin has a lower O₂-binding affinity (higher P_{50}).

Oxygenation causes hemoglobin quaternary structure to change: One $\alpha\beta$ dimer rotates and slides with respect to the other.

FIGURE 7.14

The change in hemoglobin quaternary structure during oxygenation. (a) The transition viewed along an axis perpendicular to the two-fold axis, with the $\alpha_1\beta_1$ dimer (darker blue and red areas) in front of the $\alpha_2\beta_2$ dimer. Deoxyhemoglobin is shown on the left, and oxyhemoglobin on the right. Note the rotation of $\alpha_1\beta_1$ with respect to $\alpha_2\beta_2$ and the shift of β_97 with respect to α_41 and α_44 . The rotation of about 15° is accompanied by sliding because the center of rotation is not centrally located. (b) Top views of hemoglobin, looking down the two-fold axis (dot in center). The two β subunits are in the foreground; α subunits are in the background. Note in deoxyhemoglobin that the central cavity is broad and that residue 97 on one β chain lies between residues 41 and 44 on the adjacent α chain. The shift from the deoxy to the oxy state is evident by the shrinkage of the central cavity and the shift in the contact of residue β_97 with the α chain.

The C-terminal —COO^- of Arg141 of one α globin interacts with the —NH_4^+ of Lys127 on the other α globin chain. The guanidinium side chain of Arg141 forms a salt bridge with the —COO^- of Asp126 and a hydrogen bond with the amide carbonyl group of Val34 on a nearby β globin. Finally, the Arg141 side chain makes a bridging inter-subunit interaction with a chloride ion and the N-terminal —NH_3^+ of Val1. As described in the next section, increasing $[\text{Cl}^-]$ also stabilizes the T state by promoting this bridging interaction.

All of the interactions shown in the lower left of Figure 7.15 are disrupted when hemoglobin switches from the T to the R state (see lower right of Figure 7.15). These interactions are enthalpically stabilizing; thus, in the absence of bound ligand, the T state is favored thermodynamically over the R state (Figure 7.16). The thermodynamic price for switching to the R state (which requires breaking the bonding interactions in the T state) is paid by the energy provided by binding of O_2

The energetic cost of breaking stabilizing interactions in the deoxy state is paid by the formation of Fe—O_2 bonds in the oxy state.

FIGURE 7.15

Key salt bridge interactions disrupted during the switch between T and R state hemoglobin quaternary structures. Top: A schematic drawing of the four subunits in hemoglobin. β -globins are blue, α -globins are red, each here is colored white, 2,3-BPG (see next section) is yellow and shown in a “ball and stick” rendering. Middle: Zoom showing a highly schematic drawing of the key salt bridges that are broken going between the T and R state crystal structures. Here the β -globins (blue) are transparent so interactions at the α -globin (red) N-termini can be visualized. Bottom: Zoom showing crystal structure data of the key interactions at the β -termini (circles) and α -termini (boxes). See the text for a detailed description of the residues involved. Salt bridge interactions in the T state are indicated by black dashed lines. All of these interactions are disrupted during the transition to the R state. Side chains of β -globins are highlighted in blue and those of α -globins are highlighted in magenta. The chloride ion that bridges the C-terminus of one α -globin (α_1 R141) to the N-terminus of the other α -globin (α_2 V1) is shown in orange. Note that identical sets of symmetry-related interactions occur at the other α -globin and β -globin termini. PDB IDs: T state, 1HGA; R state, 1BBB.

Courtesy of Gary Carlton.

**FIGURE 7.16**

A simplified view of ligand binding and conformational energies in hemoglobin. The deoxy (T) conformation is favored when no ligands are bound, due to the increased number of noncovalent interactions in the T state (see Figure 7.15). As Y_{O_2} increases (i.e., more ligands are bound) the energy provided by formation of the $Fe-O_2$ bond stabilizes the R conformation relative to the T conformation.

FIGURE 7.17

The essential features of the “Perutz mechanism” of the $T \rightarrow R$ transition in hemoglobin.

The binding of oxygen to deoxyhemoglobin causes conformational changes in the heme. (a) In the deoxy state, heme has a dome shape, exaggerated in this figure. (b) Binding of the O_2 ligand pulls the iron into the heme plane, flattening the heme and causing strain. (c) A shift in the orientation of His F8 relieves the strain, partly because Val FG5 is pushed to the right. In this way, the tertiary change in heme is communicated to the FG corner.

to the protein-bound heme iron ion. When the O_2 is released, the hemoglobin reverts to the lower-energy deoxy conformation.

Exactly how is the energy of O_2 binding communicated to induce this conformational switching? The essential features of the model proposed by Perutz are shown in Figure 7.17, which shows the relationship of His F8 and the neighboring Val (FG5) to the heme in deoxy- and oxyhemoglobins. The figure includes an important fact not mentioned previously: Not only is the iron ion in the deoxy conformation a bit outside the heme plane, but also the heme itself is not quite flat; it is distorted into a dome shape. Furthermore, in both deoxymyoglobin and deoxyhemoglobin, the axis of His F8 is not exactly perpendicular to the heme but is tilted by about 8° . When oxygen binds to the other side, it pulls the iron ion a short distance down into the heme and flattens the heme (Figure 7.17b,c). This change cannot happen without molecular rearrangement because such motion would bring both the ϵ -hydrogen of His F8 and the side chain of Val FG5 too close to the heme. Thus, the histidine shifts its orientation toward the perpendicular, pulling on the F helix and the FG corner as it does so. This movement in turn distorts and weakens the complex of H-bonds and salt bridges that connect FG corners of one subunit with C helices of another. Consequently, the conformational rearrangements shown in Figures 7.14 and 7.15 occur.

In the simplest terms, the binding of O_2 pulls the Fe^{2+} a fraction of a nanometer into the heme, which levers the F helix and thereby produces a much larger shift in the surrounding protein structure, particularly at the critical α - β interfaces (which are 1.7–2.3 nanometers distant from the heme). This remodeling of the α - β interfaces provides the physical link between the ligand-binding sites, which explains the observed cooperativity.

This mechanism to explain the cooperativity in oxygen binding was proposed by Perutz based on the insights he gained from identifying differences between the deoxy- and oxyhemoglobin crystal structures. As such it represents a brilliant example of the application of structural biology to explain the physiologically relevant behavior of a protein. But does it correspond to reality? Site-directed mutagenesis studies (see Tools of Biochemistry 4B) and rapid ligand binding studies (see Tools of Biochemistry 11A) have allowed many features of the Perutz mechanism to be tested, and although it is not entirely correct, much experimental data supports the general features of the model and it remains widely accepted. For example, Barrick, et al. (see References) utilized site-directed mutagenesis to replace the proximal histidine residues with glycines in α and β chains. The mutant proteins were then studied in the presence of 10 mM imidazole; the imidazole molecule can substitute for the proximal histidine side chain and bind the heme iron *but is not covalently linked to the F helix* (see Figure 7.18). As a consequence, although oxygen binding can still flatten the heme, it does not move the

F helix. Barrick, et al. observed that cooperativity in binding is largely lost, and although the subunits appear to remain in the T state, the ligand-binding affinity of the mutant is *increased* compared to wild-type hemoglobin. These findings support the main features of the Perutz model and demonstrate that the proximal histidine plays a significant role in hemoglobin cooperativity. The observation that cooperativity is not completely abolished in these hemoglobin mutants suggests that other features of hemoglobin structure, perhaps residues in the distal heme pocket, also contribute to cooperative ligand binding.

The mechanism of hemoglobin allostery remains a matter of vigorous debate (see Appendix). However, to discuss the effects of specific allosteric effectors on hemoglobin function, we will continue to use the central ideas of the Perutz and MWC models presented above. We do this for two reasons: First, the general features of these models explain much of the allosteric behavior in hemoglobin. Second, these are the models to which all others are compared; thus, any attempt to follow the criticisms/refinements of these models requires familiarity with the original proposals.

Allosteric Effectors of Hemoglobin

Cooperative binding and transport of oxygen are only part of the allosteric behavior of hemoglobin. The details of animal physiology impose further demands. For example, as oxygen is utilized in tissues, carbon dioxide is produced and must be transported back to the lungs or gills. As described in Chapter 2 (page 44), accumulation of CO₂ also lowers the pH in erythrocytes through the *bicarbonate reaction*,

This reaction in erythrocytes is catalyzed by the enzyme *carbonic anhydrase*. At the same time, the high demand for oxygen, especially in muscle involved in vigorous activity, can result in oxygen deficit, or **hypoxia**. As we shall see in Chapter 13, a consequence of this deficit is the production of lactic acid, which also lowers the pH. The falling pH in tissue and venous blood signals a demand for more oxygen delivery. Hemoglobin functions efficiently to meet these requirements. It does so through its allosteric transition between high-affinity oxy (R) and low-affinity deoxy (T) states.

As we shall see throughout this text, allostery is a general mechanism for the regulation of many important proteins; thus, we give here some general definitions of terms related to allostery. A given protein may bind specifically to several different molecules in more than one location on that protein's surface. The **active site** of a protein is where the protein must bind one or more **substrate** molecules to carry out its primary function. We can view the heme pocket as the "active site" of hemoglobin because that is where the O₂ ligand is bound. In addition to the active site, there may be other sites, called **regulatory sites**, which bind specifically to molecules that regulate the function of the protein. The molecules that regulate protein function in this way are called **effectors**, and they typically exert their effects through an allosteric mechanism.

There are many ways to characterize allosteric effectors. Those that increase protein activity are called **positive effectors**, and those that decrease activity are **negative effectors**. Effectors can also be differentiated by the site on the protein to which they bind. We have seen that O₂ binding *at the heme* has a positive cooperative effect on subsequent O₂ binding events. Because O₂ affects its own binding, by binding to the protein active site, it is called a **homotropic** effector. Effectors that bind at regulatory sites (which are typically distant from the active site) are called **heterotropic** effectors.

We now discuss the effects of four heterotropic negative effectors of hemoglobin: H⁺, CO₂, Cl⁻, and 2,3-BPG.

In the Perutz mechanism, a small movement of the heme iron upon O₂-binding is translated into a larger movement of the F helix by the covalent connection between the F helix and the proximal histidine.

FIGURE 7.18

The effect of replacing the proximal histidine in hemoglobin with a glycine residue and adding a noncovalently bonded imidazole. (a) The effect of O₂ binding according to the Perutz model: the F helix is drawn toward the heme. (b) Now lacking a connection to the heme, the F helix is not disturbed by O₂ binding and there is significantly reduced cooperativity.

FIGURE 7.19
Oxygen affinity of hemoglobin as a function of pH.

Adapted from *Journal of Inorganic Biochemistry* 99:120–130, T. Brittain, Root effect hemoglobins. © 2005, with permission from Elsevier.

A decrease in blood pH results in stabilization of the deoxy state and thereby favors greater O_2 released from hemoglobin.

FIGURE 7.20
Contributions of various His residues to the Bohr effect in hemoglobin. The net Bohr effect for Hb is shown by the green curve. The positive portion of the curve corresponds to the alkaline Bohr effect and is of the greatest physiological relevance. Contributions of some individual His residues are shown in red (β globin residues) or black (α globin residues) and are calculated using pK_a values measured by NMR titration techniques (see Figure 6A.11). The blue curve is the summation of the contributions from all 26 surface His residues. The summation does not include contributions from the N-termini.

Hemoglobin also transports CO_2 from tissues to gills or lungs. CO_2 acts as a negative allosteric effector of O_2 binding.

Response to pH Changes: The Bohr Effect

Blood plasma has a pH that is normally 7.4. As shown in Figure 7.19, a pH drop initially has the effect of raising the P_{50} of hemoglobin (i.e., lowering O_2 -binding affinity), thereby facilitating greater release of O_2 . This response of hemoglobin to pH change is called the **Bohr effect*** after Christian Bohr (father of physicist Niels Bohr), who reported it in 1904. The overall reaction may be written

where n has a value somewhat greater than 2. Physiologically, this reaction has two consequences. First, in the capillaries, H^+ ions promote the release of O_2 by driving the reaction to the right. Then, when the venous blood recirculates to the lungs or gills, the oxygenation has the effect of releasing the H^+ by shifting the equilibrium to the left. This, in turn, releases CO_2 from bicarbonate dissolved in the blood plasma by the reversal of the bicarbonate reaction (Equation 7.12). The free CO_2 can then be exhaled.

A stereochemical mechanism to explain the Bohr effect was first proposed by Perutz and coworkers in 1970. Perutz argued that certain proton binding sites in hemoglobin are of higher affinity in the deoxy form than in the oxy form, and predicted that a major contribution comes from histidine residue 146 at the C-terminus of each β chain. A change in proton affinity for some ionizable group is manifested as a change in pK_a . How can the pK_a of an amino acid side chain be altered? This can be achieved by altering the chemical environment of the ionizable side chain. Histidine $\beta 146$ in the R-state tetramer has a pK_a of roughly 6.4 and is therefore predominantly deprotonated at the normal pH of blood, 7.4. As shown in Figure 7.15, when hemoglobin is in the T state, the side chain of β Asp 94 moves close enough to β His 146 to make a salt bridge *if the histidine is protonated*. Because this salt bridge stabilizes the proton against dissociation, the pK_a of β His 146 is increased. This change in pK_a has been experimentally confirmed by NMR studies in the laboratory of Chien Ho. Ho and coworkers have measured the pK_a of β His 146 in the deoxy state to be 7.93 but 6.42 when bound to CO (which mimics the oxy state). Thus, as the proton concentration increases, protonation of β His 146 is favored, which in turn favors the *deoxy* conformation and thereby promotes the release of oxygen.

Although β His 146 makes the greatest contribution to the alkaline Bohr effect (Figure 7.20), other residues are also involved, including the N-terminal amino groups of the α chains. Proton binding to these residues favors the deoxy conformation, in a manner analogous to that for β His 146. The overall effect of lowering pH on the O_2 binding affinity of hemoglobin is illustrated in Figure 7.21. Note that a decrease in pH of only 0.8 unit shifts the P_{50} from less than 20 mm Hg to over 40 mm Hg, greatly increasing the amount of O_2 released to respiring tissues.

Carbon Dioxide Transport

Release of carbon dioxide from respiring tissues lowers the oxygen affinity of hemoglobin in two ways. First, as mentioned above, most of the CO_2 is rapidly converted to bicarbonate in erythrocytes, releasing protons that contribute to the Bohr effect. Most of this bicarbonate is transported out of the erythrocytes and is carried dissolved in the blood plasma. A small portion of the CO_2 (estimated to be 5–13%) reacts directly with hemoglobin, binding to the N-terminal amino groups of the chains to form **carbamates**:

*The effect observed above pH ~6.5 is more properly called the “alkaline Bohr effect” to distinguish it from the “acid Bohr effect,” which describes an *increase* in O_2 affinity as pH drops below a value of 6. The physiological relevance of the acid Bohr effect (at least in mammals) is not clear.

This *carbamation reaction* allows hemoglobin to aid in the transport of CO_2 from tissues to lungs or gills, and the protons released on carbamate formation contribute to the Bohr effect.

We may summarize the effects of H^+ and CO_2 in terms of the respiratory cycle shown in Figure 7.1: In the lungs or gills of an animal O_2 is abundant. Oxygenation favors the oxy conformation of hemoglobin, which stimulates the release of CO_2 . As the blood then travels via arteries into the tissue capillaries, the lower pH and high CO_2 content favor the deoxy form, promoting O_2 release and binding of CO_2 . Carbon dioxide, both in forming bicarbonate and in reacting with hemoglobin, contributes to decreasing the pH, further stimulating O_2 release.

The role of increasing CO_2 in stimulation of O_2 release is seen in hyperventilation. If a person breathes too rapidly, plasma CO_2 concentration is significantly reduced, and consequently, release of oxygen into the tissues is impaired. This condition leads to dizziness and, in extreme cases, unconsciousness. Hyperventilation can be easily corrected by breathing into a paper bag—this brings exhaled CO_2 back into the blood, thereby increasing its concentration.

Response to Chloride Ion at the α -Globin N-Terminus

The bicarbonate ions formed inside erythrocytes are transported across the erythrocyte membrane into the surrounding plasma. To maintain charge neutrality within the red cell, Cl^- ions are exchanged for HCO_3^- ions (ion transport is discussed in detail in Chapter 10). Chloride ion binds to deoxyhemoglobin, between the terminal residues in each α globin, forming a bridge between the positively charged amino-terminus of Val1 and the side chain of Arg141. This is possible due to the proximity of these groups in the deoxy conformation (see Figure 7.15). Chloride ion binding favors protonation of the N-terminal amino group of Val1, thereby increasing its pK_a . Val1 and Arg141 don't interact in the oxy conformation; thus, both the bound Cl^- and the H^+ are released. In this way chloride ion binding augments the Bohr effect.

2,3-Bisphosphoglycerate

H^+ and CO_2 are the effectors that function rapidly to facilitate the exchange of O_2 and CO_2 in the respiratory cycle. One other major effector operates over longer periods to permit organisms like humans to adapt to gradual changes in oxygen availability. It is a common observation that people who move to high altitudes at first experience some distress but gradually acclimate to the lower oxygen pressure. In the short term (1–2 days), this acclimation results from increased concentration of red cells in plasma due to a reduction in the volume of the blood plasma; but, a more significant short-term adaptive effect is due to changes in the concentration in red cells of the allosteric effector **2,3-bisphosphoglycerate** (or **2,3-BPG**; Figure 7.22a). Within 2 days of moving to higher altitude, the concentration of 2,3-BPG in red cells nearly doubles (from 4.5 mM to ~7.6 mM), resulting in increased binding of this effector to Hb. Longer-term adaptation to higher altitude, which requires 2–3 months, is the result of increased red cell production.

Like the effects of H^+ and CO_2 , binding of 2,3-BPG acts to lower the oxygen affinity of hemoglobin. At first glance this may seem like a strange way to adapt to lower O_2 pressure, but in fact, the more efficient unloading of oxygen in the tissues more than compensates for the slight decrease in loading efficiency in the lungs (see Problem 12). The action of 2,3-BPG is illustrated in Figure 7.23. 2,3-BPG binds via ionic interactions with positively charged groups lining the cavity between the β chains in the deoxy state. Comparison of the two hemoglobin conformations shown in Figure 7.14b shows that this cavity is much narrower in oxyhemoglobin than in deoxyhemoglobin. In fact, 2,3-BPG cannot be bound in the oxy form. The higher the 2,3-BPG content in red blood cells, the more the

FIGURE 7.21

The Bohr effect in hemoglobin. Oxygen-binding curves for hemoglobin (green) are shown for pH 7.6, 7.2, and 6.8. Note that the efficiency of oxygen unloading, as measured by the differences in the curves at $P_{\text{O}_2} = 30$ mm Hg (vertical blue line), increases greatly as the pH drops. As the hemoglobin circulates from lungs to tissues, the lower pH favors the lower-affinity conformation (this is also reflected in the increase in P_{50} values as pH drops). Myoglobin displays little Bohr effect, so its oxygen-binding curve (orange) is approximately the same at all three pH values.

FIGURE 7.22

Two anionic compounds that bind to deoxyhemoglobin. (a) 2,3-Bisphosphoglycerate (2,3-BPG), found in mammals. 2,3-BPG was formerly known as diphosphoglycerate (DPG); you will sometimes find the older term in the literature. (b) myo-Inositol-1,3,4,5,6-pentaphosphate (IPP), found in birds.

2,3-Bisphosphoglycerate (2,3-BPG) is found inside red blood cells and is a potent allosteric effector that lowers the O_2 affinity of hemoglobin.

FIGURE 7.23

Binding of 2,3-bisphosphoglycerate to deoxyhemoglobin. The binding site, in the central cavity of the adult hemoglobin (HbA) tetramer (see Figures 7.14 and 7.15), is lined with eight positively charged groups that help bind the negatively charged 2,3-BPG molecule (center panel). Note the His residues ($\beta 143$) that are replaced by Ser in fetal hemoglobin (HbF; rightmost panel).

FIGURE 7.24

Combined effects of CO_2 and BPG on oxygen binding by hemoglobin. Hemoglobin that has been stripped of both CO_2 and BPG has a high oxygen affinity. When both substances are added to hemoglobin at the levels found in blood emerging from the capillaries, the hemoglobin displays almost exactly the same binding curve as observed for whole blood.

British Medical Bulletin 32:209–212, J. V. Kilmartin, Interaction of haemoglobin with protons, CO_2 and 2,3-disphosphoglycerate. © 1976, by permission of Oxford University Press.

deoxy structure is favored. Once again, a decrease in O_2 affinity is explained by preferential stabilization of the deoxy structure. Increased 2,3-BPG levels are also found in the blood of smokers, who because of the carbon monoxide in smoke, also suffer from limitation in O_2 transport.

2,3-BPG plays one other subtle, but important, role in the respiration of humans and other mammals. Consider the problem faced by a fetus, which must obtain O_2 from the mother's blood by exchange through the placenta. For this exchange to work well, fetal blood must have a higher O_2 affinity than the mother's blood. In fact, the human fetus has a hemoglobin different from the adult form. Whereas adult hemoglobin (HbA) has two α and two β chains ($\alpha_2\beta_2$), in the fetus the β chains are replaced by similar, but distinctly different, polypeptides. These are called γ chains; thus, fetal hemoglobin (HbF) has an $\alpha_2\gamma_2$ structure. The intrinsic oxygen affinity of HbF is very similar to that of HbA, but HbF has a much lower affinity for 2,3-BPG than does HbA. This difference is largely due to the replacement of His 143 in the adult β chain by a Ser in the fetal γ chain. As Figure 7.23 shows, loss of the positively charged His 143 in HbF reduces the binding affinity for 2,3-BPG. The concentration of 2,3-BPG is about the same in the circulatory systems of mother and fetus. Under these conditions, HbF will have less 2,3-BPG bound than will HbA and therefore tends to favor the R state; thus, HbF will have a higher oxygen affinity and efficiently extracts O_2 from the lower-affinity maternal HbA.

The use of effectors that facilitate oxygen release is not restricted to mammals. The blood of birds contains **inositol pentaphosphate** (see Figure 7.22b), and fish use ATP for a similar purpose. All of these molecules have a high negative charge and bind in the central cleft of deoxyhemoglobin. All of these allosteric effectors, including H^+ , CO_2 , Cl^- , and 2,3-BPG, act in the same general manner—by biasing the conformational equilibrium in hemoglobin toward the deoxy form. However, they interact at distinctly different sites, and therefore their effects can be additive, as illustrated for CO_2 and 2,3-BPG in Figure 7.24.

Other Functions of the Heme Globins: Reactions with Nitric Oxide

Francis Crick is reputed to have quipped “hemoglobin has a *bore* effect,” reflecting a widely held view that there are no more profound discoveries to be made in the continued study of the most-studied protein on Earth. Given the current debate over hemoglobin allostery (see Appendix), it is clear that not everything about hemoglobin function is understood. Likewise, the long-held view of myoglobin as an essential O_2 transport protein was challenged by the startling result that mice lacking a gene for myoglobin appear to be normal, even under conditions of

exercise-induced stress. Careful investigation showed that multiple compensatory mechanisms developed in these mice to facilitate oxygenation of their tissues (e.g., increasing the density of capillaries in heart muscle). In the past decade, both myoglobin and hemoglobin have been shown to possess essential functions beyond those associated with reversible O₂ binding, and many open questions remain regarding the mechanisms whereby these other functions are carried out. The most active areas of research are those focused on the roles of myoglobin and hemoglobin in the physiological effects of the gas nitric oxide (NO), which is both an important signaling molecule and a mediator of cytotoxicity during phagocytosis. Greater detail on the biosynthesis and action of NO is presented in Chapters 21 and 23, respectively.

At the low concentrations normally found in endothelial cells ($\sim 10^{-7}$ M), NO signals the relaxation of smooth muscle cells. Before it was identified as NO, the agent that caused this relaxation was known as EDRF, or endothelium-derived relaxation factor. Oxyhemoglobin is an efficient scavenger of NO because it reacts very rapidly ($\sim 7 \times 10^7 \text{ M}^{-1}\text{s}^{-1}$) with NO and oxidizes it to nitrate in a *dioxygenation* reaction:

Work by Paul Gardner and coworkers has shown that both oxygen atoms in O₂ are added to NO when this reaction is carried out in the presence of oxymyoglobin or oxyhemoglobin, but not when the reaction is carried out in the absence of myoglobin or hemoglobin. This led Gardner to propose a *nitric oxide dioxygenase* activity for the globin family of proteins, including bacterial **flavo-hemoglobins**, which are ancestors of myoglobin and hemoglobin (see below). Flavo-hemoglobins contain, in addition to a heme binding domain, domains that bind the redox cofactors **flavin adenine dinucleotide** (FAD/FADH₂) and **nicotinamide adenine dinucleotide** (NAD⁺/NADH). The chemistry performed by these cofactors is described in greater detail in subsequent chapters covering metabolic reactions. In flavo-hemoglobin they act as reducing agents to convert the ferric (Fe³⁺) heme generated in Equation 7.13 to ferrous (Fe²⁺) heme. Why would globins have this NO dioxygenation activity, and why do microbes possess globins when they are small enough to receive sufficient O₂ by diffusion (under aerobic conditions)?

Clues to the likely answers to these questions came from the observation that in the several bacteria that have been tested, those that lack genes for flavo-hemoglobin are killed by exposure to NO at concentrations of $\sim 10 \mu\text{M}$. In addition, some bacteria that express higher than normal amounts of flavo-hemoglobin are resistant to killing by macrophages (which produce NO as part of their cytotoxic action). Thus, it seems that in these microbes, flavo-hemoglobin mediates resistance to the cytotoxic effects of NO. What of higher organisms? Compared to wild-type mice, mice lacking myoglobin genes show a phenotype for increased damage to cardiac tissue following periods of NO exposure. Among its various modes of cytotoxicity, NO inhibits aerobic respiration. These observations prompted Maurizio Brunori to propose in 2001 that myoglobin, as a potent NO dioxygenase, plays a critical role in protecting cells against such NO-mediated inhibition of cellular energy production.

The well-established dioxygenase activity of myoglobin may explain another recent observation, namely, that myoglobin is expressed at low levels in many different nonmuscle tissue types. In addition, two “new” additions to the heme globin family, **cytoglobin** and **neuroglobin**, may play important roles in NO scavenging. Cytoglobin appears to be expressed in most tissue types, whereas neuroglobin is found in neuronal tissue. Although the functions of cytoglobin and neuroglobin are not known definitively, they may act as dioxygenase enzymes to prevent tissue damage following hypoxic events (e.g., stroke or heart attack). Other proposed roles for these globins include reduction in hypertension and prevention of **apoptosis** (programmed cell death, described in more detail in Chapter 28).

Cytoglobin and neuroglobin may help to prevent tissue damage following a stroke or heart attack.

In summary, myoglobin and hemoglobin represent sophisticated molecular machines, each finely tuned to carry out its functions. In the following section, we explore how these structures might have evolved. We will focus on the O₂ transport functions of vertebrate myoglobin and hemoglobin; however, it should be noted that globins are ancient proteins that are found in greater structural and functional variety in bacteria and archaea, where the NO dioxygenase activity appears to be of primary importance. Thus, O₂ transport appears to be a relatively recent functional adaptation to the ancestral globin fold, which has been present on Earth since atmospheric levels of O₂ were much lower than they are at present.

Protein Evolution: Myoglobin and Hemoglobin as Examples

Each polypeptide sequence produced by an organism is encoded by a gene. The nucleotide sequence in that gene dictates the amino acid sequence of the protein, which in turn defines the protein's secondary, tertiary, and quaternary structures. Evolution of proteins occurs through accumulated changes in the nucleotide sequences of genes. To explore this process, we will use as an example the evolutionary development of the myoglobin–hemoglobin family of proteins. First, however, we must examine in a bit more detail the structure of eukaryotic genes and the mechanisms through which mutation can occur.

The Structure of Eukaryotic Genes: Exons and Introns

In previous chapters we stated that a direct correspondence exists between the nucleotide sequence in a gene and (via mRNA) the amino acid sequence of the polypeptide chain it encodes. For most genes in prokaryotic organisms, this concept is true. But investigation of the genomes of higher organisms has produced a surprising result: Within most eukaryotic genes are DNA sequences that are never expressed in the polypeptide chain. These noncoding regions, called **introns**, alternate with regions called **exons** that include the DNA encoding the translated polypeptide sequence and untranslated regions at the 5' and 3' ends that are important in regulating transcription and translation. Figure 7.25 shows how the exon–intron structure of the β globin gene is related to the structure of β globin.

Eukaryotic genes are discontinuous, containing regulatory and protein-encoding sequences (exons) and intervening sequences (introns).

FIGURE 7.25

Coding and noncoding regions of the β hemoglobin gene. The gene for the human β hemoglobin chain has regulatory (blue boxes) and coding (purple, red, and green boxes) regions, or exons, alternating with noncoding regions, or introns (yellow boxes). This figure follows the transcription and translation of the gene to yield the final β hemoglobin chain. **Step 1, transcription:** A primary transcript (pre-mRNA) containing complementary copies of the exons and introns is produced from the gene. **Step 2, splicing:** The intron sequences are removed and the exons spliced together to yield the final mRNA. Note: the mechanism of mRNA splicing is given in Chapter 27. **Step 3, translation:** The coding regions of the spliced mRNA produce a β chain, which adopts its favored three-dimensional structure and incorporates a heme group. Note that the entire heme-binding region (red) is coded for by one exon.

Clearly, this remarkable situation means that mRNA production in eukaryotes must be a more complex process than had been assumed at first. As Figure 7.25 shows, transcription first produces a primary transcript, or **pre-mRNA**, corresponding to the whole gene—exons, introns, and portions of flanking regions. The pre-mRNA, while still in the cell nucleus, is cut and spliced to remove the regions corresponding to introns, thereby producing an mRNA that codes correctly for expression of the polypeptide chain. We describe the details of this process in Chapter 27. For now, keep in mind that most eukaryotic genes are “patchwork” structures, containing extensive regions that do not correspond to any part of the protein sequence.

Mechanisms of Protein Mutation

When organisms reproduce, they copy their DNA, and occasionally mistakes are made. These mistakes may be random errors that occur during copying, or they may be results of damage the DNA has sustained from radiation or chemical **mutagens**, substances that produce mutations (discussed in greater detail in Chapter 26). In any event, these alterations will appear as **mutations** in the DNA of the next and subsequent generations of progeny. There are two basic kinds of changes in the DNA sequence that may give rise to mutations in proteins: (1) replacements of DNA bases by others and (2) deletion or insertion of bases in the gene.

Replacement of DNA Bases

Replacement of bases can have several possible consequences. First, the base change may not affect the protein sequence at all. The change may occur in an intron, for example. But even if it is in a protein-coding exon, this **silent**, or **synonymous mutation** (Figure 7.26a), will make no difference in the protein sequence if the new codon codes for the same amino acid as the original one. The redundancy of the genetic code (see Figure 5.18, page 152) is such that frequently a base change does not alter the protein product. Alternatively, an amino acid residue in the original protein may be replaced by a different one in the mutated protein; this type of replacement is called a **missense**, or **nonsynonymous mutation** (Figure 7.26b). Occasionally, the codon for an amino acid residue within the original protein will be changed to a *stop* codon. We call this a **nonsense mutation** because the protein will be terminated prematurely and usually be nonfunctional (Figure 7.26c). Sometimes the opposite happens—a stop codon mutates into a codon for an amino acid residue. In this case translation continues, elongating the chain.

Nucleotide Deletions or Insertions

Deletions or insertions in the gene may be large or small. Such mutations outside the coding regions will generally have no effect, unless they modify sites of

Mutations result from changes in the DNA sequence of genes, including base substitutions, deletions, or additions.

FIGURE 7.26

Mutation types. Some of the ways in which mutations can occur in the β hemoglobin chain are shown here. The first 10 residues of the normal human β chain, together with their DNA codons, are shown at top. **(a)** A silent, or synonymous, mutation has occurred in the codon for residue 2 (CAC to CAT). **(b)** A missense, or nonsynonymous, mutation has occurred in the codon for residue 6 (GAG to GTG). This is the sickle-cell mutation. **(c)** A nonsense mutation has introduced a stop signal after the codon for residue 7 (AAG to TAG), terminating the chain prematurely. **(d)** A frameshift mutation has occurred by deletion of a single T residue. The rest of the chain, with a completely altered sequence, will continue to be produced until a stop signal is encountered in the new frame. Both (c) and (d) would result in β -thalassemia (see page 266).

Residue number	1	2	3	4	5	6	7	8	9	10	
Normal β gene	...A T G	G T G Val	C A C His	C T G Leu	A C T Thr	C C T Pro	G A G Glu	G A G Glu	A A G Lys	T C T Ser	G C C ... Ala
(a) Silent, or synonymous mutation		G T G Val	C A T His	C T G Leu	A C T Thr	C C T Pro	G A G Glu	G A G Glu	A A G Lys	T C T Ser	G C C ... Ala
(b) Missense, or nonsynonymous mutation		G T G Val	C A C His	C T G Leu	A C T Thr	C C T Pro	G T G Val	G A G Glu	A A G Lys	T C T Ser	G C C ... Ala
(c) Nonsense mutation		G T G Val	C A C His	C T G Leu	A C T Thr	C C T Pro	G A G Glu	G A G Glu	T A G Stop	T C T Ser	G C C ... Ala
(d) Frameshift mutation by deletion		G T G Val	C A C His	C T G Leu	A C C	C C T Leu	G A G Arg	A G A Arg	A A G Ser	T C T Leu	G C C ... Ala

transcriptional control (e.g., the untranslated regions of the spliced mRNA). Large insertions or deletions in coding regions almost invariably prevent the production of useful protein; sometimes even whole genes may be deleted. The effect of short deletions or insertions depends on whether they involve multiples of three bases. If one, two, or more *whole codons* are removed or added, the consequence is the deletion or addition of a corresponding number of amino acid residues. However, a deletion or insertion in a coding region of any number of bases *other* than a multiple of three has a much more profound effect: It causes a shift in the reading frame during translation. Such **frameshift mutations** result in a complete change in the amino acid sequence in the C-terminal direction from the point of mutation (Figure 7.26d).

The effects of these kinds of mutations on the functionality of the protein product, and therefore on the organism itself, can be quite varied. Base substitutions may, in some cases, be neutral in effect, either not changing the amino acid coded for or changing it to another that functions equally well at that position in the protein. Frequently, the result is deleterious. Occasionally, such mutations confer some functional advantage to the protein, and the mutated organisms may be selected for in future generations. Nonsense mutations and frameshift mutations, by contrast, almost always result in loss of protein function. If the protein function is critical to the life of the organism, such mutations are strongly selected against in the course of evolution—those who inherit them do not survive to reproduce.

Gene Duplications and Rearrangements

By accumulating many small mutational changes over millions of years, proteins gradually evolve. The diversity of functions that they can collectively perform is increased by two other phenomena: **gene duplication** and **exon recombination**.

Very occasionally, replication of the genome occurs in such a way that some DNA sequence, containing a particular gene, is copied twice. Initially, the only result of such duplication is that the descendants of the organism have two copies of the same gene. This mutation may be advantageous if the protein is needed in large amounts because the capacity for its production will be increased. In such cases, there will be selective pressures to maintain two or even more copies of the same gene. Alternatively, the two copies may evolve independently. One copy may continue to express the protein fulfilling the original function, but the other may evolve through mutations into an entirely different protein with a new function. Recall from Chapter 5 that proteins that are related by a common evolutionary origin are called **homologs**. Homologous genes within an organism that arise from gene duplication are called **paralogs**. This is in contrast to **orthologs**, which are homologous genes in different species that originated from a common ancestor.

Another way in which the diversity of proteins can increase is through the *fusion* of two or more initially independent genes. Such fusion may lead to the production of multidomain proteins exhibiting new combinations of functions.

The intervening sequences in eukaryotic genes (introns) offer a further possibility for diversification of protein structure and function. Because these regions are not used for coding, they represent positions where genes can be safely cut and recombined in the process of **genetic recombination**. The mechanisms of recombination are described in Chapter 26; at this point we are concerned only with its consequences. Suppose that an exon from one gene, which codes for a protein region with physiological function B, is inserted into an intron region in a gene for a protein carrying function A. The new hybrid protein is now capable of both functions A and B and may serve a new physiological function.

Through the combined effects of mutations, gene duplication, and genetic rearrangement, organisms can develop new abilities, adapt to new environments, and become new species. The process of organismal evolution, which we see exhibited in the fossil record and in the incredible variety of existing plants, animals, and microorganisms, is largely a consequence of this molecular evolution of proteins.

Genomes can also be modified by gene duplication, gene fusion, or exon recombination.

Evolution of Protein Function at the Level of Molecular Detail

As exemplified by bacteria that rapidly develop resistance to antibiotics, protein function evolves in response to challenges that test the “fitness” of an organism for its environment. How does this happen at the level of protein structure? Genetic mutation can result in variation in amino acid sequence that may affect protein structure and function. But, we may ask, how many mutations are required to establish a new protein function that confers a selective advantage?

By combining the tools of evolutionary and molecular biology it has been possible to predict the sequences of ancestral genes and then test potential evolutionary pathways leading from the ancestral gene sequence to the modern gene sequence for a protein. To illustrate this approach, let us consider a hypothetical example of an ancestral gene and a modern homolog that differ by 4 amino acid mutations. In this case, 16 genes encoding the possible ($2^4 = 16$) combinations of the ancestral and modern amino acid sequences can be synthesized and expressed. Detailed structural and functional characterization of the 16 individual mutants allows feasible evolutionary pathways to be identified at the level of atomic detail. As shown in Figure 7.27, what emerges from such analysis is a picture of the *order* in which mutations must occur to avoid nonfunctional (e.g., unstable) intermediate species as well as those pathways that are most likely to recapitulate the actual mutational events in the evolution of the modern protein from its ancestor.

Numerous studies of protein evolution indicate that the majority of mutations that confer new functional properties tend to be destabilizing to the parent protein. There is, therefore, a limited number of such mutations that can be tolerated along the evolutionary pathway. Not all mutations are destabilizing, and some so-called **permissive mutations** do confer greater thermodynamic stability to a protein—typically without effect on the functional properties. Another conclusion drawn from *in vitro* evolution studies is that there is a threshold stability that a protein must possess to be “evolvable.” In other words, greater thermodynamic stability for a protein is correlated with a greater tolerance for a mutation that, in turn, leads to the evolution of new function. The requisite stability may be achieved in the course of evolution by incorporation of stabilizing (permissive) mutants.

An emerging view of protein evolution is focused on the dynamic nature of proteins and suggests that the greater conformational variability associated with a more dynamic structure would allow a protein to evolve more rapidly than if it were conformationally rigid. A protein with flexible loops making up its active site is likely to be promiscuous in terms of its substrate binding specificity—a situation that inherently predisposes the protein to evolve multiple new functions. Panels (a) and (b) of Figure 7.28 show examples of conformationally flexible proteins. What evidence is there for such dynamic structures in proteins? The number of well-characterized “natively unstructured” or “intrinsically disordered” proteins has grown significantly in the past ten years, particularly among proteins involved in signaling. How, then, would such a dynamic protein evolve a new function? One hypothesis suggests that the relative population of a minor conformer that binds some non-native ligand could be increased by a mutation that stabilizes that conformer over the major conformer that normally binds the native ligand. This process is illustrated in Figure 7.28c, where two mutations were shown to be sufficient to bias the conformational ensemble of a dynamic protein to favor one conformer over another.

Irrespective of the actual pathway that results in evolution of new function, mutation plays a key role; thus, the rate of mutation in a genome is an important parameter in determining the rate of evolution of new protein function. In mammalian genomes, the mutational frequency has been estimated to be $1.1\text{--}12.4 \times 10^{-9}$ per base pair per year. The slow rate in humans of protein evolution for improved function can be understood given (1) the size of the human genome ($\sim 3 \times 10^9$ base pairs), (2) that less than 2% of the genome

FIGURE 7.27

Mapping possible evolutionary pathways between an ancestral protein sequence and a modern homolog. In this hypothetical scenario, there are 16 possible combinations of mutants for an ancestral protein (AAAA) and a modern homolog (MMMM), which differ by 4 mutations and 24 pathways (shown by arrows) linking AAAA to MMMM. Proteins that are stable are shown in bold type. Red type indicates a permissive mutation that increases protein stability, and therefore promotes evolvability; green type indicates a mutation that is neither stabilizing nor destabilizing; and blue type indicates a destabilizing mutation. In this example the red (stabilizing) mutation must occur prior to either of the blue (destabilizing) mutations. This requirement for a specific order in which mutations occur limits the number of likely pathways to the eight possibilities shown by different combinations of the colored arrows.

FIGURE 7.28

Examples of conformational flexibility that might confer improved evolvability. **(a)** Local conformational changes allow promiscuous substrate binding to an enzyme. The open conformation of P450-CYP2B4, a detoxification protein found in liver (orange ribbon), allows binding to a large substrate (illustrated in red), and the closed one (light blue ribbon) binds the smaller substrate (darker blue). **(b)** Lymphotactin, a small protein that is part of the immune response, is a so-called metamorphic protein that exists in equilibrium between two native conformations: a β - α monomer (top) and an all- β dimer (bottom). **(c)** Two different topologies (mediated by three different disulfide bridges) are found in two naturally occurring cysteine-rich domains (CRDs) from proteins that are found in the venomous cells of jellyfish and sea anemones (NW1 and Mcol1C). These two CRDs show almost no sequence identity beyond the conserved cysteines. Conversion between these topologies is achieved by a single mutation Lys21 \rightarrow Pro21 (K21P) in NW1 that yields a dynamic intermediate which exists in both conformations. A second mutation Gly11 \rightarrow Val11 (G11V) completed the transition from the NW1 topology to that of Mcol1C.

encodes protein genes, (3) that the majority of these mutations do not occur in the germ line (thus, they are not passed on to progeny), and (4) the apparent need for a defined temporal order of the multiple mutations required to confer the new function (as illustrated in Figure 7.27). Much more prevalent is the observation of deleterious, pathological mutations, which may require only a single nucleotide change. We discuss a few of these for human hemoglobin later in this chapter.

Evolution of the Myoglobin–Hemoglobin Family of Proteins

We have already seen an example of the process of protein evolution. If we compare the sequences of sperm whale and human myoglobin (see Figure 5.16), we find 25 amino acid changes. Because fossil evidence indicates that the evolutionary lines that led to sperm whales and humans diverged from a common mammalian ancestor about 100 million years ago, we can gain an idea of the rate of this process. If the rate was uniform, there has been an average of one amino acid replacement every 4 million years.

If we compare human myoglobin with that of the shark, we find about 88 differences. Because these evolutionary lines diverged about 400 million years ago, the accumulated differences are about what we would expect from the preceding example. In other words, the number of amino acid substitutions in two related proteins is roughly proportional to the evolutionary time that has elapsed since the proteins (and the species) had a common ancestor. Using this principle, we can compare the sequences of both hemoglobins and myoglobins and attempt to construct a “family tree” of globin proteins. The tree is complicated by the fact that higher eukaryotes, including humans, carry genes for both myoglobin and several *different* hemoglobin chains. These different genes are expressed at different times in human development (Figure 7.29). The α and β chains, as mentioned

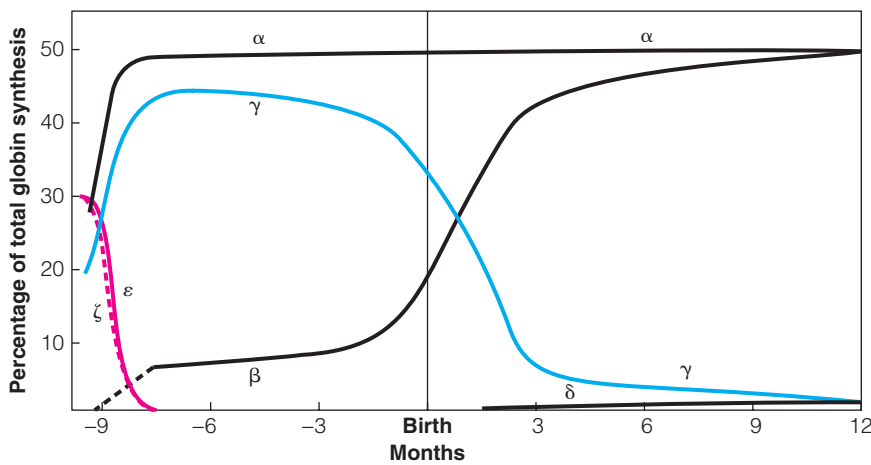

FIGURE 7.29

Expression of human globin genes at different stages in development. The human ζ and ϵ genes make the $\zeta_2\epsilon_2$ hemoglobin found in the very early embryo. This is soon supplanted by the $\alpha_2\gamma_2$ hemoglobin of the fetus. At about the time of birth, transcription of the γ gene ceases, and the β gene begins to be transcribed. By six months, the infant will have almost all $\alpha_2\beta_2$ (adult) hemoglobin. The δ gene is never transcribed at high rates. There are two copies of the α gene: α_1 and α_2 . Both contribute to the production of α chains.

British Medical Bulletin 32:282–287, W. G. Wood, Haemoglobin synthesis during human fetal development. © 1976, by permission of Oxford University Press.

earlier, are normally present in adults. But in the early embryo, the hemoglobin genes expressed are those for the embryonic chains, ζ (zeta) and ϵ . As the fetus develops, these chains are replaced by α and γ chains, ensuring efficient oxygen transfer from mother to fetus. Finally, at about the time of birth, the γ chains are replaced by β chains. In addition, after birth a small amount of a δ chain is produced. These developmental types of hemoglobin chain are slightly different, and each is coded for by a separate gene in the human genome.

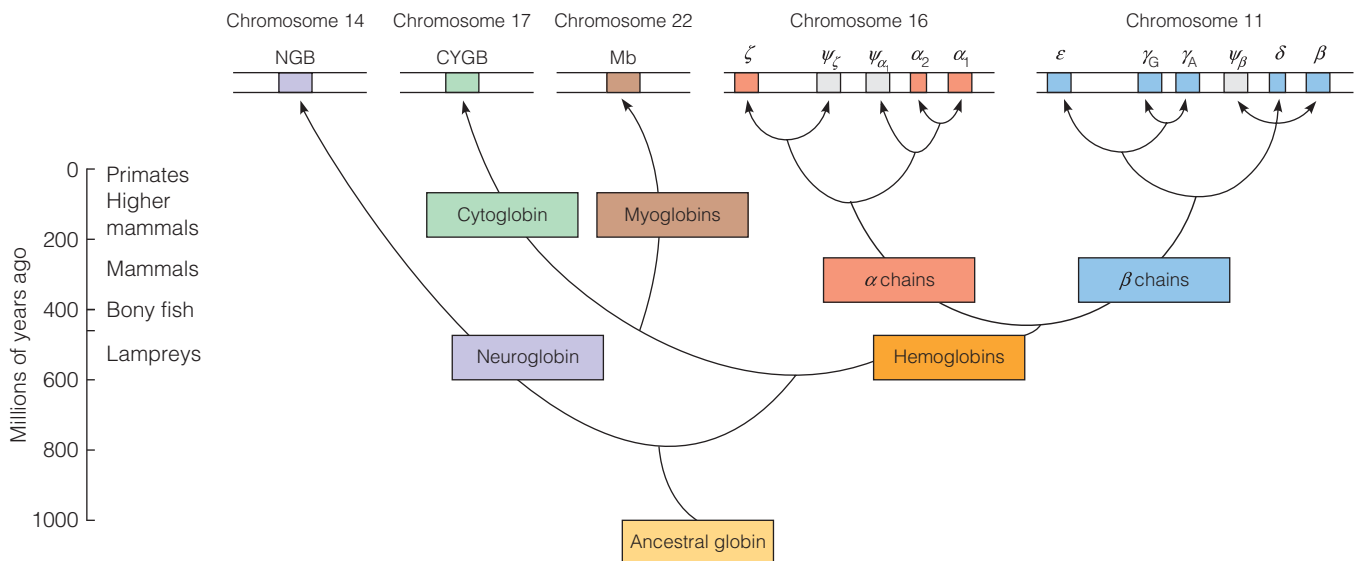

Comparison of the sequences of many globins from many different species yields the evolutionary tree shown in Figure 7.30. According to these results, very primitive animals had only a myoglobin-like, single-chain ancestral globin for oxygen storage. Most of these animals, like protozoans and flatworms, were so small that they did not require a transport protein. Roughly 500 million years ago, an important event occurred: The ancestral myoglobin gene was duplicated. One of the copies became the ancestor of the myoglobin genes of all higher organisms; the other evolved into the gene for an oxygen transport protein and gave rise to the hemoglobins.

Along the evolutionary line leading to vertebrates and mammals, the most primitive animals to possess hemoglobin are the lampreys. Lamprey hemoglobin can form dimers but not tetramers and is only weakly cooperative; it represents a first step toward allosteric binding. But subsequently a *second* gene duplication occurred, giving rise to the ancestors of the present-day α and β hemoglobin chain families. Reconstruction, from sequence comparison, indicates that this

Myoglobin and hemoglobin evolved from an ancestral myoglobin-like protein.

FIGURE 7.30

Evolution of the globin genes. The arrangement of human globin genes is shown at the top. Note that they are found in five different chromosomes. Functional genes are shown in color; pseudogenes, which are nontranscribed variants of a gene, are in gray. The diagram underneath shows the probable evolution of the globin gene family, based on sequence differences among the various globin genes in humans and other animals. The times at which gene duplications occurred are inferred from a combination of sequence and fossil evidence and are only approximate. The two α genes and the two γ genes are too similar in sequence to allow us to judge the time of their divergence. We know only that it must have happened relatively recently.

Evolution of globins has retained the common “globin fold” that holds the heme. Evidence for continuing evolution is found in the many variant proteins in existing species.

must have happened about 400 million years ago, at about the time of divergence of the sharks and bony fish. The evolutionary line of the latter led to the reptiles, and eventually to the mammals, all carrying genes for both α and β globins and capable of forming tetrameric $\alpha_2\beta_2$ hemoglobins. Further gene duplications have occurred in the hemoglobin line, leading to the embryonic forms ζ and ϵ and the fetal γ . As Figure 7.30 shows, the duplications that led to a distinction between adult and embryonic subtypes coincide fairly well with the development of placental mammals, about 200 million years ago. This concurrence is functionally appropriate because in these mammals the later stages of embryo development occur within the mother, and a special hemoglobin, adapted to promote oxygen transfer through the placenta from mother to fetus, is essential (see page 254).

During the long evolution of the myoglobin–hemoglobin family of proteins, only a few amino acid residues have remained invariant. These *conserved residues* may mark the truly essential structural features of the molecule. As Figure 7.13 shows, they include the histidines proximal and distal to the heme iron (F8 and E7; see Figure 7.5b). Interestingly, Val FG5, which has been implicated in the hemoglobin deoxy–oxy conformation change described above, is invariant in hemoglobins, replacing the isoleucine found at this position in most myoglobins. Other regions highly conserved in hemoglobins are those near the α_1 – β_2 and α_2 – β_1 contacts. These contacts are most directly involved in the allosteric conformational change.

Despite the major changes that have occurred in the primary structure of the myoglobin–hemoglobin family over hundreds of millions of years, the secondary and tertiary structures of these proteins have remained surprisingly unchanged. Figure 7.31 shows the backbone structure of members of this family, ranging from insect to horse. All are recognizable as the same basic fold, and the similarity is particularly strong in the region that binds the heme. At first glance this similarity seems inconsistent with our earlier statements that primary structure determines secondary and tertiary structure. However, careful examination of many sequences shows that many of the replacements have been *conservative*—that is, an amino acid has been replaced by another of the same general class (e.g., polar vs. nonpolar, etc.). Obviously, evolution of these proteins has proceeded not at random but under the constraint of maintaining a physiologically functional structure. Survival of mutant proteins in the globin family has been restricted to those that maintain the basic “globin fold.”

Hemoglobin Variants: Evolution in Progress

Variants and Their Inheritance

Evidence for the ongoing evolution of hemoglobin genes can be seen in the existence of hemoglobin variants or, as they are often called, abnormal hemoglobins. Today, several hundred recognized mutant hemoglobins exist within the human population. A number of mutation positions on the tetramer are shown in Figure 7.32. Most proteins in existing plants and animals probably show comparable diversity, but few of them have been as thoroughly studied as human hemoglobins. Each of the mutant forms of hemoglobin exists in only a small fraction of the total human population; some forms have been recognized in only a few

FIGURE 7.31

Evolutionary conservation of the globin folding pattern. As these drawings emphasize, the overall tertiary structure of myoglobin and hemoglobin chains has remained nearly constant despite extensive changes in the primary structure. The shaded regions delineate the E and F helices, which surround the heme. Note that they are almost invariant and that changes tend to be concentrated near the ends of the chains. The most primitive proteins shown are the single-chain hemoglobins of the marine worm *Glycera* and the fly *Chironomus*. The lamprey is the most primitive creature to have distinct myoglobin and hemoglobin. Lamprey hemoglobin forms dimers and exhibits some cooperativity in binding. The α and β chains of horse hemoglobin are almost identical to those of all other mammals.

individuals. Some of these mutant forms are deleterious and give rise to recognized pathologies; under conditions of natural selection they would eventually disappear. Most are, as far as we can tell, harmless, and are often referred to as neutral mutations. A very few may have as yet unrecognized advantages and therefore may come, in time, to dominate in the population.

We shall consider only a few of these abnormal hemoglobins. First, it is necessary to review a bit of genetics. All human cells, except for the germline cells (sperm and ova), are **diploid**; that is, they carry two copies of each chromosome. Therefore, they carry two copies of each gene, one on each of the paired chromosomes. Suppose we consider a gene such as the adult β globin gene, which can exist in two forms—the “normal” type, β , and a variant (mutant) type, β^* . An individual can have three possible combinations of these genes in his or her paired chromosomes:

- A. $\beta+\beta$: **homozygous** (same genes) in the normal type
- B. $\beta+\beta^*$: **heterozygous** (mixed genes)
- C. $\beta^*+\beta^*$: homozygous in the variant type

Having genes for only the normal β globin, individual A will produce only normal β globin chains. Individual C, who has genes for only the variant type, will produce only variant β^* globin chains. Individual B, with genes for both types, will produce both. If the mutation is deleterious, C will be expected to manifest severe disease symptoms. B, on the other hand, may be asymptomatic, or show less severe symptoms because he or she will make normal protein chains along with the variant ones.

When two individuals produce offspring, each parent donates to a child one copy of the β globin gene, the selection of which will be random. If both parents carry only the normal gene, the child must receive two copies of the same. If both carry only the variant gene, the child must also be homozygous for that gene. If both parents are heterozygous for the gene, Figure 7.33 shows that the child has one chance in four of being homozygous normal, one in four of being homozygous for the variant gene, and two in four of being heterozygous. Because most variant hemoglobin genes are rare in the human population, only occasionally do we find an individual homozygous for the variant type.

FIGURE 7.32

Distribution of mutations in human hemoglobins.

The blue and red dots represent all positions at which amino acid substitutions have been found in the α and β chains (only one pair is illustrated, for clarity). Those substitutions that have known pathological effects are shown in red. At many of these positions, more than one substitution has been observed. Position 6 in the β chain, at which the sickle-cell mutation occurs, is shown in yellow.

FIGURE 7.33

Inheritance of normal and variant proteins in a heterozygous cross.

Diploid organisms can exist as one of three types with respect to any gene: homozygous normal, homozygous variant, or heterozygous. The offspring of a heterozygous pair may be any of the three types, as shown here: homozygous normal, heterozygous, or homozygous variant, with a probability ratio of 1:2:1. We leave it as an exercise for you to work out other possibilities—for instance, the offspring of one homozygous normal parent and one homozygous variant parent. This pattern is referred to as classical Mendelian inheritance.

Pathological Effects of Variant Hemoglobins

Of the large number of hemoglobin mutations, a significant fraction have deleterious effects. As Figure 7.32 shows, the known deleterious mutations are mostly clustered about the heme pockets and in the vicinity of the α - β contact region that is so important in the allosteric transition. A few of the well-studied pathological missense mutations are listed in Table 7.1. For example, a class of variants known as *hemoglobins M* tend to be readily oxidized to methemoglobin, which cannot bind O₂. Many of these mutations involve replacement of either the proximal or the distal histidine by other residues. Individuals carrying such mutations experience difficulty in transporting enough O₂ to tissues. Other variants that involve changes at the subunit interfaces can have several kinds of effects. Some, like *hemoglobin St. Lukes*, destabilize the hemoglobin tetramer, whereas others (e.g., *hemoglobin Suresnes*) tend to stabilize either the oxy or the deoxy conformation, inhibiting the allosteric switch. Finally, there are those like *hemoglobin Hammersmith* in which the tertiary structure of the molecule is unstable.

Although most hemoglobin mutations appear to be neutral, some are deleterious.

The most infamous of all variant hemoglobins, *sickle-cell hemoglobin* (HbS), is a source of misery and early death to many humans. The variant has gained its name because it causes red blood cells to adopt an elongated, sickle shape at low oxygen concentrations (Figure 7.34a). This “sickling” is a consequence of the tendency of the mutant hemoglobin, in its deoxygenated state, to aggregate into long, rodlike structures (Figure 7.35). The elongated cells tend to block capillaries, causing inflammation and considerable pain. Even more serious is that the sickled cells are fragile (Figure 7.34b); their breakdown leads to an anemia that leaves the victim susceptible to infections and diseases. Individuals who are homozygous for the sickle-cell mutation often do not survive into adulthood, and those who do are seriously debilitated. Heterozygous individuals, who can still produce some normal hemoglobin, usually suffer

TABLE 7.1 Selected list of missense mutations in human hemoglobins

Effect	Residue Changed	Change	Name	Consequences of Mutation	Explanation
Sickling	$\beta 6$ (A3)	Glu \longrightarrow Val	S	Sickling	Val fits into EF pocket in chain of another hemoglobin molecule.
	$\beta 6$ (A3)	Glu \longrightarrow Ala	G Makassar	Not significant	Ala probably does not fit the pocket as well.
	$\beta 121$ (GH4)	Glu \longrightarrow Lys	O Arab, Egypt	Enhances sickling in S/O heterozygote	$\beta 121$ lies close to residue $\beta 6$; Lys increases interaction between molecules.
Change in O ₂ affinity	$\alpha 87$ (F8)	His \longrightarrow Tyr	M Iwate	Forms methemoglobin, decreased O ₂ affinity	The His normally ligated to Fe has been replaced by Tyr.
	$\alpha 141$ (HC3)	Arg \longrightarrow His	Suresnes	Increases O ₂ affinity by favoring R state	Replacement eliminates bond between Arg 141 and Asn 126 in deoxy state.
	$\beta 74$ (E18)	Gly \longrightarrow Asp	Shepherds Bush	Increases O ₂ affinity by decrease in BPG binding	The negative charge at this point decreases BPG binding.
	$\beta 146$ (HC3)	His \longrightarrow Asp	Hiroshima	Increases O ₂ affinity, reduced Bohr effect	Disrupts salt bridge in deoxy state and removes a His that binds a Bohr-effect proton.
	$\beta 92$ (F8)	His \longrightarrow Gln	St. Etienne	Loss of heme	The normal bond from F8 to Fe is lost, and the polar glutamine tends to open the heme pocket.
Heme loss	$\beta 42$ (CD1)	Phe \longrightarrow Ser	Hammersmith	Unstable, loses heme	Replacement of hydrophobic Phe with Ser attracts water into heme pocket.
Dissociation of tetramer	$\alpha 95$ (G2)	Pro \longrightarrow Arg	St. Lukes	Dissociation	Chain geometry is altered in subunit contact region.
	$\alpha 136$ (H19)	Leu \longrightarrow Pro	Bibba	Dissociation	Pro interrupts helix H.

distress only under conditions of prolonged oxygen deprivation. For example, flying may be dangerous for HbS heterozygotes because of the lower oxygen level in the cabin of the aircraft.

Linus Pauling first suggested in 1949 that sickle-cell disease was a “molecular disease” resulting from a mutation in the hemoglobin molecule. Remarkably, sickling stems from what we might expect to be an innocuous mutation in a part of the molecule far from the critical regions mentioned earlier. The glutamic acid residue normally found at position 6 in β chains is replaced by a valine (see Figure 7.26b). This hydrophobic valine can fit into a pocket at the EF corner of a β chain in another hemoglobin molecule, and thus, as shown in Figure 7.35c, adjacent hemoglobin molecules can fit together into a long, rodlike helical fiber. Why sickling occurs with deoxyhemoglobin, but not with the oxygenated form, is simply explained: In the oxy form the rearrangement of subunits makes the EF pocket inaccessible to Val 6.

Sickle-cell disease is confined largely to populations originating in tropical areas of the world. At first glance, this distribution seems unexpected. Why should a *genetic* disease be climate-related? The answer tells us something about the persistence of what seem to be unfavorable traits. A high incidence of sickle-cell disease in a population generally coincides with a high incidence of malaria, a parasitic disease carried by a tropical mosquito. Individuals *heterozygous* for sickle-cell hemoglobin have a higher resistance to malaria than those who do not carry the sickle-cell mutation. The malarial parasite spends a portion of its life cycle in human red cells, and the increased fragility of the sickled cells, even in heterozygous individuals, tends to interrupt this cycle. In addition, the distortion of the cell membrane of intact sickled cells leads to a loss of potassium ions from these cells, providing a less favorable environment for the parasite. Heterozygous individuals have a higher survival rate—and therefore a better chance of passing on their genes—in malaria-infested regions. However, the high incidence of these genes in the population leads to the birth of many people who are homozygous for the mutant trait.

Many hope that sickle-cell disease will eventually be treatable by gene therapy. Introduction of functional β globin genes into an individual homozygous for the sickle-cell mutation would effectively render them heterozygous, with greatly increased chances for survival. However, it is important to keep in mind that gene therapy is not yet established for treatment of any disease, and it has been associated with considerable risk to patients. In 1998, the U.S. Food and Drug Administration approved hydroxyurea as a treatment for sickle-cell disease. Hydroxyurea appears to induce expression of the HbF $\alpha_2\gamma_2$ tetramer to levels of 10%–15% of total hemoglobin, which is sufficient to reduce some of the symptoms of the disease. Unfortunately, not all patients are responsive to hydroxyurea, and its long-term safety is not known.

Thalassemias: Effects of Misfunctioning Hemoglobin Genes

The human hemoglobin variants we have mentioned so far are all consequences of missense, or nonsynonymous, mutations. Because of a base substitution in a gene coding for one of the chains, one amino acid is substituted for another. There are, however, other genetic defects involving hemoglobin in which one or more of the chains are simply not produced or are produced in an insufficient amount. The pathological condition that arises is called **thalassemia**. The condition of thalassemia can arise in several ways:

1. One or more of the genes coding for hemoglobin chains may have been deleted.
2. All genes may be present, but one or more may have undergone a nonsense mutation that produces a shortened chain or a frameshift mutation that produces a nonfunctional chain (see Figure 7.26c and d).

FIGURE 7.34

Sickle-cell disease results from a single base substitution in the β chain.

FIGURE 7.35

Sickle-cell hemoglobin. Molecules of sickle-cell hemoglobin tend to aggregate, forming long fibers. (a) An electron micrograph of one sickle-cell fiber. (b) A computer-graphic depiction of one fiber. (c) A schematic model of fiber formation. Deoxyhemoglobin S molecules lock together to form a two-stranded cluster because Val 6 in the β chain of one hemoglobin molecule fits into a pocket in an adjacent molecule. Interaction of these two-stranded structures with one another produces the multistrand fibers shown in (a) and (b).

Courtesy of B. Carragher, D. Bluemke, M. Potell, and R. Josephs.

Thalassemias are hemoglobin mutations in which one or more genes are wholly or partially nonfunctional.

3. All genes may be present, but a mutation may have occurred outside the coding regions, leading to a block in transcription or to improper processing of the pre-mRNA so that the protein is not produced or is not functional.

In case 1 or 2, the gene produces no functional protein. In case 3, limited transcription and translation of the correct polypeptide sequence may occur.

The human genome contains a number of globin genes, corresponding to the protein chains used at different developmental stages, so there are many varieties of thalassemia. We describe here only two major classes—those involving loss or malfunction of genes for the adult β and α chains.

β -Thalassemia

If the β globin gene is lost or cannot be expressed, a most serious condition arises in individuals homozygous for this defect. They can make *no* β chains and must rely on continued production of the fetal γ chains to make a functional hemoglobin, $\alpha_2\gamma_2$ (see Figure 7.29). Such individuals may produce γ chains well into childhood, but they usually die before reaching maturity. Much less serious is the heterozygous state, in which one β gene is still functioning. There are also milder thalassemias (called β^+) in which transcription or processing of the β genes is partially inhibited; thus β globin production is limited but not entirely blocked.

α -Thalassemias

Thalassemias involving the α chain present a more complicated situation. Two copies of the gene (α_1 and α_2) are next to each other on the human chromosome 16 (Figure 7.30). The α_1 and α_2 chains differ by only one amino acid, and one can replace the other in the assembled hemoglobin tetramer. An individual can have 4, 3, 2, 1, or 0 copies of an α gene. Only if three or more genes are nonfunctional are serious effects observed. Individuals with only one α gene are anemic because their total hemoglobin production is low. The low level of α hemoglobin is partially compensated for by formation of β_4 tetramers (*hemoglobin H*) and γ_4 tetramers (*hemoglobin Bart's*). These tetramers can bind and carry oxygen, but they do not exhibit the allosteric transition (they remain always in the R state), nor do they exhibit a Bohr effect. So unloading of oxygen to tissues is inefficient. In the condition known as *hydrops fetalis*, all four α gene copies are missing. Individuals with this condition are inevitably stillborn. They can form only a γ_4 hemoglobin, and because the supply of α chains falls near birth, not enough hemoglobin is available to support the near-term fetus.

Because there are two copies of the α gene but only one of the β gene, most of the deleterious mutations in mammalian hemoglobins occur in the β chains (see Figure 7.32). This phenomenon may suggest a functional role for gene duplication: If two or more copies of a gene are present, the species is somewhat protected from the harmful effects of mutations.

We have concentrated our discussion of protein mutation on hemoglobin, but it must be understood that the same principles apply to all other proteins. Although our knowledge of hemoglobin mutations is the most complete, missense mutations and deletions are found in many other proteins as well—those that are deleterious give rise to the wide class of *genetic diseases*, of which hemoglobin pathologies are only one subclass. Many other examples will be encountered in the chapters on metabolism.

Immunoglobulins: Variability in Structure Yields Versatility in Binding

In the remainder of this chapter, we turn to the **immunoglobulin** proteins, whose primary function is specific, and essentially *irreversible*, binding of substances that appear to be of nonself origin, such as bacterial or viral pathogens.

The Adaptive Immune Response

When a foreign substance—a virus, a bacterium, or even a foreign molecule—invades the tissues of a higher vertebrate (like a human), the organism defends itself by the **immune response**. The innate and adaptive immune responses are multilayered and complex, operating through several distinct mechanisms that can occur independently or in concert. Even a superficial description of the various modes of cellular self-defense would require several chapters in a textbook; thus, we restrict our attention to only a narrow range of topics in this vast and fascinating area.

We start with a brief description of the **adaptive immune response**, which includes humoral and cellular components. In the **humoral immune response**, lymphatic cells called **B lymphocytes** synthesize specific immunoglobulin molecules that are secreted from the cell and bind to the invading substance. This binding aggregates the foreign substance and marks it for destruction by cells called **macrophages**. In the **cellular immune response**, lymphatic cells called **T lymphocytes**, bearing immunoglobulin-like molecules on their surfaces, recognize and kill foreign or aberrant cells. In this section we shall be mainly concerned with the humoral immune response.

The substance that elicits an immune response is called the **antigen**, and a specific immunoglobulin that binds to this substance is called the **antibody**. If the invading particle is large, like a cell, a virus, or a protein, many different antibodies may be elicited, each type binding specifically to a given **antigenic determinant** (or **epitope**) on the surface of the particle (Figure 7.36a). Such antigenic determinants may be, for example, groups of sugar residues in a carbohydrate or groups of amino acids on a protein surface; an example is shown in Figure 7.36b.

The immune response, in all its various forms, is our major line of defense against infection and against cancer cells as well. It is the crippling of the immune system by the human immunodeficiency virus (HIV) that makes **AIDS (acquired immune deficiency syndrome)** a disease that has proved so devastating. Victims of AIDS do not die of the direct effects of the virus—they perish from infectious diseases or cancers that their immune system is no longer able to defend against.

The adaptive immune response has some remarkable features. First, it is incredibly versatile, being able to respond to an enormous number of different foreign substances. These foreign substances range from cells of another individual of the same species (the basis of tissue graft or organ transplant rejection) to synthetic molecules that could never have been encountered in nature. Second, the adaptive immune response has a so-called *memory*: After an initial exposure to a given antigen, a second exposure at a later date will result in rapid and much more massive production of the specific antibodies.

The immune response involves the defense of the body against foreign substances or pathogens and operates via many different cellular mechanisms.

In the humoral immune response, B lymphocytes secrete antibodies (immunoglobulins) that react with specific antigens.

FIGURE 7.36

Antigenic determinants. (a) A foreign object, or antigen (such as a virus, a bacterial cell, or a foreign protein molecule), may elicit the production of antibodies to several different antigenic determinants on its surface.

When the antigen is mixed with this collection of antibodies, precipitation occurs because each antibody molecule has two binding sites for its determinant. Thus, a crosslinked network is formed. (b) The antigenic determinants of sperm whale myoglobin. The purple portions represent segments of the polypeptide chain that act as antigens. Some antigenic determinants involve portions of chain that are far apart in the primary sequence but close together in the tertiary structure, a so-called discontinuous epitope.

(b) Antigenic determinants, sperm whale myoglobin

Modern explanations for the adaptive immune response are based on the clonal selection theory.

As described by the so-called **clonal selection theory**, the body has an inherent ability to produce an immense diversity of antibodies with different amino acid sequences that are able to bind an enormous range of antigens. The basic postulates of the clonal selection theory, illustrated in Figure 7.37, are as follows:

1. **B stem cells** in the bone marrow differentiate to become B lymphocytes, each producing a single type of immunoglobulin molecule, each type with a binding site that will recognize a specific molecular shape. These immunoglobulins, or antibodies, are attached to the cell membrane and exposed on the outer surfaces of the B lymphocytes.
2. Binding of an antigen to one of these antibodies stimulates the cell carrying it to replicate, generating a **clone** (a collection of cells with identical genetic information). This *primary response* is aided by a special class of T cells called **helper T cells**. If a helper T cell recognizes a bound antigen, it binds to the appropriate B lymphocyte and transmits to it a signal protein (**interleukin-2**) that stimulates B-cell reproduction. Thus, only those clones of B cells that recognize antigens are stimulated to continued cell division.
3. As shown in Figures 7.37 and 7.38, two classes of cloned B cells are produced. **Effector B cells**, or **plasma cells**, now produce *soluble* antibodies, which are secreted into the circulatory system. These antibodies have the same antigen binding sites as the surface antibodies of the B lymphocyte from which the effector cells arose, but they lack the hydrophobic tail that bound the surface antibodies to the lymphocyte membrane. The other class of cells in the clone—**memory cells**—will persist for some time, even after antigen is no longer present. This persistence constitutes the immune memory: It allows a rapid *secondary response* to a second stimulation by the same antigen, as shown in Figure 7.38.

FIGURE 7.37

The clonal selection theory of the adaptive immune response. Stem cells in the bone marrow (B stem cells, top) differentiate and migrate to the lymphoid tissue. Each of the differentiated cells (B lymphocytes) synthesizes a unique kind of antibody, which it carries on its surface. When the B lymphocytes encounter antigens (shown as an orange hexagon; middle), the B cells that carry antibodies to the antigenic determinants are stimulated by helper T cells (“Th2” cell) to multiply, forming B-cell clones. In this case, the cells stimulated to form clones are those bound to either the “red” or “green” epitope on the foreign antigen. Th2 cells stimulate the B-lymphocytes by secretion of interleukin-2 (lightning bolt symbol). Some of the cloned B cells, called plasma cells, produce soluble antibodies, with each clone producing antibody against a single antigenic determinant (epitope). Other cloned B cells are called memory cells; their role is illustrated in Figure 7.38.

Courtesy of Gary Carlton.

**FIGURE 7.38**

Two developmental paths for stimulated B lymphocytes. Exposure to antigen causes two kinds of cells to develop from B lymphocytes. Cells of one type (effector B cells, or plasma cells) synthesize soluble antibody (see Figure 7.37). Cells of the second class (memory cells) carry membrane-bound antibody to allow a rapid and enhanced response to a second exposure of the same antigen.

The clonal selection theory explains many features of the adaptive immune response, but a critical question may have occurred to you: Why do we not find clones producing antibodies against *our own* proteins and tissues? The answer is a fascinating one that tells much about how biochemical “self” is established. When immature B cells in the fetus encounter substances that bind to their surface antibodies, they are *not* stimulated to replicate. Rather, these fetal B cells are destroyed. Thus, B cells producing antibodies against all of the potential “self” antigens to which we might react are eliminated before birth. The only B cells that mature are those that produce antibodies against “nonself” substances.

Occasionally, the immune system goes awry and produces antibodies against the normal tissues of an adult. The causes for such **autoimmunity** are not wholly understood, but the resulting diseases can be devastating. In *lupus erythematosus*, for example, the individual’s own nucleic acids become the object of attack. Other autoimmune diseases include rheumatoid arthritis, multiple sclerosis, type 1 diabetes mellitus, and psoriasis.

In autoimmune diseases, the immune system attacks normal tissues.

The Structure of Antibodies

To see how clonal selection actually works at the molecular level, we must explore the structure of the immunoglobulin molecules that constitute the antibody arsenal. There are five classes of immunoglobulin molecules, which carry out various

functions in the immune system (Table 7.2). However, all are built from the same basic immunoglobulin structure, which is shown schematically in Figure 7.39. Different kinds of antibodies may contain from one to five immunoglobulin molecules; when more than one is present, the monomers are linked by an additional polypeptide, called a J chain (see Table 7.2).

Immunoglobulin molecules contain both constant and variable regions. The variable regions are the antigen binding sites.

Each immunoglobulin monomer consists of four chains, two identical **heavy chains** ($M_W = 53,000$ Da each) and two identical **light chains** ($M_W = 23,000$ Da each), held together by disulfide bonds. In each chain are **constant domains** (identical in all antibodies of a given class) and a **variable domain**. It is variation in the amino acid sequence (and therefore the tertiary structure) of the variable domains of the light and heavy chains that confers the multitudinous specificities of antibodies to different antigens. Note that the four variable domains are carried at the ends of the Y-like fork of the molecule, where they form two identical binding sites for antigens.

A large protein, a virus, or a bacterial cell has on its surface many different potential antigenic determinants. Antibodies may be generated to several of these determinants, binding many antigen molecules together and thereby aggregating the antigen (see Figure 7.36a). If the antigen is so small that it has only one determinant, binding will occur but aggregation will not. Antibody-mediated aggregation, also called **immunoprecipitation**, requires the antibody to be *bivalent* (to have two binding sites). In the laboratory it is possible to cleave antibodies at the *hinge* regions (see Figure 7.39) with specific protein-cleaving enzymes, to produce an **F_c fragment** and two **F_{ab} fragments** with only one binding site each. The F_{ab} fragments will bind but not precipitate antigen.

The constant domains of the heavy chains in the base of the Y-shaped molecule serve to hold the chains together. More important, these regions also function

TABLE 7.2 The five classes of immunoglobulins

IgM is produced during the early response to an invading microorganism. It is the largest immunoglobulin, containing five Y-shaped units of two light and two heavy chains each. The units are held together by a component called a J chain. The relatively large size of IgM restricts it to the bloodstream. It is also effective in triggering an important mechanism for foreign cell destruction, called the complement system.

IgG molecules, also known as γ -globulin, are the most abundant of circulating antibodies. A variant is attached to B-cell surfaces. IgG molecules consist of a single Y-shaped unit and can traverse blood vessel walls rather readily; they also cross the placenta to carry some of the mother's immune protection to the developing fetus. Specific receptors allow such passage. IgG also triggers the complement system.

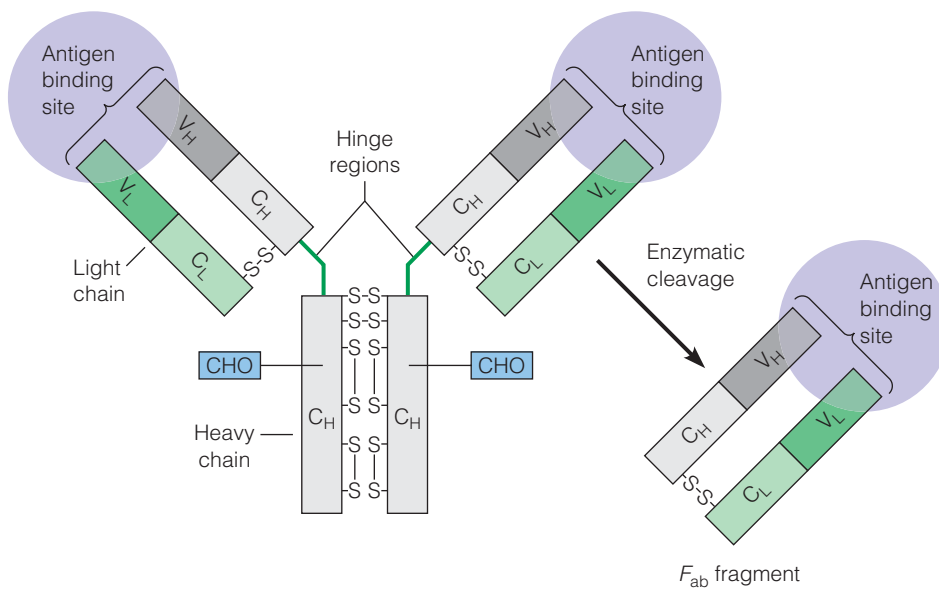

IgA is found in body secretions, including saliva, sweat, and tears, and along the walls of the intestines. It is the major antibody of colostrum, the initial secretion from a mother's breasts after birth, and of milk. IgA occurs as a monomer or as double-unit aggregates of the Y-shaped protein molecule. IgA molecules tend to be arranged along the surface of body cells and to combine there with antigens, such as those on a bacterium, thus preventing the foreign substance from directly attaching to the body cell. The invading substance can then be swept out of the body together with the IgA molecule.

Less is known about the IgD and IgE immunoglobulins. IgD molecules are found on the surface of B cells, though little is known about their function. IgE is associated with some of the body's allergic responses, and its levels are elevated in individuals who have allergies. The constant regions of IgE molecules can bind tightly to mast cells, a type of epithelial and connective tissue cell that releases histamines as part of the allergic response. Both IgD and IgE consist of single Y-shaped units.

FIGURE 7.39

Schematic models of an IgG antibody molecule and an F_{ab} fragment. The IgG is made from two identical heavy chains and two identical light chains, all held together by disulfide bonds. Each chain contains both *constant* domains (C) and *variable* domains (V). Constant domains are the same in all antibody molecules of a given class (see Table 7.2), whereas variable domains confer specificity to a given antigenic determinant. Cleavage by certain proteolytic enzymes such as papain at the *hinge regions* allows production of two identical monovalent F_{ab} fragments and one F_c fragment (see Figure 7.40). The carbohydrate (CHO) attached to the heavy chains aids in determining the destinations of antibodies in the tissues and in stimulating secondary responses such as phagocytosis. The crystal structure of an immunoglobulin molecule is shown in Figure 7.40.

as effectors, to signal other cells of the immune response, such as killer T-cells or macrophages, to attack particles or cells that have been marked for destruction by antibody binding. Macrophages are large white blood cells that are specially adapted to engulf and digest foreign particles. In addition, differences in heavy chains identify immunoglobulin types for delivery to different tissues or for secretion (see Table 7.2).

The antigen binding sites lie at the extreme ends of the variable domains (Figures 7.39 and 7.40) and involve amino acid residues from the variable regions of both heavy and light chains. Different sequences in these variable regions give rise to different local secondary and tertiary structure and can thereby define binding sites to fit different antigens with exquisite specificity.

The domains in immunoglobulins and other members of the **immunoglobulin superfamily** are built on a common motif—the *immunoglobulin fold*, in which two antiparallel β sheets lie face to face (Figure 7.41). This structure probably represents the primitive structural element in the evolution of the adaptive immune response. Indeed, the immunoglobulin fold is also found in a number of other proteins that are involved in cell recognition. The immunoglobulin fold is a stable scaffold on which to display the hypervariable loops that determine the shape and charge complementarity of the antigen binding site (Figure 7.42). These hypervariable loops are known as **complementarity determining regions**, or **CDRs**. Figure 7.42 shows the results of X-ray diffraction studies of the interaction of an F_{ab} fragment with a viral protein antigen, neuraminidase, an enzyme which facilitates viral infection

The diversity as well as the exquisite specificity of antigen binding sites is determined by the hypervariable complementarity determining regions from both the light and the heavy chains.

FIGURE 7.40

The crystal structure of an IgG molecule from mouse. The identical heavy chains are colored yellow and cyan; the identical light chains are magenta and green. A cartoon model, illustrating the high degree of β secondary structure, is shown on the left. On the right is a surface rendering showing the intimate contact between the chains. The carbohydrate attached to the heavy chain is indicated in the leftmost figure. PDB ID: 1IGT.

**FIGURE 7.41**

The immunoglobulin fold. The immunoglobulin fold is a common structure in domains of many proteins in the immunoglobulin superfamily (see text). Two antiparallel β sheets (cyan and orange) are stacked face to face and covalently bonded by a disulfide bond (not shown). This folding motif is found 12 times in the IgG molecule (see leftmost panel of Figure 7.40) and 4 times within an F_{ab} . PDB ID: 1IGT.

Through somatic recombination and rapid mutation, a human can generate over 10 billion different antibodies.

The cellular immune response uses killer T cells to destroy foreign or infected cells.

(discussed in Chapter 9). Note that the antigen and antibody surfaces fit together in a highly complementary fashion.

Generation of Antibody Diversity

How can the enormous diversity of immunoglobulin molecules be generated so that antibodies to an almost unlimited range of antigens are provided? The human genome simply does not have enough room to encode a gene for each of the millions of different immunoglobulin molecules occurring in B stem cells. Instead, two special processes occur in these cells.

The major source of antibody diversity is *recombination of exons*. The genomes of higher vertebrates contain “libraries” of exons corresponding to different portions of the immunoglobulin molecule. In antibody-producing cells, these exons are rearranged and spliced to create different sequence combinations in both the heavy and light chains. We have already mentioned that such rearrangements, when they occur in germline cells, play a role in protein evolution. The same process, when it occurs in B cells, creates new immunoglobulins in individual cells. The details and mechanism of this process are described in Chapter 26, as is an additional source of antibody diversity: *somatic hypermutation*. Such mutations are not inherited because they occur in somatic cells (cells that are not germline). In the cells that generate antibodies, the portions of the variable regions corresponding to the CDR loops in the immunoglobulin genes mutate at an unusually high rate. This process, together with recombination of gene fragments, can account for the generation of an immense diversity of immunoglobulin molecules. It has been estimated that about 10 billion combinations can be made from the library of immunoglobulin gene fragments available in the human genome.

T Cells and the Cellular Response

Whereas the humoral immune response of the adaptive immune system is based on antibody-produced aggregation, usually followed by digestion by macrophages, the cellular immune response involves a quite different mechanism for killing of foreign cells. The cellular response plays a major role in tissue rejection and in destroying virus-infected cells. It can also destroy potential cancer cells before they have a chance to propagate. Although the mechanisms of the humoral and cellular processes are quite different, structurally similar protein molecules (from the immunoglobulin superfamily) are involved in both cases, pointing to a common evolutionary origin for the humoral and cellular responses.

The major participants in the cellular immune response are **cytotoxic T cells**, also referred to as **killer T cells**. These cells carry on their surfaces receptor molecules that are structurally similar to the F_{ab} fragments of antibody molecules (Figure 7.43c). Like antibodies, these fragments have a wide range of binding specificities, mostly directed toward short oligopeptide sequences. Such oligopeptides might be produced, for example, by a virus-infected cell when it partially digests virus particles within it. The T-cell receptor does not recognize free oligopeptides. Instead, the oligopeptides must be presented on the surface of the infected cell and bound to another class of immunoglobulin-like molecules, proteins of the **major histocompatibility complex**, or **MHC** (see Figure 7.43a–c). When a killer T cell identifies (via its receptor) an appropriate antigen carried on the surface of another cell by an MHC protein, it releases a protein called **perforin**. This protein forms pores in the plasma membrane of the cell being attacked, allowing critical ions to diffuse out and thereby killing the cell.

It is instructive to compare the immunoglobulin family of proteins with the myoglobin–hemoglobin family. In both cases the primary function of the proteins is binding. In the myoglobin–hemoglobin family we see evidence for the progressive evolution of increasingly sophisticated methods for regulating the binding of a particular molecule—oxygen—and for coupling oxygen binding to the removal of

FIGURE 7.42

Antigen binding by an F_{ab} fragment. Panel (a): Backbone structure of an F_{ab} fragment, which contains four immunoglobulin fold domains: two on the light chain (forest and lime green), and two on the heavy chain (tan and yellow). The constant domains on each chain are to the left and the variable domains are on the right. The CDRs are shown in cyan (light chain) and orange (heavy chain). The CDRs from both the heavy and light chains are hypervariable in sequence and determine the shape and specificity of the antigen binding site. PDB ID: 1AQK. Panel (b): Surface rendering of F_{ab} fragment shown in (a). Panel (c): Same rendering as in (b), but rotated 90 degrees to view the surface of the antigen binding site formed by the CDR loops. Panels (d) and (e): The close contact that occurs between antigen and antibody surfaces is shown in the backbone and surface renderings of a murine F_{ab} fragment bound to the viral protein neuraminidase (PDB ID: 1NCA). The antibody light chain is shown in green, the heavy chain fragment in yellow, and the neuraminidase molecule in purple. The surfaces of the antigen and the antibody binding site fit together with a high degree of shape and charge complementarity.

FIGURE 7.43

Structural similarity of proteins from the immunoglobulin superfamily. This figure shows crystal structures for a few members of the immunoglobulin superfamily of proteins, which includes not only the immunoglobulin family but many related cell-surface and soluble proteins involved in cell recognition and binding. Notice the occurrence of several immunoglobulin domains in all these proteins. **(a)** Human major histocompatibility complex (MHC) class I protein (cyan and green) bound to a fragment of an HIV protein (magenta). PDB ID: 1A1M. **(b)** Human MHC class II protein (green and cyan) bound to an influenza virus peptide (magenta). PDB ID: 1DLH. **(c)** Human T-cell receptor (rose and yellow) binding to an MHC class I molecule (cyan and green) displaying a viral peptide (magenta). PDB ID: 1BD2. **(d)** Murine F_{ab} fragment of IgG bound to neuraminidase (magenta; see Figure 7.42, PDB ID: 1NCA).

CO₂. In the immunoglobulin family, evolution from a simple motif has led to an enormous diversification in binding function. A mechanism has evolved that allows the production of an immense range of molecules with specific binding capacities.

The Innate Immune Response

In 1989 Charles A. Janeway, Jr. hypothesized that cells of the so-called **innate immune response**, distinct from the B and T cells described above, detect bacterial infection by recognizing metabolites specific to microbial pathogens. Extensive research since then has validated Janeway's hypothesis and led to the identification of a myriad of proteins and effectors that recognize bacterial, viral, fungal, and protozoan invaders and mount an immune response. Among the many important proteins in the innate immune response are the so-called **toll-like receptors** (TLRs), which recognize a diverse set of foreign molecules. These include double-stranded RNA (typical of many viruses) and organic molecules, such as **lipopolysaccharide** (LPS), which is found in the membranes of gram-negative bacteria. Figure 7.44 shows crystal structures of two different TLRs bound to their targets. Note that the TLR structures and modes of target recognition are very different from those described above for the immunoglobulin superfamily. Although the innate immune response can act independently, it can also stimulate the adaptive immune response.

FIGURE 7.44

Structure of two toll-like receptors (TLRs) bound to foreign molecules. **(a)** The extracellular domain of human TLR-4 (cyan and green) combines with myeloid differentiation factor-2 (purple and yellow) to bind *E. coli* lipopolysaccharide (spacefilling) PDB ID: 3FXI. **(b)** A model of an entire TLR. The model is a composite of the extracellular domain of murine TLR-3 (cyan and green) bound to a dsRNA (red and blue), which is connected via a trans-membrane helix to the intracellular domain of a human TLR. PDB IDs: 3CIY and 2J67.

AIDS and the Immune Response

AIDS (acquired immune deficiency syndrome) is a disease of the immune system. It is caused by the **human immunodeficiency virus**, or HIV (Figure 7.45), which attacks a number of kinds of cells but is particularly virulent toward a class of helper T cells. The virus wages a long battle with rapidly replicating T cells, but eventually the rate of cell destruction exceeds the rate of replication. The consequence is a deterioration of the whole immune response, in particular the ability of B cells to proliferate in response to antigen stimulation. In addition, there is a general failure in T-cell activation. Most AIDS patients succumb either to diseases they could have easily resisted before contracting AIDS or to certain kinds of cancer. AIDS is so deadly because it attacks our most fundamental defenses against all disease.

Since 1983 more than 60 million people, predominantly in the developing world, have been infected with HIV, and nearly half of those have died. Because AIDS poses such a grave threat to world health, efforts to develop a vaccine are being intensely pursued. Such research entails unusual problems because the AIDS virus has an unparalleled capacity to mutate and thus develop strains resistant to any vaccine. Mutations occur in the HIV genome at a rate many times higher than in the human genome. The genetic variation is increased by the error-prone viral replication cycles (discussed in Chapter 25), resulting in a high level of amino acid mutation in the viral coat proteins which would be the typical immunological targets in a vaccine development strategy. The magnitude of the problem can be grasped by considering our experience with the influenza virus. We have never been able to produce a lifelong “flu” vaccine because of the great variability of the influenza virus. HIV mutates about 60 times faster than the influenza virus.

Unfortunately, no effective vaccine has yet been developed for HIV. Antiviral drugs have been developed that target virus-specific enzymes involved in replication of the viral genome or processing of the gene products. These therapies can slow the progression of AIDS; but they do not constitute a cure for the disease. One may hope that improved therapeutics, and an eventual vaccine, will halt the AIDS pandemic.

Antibodies and Immunoconjugates as Potential Cancer Treatments

Current cancer treatments frequently include radiation and/or chemotherapy with highly toxic drugs. Chemotherapy is associated with many undesirable side effects, in large part due to the broad cytotoxicity of the drugs. The efficacy of chemotherapeutics could be increased if they could be delivered specifically to cancer cells

In AIDS, the causal virus attacks helper T cells, destroying the body's immunological defense system.

FIGURE 7.45

(a) Electron micrograph of the human immunodeficiency virus (HIV) that is responsible for AIDS. (b) A schematic model of HIV. The surface protein gp160 is composed of two fragments, gp41 and gp120. The RNA genome is transcribed into DNA by an error-prone reverse transcriptase. This DNA integrates into the host cell genome, and is then retranscribed to produce new viral RNA. (c) False-color scanning electron micrograph of budding HIV-1 virus particles (green spheres) on the surface of a human lymphocyte (red).

rather than systemically. To that end, hybrid drugs, called **immunoconjugates**, have been designed which link a cytotoxic agent to an antibody that has been raised against a tumor-specific antigen (Figure 7.46). In principle, the antibody specifically delivers the drug to the target tumor cell, where it is taken up by the cell. Once inside the cell, the covalent link between the antibody and drug is cleaved, releasing the drug to exert its cell-killing effect. In addition to cytotoxic drugs, such as taxol, radioactive isotopes have also been conjugated to antibodies. A few such immunoconjugates have been approved for clinical use, with more in clinical trials.

Because antibody binding is the first step in the recruitment of a cytotoxic response, antibodies that specifically recognize tumor antigens have been actively developed as anti-cancer drugs that can selectively target tumors for destruction. As of 2010, roughly 25 antibodies or immunoglobulin derivatives have been approved for use as human therapeutics, primarily as anti-cancer and anti-inflammatory agents.

SUMMARY

Most organisms need oxygen. Vertebrates use hemoglobin for oxygen transport between lungs/gills and respiring tissues. In the heme globins, O_2 is bound at an Fe(II)-porphyrin (heme); the heme is carried in a hydrophobic pocket, inhibiting oxidation of the iron. Myoglobin carries a single oxygen binding site and consequently exhibits a noncooperative, hyperbolic binding curve. Hemoglobin binds O_2 cooperatively, with a sigmoidal binding curve that leads to more efficient O_2 delivery. Binding O_2 to hemoglobin sites causes tertiary structure changes. When strain from these changes accumulates, a quaternary (T \rightarrow R) transition occurs, shifting the molecule from the lower-affinity form to the higher-affinity form. The allosteric transition also allows allosteric effectors (H^+ , CO_2 , Cl^- , and 2,3-BPG) to modify oxygen binding, leading to more efficient O_2 and CO_2 transport. Globins are also potent nitric oxide (NO) dioxygenases and can protect cells from the toxic effects of elevated NO levels.

Myoglobin and hemoglobin, like other proteins, are evolving via mutations, duplications, and recombinations in their genes. Both types of globin evolved from a myoglobin-like ancestral protein, with the development of a true hemoglobin coinciding approximately with the emergence of vertebrates. Evolution of these proteins continues, as evidenced by the existence of a multitude of variant hemoglobins in the human population. Most base substitution (missense) mutations are neutral, but some, like the sickle-cell hemoglobin mutation, are deleterious. Thalassemias are hemoglobin pathologies that involve either deletion or faulty expression of whole genes or sets of genes.

The innate and adaptive immune responses are among the body's main defenses against infection. In the humoral response of the adaptive immune system, antibodies (specific immunoglobulin molecules) that will bind with specific antigens are generated and secreted. This process occurs because recognition of the antigen by a few cells leads to clonal selection of a large number of cells producing the appropriate antibody. Immense antibody diversity is achieved through multiple somatic recombinations and rapid mutation in antibody-producing cells. The cellular immune response involves receptor-bearing killer T cells. AIDS is a disease of the immune system; HIV attacks T cells essential to the growth of B-cell clones.

APPENDIX

A Brief Look at Multistate and Dynamic Models of Hemoglobin Allostery

The conformational changes described in the Perutz model of hemoglobin allostery constitute a rearrangement of the *tertiary* structure of each subunit upon oxygen binding, which is presumed to trigger the observed changes in *quaternary* structure between the fully deoxy (T) and fully oxy (R) states of the hemoglobin tetramer (see Figure 7.14). For the discussion below we will use upper-case T and R to represent quaternary structures, and lower-case *t* and *r* to represent the tertiary structures, associated with the deoxy and oxy conformations. The Perutz model is based on the two hemoglobin conformations that were crystallized at that time, but more recent data have called into question many of the assumptions of the MWC and Perutz models. For example, the central tenet of the symmetry model—that the *t* conformation is not tolerated in the R-state quaternary structure, nor is the *r* conformation allowed in the T-state quaternary structure—has been disproven in the case of hemoglobin by X-ray crystal and solution NMR structures of hemoglobin that are in the T quaternary state but have subunits in the *r* tertiary state. Ultrafast kinetic studies of ligand binding to hemoglobin encapsulated in gels, performed on timescales where tertiary conformation switching can occur but quaternary structure switching cannot, have also shown that the *r* state can exist in T tetramers. How, then, are the tertiary and quaternary structural changes correlated? Not surprisingly, there are several competing theories. We briefly summarize three, which have been chosen to illustrate the breadth of current vigorous debate over the structural basis for cooperative ligand binding in hemoglobin. The interested reader will find citations to more complete descriptions of these models in the References section.

The *symmetry rule* model proposed in 1992 by Gary Ackers and coworkers suggests that the tertiary structure changes that accompany oxygen binding can be tolerated up to a certain point

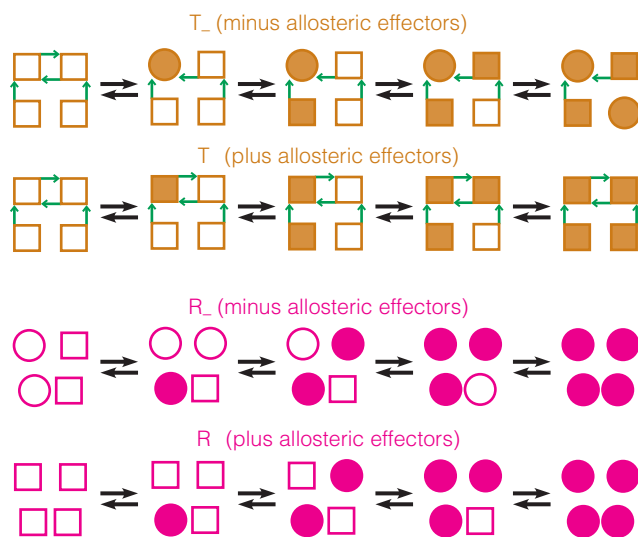

FIGURE 7.47

The tertiary two-state model for the cooperative transition of hemoglobin. Subunits are depicted here with $\alpha_1\beta_1$ dimers on the left, $\alpha_2\beta_2$ on the right. R state tetramers are magenta, T state tetramers are brown. The salt bridge interactions that characterize the T state (see Figure 7.15) are shown as green arrows. Subunits with ligand bound are shown as solid shapes. In this model both *r* (circles) and *t* (squares) tertiary structures are found within the T and R quaternary structures. In the presence of allosteric effectors (2,3-BPG, H^+ , CO_2 ...) the $t \rightleftharpoons r$ equilibrium is perturbed in the direction of the *t* state.

IUBMB Life 59:586–599, W. A. Eaton, E. R. Henry, J. Hofrichter, S. Bettat, C. Viappiani and A. Mozzarelli, Evolution of allosteric models for hemoglobin. © 2007 John Wiley & Sons, Inc. Reproduced with permission from John Wiley & Sons, Inc.

before the $T \rightarrow R$ switch occurs. Specifically, whenever one site is occupied on *each* of the two $\alpha\beta$ dimers, the molecule as a whole adopts the R quaternary structure. This model proposes that hemoglobin acts as a dimer of cooperative dimers, in a fashion that is in accord with the KNF model but not with the MWC model shown in Figure 7.12.

The *tertiary two-state* model proposed in 2002 by William Eaton and colleagues assumes that the quaternary T and R states of hemoglobin can be populated by both the *t* and *r* tertiary states. As shown schematically in Figure 7.47, the relative populations of *r* and *t* states within a tetramer are influenced by quaternary structure, ligand binding, and the binding of allosteric effectors. In this model, the ligand-binding affinity of a subunit is determined by its tertiary structure and is independent of the hemoglobin quaternary structure. In other words, the ligand-binding affinity of the *r* state is the same whether it resides in a T or an R tetramer. This model explains the *biphasic* kinetics of ligand binding to hemoglobin trapped in the T state within gels. The faster phase is attributed to binding to *r* state subunits in the tetramer and the slower phase is due to binding to the *t* state subunits.

The *dynamic allostery* model proposed in 2008 by Takashi Yonetani and coworkers was developed in part to explain their observations that (1) the binding of some allosteric effectors dramatically reduces the ligand-binding affinities of both R and T state hemoglobins and (2) in extreme cases the ligand-binding affinities of the T and R states have the *same* low value, even though they have *different* quaternary and tertiary conformations. How is this possible, given the foregoing discussion of the Perutz mechanism, which correlates structural differences to differences in binding affinity? Yonetani and his colleagues argue that differences in ligand-binding affinity are determined by differences in protein dynamics, where increased dynamic motions of the hemoglobin molecule are the basis for reduced ligand-binding affinity. Recall from our earlier discussion that heme-pocket dynamics appears to play a significant role in the binding and release of ligands in myoglobin (see Figure 7.8). In particular, the dynamic allostery model focuses on the changes in dynamic behavior of the E and F helices, which include the proximal and distal His residues. Molecular dynamics simulations of oxy and deoxy hemoglobins yield the counterintuitive result shown in Figure 7.48, namely, that the binding of 2,3-BPG

**FIGURE 7.48**

Molecular dynamics of oxy and deoxy hemoglobins. The results of a 2-ns all-atom simulation are shown in each panel. For clarity, only the E and F helices of one α subunit are shown. The starting structure ($t = 0$) in each case is shown in blue and the last structure ($t = 2$ ns) is shown in red. Eight intermediate structures are shown in the order: blue \rightarrow green \rightarrow yellow \rightarrow red. OxyHb (R) is less dynamic than is deoxyHb (T). The addition of 2,3-BPG to the simulations resulted in increased motions in both oxy and deoxy molecules.

Reprinted from *Biophysical Journal* 94:2737–2751, M. Laberge and T. Yonetani, Molecular dynamics simulations of hemoglobin A in different states and bound to DPG: Effector-linked perturbation of tertiary conformations and HbA concerted dynamics. © 2008, with permission from Elsevier.

increases the dynamic motions of the E and F helices in both the oxy (R) and deoxy (T) states. This is surprising, as 2,3-BPG binds to hemoglobin in a cleft *between* the β_1 and β_2 subunits

(see Figure 7.23) and therefore might be expected to *reduce* dynamic motions in the hemoglobin molecule.

PROBLEMS

1. The following data describe the binding of oxygen to human myoglobin at 37 °C.

P_{O_2} (mm Hg)	Y_{O_2}	P_{O_2} (mm Hg)	Y_{O_2}
0.5	0.161	6	0.697
1	0.277	8	0.754
2	0.434	12	0.821
3	0.535	20	0.885
4	0.605		

From these data, estimate (a) P_{50} and (b) the fraction saturation of myoglobin at 30 mm Hg, the partial pressure of O_2 in venous blood.

2. What qualitative effect would you expect each of the following to have on the P_{50} of hemoglobin?

- (a) Increase in pH from 7.2 to 7.4
 (b) Increase in P_{CO_2} from 20 to 40 mm Hg
 (c) Dissociation into monomer polypeptide chains

- *3. Measurements of oxygen binding by whole human blood, at 37 °C, at pH 7.4, and in the presence of 40 mm Hg of CO_2 and normal physiological levels of BPG (5 mmol/L of cells), give the following:

P_{O_2} (mm Hg)	% Saturation (=100 × Y_{O_2})
10.6	10
19.5	30
27.4	50
37.5	70
50.4	85

(a) From these data, construct a binding curve, and estimate the percent oxygen saturation of blood at (1) 100 mm Hg, the approximate partial pressure of O_2 in the lungs, and (2) 30 mm Hg, the approximate partial pressure of O_2 in venous blood.

(b) Under these conditions, what percentage of the oxygen bound in the lungs is delivered to the tissues?

(c) Using the data in Figure 7.16 (page 253), repeat the calculation of part (b) if the pH drops to 6.8 in capillaries but goes back to 7.4 as CO_2 is unloaded in the lungs.

4. Crocodile hemoglobin does not bind 2,3-BPG. Instead, it binds bicarbonate ion, which is a strong negative allosteric effector. Why might crocodiles have a hemoglobin that is responsive to HCO_3^- instead of 2,3-BPG? Recall that crocodiles hold their prey underwater to kill them.

5. Precise data have been obtained for the oxygen binding of stripped human hemoglobin at 25 °C:

P_{O_2} (mm Hg)	% Saturation (= 100 × Y_{O_2})	P_{O_2} (mm Hg)	% Saturation (= 100 × Y_{O_2})
0.10	0.315	5.75	76.0
0.350	0.990	7.94	90.9
0.794	3.06	12.88	96.9
1.748	9.09	29.51	99.0
2.884	24.0	67.60	99.7
4.467	50.0		

Use a Hill plot to determine (a) P_{50} , (b) h (maximum slope), and (c) the P_{50} values corresponding to the T and R states.

- *6. G. Ackers, M. L. Johnson, F. C. Mills, et al., in *Biochemistry* (1975) 14:5128–5134, have observed that the P_{50} of purified hemoglobin decreases as the concentration of hemoglobin in solution is decreased. Suggest an explanation.

7. Oxygen binding by the hemocyanin of the shrimp *Callinassa* has been measured. Using the following data, prepare a Hill plot and determine (a) P_{50} , (b) h (the Hill coefficient), and (c) the *minimum* number of oxygen binding sites on the protein molecule.

P_{O_2} (mm Hg)	Y_{O_2}	P_{O_2} (mm Hg)	Y_{O_2}
1.1	0.003	136.7	0.557
7.7	0.019	166.8	0.673
10.7	0.035	203.2	0.734
31.7	0.084	262.2	0.794
71.9	0.190	327.0	0.834
100.5	0.329	452.0	0.875
123.3	0.487	736.7	0.913

8. Suggest probable consequences of the following real or possible hemoglobin mutations. [Note: Consult Figures 7.15 (page 249), 7.17 (page 250), and 7.23 (page 254).]

- (a) At $\beta 146$ (HC3) His → Asp
 (b) At $\beta 92$ (F8) His → Leu
 (c) At $\beta 2$ (NA2) His → Asp

In each case, tell whether a single base change is sufficient for the mutation.

9. Suppose each of the mutants listed in Problem 8 were electrophoresed in comparison with native hemoglobin ($pI = 7.0$) at pH 8.0. Which would move faster toward the anode than native protein, and which would move more slowly?

- *10. In principle, an allosteric molecule could exhibit *negative* cooperativity; that is, binding of the first ligands could decrease affinity for additional ones.

- (a) What would a Hill plot look like for negative cooperativity?
 (b) It has been noted that the KNF theory allows negative cooperativity but the MWC theory doesn't. Explain.

11. In the experiments of Barrick, et al. (see Figure 7.18, page 251) it was observed that replacement of histidine by a noncovalently bonded imidazole not only reduced cooperativity but also increased the oxygen affinity of the hemoglobin. Suggest an explanation.

12. Suppose you visit the Dalai Lama in Dharamsala, India (elevation 1460 m), and you begin to ponder the “big questions,” such as, “What is the fractional saturation of the Dalai Lama’s hemoglobin?”

(a) Assuming the Dalai Lama’s hemoglobin has a Hill coefficient = 3.2, and a $P_{50} = 31$ torr, calculate the change in fractional O_2 saturation of his hemoglobin going from his lungs (where $P_{O_2} = 85$ torr) to his capillaries (where $P_{O_2} = 25$ torr). (b) Why do you suppose the Dalai Lama’s hemoglobin has a P_{50} higher than normal (where “normal” = 27 torr)?

13. Assume that a new oxygen-transport protein has been discovered in certain invertebrate animals. X-ray diffraction of the deoxy protein reveals that it has the dimeric structure shown here in part (a) with a salt bridge between residues histidine 13 and aspartic acid 85.

The two monomers interact by salt bridges between the C- and N-termini. The O₂-binding site lies *between* the two iron atoms shown, which are rigidly linked to helices A and C (see part (b)). In the deoxy form, the space between the iron atoms is too small to hold O₂, and so the Fe atoms must be forced apart when O₂ is bound.

Answer the following questions, explaining your answer in each case in terms of the structure shown below.

- Is this molecule likely to show cooperative oxygen binding?
- Is this molecule likely to exhibit a Bohr effect?
- Predict the likely effect of a mutation which replaced aspartic acid 85 by a lysine residue?

(d)

- (a)** Structure of deoxy protein. N and C denote N-termini and C-termini. The dyad axis (d) is perpendicular to this page.

- (b)** Detail of the oxygen-binding site in the oxy form.

- *14. The binding of antigens to antibodies can be thought of in ways similar to those we have used for discussing oxygen binding. Assuming we have monovalent antigens and n -valent antibodies, we can write the following equation for the number (r) of antigen molecules bound to an antibody at a concentration (c) of free antigen:

$$r = \frac{nKc}{1 + Kc}$$

where K is the equilibrium constant for the binding (the affinity constant).

- (a) Show that this equation can be rearranged to give

$$\frac{r}{c} = Kn - Kr$$

This is called the *Scatchard equation*. It predicts that a graph of r/c versus r will be a straight line.

- (b) Use the following data and a graph according to the Scatchard equation to obtain n and K for an antibody-antigen reaction.

c (M)	r
1.43×10^{-5}	0.50
2.57×10^{-5}	0.77
6.00×10^{-5}	1.20
1.68×10^{-4}	1.68
3.70×10^{-4}	1.85

15. What physiological effect would you predict from a mutation that replaced with serine the cysteine in the constant part of the immunoglobulin light chain that is involved in disulfide-bond formation with the heavy chain? (See Figure 7.39 page 271.)

TOOLS OF BIOCHEMISTRY 7A

IMMUNOLOGICAL METHODS

Because of the ease with which antibodies against biological materials can be prepared in the laboratory, and because of their great specificity, antibodies form the core of many important analytical and preparative biochemical procedures. We shall discuss here some of the methods most important to biochemists.

Experiments in which an antigen is injected into an animal show that one antigen can elicit formation of several different antibodies. Each of these antibodies recognizes one particular portion of the antigen molecule, called an *antigenic determinant*, or *epitope*. Figure 7.36b shows the epitopes that have been identified in sperm whale myoglobin. Each epitope is a region encompassing five or six residues in the myoglobin sequence. Thus, a myoglobin **antiserum** (that is, serum from an animal immunized against myoglobin) carries at least five different antimyoglobin antibodies, each directed against one of the five epitopes shown in the figure. Most antibodies that are useful in biochemistry are of the IgG type (see Table 7.2 and Figure 7.40). Each of these Y-shaped monomers has two antigen-combining sites. In an antigen–antibody reaction, each site usually binds to a different antigen molecule if sufficient antigen is present.

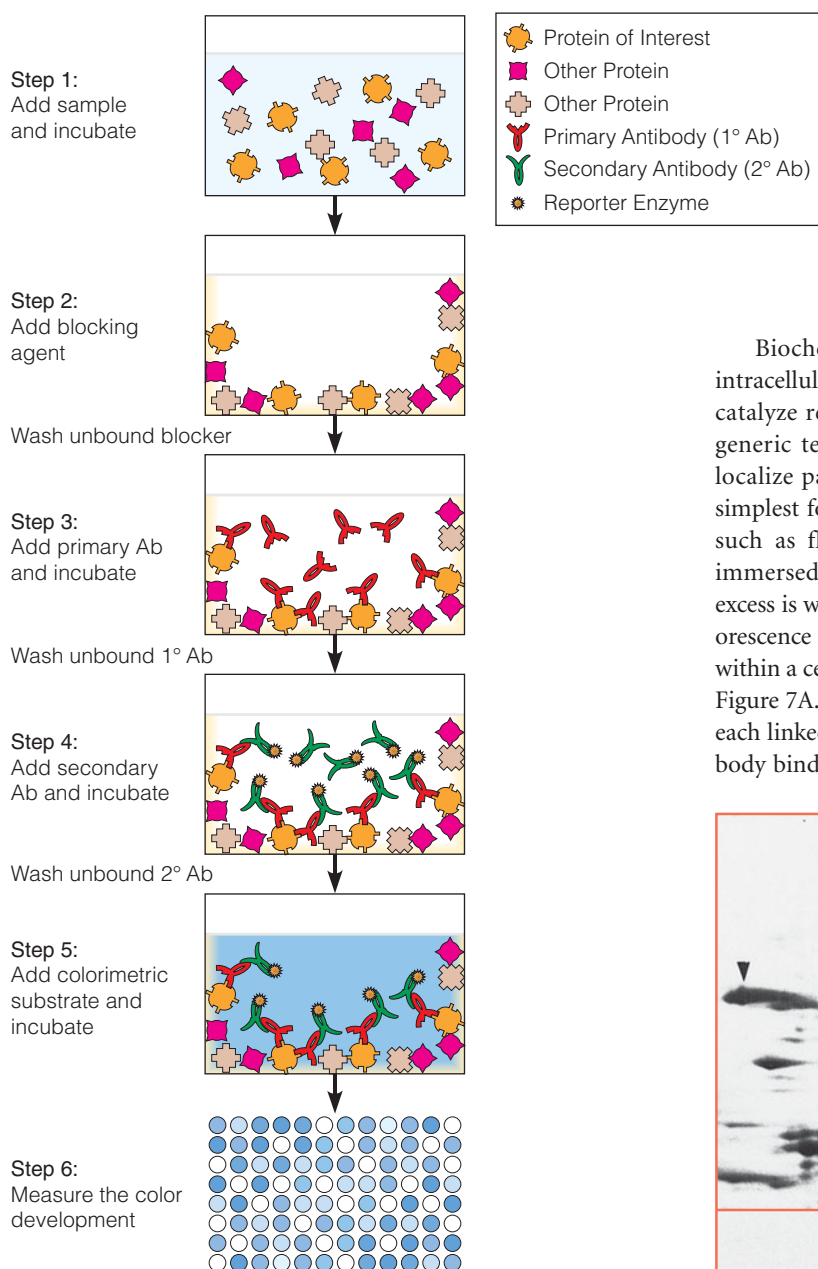

Generally speaking, immunogenic substances (substances that elicit an immune reaction, such as synthesis of antibodies) are macromolecules. However, some of the most useful immunological reagents are antibodies against low-molecular-weight substances. These low-molecular-weight compounds are not typically immunogenic per se; however, when covalently coupled to an antigenic carrier protein, such as bovine serum albumin (BSA) or keyhole limpet hemocyanin (KLH), the resultant conjugate is immunogenic. Some of the antibodies produced in response to the conjugate are directed against the low-molecular-weight, nonprotein constituent, which is called a **hapten**. The antibodies that bind specifically to the hapten can be isolated by affinity chromatography (see Tools of Biochemistry 5A) using a solid support to which the hapten has been covalently linked.

One of the earliest uses of immunoglobulins as analytical tools was in **radioimmunoassay**, in which soluble IgG is used to test for levels of steroid hormones or drugs in complex biological fluids such as blood plasma. This is a binding competition assay between radioactively labeled and unlabeled antigen for the IgG. A known amount of radioactive antigen (usually labelled with ^{125}I or ^{131}I) is incubated with the antibody in the presence of the unlabeled antigen in the sample. As the concentration of the unlabeled antigen in the sample increases, it will more effectively compete for binding to the antibody and displace the radioactive antigen from the IgG. Once the binding equilibrium has been established, the antibody is precipitated from solution. This can be achieved by adding a synthetic bead that is coated with **protein A**, or a second anti-IgG antibody (a “secondary antibody”). The secondary antibody and protein A both work in the same way—by binding specifically to the F_c region of the first IgG (or “primary” antibody) and thereby precipitating it from the solution. The ratio of

radioactivity in the supernatant vs. that in the precipitate is then compared to a standard curve to determine the concentration of the unlabeled antigen in the biological sample. This technique was developed by Rosalyn Yalow and Solomon Berson in the 1950s at the Bronx Veteran’s Administration Hospital, and it revolutionized the study of several hormone-mediated processes (including type I diabetes). In 1977, Yalow was awarded the Nobel Prize in Medicine in recognition of the impact of RIA in diagnostic medicine (Berson had passed away in 1972).

A technique widely used to quantify antigen–antibody reactions is the **enzyme-linked immunosorbent assay (ELISA)**. The ELISA has largely replaced RIA due to its convenience (it can be easily carried out in 96-well plates for high-throughput applications) and the fact that it does not require the use of radioactivity. We illustrate the widely used **indirect ELISA** in Figure 7A.1. In the first step, a 96-well plate is coated with a solution containing the sample mixture. Proteins stick nonspecifically to the polystyrene surfaces of the well via van der Waals forces. Next, a blocking protein is added to bind to any bare polystyrene surfaces (this prevents nonspecific binding of the antibody to the well). A primary antibody that specifically binds to the target antigen is then added (step 3). This is the “immunosorbent” part of the assay in which the detection of a specific antibody–antigen interaction occurs. The detection of this antigen–antibody interaction is achieved using a secondary antibody that recognizes the F_c region of the primary antibody (steps 4–6). If, for example, a murine antibody was used as the primary antibody, an antibody from goats or rabbits raised against murine antibodies could be used as the secondary antibody. The secondary antibody is covalently crosslinked to an enzyme (typically, horseradish peroxidase) whose activity can be easily assayed spectrophotometrically using a chromogenic substrate—this is the “enzyme-linked” part of the assay. The development of color in the wells of the plate indicates the presence of the target antigen (step 6). Because the readout is based on the activity of the enzyme it is *indirect* detection; however, it is also *general* because the secondary antibody will react with *any* murine primary antibody (so, the same equipment can be used to run assays for several different target antigens by altering the primary antibody in step 3, in Figure 7A.1). Although this method has many variations, the principle is to assay for bound antibody by analyzing for the activity of the conjugated enzyme. This technique forms the basis of many clinical diagnostic tests, such as the most widely used current test for HIV infection. An enzyme-linked antibody to one of the surface proteins of the human immunodeficiency virus is used to detect the presence of the viral antigen in human blood samples. The presence of the enzyme activity on antigen–antibody complexes can be detected with great sensitivity.

Another analytical technique useful to characterize proteins is **western blotting**, so called because of its superficial resemblance to a nucleic acid analytical technique called Southern

**FIGURE 7A.1**

The indirect ELISA assay. Detection of one protein in a complex mixture is shown. The assay is typically carried out in a 96-well plate. Steps 1–5 show a close-up view of a single well. In step 5 color develops in the well due to the action of the enzyme linked to the 2° antibody. The enzyme causes a chromogenic substrate to change color. In step 6, the entire 96-well plate is analyzed (each circle represents one of the 96 wells). Those wells with color are presumed to contain the target antigen, where a darker color indicates a higher concentration of the antigen in the sample well.

Biochemists, like cell biologists, must be concerned with intracellular organization and with the location of enzymes that catalyze reactions of interest. An array of techniques with the generic term **immunocytochemistry** uses antibodies to help localize particular antigens in cytological preparations. In the simplest form, an antibody is conjugated with a fluorescent dye such as fluorescein. A thin section of cell or tissue is then immersed in a solution of the fluorescent antibody. After the excess is washed off, the bound antibody can be visualized by fluorescence microscopy. It is possible to visualize different antigens within a cell simultaneously using multiple dye-linked antibodies. Figure 7A.3 shows a cell stained with three different antibodies—each linked to a different fluorescent dye. Each fluorescent antibody binds to a different macromolecular complex, in this case

**FIGURE 7A.2**

Western blotting. On the top is a 2-D gel of total protein from tobacco leaf. On the bottom is the same gel, blotted with an antibody against proteins containing phosphothreonine residues.

blotting (see Figure 24.14, page 1016). Western blotting (also called **immunoblotting**) is used to detect, in a mixture of proteins or fragments of proteins, those that react with the same antibody. It can be used, for example, in studying the post-translational cleavage of proteins that often occurs as part of protein maturation. In this technique the antibody-reactive proteins in a mixture are analyzed by first resolving the proteins in that mixture by denaturing gel electrophoresis. Often, 2-D gels are used. After electrophoresis, the gel is placed in contact with a sheet of nitrocellulose, and the proteins are transferred (or “blotted”) to the nitrocellulose by an electric current. The proteins are bound irreversibly to the nitrocellulose sheet, so the antigen–antibody reactions can be visualized after treatment of the sheet with primary and secondary antibodies, as described above for indirect ELISA. Alternatively, the target can be detected by autoradiography using a primary (or secondary) antibody labeled with radioactive ^{125}I . An example is shown in Figure 7A.2.

**FIGURE 7A.3**

The actin microfilaments (red) and tubulin microtubules (green) of the cytoskeleton maintain the structure of the cell. Antibodies have been used to attach different fluorescent dyes to the chromatin, actin, and tubulin.

R. Alexey Khodjakov/SciencePhoto Library.

chromatin, actin filaments, and microtubules. Alternatively, the antibody can be linked to the iron-binding protein ferritin, and the bound iron can be visualized from its high electron density in the electron microscope.

Because of their high specificity in protein binding, antibodies can also be used to purify proteins. In this technique, called immunoaffinity chromatography (see Tools of Biochemistry 5A), the antibody is coupled to a chromatographic support and a column of this material is used to adsorb selectively the protein being purified. The protein is then desorbed, usually by a pH adjustment in the eluting solution (typically as low as pH 2.5 or as high as pH 11.5), and often in a state close to homogeneity.

As noted earlier, an antiserum prepared against a pure antigen, such as a protein, usually contains several different antibodies against that antigen. Moreover, the serum also contains all other antibodies that the animal carried in its bloodstream at the time that it was immunized against the protein of interest. Clearly the specificity, sensitivity, and reproducibility of all of the foregoing techniques would be increased greatly if they could be carried out

with purified antibodies that have identical sequence, and therefore identical binding specificity. Because of the chemical similarities among different IgGs, their purification by standard protein fractionation techniques is virtually impossible. Fortunately, the use of **monoclonal antibodies** (mAbs) is an alternative way to attain a highly purified antibody with a unique binding specificity in unlimited quantity.

Each antibody-forming B lymphocyte is specialized for the synthesis and secretion of one and only one antibody. If such cells could be grown in cell culture, it would be possible in principle to isolate a clone, or population derived from one cell, that synthesized one antibody directed against one site on the protein of interest. Although B lymphocytes themselves do not grow in culture, Georges Köhler and César Milstein in 1975 discovered a way to propagate antibody-forming lymphocytes with cultured cells from a mouse with multiple myeloma, a cancerous proliferation of white cells (Figure 7A.4). A mouse is immunized with the antigen of interest, and then lymphocytes from its spleen are fused with the myeloma cells. This fusion gives rise to cell lines called **hybridomas**—cells that proliferate endlessly in culture, like cancer cells, but synthesize only one antibody (see Chapter 22 for more detail on hybridoma culture). By screening a large number of hybridoma clones, several can usually be isolated that synthesize antibody to the antigen of interest, each making antibody to a different antigenic determinant. Antibodies can easily be purified from cultures of the appropriate hybridomas, and they have many uses in addition to the techniques already described. Note that this method does not require a homogeneous antigen. An investigator who has the patience to examine many hybridomas can immunize the animal at the outset with a crude preparation of the antigen of interest. Later, after the desired monoclonal antibody has been obtained, it can be used as the basis of an immunoaffinity purification of the antigen.

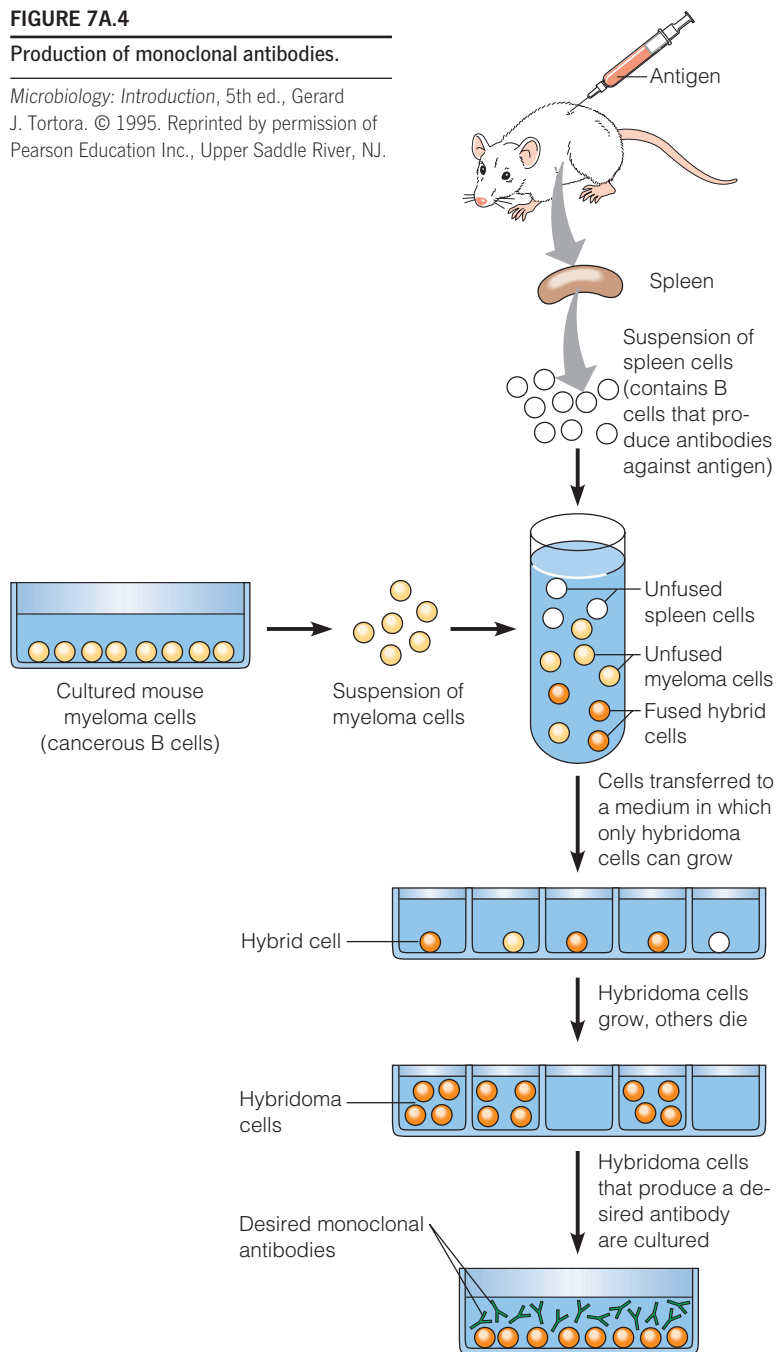

The ability to isolate mAbs has had a profound impact on biochemistry, molecular biology, and biopharmaceutical development. In 1984, the work of Milstein and Köhler was recognized with the Nobel Prize in Physiology or Medicine.

A particularly useful application of mAbs is in the identification of proteins in a multiprotein complex using **co-immunoprecipitation (co-IP)** or “**pull-down**.” In this technique, an antibody specific for a protein that is thought to be part of a multiprotein complex is used to precipitate the entire complex. The precipitating antibody is typically bound to a magnetic particle, an agarose bead, or a protein A-coated bead. The various proteins “pulled down” by this procedure can be identified by SDS-PAGE followed by mass spectrometry (see Tools of Biochemistry 5A, 5B, and 5D). To verify the results of a co-IP, several different antibodies against different proteins in the complex should be used. In this way, it is possible to identify the proteins with which some target of interest interacts.

Because it can be challenging to get suitable antibodies for IP experiments, a variation of the technique is often used. In this

FIGURE 7A.4**Production of monoclonal antibodies.**

case, a protein is “tagged” with a short peptide epitope, such as $(\text{His})_6$, (see Figure 5A.4) or the “FLAG” sequence (DYKDDDDK), and an antibody that binds the tag is used in the pull-down. It is important to show that the presence of the tag doesn’t alter the properties of the tagged protein.

CHAPTER 8

Contractile Proteins and Molecular Motors

In the previous two chapters, we have seen how proteins, either as monomers or in defined multisubunit structures, carry out a variety of functions. To continue to explore this idea, we now turn to examples in which proteins organize into large, complex structures involving many kinds of polypeptide chains. Such supramolecular structures perform many cellular functions; the one we shall consider here is the mechanical work of motion carried out by **motor proteins**. This motion may involve the whole organism, parts thereof, cells, or subcellular constituents. We will see that protein conformational change mediated by the binding, hydrolysis, and release of ATP is a key feature of motor protein function.

Of the many kinds of motion that living systems exhibit, the one we are most aware of is the muscle contraction required for bodily movement. However, muscle contraction accomplishes a remarkable variety of other things as well. Even the emission of sound is a muscular action, as is the injection of venom by an insect or a snake. Equally important muscular motions maintain the animal's internal world, including the beating of its heart, the breathing motions of its lungs or gills, and the peristaltic motions of its digestive system. Each of these kinds of movements is produced by a specific muscular tissue.

All muscles, as well as some other contractile systems, are based on the interaction of two major proteins, **actin** and **myosin**. We often refer to these systems as **actin–myosin contractile systems**. However, certain kinds of directed motions exist—motions of individual cells and parts of cells—that do not depend on the actin–myosin system at all but use other protein mechanisms. For example, the beating of cilia and flagella and the movement of chromosomes and organelles within cells are accomplished by the interactions of a number of proteins with **microtubules**, filamentous structures made of a protein called **tubulin**. Even more remarkable are the variety of “molecular motors” that have been described in increasing detail in recent years. Some of these serve to carry molecules and vesicles along microtubules and other filaments; others produce rotation of flagella and are true microscopic motors. Also, some very well-known protein complexes are now recognized as molecular motors. These include **ATP synthase**

(Chapter 15), which uses a proton gradient to drive ATP synthesis in mitochondria, and **RNA polymerase** (Chapters 26 and 28), which uses nucleoside triphosphate hydrolysis to move along and untwist a DNA template.

The biological systems that produce movement share one common feature—they hydrolyze ATP. The energy released by the hydrolysis of ATP is converted into work by producing motions in parts of protein molecules. Thus, proteins can act as **energy transducers**. That is, some proteins can convert the chemical energy of ATP hydrolysis into mechanical work. When the motions of proteins are properly coordinated, directed macroscopic motion occurs.

Muscles and Other Actin–Myosin Contractile Systems

The major proteins in muscle tissue are actin and myosin; however, actin and myosin are also found in many other types of cells and are involved in several kinds of cellular and intracellular motions. To understand how muscles and other actin–myosin systems work, we must consider the properties of these two proteins.

Actin and Myosin

Actin

Under physiological conditions, actin exists as a long, helical polymer (filamentous actin, or **F-actin**) of a globular protein monomer (**G-actin**). The G-actin monomer, shown in Figure 8.1, is a four-domain molecule with a molecular weight (M_W) of 42 kDa. The binding of ATP by a G-actin monomer leads to polymerization; the ATP is subsequently hydrolyzed, but the ADP is held in the actin filament. In F-actin filaments, the G-actin monomers are arranged in a two-strand helix (Figure 8.2; see also Figure 6.39a, page 214). Because of the asymmetry of the subunits, the F-actin filament has a defined directionality, and the two ends have been called the “**barbed**” or “**plus**” end, and the “**pointed**” or “**minus**” end. The polymerization reaction exhibits a preferred direction, and the plus end is defined as that end that grows more rapidly under physiological conditions. The sites on the F-actin filament that bind to myosin are located on domain 1 of each actin subunit.

Myosin

Six of the 20 or so forms of myosin found in cells, and their various functions, are listed in Table 8.1. The most studied myosin molecule is myosin II from striated muscle. In the following discussion we will refer to myosin II simply as “myosin.” The functional myosin molecule (Figure 8.3) is composed of six polypeptide chains: two identical heavy chains ($M_W = 230$ kDa) and two each of two kinds of light chains ($M_W = 20$ kDa). Together, they form a complex of molecular weight

Certain proteins act as energy transducers, using free energy from ATP hydrolysis or free energy stored in ion gradients to do the mechanical work of motion.

FIGURE 8.1

G-actin. Cartoon representations of the X-ray crystal structures of the G-actin monomer are shown. **Top:** with ATP bound (PDB ID: 1ATN); **bottom:** with ADP bound (PDB ID: 1J6Z). Domain 1 is red, domain 2 is blue, domain 3 is green, and domain 4 is yellow. Nucleotides are shown as spheres. The “plus” end is down in each panel.

FIGURE 8.2

A model for F-actin filaments. **Left:** The α -carbon backbones of five G-actin monomers are shown. Individual monomers are distinguished by colors, with bound ATP shown in red. The green residues on domain 1 of the gray actin monomer show the myosin-binding site. **Right:** a model of the myosin S1 fragment (see text) bound to F-actin. The myosin motor domain is shown in green and the essential and regulatory light chains are, respectively, magenta and cyan (PDB ID: 1ALM).

TABLE 8.1 Myosin types and their functions

Myosin Type	Primary Functions
I	Vesicle transport
II	Muscle contraction; cytokinesis; cell motility
V	Vesicle transport and localization at cell periphery
VI	Transport of endocytotic vesicles into cell center
VIII	Cell division in plants
XV	Part of acoustic sensor in inner ear

FIGURE 8.4

Dissection of myosin II by proteases. Trypsin cleavage cuts through the myosin tail to produce light meromyosin (LMM) and heavy meromyosin (HMM). Treatment of heavy meromyosin with the protease papain digests part of the stalk structure, allowing separation of the two S1 fragments from the S2 fragment (see text).

The major muscle systems of animals are based on the proteins actin and myosin.

Myosins are motor proteins that move toward the (+) end of the actin filament.

FIGURE 8.3

The myosin II molecule. This schematic model depicts the six polypeptide chains of myosin. The two heavy chains (green and brown) of the molecule are connected by the intertwining of the two α helices of the heavy chains in the rod-like coiled-coil tail. Each of the two globular head domains carries two noncovalently bound light chains: the essential light chain (red) and the regulatory light chain (blue).

540 kDa. The heavy chains have long α -helical tails, which form a two-stranded coiled coil, and globular head domains to which the light chains are bound. Between each head domain and tail domain the heavy chain acts as a flexible stalk. The coiled-coil structure of the tails is reminiscent of the structure of α -keratin (see Figure 6.14).

The myosin molecule can be cleaved by proteases, as shown in Figure 8.4. The tail domain can be cleaved at a specific point by trypsin to yield fragments called **light meromyosin** and **heavy meromyosin**. Further cleavage of heavy meromyosin by papain cuts the stalks to yield two **S1 fragments**, each consisting of a head domain carrying the light chains. The stalk removed by papain is called an **S2 fragment**. The ability to cleave the myosin molecule in these specific ways has helped researchers understand the functions of its several parts. Myosin exhibits aspects of both fibrous and globular proteins, and its functional domains play quite different roles. The tail domains have a pronounced tendency to aggregate, causing myosin molecules to form the kind of thick bipolar filaments shown in Figure 8.5. The S1 fragment, or **headpiece**, includes the

(b)

FIGURE 8.5

A thick filament of myosin II molecules. (a) An electron micrograph. The zone that is bare of headpieces is indicated by l ; some myosin headpieces are indicated by arrowheads. (b) A drawing of the filament structure, showing dimensions in nanometers. The projections are the pairs of headpieces on each myosin molecule.

Courtesy of Thomas D. Pollard, Yale University.

globular **motor domain**, which binds ATP and actin and two light chains—the **essential** and the **regulatory** light chains. The crystal structure of an S1 fragment is shown in Figure 8.6.

The Reaction of Myosin and Actin

If an actin filament is allowed to react with isolated S1 fragments, the filament will become decorated with these myosin headpieces, producing an asymmetric arrowhead pattern that demonstrates the polarity of the actin filament (Figures 8.7 and 8.2). Most myosin types are motor proteins that move toward the (+) end of the actin filament. As we shall see, myosin's **ATPase activity** (i.e., ATP binding and hydrolysis), as well as its ability to bind and release F-actin, are essential parts of the multistep mechanism of muscle contraction.

The Structure of Muscle

In muscle tissue, the actin and myosin filaments interact to produce the contractile structure. Vertebrates have three morphologically distinct kinds of muscle. *Striated muscle* is the kind most often associated with the term *muscle*, for it is the striated muscles in arms, legs, eyelids, and so forth that make voluntary motions possible. *Smooth muscle* surrounds internal organs such as the blood vessels, intestines, and gallbladder, which are capable of slow, sustained contractions that are not under voluntary control. *Cardiac muscle* can be considered a specialized form of striated muscle, adapted for the repetitive, involuntary beating of the heart. In the following discussion we will consider only the structure of striated muscle.

Figure 8.8 shows successive levels of organization of a typical vertebrate striated muscle. The individual muscle fibers, or **myofibers**, are very long (1–40 mm) multinucleate cells, formed by the fusion of muscle precursor cells. Each myofiber contains a bundle of protein structures called **myofibrils**. A myofibril exhibits a periodic structure when examined under the light microscope. Dark **A bands** alternate with lighter **I bands**. The I bands are divided by thin lines called **Z disks** (or sometimes **Z lines**). At the center of the A band is found a lighter region called the **H zone**. The repeating unit of muscle structure can be taken as extending from one Z disk to the next. It is called the **sarcomere** and is about $2.3\mu\text{m}$ long in relaxed muscle.

The molecular basis for this periodic structure of the myofibril can be seen by electron microscopic studies of thin sections of muscle, as shown in Figure 8.9. **Thin filaments** of actin extend in both directions from the Z disks, interdigitating with myosin **thick filaments**. The regions in which the thick and thin filaments overlap form the dark areas of the A band. The I bands contain only thin filaments, which extend to the edges of the H zones. Within the H zones, only thick filaments are found. The dark line at the center of the H zone (sometimes called the M band) is believed to indicate positions where thick filaments associate with one another.

The composition of the thick and thin filaments has been demonstrated by extracting myofibrils with appropriate salt or detergent solutions to remove virtually all of the myosin. Because the A bands are abolished in this process, the thick A-band filaments must be composed of myosin. The myosin thick filaments are bipolar structures of the kind shown in Figure 8.5, in which the helical tails of the myosin molecules join together, with the headpieces projecting with a regular 14.3-nm spacing at either end. This spacing appears to be generated by a 14.3-nm periodicity in the amino acid sequence in the myosin tails.

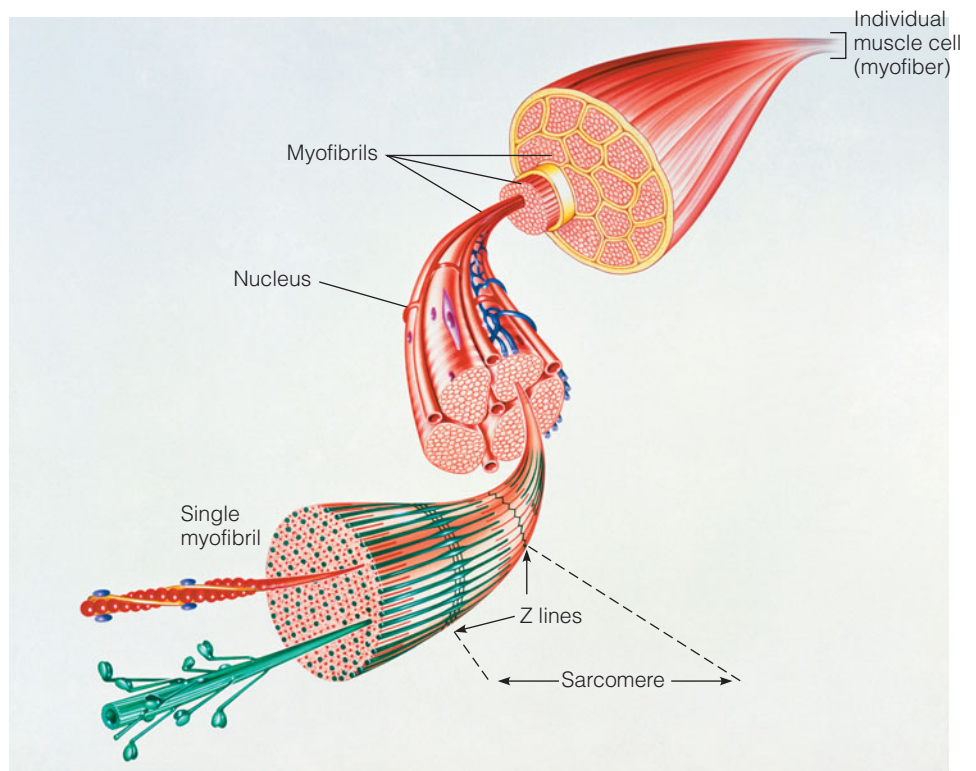

FIGURE 8.8

Levels of organization in striated muscle.

John Bavosi/Science Photo Library.

If myofibrils from which myosin has been removed are perfused with a solution of S1 fragments, the thin filaments are decorated in the arrowhead pattern (Figure 8.7); thus, the thin filaments contain actin. Furthermore, the arrowhead patterns always point outward from the Z disks, demonstrating the polarity of these thin filaments (i.e., the “plus” end of each F-actin filament is anchored to the Z disk). However, the thin filaments are not composed entirely of F-actin. As we shall see later in this chapter, they contain other important proteins as well.

The sarcomere is the basic repeating unit of a muscle myofibril.

If we look closely at electron micrographs of myofibrils (see Figure 8.9d), we can see small projections extending from the thick (myosin) filaments, often contacting the thin (actin) filaments. The projections correspond to the headpieces of the myosin molecules. These *cross-bridges* between myosin and actin filaments are the key to muscle contraction.

Thin filaments are mainly actin; thick filaments are mainly myosin. They are connected by noncovalent cross-bridges.

The organization of actin, myosin, and other muscle proteins into this elaborate yet specific structure found in the sarcomere is a remarkable example of how several kinds of protein can combine in a specific way to form a functional structure. We will now examine how this structure works.

The Mechanism of Contraction: The Sliding Filament Model

Our understanding of the mechanism of muscle contraction has come from observation both of the fine details of muscle structure and of changes in the sarcomere-banding pattern during contraction. The muscle sections shown in Figures 8.8 and 8.9, and the top of Figure 8.10, are in the relaxed, or extended, state. In a fully contracted muscle, each sarcomere shortens from a length of about $2.3\ \mu\text{m}$ to $2.0\ \mu\text{m}$. During this process, the I bands and H zones disappear, and the Z disks move right up against the A bands (bottom of Figure 8.10). Such observations led two independent (and unrelated) investigators, Hugh Huxley and Andrew Huxley, to propose in the 1950s the **sliding filament model** of muscle contraction depicted in Figure 8.10. According to this model, the myosin headpieces are presumed to “walk” along the interdigitated actin filaments, pulling them past, and thereby shortening the sarcomere.

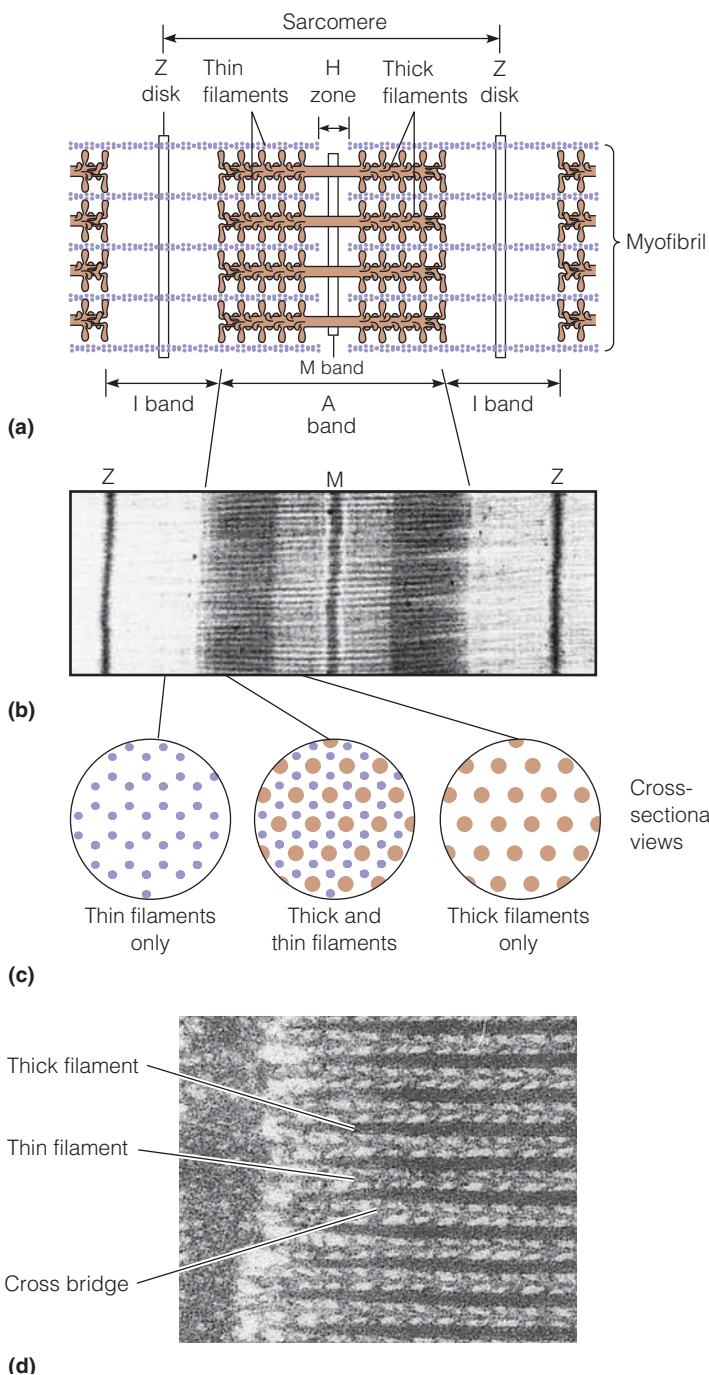

FIGURE 8.9

Muscle structure seen at the EM level. (a) A model of the sarcomere, the repeating unit in striated muscle. The I bands, A bands, and Z disks shown in Figure 8.8 are identified, and structural elements of the sarcomere are indicated. (b) An electron micrograph showing the same features. (c) A schematic drawing of cross sections of a sarcomere in the various regions shown in (a) and (b). Thick filaments are indicated by heavy brown dots, thin filaments by small purple dots. (d) A higher magnification within an A band showing cross-bridges between actin and myosin filaments.

FIGURE 8.10

The sliding filament model of muscle contraction. Contraction of striated muscle occurs when the myosin headpieces pull the actin filaments toward the center of the sarcomere.

To produce such directed motion against an opposing force on the muscle, energy must be expended. You might expect that energy would be derived in some way from ATP hydrolysis, and our previous mention of the ATPase activity of the actin–myosin complex alludes to how this energy could be gained: According to a refinement of the sliding filament model called the **swinging cross-bridge model**, each myosin headpiece takes part in a repetitive cycle of making and breaking cross-bridges to an adjacent thin filament. We imagine the cycle starting with the myosin attached to actin, as shown at the top of Figure 8.11. Binding of ATP leads to release of the myosin cross-bridge (step 1). Hydrolysis of ATP then causes a conformational change, “cocking” the headpiece (step 2). Myosin, because it has now cocked, binds to the thin filament at a site that is closer to the Z disk—where the (+) end of the actin filament is anchored (step 3).

**FIGURE 8.11**

A model of the ATP cycle in muscle contraction. For clarity, only one of the two myosin headpieces is shown going through a binding, power stroke, and release cycle. The second myosin headpiece is shown in light green. The individual steps of the cycle are described in the text.

Courtesy of Gary Carlton.

In the swinging cross-bridge model, the periodic attachment and release of cross-bridges, with a cross-bridge conformational change, slide the thin and thick filaments past one another.

This initial binding is weak. Phosphate release (step 4) results in strong binding to the thin filament prior to the power stroke (step 5), which pulls the thin filament toward the center of the sarcomere. Release of ADP (step 6) and binding a new ATP will then restart the cycle.

It is the "neck region" of the S1 fragment (Figure 8.6), where the light chains are bound, that undergoes the greatest conformational change during the power stroke. Based on comparisons of X-ray crystal structures of myosin in the ADP-bound and nucleotide-free states, it is thought that the C-terminal part of the myosin neck moves about 10 nm during the power stroke (Figure 8.12).

At the end of each cycle, the actin filament has been moved with respect to the myosin so that each headpiece makes successive steps along the thin filament. The "walking" is rather like that of a millipede—there is always contact between some of the thick filaments "legs" (i.e., the many S1 headpieces) and the thin filament.

Thus, the thick filament doesn't slip back during muscle contraction. A thick filament displays several hundred S1 fragments and each contacts the thin filament 5 times per second during muscle contraction.

The force developed and the distance moved in each power stroke have been measured experimentally. The force is found to depend upon the load placed on the myosin–actin complex, but averages about 5 pN (piconewtons) at high load. This corresponds to an energy expenditure of about 10^{-20} J per power stroke—approximately one-fifth of the energy released when a single ATP molecule is hydrolyzed. At lower loadings, there is evidence that several power strokes can be accomplished per ATP cycle. The distance the actin filament is moved per power stroke is about 10–20 nm, and this is what can be accomplished per ATP cycle at high loading. When working against weaker resistance, the multiple power strokes can propel the actin for as much as 100 nm per ATP.

Regulation of Contraction: The Role of Calcium

The critical substance in stimulating contraction is not ATP, which is generally available in the myofibril; rather, it is a sudden increase in Ca^{2+} concentration. To understand how calcium regulates muscle contraction, we must examine the molecular structure of the thin filament in a bit more detail.

A thin filament, as found in striated muscle, is more than just an F-actin polymer. Four other proteins, shown in Figure 8.13, are essential to the thin filament's contractile function. One of these proteins is **tropomyosin**, a fibrous coiled-coil protein that overlaps the myosin-binding site in the F-actin helix. Bound to each tropomyosin molecule are three small proteins called **troponins I, C, and T**. Troponin C (TnC) is homologous to the Ca^{2+} -binding protein **calmodulin**, and

FIGURE 8.13

F-actin and its associated proteins. Panel (a): This schematic drawing shows the proteins present in the thin filaments of striated muscle: F-actin, tropomyosin, and troponins (Tn) I, C, and T. Panel (b): Crystal structure of a fragment of rat skeletal tropomyosin showing the coiled coil (PDB ID: 2B9C). Panel (c): The troponin complex from chicken skeletal muscle (PDB ID: 1YTZ). TnI is shown in yellow, TnT in orange, and TnC in red with four bound Ca^{2+} ions shown as blue spheres. Panels (b) and (c) are not drawn to scale.

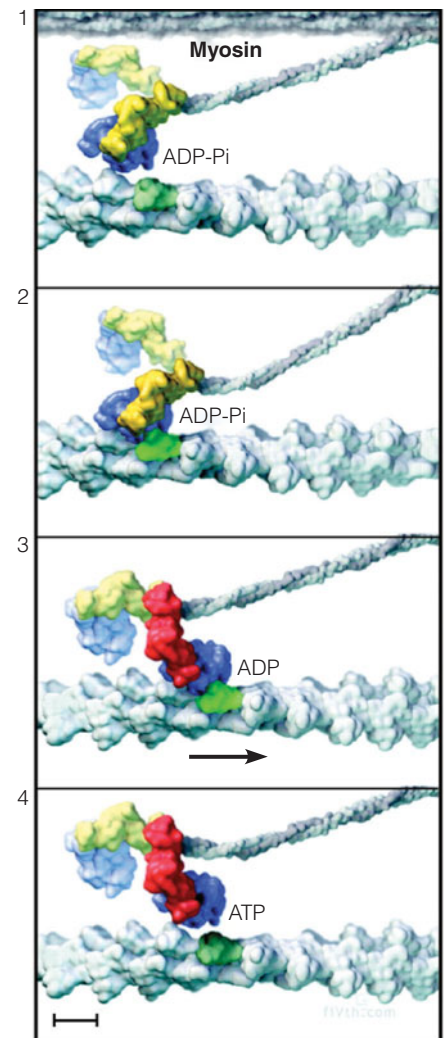

FIGURE 8.12

Model for the motility cycle of myosin II. The coiled coil (gray) extends from a myosin filament. Frame 1: The two identical S1 headpieces from a single myosin II dimer are shown, with motor domains in blue; lever arms (including the light chains) in the pre-stroke state are yellow. With ADP and P_i bound, the motor domain binds weakly to actin (see Figure 8.11, step 3). Frame 2: One motor domain forms a strong complex with an actin binding site (green). Frame 3: Upon phosphate release, the power stroke occurs and moves the actin filament by ~10 nm (see Figure 8.11, steps 4 and 5). The lever arm in the post-stroke state is colored red. Frame 4: Following the power stroke, ADP dissociates and ATP binds to the motor domain, releasing it from actin. Following hydrolysis of ATP to ADP· P_i , the lever arm reverts back to its pre-stroke state (i.e., Frame 1). Scale bar 6 nm. The (+) end of the thin filament is to the left.

FIGURE 8.14

The regulation of muscle contraction by calcium.

A single myosin headpiece is shown next to a thin filament, in cross-sectional view. **Left:** Relaxed muscle. At low Ca^{2+} levels, the configuration of actin, tropomyosin, and the troponin complex in the thin filament blocks most myosin headpieces from contacting the thin filament. **Right:** The binding of Ca^{2+} to TnC opens a binding site on TnC for the inhibitory domain of TnI, which also binds actin (see left panel). The release of TnI from actin allows the tropomyosin–troponin complex to slide closer to the central groove in F-actin, thereby exposing the myosin-binding site. Cross-bridge formation (step 3 of Figure 8.11) can then occur, and the muscle contracts.

Courtesy of Gary Carlton.

Muscle contraction is stimulated by an influx of Ca^{2+} into the sarcomere. Ca^{2+} binding by troponin C causes a rearrangement of the troponin–tropomyosin–actin complex, allowing actin–myosin cross-bridges to form.

like calmodulin, TnC undergoes a conformational change upon binding Ca^{2+} . The structure and function of calmodulin are presented in greater detail in Chapter 13 (see Figure 13.33, page 570). The presence of tropomyosin and the troponins inhibits the binding of myosin heads to actin *unless calcium is present* at a concentration of about 10^{-5} M. In resting muscle, Ca^{2+} concentrations are approximately 10^{-7} M, so new cross-bridges cannot be formed. An influx of Ca^{2+} stimulates contraction because the ion is bound by troponin C, causing a rearrangement of the troponin–tropomyosin complex, which moves the tropomyosin ~ 1.0 nm closer to the central groove of the F-actin helix. This shift reveals the sites on actin to which the myosin headpieces bind. The postulated mechanism, shown in Figure 8.14, permits step 3 and the subsequent steps in the cycle of Figure 8.11 to take place.

We have now traced the activation of muscle contraction to the influx of calcium into the myofibrils. But why does this influx occur? In particular, how can it be brought about by the nerve impulses that excite muscles to contract? The answer can be found from a closer examination of the myofiber, or muscle cell (Figure 8.15). Within the cell, each myofibril is surrounded by a structure called the **sarcoplasmic reticulum**, formed of membranous tubules. In resting muscles the level of Ca^{2+} in the myofibrils is maintained at about 10^{-7} M, whereas the Ca^{2+} level within the lumen of the sarcoplasmic reticulum may be 10,000-fold higher. Impulses from motor nerves depolarize the membrane of the sarcoplasmic reticulum, opening gated Ca^{2+} channels (see Chapter 10), and Ca^{2+} pours out of the lumen into the myofibrils, stimulating contraction. The signal is rapidly transmitted to the entire sarcoplasmic reticulum of a myofiber via **transverse tubules**, invaginations of the plasma membrane that connect at periodic intervals with the reticulum. Following the contraction, a Ca^{2+} -specific transport protein pumps

FIGURE 8.15

Structure of a myofiber (muscle cell). The sarcoplasmic reticulum (SR, white, see solid arrows) is a network of specialized endoplasmic reticulum tubules that surrounds the myofibrils within the myofiber. In resting muscle, the SR accumulates Ca^{2+} , which it discharges into the myofibrils when a neural signal reaches the plasma membrane. The transverse tubules (T system, see dashed arrows) are invaginations of the plasma membrane that make contact with the SR at many points, ensuring uniform response to the signal.

MedicalRF.com/Visuals Unlimited, Inc.

Ca^{2+} ions out of the sarcomere to restore the resting $[\text{Ca}^{2+}]$ to 10^{-7} M. The activities of such ion transporters are described in Chapter 10.

Although the abrupt change in Ca^{2+} level is the universal *signal* for muscle contraction, it obviously cannot in itself provide the necessary energy. What are the sources of the energy required for muscular work?

Energetics and Energy Supplies in Muscle

Basically, muscle is a mechanism for converting the chemical free energy released in ATP hydrolysis into mechanical work. The conversion can be remarkably efficient, approaching values of 80% under optimal circumstances.

How is the ATP for muscle contraction generated? Even in striated muscle the answer can vary, depending on the particular *kind* of muscle and its function. Striated muscles can be divided into two categories—*red muscle*, designed for relatively continuous use, and *white muscle*, employed for occasional, often rapid, motions. Red muscle owes its dark color to its abundant heme proteins: It is well supplied with blood vessels and therefore hemoglobin, it has many mitochondria with cytochromes, and it has large stores of myoglobin. Red muscle depends heavily on aerobic metabolism in mitochondria, so the primary energy source in red muscle is the oxidation of fat. White muscle, on the other hand, relies on glycogen as a primary energy source. Glycogen is excellent for quick energy production but cannot sustain activity for long periods (see Table 8.2 for a more detailed comparison of red and white muscle, and Chapters 13 and 18 for a more extensive discussion of glycogen metabolism).

The functional differences between the two types of striated muscle are clearly revealed in birds. In the domestic chicken, the flight muscles of the breast, used only for brief fluttering or short flights, are white, whereas the heavily used leg muscles are red. Wild flying birds, which make sustained flights but rarely walk, have just the opposite distribution of light and dark meat.

Careful measurement of ATP levels in red striated muscle has shown that the provision of energy is more complicated than it might appear at first. The amount of ATP needed for a single contraction may be greater than all the ATP immediately available to a sarcomere. Yet even after relatively long exercise, ATP levels in the sarcomeres remain essentially constant. This finding suggests that ATP is an intermediary, and not an energy *storage* compound in muscles. Indeed, aerobic muscle tissue continuously resynthesizes ATP from ADP and P_i to support prolonged muscular activity. This requires a steady import of fuel molecules, which are oxidized by O_2 in mitochondria to drive the unfavorable synthesis of ATP (see Chapter 15). Bursts of intense activity may exceed the capacity of aerobic metabolism to supply the needed ATP. To bridge the short interval between the moderate demand for ATP met by aerobic metabolism and the high demand met by anaerobic ATP production, muscles carry a small reserve of the high-energy compound *creatine phosphate*. As its high phosphate transfer potential suggests (see

TABLE 8.2 Comparison of red and white striated muscle

	Red	White
Relative fiber size	Small	Large
Mode of contraction	Slow twitch	Fast twitch (about 5 times faster)
Vascularization	Heavy	Lighter
Mitochondria	Many	Few
Myoglobin	Much	Little
Major stored fuel	–	Glycogen in muscle
Main source of ATP	Fatty acid oxidation	Glycolysis

Figure 3.7), this compound is capable of phosphorylating ADP very efficiently. The reaction is catalyzed by the enzyme *creatine kinase*.

An alternate energy source in red muscle is creatine phosphate, which regenerates ATP continually as it is depleted by muscle contraction.

Because the equilibrium lies well to the right, virtually all of the muscle adenylate is maintained in the ATP form, rather than as ADP or AMP, as long as creatine phosphate is available. The consumption of creatine phosphate during exercise, while an almost constant level of ATP is maintained, is clearly demonstrated by the NMR studies of human muscle shown in Figure 12.13 (page 503).

Nonmuscle Actin and Myosin

The functions of actin and myosin are not limited to muscle contraction. Indeed, members of the actin and myosin families are found in most eukaryotic cells, even those that are in no way involved in muscular tissues (see Table 8.1). Actin and myosin play significant roles in cell motility and changes of cell shape. Actin is the major component of the **microfilaments** of the **cytoskeleton**—the fibrous array that pervades almost every kind of cell and gives it a specific shape (Figure 8.16a). Staining with fluorescent antibodies reveals that an isoform of myosin II (**nonmuscle myosin II**; Figure 8.16b) and other types of myosin (see Table 8.1) are also associated with this network. The nonmuscle myosin II (NM II) in such intracellular networks is different in sequence from muscle myosin II, and its assembly into filaments is regulated by phosphorylation of the associated regulatory light chains. The bipolar filaments formed by NM II contain roughly 14–20 myosin molecules, making them significantly smaller than the thick filaments in myofibrils. Several cellular proteins are involved in anchoring microfilaments to the cell membrane, and we will not mention them here. Rather, we point out that organized contraction and relaxation of such anchored microfilament and NM II networks (Figure 8.16c) can lead to a wide variety of cell distortions and movements, including amoeboid crawling.

A nonmuscle actin–myosin system generates the motion and shape changes of many types of cells.

FIGURE 8.16

Cytoskeletal actin and nonmuscle myosin II in fibroblasts. (a) Actin fibers as detected by fluorescent phalloidin, which binds specifically to actin. (b) Myosin in the same cell detected by an injected fluorescent antibody. (c) A mechanism for contractility in the cytoskeleton. An NM II filament (green and olive) will bring together two anchored actin microfilaments (red). NM II moves toward the “+” end of the microfilament. The direction of movement of the actin microfilaments is shown by the arrows.

Another intracellular process involving an actin–myosin contractile complex is **cytokinesis**, the division of cells in the last stages of mitosis (Chapter 24). The process can be seen clearly in the sea urchin egg, a favorite model system for such studies (Figure 8.17). Toward the end of mitosis, when the daughter nuclei are clearly separated at the two poles of the cell, a ring of indentation is observed in the cell surface, defining a plane perpendicular to the mitotic spindle. This ring then contracts, as proposed in Figure 8.16c, forming the **cleavage furrow** and eventually cutting the cell in two. Electron microscopy shows that the ring consists of fibers, and staining with fluorescent antibodies shows that the fibers contain both actin and myosin.

The involvement of myosin in cytokinesis has been most elegantly demonstrated by S. Inoué and his colleagues in the experiment depicted in Figure 8.18. After the sea urchin egg had undergone one division, the daughter cell on the right was microinjected with antimyosin antibodies, which should make myosin nonfunctional. After 10 h, the control cell (left) had undergone many divisions to construct half of an embryo. In the treated cell, mitosis continued, as evidenced by the many nuclei present, but *cytokinesis had been completely blocked*. Therefore, myosin is essential for cytokinesis.

The experiment demonstrates one other important fact. Because mitosis continued even in the cell treated with antimyosin antibodies, the contractile process in the mitotic spindle apparently does *not* require the participation of myosin. There have been many reports of the presence of actin and myosin in the spindle, and it was long believed that they were essential for chromosome separation. But these and other experiments show that some other contractile system must be involved. It is to this second general class of motility-generating systems that we now turn.

Microtubule Systems for Motility

A class of motile systems completely different from, and unrelated to, the actin–myosin contractile systems is used in places as diverse as the mitotic spindle, protozoan and sperm flagella, and nerve axons, to name only a few. These systems are constructed from **microtubules**, very long, tubular structures built from a helical arrangement of the protein **tubulin** (Figure 8.19). There are two homologous tubulin subunits, α and β , each of molecular weight 55 kDa. They are present in equimolar quantities in the microtubule, which can be considered a helical array of $\alpha\beta$ dimers. Alternatively, we can view the microtubule as consisting of 13 rows, or **protofilaments**, of alternating α and β subunits. Because the α and β units are asymmetrical proteins, with a defined and reproducible orientation in the fiber, the microtubule has directionality as indicated by the (+) and (–) ends in Figure 8.19.

The assembly of microtubules bears resemblance to that of actin, but GTP, rather than ATP, is required. The α and β subunits each bind GTP and then associate to form $\alpha\beta$ dimers and oligomers. These oligomers form nucleation sites for the growth of microtubules (Figure 8.20). One end, called the plus end, grows more

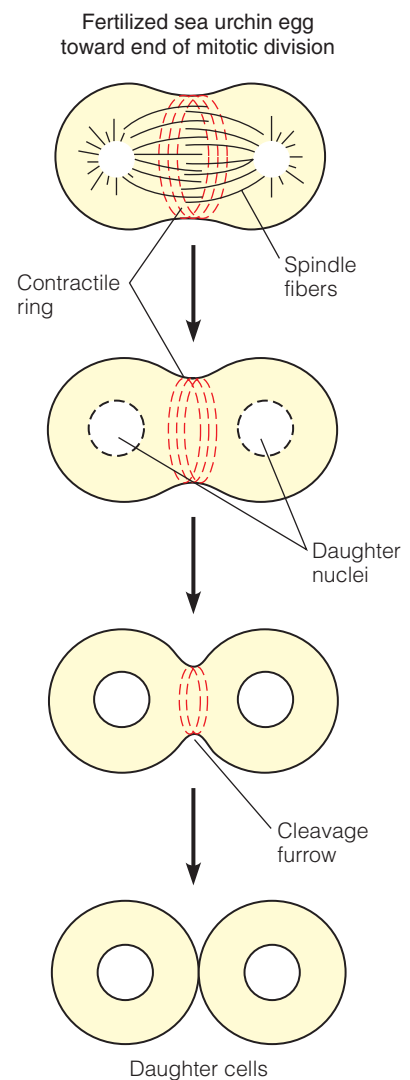

FIGURE 8.17

Actin and nonmuscle myosin II in cytokinesis. This drawing depicts cytokinesis in a fertilized sea urchin egg. The contractile ring that cleaves the cell in two is an actin–myosin complex located just beneath the plasma membrane.

Microtubules are helical, tubular polymers made from α and β tubulin heterodimers.

FIGURE 8.18

Myosin is essential to cytokinesis but not to mitosis. (a) A sea urchin embryo at the two-cell stage. The cell on the right has been injected with antimyosin antibodies; the oil droplet shows the site of injection. (b) After 10 h, the cell on the left has undergone many divisions, forming half of a normal embryo. In the cell on the right cytokinesis has been completely blocked, but the many new nuclei show that mitosis has continued.

FIGURE 8.19

A helical array of α and β tubulin forms a microtubule. **Left:** The crystal structure of an $\alpha\beta$ dimer is shown. The three domains in each subunit are color-coded (blue, green, and orange). The α subunit is on top and has GTP (red spheres) bound. The β subunit has GDP (purple) and the anticancer drug paclitaxel (white, blue, and red spheres) bound. With the subunits in this orientation the (-) end is up and the (+) is down.

Right: A schematic model of a microtubule. The α and β tubulin subunits are shown in tan and blue, respectively. The microtubule can be thought of either as a helical array of $\alpha\beta$ dimers or as 13 parallel rows of $\alpha\beta$ dimers. These rows are referred to as protofilaments.

rapidly than the other, minus end. The β subunit has GTPase activity, and as in actin polymerization, the nucleotide is hydrolyzed but is held in the filament. Both microfilaments and microtubules are dynamic structures that can be disassembled and reassembled from either end. In fact, this is a critical feature of the cytoskeleton, and compounds that interfere with cytoskeleton dynamics are toxic to cells.

**FIGURE 8.20**

Assembly of microtubules. During an initial lag period, $\alpha\beta$ dimers form oligomers large enough to nucleate fiber formation. The microtubules then grow until most of the free dimers are used up and equilibrium between growth and dissociation is reached. For simplicity, we show growth only at one end because growth is more rapid at the plus end.

Because cancer cells are rapidly dividing, the disruption of microtubule assembly during mitosis is the target of several anti-cancer treatments. For example, colchicine and paclitaxel (Taxol) both affect microtubule dynamics and thereby interfere with cell division. Colchicine binds to tubulin subunits and thereby prevents microtubule polymerization. Paclitaxel binds to the β subunit of tubulin (see Figure 8.19) and stabilizes the microtubule structure to the point that the breakdown and recycling of the microtubules is inhibited, which ultimately kills the cell. Nonmalignant cells are also affected adversely by such chemotherapeutic treatment, but the rapidly dividing cancer cells are more susceptible to cell-killing by such drugs.

Microtubules are larger and appear to be more mechanically stable than actin microfilaments; thus, microtubules are better suited to high-stress functions. The final assembly of a functional microtubule usually involves the binding of other proteins to its surface. Some of these **microtubule-associated proteins (MAPs)** play functional roles, as we shall see. Other MAPs stabilize microtubule structure and/or promote the association of microtubules into bundles. A member of this family that has drawn considerable attention is the tau (τ) MAP found in neuronal tissue. Phosphorylation of tau results in its dissociation from microtubules, leading to destabilization of the microtubule structure. Hyperphosphorylation has a much more dramatic effect, resulting in the formation of tangles of τ -filaments in neural axons, one of the major cellular symptoms of Alzheimer's disease. This in turn may imply that inappropriate synthesis or activation of the enzymes (kinases) involved in tau phosphorylation may trigger the onset of the disease. We shall now consider some of the things that microtubules do.

Motions of Cilia and Flagella

Many kinds of prokaryotic and eukaryotic cells are propelled by the motions of cilia or flagella. Cilia are shorter than flagella and exert a coordinated rowing motion to move a microorganism through solution (Figure 8.21a). Eukaryotic flagella, such as sperm tails, are longer and propel the cell by an undulatory motion (Figure 8.21b). The structures of the two types of motile appendages have many elements in common (Figure 8.22). Each of them contains a highly organized bundle of microtubules

Colchicine and paclitaxel act as anti-cancer agents by disrupting microtubule dynamics.

Many kinds of cells are propelled by cilia or flagella containing microtubules.

Bending of cilia and flagella is accomplished by the dynein-driven sliding of microtubules past one another.

called an **axoneme**, enveloped by an extension of the plasma membrane and connected to a **basal body**, an anchoring structure within the cell.

The internal structure of the axoneme is truly remarkable. As the cross-section in Figure 8.22c shows, the most obvious feature is the arrangement of microtubules known as a 9 + 2 array: two central microtubules ringed by nine microtubule doublets. The single microtubules in the center are complete, each having 13 protofilaments of $\alpha\beta$ tubulin dimers. By contrast, each of the nine surrounding doublets is composed of one complete microtubule (the **A fiber**) to which is fused an incomplete microtubule, carrying only 10 or 11 protofilaments (the **B fiber**). Closer inspection of electron micrographs reveals even greater complexity, as diagrammed in Figure 8.23. The outer doublets are periodically interconnected by a protein called *nexin* and carry at regular intervals *sidearms* composed of the motor protein **dynein**. In addition, *radial spokes*, each consisting of a head and an arm, project from the outer doublets to connect with the central pair.

The full complexity of axoneme structure is revealed by gel electrophoresis studies of isolated axonemes. About 200 polypeptides can be resolved. Analysis indicates at least 6 proteins in the spoke heads and 11 others in the arms of the spokes. Much of this apparatus seems to be directly involved in the beating motions of cilia and flagella. If ATP is added to isolated axonemes, adjacent doublets can be seen to slide past one another. The best current model holds that this sliding occurs by “walking” of the dynein sidearms along the adjacent doublet (Figure 8.24a). Doublets slide past each other first on one side of the axoneme and then the other, with the length of the slide limited by the central spokes and nexin connectors. In this way, the sliding of doublets is transformed into back-and-forth bending of the whole cilium or flagellum (Figure 8.24b). If connections within the axoneme are removed by careful proteolysis, ATP simply causes axonemes to extend and thin, as the outer doublets slide past one another with no stopping point.

It has been demonstrated that dynein has ATPase activity, with binding of ATP associated with the *breaking* of dynein cross-bridges. Thus, an obvious similarity exists between the mechanisms of beating of cilia and flagella and the ATP-driven walking of myosin heads along the actin fiber.

Intracellular Transport

At one time, all transport of materials within the cytoplasm of cells was thought to occur through simple diffusion. It is now known that some proteins and organelles are rapidly transported over long distances along microtubules, which serve as tracks that direct and facilitate the motion.

The clearest evidence comes from studies of transport in **axons**, the long projections that allow one nerve cell to contact another (see Figure 10.45, page 397). Because nerve axons can be many centimeters in length, sufficiently rapid movement

FIGURE 8.23

Diagram of the cross-section of an axoneme. The dynein arms have ATPase activity and can cause adjacent doublets to slide with respect to each other. The nexin connections between doublets and the radial spoke system give stability to the whole assembly.

of materials between the cell body and the end of the axon cannot be accomplished by diffusion. The problem can be studied directly by using the mammalian sciatic nerve, which has very long axons extending from the cell body in the spinal cord. If radiolabeled amino acids are injected into the cell body, they are incorporated into proteins by the cell's ribosomes. After some time, the axon can be sectioned, and the location of newly synthesized, radiolabeled proteins can be determined. This method reveals that although transport rates vary greatly, some proteins, especially those associated with lipid vesicles, move as rapidly as 40 cm/day, much faster than could be accounted for by diffusion.

As shown in Figure 8.25, small vesicles or whole organelles can actually be seen moving along microtubule bundles in an axon. Transport along the microtubules occurs in both directions, in each case by the attachment of "molecular motors" to the objects to be transported. These motors are of two kinds. One, called **cytoplasmic dynein**, resembles the dynein involved in the motion of cilia and flagella (see previous section) and is responsible for transport from the plus end of the microtubule toward the minus end. The other, called **kinesin**, is used to transport objects in the opposite direction. Kinesin and cytoplasmic dynein represent different families of motor proteins, with similar but distinct transport functions in a wide variety of cell types. The two proteins have different structures (Figure 8.26); however, kinesin bears similarity to the myosin family in both structure and function. The helical tail of each molecule connects it to whatever "cargo" the dynein or kinesin is carrying, perhaps through associated proteins (shown in green in Figure 8.26).

Similarities in function between myosin and kinesin can be seen by comparing an ATP-hydrolysis cycle for each protein, as depicted in Figures 8.12 and 8.27. Both proteins have a globular motor domain that binds both its target filament and ATP. A significant difference between myosin and kinesin is seen in their respective "duty ratios," or the time each motor domain spends bound to its target. Because at any given time only a few myosin headpieces in a myosin filament will be attached to the actin microfilament, an individual myosin motor domain spends most of its time in the unbound state (see Figure 8.12, panels 1 and 4). Kinesin doesn't form oligomeric filaments; thus, it must always have one of its motor domains securely bound to the microtubule as it carries its cargo. Once bound to a microtubule, kinesin hydrolyzes roughly 100 ATP before it dissociates. Thus, the motor domains of kinesin work in concert, whereas the motor domains of myosin work independently.

The mechanism of dynein movement is not yet understood in detail; however, binding and hydrolysis of ATP in the motor domain results in large conformational changes between the motor domain and the linker to the cargo domain.

Careful studies of the motion of kinesin and dynein on microtubules indicate that they move stepwise along the microtubule track, with a step size of about

FIGURE 8.24

Model for the bending of cilia and flagella. (a) Isolated microtubule doublets can "walk" past one another by making and breaking dynein arm contacts, if ATP is present. (b) The back-and-forth bending of a cilium or flagellum is produced by synchronized short "walks" by microtubules on opposite sides of the appendage. Long walks are prevented by the cross-connections between microtubules.

Organelles and individual molecules are transported by motor proteins within cells, along molecular "tracks" of microtubules or actin microfilaments.

FIGURE 8.25

Movement on microtubule tracks. A series of time-lapse video micrographs shows the bidirectional motion of organelle vesicles on a single microtubule filament from squid giant axon. The two organelles (pointed to by the open and solid red triangles) move in opposite directions and pass each other. Elapsed time (s) is given in the upper right corner of each frame.

FIGURE 8.26

Structural models of kinesin I and cytoplasmic dynein. Models for kinesin and dynein were built from crystal structures of several isolated domains. Motor domains are shown in blue/purple. The microtubule-binding portions are on the left and the cargo-binding portions are on the right. The motor domain of kinesin resembles the S1 headpiece of muscle myosin. The motor domain of dynein binds ATP and contains six different subunits arranged in a circle. The microtubule-binding stalk and the linker to the cargo domain are covalently linked to the hexameric motor domain.

Adapted from *Cell* 112:467–480, R. D. Vale, The molecular motor toolbox for intracellular transport. © 2003, with permission from Elsevier.

Kinesin is a motor protein that transports its cargo toward the (+) end of a microtubule. Dynein is a motor protein that transports its cargo toward the (–) end of a microtubule.

8 nm. This is exactly the distance from one tubulin dimer to the next. This means that kinesin can transport its cargo for ~100 steps, or about 1 micron, before it falls off the microtubule. Such behavior is defined as **processive** and is a critical feature of several proteins that travel along large linear biopolymers as part of their function (e.g., the cellular transport proteins and the polymerases that copy genomic DNA). In the current model for the motility cycle of kinesin (Figure 8.27), the molecule is believed to pivot, binding one head group and then the other to the tubulin monomers in a “hand-over-hand” fashion.

There is also clear evidence for yet another mechanism of transport in the cytoplasm. Careful observation of motions of cellular organelles revealed that some organelles periodically make short linear movements, with abrupt changes in direction, in regions where *no microtubules can be observed*. This research led to the conclusion that cellular transport also occurs on some or all of the actin microfilaments in cells. Further studies have shown that the motors in this case are myosins different from myosin II (e.g., myosins I, V, VI, etc.—see Table 8.1).

Myosin V is the best studied of these, and differs from myosin II in three important ways: (1) myosin V is a dimer with a shorter coiled-coil tail that binds cargo rather than forming filaments; (2) the lever arm of myosin V binds six calmodulin-like light chains, making it three times longer than the lever arm in myosin II; and (3) myosin V binds actin processively. Like kinesin, myosin V

FIGURE 8.27

Model for the motility cycle kinesin I. Kinesin I is modeled on a single tubulin protofilament. The coiled coil (gray) extends toward the kinesin cargo. Motor domains are attached to the coiled coil by “neck linkers.” Frame 1: Each motor domain (blue) is bound to tubulin (green = β subunit; white = α subunit) along a microtubule. In this state the neck linker (orange) points *forward* (right) on the trailing head and *rearward* on the leading head (red). ATP binding to the leading head initiates conformational change in the leading neck linker, and weakens microtubule binding by the trailing head. Frame 2: The conformational change in the neck linker of the leading head (yellow) pitches the unbound trailing head forward by 16 nm (arrow) toward the next tubulin binding site. Frame 3: The new leading head docks tightly onto the microtubule, moving the attached cargo 8 nm closer to the “plus” end. During this time, the trailing head hydrolyzes ATP to ATP-P_i, and then ADP dissociates from the leading motor domain. Frame 4: ATP binds to the leading head and the cycle begins again. Scale bar 4 nm.

moves in a stepwise, hand-over-hand fashion; however, myosin V takes much larger (36 nm) steps than kinesin (see Figure 8.28).

In the cell, we can think of the microtubules as major roads for cargo transport and microfilaments as side streets. The successful delivery of cargo requires both. Experimental evidence suggests that kinesin and myosin V can both bind to the same cargo and work together to deliver it to its final destination. Although only the kinesin moves the cargo along the microtubule, the bound myosin V can interact nonspecifically with the tubulin. In the event the kinesin falls off the microtubule, the myosin V holds it in place long enough for the kinesin to rebind and continue the journey. On the actin microfilament, these roles reverse. Cargo bound to both carriers is transported farther on each filament type than when one or the other carrier is absent (Figure 8.29).

Table 8.3 summarizes the essential features of the activities of the different motor proteins we have discussed in this chapter. Each carries out contractile or transport functions by binding to a polymeric protein target and undergoing ATP-driven conformational change. We now turn to a protein motor that functions in a completely different manner.

**FIGURE 8.29**

Myosin V and kinesin I work together to deliver cargo. The distance a cargo is transported along a microtubule or microfilament is significantly greater when both carriers are present. Nonspecific interaction between myosin V and tubulin, and kinesin and actin, keep the active carrier close to its target filament in the event it falls off too early.

TABLE 8.3 Motor proteins and their functions

Motor Protein	Primary Function	Binding Target/Direction of Movement
Muscle myosin II	Muscle contraction	Actin filament; moves toward (+) end
Nonmuscle myosin II	Cytokinesis; cell motility	Actin filament; moves toward (+) end
Myosin V	Cargo transport	Actin filament; moves toward (+) end
Kinesin	Cargo transport	Microtubule; moves toward (+) end
Cytoplasmic dynein	Cargo transport	Microtubule; moves toward (-) end
Axonemal dynein	Bending of cilia/flagella	Microtubule; moves toward (-) end

Some bacteria move by the rotation of flagella, using molecular rotating motors set in the cell membrane.

FIGURE 8.30

Structure of the bacterial flagellar motor from *Salmonella enterica*. A model of the flagellar motor, drawn to scale, compared to reconstructed images from electron microscopy. Labels indicate the different proteins (named for their genes) that make up the various components of the complex. The general morphological features, starting below the inner membrane and working out, are: C-ring (located on the cytoplasmic side of the inner membrane), MS-ring (in the inner membrane), P-ring (in the peptidoglycan layer), L-ring (in the outer membrane), hook, hook-associated proteins, and the flagellum (labeled “filament” in the figure).

Bacterial Motility: Rotating Proteins

It is appropriate to close this chapter by examining a complex, self-assembling macromolecular machine that is almost without rival in its elegance. The bacterial flagellum is a right-handed helical fiber, composed almost entirely of one fibrous protein, **flagellin**. It does not contain microtubules, actin, myosin, or any contractile system. Yet for many years it was assumed that the bacterial flagellum underwent in-plane bending motions, like those of sperm tails. Thus, researchers were surprised to learn that, in fact, it *rotates*. This mechanism was demonstrated most simply when the flagellum of a bacterium was stuck to a glass plate by anti-flagellin antibodies. Because the flagellum could no longer rotate, the bacterium did.

The remarkable structure that attaches the flagellum to the bacterium and generates the rotation is shown in Figure 8.30. The fiber of the flagellum is attached through a hook structure to a rod that passes through a “bushing” (L- and P-rings in Figure 8.30) in the outer bacterial membrane and into the

inner membrane. There it terminates in a multisubunit “rotor” (MS- and C-rings) that is surrounded by a “stator” ring (Mot A and B). Each of these components is made up of protein molecules, and most have been characterized. In other words, the flagellum is made to rotate by an ultramicroscopic motor consisting entirely of protein subunits. In a sense, it is an electric motor because the driving force comes from protons moving across the bacterial inner membrane. Ion gradients across membranes are a source of free energy to drive many critical processes in cells (see Chapters 10 and 15). In vivo, the motor runs at ~100–200 revolutions per second and requires the passage of about 1000 protons per revolution.

Such rotary motors are widely used in cells and exhibit a variety of functions and mechanisms. Certain marine bacteria propel themselves using motors driven by sodium ion fluxes rather than proton fluxes. On the other hand, proton flux through a rotary device is used to generate ATP from oxidative metabolism in most organisms, as we describe in Chapter 15.

The flagellar motor has still one more remarkable property—it can be reversed without changing the direction of H^+ movement through the motor. That is, it can rotate the flagellum in either a clockwise or a counterclockwise direction. This ability is important to the bacterium, for it allows for both steady, linear motion and changes in direction. If the multiple flagella are all rotating counterclockwise (Figure 8.31a), their right-handed helical sense makes them *push* together. They tend to be drawn together in a bundle and propel the bacterium in a straight line, a movement known as *running*. But if the flagella rotate clockwise (Figure 8.31b), they fly out from the surface and *pull* in all directions. The result is that the bacterium *tumbles* and thereby, changes direction.

Escherichia coli and a number of other flagellated bacteria demonstrate a response to chemicals, called **chemotaxis**. The general phenomenon of **taxis**, widespread throughout the animal and plant worlds, comprises movements in

FIGURE 8.31

Effect of the direction of flagellar rotation.

These electron micrographs and accompanying diagrams show how the direction of flagellar rotation affects a bacterium with several flagella. **(a)** If the flagella rotate counterclockwise, their right-helical structure makes them be pulled together into a bundle and drive the bacterium in a straight line (running).

(b) When rotation is clockwise, the flagella fly out in all directions, and the bacterium tumbles randomly.

Reprinted from *Journal of Molecular Biology* 112:1–30, R. M. McNab and M. K. Ornston, Normal-to-curly flagellar transitions and their role in bacterial tumbling: Stabilization of an alternative quaternary structure by mechanical force. © 1977, with permission from Elsevier.

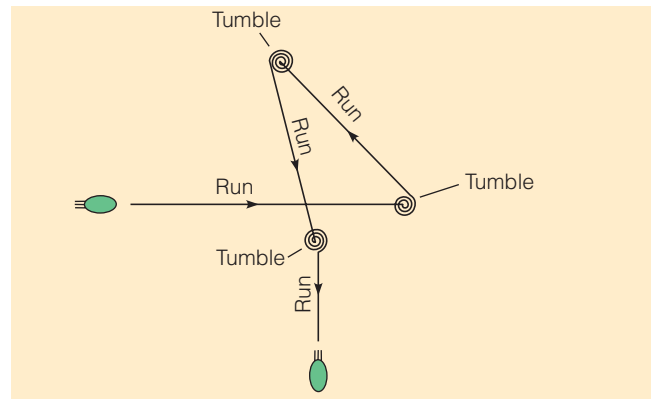

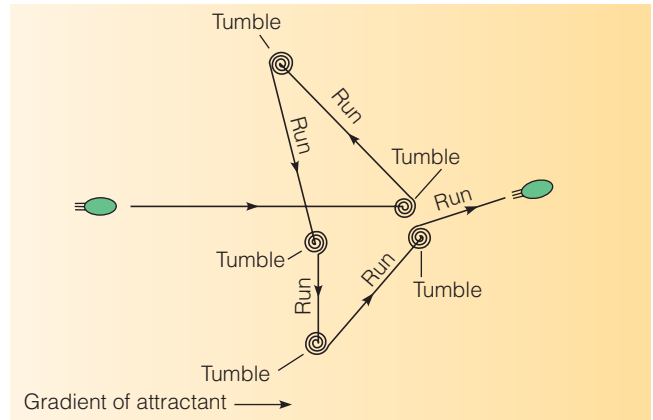

FIGURE 8.32

Chemotactic motion of bacteria. (a) In the absence of either attractants or repellents, the bacterium stops and tumbles frequently, each time starting out in a new, random direction. **(b)** When a gradient of an attractant is present, a bacterium heading toward the attractant tends to run for longer periods without tumbling. **(c)** A gradient of a repellent has the opposite effect, favoring long runs away from the repellent source.

**(a)****(b)****(c)**

response to external stimuli. Chemotactic bacteria move preferentially toward attractants, such as nutrients, and away from repellents, such as poisons. We can now describe bacterial chemotaxis in terms of running and tumbling motions (Figure 8.32). In a neutral and uniform environment, periods of running lasting a few seconds alternate with brief periods of tumbling, and the bacterium wanders about randomly (Figure 8.32a). The presence of a gradient of either a nutrient or a noxious repellent biases this distribution of running and tumbling. If a bacterium is moving up a gradient of nutrient, tumbling is delayed, resulting in net motion toward the source of nutrition (Figure 8.32b). Conversely, a bacterium moving away from a repellent continues to do so for longer than usual before tumbling, resulting in an avoidance reaction (Figure 8.32c).

These observations imply that flagellated bacteria must have some mechanism for sensing gradients of attractants or repellents and relaying this information to the motors of their flagella. In fact, they do. We do not have space to describe this remarkable mechanism here. The interested reader should consult the references at the end of the chapter (e.g., L. D. Miller et al.; C. V. Rao, et al.; and Shimizu et al.).

Finally, the bacterial flagellum has received attention as a putative example of “irreducible complexity,” a concept that has been used to argue against the

possibility that this remarkable molecular machine evolved from simpler precursors by Darwinian principles. In fact, many of the components of the bacterial flagellum are homologous to other bacterial proteins—in particular, to proteins involved in the secretion of bacterial toxins; thus, the flagellum is not “irreducibly complex.” Entire books have been devoted to this discussion, and we do not have the space to do justice to this wide-ranging debate. Again, we refer the interested reader to the leading references cited at the end of this chapter (e.g., the papers by K. Miller; and M. J. Pallen and N. J. Matzke).

SUMMARY

A number of macromolecular protein systems exist in cells to convert ATP energy into mechanical work. A major example is the actin–myosin system of muscle. In muscle, interdigitating filaments of actin and myosin are driven past one another by attachment, motion, and detachment of myosin cross-bridges. Muscle contraction is stimulated by the influx of calcium ions, which causes rearrangement of actin-associated proteins. The direct source of contractile energy is ATP, with creatine phosphate being a short-term energy store.

There also exist many other nonmuscle systems for producing motion and doing work. Many kinds of cell motion, including amoeboid crawling and cytokinesis, use nonmuscle actin and myosin. On the other hand, flagella and cilia are driven by the ATP-driven sliding of microtubules, filaments formed by the polymerization of tubulin. Microtubules do many other things, including acting as “roadways” for transport of organelles and proteins within cells and accomplishing the separation of chromosomes in mitosis.

A remarkable molecular motor drives the rotation of bacterial flagella. This motor, by reversing its direction, can cause the bacterium either to move in a straight line toward nutrients and away from toxic substances, or to tumble randomly and change direction.

PROBLEMS

- A typical relaxed sarcomere is about $2.3 \mu\text{m}$ in length and contracts to about $2 \mu\text{m}$ in length. Within the sarcomere, the thin filaments are about $1 \mu\text{m}$ long and the thick filaments are about $1.5 \mu\text{m}$ long.
 - Describe the overlap of thick and thin filaments in the relaxed and contracted sarcomere.
 - An individual “step” by a myosin head in one cycle pulls the thin filament about 15 nm. How many steps must each actin fiber make in one contraction?
- Each gram of mammalian skeletal muscle consumes ATP at a rate of about 1×10^{-3} mol/min during contraction. Concentrations of ATP and creatine phosphate in muscle are about 4 mM and 25 mM, respectively, and the density of muscle tissue can be taken to be about 1.2 g/cm^3 .
 - How long could contraction continue using ATP alone?
 - If all creatine phosphate were converted into ATP and utilized as well, how long could contraction continue?
 - What do these answers tell you?
- The drug cytochalasin is known to bind to the ends of actin fibers. It does not affect striated muscle contraction, but it completely inhibits motility and changes in cell shape in eukaryotic cells. What do these findings suggest?
- *4. Tubulin binds GTP, and the polymerization of a microtubule is greatly stimulated when a tubulin molecule at the growing end carries GTP. Tubulin also has a GTPase activity, with a low-turnover number.

Microtubules carrying GDP at their ends are more likely to lose tubulin monomers. Show how these facts can explain the remarkable observation that at certain GTP levels some microtubules in a mixture will grow while others simultaneously shrink.
- A few hours after the death of an animal the corpse will stiffen as a result of continued contraction of muscle tissue (this state is called *rigor mortis*). This phenomenon is the result of the loss of ATP production in muscle tissue.
 - Consult Figure 8.11 (page 292) and describe, in terms of the six-step model of muscle contraction, how a lack of ATP in sarcomeres would result in *rigor mortis*.
 - The Ca^{2+} transporter in sarcomeres that keeps the $[\text{Ca}^{2+}] \sim 10^{-7} \text{ M}$ requires ATP to drive transport of Ca^{2+} ions across the membrane of the sarcoplasmic reticulum. How would a loss of this Ca^{2+} transport function result in the initiation of *rigor mortis*?
 - Rigor mortis* is maximal at ~ 12 hrs after death, and by 72 hrs is no longer observed. Propose an explanation for the disappearance of *rigor mortis* after 12 hrs.
- *6. The distance actin and myosin filaments can slide past one another as a consequence of hydrolysis of one ATP molecule is variable. At high loads, the result appears to be consistent with the stroke length (about 10 nm), but at low loads much greater distances have been claimed by some researchers. Discuss this problem in terms of the model proposed in Figure 8.11.

CHAPTER 9

Carbohydrates: Sugars, Saccharides, Glycans

We turn now to the third major class of biological molecules, the **carbohydrates**, or **saccharides**. Like the nucleic acids and proteins, carbohydrates play biological roles both as their constituent monomeric units, such as glucose or ribose, and as polymers, such as starch or glycogen. Unlike proteins and nucleic acids, which are strictly linear polymers, macromolecular polysaccharides also exist as branched polymers. For much of this book we concern ourselves with roles of carbohydrates in generating and storing biological energy. However, carbohydrates play numerous additional functions—as diverse as molecular recognition (as in the immune system), cellular protection (as in bacterial and plant cell walls), cell signaling, cell adhesion, as biological lubricants, in controlling protein trafficking, and in maintaining biological structure (e.g., cellulose).

Many of these substances are already familiar to you. The simplest carbohydrates are small, monomeric molecules—the **monosaccharides**, typically containing from three to nine carbon atoms, which include simple sugars such as *glucose* (Figure 9.1a). Other important carbohydrates are formed by linking such monosaccharides together. If only a few monomer units are involved, we call the molecule an **oligosaccharide**. An example is *maltose* (Figure 9.1b), a **disaccharide** made by linking two glucose molecules together. Long polymers of the monosaccharides, like the starch *amylose* (Figure 9.1c), are called **polysaccharides**. Many kinds of polysaccharides exist, some of which are complex polymers made from many types of sugar monomers. Oligosaccharides and polysaccharides are also referred to as **glycans**.

Saccharides are often called by the more familiar name *carbohydrates* because many of them can be represented by the simple stoichiometric formula $(\text{CH}_2\text{O})_n$. The name was first given when chemists knew only the stoichiometry of saccharides and thought of them as “hydrated carbon.” The formula is an oversimplification, however, because many saccharides are modified, and some contain amino, sulfate, and phosphate groups. Nevertheless, all of the compounds described in this chapter either have this formula or can be derived from substances that do.

Carbohydrates are compounds with the empirical formula $(\text{CH}_2\text{O})_n$, while saccharides include carbohydrates and all of their derivatives.

**FIGURE 9.1**

Representative carbohydrates. The three compounds shown here are composed entirely of C, H, and O, with glucose forming the monomer for the oligomer and the polymer. **(a)** Glucose, a monosaccharide. **(b)** Maltose, a disaccharide containing two glucose units. **(c)** A portion of a molecule of amylose, a glucose polymer found in starch.

Carbohydrate formation in photosynthesis and its oxidation in metabolism together constitute the major energy cycle of life.

**FIGURE 9.2**

The energy cycle of life. In photosynthesis, plants use the energy of sunlight to combine carbon dioxide and water into carbohydrates, releasing oxygen in the process. In respiration, both plants and animals oxidize the carbohydrates made by plants, releasing energy and re-forming CO_2 and H_2O .

Strictly speaking, the term carbohydrate is reserved for compounds with the $(\text{CH}_2\text{O})_n$ empirical formula, while the term saccharide covers both these compounds and all derivatives of carbohydrates. We will occasionally stray from strict usage and use the terms carbohydrate and saccharide interchangeably. The term *sugar* generally refers to underivatized monosaccharides and small oligosaccharides, such as *sucrose*, a disaccharide containing glucose and fructose. As noted earlier, an oligosaccharide or polysaccharide is also called a glycan.

As mentioned above, the saccharides play diverse roles in organisms. Indeed, the major energy cycle of the biosphere depends largely on carbohydrate metabolism. Before we turn to carbohydrate structure, let us look briefly at this cycle, as schematized in Figure 9.2. In *photosynthesis*, plants take up CO_2 from the atmosphere and “fix” it into carbohydrates. The basic reaction can be described in a simplified way as the light-driven reduction of CO_2 to carbohydrate, here represented as glucose. Much of this carbohydrate is stored in the plants as polymeric starch or cellulose. Animals obtain their carbohydrates by eating plants or plant-eating animals. Thus, plant-synthesized carbohydrates ultimately become the principal sources of carbon in all animal tissues. In the other half of the cycle, both plants and animals carry out, via oxidative metabolism, a reaction that is essentially the reverse of photosynthesis, to yield once again CO_2 and H_2O (Figure 9.2). This oxidation of carbohydrates is the primary energy-generating process in metabolism. The central role of carbohydrates is obvious when we consider that the staple nutrient of most humans is the starch in such plant foods as rice, wheat, or potatoes. Even the meat consumed by many of us ultimately can be traced in large part to the carbohydrates eaten by grazing animals.

As critical as energy storage and generation are, they are not the only functions of carbohydrates. As mentioned above, many biological structural materials are polysaccharide in whole or in part. Important examples are the cellulose of plant fibers, the cell walls of bacteria, and the exoskeletons of insects and other arthropods. Additionally, polysaccharides on cell surfaces or attached to proteins aid in molecular recognition. Examples include highly specific processes such as the binding of viruses or antibodies on particular cells. Thus, like proteins, carbohydrates are extremely versatile molecules, essential to all organisms.

Monosaccharides

We begin our discussion of carbohydrates with the simple, monomeric sugars—the monosaccharides. The simplest compound with the empirical formula of the class $(\text{CH}_2\text{O})_n$ is found when $n = 1$. However, *formaldehyde*, $\text{H}_2\text{C}=\text{O}$, has little in common with our usual concept of sugars; indeed, it is a noxious, poisonous gas. The smallest molecules usually regarded as monosaccharides are the **trioses**, with $n = 3$. (The suffix *ose* is commonly used to designate compounds as saccharides.) Monosaccharides are generally characterized by the presence of one carbonyl group (aldehyde or ketone) and one or more hydroxyl groups.

Aldoses and Ketoses

There are two trioses: *glyceraldehyde* and *dihydroxyacetone* (Figure 9.3). These molecules, as simple as they are, exhibit certain features that we shall encounter again and again in discussing sugars. In fact, they represent the two major classes of monosaccharides. Glyceraldehyde is an aldehyde, one of a class of monosaccharides called **aldoses**. Dihydroxyacetone is a ketone; such monosaccharides are called **ketoses**. Note that glyceraldehyde and dihydroxyacetone each have one carbonyl carbon and both have the same atomic composition. They are *tautomers* (structural isomers differing in location of hydrogen atoms and double bonds) and can interconvert via an unstable *enediol* intermediate, as shown also in Figure 9.3. Such tautomeric interconversions occur to a certain extent between all such pairs of aldose and ketose monosaccharides, but the reactions are usually very slow unless catalyzed. Thus, glyceraldehyde and dihydroxyacetone can each exist as a stable compound.

The two major classes of monosaccharides are aldoses and ketoses.

Enantiomers

An important feature of monosaccharide structure can be seen by examining the formula for glyceraldehyde a bit more carefully. The second carbon atom carries four different substituents, so it is *chiral*, like the α -carbon in most α -amino acids. Therefore, glyceraldehyde has two stereoisomers of the type called **enantiomers**, which are nonsuperimposable mirror images of one another. Three-dimensional drawings of the two forms, designated as D- and L-glyceraldehyde, are shown in

FIGURE 9.3

Trioses, the simplest monosaccharides. The two triose tautomers illustrate the difference between aldose and ketose monosaccharides, also called more descriptively aldotriose and ketotriose, respectively. Carbon numbering begins in all aldoses with the aldehyde carbon and in ketoses with the end carbon closest to the ketone group. (Because dihydroxyacetone has only three carbons, the two end carbons are equivalent and either of them could be designated number one.) The enediol intermediate through which they are interconverted is unstable and cannot be isolated.

FIGURE 9.4

The enantiomers of glyceraldehyde. The configuration of groups around the chiral carbon 2 (shown in darker gray) distinguishes *D*-glyceraldehyde from *L*-glyceraldehyde. The two molecules are mirror images and cannot be superimposed on one another.

D and *L* forms of a monosaccharide are nonsuperimposable mirror images and are called enantiomers.

FIGURE 9.5

***R*-*S* nomenclature.** The *R*-*S* system describes absolute stereochemical configuration, as shown in this example. Each type of group attached to a chiral carbon (gray) is given a priority, according to a set of defined rules. Priorities for groups common in carbohydrate chemistry are $\text{SH} > \text{OR} > \text{OH} > \text{NH}_2 > \text{CO}_2\text{H} > \text{CHO} > \text{CH}_2\text{OH} > \text{CH}_3 > \text{H}$. We view the molecule with the group of lowest priority away from us (H in our example). If the priority of the remaining three groups decreases clockwise, the absolute configuration is called *R* (from Latin *rectus*, "right"). If priority decreases counterclockwise, the configuration is *S* (from Latin *sinister*, "left"). In this notation, *D*-glyceraldehyde is *R*-glyceraldehyde, and *L*-glyceraldehyde is *S*-glyceraldehyde.

Figure 9.4. Such three-dimensional orientation about the asymmetric carbon can also be represented by the bond convention we used in Chapter 5:

Note that we do not need to draw the spatial orientation of atoms about carbons 1 or 3 because these carbons are not chiral centers.

The most compact way to represent enantiomers is to use a **Fischer projection**. In a Fischer projection the bonds that are drawn horizontally are imagined as coming toward you; those drawn vertically are receding (see also Figure 5.3, page 139). Thus, for *D*-glyceraldehyde and *L*-glyceraldehyde, we have

Alternative Designations for Enantiomers: *D*-*L* and *R*-*S*

Originally, the terms *D* and *L* were meant to indicate the direction of rotation of the plane of polarization of polarized light: *D* for right (dextro), *L* for left (levo). It is true that a solution of *D*-glyceraldehyde does rotate the plane of polarization to the right, as do many other *D*-monosaccharides, but this correspondence does not always hold because the magnitude and even the direction of optical rotation are a complicated function of the electronic structure surrounding the chiral center. Another disadvantage of the *D*-*L* nomenclature is that it is not absolute; the designation is always with respect to some reference compound. Accordingly, a systematic convention has been developed that allows us to assign a stereochemical designation to any compound from examination of its three-dimensional structure. This *R*-*S* convention, shown in Figure 9.5, is also called the Cahn-Ingold-Prelog convention, after its inventors. Although the *R*-*S* convention is more general and it gives the absolute configuration about a chiral center, the *D*-*L* convention is often preferred by biochemists and will be used in this chapter.

Monosaccharide Enantiomers in Nature

Just as in the case of amino acids, one enantiomeric form of monosaccharides dominates in living organisms. In proteins it is the *L*-amino acids; in carbohydrates it is the *D*-monosaccharides. Again, there is no obvious reason why this preference was established in nature. But once fixed in early evolution, it has persisted, for most of the cellular machinery has become geared to operate with *D*-sugars. However, just as *D*-amino acids are sometimes found in living organisms, so are *L*-monosaccharides. Like the "abnormal" *D*-amino acids, the *L*-monosaccharides play rather specialized roles. Table 9.1 includes, along with *D*-monosaccharides, the most commonly occurring *L*-monosaccharides, with examples of their occurrence and functions.

Diastereomers

When we consider monosaccharides with more than three carbons, a further structural complication appears. Such a monosaccharide may have more than one

TABLE 9.1 Examples of occurrence and biochemical roles of monosaccharides

Monosaccharides	Natural Occurrence	Physiological Role ^a
Trioses		
Glyceraldehyde	Widespread (as phosphate)	The 3-phosphate is an intermediate in glycolysis
Dihydroxyacetone	Widespread (as phosphate)	The 1-phosphate is an intermediate in glycolysis
Tetroses		
D-Erythrose	Widespread	The 4-phosphate is an intermediate in carbohydrate metabolism
Pentoses		
D-Arabinose	Some plants, tuberculosis bacilli	Plant glycosides, cell walls
L-Arabinose	Widely distributed in plants, bacterial cell walls	Constituent of cell walls, plant glycoproteins
D-Ribose	Widespread, in all organisms	Constituent of RNA and ribonucleotides
D-Xylose	Woody materials	Constituent of plant polysaccharides
Hexoses		
D-Galactose	Widespread	Milk (as part of lactose); structural polysaccharides
L-Galactose	Agar, other polysaccharides; component of lactose	Polysaccharide structures
D-Glucose	Widespread	Major energy source for animal metabolism; structural role in cellulose
D-Mannose	Plant polysaccharides, animal glycoproteins	Polysaccharide structures
D-Fructose	A major plant sugar; part of sucrose	Intermediate in glycolysis (phosphate esters)
Heptoses		
D-Sedoheptulose	Many plants	Intermediate in Calvin cycle in photosynthesis and pentose phosphate pathway

^aSome of these monosaccharides have additional roles that are not listed.

chiral carbon, which results in its having two types of stereoisomers. These types are *enantiomers* (mirror image isomers), which we have already discussed, and *diastereomers*, which we first encounter in the tetrose monosaccharides.

The most important naturally occurring saccharides are the D-enantiomers.

Tetrose Diastereomers

Tetroses, with the empirical formula $(\text{CH}_2\text{O})_4$, have two chiral carbons in the aldose forms. Therefore, an aldotetrose will have four stereoisomers, as shown in Figure 9.6. In general, a molecule with n chiral centers will have 2^n stereoisomers because there are two possibilities at each chiral center. The following convention attempts to give a rational method for naming and distinguishing the

FIGURE 9.6

Stereochemistry of aldotetroses.

These molecules have two chiral carbons (2 and 3) and thus have two diastereomeric forms, threose and erythrose, each with a pair of enantiomers. Note that the threose enantiomers have *opposite* configuration about carbons C2 and C3, whereas erythrose enantiomers have the *same* configuration about these two carbons.

FIGURE 9.7

The two enantiomers of erythrulose. When converting from an aldose to a ketose, the number of chiral carbons decreases by one. Hence, unlike the four-carbon aldoses (see Figure 9.6), the four-carbon ketose has only one chiral carbon (C3) and only one pair of enantiomers.

When monosaccharides contain more than one chiral carbon, the prefix *D* or *L* designates the configuration about the carbon farthest from the carbonyl group. Isomers differing in orientation about other carbons are called diastereomers and given different names.

stereoisomers of such a molecule: The prefix *D* or *L* is used to designate the orientation about the chiral carbon *farthest* from the carbonyl group—carbon number 3 in this case. Molecules with different orientations about the carbons preceding this reference carbon are given separate names. Thus, *threose* and *erythrose* are two aldotetroses with opposite orientations about carbon 2. Stereoisomers of this kind, which are *not* mirror images, are called **diastereomers**. Threose and erythrose are diastereomers, and each has two enantiomers (*D* and *L*) that are non-superimposable mirror images. Unfortunately, there is no general logical rule for forming the specific names (such as threose and erythrose); they must simply be learned, like the names of the amino acids.

The four-carbon ketose, which is called *erythrulose*, has only one pair of enantiomers because this monosaccharide has only one chiral carbon (Figure 9.7). Another naming convention appears at this point: Often the ketose name is derived from the corresponding aldose name by insertion of the letters *ul*. Thus *erythrose* becomes *erythrulose*. As with glyceraldehyde (and other monosaccharides), the ketose and aldose forms are interconvertible via tautomerization in dilute alkali. The aldose–ketose conversion also provides a route for interconversion of aldose diastereomers, using the ketose as an intermediate.

Pentose Diastereomers

Adding one more carbon, we obtain the **pentoses**. The **aldopentoses** have three chiral centers; therefore we expect 2^3 , or eight, stereoisomers—in four pairs of enantiomers. The *D* forms of the pentoses are shown in Figure 9.8a, which provides a summary of the aldoses containing from three to six carbons. Note that each of the aldopentoses shown has the *D* orientation about carbon 4 and that all possible combinations of orientations about carbons 2 and 3 are included. (From here on, in our illustration of carbohydrate structure we will show only the *D* forms; you can easily draw the *L* forms from the rules given above.)

Ketopentoses, as shown in Figure 9.8b, have two chiral carbons, so four isomers (two pairs of enantiomers) must exist. The *D* diastereomers are called *D-ribulose* and *D-xylulose*.

Hexose Diastereomers

Monosaccharides containing six carbon atoms are called **hexoses**. As you might imagine, there is a large number of possible hexoses. To keep their structures in mind, it is useful to relate them to the simpler pentoses, tetroses, and trioses. Figure 9.8 provides a compact summary of these relationships. The hexoses we will most frequently encounter are *glucose* and *fructose*. However, *mannose* and *galactose* are also widespread in nature (see Table 9.1). In fact, almost all of the *D*-hexoses play some significant biological role.

Aldose Ring Structures

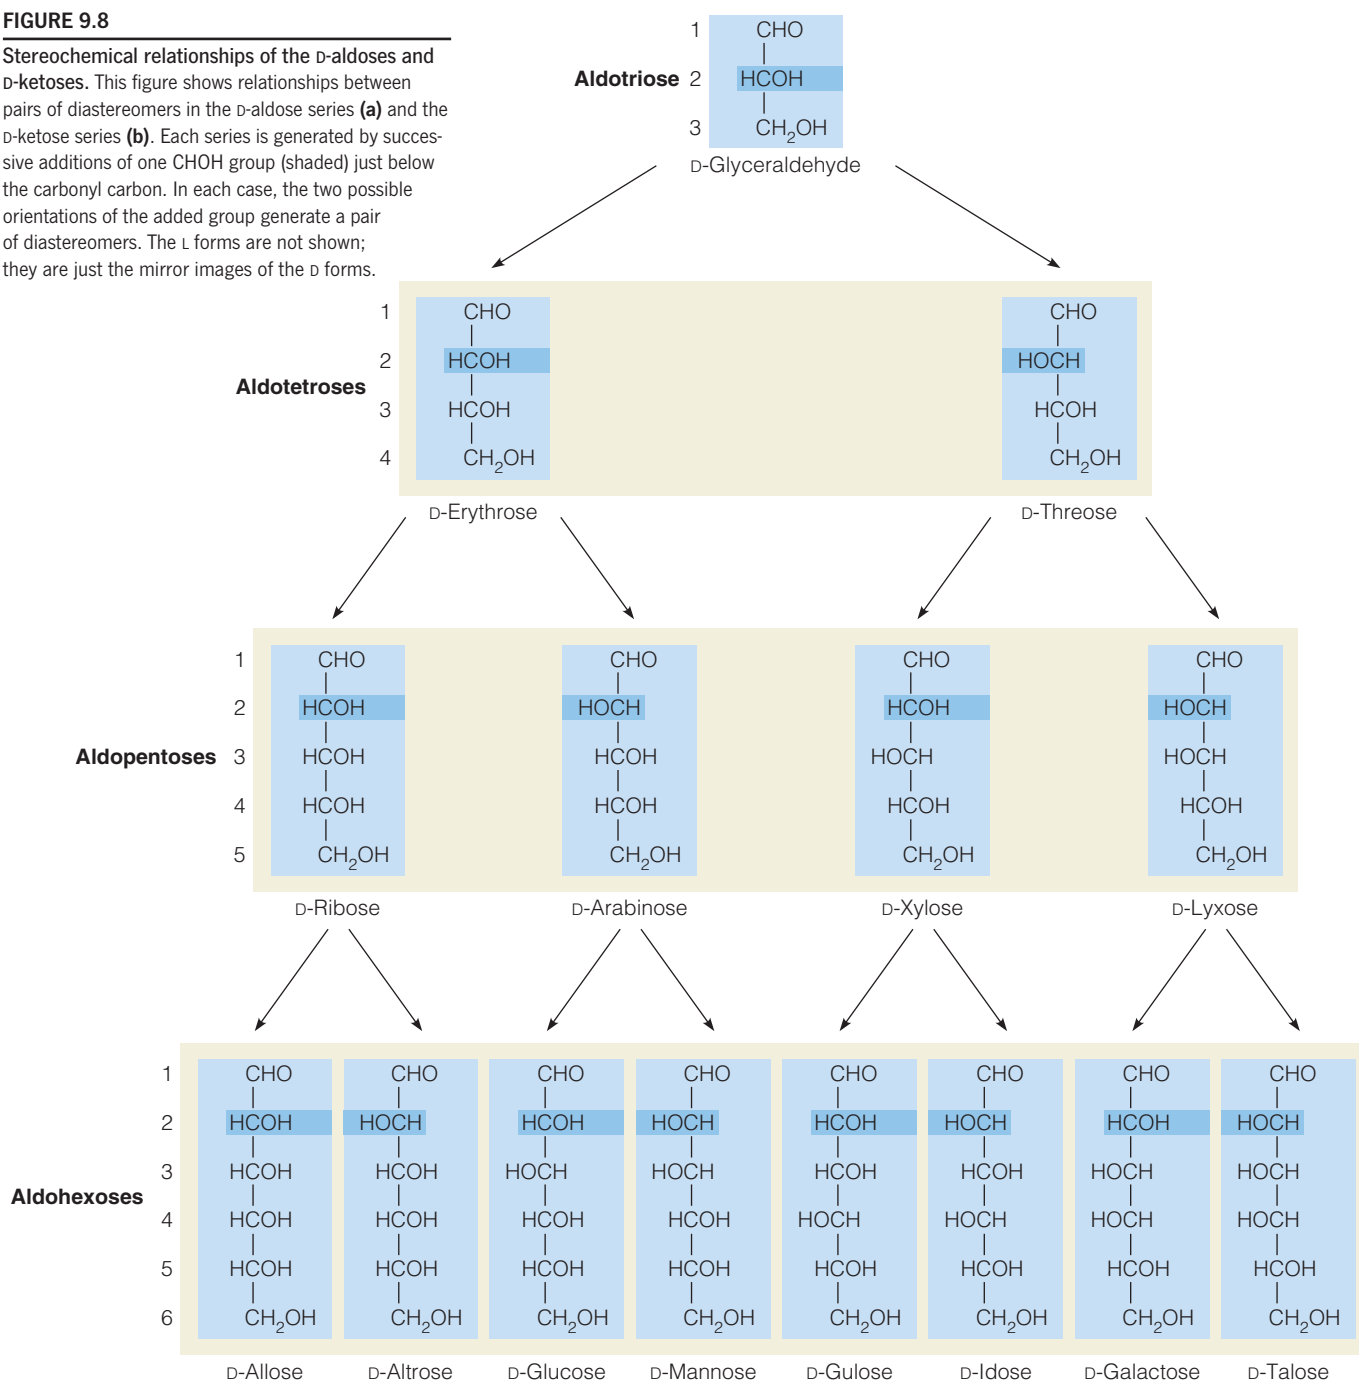

With the pentoses and hexoses, another feature of monosaccharide chemistry assumes critical importance. Having five or six carbons in the chain gives these compounds the potential to form very stable ring structures via internal *hemiacetal* formation. A hemiacetal results from reaction of an aldehyde with an alcohol. Hemiketals form similarly, from a ketone and an alcohol.

The bond angles characteristic of carbon and oxygen bonding are such that rings containing fewer than five atoms are strained to a considerable extent, whereas five- or six-membered rings are easily formed. In principle, aldotetroses can also form five-membered ring structures, but they rarely do.

FIGURE 9.8

Stereochemical relationships of the D-aldoses and D-ketoses. This figure shows relationships between pairs of diastereomers in the D-aldose series (a) and the D-ketose series (b). Each series is generated by successive additions of one CHOH group (shaded) just below the carbonyl carbon. In each case, the two possible orientations of the added group generate a pair of diastereomers. The L forms are not shown; they are just the mirror images of the D forms.

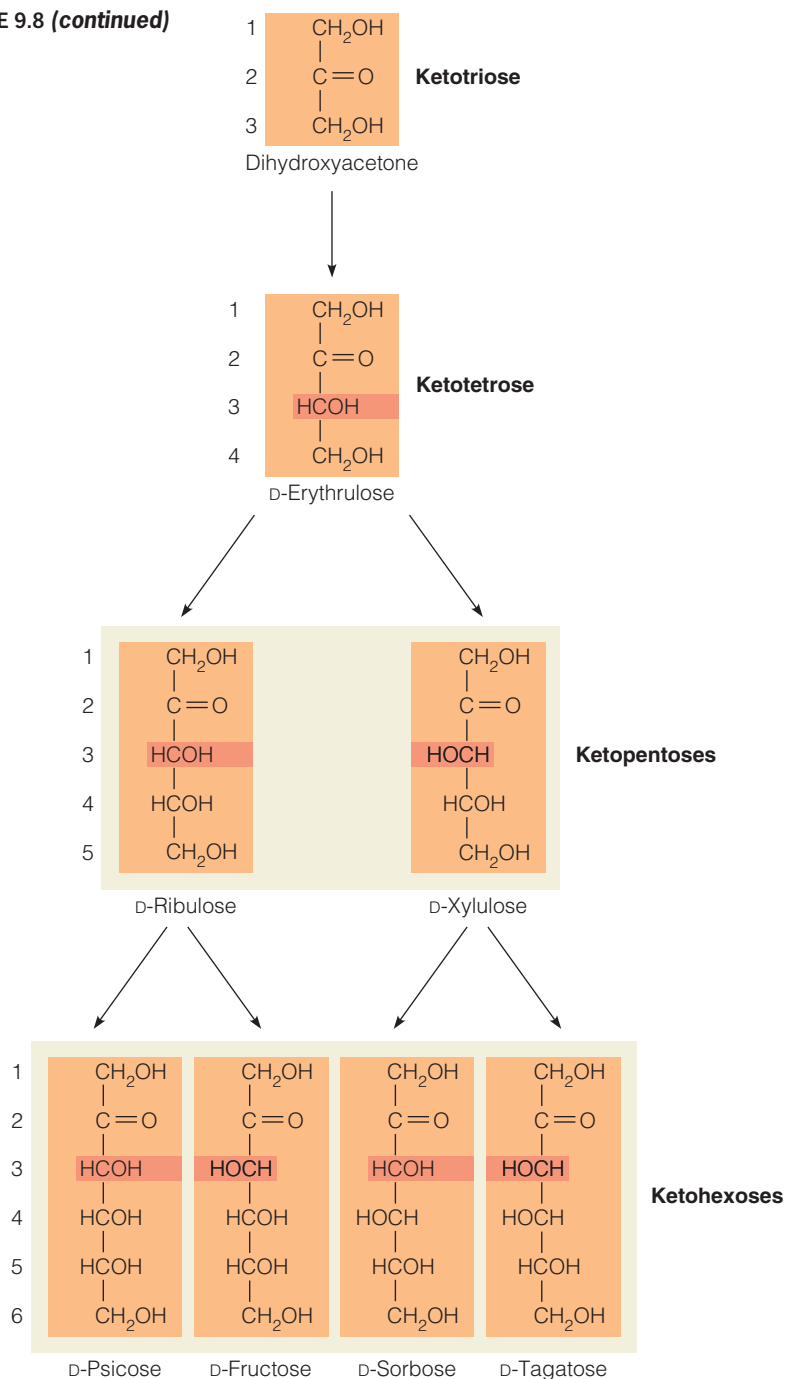

(a) D-Aldoses

Pentose Rings

Consider this hemiacetal ring formation in an aldopentose, such as D-ribose (see Figure 9.8a). Two modes of ring closure are possible, as shown in Figure 9.9. Reaction of the C-1 of D-ribose with the C-4 hydroxyl produces a five-membered ring structure called a **furanose**; the name reflects its structural similarity to the heterocyclic compound furan. Alternatively, a six-membered ring is obtained if the reaction occurs with the C-5 hydroxyl. Such a six-membered ring is called a **pyranose**, to indicate its relation to the heterocyclic compound pyran.

Monosaccharides with five or more carbons exist preferentially in five- or six-membered ring structures, resulting from internal hemiacetal formation.

FIGURE 9.8 (continued)

**(b)** D-Ketoses

Both of the reactions shown in Figure 9.9 have equilibria that highly favor the cyclic structures for pentoses or larger sugars. Under physiological conditions in solution, monosaccharides with five or more carbons exist typically more than 99% in the ring forms. The distribution between pyranose and furanose forms depends on the particular sugar structure, the pH, the solvent composition, and the temperature. Representative data obtained from nuclear magnetic resonance studies are shown in Table 9.2. When the monomers are incorporated into polysaccharides, the structure of the polymer may also influence the ring form chosen. For example, as Table 9.2 shows, D-ribose exists in solution as a mixture of the two ring forms. But in

FIGURE 9.9

Formation of ring structures by pentoses. The example shown here is D-ribose, which can form either a five-membered furanose ring or a six-membered pyranose ring. The reactions involve formation of hemiacetals from the aldehyde group. In each case, two anomeric forms, α and β , are possible. (Anomers differ in conformation only at the carbonyl carbon, which in this case is carbon 1.) The sugar rings are depicted here as *Haworth projections*, with bonds closer to the viewer drawn more darkly to suggest perspective.

biological compounds, specific forms are stabilized. RNA, for example, contains ribose exclusively as ribofuranose, whereas some plant cell wall polysaccharides have pentoses entirely in the pyranose form.

Let us look more closely at the ring structures shown in Figure 9.9. Cyclization has created a new asymmetric center at carbon 1. That is why we have had to draw two stereoisomers of D-ribofuranose, referred to as α -D-ribofuranose and β -D-ribofuranose, as well as a corresponding pair of ribopyranoses. Like other kinds of stereoisomers, these α and β forms rotate the plane of polarized light differently and can be distinguished in that way. Such isomers, differing in configuration only at the carbonyl carbon (C1 in this case), are called **anomers**, and carbon 1 is often referred to as the *anomeric carbon atom*. The monosaccharides can undergo interconversion between the α and β forms, using the open-chain structure as an intermediate. This process is referred to as **mutarotation**. A purified anomer, dissolved in aqueous solution, will approach the equilibrium mixture, with an accompanying change in the optical rotation of the solution. Enzymes called **mutarotases** catalyze this process in vivo.

TABLE 9.2 Relative amounts of tautomeric forms for some monosaccharide sugars at equilibrium in water at 40 °C

Monosaccharide	Relative Amount (%)				Total Furanose
	α -Pyranose	β -Pyranose	α -Furanose	β -Furanose	
Ribose	20	56	6	18	24
Lyxose	71	29	— ^a	— ^a	<1
Altrose	27	40	20	13	33
Glucose	36	64	— ^a	— ^a	<1
Mannose	67	33	— ^a	— ^a	<1
Fructose	3	57	9	31	40

Note: In all cases, the open-chain form is much less than 1%. For data on other sugars, see S. J. Angyal, The composition and conformation of sugars in solution, *Angew. Chem.* (1969) 8:157–226.

^aMuch less than 1%.

(a) β -D-Ribofuranose, C-2 endo(b) β -D-Ribofuranose, C-3 endo**FIGURE 9.10**

Conformational isomers. These models show two of the possible ring conformations for β -D-ribofuranose. In both of them, C-1, O, and C-4 define a plane. In the C-2 endo conformation (a), C-2 is above the plane. In the C-3 endo conformation (b), C-3 is above the plane. These isomers are the two most common conformations for ribose and deoxyribose in nucleic acids. (In DNA the hydroxyl at carbon 2, indicated here by *, is replaced by hydrogen.) A C-3 exo conformation would look like the figure in (b), but C-3 would be flipped below the plane.

The representation of a cyclic sugar structure we have used in Figure 9.9 is called a **Haworth projection**. Imagine that you are seeing the ring in perspective, and the groups attached to the ring carbons (H, OH, CH₂OH) are pictured as being above or below the ring. In all D-monosaccharides, the —CH₂OH is above the ring. The relationship between hydroxyl orientations in a Fischer and a Haworth projection is straightforward. Those represented to the right of the chain in a Fischer projection are shown below the ring in a Haworth. For example, Fischer projections of α -D-ribofuranose and β -D-ribofuranose would look like this:

Even Haworth projections do not accurately depict the three-dimensional structure of molecules like ribofuranose or ribopyranose. Saturated five- and six-membered rings cannot be planar because the C—C—C bond angles are about 109° and the C—O—C angle is about 118°. Furthermore, the ring can pucker out of plane in many different ways. The different ring conformations produced by slightly different bond angles are called **conformational isomers**. Ball-and-stick models of two of the several possible conformational isomers of β -D-ribofuranose are shown in Figure 9.10.

We have already encountered β -D-ribofuranose (and its close relative β -D-2-deoxyribofuranose) in Chapter 4. These sugars play critical roles in biochemistry, for they are part of the backbone structures of RNA and DNA, respectively. Only the β anomers are involved in nucleic acid structure, and the C-2 endo and C-3 endo conformations shown in Figure 9.10 are favored. However, there is some variation in ring conformation, even locally, along DNA and RNA chains, with resulting changes in secondary structure. This flexibility points up a fundamental difference between *conformation* and *configuration*. Conformational isomers can interchange by a simple deformation of the molecule. But *configurational* isomers, such as the various kinds of stereoisomers described earlier, can interconvert only through the breaking and re-formation of covalent bonds.

Like the aldopentoses, the ketopentoses exist almost entirely in the ring form under physiological conditions. However, only the furanose form is possible for ketopentoses. An example is α -D-ribulose, which is an intermediate in the carbon fixation processes in photosynthesis.

Hexose Rings

The hexoses also exist primarily in ring forms under physiological conditions. As with the aldopentoses, two kinds of rings are found: five-membered furanoses and six-membered pyranoses. In each case, α and β anomers are possible. An example, illustrated by Haworth projections, follows:

FIGURE 9.11
The four most common hexoses. These Haworth projections represent the D enantiomers; only the β anomers are shown.

Figure 9.11 shows Haworth projections of the structures of the four most common hexoses in their usual configurations. Table 9.2 gives the fractions of the furanose and pyranose forms found at equilibrium for several hexoses. Clearly, which forms are favored depends greatly on the structure of the particular sugar and its environment, although we can make the generalization that hexoses prefer the pyranose ring structure when in aqueous solution. This preference is also true of fructose, but we have depicted D-fructose in Figure 9.11 in its furanose configuration because that is how it is found in its most common biological source, the disaccharide sucrose. Elucidation of the distribution of anomeric and tautomeric forms of the sugars existing in solutions has been greatly facilitated by nuclear magnetic resonance spectroscopy (see Tools of Biochemistry 6A), which allows determination of molecular conformation in solution.

There is something else to note from Figure 9.11. Glucose and mannose differ from each other only in the configuration about C2. Sugars of this type, differing in configuration about only one carbon, are called **epimers**. Similarly, glucose and galactose are epimers, for they differ in configuration only about C4.

We have already shown that Haworth projections of the furanoses do not depict the actual three-dimensional structure correctly. The same is true for the pyranoses. Two major classes of pyranose conformations exist for the 6-carbon sugars—the more stable “chair” form and the less favored “boat” form. These two conformations are depicted as ball-and-stick models in Figure 9.12a. We will frequently depict them by skeletal diagrams in the ways shown in Figure 9.12b. For

Hexoses can exist in boat and chair conformations. Usually the chair is more stable.

FIGURE 9.12
The pyranose ring in chair and boat conformations. Three-dimensional representations of α -D-glucopyranose in the chair form (left) and the boat form (right). (a) Ball-and-stick models. (b) Skeletal diagrams of the bonding. Axial bonds (a) and equatorial bonds (e) are indicated.

 α -D-Sedoheptulopyranose

both the boat and chair forms of pyranose rings, a molecular axis can be defined perpendicular to the central plane of the molecule. Bonds to substituents on ring carbons can then be classed as *axial* (a) or *equatorial* (e), depending on whether they are approximately parallel or perpendicular to the axis (Figure 9.12b). For most sugars, the chair form is more stable because substituents on axial bonds tend to be more crowded in the boat form.

Sugars with More than Six Carbons

Monosaccharides with seven or even more carbons exist in nature, but most are of minor importance. However, one heptose, called *sedoheptulose*, plays a major role in the fixation of CO_2 in photosynthesis (see Table 9.1 and Chapter 16) and also in the pentose phosphate pathway (see Chapter 13).

At this point we have introduced several terms used to describe the structures of sugar molecules—enantiomers, diastereomers, anomers, epimers, and ring conformations. For review, this terminology is summarized in Figure 9.13.

FIGURE 9.13

Terminology describing the structure of sugar molecules. Conformational isomers are distinguished from configurational isomers in that the former can interconvert without breaking and re-forming bonds. Not shown are epimers, stereoisomers differing in their configuration about only one asymmetric carbon atom.

Configurational isomers

Enantiomers

Stereoisomers that are mirror images of one another

The boxed asymmetric carbon (farthest from aldehyde) determines D/L designation

D-Threose

L-Threose

Diastereomers

Stereoisomers that are not mirror images of one another

Anomers

Stereoisomers that differ in configuration at the anomeric carbon

 α -D-Glucopyranose β -D-Glucopyranose

Conformational isomers

Molecules with the same stereochemical configuration, but differing in three-dimensional conformation

 β -D-Glucopyranose chair form β -D-Glucopyranose boat form

Derivatives of the Monosaccharides

The monosaccharides each carry a number of hydroxyl groups to which substituents might be attached or which could be replaced by other functional groups. An enormous number of sugars are in fact modified in this way. We shall describe here only a few of them—primarily those that play biologically important roles.

Phosphate Esters

We have already encountered sugar phosphorylation, in compounds like AMP, ATP, and the nucleic acids. As we see in later chapters, the phosphate esters of the monosaccharides themselves are major participants in many metabolic pathways. Table 9.3 illustrates some of the more important phosphate esters and includes

Sugar phosphates are important intermediates in metabolism, functioning as activated compounds in syntheses.

TABLE 9.3 Some biochemically important phosphate esters of monosaccharides

Name	Structure	$\Delta G^{\circ'a}$ (kJ/mol)	pK_{a1}	pK_{a2}
D-Glyceraldehyde-3-phosphate		~-12	2.10	6.75
β -D-Glucose-1-phosphate		-20.9	1.10	6.13
β -D-Glucose-6-phosphate		-13.8	0.94	6.11
α -D-Fructose-6-phosphate		-13.8	0.97	6.11

^aFree energy of hydrolysis at pH 7.0 and 37 °C.

values for the standard state free energies of hydrolysis. In all cases, these values are less negative than the free energy of hydrolysis of ATP (-31 kJ/mol); thus, ATP can act as a phosphate donor to monosaccharides. On the other hand, because hydrolysis of the phosphate esters of sugars is thermodynamically favorable, these derivatives can behave as “activated” compounds in many metabolic reactions.

Sugar phosphate esters are quite acidic, with pK_a values for the two stages of phosphate ionization of about 1–2 and 6–7, respectively (see Table 9.3).

Consequently, these compounds exist under physiological conditions as a mixture of the monoanions and dianions.

In addition to the sugar phosphates, a large number of other derivatives of monosaccharides play varied and important roles in biochemistry. We consider here a few of them and the reactions by which they may be generated from monosaccharides.

Acids and Lactones

Oxidation of monosaccharides can proceed in several ways, depending upon the oxidizing agent used. For example, mild oxidation of an aldose with alkaline Cu(II) (Fehling’s solution) produces the **aldonic acids**, as in the following example:

The production of a red precipitate of Cu_2O is a classic sugar test and was used formerly to test for excess sugar in the urine of persons thought to have diabetes. Another, similar reaction involves the use of Ag^+ ion as an oxidant; its reduction to metallic silver leaves a characteristic “mirror” on the glassware. These older methods have now been replaced by more specific enzyme assays. Free aldonic acids, such as gluconic acid, are in equilibrium in solution with **lactones**, which are cyclic esters, in this case involving the C1 carboxyl and the C5 hydroxyl.

Enzyme-catalyzed oxidation of monosaccharides gives other products, including **uronic acids** such as **glucuronic acid**, in which oxidation has occurred at carbon 6. Uronic acids are, as we see later in this chapter, important constituents of certain natural polysaccharides.

Alditols

Reduction of the carbonyl group on a sugar gives rise to the class of polyhydroxy compounds called **alditols**. Important naturally occurring ones are *erythritol*, *D-mannitol*, and *D-glucitol*, often called *sorbitol*.

Each is named from the corresponding monosaccharide. When sorbitol accumulates in the lens of the eye of a person with diabetes, it can lead to the formation of cataracts.

Amino Sugars

Two amino derivatives of simple sugars are widely distributed in natural polysaccharides: *glucosamine* and *galactosamine*, derived from glucose and galactose, respectively. Further modifications of these amino sugars are common. For example, the following compounds are derived from β -D-glucosamine:

β -D-N-Acetylglucosamine

Muramic acid

N-Acetylmuramic acid

β -D-Glucosamine

β -D-Galactosamine

These sugar derivatives are important constituents of many natural polysaccharides. Two others we shall encounter are the following:

β -D-N-Acetylgalactosamine

**N-Acetylneuraminic acid
(sialic acid)**

Amino sugars are found in many polysaccharides.

*Erythritol, although it contains chiral carbons, is not optically active because it has a plane of symmetry, between C-2 and C-3.

<i>N</i> -Acetylneuraminic acid (or sialic acid)	NeuNAc (or Sia)

The modified sugars—especially the amino sugars—are most often found as monomer residues in complex oligosaccharides and polysaccharides. To aid in writing the structures of such molecules, it is useful to have a shorthand notation, as is used in describing nucleic acid and protein structure. Therefore, a set of abbreviations has been defined for the simple sugars and their derivatives. A number of the most important ones are listed in Table 9.4.

Glycosides

Elimination of water between the anomeric hydroxyl of a cyclic monosaccharide and the hydroxyl group of another compound yields an **O-glycoside** (the O signifying attachment at a hydroxyl). The acetal bond formed is referred to as a **glycosidic bond**. A simple example is the formation of methyl- α -D-glucopyranoside:

Unlike the anomers of the sugars themselves, the anomeric glycosides (e.g., methyl- α -D-glucopyranoside in the example shown, and methyl- β -D-glucopyranoside) do not interconvert by mutarotation in the absence of an acid catalyst, a property that makes them useful in the determination of sugar configurations.

Many glycosides are found in plant and animal tissues. Some are toxic substances, in most cases because they act as inhibitors of enzymes involved in ATP utilization. Two toxic glycosides, ouabain and amygdalin, are shown in Figure 9.14. *Ouabain* inhibits the action of the enzymes that pump Na⁺ and K⁺ ions across cell membranes to maintain necessary electrolyte balance. It comes from an African shrub and was discovered when it was observed that Somali hunters dipped arrowheads in an extract from the plant. Ouabain now finds use in treatment of some cardiac conditions (see page 393). *Amygdalin* is toxic for a quite different reason. Found in the seeds of bitter almonds, this glycoside yields hydrogen cyanide (HCN) upon hydrolysis. It is for this reason that HCN gas is said to have the odor of bitter almonds.

O-glycosides are formed by elimination of a water molecule between a hydroxyl group on a saccharide and a hydroxyl on another compound.

Oligosaccharides

Just as monosaccharides can form glycosidic bonds with other kinds of hydroxyl-containing compounds, they can do so with one another. Such bonding gives rise to glycans—the oligosaccharides and polysaccharides.

FIGURE 9.14

Two naturally occurring glycosides. Ouabain and amygdalin are highly toxic glycosides produced by plants.

Oligosaccharide Structures

The simplest and biologically most important oligosaccharides are the *disaccharides*, made up of two residues. As Table 9.5 shows, the disaccharides play many biological roles. Some, like *sucrose*, *lactose*, and *trehalose*, are soluble energy stores in plants and animals. Others, like *maltose* and *cellobiose*, can be regarded primarily as intermediate products in the degradation of much longer polysaccharides. Still others, like *gentiobiose*, are found principally as constituents of more complex, naturally occurring substances. The structures of these disaccharides are depicted in Figure 9.15.

Distinguishing Features of Different Disaccharides

Four major features distinguish disaccharides from one another:

1. *The two specific sugar monomers involved, and their stereoconfigurations.* The monomers may be of the same kind, as the two D-glucopyranose residues in maltose, or they may be different, as the D-glucopyranose and D-fructofuranose residues in sucrose.
2. *The carbons involved in the linkage.* Although many possibilities exist, the most common linkages are 1 → 1 (as in trehalose), 1 → 2 (as in sucrose), 1 → 4 (as in lactose, maltose, and cellobiose), and 1 → 6 (as in gentiobiose). Note that all of these disaccharides involve the anomeric hydroxyl of at least one sugar as a participant in the bond.
3. *The order of the two monomer units, if they are different kinds.* The glycosidic linkage involves the anomeric carbon on one sugar, but in most cases the other is free. Thus, the two ends of the molecule can be distinguished by their chemical reactivity. For example, the glucose residue in lactose, having a free anomeric carbon and thus a potential free aldehyde group, could be oxidized by Fehling's solution; the galactose residue could not be. Lactose is therefore a reducing sugar, and the glucose residue is at its *reducing end*. The other end is called the *nonreducing end*. In sucrose, neither residue has a potential free aldehyde group; both anomeric carbons are involved in the glycosidic bond. Therefore, sucrose is a nonreducing sugar.
4. *The configuration of the anomeric hydroxyl group of each residue.* This feature is especially important for the anomeric carbon(s) involved in the glycosidic bond. The configuration may be either α (as in the disaccharides shown in Figure 9.15a) or β (as in those in Figure 9.15b). This difference may seem small, but it has a major effect on the shape of the molecule, and the difference in shape is recognized readily by enzymes. For example, different enzymes are needed to catalyze the hydrolysis of maltose and

TABLE 9.5 Occurrence and biochemical roles of some representative disaccharides

Disaccharide	Structure	Natural Occurrence	Physiological Role
Sucrose	$\text{Glc}\alpha(1 \rightarrow 2)\text{Fru}\beta$	Many fruits, seeds, roots, honey	A final product of photosynthesis; used as primary energy source in many organisms
Lactose	$\text{Gal}\beta(1 \rightarrow 4)\text{Glc}$	Milk, some plant sources	A major animal energy source
α , α -Trehalose	$\text{Glc}\alpha(1 \rightarrow 1)\text{Glc}\alpha$	Yeast, other fungi, insect blood	A major circulatory sugar in insects; used for energy
Maltose	$\text{Glc}\alpha(1 \rightarrow 4)\text{Glc}$	Plants (starch) and animals (glycogen)	The dimer derived from the starch and glycogen polymers
Cellobiose polymer	$\text{Glc}\beta(1 \rightarrow 4)\text{Glc}$	Plants (cellulose)	The dimer of the cellulose
Gentiobiose	$\text{Glc}\beta(1 \rightarrow 6)\text{Glc}$	Some plants (e.g., gentians)	Constituent of plant glycosides and some polysaccharides

(a) Disaccharides with α -connections

Maltose:

 (1 \rightarrow 4) α -D-glucopyranose

α,α -Trehalose:
 α -D-glucopyranosyl
 (1 \rightarrow 1) α -D-glucopyranose

Sucrose:
 α -D-glucopyranosyl
 (1 \rightarrow 2) β -D-fructofuranoside

FIGURE 9.15

Structures of some important disaccharides. Ball-and-stick models are shown on the left, with anomeric oxygens in red. On the right are Haworth projections of the same molecules, with color-coded monomers: blue = glucose, yellow = fructose, teal = galactose. **(a)** Disaccharides linked through the C-1 of the α anomer: maltose, trehalose, and sucrose. **(b)** Disaccharides with β linkage: cellobiose, lactose, and gentiobiose. Note the convention used to draw glycosidic bonds between monomers in disaccharides. The “bent bonds” allow the Haworth projections of the monomers to be drawn in parallel. The “corners” do not imply extra carbon atoms, as they often do in organic structure representations.

cellobiose, even though both are dimers of D-glucopyranose. Furthermore, we shall see that in polysaccharides the anomeric orientation plays a critical role in determining the secondary structures adopted by these polymers.

Writing the Structure of Disaccharides

A convenient way to describe the structures of these and more complex oligosaccharides has been devised. The rules are as follows:

1. The sequence is written starting with the nonreducing end at the left, using the abbreviations defined in Table 9.4.
2. Anomeric and enantiomeric forms are designated by prefixes (e.g., α -, D-).
3. The ring configuration is indicated by a suffix (*p* for pyranose, *f* for furanose).
4. The atoms between which glycosidic bonds are formed are indicated by numbers in parentheses between residue designations (e.g., (1 \rightarrow 4) means a bond from carbon 1 of the residue on the left to carbon 4 of the residue on the right).

(b) Disaccharides with β connections

Cellobiose:
 β -D-glucopyranosyl
 (1 \rightarrow 4) β -D-glucopyranose

Lactose:
 β -D-galactopyranosyl
 (1 \rightarrow 4) β -D-glucopyranose

Gentiobiose:
 β -D-glucopyranosyl
 (1 \rightarrow 6) β -D-glucopyranose

As an example, we can write the structure of sucrose as

In many cases, the nomenclature is further shortened by omitting the D and L designations (except in the unusual cases in which L enantiomers are encountered) and by omitting the *p* and *f* suffixes when the monomers have their usual ring forms. Thus, we would more likely write sucrose in the way shown in Table 9.5. The system can be applied to oligosaccharides of any length and can include branched structures, as we will see in the discussion of starch later in this chapter. If only one carbon involved in the linkage between two residues is anomeric, the representation can be even more condensed because the anomeric configuration at the reducing end will equilibrate in solution. For example, maltose can be represented as $\text{Glc}\alpha(1 \rightarrow 4)\text{Glc}$.

The list of biologically important oligosaccharides is by no means restricted to dimeric structures. Many trimers, tetramers, and even larger, yet specifically constructed, molecules are known. Examples of these compounds will be encountered later in this chapter, when we examine the oligosaccharides attached to certain proteins and to cell surfaces. Tools of Biochemistry 9A describes techniques used to sequence oligosaccharides.

Stability and Formation of the Glycosidic Bond

Formation of the glycosidic bond between two monomers in an oligosaccharide is a condensation reaction, involving the elimination of a molecule of water. Thus, we might expect the synthesis of lactose to proceed as follows:

This reaction is analogous to the elimination of water between amino acids in the formation of polypeptides or between nucleotides in the formation of nucleic acids. As in those cases, the reaction as written is thermodynamically unfavored. Instead, the hydrolysis of oligosaccharides and polysaccharides is favored under physiological conditions by a standard state free energy change of about 15 kJ/mol, corresponding to an equilibrium constant of about 800 in favor of the hydrolysis products. Nevertheless, like peptides and oligonucleotides, saccharide polymers are sufficiently metastable to persist for long periods unless their hydrolysis is catalyzed by enzymes or acid. So the situation is the same as we have encountered with the other important biopolymers: The breakdown of oligosaccharides and polysaccharides *in vivo* is controlled by the presence of specific enzymes. Furthermore, *synthesis* of these sugar polymers never proceeds in living cells by reactions like the one we have just shown. As in protein or nucleic acid synthesis, activated monomers are required. For glycan biosynthesis those activated monomers are usually nucleotide-linked sugars. The activated sugar molecule in lactose biosynthesis is **uridine diphosphate galactose** (UDP-galactose or UDP-Gal), a nucleotide-linked sugar formed by reaction of uridine triphosphate with galactose-1-phosphate. Here and elsewhere in this chapter a single bond with no substituent shown represents a single-bonded hydrogen atom.

Like the phosphodiester bond in nucleic acid and amide bond in proteins, the glycosidic bond is metastable. Enzymes control its hydrolysis.

From the principles outlined in Chapter 3, you will probably recognize UDP-galactose as a high-energy compound. Hence, there is a thermodynamic tendency for one of the bonds to break, and in the process the activated galactosyl moiety can be transferred to a carbohydrate acceptor. In the reaction catalyzed by the enzyme **lactose synthase** that acceptor is glucose, as shown in Figure 9.16, and the product is lactose (Gal β (1 \rightarrow 4)Glc). Note the specificity of the enzyme. Although glucose has five different hydroxyl groups to which the galactosyl moiety could be transferred, only the hydroxyl at carbon 4 serves as an acceptor for this enzyme. Also shown in Figure 9.16 is the fact that the synthesis of UDP-Gal is driven in part by the subsequent hydrolysis of the other product, inorganic pyrophosphate, which is also a high-energy compound.

Because different disaccharides (and oligosaccharides and polysaccharides) are distinguished both by the kinds of monomers involved and by the precise glycosidic linkages between them, the enzymes needed for their breakdown must

also be specific. For example, hydrolysis of the common nutritional disaccharides maltose, lactose, and sucrose, which takes place in cells lining the wall of the small intestine, requires three different and specific enzymes (see page 560). None will substitute for another.

Lactose synthase is an example of a **glycosyltransferase**. Reactions of this type all involve transfer of an activated glycosyl moiety to an acceptor. The first known glycosyltransferase was the enzyme responsible for synthesis of **glycogen**, a carbohydrate storage polymer in animals (see page 330 and Chapter 13). This enzyme uses **UDP-glucose** (UDPG or UDP-Glc) as the activated glycosyl donor. Although both glycosyltransferases mentioned so far use uridine nucleotides for activation, there are numerous exceptions. For example, the biosynthesis of starch in plants uses **adenosine diphosphate glucose** (ADP-glucose or ADPG) as the activated nucleotide.

Another glycosyltransferase is responsible for the synthesis of sucrose in plants:

The product, sucrose-6-phosphate, is subsequently hydrolyzed to sucrose plus phosphate. An important feature of sucrose metabolism is that sucrose is involved in a glycan biosynthetic reaction that does not involve nucleotide-linked sugars. Some bacteria carry out the synthesis of **dextran**, an $\alpha(1 \rightarrow 6)$ -linked polymer of glucose with $\alpha(1 \rightarrow 2)$, $\alpha(1 \rightarrow 3)$, or $\alpha(1 \rightarrow 4)$ branch points. The polymerization, catalyzed by **dextran sucrose**, uses sucrose itself as the substrate:

Several bacteria growing in the human oral cavity synthesize large quantities of dextran, which contributes toward formation of dental plaque—hence, another concern that nutritionists have about excessive sucrose consumption in the population, in addition to their concern about obesity.

As we see later in this chapter, the larger oligosaccharides and the polysaccharides can exhibit complex structures. There is one important way in which oligosaccharide and polysaccharide synthesis differs from synthesis of nucleic acids and proteins. These sugar polymers are never copied from template molecules. Instead, in the formation of glycans, a different enzyme is employed to catalyze the addition of each kind of monomer unit. Clearly, a vast array of plant and animal enzymes must be devoted to the synthesis and degradation of saccharide polymers.

Polysaccharides

Polysaccharides fulfill numerous biological functions. Some, like starch and glycogen (sometimes called animal starch), serve mainly to store sugars for energy in plants and animals, respectively. Others, like **cellulose**, **chitin**, and the polysaccharides of bacterial cell walls, are structural materials analogous to the structural proteins. It is simplest to consider these molecules in terms of their functional categories.

As with polypeptides and polynucleotides, the sequence of monomer residues in a polysaccharide defines its primary structure. Whereas proteins usually have complex sequences, polysaccharides often have rather simple primary structures. In some cases (e.g., cellulose), the polymer is made from only one kind of monomer residue (β -D-glucose for cellulose); these kinds of polymers are referred to as **homopolysaccharides**. If two or more different monomers are involved, the

Glycan biosynthesis is carried out by **glycosyltransferases**, enzymes that transfer an activated glycosyl moiety, such as UDP-glucose, to a specific position on a carbohydrate acceptor.

FIGURE 9.16

Enzymatic formation of lactose. The reaction shown occurs in the formation of milk in mammary tissue. Galactose is phosphorylated by ATP, then transferred to uridine diphosphate (UDP). UDP-galactose transfers galactose to glucose, with the accompanying cleavage of a phosphate bond. The reaction is catalyzed by the enzyme lactose synthase. In keeping with the convention adopted in Chapter 4, a P within a diamond shape denotes phosphate. When shown in yellow, it is a high-energy phosphate.

polymer is called a **heteropolysaccharide**. Even those storage and structural polysaccharides that are heteropolymers are rarely complex; usually no more than two kinds of residues are involved. In further contrast to protein and nucleic acid molecules, which are almost always of defined length, polysaccharide chains grow to random lengths. And, as mentioned earlier, glycans are distinctive in that they can form branched chains. The ability to branch, plus the numbers of functional groups on each monomer that can participate in bond formation, give polysaccharides amazing structural diversity, and this undoubtedly contributes to the large number of roles played by polysaccharides.

The functional reasons for the distinctions from proteins and nucleic acids are not hard to find. A storage material, such as starch, needs neither to convey information nor to adopt a complicated three-dimensional form. It is simply a bin in which to put away glucose molecules for future use. Many structural polysaccharides (like structural proteins) form extended, regular secondary structures, well suited to the formation of fibers or sheets. Often a regular repetition of some simple monosaccharide or disaccharide motif will serve this function. (Recall, for comparison, the simple and repetitive amino acid sequences of collagen and silk fibroin described in Chapter 6.) The only glycan polymers in which well-defined and complex sequences are found are some of the oligosaccharides attached to cell surfaces or those attached to specific glycoproteins. Because these oligomers serve to identify cells or molecules, they must convey information. This function requires precisely defined “words” in the polysaccharide language, just as nucleic acid sequences spell out information in their own language.

Storage Polysaccharides

The principal storage polysaccharides are **amylose** and **amylopectin**, which together constitute starch in plants, and **glycogen**, which is stored in animal and microbial cells. Both starch and glycogen are stored in granules within cells (Figure 9.17). Starch is found in almost every kind of plant cell, but grain seeds, tubers, and unripe fruits are especially rich in this material. Glycogen is deposited in the liver, which acts as a central energy storage organ in many animals. Glycogen is also abundant in muscle tissue, where it is more immediately available for energy release.

Glycogen and the components of starch—amylose and amylopectin—are storage polysaccharides. Amylose is linear; amylopectin and glycogen are branched.

FIGURE 9.18

Amylopectin, a branched glucan. (a) The primary structure of amylopectin. Nonreducing ends (N) and reducing ends (R) are indicated. **(b)** Detailed structure of a branch point. To simplify the figure some ring hydroxyls are not shown.

Amylose, amylopectin, and glycogen are all polymers of α -D-glucopyranose. They are homopolysaccharides of the class called **glucans**, the polymers of glucose. The polymers differ in size and the kinds of linkages between glucose residues. Amylose is a linear polymer involving exclusively $\alpha(1 \rightarrow 4)$ links between adjacent glucose residues. Amylopectin (Figure 9.18) and glycogen are both branched polymers, because they contain, in addition to the $\alpha(1 \rightarrow 4)$ links, some $\alpha(1 \rightarrow 6)$ links as well. The branches in glycogen are somewhat more frequent and shorter than those in amylopectin, and glycogen is usually of higher molecular weight, but in most respects the structures of these two polysaccharides are very similar.

The regular and simple primary structure of amylose allows a regular secondary structure for this molecule. As with polynucleotides and polypeptides, the details of this structure initially came from X-ray diffraction studies. In fact, amylose was the first biopolymer whose structure was elucidated by this method. Because of the $\alpha(1 \rightarrow 4)$ link, each residue is angled with respect to the preceding residue, favoring a regular helical conformation (Figure 9.19). The branched nature of amylopectin and glycogen inhibits the formation of helices because the helix requires 6 residues for each turn; there is a branch point about every 20–30 residues in amylopectin and about every 8–10 in glycogen.

The storage polysaccharides are admirably designed to serve their function. Glucose and even maltose are small, rapidly diffusing molecules, which are difficult to store. Were such small molecules present in large quantities in a cell, they would give rise to a very large cell osmotic pressure, which would be deleterious in most cases. Therefore, most cells build the glucose into long polymers so that large quantities can be stored in a manner that prevents its diffusion and loss. Whenever glucose is needed, it can be obtained by selective degradation of the polymers by specific enzymes. These processes are discussed in detail in Chapter 13, but one aspect should be mentioned now. Most of the enzymes employed attack the chains at their nonreducing ends, releasing one glucose residue at a time. Such “end-nibbling” (as opposed to internal cutting) prevents the continual breakup of the long polymers, which would lead to their complete solubilization. The

FIGURE 9.19

The secondary structure of amylose. The orientation of successive glucose residues favors helix generation. Note the large interior core. Hydrogen bonds (not shown) stabilize the helix.

branched structure of both amylopectin and glycogen is such that each molecule has *many* nonreducing ends that can be attacked simultaneously (see Figure 9.18), allowing rapid mobilization of glucose when it is needed. On the other hand, the linear chain of amylose with its single nonreducing end is used mainly for long-term storage of glucose.

Structural Polysaccharides

Plants seem not to synthesize or use fibrous structural proteins (like keratin and collagen) but instead rely entirely on special polysaccharides. Animals use both kinds of materials. Because each structural use requires different properties, a great variety of structural polysaccharides exists. We begin by considering those from plants.

Cellulose

The major polysaccharide in woody and fibrous plants (like trees and grasses), cellulose is the most abundant single polymer in the biosphere. Like amylose, cellulose is a linear polymer of D-glucose (and hence is also a glucan), but in cellulose the sugar residues are connected by $\beta(1 \rightarrow 4)$ linkages (Figure 9.20). This seemingly small distinction from starch (specifically amylose) has remarkable structural consequences. Cellulose can exist as fully extended chains, with each glucose residue flipped by 180° with respect to its neighbor in the chain. In this extended form, the chains can form ribbons that pack side by side with a network of hydrogen bonds within and between them. This arrangement is reminiscent of the β -sheet structure in silk fibroin, and as in fibroin, the fibrils of cellulose have great mechanical strength but limited extensibility.

The same small difference between cellulose and starch has another important consequence: Animal enzymes that are able to catalyze cleavage of the $\alpha(1 \rightarrow 4)$ link in starch cannot cleave cellulose. For this reason, humans, even if starving, are unable to utilize the enormous quantities of glucose all around them in the form of cellulose. Ruminants such as cows can digest cellulose only because their digestive tracts contain symbiotic bacteria that produce the necessary **cellulases**. Termites manage to eat woody substances in a somewhat more complicated fashion—their guts harbor protozoans capable of cellulose digestion but their salivary glands also produce a cellulase. Many fungi also produce such enzymes, which is why some mushrooms can live on wood as a carbon source.

Although humans don't digest cellulose, high-fiber foods containing cellulose are important nutritionally. The bulk in fiber produces a feeling of satiety, or

FIGURE 9.20

Cellulose structure. The $\beta(1 \rightarrow 4)$ linkages of cellulose generate a planar structure. The parallel cellulose chains are linked together by a network of hydrogen bonds. Hydrogens involved in such bonds are shown in blue. For clarity, all of the carbons are numbered in only one glucose residue. Not all hydrogen atoms are shown.

fullness, signaling when we have probably had enough to eat. Insoluble fiber increases the rate of transport of digestion products through the alimentary tract, by increasing its bulk, and is thought to reduce exposure to potential toxins or carcinogens in the diet.

A major goal of the biofuels industry is to develop efficient means for industrial-scale conversion of cellulose in plant waste materials to glucose or other substrates that can be fermented to ethanol or other potential fuels. A particular challenge is that cellulose in plant tissues is closely associated with *lignin*, a complex polymer, primarily in woody tissue, that resists breakdown much more strongly than cellulose (Chapter 21). So cellulose must be separated from lignin, or else means must be found to degrade lignin also to potential fuel molecules.

Fibrous parts of plants are not made exclusively from cellulose. A variety of other polysaccharides are present in plant cell walls. These include the **xylans**, which are polymers with $\beta(1 \rightarrow 4)$ -linked D-xylopyranose, often with substituent groups attached; the **glucomannans**; and many other polymers. Often these polysaccharides are grouped together under the term **hemicellulose**.

The cell wall of a plant is a complex structure, made up of several layers. Microfibrils of cellulose are laid down in a crosshatched pattern (Figure 9.21) and impregnated with a matrix of the other polysaccharides and some proteins. The same principle is used when glass fibers are embedded in a tough resin to produce strong, durable sheets of fiberglass.

Cellulose is not confined exclusively to the plant kingdom. The marine invertebrates called *tunicates*, such as the sea squirt, contain considerable quantities of cellulose in their hard outer mantle. There are even reports of small amounts of cellulose in human connective tissue. However, as a structural material, cellulose seems to have been largely passed over in animal evolution. In the fungi, extensive use is made of other glucans, with $\beta(1 \rightarrow 3)$ or $\beta(1 \rightarrow 6)$ linkages between glucose residues, as structural polysaccharides.

Chitin

A homopolymer of *N*-acetyl- β -D-glucosamine, chitin has a structure basically similar to that of cellulose, except that the hydroxyl on carbon 2 of each residue is replaced by an acetylated amino group.

Cellulose and chitin are examples of structural polysaccharides. Unlike starches, which have $\alpha(1 \rightarrow 4)$ links, these fibrous polymers have $\beta(1 \rightarrow 4)$ linkages.

FIGURE 9.21

Organization of plant cell walls. Microfibrils of cellulose are embedded in a matrix of hemicellulose. Note that the fibers are laid down in a crosshatched pattern to give strength in all directions.

Chitin is widely distributed among all kingdoms. It is a minor constituent in most fungi and some algae, where it often substitutes for cellulose or other glucans. In dividing yeast cells, chitin is found in the septum that forms between the separating cells. The best known role of chitin, however, is in invertebrate animals; it constitutes a major structural material in the exoskeletons of many arthropods and mollusks. In many of these exoskeletons, chitin forms a matrix on which mineralization takes place, much as collagen acts as a matrix for mineral deposition in vertebrate bones. The evolutionary implications are interesting. As animals evolved to the size that made rigid body parts essential, quite different paths were taken. The ancestors of the vertebrates developed a mineral skeleton on a collagen matrix. Annelids such as earthworms also use collagen, but in a segmented exoskeleton. The arthropods and mollusks also developed exoskeletons, but theirs were built on chitin—a carbohydrate rather than a protein matrix.

Glycosaminoglycans

One group of polysaccharides is of major structural importance in vertebrate animals—the **glycosaminoglycans**, formerly called *mucopolysaccharides*. Important examples are the *chondroitin sulfates* and *keratan sulfates* of connective tissue, the *dermatan sulfates* of skin, and *hyaluronic acid*. All are polymers of repeating disaccharide units, in which one of the sugars is either *N*-acetylgalactosamine or *N*-acetylglucosamine or one of their derivatives. All are acidic, through the presence of either sulfate or carboxylate groups. Representative structures of glycosaminoglycans are shown in Figure 9.22.

Glycosaminoglycans are negatively charged heteropolysaccharides that serve a number of structural functions in animals.

The Proteoglycan Complex

A major function of the glycosaminoglycans is the formation of a matrix to hold together the protein components of skin and connective tissue. An example is given

**FIGURE 9.22**

Repeating structures of some glycosaminoglycans. In each case, the repeating unit is a disaccharide, of which two are shown for each structure. Abbreviations of residues (6s means sulfonated at carbon 6) are in Table 9.4. To simplify the figure, hydrogens and nonreacted hydroxyls are not shown.

in Figure 9.23, which illustrates the protein–carbohydrate, or **proteoglycan**, complex in cartilage. The filamentous structure is built on a single long hyaluronic acid molecule, to which extended core proteins are attached noncovalently. The core proteins, in turn, have chondroitin sulfate and keratan sulfate chains covalently bound to them through serine side chains. In cartilage, this kind of structure binds collagen (see Chapter 6) and helps hold the collagen fibers in a tight, strong network. The binding apparently involves electrostatic interactions between the sulfate and/or carboxylate groups of the proteoglycan complex and the basic side chains in collagen.

The proteoglycan complexes of connective tissue constitute one of the few examples in which the element silicon enters into biology. Some of the carbohydrate chains are cross-linked by bridges of the type

where R and R' are sugar monomers of adjacent chains. There is about one silicon atom for every 100 sugar monomers.

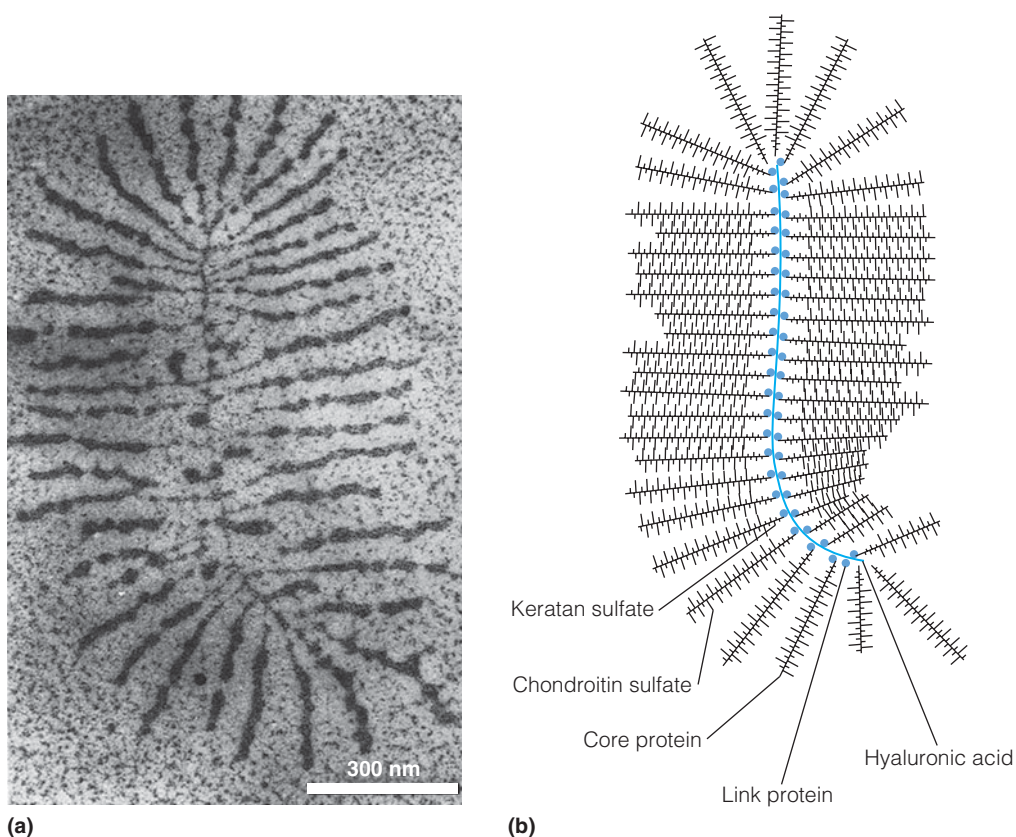

Nonstructural Roles of Glycosaminoglycans

Hyaluronic acid has other functions in the body besides being a structural component. The polymer is highly soluble in water and is present in the synovial fluid

FIGURE 9.23

Proteoglycan structure in bovine cartilage. (a) An electron micrograph of a proteoglycan aggregate. (b) A schematic drawing of the same structure. Keratan sulfate and chondroitin sulfate are covalently linked to extended core protein molecules. The core proteins are noncovalently attached to a long hyaluronic acid molecule with the aid of a link protein.

of joints and in the vitreous humor of the eye. It appears to act as a viscosity-increasing agent or lubricating agent in these fluids, possibly related to electrostatic repulsion among the many carboxylate groups in the polymer.

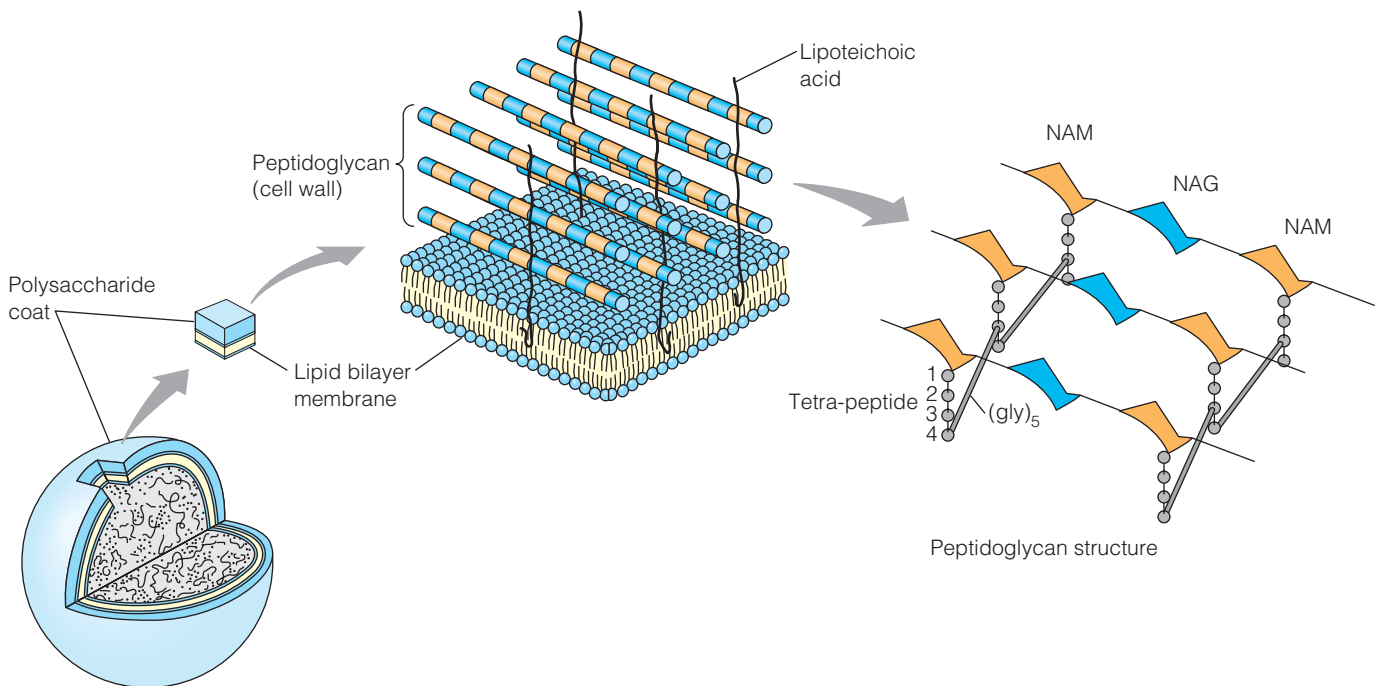

Another highly sulfated glycosaminoglycan is **heparin**. One repeat unit of its complex chain is shown below. Heparin appears to be a natural anticoagulant and is found in many body tissues. It binds strongly to a blood protein, antithrombin III, and the complex inhibits enzymes of the blood clotting process (see Chapter 11). Therefore, heparin is used medicinally to inhibit clotting in blood vessels.

The glycosaminoglycans are interesting examples of how sugar residues can be modified to provide polymers with a wide variety of properties and functions.

Bacterial Cell Wall Polysaccharides

In Chapter 1 we noted that bacteria and most other unicellular organisms possess a *cell wall*. The nature of this cell wall is the basis for categorizing bacteria into two major classes: those that retain the Gram stain (a dye–iodine complex), which are called *Gram-positive* bacteria, and those that do not, which are termed *Gram-negative* (Figure 9.24). Gram-positive bacteria have a cell wall with a cross-linked, multilayered polysaccharide–peptide complex called **peptidoglycan** at the surface, outside the lipid cell membrane (Figure 9.24a). Gram-negative

(a) Gram positive:
Staphylococcus aureus

(b) Gram negative:
Escherichia coli

FIGURE 9.24

Bacterial cell walls. These schematic drawings show the structures of the two types of bacterial cell wall. (a) The cell wall of a representative Gram-positive bacterium, *Staphylococcus aureus*, consists of a thick peptidoglycan layer made up of polysaccharide chains and short peptides. The peptides are linked by glycine pentapeptides. (b) The cell wall of a representative Gram-negative bacterium, *Escherichia coli*, has a thin peptidoglycan layer and an outer lipid membrane. The cross-links here are between tetrapeptides attached to the *N*-acetylmuramic acid (NAM; page 323) residues in adjacent chains.

bacterial cell walls also contain peptidoglycan, but it is single-layered and covered by an outer lipid membrane layer (Figure 9.24b). This difference allows the Gram stain to be washed from Gram-negative bacteria.

The chemical structure of the peptidoglycan of a Gram-positive bacterium is shown in Figure 9.25. Long polysaccharide chains, which are strictly alternating copolymers of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM),

The cell walls of many bacteria are constructed of peptidoglycans, composite polymers of polysaccharides and oligopeptides.

FIGURE 9.25

The peptidoglycan layer of Gram-positive bacteria. Cross-links between the peptides are formed by pentaglycine chains between the ϵ -amino group of the lysine (*) on one chain and the C-terminal carboxyl group of the alanine (**) on an adjacent chain. To simplify the figure, hydrogens and nonreacted hydroxyls are not shown.

FIGURE 9.26

The structure of a lipoteichoic acid. D-Alanyl and NAG groups are arranged irregularly on the chain, which is anchored in the membrane by lipid.

are cross-linked through short peptides (see Figure 9.24a). These peptides have unusual structures. Attached to the lactic acid moiety of the *N*-acetylmuramic acid is a tetrapeptide with the sequence

This peptide is unusual in two respects: It contains some D-amino acids, and the glutamic acid residue is linked into the chain through its γ -carboxyl instead of the usual α -carboxyl linkage. To the ϵ -amino group of each lysine residue is attached a glycine pentapeptide, which is bonded at its other end to the terminal D-Ala residue of an adjacent chain. The result is the formation of a covalently cross-linked structure that envelops the bacterial cell. The entire cell wall can be regarded as a single enormous molecule made up of multiple layers of cross-linked peptidoglycan strands. In addition to the components mentioned above, elongated lipid-oligosaccharide complexes called **lipoteichoic acids** (Figure 9.26) protrude from the membrane through the peptidoglycan wall. The cell wall protects bacteria from lysis when they are in the blood of host animals.

In the Gram-negative bacteria, the peptidoglycan layer is much thinner. Although the same basic polysaccharide structure is present, the peptide chains and their linkage are somewhat different (see Figure 9.24b).

Clearly, assembly of a structure as complex as the bacterial cell wall requires a battery of enzymes and reactions. A number of antibiotics (for example, penicillin) inhibit bacterial growth by interfering with the formation of the peptidoglycan layer. Synthesis of peptidoglycan involves chemistry quite alien to the human or animal host to a pathogenic bacterium, making cell wall biosynthesis a specific target for drug action. We return to this topic later in this chapter. However, we should note that one class of naturally occurring antibiotic substances acts not by interfering with cell wall synthesis but by attacking the peptidoglycan layer itself. These substances are the **lysozymes**, enzymes with wide distribution—they are found in bacteriophages, egg white, and human tears, for example. In egg white and tears they help maintain asepsis; in bacteriophage they help the phage to rupture an infected bacterium, releasing progeny phage at the conclusion of a lytic cycle of growth. Lysozymes (see Chapter 11 for mechanism) catalyze hydrolysis of the glycosidic links between GlcNAc and MurNAc residues in the polysaccharide. Thus, they dissolve the cell wall, resulting in osmotic rupture of the membrane and bacterial death.

Glycoproteins

More than half of all eukaryotic proteins carry covalently attached oligosaccharide or polysaccharide chains. There is an astonishing variety of these modified proteins, which are known as **glycoproteins**, and they serve multiple functions, including cell adhesion and the recognition of eggs by sperm cells.

N-Linked and O-Linked Glycoproteins

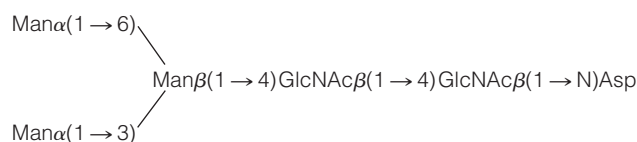

The saccharide chains, or glycans, can be linked to proteins in two major ways. *N-linked glycans* are attached, usually through *N*-acetylglucosamine, or sometimes through *N*-acetylgalactosamine, to the side chain amide group in an asparagine residue. A common sequence surrounding the asparagine is $-\text{Asn}-\text{X}-\text{Ser}/\text{Thr}-$, where X may be any amino acid residue. *O-linked glycans* are usually attached by an O-glycosidic bond between *N*-acetylgalactosamine and the hydroxyl group of a threonine or serine residue, although in a few cases—collagen, for example (Chapter 6)—hydroxylysine or hydroxyproline is employed.

Oligosaccharides and proteins can be linked to form glycoproteins in two ways: O-linked glycans are attached via threonine or serine hydroxyls and N-linked glycans via asparagine amino groups.

N-Linked Glycans

Careful study of many glycoproteins has revealed an enormous variety of N-linked oligosaccharide side chains, often exhibiting a complex branched structure. However, a common motif is often seen. The following structure often serves as a foundation for further elaboration:

This motif can be seen, for example, in the glycan moieties of ovalbumin in egg whites, and in the immunoglobulins. The structure of the oligosaccharide found attached to a human immunoglobulin G (IgG) is shown in simplified form below.

The residue denoted Fuc is α -L-fucose, a residue often attached near the protein connection of N-linked glycans. The immunoglobulins represent an important example of the informational function of the glycan chains on glycoproteins. Recall from Chapter 7 that every immunoglobulin has carbohydrate attached to the constant domain of each heavy chain. The different types of immunoglobulins must be recognized, both for proper tissue distribution and for interaction with phagocytic cells, which will destroy the antigen–immunoglobulin complex. A part, at least, of this recognition is based on differences in the oligosaccharide chains.

An important further use of N-linked oligosaccharides is in intracellular targeting in eukaryotic organisms. Later in this chapter, and also in Chapter 28, we see how proteins destined for certain organelles or for secretion from the cell are marked specifically by oligosaccharides during post-translational processing. This marking ensures that they pass appropriately through the endoplasmic reticulum, organelle membranes, the Golgi complex, and/or the plasma membrane so that each glycoprotein arrives at its proper destination.

O-Linked Glycans

Many proteins carry O-linked oligosaccharides that serve a variety of functions. Antarctic fish contain a glycoprotein that serves as an “antifreeze,” preventing the freezing of body fluids even in extremely cold water. The **mucins**, glycoproteins found extensively in salivary secretions, contain many short O-linked glycans. The highly extended and highly hydrated mucins increase the viscosity of the fluids in which they are dissolved. Some O-linked glycans also function in intracellular targeting and molecular and cellular identification. An example significant to human biology is found in the *blood group antigens*.

Blood Group Antigens

An important group of oligosaccharides is the **blood group antigens**. On some cells these antigens are attached as O-linked glycans to membrane proteins. Alternatively, the oligosaccharide may be linked to a lipid molecule to form a **glycolipid** (see Chapter 10). The lipid portion of the molecule helps anchor the antigen to the outside surface of erythrocyte membranes. It is these oligosaccharides that determine the blood group types in humans. Their presence in a blood sample is detected by blood typing—determining whether antibodies to a particular antigen cause the red cells of that blood sample to clump, or agglutinate. Although the system consisting of blood types A, B, AB, and O is probably most familiar to you, it is just one of 14 genetically characterized blood group systems, with more than 100 different blood group antigens. These substances are also present in many cells and tissues other than blood, but we often focus on blood because of the widespread use of typing in establishing familial relationships and selecting blood for transfusion.

For simplicity, we will take the ABO system as an example. Figure 9.27 depicts cell surface oligosaccharides corresponding to each of these blood types. Almost all humans can produce the type O saccharide, but addition of either galactose (to make type B) or N-acetylgalactosamine (to make type A) requires an additional enzyme. Synthesis of these oligonucleotides is outlined on page 346. Some individuals possess one of these enzymes, some possess the other, and a few are heterozygous and can produce both. The heterozygous individuals have type AB blood, with both A and B oligosaccharides present on cell surfaces.

FIGURE 9.27

The ABO blood group antigens. The O oligosaccharide (top) does not elicit antibodies in most humans. The A and B antigens are formed by addition of GalNAc or Gal, respectively, to the O oligosaccharide. Each of the A and B antigens can elicit a specific antibody. In this figure, R can represent either a protein molecule or a lipid molecule.

Humans can produce antibodies against the A and B oligosaccharides, but the O type are nonantigenic. Normally, a person does not produce antibodies against his or her own antigen but does produce them against the other antigen type. Thus, an individual with type A blood carries antibodies directed against the B polysaccharide. If he or she accepts blood from a type B donor, these antibodies will cause clumping and precipitation of the donated blood cells. Nor can a type B individual safely accept type A blood. People with type O blood normally have antibodies against both A and B and thus can receive from neither. Those with AB type, because they carry both A and B antigens themselves, have antibodies against neither.

In donating blood, an inverse relationship holds. Those with type O blood, which carries no antigenic determinants, can safely donate to any other person—they are the “universal donors.” Type AB individuals can donate *only* to other ABs; a person of any other type will carry antibodies to A, or B, or both. These relationships are summarized in Table 9.6.

Erythropoietin: A Glycoprotein with Both O- and N-Linked Oligosaccharides

The glycoprotein **erythropoietin** is a hormone synthesized in kidney, which stimulates the production of red blood cells. The hormone, often called EPO, is a 165-residue polypeptide with N-linked oligosaccharides (13-mers) at Asn 24, 38, and 83 and an O-linked trisaccharide at Ser-126. The carbohydrate stabilizes EPO within the blood, preventing rapid removal by the kidney. Anemia—low red blood cell count—is a common side effect of cancer chemotherapy, and EPO is often administered along with anticancer drugs to counteract this effect. EPO is also subject to misuse, particularly by athletes who wish to improve their aerobic status. Recombinant EPO, which is usually used for this purpose, can be identified by drug-testing laboratories on the basis of its abnormal glycosylation pattern.

Influenza Neuraminidase, a Target for Antiviral Drugs

The concept that virus infection induces enzymes that carry out new metabolic pathways within infected cells was established in the 1950s and 1960s, through studies with bacterial viruses, or bacteriophages (Chapter 22, page 950). However, long before that it was known that the influenza virus, an RNA virus, carries on its surface a virus-coded enzyme, **neuraminidase**. As shown in Figure 9.28, the spherical virus particle has two kinds of spikes on its exterior surface. One such spike, made up of a protein called *hemagglutinin*, binds to *N*-acetylneuraminic acid (also called sialic acid, see page 323). The virus attaches to host cells through binding of the hemagglutinin to sialic acid residues in cell surface glycoproteins or glycolipids. At the conclusion of the virus infection cycle, release of virus from infected cells requires cleavage of the sialic acid from the rest of each oligosaccharide chain, and this is carried out by the viral neuraminidase. The crystal structure of the neuraminidase complex with sialic acid was solved in the 1980s (see Figure 7.43, page 274), leading to synthesis of sialic acid analogs that might inhibit the enzyme, and, hence, block release of virus particles from infected cells. Two such analogs, *zanamivir* and *oseltamivir*, are shown in Figure 9.29, along with the partial structure of the neuraminidase. Oseltamivir, marketed as *Tamiflu*, assumed great importance during the H1N1 influenza epidemic

The blood group substances are a set of antigenic oligosaccharides attached to the surfaces of red cells.

TABLE 9.6 Transfusion relationships among ABO blood types

Person Has Blood Type:	Makes Antibodies Against:	Can Safely Receive Blood from:	Can Safely Donate Blood to:
O	A, B	O	O, A, B, AB
A	B	O, A	A, AB
B	A	O, B	B, AB
AB	None	O, A, B, AB ^a	AB

^aIn principle, this relationship is true. However, ABs are never given donations from other types because the donor's antibodies could react with the recipient's antigens.

FIGURE 9.28

of 2009, before an effective vaccine had become available. Tamiflu acts, as predicted, by blocking release of newly formed virus particles from infected cells, but it must be administered very soon after the onset of flu symptoms in order to be effective.

Oligosaccharides as Cell Markers

Biologists realize that molecules such as the blood group antigens represent only a special case of a much more general phenomenon—cell marking by glycans. In a multicellular organism, it is essential that different kinds of cells be marked on their surfaces so that they can interact properly with other cells and molecules and so that an organism can recognize its own cells as immunologically distinct from foreign cells. In accord with this view is the growing appreciation that the surfaces of many cells are nearly covered with polysaccharides, which are attached to either proteins or lipids in the cell membrane (Figure 9.30a). Some animal cells have an extremely thick coating of polysaccharides called a **glycocalyx** (literally “sugar coat”); Figure 9.30b shows the glycocalyx of an intestinal cell. Glycocalyx oligosaccharides interact with other substances: with bacteria in the intestine and with collagen of the intercellular matrix in some other tissues.

For glycans to serve as recognition signals there must be proteins that bind to them specifically. One such class is the immunoglobulins. Another, very diverse group of saccharide-binding proteins is the **lectins**. The lectins were first recognized in plant tissues, where they appear to play defensive roles and to aid in adhering nitrogen-fixing bacteria to roots. We now know that lectins are widely distributed and play a great variety of roles in animals as well. For example, lectins seem to be involved in interactions between cells and proteins of the intercellular matrix, such as collagen, and help to maintain tissue and organ structure. Lectins in the walls of intestinal bacteria help to bond the bacteria to the glycocalyx of the intestinal epithelium. The fact that cell surface polysaccharides are important in determining cell–cell interactions (including both adhesion and avoidance) has much medical significance. For example, we know that the polysaccharides on the surfaces of many cancer cells are abnormal. This may account in part for the loss in tissue specificity that such cells commonly exhibit.

In animals, a related class of proteins is the **selectins**, which are mobilized as part of an inflammatory response. One such protein, *P-selectin*, is stored in platelets and epithelial cells. Early events in the inflammatory process release this protein from intracellular stores to the cell surface. There the carbohydrate moiety of P-selectin interacts with carbohydrates on the surface of leukocytes, a class of white blood cells. This slows movement of the leukocyte through the blood vessel, allowing it to leave the blood vessel and enter the site of an infection.

Why do oligosaccharides so often play the role of cellular markers? We don't know, but certain possibilities suggest themselves. First, oligosaccharides can

Many cells carry a complex layer of polysaccharides—the glycocalyx—on their surfaces.

FIGURE 9.30

Cell surface recognition factors. (a) Schematic view of a lipid membrane. Oligosaccharides are attached to the outer surface, through either membrane-embedded proteins or special lipid molecules. (b) Electron micrograph of the surface of an intestinal epithelial cell. The cellular projections, called microvilli, are covered on their outer surface by a layer of branched polysaccharide chains attached to proteins in the cell membrane. This carbohydrate layer, called the glycocalyx, is found on many animal cell surfaces.

FIGURE 9.31

Imaging cell surface glycoproteins in living cells. Zebrafish embryos were allowed to incorporate an azido derivative of GalNAc and at fixed intervals the embryos were treated with a fluorescent reagent that couples to the azido group in the incorporated analog. In the example shown the embryos were treated with reagents of three different colors, each for a specific time interval, as described in the text. Scale, 100 μm .

From *Science* 320:664–667, S. T. Laughlin, J. M. Baskin, S. L. Amacher, and C. R. Bertozzi, In vivo imaging of membrane-associated glycans in developing zebrafish. © 2008. Reprinted with permission from AAAS.

present a seemingly limitless variety of structures in relatively short chains. The multiple choices of monomers (including modified sugars), linkages, and branching patterns allow a vast but specific vocabulary. Second, oligosaccharides are especially potent antigens, which means that specific antibodies can be elicited swiftly against them (see Chapter 7). Whether this interaction is the result of some intrinsic property of sugar molecules or of the antibody molecules is unclear. It is possible that antibodies evolved as a defense against bacteria, which have polysaccharide-rich walls, and thus have always favored glycans as targets.

With the realization that cell-surface glycoproteins are highly selective cell markers has come the desirability of imaging these markers in living cells, in much the same way that green fluorescent protein is used to image proteins in living cells (Chapter 6). An example of this emerging technology is shown in Figure 9.31. In this study, from the laboratory of Carolyn Bertozzi, living zebrafish embryos were incubated in the presence of peracetylated *N*-azidoacetylgalactosamine (Ac_4GalNAz), which is readily incorporated into mucin-type O-linked glycoproteins. At intervals after fertilization the embryos were treated with fluorescent reagents of different colors, each of which could react covalently with the azido group in the cell surface glycoproteins. In the figure shown, the intervals of fluorescent reagent treatment were 60–61, 62–63, and 72–73 hours post-fertilization, each period involving labeling with a dye of a different color. This experiment shows distinct spatial patterns of cell surface glycoprotein synthesis at different times during development of a live, developmentally normal embryo, thereby setting the stage for mechanistic analysis of glycoprotein metabolism in embryogenesis.

Peracetyl *N*-azidoacetylgalactosamine

Biosynthesis of Glycoconjugates: Amino Sugars

A full appreciation of the excitement of contemporary *glycobiology* requires some understanding of the routes for biosynthesis of these diverse metabolites. Although enzymes and metabolic processes are dealt with in more detail in later chapters, we present some of the most significant processes here, with the realization that full appreciation of this material may come only after you have considered enzymes in Chapter 11 and carbohydrate metabolism in Chapter 13.

Because amino sugars such as glucosamine are major constituents of glycoconjugates, we first deal with their metabolic origins. Simple sugars, such as glucose and fructose, arise chiefly through photosynthesis, as was outlined in Figure 9.2. Sugar phosphates arise as intermediates in glycolysis, gluconeogenesis, and the pentose

phosphate pathway, all of which are presented in Chapter 13. All amino sugars are derived metabolically from **glucosamine-6-phosphate**, which arises in turn from **fructose-6-phosphate** through an **amidotransferase** reaction, as shown below.

In this reaction the amide nitrogen of glutamine is transferred to C-2 of fructose-6-phosphate, with the glutamine being converted to glutamate; also the sugar undergoes an internal oxidoreduction, with the carbonyl moiety moving from C2 to C1. Several amidotransferases are involved in nucleotide metabolism and are discussed more fully in Chapter 22.

The further metabolism of glucosamine-6-phosphate involves acetylation of the amino group by **acetyl-coenzyme A**, or acetyl-CoA, as indicated in Figure 9.32. Acetyl-CoA is an active acetylating species, formed largely in mitochondria from oxidation of fatty acids and pyruvate (Chapter 12). The acetyl group is transferred to the nitrogen on glucosamine-6-phosphate. A **mutase** then isomerizes the sugar phosphate by transferring the phosphate from C6 to C1. Finally, a reaction with uridine triphosphate, like that shown on page 328, generates a nucleotide-linked sugar, prepared for further biosynthetic reactions.

The pathway outlined in simplified form in Figure 9.33 leads in five steps from UDP-*N*-acetylglucosamine to sialic acid, but in the process it generates several other intermediates in glycoconjugate synthesis. The **epimerase** enzyme in the first reaction inverts the sugar configuration at C4. Next, the uridine nucleotide is removed hydrolytically, and this is followed by an ATP-dependent phosphorylation at C6 coupled with another epimerization at C4. A complex reaction follows, in which the three carbons of **phosphoenolpyruvate** are incorporated into the sugar ring, giving a nine-carbon sugar phosphate. Hydrolytic removal of the phosphate gives *N*-acetylneuraminic acid, or sialic acid. Phosphoenolpyruvate, an intermediate in glycolysis (Chapter 13), was introduced in Chapter 3 as an ultra-high-energy compound.

As indicated earlier, the biosynthetic pathways leading to glycoconjugates involve glycosyltransferase reactions, which use a sugar activated for transfer to a growing glycan chain by formation of a nucleotide-linked sugar. Usually that nucleotide is UDP or another nucleoside diphosphate. Sialic acid presents an exception, in that the activating nucleotide is *cytidine* triphosphate and the activated product is an activated nucleoside *monophosphate* sugar.

For reasons unknown, this reaction occurs in the nucleus of animal cells, while all other nucleotide-linked sugars are synthesized in the cytosol.

Glycoconjugates of Interest

As noted throughout this chapter, the vast structural diversity possible among carbohydrates allows them to be used for both intracellular and extracellular molecular recognition in glycoproteins, even when present in very small amounts. The carbohydrate components of cell surface glycoproteins direct the interaction of the cells with other cells and with their environment. Such interactions involve processes as diverse as cell movements in development, cell adhesion, cell motility, cell growth control, oncogenic transformation, and **endocytosis** (internalization of material from the extracellular milieu—see Chapter 17).

FIGURE 9.32

Biosynthesis of UDP-*N*-acetylglucosamine from glucosamine-6-phosphate.

FIGURE 9.33

Biosynthesis of *N*-acetylneuraminic acid (sialic acid) from UDP-*N*-acetylglucosamine.

In this section we consider the biosynthesis of the carbohydrate components of some selected glycoconjugates—the glycan components of glycoproteins and the peptidoglycan and O-antigen portions of bacterial cell walls. The examples chosen have general biological interest, and they illustrate mechanisms used in synthesizing the vast known array of glycoconjugates. In general, as mentioned earlier, these mechanisms involve the action of specific glycosyltransferases that transfer a monosaccharide unit from a nucleotide-linked sugar to the nonreducing end of an oligosaccharide chain or to an appropriate functional group on the protein component. The glycosyltransferases are bound to membranes of the smooth or rough endoplasmic reticulum or the Golgi apparatus.

A particularly fascinating part of glycoprotein synthesis is the protein sorting, or traffic, that occurs as oligosaccharide chains are growing. In some cases the structure of the oligosaccharide chain or chains on a protein serves as a molecular recognition determinant, directing that protein to the proper intracellular location for the next step in oligosaccharide synthesis and, ultimately, to the site where the mature protein will reside. We introduce this topic here and return to it in Chapter 28.

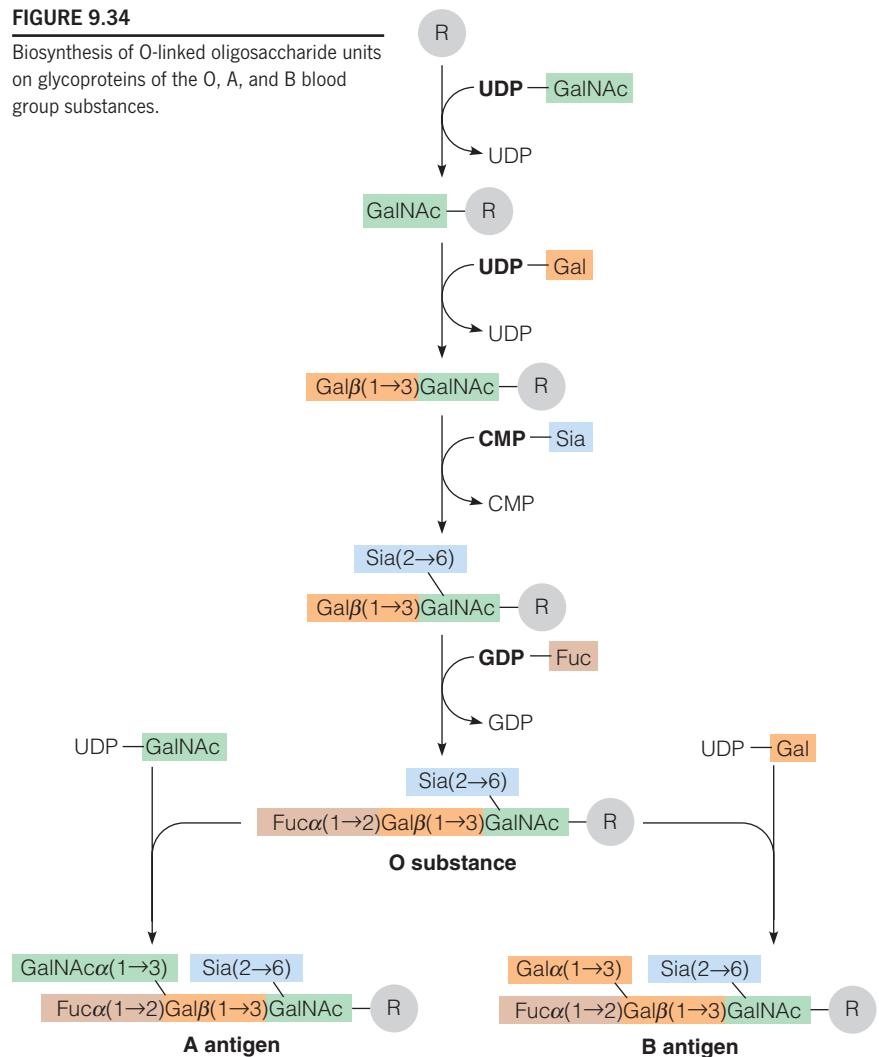

O-Linked Oligosaccharides: Blood Group Antigens

The presence or absence of one or two specific glycosyltransferases involved in O-linked oligosaccharide synthesis determines blood type A, B, AB, or O.

Recall from page 340 that the blood group antigens are oligosaccharides bound to cell-surface proteins or lipids. As shown in Figure 9.34, the biosynthetic pathway begins with transfer of *N*-acetylgalactosamine from UDP-GalNAc to a serine or threonine hydroxyl group on a protein acceptor (R in the figure; the receptor can also be a lipid). Three successive glycosyltransferase reactions follow, leading to

FIGURE 9.34

Biosynthesis of O-linked oligosaccharide units on glycoproteins of the O, A, and B blood group substances.

the tetrasaccharide O substance (not an antigen because it is not immunogenic). On the lower left of the figure, a glycosyltransferase transfers GalNAc from UDP-GalNAc to position 3 of the galactose residue in the O tetrasaccharide, giving the pentasaccharide A antigen. This is the enzyme missing in type B or type O individuals. Similarly, the enzyme shown at the lower right, which transfers Gal from UDP-galactose to the O substance, generates the B antigen, and this enzyme is missing in type A or O individuals. See page 340 for further details.

N-Linked Oligosaccharides: Glycoproteins

Quite a different process is involved in the synthesis of N-linked glycans, common to most glycoproteins. Here, oligosaccharide assembly occurs not on the polypeptide chain but on a *lipid-linked intermediate*. A precursor oligosaccharide is then transferred to a polypeptide chain, which is itself still in the midst of being synthesized. This type of reaction is called **cotranslational**. Finally, the transferred oligosaccharide is subject to further processing steps as it passes from the rough and smooth endoplasmic reticulum through the Golgi apparatus.

The many N-linked glycoproteins of known structure can be categorized according to three basic oligosaccharide structures, as summarized in Figure 9.35: **complex**, **hybrid**, and **high-mannose**. All of the known N-linked glycans have a common core pentasaccharide structure (the boxed areas in the figure; see also page 339).

That core is assembled as part of a larger oligosaccharide intermediate linked to the lipid compound **dolichol phosphate**. Dolichol phosphate is an *isoprenoid* compound, related metabolically to cholesterol (Chapter 10).

Dolichol phosphate

In vertebrate tissues, dolichol contains 18 to 20 branched C₅ (isoprenoid) units with two *trans* double bonds, the remainder being *cis*, except for a saturated terminal isoprene unit. Dolichol is synthesized from the same pathway that yields cholesterol, other sterols, and other isoprenoid compounds (see Chapter 19) and is then phosphorylated.

Synthesis of the Lipid-Linked Intermediate

The first step in glycoprotein synthesis is assembly of a lipid-linked oligosaccharide intermediate, which serves as precursor to all known N-linked oligosaccharides. That process takes place in the endoplasmic reticulum (ER). Figure 9.36 summarizes the biosynthetic pathway leading to this intermediate. The first seven sugars are transferred to dolichol phosphate from nucleoside diphosphate sugars, UDP-GlcNAc and GDP-Man. Each reaction is catalyzed by a separate glycosyltransferase. The first of these enzymes is specifically inhibited by the antibiotic *tunicamycin*, which blocks the reaction of UDP-GlcNAc and Dol-P and hence inhibits the synthesis of all N-linked glycoproteins.

FIGURE 9.35

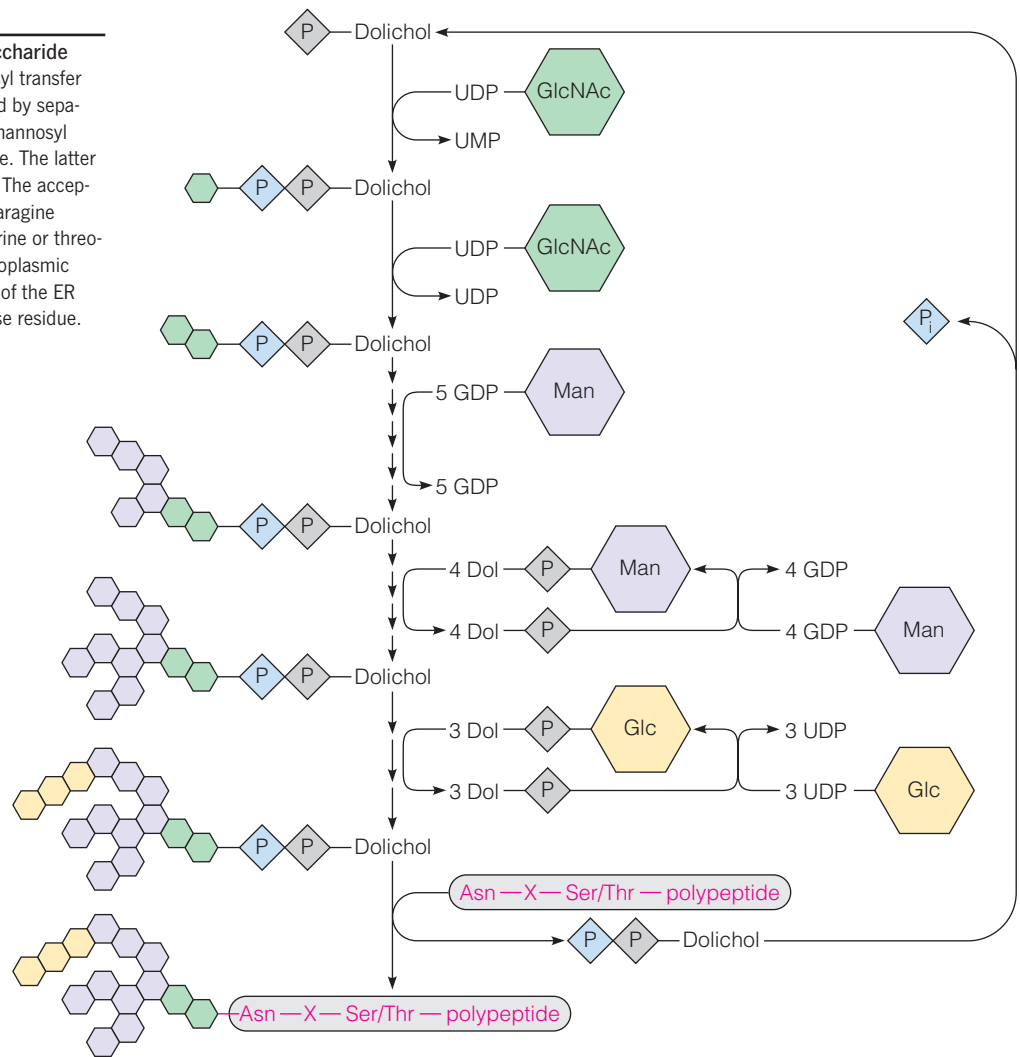

Structures of the major types of asparagine-linked (N-linked) oligosaccharides. The red boxes contain the pentasaccharide core common to all known N-linked structures. Here and in subsequent figures the carbohydrate rings are shown "fused" for simplicity.

The polysaccharide chains of N-linked glycoproteins are formed while linked to a lipid compound, dolichol phosphate.

Modifications of the carbohydrate chains of N-linked glycoproteins help target these proteins to their intra- or extracellular destinations.

FIGURE 9.36

Biosynthesis of the lipid-linked oligosaccharide intermediate. The five sequential mannosyl transfer reactions from GDP-mannose are catalyzed by separate glycosyltransferases, as are the four mannosyl transfers from dolichol phosphate mannose. The latter is synthesized in turn from GDP-mannose. The acceptor site on the polypeptide chain is an asparagine residue two positions to the N side of a serine or threonine. The whole process occurs in the endoplasmic reticulum, with translocation to the lumen of the ER occurring after transfer of the fifth mannose residue.

The next seven glycosyltransferases utilize as substrates not nucleotide-linked sugars but *dolichol-linked* sugars, Dol-P-Man and Dol-P-Glc. These in turn are synthesized from Dol-P plus GDP-Man or UDP-Glc, respectively. During this stage the lipid-linked intermediate (Man₅GlcNAc₂-P-P-Dol, the third intermediate in Figure 9.36) is somehow translocated from the exterior surface of the ER membrane to the luminal, or interior, side. This translocation explains the need for dolichol phosphate-linked sugars for the subsequent glycosylations because the nucleoside diphosphate-linked sugars cannot penetrate to the luminal side of the membrane.

The next step, transfer of the oligosaccharide unit to a polypeptide acceptor, also occurs in the lumen, catalyzed by a specific **oligosaccharyltransferase**. The acceptor site is an asparagine residue in the sequence Asn-X-Ser/Thr, where X is any amino acid. The acceptor site must be accessible in a loop or a bend in the polypeptide chain, which is probably why the transfer occurs simultaneously with translation of the acceptor polypeptide. The three glucosyl residues on the transferred oligosaccharyl unit somehow facilitate the transfer but are not absolutely required. For virtually all glycoproteins, these glucosyl residues are removed in subsequent processing steps.

Processing of the Oligosaccharides

Processing of the oligosaccharide-linked polypeptides begins in the lumen of the rough endoplasmic reticulum (ER) and continues as the nascent glycoprotein moves into the smooth ER and ultimately through various cisternae of the Golgi apparatus. A great variety of oligosaccharide structures is generated during this

**FIGURE 9.37**

Schematic pathway of oligosaccharide processing on newly synthesized glycoproteins. Starting at the bottom of the figure, the oligosaccharide is first transferred from its dolichol phosphate carrier to a polypeptide chain (magenta) while the latter is still being synthesized on the ribosome (step 1). As the peptide chain grows within the endoplasmic reticulum, monosaccharides may be cleaved from the nonreducing ends of the oligosaccharide (step 2). After completion of the polypeptide chain synthesis (step 3), the nascent glycoprotein is carried in a transport vesicle (step 4) to the Golgi apparatus, where further modification of the oligosaccharide occurs. New monosaccharides may be added and others removed in a multistep process involving several transfers to different parts of the Golgi (steps 5–9). The completed glycoprotein is transported to its ultimate destination in a membrane (step 10) or is secreted.

processing. Part of the diversity arises from differences in conformation of the protein moiety in the vicinity of a carbohydrate chain, which affect the accessibility of the chain to glycosyltransferases and **glycosidases** (enzymes that hydrolytically remove sugars). Oligosaccharide chains probably generate recognition sites for targeting each processed compound to different sites both inside and later outside the Golgi, where specific membrane-bound processing enzymes are found (Figure 9.37). In virtually all cases, processing begins (after transfer to a polypeptide chain) with removal of the three glucosyl residues in the rough ER, followed by removal of some of the mannosyl residues in the Golgi apparatus. These processes are critical to the proper folding of some proteins in the ER. Those glycoproteins destined to be of the “complex” type are further processed by addition

of *N*-acetylglucosamine, followed by further trimming of mannosyl residues. Fucosyl, galactosyl, and sialyl residues are added from appropriate nucleotide-linked sugars by specific glycosyltransferases. Comparable pathways lead to the other classes of glycoproteins.

Processing and Intracellular Protein Traffic

As mentioned earlier, oligosaccharide chains help direct glycoproteins to their ultimate intracellular destinations. A graphic demonstration is provided by the generation of mannose-6-phosphate residues during processing of the glycoproteins known as lysosomal acid hydrolases. All known enzymes of this type contain between one and five mannose-6-phosphate units, which evidently help target proteins to, and through, the lysosomal membrane. The role of mannose-6-phosphate in directing protein traffic is confirmed by the existence of a rare and fatal congenital abnormality called **I-cell disease**. In this condition, lysosomes cannot perform their normal function of intracellular digestion because a deficiency of the first glycosyltransferase that generates a mannose-6-phosphate residue causes the acid hydrolase content of lysosomes to be very low. Lysosomal enzymes, manufactured in the ER, cannot be targeted to their ultimate destinations but instead are secreted into the extracellular milieu. When purified and characterized, these enzymes are also found to lack mannose-6-phosphate in their oligosaccharide chains. Our understanding of the molecular recognition involved in targeting these proteins has been advanced by cloning of the gene for the lysosomal membrane mannose-6-phosphate receptor.

Microbial Cell Wall Polysaccharides: Peptidoglycan

Recall from Figure 9.24a that Gram-positive bacteria contain a rigid peptidoglycan cell wall surrounding the cytoplasmic membrane. Gram-negative bacteria, on the other hand, contain a third layer, in addition to the cytoplasmic membrane and peptidoglycan layer. This outer membrane is a complex structure that contains lipoproteins and lipopolysaccharides (see Figure 9.24b). The structural diversity of these macromolecules among different bacterial species is enormous, and space permits introduction of only two of the most interesting pathways. The first pathway, biosynthesis of the peptidoglycan layer in *Staphylococcus aureus*, is of interest for two reasons. First, as mentioned above, the pathway is the site of action of several important antibiotics, notably penicillins. Second, much of the biosynthetic process occurs on the outside of the cell, where there is no ready supply of energy in the form of ATP.

Recall from Figure 9.24 that bacterial peptidoglycans consist of polymeric chains of amino sugars cross-linked by oligopeptide chains to form a huge three-dimensional network in which the entire peptidoglycan layer of a cell is one giant macromolecule. The glycan, or polysaccharide, chain is an alternating polymer of *N*-acetylglucosamine and *N*-acetylmuramic acid, the latter a derivative of *N*-acetylglucosamine. In *S. aureus*, the carboxyl groups of all the *N*-acetylmuramic acid residues are linked to the terminal amino group of the tetrapeptide L-alanyl-D- γ -isoglutaminyl-L-lysyl-D-alanine. Each cross-link takes the form of a pentaglycine chain that joins the carboxyl group of a D-alanine residue to the ϵ -amino group of a lysine residue in an adjacent oligopeptide.

Biosynthesis of the *S. aureus* peptidoglycan can be considered in three distinct stages: (1) synthesis of *N*-acetylmuramylpeptide, (2) formation of the polysaccharide chain by polymerization of *N*-acetylglucosamine and *N*-acetylmuramylpentapeptide, and (3) cross-linking of individual peptidoglycan strands. Much of this pathway was elucidated in studies of the action of penicillin, which kills bacterial cells by blocking synthesis of the cell wall through inhibition of peptidoglycan synthesis.

Synthesis of *N*-Acetylmuramylpeptide

The first stage begins with synthesis of UDP-*N*-acetylmuramic acid from UDP-*N*-acetylglucosamine (see margin). One mole of phosphoenolpyruvate is transferred, giving a three-carbon side chain. This three-carbon group (shown in

magenta) is reduced by NADPH (a biological reductant; see Chapter 12) to give the 3-O-D-lactyl ether of *N*-acetylglucosamine, or *N*-acetylmuramic acid. Then a pentapeptide is built up in stepwise fashion, as shown in Figure 9.38. No messenger RNA template or ribosomes are involved here, as they are in the synthesis of polypeptide chains in protein synthesis. The specificity lies in the sequential actions of a series of ATP-dependent enzymes, which add first L-alanine, followed by D-glutamate (later amidated to *D*-isoglutamine), then L-lysine (linked to the γ -carboxyl group of glutamate), and finally the dipeptide D-alanyl-D-alanine. One of these two D-alanyl residues will be removed at a later step (see Figure 9.39).

Formation of the Peptidoglycan Chain

The next stage is polymerization of *N*-acetylglucosamine and *N*-acetylmuramylpentapeptide to give a linear peptidoglycan chain. This process involves a lipid carrier, **undecaprenol phosphate**, comparable to dolichol phosphate, which we just encountered in the synthesis of N-linked oligosaccharides.

Undecaprenol phosphate

Undecaprenol phosphate is a 55-carbon compound containing 11 isoprenoid C_5 units, with phosphate linked at the terminus. To this phosphate is transferred the *N*-acetylmuramylpentapeptide moiety from UDP-*N*-acetylmuramylpentapeptide (Figure 9.39, step 1). This compound then accepts *N*-acetylglucosamine

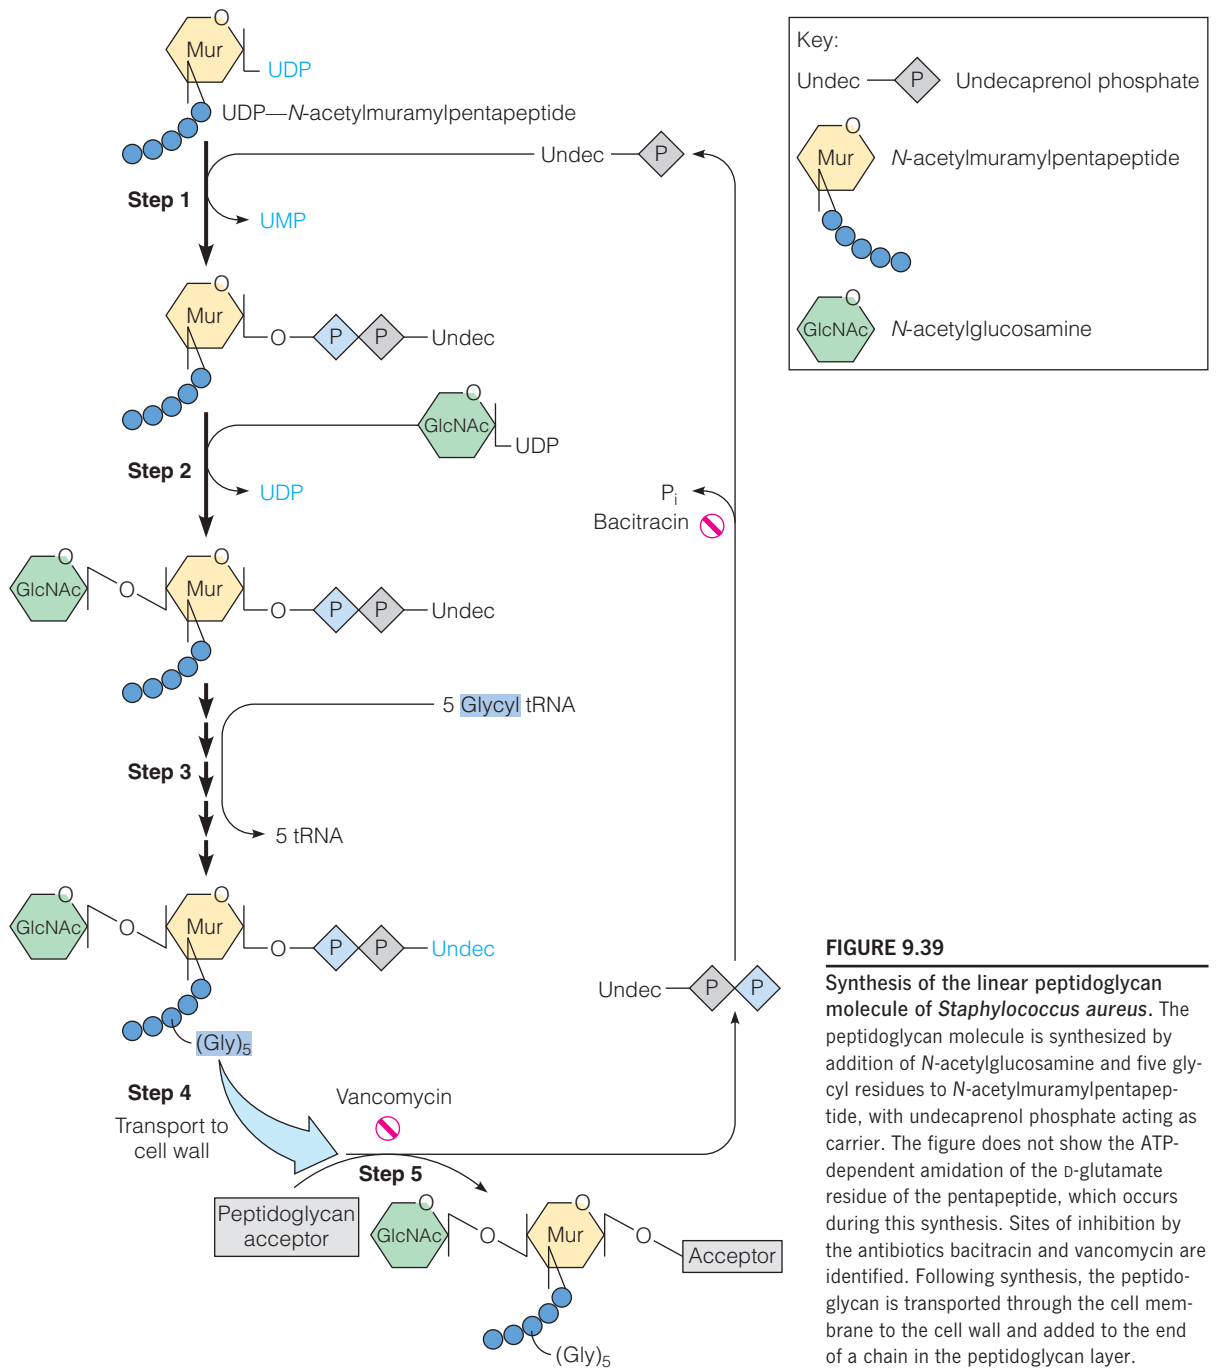

FIGURE 9.38

Biosynthesis of UDP-*N*-acetylmuramylpentapeptide from UDP-*N*-acetylmuramic acid. The sugar structure is shown in outline form.

from UDP-*N*-acetylglucosamine (step 2), followed by the sequential addition of five glycylic residues, from glycylic transfer RNA (step 3). It seems likely that the phospholipid carrier then transports the peptidodisaccharide unit through the membrane at this stage (step 4) because polymerization—addition to the reducing end of a preexisting peptidoglycan chain—occurs on the outside of the cell wall (step 5). The antibiotics *bacitracin* and *vancomycin* inhibit specific steps in this process at the sites shown in Figure 9.39.

Much of the biosynthesis of peptidoglycan oligosaccharide chains occurs outside the cell wall, using activated intermediates synthesized inside the cell.

Cross-linking of Peptidoglycan Strands

Finally, the cross-linking occurs between adjacent chains, also outside the cell. This involves a **transpeptidation** reaction, with the cleavage of one peptide bond providing the energy needed to drive formation of another peptide bond. This means that the free

FIGURE 9.40

The cross-linking reaction in peptidoglycan synthesis (left) and inhibition of the transpeptidase enzyme, E, by penicillin (right). Cross-links between adjacent peptidoglycan chains are formed by the action of a transpeptidase enzyme, as shown at the left. At the right is shown how penicillin, a structural analog of the natural substrate, reacts with the active form of the enzyme to form an inactive covalent complex that resembles the enzyme-substrate complex.

energy needed to drive cross-link formation was built into the structures while they were still accessible to ATP, inside the cell. As shown in Figure 9.40, the transpeptidation involves nucleophilic attack by the free terminal amino group of the pentaglycine chain on the amide carbon linking the terminal D-alanines in an adjacent chain.

The cross-linking reaction is the target for the action of two important classes of antibiotics, the *penicillins* and the *cephalosporins*. Penicillin is thought to react irreversibly with the transpeptidase that catalyzes cross-linking. That enzyme normally forms an acyl-enzyme intermediate, via the penultimate D-alanine of the pentapeptide chain (Figure 9.40, right). Penicillin resembles the terminal dipeptide of this structure to the point that it can also react with the transpeptidase. The reaction is driven in part by the strain built into the four-membered **lactam ring** of penicillin, for that ring opens during the reaction. Penicillin has been widely studied as an “ideal” antibiotic because the cross-linking reaction has no counterpart in animal metabolism. Because the bacterial cell must continue to synthesize cell wall in order to grow and divide, inhibition of a step in this process provides a completely specific way to interfere with the growth of bacterial pathogens. Unfortunately, resistance to penicillin can be acquired. This resistance usually involves the synthesis, directed by an extrachromosomal gene, of **β -lactamase**, an enzyme that hydrolyzes the lactam ring of penicillin and destroys its ability to interfere with peptidoglycan synthesis.

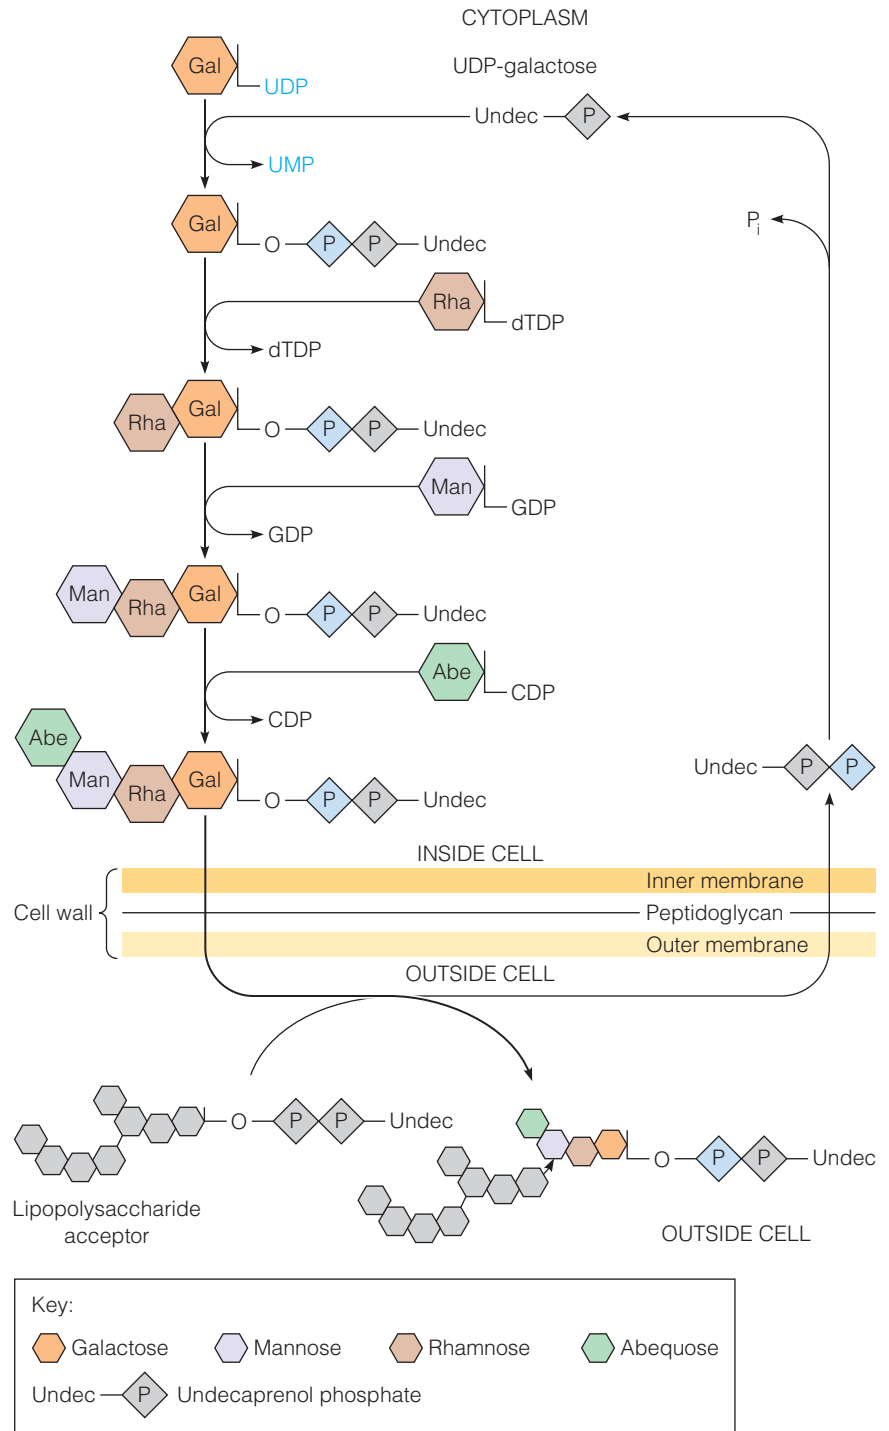

The antibiotic activity of penicillin derives from its interference with extracellular peptidoglycan synthesis.

Microbial Cell Wall Polysaccharides: O Antigens

The final example we consider is the biosynthesis of the O antigen of the Gram-negative *Salmonella typhimurium*. The O antigen (not to be confused with the type O blood group substance of human erythrocytes) is the major lipopolysaccharide component of the outer membrane (see Figure 9.24b). Lipopolysaccharides contain repeating oligosaccharide units that are attached to a basal core polysaccharide. The latter is, in turn, attached to a complex called lipid A. The repeating oligosaccharide units protrude like minute fibers from the outer membrane surface. Because they represent the outer surface of the cell and are composed of specific carbohydrate structures, these fibers provoke strong immune reactions—hence the term *O antigen* that is applied to the fibers. Production of antibodies directed against O antigens represents a primary defense mechanism used by

FIGURE 9.41

Biosynthesis of the repeating oligosaccharide unit of the O antigen of *Salmonella typhimurium*. The first four reactions occur within the inner membrane. Transfer of the activated tetrasaccharide unit to the unactivated terminus of a growing polysaccharide unit occurs on the outside of the outer membrane.

vertebrates against bacterial infection. Bacteria have responded evolutionarily by being able to change O-antigen structure through extremely rapid genetic change, the mechanism of which is not fully understood. Consequently, hundreds of different serotypes (immunologically distinct strains) of bacteria such as *S. typhimurium* exist, each with a different O-antigen repeating unit.

In wild strains of *S. typhimurium* the O-antigen repeating unit has the structure abequeose α (1 \rightarrow 3) mannose α (1 \rightarrow 4) rhamnose β (1 \rightarrow 3) galactose. Note from the margin that abequeose and rhamnose are both deoxy sugars.

The oligosaccharide unit is assembled on a lipid carrier, undecaprenol phosphate, the same carrier we encountered in peptidoglycan synthesis. A lipid-linked tetrasaccharide is assembled within the inner membrane as shown in Figure 9.41 and then passes outward through the outer membrane, where the activated galactose of a lipid-linked polymer attacks the mannose of the activated tetrasaccharide. As noted earlier, this general scheme can lead to tremendous structural diversity among the lipopolysaccharides.

With development of new methods for structural analysis and synthesis of complex carbohydrates, the field has entered a new and exciting phase. As biochemists in the emerging field of glycobiology turn their attention more and more to the relationships between cells and tissues that make for an integrated organism, they are finding that carbohydrates are intimately involved in these processes. Understanding the roles of carbohydrates in these relationships is opening windows upon embryonic development, wound healing, inflammation, immunity, cell growth control, and fundamentally, all biological processes.

SUMMARY

Carbohydrates (or saccharides) are compounds with the stoichiometric formula $(\text{CH}_2\text{O})_n$ or derivatives of such compounds. They are the primary product of photosynthesis, and their oxidation provides a major energy source for both plants and animals. Because most monosaccharides have multiple chiral centers, these saccharides exist as enantiomeric pairs (D and L mirror images) of multiple diastereomers. Monosaccharides may be either aldoses or ketoses. Those containing five or more carbons exist mainly in the form of rings of five (furanose) or six (pyranose) atoms, resulting from internal hemiacetal formation. Such rings exist as α or β anomers and exhibit multiple conformations (e.g., boat and chair) as well.

Important derivatives of monosaccharides include phosphate esters, acids and lactones, alditols, amino sugars, and glycosides. Phosphate esters are important as metabolic intermediates; glycosides represent a large class of compounds formed by elimination of water between a sugar and another hydroxy compound. Oligosaccharides and polysaccharides are formed by making glycosidic links between monosaccharides; the glycosidic linkage is metastable, so enzymes control its hydrolysis in vivo. Polysaccharides serve multiple functions—energy storage (starch and glycogen), structural roles (cellulose, xylans, chitin, glycosaminoglycans, cell wall polysaccharides), and identification tags (the oligosaccharides and polysaccharides on glycoproteins and cell surfaces). The blood group antigens are important examples of the identification function.

Complex glycan chains are assembled by stepwise transfer of monosaccharide units from nucleotide-linked sugars through the action of glycosyltransferases. In the assembly of N-linked glycans, which occurs cotranslationally with synthesis of the polypeptides, the activation of sugars involves not a nucleotide, but the isoprenoid compound dolichol phosphate. Processing of N-linked glycans occurs as nascent glycoproteins are guided through membranes of the endoplasmic reticulum and the Golgi apparatus, en route to their ultimate destinations. The biosynthesis of peptidoglycan components of bacterial cell walls also involves a lipid sugar carrier, undecaprenol phosphate. In Gram-positive bacteria, the cross-linking of peptidoglycan chains is the site of action of penicillin and related antibiotics. In Gram-negative bacteria, the peptidoglycan undergoes rapid changes in structure, to help the bacterium evade immune system detection.

PROBLEMS

1. Draw Haworth projections for the following:

(a) CHO in α -furanose form. Name the sugar.

(b) The L isomer of (a)

(c) α -D-GlcNAc

(d) α -D-Fructofuranose

2. α -D-Galactopyranose rotates the plane of polarized light, but the product of its reduction with sodium borohydride (galactitol) does not. Explain the difference.

3. Provide an explanation for the fact that α -D-mannose is more stable than β -D-mannose, whereas the opposite is true for glucose.

*4. Using data in Table 9.2, calculate the standard state free energy change for the conversion of D-glucose from the α to the β anomer at 40 °C. Can you provide a qualitative explanation for this? Do you think that ΔG arises primarily from an enthalpy or entropy contribution?

5. The disaccharide α , β -trehalose differs from the α , α structure in Figure 9.16a by having an (α 1 \rightarrow β 1) linkage. Draw its structure.

6. A *reducing* sugar will undergo the Fehling reaction (see page 322), which requires a (potential) free aldehyde group. Which of the disaccharides shown in Figure 9.15 are reducing, and which are nonreducing?

7. *Dextrans* are polysaccharides produced by certain species of bacteria. They are glucans, with primarily α (1 \rightarrow 6) linkages and with frequent α (1 \rightarrow 3) branching. Draw a Haworth projection of a portion of a dextran, including one (1 \rightarrow 3) branch point.

8. What is the natural polysaccharide whose repeating structure can be symbolized by $\text{GlcUA}\beta(1 \rightarrow 3)\text{GlcNAc}$, with these units connected by $\beta(1 \rightarrow 4)$ links?

*9. Indicate whether the structures shown are R or S in the absolute system.

*10. The reagent periodate (IO_4^-) oxidatively cleaves the carbon-carbon bonds between two carbons carrying hydroxyl groups. Explain how periodate oxidation might be used to distinguish between methyl glycosides of glucose in the pyranose and furanose forms.

11. Draw (using Haworth projections) the fragments of xylan and glucmannan structure shown on page 333.

12. A research student is attempting to sequence an oligosaccharide attached to an orosomucoid (see Figure 9A.1) from a mutant cell

line. She finds from analysis the presence of Sia, Gal, and GlcNAc. Neuraminidase cleavage succeeds, but β -galactosidase is without effect. Suggest an explanation.

13. One or more of the compounds shown below will satisfy each of the following statements. Not all compounds may be used; some may be used twice. Put the letter(s) in the blank.

(a) Found in chitin. _____

(b) An L-saccharide. _____

(c) The first residue attached to asparagine in N-linked glycans. _____

(d) A uronic acid. _____

(e) A ketose. _____

(a)

(b)

(c)

(d)

(e)

(f)

14. Why, do you suppose, is the influenza virus protein that binds the virus to an infected cell called hemagglutinin? Hemagglutination is the clumping together of red blood cells.

15. The diversity of functional groups on sugars that can form glycosidic bonds greatly increases the information content of glycans relative to oligopeptides. Consider three amino acids, A, B, and C. How many tripeptides can be formed from one molecule of each amino acid? Now consider three sugars—glucose, glucuronic acid, and N-acetylglucosamine. Use shorthand (e.g., $\text{Glc}[1 \rightarrow 4]\text{GlcUA}[1 \rightarrow 4]\text{GlcNAc}$) to represent ten trisaccharides with the sequence Glc-GlcUA-GluNAc . Is your list exhaustive?

16. Are mannose and galactose epimers? Allose and altrose? Gulose and talose? Ribose and arabinose? Explain your answers.

*17. Propose synthetic pathways for the following nucleotide sugar intermediates involved in the biosynthesis of *Salmonella typhimurium* O antigen: UDP-Gal, GDP-Man, CDP-abequose, and dTDP-L-rhamnose.

18. Write the structure of each nucleotide-linked sugar in the pathway shown in Figure 9.33.

TOOLS OF BIOCHEMISTRY 9A

SEQUENCING OLIGOSACCHARIDES

Determining oligosaccharide sequences presents problems similar to, but more difficult than, those encountered in protein sequencing. Because of the many types of monomers that may be encountered and the variety of linkages between them, no single method like the Edman degradation of polypeptides has been devised.

The first step in any sequence analysis is, as in polypeptide analysis, the determination of composition. The oligomer is hydrolyzed in acidic solution, yielding a mixture of monosaccharides. At present, these monosaccharides are almost always separated, identified, and quantified by gas or liquid chromatography.

Determination of the oligosaccharide sequence itself is much more difficult. In the past, chemical methods were extensively used, but they have been largely supplanted by enzymatic cleavage of the oligomer followed by sophisticated methods for identification of the fragments. Researchers are now familiar with a large number of enzymes (**glycosidases**) that catalyze the cleavage of glycosidic bonds between sugar moieties. Some of these enzymes are very specific in their action. They may be divided into two groups: *exoglycosidases*, which remove the terminal residue from an oligosaccharide chain, and *endoglycosidases*, which catalyze cleavage within the chain. A few examples of these enzymes are listed in Table 9A.1.

A simple example of the application of specific glycosidases to sequence determination is shown in Figure 9A.1. The oligosaccharide shown is a portion of one of several oligosaccharides attached to the blood serum protein *orosomuroid*. The residue at the nonreducing end of the chain can be removed by neuraminidase. According to Table 9A.1, the terminal residue must be sialic acid, attached to either Gal or GlcNAc. Sialic acid is found, and subsequent release of Gal by *Streptococcus* β -galactosidase indicates that the next residue is Gal, attached by a 1 \rightarrow 4 linkage to GlcNAc. The latter residue is confirmed by its release by β -N-acetylglucosaminidase. Using modern techniques for analysis, sequences may be determined in this manner at the picomole level.

Although such procedures can often provide definitive information, they are laborious and not always effective. In recent years there has been remarkable development of high-resolution NMR and mass spectrometry as techniques for identification of complex oligosaccharides. The use of these methods is described in the References, but is too technical to be presented here.

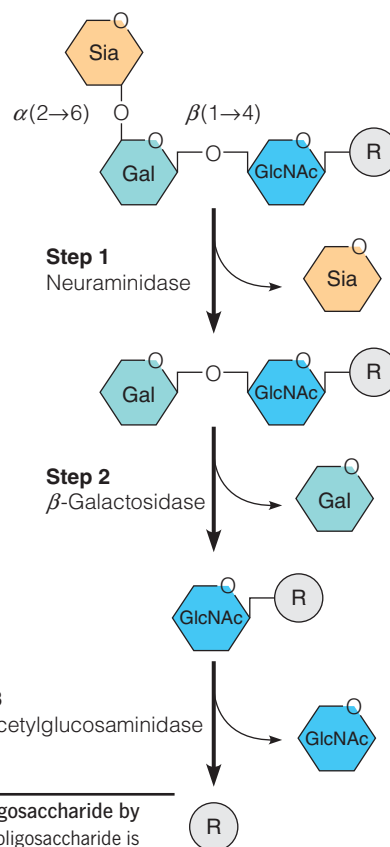

FIGURE 9A.1
Cleavage of an oligosaccharide by glycosidases. The oligosaccharide is attached to the protein orosomuroid (R).

CHAPTER 10

Lipids, Membranes, and Cellular Transport

The lipids are a structurally and functionally diverse group of molecules. They are generally hydrophobic, although many also possess polar or charged groups in addition to a hydrocarbon core. Given their structural diversity, lipids carry out multiple functions. Primary among these are energy storage, signaling, and formation of membrane structures. In this chapter we focus on the structures of lipid molecules, the general features of membranes formed from lipids, and selective transport across membranes. The roles of lipids as energy stores and signaling molecules are described in great detail in Chapters 17, 19, and 23. In those chapters, we also discuss lipid biosynthesis as well as lipid transport and the lipid–protein complexes, or *lipoproteins*, involved in that process.

The largest fraction of the lipids in most cells is used to form **membranes**, the partitions that divide compartments from one another and separate the cell from its surroundings. Cellular membranes are much more than passive walls, for they contain highly selective gates that control the passage of materials in specific directions. It is this property of *selective membrane permeability* that allows each part of the cell to carry out its specific operations. It is difficult to imagine the organization and evolution of complex multicellular organisms without membranes. Membranes establish order (by compartmentation) and allow free energy to be stored in the form of concentration gradients (e.g., proton gradients in mitochondria, or ion gradients in nerve cells). Thus, membranes have a vital role in maintaining the living state, which is essentially an ongoing campaign against entropy and the tendency to move toward chemical equilibrium.

The Molecular Structure and Behavior of Lipids

Compared to the other classes of biomolecules we have considered in earlier chapters, lipids are not generally water-soluble, due to the large portion of their structure that is hydrocarbon. This means that lipids are rarely found free in solution, rather, they are either in complex with soluble protein transporters, or part of

Lipid molecules tend to be insoluble in water, but they can associate to form water-soluble structures, such as micelles, vesicles, and bilayers.

A simplified representation of an amphipathic lipid molecule

higher order assemblies that sequester the hydrophobic surface area from the surrounding aqueous environment.

Unlike the amino acids in proteins, the nucleotides in nucleic acids, and the monosaccharides in complex carbohydrates, lipids do not form large covalent polymers. Rather, they tend to associate with each other through noncovalent forces. For example, the lipids that make up membranes are usually characterized by the kind of structure shown in the margin: a polar, hydrophilic “head” connected to a larger nonpolar, hydrophobic hydrocarbon “tail.” Such lipids in an aqueous environment tend to associate together by noncovalent interactions for two fundamental reasons. Just as nonpolar groups in proteins associate via an entropy-driven hydrophobic effect, so do the nonpolar tails of lipids. A second stabilizing force comes from the van der Waals interactions between the hydrocarbon regions of the molecules.

The polar, hydrophilic head groups of membrane lipids tend to associate with water. Such lipids are prime examples of the kind of amphipathic substance described in Chapter 2. The amphipathic nature of membrane lipids has a number of consequences, including the formation of surface monolayers, bilayers, micelles, and vesicles by lipids in contact with water (see Figure 2.15, page 38). From a biological point of view, the most important of these consequences is the tendency of lipids to form micelles and membrane bilayers. Exactly what kind of structure is formed when a lipid is in contact with water depends on the specific molecular structure of the hydrophilic and hydrophobic parts of that lipid molecule. Thus, it is appropriate that we now examine the structure of some of the major types of lipids.

Fatty Acids

The simplest lipids are the **fatty acids**, which are also constituents of many more complex lipids. Their basic structure exemplifies the general lipid model described above: A hydrophilic carboxylate group is attached to one end of the hydrocarbon chain, which contains typically 12 to 24 carbons. An example is *stearic acid*, which is widely distributed in organisms. We show it in Figure 10.1 as the ionized form, the *stearate* ion. Stearic acid is an example of a **saturated** fatty acid, one in which the carbons of the tail are all saturated with hydrogen atoms (i.e., no C=C double bonds). A number of the more biologically important saturated fatty acids are listed in Table 10.1. Note that each has a common name (such as stearic acid) and a systematic name (in this case, octadecanoic acid).

Many important naturally occurring fatty acids are **unsaturated**—that is, they contain one or more double bonds (see Table 10.1). One such example is *oleic acid* (or oleate), which is found in many animal fats (Figure 10.1). In most of the

FIGURE 10.1

Structures of the ionized forms of some representative fatty acids. Hydrophilic portions (head groups) of the molecules are indicated by a pale blue background in the models, hydrophobic portions (tails) by yellow. (a) Stearate (the anion of stearic acid) is a saturated fatty acid. (b) Oleate is an unsaturated fatty acid with one *cis* double bond. (c) Alternate representations for (a) and (b).

TABLE 10.1 Some biologically important fatty acids

Common Name	Systematic Name	Abbreviation	Structure	Melting Point (°C)
Saturated Fatty Acids				
Capric	Decanoic	10:0	$\text{CH}_3(\text{CH}_2)_8\text{COOH}$	31.6
Lauric	Dodecanoic	12:0	$\text{CH}_3(\text{CH}_2)_{10}\text{COOH}$	44.2
Myristic	Tetradecanoic	14:0	$\text{CH}_3(\text{CH}_2)_{12}\text{COOH}$	53.9
Palmitic	Hexadecanoic	16:0	$\text{CH}_3(\text{CH}_2)_{14}\text{COOH}$	63.1
Stearic	Octadecanoic	18:0	$\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$	69.6
Arachidic	Eicosanoic	20:0	$\text{CH}_3(\text{CH}_2)_{18}\text{COOH}$	76.5

naturally occurring unsaturated fatty acids, the orientation about double bonds is *cis* rather than *trans*. This orientation has an important effect on molecular structure, for each *cis* double bond inserts a bend into the hydrocarbon chain. Keep in mind, however, that although Figure 10.1 depicts the molecules as extended structures, there is freedom of rotation about each single bond in the hydrocarbon chain. Thus, many conformations are possible.

Most of the naturally occurring fatty acids have an even number of carbon atoms because they are synthesized by sequential additions of a two-carbon precursor (see Chapter 17). Although the hydrocarbon chains are linear in most fatty acids, some fatty acids (found primarily in bacteria) contain branches or even cyclic structures (Table 10.1).

To provide a more convenient and definitive way of referring to fatty acids, a system of abbreviations has been developed; it is illustrated in Table 10.1. The rules are as follows: The number before the colon gives the total number of carbons, and the number after the colon gives the count of double bonds. The configurations and positions of double bonds are indicated by *c* (*cis*) or *t* (*trans*) followed by Δ and one or more numbers. These numbers denote the carbon atom (the carboxylic carbon is designated as “1”) where each double bond starts. Thus, oleic acid is designated by 18:1*c*Δ9 and linolenic by 18:3*c*Δ9, 12, 15. With several bonds, linolenic acid is an example of a **polyunsaturated fatty acid** or **PUFA**.

Animals generally do not produce via biosynthesis all the PUFAs they need for proper cellular function; thus, these fatty acids must be part of their diet. The nutritional value and consequences of ingesting various fats are discussed in Chapter 17 in the context of fuel metabolism. It should be mentioned here that in contrast to the nomenclature rules listed above, nutritionists use an alternative

Membrane lipids are amphipathic. They tend to form surface monolayers, bilayers, micelles, or vesicles when in contact with water.

Most naturally occurring fatty acids contain an even number of carbon atoms. If double bonds are present (unsaturation), they are usually *cis*.

Fats, or triacylglycerols, are triesters of fatty acids and glycerol. They are the major long-term energy storage molecules in many organisms.

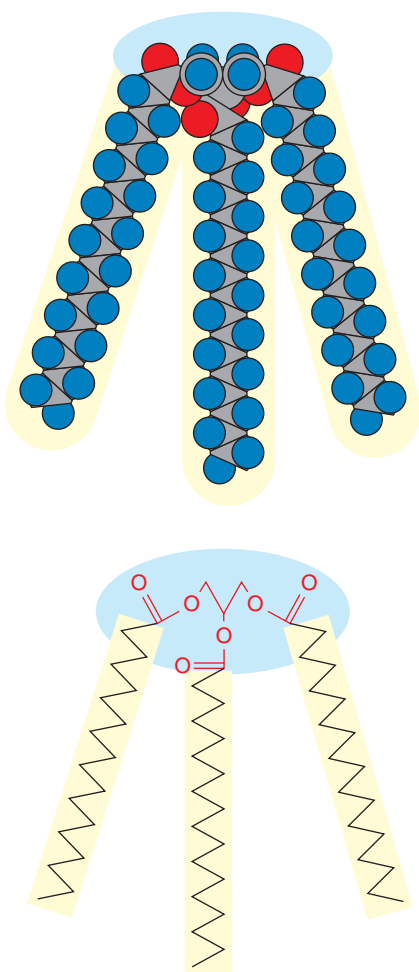

FIGURE 10.2

The structure of tristearin, a fat. Tristearin is a triacylglycerol (fat) composed of glycerol and three stearate molecules.

naming convention in which the locations of the C=C bonds are referenced to the “omega carbon” (ω -carbon; i.e., the last C atom in the chain), where the α -carbon is the —COO^- carbon. In this system, the so-called ω -3 fatty acids have a C=C bond that includes the third C atom from the ω carbon. Linolenic acid is one example of an ω -3 fatty acid.

The fatty acids are weak acids, with $\text{p}K_a$ values averaging about 4.5:

Thus, these acids exist in the anionic form (RCOO^-) at physiological pH. Due to this hydrophilic charge and the long hydrophobic tail, fatty acids behave like amphipathic substances when dissolved in water. As shown in Figure 2.15, they tend to form **monolayers** at the air–water interface, with the carboxylate groups immersed in water and the hydrocarbon tails out of water.

If fatty acids are shaken with water, they will make spherical **micelles**, in which the hydrocarbon tails cluster together within the structure and the carboxylate heads are in contact with the surrounding water. If fatty acids are mixed with water *and* an oily or greasy substance (for example, a hydrocarbon), the micelles will form around the oil droplets, emulsifying them. In this way soaps and synthetic detergents solubilize grease.

Although the fatty acids play important roles in metabolism, large quantities of the free acids or their anions are not found in living cells. Instead, these compounds almost always occur as constituents of more complex lipids. We now turn to consideration of some of these classes of biologically important lipid molecules.

Triacylglycerols: Fats

The long hydrocarbon chains of fatty acids are extraordinarily efficient for energy storage because they contain carbon in a reduced form and will therefore yield a large amount of energy on oxidation. They are, in fact, much more efficient energy stores than are carbohydrates (quantitative analysis of this difference is made in Chapter 17). Because they are hydrophobic, fat stores are also anhydrous, whereas glycogen is hydrated. Thus, a gram of stored fat yields much more metabolic energy than a gram of stored carbohydrate. For these reasons, lipids are used by many organisms, including humans, for storage of metabolic energy. A typical human stores sufficient calories in fats to survive for several weeks (assuming access to water).

Storage of fatty acids in organisms is largely in the form of **triacylglycerols**, or **triglycerides**, or simply, **fats**. These substances are *triesters* of fatty acids and **glycerol**; the general formula is shown here.

Here R_1 , R_2 , and R_3 correspond to the hydrocarbon tails of various fatty acids. We have depicted the structure with the hydrophobic chains to the right, according to our convention. This convention does not indicate stereochemical configuration (the correct stereochemical configuration around each C atom in the glycerol moiety is depicted in Figure 10.7a, page 366). As a particular example, if $\text{R}_1 = \text{R}_2 = \text{R}_3 = (\text{CH}_2)_{16}\text{CH}_3$, the hydrocarbon tail of stearic acid, the molecule is *tristearin* (Figure 10.2). Triacylglycerols with the same fatty acid esterified at each position are called “simple fats.” Most triacylglycerols, however, are “mixed fats” that

contain a mixture of fatty acids, often including unsaturated ones. Table 10.2 lists the fatty acid composition of some naturally occurring fats.

Comparison of common experience with these fats and data in the table reveals an interesting correlation. Fats rich in unsaturated fatty acids (like olive oil) are liquid at room temperature, whereas those with a higher content of saturated fatty acids (like butter) are more solid. Indeed, a wholly saturated fat yields a firm solid, especially if the hydrocarbon chains are long. This is made clear from the melting point data in Table 10.1. The reason is simple: Long saturated chains can pack closely together, thereby increasing the number of van der Waals contacts to form regular, semicrystalline structures. In contrast, the kind of bend imposed by one or more *cis* double bonds (see Figure 10.1b) makes molecular packing less regular, and therefore more dynamic. Indeed, partial **hydrogenation** of unsaturated fat oils (like corn oil) is used commercially to convert them to firmer fats, which can be used as butter substitutes such as oleomargarine or to stabilize them against spoilage. Oxidative cleavage of the double bonds in fats yields volatile aldehydes and carboxylic acids, which contribute to the rancid odor of spoiled fats. Hydrogenation reduces such bonds to single bonds, but it also converts some *cis* double bonds to *trans* double bonds, yielding so-called *trans* fats. Because *trans* fats have been associated with an elevated risk of cardiovascular disease, the FDA requires food packaging to list the content of *trans* fats and several cities have banned use of *trans* fats for cooking in restaurants.

Esterification with glycerol diminishes the hydrophilic character of the head groups of the fatty acids. As a consequence, triacylglycerols are water-insoluble. Fats accumulated in plant and animal cells therefore form as oily droplets in the cytoplasm. In **adipocytes**, animal cells specialized for fat storage, almost the entire volume of each cell is filled by a fat droplet (Figure 10.3). Such cells make up most of the adipose (fatty) tissue of animals.

Fat storage in animals serves three distinct functions:

1. **Energy production.** As described in Chapter 17, most fat in most animals is oxidized for the generation of ATP, to drive metabolic processes.
2. **Heat production.** Some specialized cells (in “brown fat” of warm-blooded animals, for example) oxidize triacylglycerols for heat production, rather than to make ATP.
3. **Insulation.** In animals that live in a cold environment, layers of fat cells under the skin serve as thermal insulation. The blubber of whales is one obvious example.

Soaps and Detergents

If fats are hydrolyzed with strong bases such as NaOH or KOH (in earlier times, wood ashes were used), a *soap* is produced. This process is called **saponification**. The fatty acids are released as either sodium or potassium salts, which are fully ionized. However, as cleansers, soaps have the disadvantage that the fatty acids are precipitated by the calcium or magnesium ions present in “hard” water, forming a scum and destroying the emulsifying action. Synthetic detergents have been devised that do not have this defect. One class is exemplified by *sodium dodecyl sulfate* (SDS):

The salts of dodecyl sulfate with divalent cations (i.e., Ca^{2+} and Mg^{2+}) are more soluble. Recall that SDS is widely used in forming micelles about proteins for gel electrophoresis (see Tools of Biochemistry 6B, page 228). There are also synthetic nonionic detergents, like *Triton X-100*:

TABLE 10.2 Composition of some natural fats in percent of total fatty acids

Number of C Atoms in Chain	Percent Present in:		
	Olive Oil	Butter ^a	Beef Fat
Saturated			
4–12	2	11	2
14	2	10	2
16	13	26	29
18	3	11	21
Unsaturated			
16–18	80	40	46

^aNumbers do not total 100% because the substance contains small amounts of other fatty acids.

FIGURE 10.3

Adipocytes. Adipocytes, or animal fat storage cells, make up a large part of adipose tissue. The designations MFC and VSFC correspond to “mature fat cell” and “very small fat cell,” respectively.

**FIGURE 10.4**

Structure of a typical wax. Waxes are formed by esterification of fatty acids and long-chain alcohols. The small head group can contribute little hydrophilicity, in contrast to the significant hydrophobic contribution of the two long tails.

The major lipid components of biological membranes are glycerophospholipids, sphingolipids, glycosphingolipids, and glycolipids.

The hydrophilic head group here is the polyoxyethylene group (shown in blue), which in the commercial product averages about 9.5 residues in length.

Waxes

In the natural **waxes**, a long-chain fatty acid is esterified to a long-chain alcohol (Figure 10.4). This yields a head group that is only weakly hydrophilic, attached to two long hydrocarbon chains. As a consequence, the waxes are completely water-insoluble. In fact, they are so hydrophobic that they often serve as water repellents, as in the feathers of some birds and the leaves of some plants. In some marine microorganisms, waxes are used instead of other lipids for energy storage. In beeswax, they serve a structural function. As with the triacylglycerols, the firmness of waxes increases with chain length and degree of hydrocarbon saturation.

The Lipid Constituents of Biological Membranes

All biological membranes contain lipids as major constituents. The molecules that play the dominant roles in membrane formation all have highly polar head groups and, in most cases, two hydrocarbon tails. This composition makes molecular sense: If a large head group is attached to a single hydrocarbon chain, the molecule is wedge-shaped and will tend to form spherical micelles (Figure 10.5a). A double tail yields a roughly cylindrical molecule (Figure 10.5b); such cylindrical molecules can easily pack in parallel to form extended sheets of **bilayer** membranes with the hydrophilic head groups facing outward into the aqueous regions on either side (Figure 10.5c). The four major classes of membrane-forming lipids—glycerophospholipids, sphingolipids, glycosphingolipids, and glycolipids—share this type of cylindrical molecular structure. They differ principally in the nature of the head group. We shall describe a few examples of each class.

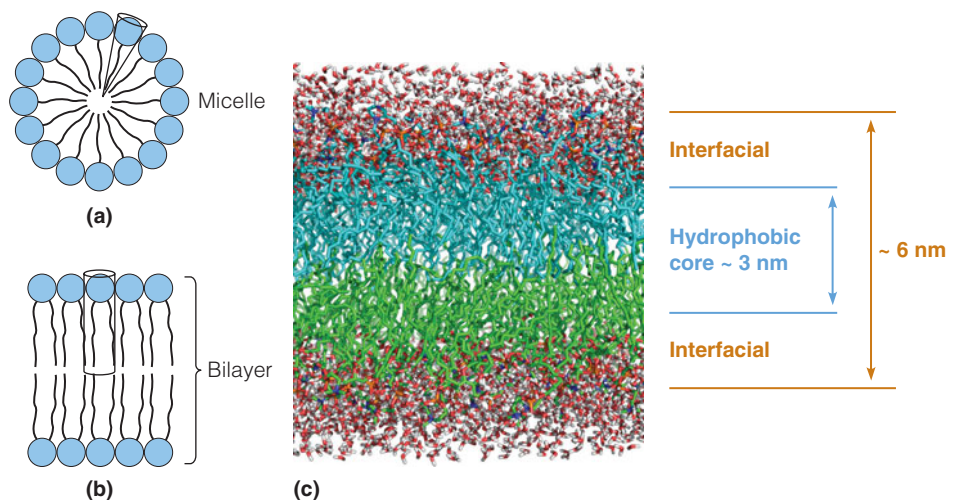

The bilayer is roughly 6 nm thick, with ~1.5 nm of interface on either side of the ~3 nm hydrophobic core (Figure 10.5c). The interface region is composed of the lipid head groups and associated water molecules. Beyond the interface is the bulk water.

Glycerophospholipids

Glycerophospholipids (also called *phosphoglycerides*) are the major class of naturally occurring **phospholipids**, lipids with phosphate-containing head groups. These compounds make up a significant fraction of the membrane lipids throughout the bacterial, plant, and animal kingdoms. Like the other biomolecular building

FIGURE 10.5

Phospholipids and membrane structure. (a) Fatty acids are wedge-shaped and tend to form spherical micelles. (b) Phospholipids are more cylindrical and pack together to form a bilayer structure. (c) A computer simulation of a phospholipid bilayer showing approximate boundaries for the hydrophobic core, the interface regions, and the bulk water (above and below the interfacial regions). blocks we have considered, lipids possess a specific stereochemistry. Glycerol does not possess any stereocenters; however, derivatization of one or the other of the equivalent $\text{—CH}_2\text{OH}$ groups bonded to the central carbon atom will generate an asymmetric center with a defined stereochemistry at C2 (Figure 10.6a). Thus, glycerol is an example of a **prochiral** molecule—it has no stereocenter until it is derivatized. As shown in Figure 10.6b, the two conventions for assigning stereochemistry that we have discussed so far, the *D/L* and the *R/S* systems, do not assign a uniform carbon numbering to glycerol derivatives. To avoid potential confusion in naming such compounds, the *sn* (stereospecific numbering) system has been developed (Figure 10.6c).

As shown in Figure 10.6a, we can define the carbon atoms in the two $\text{—CH}_2\text{OH}$ groups as **pro-*S*** or **pro-*R*** based on the stereochemistry of the product that results from derivatization of one or the other of these groups. Consider *R*-glycerol phosphate, which can be described equally well as *L*-glycerol-3-phosphate or *D*-glycerol-1-phosphate, depending on which carbon is designated as #1 (Figure 10.6b). As we consider more complex lipids it is desirable to have a carbon numbering convention that is referenced to a single stereochemical representation. The *sn* system provides this by assigning C1 to the pro-*S* carbon of glycerol (Figure 10.6c). Following this convention, all glycerophospholipids can be considered to be derivatives of *sn*-glycerol-3-phosphate. The general structure and stereochemistry for a glycerophospholipid is shown in Figure 10.7a. Because the groups at C1 and C2 are generally hydrophobic and make up the interior of the

Glycerol-3-phosphate

TABLE 10.3 The hydrophilic groups^a that distinguish common glycerophospholipids

Name of Glycerophospholipid	R_3 (in Figure 10.7)
Phosphatidic acid	H— (ionized at neutral pH)
Phosphatidylethanolamine (PE)	$\text{H}_3\text{N}^+ - \text{CH}_2 - \text{CH}_2 -$
Phosphatidylcholine (PC)	$(\text{CH}_3)_3\text{N}^+ - \text{CH}_2 - \text{CH}_2 -$
Phosphatidylserine (PS)	$\text{H}_3\text{N}^+ - \text{C}(\text{H})(\text{COO}^-) - \text{CH}_2 -$
Phosphatidylinositol (PI)	

^aThese are the R_3 groups in Figure 10.7. In addition to this variation, there is also a great deal of variation in the hydrocarbon tails (R_1 , R_2 groups).

bilayer, and the group at C3 is polar and on the outside face of the bilayer, we will draw these groups in the manner shown in Figure 10.7b, with the hydrophobic tails drawn to the right and the hydrophilic head group to the left.

Typically, the groups R_1 and R_2 are acyl side chains derived from the fatty acids; often R_1 is saturated, and R_2 is unsaturated. The hydrophilic R_3 head group varies greatly, and confers the greatest variation in properties among the glycerophospholipids. A gallery of the most common glycerophospholipid head groups is shown in Table 10.3, and their relative abundances in some membranes are given in Table 10.4. The simplest member of the group, **phosphatidic acid**, is only a minor membrane constituent; its principal role is as an intermediate in the synthesis of other glycerophospholipids or triglycerides (described in Chapter 19). The names of glycerophospholipids are derived from phosphatidic acid: *phosphatidylcholine*, *phosphatidylethanolamine*, and so on. As Table 10.3 shows, the glycerophospholipids have very polar head groups. The net charge on a phospholipid is

TABLE 10.4 Lipid composition of some biological membranes

Lipid	Percentage of Total Composition in			
	Human Erythrocyte Plasma Membrane	Human Myelin	Bovine Heart Mitochondria	<i>E. coli</i> Cell Membrane

a function of the charge (if any) on the R_3 group in combination with the negatively charged phosphodiester in the head group. Because the hydrocarbon tails are derived from the naturally occurring fatty acids in various combinations, an enormous variety of glycerophospholipids exists. For example, the erythrocyte membrane contains molecules with hydrocarbon chains of 16 to 24 carbons, with 0 to 6 double bonds. Such variation in membrane composition allows “fine-tuning” of membrane properties for the diverse functions that different membranes must perform.

Sphingolipids and Glycosphingolipids

A second major class of membrane constituents is built on the amino alcohol **sphingosine**, rather than on glycerol. The structure of sphingosine includes a long-chain hydrophobic tail, so it requires the addition of only one fatty acid to make it suitable as a membrane lipid. If a fatty acid is linked via an amide bond to the NH_2 group, the class of **sphingolipids** referred to as **ceramides** is obtained:

A wide variety of sphingolipids is built upon a sphingosine core.

Ceramides consist of sphingosine and a fatty acid. Further modification, by addition of groups to the C-1 hydroxyl of sphingosine, leads to a variety of other sphingolipids. An especially important example is *sphingomyelin*, in which a *phosphocholine* group is attached to the C-3 hydroxyl.

In some of the membrane lipids built on sphingosine, the head group contains saccharides. Lipids containing saccharide groups go under the general name of **glycolipids**. The **glycosphingolipids** constitute the third major class of membrane lipids. Their general structure is shown in the margin. In addition to being constituents of the ABO blood group antigens (described in Chapter 9), they include such molecules as the **cerebrosides** (monoglycosyl ceramides) and **gangliosides**, anionic glycosphingolipids containing one or more sialic acid residues. Examples of these are shown in Figure 10.8. As the names of these compounds suggest, they are especially common in the membranes of brain and nerve cells.

(a) Galactosylceramide

(b) GalNAcβ(1→4)Galβ(1→4)Glcβ(1→1)ceramide or, Ganglioside GM₂**FIGURE 10.8**

Examples of glycosphingolipids. (a) A cerebroside, an important constituent of brain cell membranes. (b) A ganglioside. This particular ganglioside, called GM₂ or the Tay-Sachs ganglioside, accumulates in neural tissue of infants with Tay-Sachs disease. The defect responsible for this inherited condition is the lack of an enzyme that normally cleaves the terminal GalNAc (see Chapter 19).

Glycoglycerolipids

Another class of lipids, less common in animal membranes but widespread in plant and bacterial membranes, are the **glycoglycerolipids**, exemplified by **monogalactosyl diglyceride**:

This compound may actually be the most abundant of all polar lipids, for it constitutes about half the lipid in chloroplast membranes (see Chapter 16). Such lipids are also abundant in archaea, where they are the major membrane components.

Cholesterol

One important lipid constituent of many membranes bears little superficial resemblance to the compounds we have studied so far. This substance is **cholesterol**, the structure of which is shown in Figure 10.9. Cholesterol is a member of a large group of substances called **steroids**, which include a number of important hormones, among them the sex hormones of higher animals. In fact, cholesterol is the precursor for many of these substances. Its role in these syntheses is discussed in Chapter 19, along with a detailed description of other steroids and their functions in cell signaling. Another important and diverse class of signaling molecules derived from lipids is the **eicosanoids**, which are derived from arachidonic acid (Table 10.1). These are potent activators of a wide range of physiological functions, including inflammation, blood clotting, blood pressure regulation, and reproduction. The biosynthesis and activities of the steroids and eicosanoids are described in Chapter 19.

Cholesterol is a weakly amphipathic substance because of the hydroxyl group at one end of the molecule. As the conformational structure in Figure 10.9b shows, the fused cyclohexane rings in cholesterol are all in the chair conformation. This makes cholesterol a bulky, rigid structure as compared with other hydrophobic membrane components such as the fatty acid tails; thus, the cholesterol molecule tends to disrupt regular packing of fatty acid tails in membrane structure. This property can have a major effect because cholesterol constitutes 25% or more of the lipid content in some membranes (see Table 10.4). Such changes in membrane structure can have, as we shall see, profound effects on such properties as membrane stiffness and permeability. Other steroids are also found in membranes; for example, *lanosterol* (page 798) is prominent in plant cell membranes.

The molecules described above constitute the major portion of membrane lipids in most organisms. However, one of the “three kingdoms” of organisms—the archaea—are unique in having glycoacyl lipids as their major membrane lipids.

The Structure and Properties of Membranes and Membrane Proteins

The membranes of living cells are remarkable bits of molecular architecture, with many and varied functions. To say that a membrane is essentially a phospholipid bilayer is a gross oversimplification. To be sure, the phospholipid bilayer, as depicted in Figure 10.5b and c, forms the basic structure, but there is much more to the membranes found in living cells. Some of the complex features of a typical eukaryotic cell membrane are shown in Figure 10.10. An important feature of cellular membranes is the wide variety of specific proteins contained within the lipid bilayer or bound to its surface. Many of these proteins carry oligosaccharide groups that project into the surrounding aqueous medium. Other oligosaccharides are carried by glycolipids, with the lipid portions inserted in the membrane. The two sides of the bilayer are usually different, both in lipid composition and in the placement and orientation of proteins and oligosaccharides.

The protein content varies greatly among different kinds of membranes (see Table 10.5) and appears to be directly related to the functions a particular membrane must carry out. Mitochondrial inner membranes and bacterial cell-wall membranes, which carry out many functions, are about 75% protein. The myelin of nerve fibers, which acts primarily as an electrical insulator, has a much lower protein content (~20%). As a rule of thumb, a typical membrane is roughly 60% protein and 40% lipid by mass.

Much of our current understanding concerning biological membranes is based upon the **fluid mosaic model** proposed by S. J. Singer and G. L. Nicolson in 1972. This is the model depicted in Figure 10.10. The fluid, asymmetric lipid bilayer carries within it a host of proteins. Some of them, called **peripheral membrane**

Cholesterol, a component of many animal membranes, influences membrane fluidity by its bulky structure.

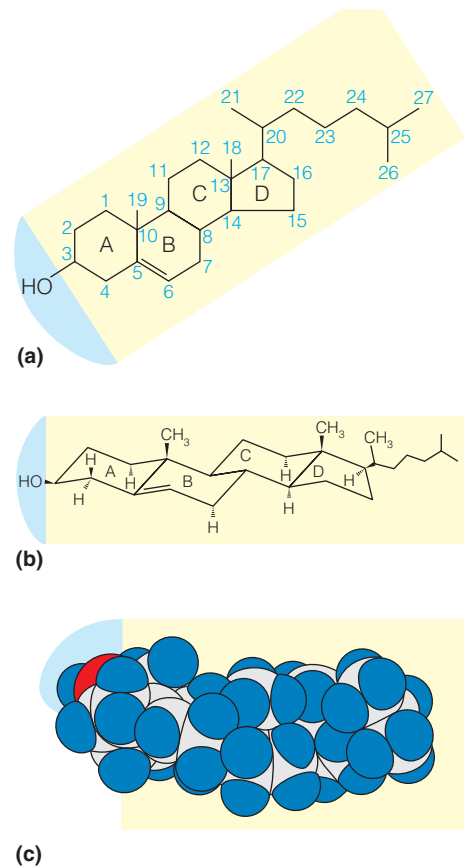

FIGURE 10.9

Cholesterol. (a) Structural formula. (b) Conformational model. (c) Space-filling model.

FIGURE 10.10

Structure of a typical cell membrane. In this schematic view, a strip of the plasma membrane of a eukaryotic cell has been peeled off. Proteins are embedded in and on the phospholipid bilayer; some of them are glycoproteins, carrying oligosaccharide chains. The membrane is about 6 nm thick. Most membranes are more densely packed with proteins than is shown here.

According to the fluid mosaic model, a membrane is a fluid mixture of lipids and proteins.

Peripheral membrane proteins are associated with one side of the bilayer and can be separated from the membrane without disrupting the bilayer. Integral membrane proteins are more deeply embedded in the bilayer and can only be extracted under conditions that disrupt membrane structure. Many integral membrane proteins extend through the bilayer.

proteins, are exposed at only one membrane face or the other. They are held to the membrane by interaction with lipid heads or integral membrane proteins. The **integral membrane proteins** are largely buried within the membrane but are usually exposed on both faces. Integral proteins are frequently involved in transmitting either specific substances or transducing chemical signals through the membrane. The whole membrane is a mosaic of lipids and proteins. Current research suggests that the membrane surface is more crowded, and the distribution of proteins in membranes is more highly organized than is depicted in Figure 10.10.

Motion in Membranes

A functioning biological membrane is not a rigid, frozen structure. In fact, most of the lipid and protein components are in constant motion. This motion can be demonstrated in a direct and dramatic way. If human and mouse cells, each carrying a distinctive fluorescent marker in its plasma membrane, are fused together, the two kinds of markers gradually become intermixed (Figure 10.11). This

**FIGURE 10.11**

Experimental demonstration of membrane fluidity. When cells with surface membrane protein marked by fluorescent tags are induced to fuse, the proteins gradually mix over the fused surface.

TABLE 10.5 Protein, lipid, and carbohydrate content of some membranes

Membrane	Percent by Weight		
	Protein	Lipid	Carbohydrate
Myelin	18	79	3
Human erythrocyte (plasma membrane)	49	43	8
Bovine retinal rod	51	49	0
Mitochondria (outer membrane)	52	48	0
Amoeba (plasma membrane)	54	42	4
Sarcoplasmic reticulum (muscle cells)	67	33	0
Chloroplast lamellae	70	30	0
Gram-positive bacteria	75	25	0
Mitochondria (inner membrane)	76	24	0

demonstrates that *lateral diffusion* (parallel to the membrane surface) can occur in the membrane. The rapidity with which such two-dimensional diffusion can occur depends on the membrane fluidity, which in turn depends on temperature and lipid composition. Under physiological conditions, the average time required for a phospholipid molecule to wander completely around a cell is on the order of seconds to minutes; membrane proteins also move, but more slowly, and their range may be constrained by other structural features of the membrane.

Motion in Synthetic Membranes

The effects of temperature and composition on fluidity can be most simply studied using artificial membranes containing only one or a few kinds of lipids and no proteins (see Tools of Biochemistry 10A). Figure 10.12a depicts the behavior of a membrane made entirely from phosphatidylcholine carrying two 16-carbon saturated chains (PC-16:0/16:0, in shorthand). At low temperatures the hydrocarbon tails pack together closely to form a nearly solid *gel* state. If the temperature is raised above 41 °C, a **phase change** occurs in which this regular order is lost, and the hydrocarbon tails become free to move about. The membrane “melts” to adopt a semifluid *liquid crystalline* state. The temperature at which this happens is called the *transition temperature*. This abrupt change in synthetic membrane properties can be detected by a number of the techniques described in Tools of Biochemistry 10A. Figure 10.12b shows the transition as detected by calorimetry (see Tools of Biochemistry 6C).

The transition temperature is very sensitive to the nature of the hydrocarbon tails. If a PC-14:0/14:0 membrane is used (with tails only two carbons shorter than those just described), the transition temperature drops to 23 °C. If a single *cis* double bond is incorporated into each 16-carbon tail (PC-16:1/16:1), melting occurs at 36 °C. As explained earlier, *cis* double bonds put bends in the chains, disrupting their close packing; thus, such chains must be cooled to a lower temperature to produce the gel phase. Changing the head group can also make a big difference: If phosphatidylethanolamine (Table 10.3) is substituted for phosphatidylcholine in PC-16:0/16:0, the thermal transition is raised to 63 °C. The sensitivity of the transition to lipid composition is shown dramatically by the fact that combining several of the changes described above can change the membrane transition temperature over a range of 100 °C.

Motion in Biological Membranes

Biological membranes, which contain complex mixtures of lipid components plus protein, exhibit much broader and more complex phase transitions than those observed for synthetic bilayers of the kind described above. Indeed, there is now evidence for the existence of quite stable “domains” of different composition in different parts of a cell membrane. This explains the broader transition observed. Because it is essential that the membranes in living cells be fluid, the membrane composition is regulated so as to keep the transition temperature below the body temperature of the organism. One example is found in bacteria, which will alter the saturated/unsaturated fatty acid ratio in their membranes in response to a change in the temperature at which they are grown. A remarkable case in the animal kingdom is that of the reindeer’s leg. Its cell membranes show an increase in relative amount of unsaturated fatty acids near the hoof, which is usually cooler than the rest of the body.

Cholesterol has a specific and complex effect on membrane fluidity. As Figure 10.12b shows for a synthetic membrane, cholesterol does not influence the transition temperature markedly, but it does broaden the transition. It has been hypothesized that this broadening occurs because cholesterol can both stiffen the membrane above the transition temperature and inhibit regularity in structure formation below the transition temperature. Thus, it blurs the distinction between the gel and the fluid state. There is evidence that variations in cholesterol content are used to regulate membrane behavior in some organisms.

(a) Transition

(b) Transition with and without cholesterol

FIGURE 10.12

The gel–liquid crystalline phase transition in a synthetic lipid bilayer. (a) A schematic view of the change at the transition temperature. Below this temperature the hydrocarbon tails are packed together in a nearly crystalline gel state (left). Above this temperature the movement of the chains becomes more dynamic, and the interior of the membrane resembles a liquid hydrocarbon (right). (b) Detection of the transition by calorimetry (see Tools of Biochemistry 6C). Measurement of the heat absorbed by a membrane as the temperature is raised each degree shows a sharp spike at the transition temperature (T_m) for a pure dipalmitoylphosphatidylcholine bilayer. This well-defined transition from gel to liquid is called melting of the membrane. When 20 mol % cholesterol is mixed into the bilayer, the transition temperature is not changed, but the transition is broadened.

The transition temperature for a membrane depends on its lipid composition. Lipids with longer, saturated tails tend to increase the transition temperature, whereas those with more *cis* double bonds and/or shorter tails will reduce the transition temperature.

Under physiological conditions, biological membranes exist in a semifluid liquid crystalline state.

FIGURE 10.13

A schematic model of the effects of cholesterol on synthetic membrane structure. The data indicate an initial effect of the cholesterol/phospholipid ratio, C:PL, on membrane width. At C:PL mole ratios at or below 0.8:1, bilayer width increases with increasing C:PL. At C:PL mole ratios above 0.9:1, two separate lamellar phases form, one representing a liquid crystalline lipid bilayer and another representing an immiscible cholesterol phase. The immiscible cholesterol phase forms by phase separation as the membrane “saturates” with cholesterol.

The Journal of Lipid Research 39:947–956, T. Tulenko, M. Chen, P. E. Mason, and R. P. Mason, Physical effects of cholesterol on arterial smooth muscle membranes: Evidence of immiscible cholesterol domains and alterations in bilayer width during atherogenesis. Adapted with permission. © 1998 The American Society for Biochemistry and Molecular Biology. All rights reserved.

The effects of cholesterol on membrane structure are strongly dependent on its concentration in the membrane. X-ray scattering studies on reconstituted synthetic bilayers have shown that at moderate concentrations cholesterol fits into the bilayer and may thicken it (Figure 10.13), whereas at higher concentrations, “islands” of cholesterol bilayers form. These, it is speculated, may provide nuclei for the formation of cholesterol plaques in the circulatory system. The formation of such structures has been demonstrated to be an *in vivo* effect by experiments in which rats were fed high levels of cholesterol for many weeks. As we discuss later in this chapter, cholesterol also appears to play a role in organizing smaller regions of the bilayer into functional units referred to as “lipid rafts.” The effect of cholesterol on modulating the thickness of biological membranes appears to be marginal, based on recent experiments in which cholesterol was removed from the membranes of rat liver cells and the associated organelles. In these membrane systems, protein content of the membrane had a much greater effect on regulating bilayer thickness than did cholesterol.

The Asymmetry of Membranes

In contrast to the ease of lateral movement, the “flip-flop” of lipid molecules *across* synthetic lipid bilayers, from one side to the other, is much slower. The reason is not hard to see: When a phospholipid molecule turns from one face to the other, it must pass its very hydrophilic head through the hydrophobic medium of the hydrocarbon tails. Such an event is very unfavorable from an energetic point of view, and hence the process is slow. There exist enzymes (*translocases* and *flippases*) that catalyze membrane lipid flipping. In contrast to phospholipids, the transport of fatty acids across membranes is much more rapid (less than a second), for a simple reason. Unlike the phosphate groups on phospholipids, the carboxylates on fatty acids have a pK_a that is sufficiently high to allow protonation in the nonpolar environment of the lipid bilayer. Thus, they lose their negative charge and can partition into the hydrophobic core of the membrane more favorably than an ionized molecule.

Every biological membrane has two distinct faces, each encountering a different environment. Examples can be seen in the illustrations of cell ultrastructure shown in Chapter 1. The plasma membrane of a cell faces the external environment on the outside and the cytoplasm on the inside, whereas the membrane around a chloroplast faces the photosynthetic apparatus on the inside and the cytoplasm on the outside. Because the two faces of a membrane must deal with different surroundings, the faces are usually quite different in composition and structure.

This difference extends even to the level of phospholipid composition. Recall that all phospholipid membranes are bilayers; the two individual layers are called *leaflets*. The compositions of the two leaflets in the plasma membranes of several kinds of cells are shown in Figure 10.14. Not only are the individual lipids distributed very asymmetrically, but the distribution also varies considerably among cell types.

The two leaflets of a membrane usually differ in lipid composition.

**FIGURE 10.14**

Phospholipid asymmetry in plasma membranes. Lipid composition in the outer leaflet (green) and inner leaflet (gold) of the plasma membrane is graphed for three cell types. PC = phosphatidylcholine; PE = phosphatidylethanolamine; PS = phosphatidylserine; PI = phosphatidylinositol; SP = sphingomyelin.

Membranes are highly specialized structures that serve diverse functions in different cells/tissues. The lipid and protein content of a given membrane is tailored to the specific function of that membrane. For example, differences in charged groups between bilayer leaflets lead to differences in the electrical potentials (discussed later in this chapter) across various membranes. Glycoproteins and glycolipids carried in the outer leaflet of a plasma membrane contribute, via their oligosaccharide chains, to identification of cells (see Chapter 9).

Much of our knowledge of membrane asymmetry comes from studies of **vesicles**, fragments of membrane that have resealed to form hollow shells, with an inside and an outside. Reagents can be either captured inside the vesicle or added only to the surrounding solution so that they can react specifically with either outward-facing or inward-facing proteins or lipids. A membrane protein in a vesicle may be reacted covalently with a radioactively labeled reagent, isolated, and cleaved into peptides by proteases. Identification of which peptides are labeled by “inside” or “outside” reactants can reveal which portions of the protein were on the inner face and which were on the outer face. In a similar way, lipids can be tested, using enzymes or other reagents that cleave off or otherwise modify the head groups. Experiments of this kind, performed inside or outside vesicles, have provided much of the information shown in Figure 10.14.

Biological membranes are highly dynamic structures. Not only must they continually expand as cells grow and divide but also, even in resting cells, a continual turnover and renewal of the membrane components apparently occurs. Indeed, this dynamic, nonequilibrium state is a necessity if asymmetry is to be maintained. From the second law of thermodynamics (see Chapter 3) we know that the equilibrium state of a two-layer membrane would require an equal distribution of every component on either side. Like so many other biological systems, membranes exist as they do because they are *not* in equilibrium but rather represent dynamic, steady-state structures.

Characteristics of Membrane Proteins

Membrane proteins possess special characteristics that distinguish them from other globular proteins. They often contain a high proportion of hydrophobic amino acids in the parts of the protein molecules that are embedded in the membrane (see Figure 10.15). The segments of proteins that span membranes are often α -helical, although β -barrels are also common membrane-spanning motifs. Figure 10.16 depicts bacteriorhodopsin, an integral membrane protein whose structure has been solved to high resolution. Like many such proteins, it contains a bundle of seven α -helical segments that pass back and forth through the

FIGURE 10.15

Examples of structures for several integral membrane proteins. Each protein is rendered half in a space-filling model (left half of each structure) and half in a cartoon (right half). The cartoon rendering shows the differences in membrane-spanning structure, whereas the space-filling models show similar distributions of hydrophilic (red and blue) and hydrophobic (green and gray) surface areas for both classes of proteins. The membrane-spanning regions are dominated by hydrophobic surface area. The bilayer is indicated by the brown band, and the cytosolic region is indicated by the aqua-colored region. **Top panel:** Examples of β -barrel transmembrane structures. **Bottom panel:** Examples of α -helical transmembrane proteins. *E. coli* outer membrane protein X (PDB ID: 1QJ9) is involved in biofilm formation. *S. typhimurium* maltoporin (PDB ID: 2MPR) facilitates diffusion of certain saccharides across the outer membrane of gram negative bacteria. *S. aureus* hemolysin (PDB ID: 7AHL) is a toxin that opens a pore in target cells and lyses them. *H. salinarum* bacteriorhodopsin (PDB ID: 1C3W) is a proton pump in photosynthetic bacteria. Cytochrome *b6f* from *C. reinhardtii* (PDB ID: 1Q90) is a photosynthetic proton pump and electron transporter. *E. coli* quinol-fumarate reductase (PDB ID: 1LOV) is an electron transport protein that catalyzes the reduction of fumarate to succinate.

membrane. The presence of such transmembrane segments can sometimes be inferred from the kind of **hydrophobicity plot** shown in Figure 10.17. This plot has been calculated according to the hydrophobicity scale of Kyte and Doolittle given in Table 6.5. It reveals maxima in regions of the sequence corresponding to the transmembrane helices. Transmembrane helices typically contain 20–25 residues, which are predominantly hydrophobic.

Another class of membrane-associated proteins is covalently modified with lipids as shown in Figure 10.18. Many proteins involved in signaling are modified in this way, via reactions that are formally acyl group transfers, or **acylations**. Specific sequences at the N-terminus or C-terminus of the protein are required for the addition of **geranylgeranyl**, **farnesyl**, and **myristoyl** groups. For example, myristoylation occurs at N-terminal Gly residues following cleavage of the N-terminal Met, and farnesylation requires a C-terminal “CaaX” motif (where C = Cys, a = an aliphatic amino acid, and X = any amino acid except Pro). These processes are presented in greater detail in Chapters 19 and 23. Another common protein modification is the addition of one or more palmitoyl groups to a Cys sidechain (or to a lesser extent, the N-terminal amino group).

As discussed below, the attached lipid may serve primarily to target the modified protein to a particular subcellular organelle or to a specific location in the plasma membrane. For example, proteins linked to **glycosylphosphatidylinositol** (GPI) are frequently associated with regions of the outer leaflet rich in cholesterol and

sphingolipids. Although the lipid moiety may insert directly into the bilayer, several membrane proteins with lipid-binding sites are known. Thus, the association of a lipid-linked protein with the membrane may be mediated by protein-lipid binding.

Membranes are complex structures, with specific compositions for each of the two leaflets. To make the picture more concrete, let us consider in some detail the structure of one example, the plasma membrane of the erythrocyte (red blood cell).

The Erythrocyte Membrane: An Example of Membrane Structure

The erythrocytes of mammals are among the simplest of all cells. In their mature state in the circulating blood, they lack mitochondria, internal membranes, and a nucleus. They are essentially bags containing a concentrated solution of hemoglobin. They can easily be lysed to release their contents and produce membrane *ghosts*, large vesicles that represent a nearly pure preparation of the plasma membrane of the cells. Erythrocyte ghosts have the lipid composition given in Table 10.4, distributed between inner and outer leaflets as shown in Figure 10.14. If the total protein content of the erythrocyte ghost is extracted with detergent and analyzed by SDS gel electrophoresis, the pattern shown in Figure 10.19a is obtained.

Separating Peripheral and Integral Proteins

The plasma membrane of erythrocytes contains far fewer proteins than are found in most other cell membranes, in keeping with the simple metabolism of these cells. What are these proteins, and what do they do? To begin, these proteins are classified as either peripheral or integral membrane proteins. The peripheral proteins can be washed off the ghosts by simple changes in ionic strength or pH. All the peripheral proteins in erythrocytes are attached to the inside (cytoplasmic face) of the erythrocyte membrane (Figure 10.20). Electron microscopy after freeze-etching (see Tools of Biochemistry 10A) reveals a nearly smooth outer surface, with only integral membrane proteins and attached carbohydrates decorating the surface, whereas the inside of the membrane and the inner surface are rich in protein particles.

The major integral proteins of this membrane are the anion channel (band 3), band 4.5, and the glycophorins. Note that glycophorin and band 4.5 do not appear in Figure 10.19 because of the particular dye used in the analysis. The integral proteins, along with much of the lipid material, can be extracted from intact membranes by use of the nonionic detergent Triton X-100.

The Protein Skeleton

Surprisingly, treatment with Triton X-100 leaves intact a protein skeleton, which retains the shape of the membrane ghost. The proteins of this membrane skeleton

FIGURE 10.16

Bacteriorhodopsin—an integral membrane protein. Bacteriorhodopsin (PDB ID: 1C3W) functions as a light-driven proton pump in certain bacteria. Seven helices span the membrane and hold a molecule of the light-absorbing pigment **retinal** (magenta). The biosynthesis of retinal is described in Chapter 19.

**FIGURE 10.20**

Model of the postulated structure of the erythrocyte membrane skeleton. The proteins are identified in Figure 10.19. Note that ankyrin anchors the membrane to the skeleton by interacting with both spectrin and the integral band 3 protein (anion channel).

are identified in Figure 10.19b, and a schematic picture is shown in Figure 10.20. The skeleton is a two-dimensional network of some of the peripheral proteins, the major constituents being **spectrins**, actin, and band 4.1. The 200-nm-long fibers in this network are made up of $\alpha_2\beta_2$ tetramers of spectrin molecules. These very elongated molecules contain a large fraction of α -helix and appear to be linked at their ends through short chains of actin molecules, together with the band 4.1 protein and adducin. The actin is also complexed with an erythrocyte-specific tropomyosin (see Chapter 8). The skeleton is anchored to the membrane itself by the protein **ankyrin**, which binds to both spectrin and the band 3 integral protein. Band 4.1 adds to the structure by also binding to glycophorin, another integral protein.

What purpose does this elaborate underpinning to the erythrocyte membrane serve? An obvious suggestion is that it helps to maintain the shape of the erythrocyte under the extreme distortions and shear stress the red cell suffers in passing through the circulatory system. The erythrocyte is durable, typically surviving for about 120 days, or 10 million heartbeats. The discoid shape of the cell allows efficient exchange of O_2 and CO_2 to the hemoglobin inside, and even if that shape is momentarily deformed, the skeleton helps to re-establish it. Indeed, deficiencies in these skeletal proteins result in easy lysis of erythrocytes, which is the cause of some forms of anemia. The kind of structure described here is not confined to erythrocytes; many other cell types contain similar but distinct membrane skeletons. It seems likely that connections exist between the membrane skeleton and the cytoskeleton (see Chapter 8) so that the membrane is linked to intracellular structure.

The Major Integral Membrane Proteins

The most abundant protein in the erythrocyte membrane is the band 3 protein, which is an anion channel, facilitating the exchange of HCO_3^- for Cl^- across the erythrocyte membrane. Recall from Chapter 7 the importance of bringing HCO_3^- into the erythrocytes to accomplish CO_2 transport; exchange for Cl^- keeps ionic balance. Band 3 protein functions as a complex of 2 or 4 subunits. Each subunit chain crosses and recrosses the membrane a number of times, to create the channel through which the ions can be exchanged. The N-terminal portion of the protein extends into the cytosol, where it makes a number of interesting interactions. As mentioned previously, it contacts the skeletal protein ankyrin, providing a major attachment between the skeleton and the membrane. In addition, band 3 protein contacts a number of cytosolic proteins, including some glycolytic enzymes (glyceraldehyde-3-phosphate dehydrogenase and aldolase, for example; see Chapter 13) and hemoglobin. The significance of these interactions is not wholly clear.

The erythrocyte, like many other cells, has a complex “skeleton” of proteins underlying and attached to its plasma membrane.

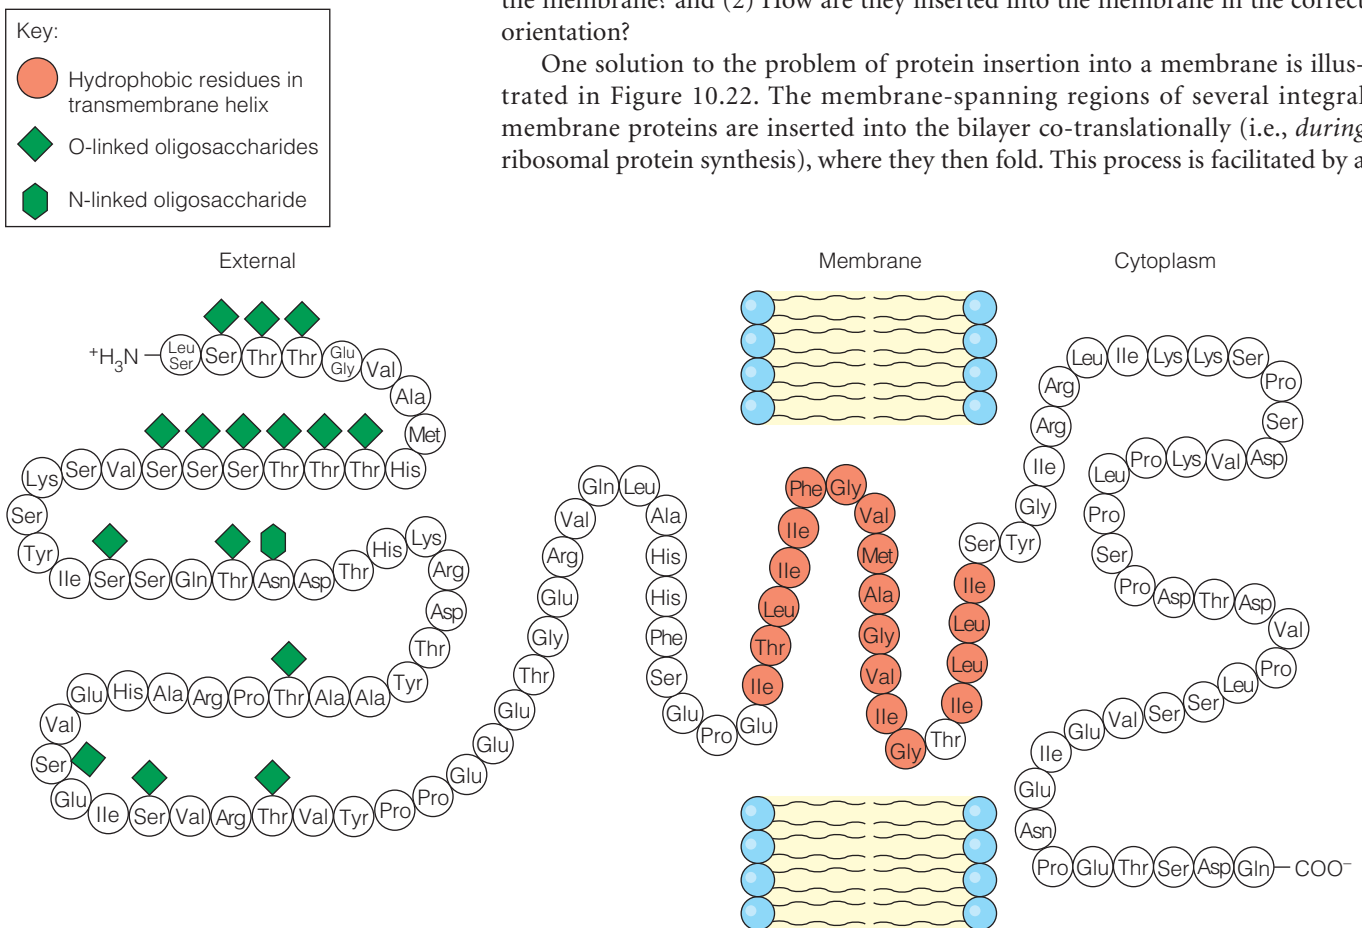

The other major integral red cell membrane proteins are the **glycophorins**, which apparently serve a variety of functions. Each of these proteins has an external carbohydrate-carrying domain, a single transmembrane helix, and a cytosolic C-terminal domain (see Figure 10.21). The O-linked carbohydrate groups on the external N-terminal domain carry sialic acid residues, giving a negative charge to the exterior of the red blood cell. This may minimize the chances of such cells sticking to capillary walls during circulation. The role of the cytosolic domain is less clear, but in some glycophorins it appears to interact with band 4.1, stabilizing skeleton–membrane adhesion.

The asymmetry of the orientation of integral proteins must be emphasized. Just as the erythrocyte membrane is asymmetric in its distribution of lipid components, it is equally asymmetric in its distribution of proteins because each kind of protein is oriented in a particular direction. There appear to be special components of the cellular protein synthesis machinery that direct the placement of proteins in membranes and ensure their asymmetric orientation. We discuss only one aspect of that now: The co-translational insertion of transmembrane helices into the bilayer.

FIGURE 10.21

The sequence and postulated structure of glycophorin A. This protein was the first integral membrane protein to be sequenced. The external (N-terminal) domain carries 15 O-linked and one N-linked oligosaccharides; together these constitute about 60% of the total protein mass. The single transmembrane helix is highly hydrophobic, whereas the cytosolic C-terminal domain is quite hydrophilic.

Insertion of Proteins into Membranes

Greater than 30% of proteins must cross, or integrate into, a cellular membrane. How do hydrophilic, globular proteins make it across a hydrophobic membrane bilayer during, or following, their ribosomal synthesis? The ribosomes are either free in the cytosol or bound to the rough endoplasmic reticulum (see Chapter 28 for a discussion of protein **secretion**). Given the cytosolic location of protein synthesis and the asymmetric orientation of integral membrane proteins, two fundamental questions arise: (1) How do integral membrane proteins get inserted into the membrane? and (2) How are they inserted into the membrane in the correct orientation?

One solution to the problem of protein insertion into a membrane is illustrated in Figure 10.22. The membrane-spanning regions of several integral membrane proteins are inserted into the bilayer co-translationally (i.e., *during* ribosomal protein synthesis), where they then fold. This process is facilitated by a

protein-conducting channel called a **translocon**. These protein channels are multisubunit complexes called **SecY** in prokaryotes and **Sec61** in eukaryotes, where “Sec” refers to proteins involved in secretion.

In the process of protein integration into the membrane, the translocon must perform three critical tasks. First, it must allow the hydrophobic transmembrane sequences of the emerging, or “nascent,” protein to remain in the bilayer while conducting certain hydrophilic sequences across the membrane. Second, it must facilitate correct orientation, or “topology,” of the transmembrane sequences. Membrane proteins must be properly oriented in the bilayer to ensure they can carry out their function. For example, a hormone receptor must display its ligand-binding site on the *extracellular* side of the membrane if it is to detect the presence of the hormone in circulation. Likewise, many transport proteins must move their substrates *in only one direction* across the bilayer to create electrochemical gradients that are critical for several cell functions. Thus, inserting transmembrane peptide sequences with the correct topology is a matter of survival. Finally, the translocon must do all of this while preventing the nonspecific transport of other molecules or ions across the bilayer, which would result in cell death due to collapse of electrochemical gradients.

A model for the function of the translocon is suggested by the crystal structure of the three subunit SecY complex from the bacterium *M. jannaschii* shown in Figure 10.23. The α subunit is largest, and it forms the protein channel from eight transmembrane helices and two others that do not completely traverse the bilayer. The β and γ subunits each have a single transmembrane helix. The α subunit is shaped like an hourglass, with a ring of six conserved Ile, Val, and Leu residues at the narrowest part of the channel. This ring is just large enough to accommodate the polypeptide chain as it emerges from the ribosome. As shown in Figures 10.23 and 10.24a, when the pore is not occupied by a translocating peptide, it is plugged with a small helix from the N-terminal sequence of the α subunit, thus explaining how SecY can seal itself and thereby prevent nonspecific transport of ions and other molecules.

How are the hydrophobic transmembrane segments of the inserted peptide recognized, and how do they get out of the channel and into the bilayer? One plausible explanation is that the channel opens along its length to allow the peptide to slide out laterally (Figure 10.24b and c). Hydrophobic peptides will be more likely to partition into the bilayer core, whereas polar sequences will remain in the channel and partition into the polar interface region of the membrane. In essence, the translocon is acting like a molecular separatory funnel, exposing the peptide sequence to polar and nonpolar phases. The peptide will move to the phase that best matches its polarity. This proposal is supported by the crystal

FIGURE 10.22

Co-translational insertion and folding of transmembrane helices in an integral membrane protein. The bilayer lipids are indicated in tan, the ribosome in brown, the translocon channel in purple, and the peptide in green. Some parts of the protein (in this case, the loops) are conducted across the bilayer through the translocon; transmembrane portions exit the translocon (see text) and remain embedded in the bilayer. The transmembrane helices fold after they are inserted.

FIGURE 10.23

Crystal structures of SecY complex in “closed” and “open” conformations. The α subunit is highlighted in purple and red, with the β and γ subunits in gray. The small helix in the α subunit that plugs the pore is shown in blue. Panel (a): Side view, looking toward the “exit,” of SecY from *M. jannaschii* in the closed conformation (PDB ID: 1RHZ). The two helices on either side of the closed exit are highlighted in red. Note the location of the blue helix in the center of the channel. Panel (b): Top view looking down the protein channel in the closed conformation. Panel (c): Top view of SecY from *P. furiosus* in the open conformation (PDB ID: 3MP7). The two red helices have moved apart, opening a gap that runs the length of the channel and allows the nascent peptide sequence in the translocon access to the hydrophobic core of the membrane.

A protein channel called the “translocon” facilitates the insertion of integral membrane proteins into the membrane bilayer.

FIGURE 10.24

Model for translocon function. In all panels the cytoplasm is above the bilayer and the color coding matches that in Figures 10.22 and 10.23. **(a)** The “resting” translocon. The protein pore is plugged by a small helix (light blue). The ring of hydrophobic residues at the waist of the hourglass is shown in dark blue. **(b)** The “active” translocon. A nascent peptide (green) exits the ribosome and enters the translocon protein channel. The nascent peptide has access to the bilayer through a lateral opening in the translocon. In the yeast translocon, charged residues (yellow and red circles) in the channel facilitate the proper orientation of the nascent peptide in the bilayer. **(c)** If a segment of the nascent peptide is sufficiently hydrophobic it will partition into the lipid bilayer. Hydrophilic sequences (loops) partition to either side of the bilayer, depending on the orientation of the transmembrane segments.

structure of SecY from *P. furiosus*, which shows a lateral opening in the translocon (Figure 10.23c).

Given this model for insertion of transmembrane helices, how are they inserted in the correct orientation? Several factors are likely at work to assure the proper topology for the inserted protein. Work by Gunnar von Heijne and colleagues has supported an “inside positive” rule that explains the enrichment in Lys and Arg residues in the cytoplasmic portions of proteins with multiple membrane-spanning regions. Due to the electrical potential across the membrane, $\Delta\psi$, the cytoplasmic side of the bilayer is more negatively charged compared to the outside; thus, a cluster of positively charged side chains would tend to migrate to the cytoplasmic side of the membrane. As a test of this hypothesis, von Heijne made a mutant of *E. coli* leader peptidase (Lep) in which four Lys residues were added to the N-terminus and several basic amino acids were removed from a cytoplasmic loop. The membrane topology of the mutant Lep was reversed compared to the wild-type (Figure 10.25). This “inside positive” orientation of transmembrane proteins is also aided by the preponderance of acidic (i.e., negatively charged) phospholipids on the inside of membranes. Finally, in some species, the translocon plays a role in directing the orientation of transmembrane peptides, via key charge–charge interactions. In the yeast translocon Sec61, basic residues on the periplasmic side and acidic residues on the cytoplasmic side of the channel (see Figure 10.24b) have been shown to be critical in determining the proper orientation of transmembrane segments. Reversing these charges in Sec61 results in a reversal of transmembrane protein topology.

FIGURE 10.25

The “inside positive” rule. Wild-type leader peptidase (Lep) from *E. coli* orients its two transmembrane helices with the termini in the periplasm and the loop between the helices in the cytoplasm. Addition of four Lys to the N-terminus and removal of positive charge from the loop yield a mutant Lep that has the opposite membrane topology. The membrane potential is indicated by greater negative charge on the cytoplasmic side compared to the periplasmic side.

Evolution of the Fluid Mosaic Model of Membrane Structure

Many features of the Singer–Nicolson fluid mosaic model have been confirmed since it was proposed in 1972; however, with improvements in imaging technology more details have emerged and prompted reinterpretation of the model. Specifically, most membranes appear to be very crowded with proteins and show

significant variation in both thickness of the bilayer and distribution of proteins and lipids within a leaflet.

We mentioned previously that GPI-modified proteins are frequently localized in regions of the membrane that are enriched in cholesterol and sphingolipids. This observation led to the proposal that these three membrane components can coalesce to form separate membrane domains called **lipid rafts** (or **membrane rafts**). These membrane rafts are small (~10 nm), short-lived dynamic structures that, in response to certain stimuli, can transiently associate with each other to form larger “raft platforms” (Figure 10.26). Actin fibers may act to stabilize and/or initiate formation of the rafts. These raft platforms are thought to play significant roles in cell signaling and the sorting of proteins into specific organelles within a cell. GPI-anchored proteins are frequently involved in cell signaling, and the clustering of GPI proteins in raft platforms may accelerate signal transduction across the membrane—particularly in cases where dimerization of a signal receptor is required. More recently, rafts have been implicated in facilitating bacterial entry into host cells.

From studies in model membranes it is known that the bilayer thickness is a function of the lipid and protein composition in membrane domains (Figure 10.27). This may be due to the effect of cholesterol on the phase behavior of lipids (see Figure 10.13). At certain concentration ratios of sterols to lipids, membrane lipids form more ordered and elongated structures. For example, the membrane rafts described in Figure 10.26 are thicker than the surrounding

Membrane rafts are rich in cholesterol, sphingolipids, and GPI-linked proteins. The bilayer is thicker in the raft domains than in the surrounding membrane.

FIGURE 10.26

Membrane rafts. (a) Cholesterol, sphingolipids, and GPI-anchored proteins coalesce and form nanometer-sized dynamic raft domains, which may be stabilized by interactions with actin fibers. (b) Rafts can associate to form larger structures (“platforms”). Certain proteins interact preferentially with rafts (orange shading), while others do not (brown shading) or are excluded. Abbreviations: GPL, glycerophospholipid; GSL, glycosyl sphingolipid; GPI, glycosyl phosphatidylinositol.

FIGURE 10.27

Atomic force microscopy image of lipid domains in a model membrane. Top view of a bilayer composed of a mixture of 1,2-dilauroylphosphatidylcholine (DLPC) and 1,2-distearoylphosphatidylcholine (DSPC) separates into two phases as the temperature is lowered from 70 °C to 25 °C. The DSPC molecules coalesce and form thicker gel-like “islands” or domains (lighter gray spots) in a “sea” of fluid DLPC (darker gray background). Such simple systems have been used to model the more complex lipid rafts described in Figure 10.26.

Reprinted from *Biophysical Journal* 83:3380–3392, T. V. Ratto and M. L. Longo, Obstructed diffusion in phase-separated supported lipid bilayers: A combined atomic force microscopy and fluorescence recovery after photobleaching approach. © 2002, with permission from Elsevier.

Membrane curvature generates mechanical forces in the bilayer that can affect protein function, such as the opening and closing of membrane channels.

nonraft membrane. Membrane thickness is also influenced by the proteins in the bilayer. This raises the interesting question illustrated in Figure 10.28: Do proteins change conformation to optimize interactions with the bilayer as membrane thickness changes, or do lipids change their structure to accommodate proteins? Current evidence suggests that it is more common for lipids to adjust to proteins than vice versa; however, both adaptations are observed in cell membranes.

Lipid Curvature and Protein Function

As mentioned previously, X-ray scattering studies of membranes from various organelles have shown that protein composition, rather than lipid composition, is the major determinant of membrane thickness. Nonetheless, lipids are not passive constituents of the membrane. The lipid bilayer exerts significant lateral pressure on embedded proteins. This pressure can be up to 400 atm, and it arises due to the balancing of attractive and repulsive forces in the plane of the bilayer. The resulting pressures are experienced by proteins imbedded in the bilayer (Figure 10.29). If the membrane surrounding a cell or organelle expands or contracts, the resulting change in bilayer curvature will alter the magnitude and position of the forces acting on imbedded proteins. Thus, a *mechanical* stress on the bilayer is translated to these proteins. Such stress can alter protein conformation, as is observed in the opening and closing of the mechanosensitive channel of *Mycobacterium tuberculosis*, MscL (Figure 10.30). When a cell or bacterium is placed in a solution with a low solute concentration, or low **osmolarity**, the osmotic pressure on the cell changes and water will enter the cell. The resulting swelling changes the membrane curvature, which, in turn, alters the pressure on the MscL channel such that it opens (Figure 10.30b). The opening of the MscL channel allows the bacterium to rapidly expel internal fluid in response to changes in solution osmolarity that would otherwise result in rupture of the membrane and cell death.

For a cell to survive, its membrane(s) must tightly regulate the transport of materials across the bilayer. It is to that topic that we now turn.

Transport Across Membranes

A cell or an organelle can be neither wholly open nor wholly closed to its surroundings. Its interior must be protected from certain toxic compounds, and metabolites must be taken in and waste products removed. Because the cell must contend with thousands of substances, it is not surprising that much of the complex structure of membranes is devoted to the regulation of transport.

In this section we describe various ways in which molecules are transported across membranes. These include the actions of small molecules that act as ion carriers, larger proteins that are highly specific transporters, and proteins that promote the formation of membrane vesicles. Before considering specific mechanisms of transport, we review the underlying thermodynamics of transport processes.

FIGURE 10.28

Adaptation to hydrophobic mismatch in a membrane. If the thickness of the bilayer core and the hydrophobic surface area of an embedded protein do not match (middle image), either the protein will undergo conformational change (left) or the bilayer will change composition (right) until the dimensions of these hydrophobic regions match.

FIGURE 10.29

Lateral pressure in membranes. Formation of the bilayer results in opposing forces, of equal overall magnitudes, that exert lateral pressure, π , in the plane of the membrane. Head group and alkyl chain repulsions (green shading, left side of diagram) oppose interfacial tension (blue shading). Note that the surface area over which interfacial tension acts is much smaller than that over which the repulsive forces act. The repulsive forces exert a positive pressure (green arrows) on a protein imbedded in the membrane (red shading), whereas the interfacial tension exerts a negative pressure as indicated by the blue arrows. The length of the arrows is a rough indication of the magnitude of the pressure exerted at that point in the membrane.

The Thermodynamics of Transport

In Chapter 3 we discussed the general thermodynamic principles governing the transfer of substances across membranes. It was shown that the free energy change, ΔG , for transporting one mole of a substance from a location in which its concentration is C_1 to a different location where its concentration is C_2 is given by

$$\Delta G = \Delta G^{o'} + RT \ln Q = -RT \ln K_{eq} + RT \ln \frac{[C_2]}{[C_1]} \quad (10.1a)$$

For a process that only involves transport of some substance across a membrane, the term $\Delta G^{o'}$ equals zero. Why is this so? Recall that $\Delta G^{o'}$ describes the *equilibrium state* for a process, and for the case of transport across a membrane, the equilibrium state is reached when the concentrations of the substance are the same on both sides of the membrane (i.e., at equilibrium $[C_2] = [C_1]$). In this case $K_{eq} = [C_2]/[C_1] = 1$. Since $\Delta G^{o'} = -RT \ln K_{eq}$, if $K_{eq} = 1$, $\Delta G^{o'} = 0$ for the process. Note that, when $[C_2] = [C_1]$, the term $Q = 1$; thus, $\Delta G = 0$, as expected for a system at equilibrium.

For a transport process that is not at equilibrium $[C_2] \neq [C_1]$; thus, $RT \ln Q \neq 0$, and ΔG for the process is given by

$$\Delta G = \Delta G^{o'} + RT \ln Q = 0 + RT \ln Q = RT \ln \frac{[C_2]}{[C_1]} \quad (10.1b)$$

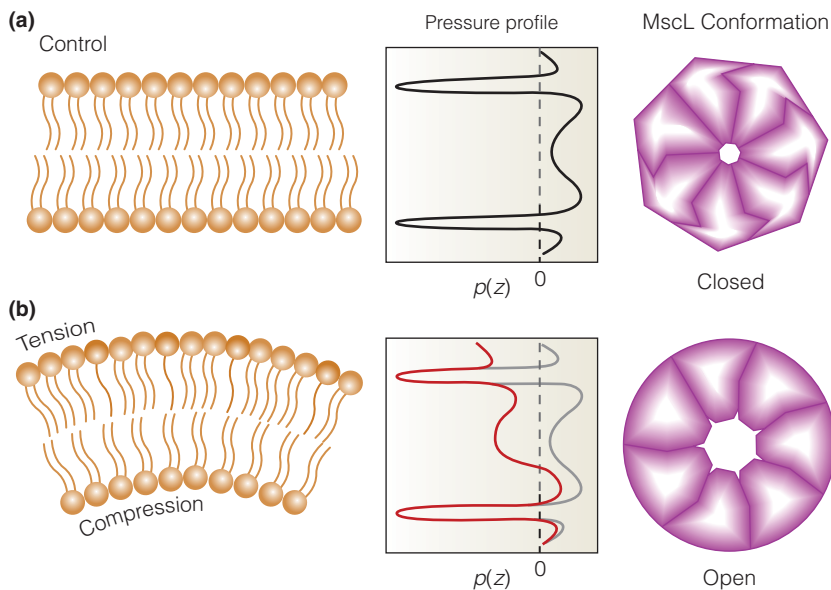

FIGURE 10.30

Mechanical stress influences protein conformation. Changes in bilayer curvature (left panels) alter the lateral pressure profile in the membrane (middle panels). This results in a conformational switch in MscL that opens or closes the channel (right panels; the view is looking along the channel opening through the bilayer).

For a substance that can pass through a membrane, the normal state of equilibrium is achieved when the concentrations of the substance are equal on both sides of the membrane.

A more detailed derivation of this equation is given in Chapter 3 (see Equation 3.19, pages 69–71). According to this equation, if $[C_2]$ is less than $[C_1]$, ΔG is negative, and the process is thermodynamically favorable. As more and more substance is transferred (between the two locations), $[C_1]$ decreases and $[C_2]$ increases, until $[C_2] = [C_1]$. At this point $\Delta G = 0$, and the system is at equilibrium. *Unless other factors are involved*, this equilibrium is the ultimate state approached by transport across any membrane. In short, a substance that can traverse the membrane will eventually reach the same concentration on both sides. We can describe the same process in kinetic terms. If the molecules are colliding with the membrane at random, the number entering from any side will be proportional to the concentration on that side. When the concentrations become equal, the rates of transport in the two directions will be the same, and no net transport will occur.

There are three circumstances under which this equilibrium state can be circumvented, and each is important in the behavior of real membranes:

Equalization of the concentrations of some substance across a membrane can be circumvented (1) by binding of the substance to macromolecules, (2) by maintaining a membrane potential (if the substance is ionic), or (3) by coupling transport to an exergonic process.

1. A substance may be preferentially bound by macromolecules confined to one side of the membrane or it may be chemically modified once it crosses. We may find that compound A is more concentrated inside a cell (in terms of total moles of A per unit volume) than outside. But much of A may be bound to some cellular macromolecules or may have been modified; that portion does not really count in Equation 10.1, which simply states that the concentrations of *free* A on the two sides must be equal at equilibrium. An appropriate example is oxygen in erythrocytes. If we were to measure the *total* oxygen concentration in an erythrocyte, we would find it higher than the concentration of O_2 in the surrounding blood plasma. But the total concentration inside the cell includes oxygen bound to hemoglobin. The *free* oxygen concentration in the fluids inside and outside an erythrocyte is the same at equilibrium.
2. A **membrane electrical potential** may be maintained across a membrane that influences the distribution of ions. This tendency can be expressed quantitatively in the following way. For an ion of charge Z , the free energy change for transport across a cell or organelle membrane now involves two contributions: the normal concentration term, as given in Equation 10.1b, plus a second term describing the energy change (or work involved) in moving a mole of ions across the potential difference. We consider a process in which one mole of ions is transported from *outside* to inside.

$$\Delta G = RT \ln \frac{[C_{in}]}{[C_{out}]} + ZF\Delta\psi \quad (10.2)$$

Here F is the Faraday constant ($96.5 \text{ kJ mol}^{-1}\text{V}^{-1}$), and $\Delta\psi$ is the membrane potential in volts. We define $\Delta\psi$ in terms of the initial and final locations of the transported ion ($\Delta\psi = \psi_{\text{final}} - \psi_{\text{initial}}$; in this case, $\Delta\psi = \psi_{\text{in}} - \psi_{\text{out}}$). In this example, $\Delta\psi$ will be negative if the inside of the membrane is negatively charged compared to the outside. Under these conditions, if Z is positive, the $ZF\Delta\psi$ term in Equation 10.2 is negative and makes ΔG more exergonic (favorable). That is, the transport of cations *into* this hypothetical cell is favored. For anions, of course, the opposite is true; they will be driven out. In the presence of a non-zero membrane potential, the equilibrium state ($\Delta G = 0$) will *not* correspond to the same concentration of ions on the two sides of the membrane. However, energy must be expended continually to keep up the potential difference; otherwise migration of ions would neutralize it. Conversely, Equation 10.2 may be interpreted to mean that if a difference in ionic concentration is maintained, an electrical potential will be produced across the membranes (see Problem 9).

3. If some thermodynamically favored process is *coupled* to the transport, then the ΔG° and $RT \ln Q$ for this favorable process must be included in the free energy equation. This is the general case of *active transport*, for which we can write

$$\Delta G = \Delta G^{\circ'} + RT \ln \frac{Q[C_{\text{in}}]}{[C_{\text{out}}]} \quad (10.3a)$$

where the term Q includes activities for the species in the favorable reaction that is coupled to the transport of C . If the substance C being transported is an ion we must also include the $ZF\Delta\psi$ term

$$\Delta G = \Delta G^{\circ'} + RT \ln \frac{Q[C_{\text{in}}]}{[C_{\text{out}}]} + ZF\Delta\psi \quad (10.3b)$$

The quantities $\Delta G^{\circ'}$ and Q could correspond to a thermodynamically favored reaction (like hydrolysis of one mol ATP) that is coupled to the process of transport. This equation is a generalization of Equation 10.2, now allowing a variety of processes—not just those that maintain an electrical potential difference—to participate in the transport. In the case where hydrolysis of one mol of ATP results in transport of n mol of an ion C , we must modify Equation 10.3b to include the proper stoichiometry:

$$\Delta G = \Delta G^{\circ'} + RT \ln \frac{Q[C_{\text{in}}]^n}{[C_{\text{out}}]^n} + nZF\Delta\psi \quad (10.3c)$$

where n = mol of C transported per mol of ATP. We will show examples of such calculations in the discussion that follows.

With this background, we turn now to the mechanisms whereby substances are passed through membranes. We introduce the problem by asking two questions: (1) Does the process approach a state in which there are equal concentrations of the free substance on both sides, or is it maintained far from equilibrium? (2) How fast does the transport occur? Some molecules that are not actively transported against a concentration gradient can still traverse some membranes very rapidly, whereas others are transported so slowly as to be effectively excluded.

Nonmediated Transport: Diffusion

Nonmediated diffusion across membranes is accomplished by the random wandering of molecules through membranes. The process is the same as the Brownian motion of molecules in any fluid, which is termed **molecular diffusion**. Nonmediated transport ultimately results in the free concentration of the diffusing substance being the same on both sides of the membrane. The net rate of transport, J (in moles per square centimeter per second), is, as you might expect, proportional to the concentration difference ($C_2 - C_1$) across the membrane:

$$J = -\frac{KD_l(C_2 - C_1)}{l} \quad (10.4)$$

where l is the thickness of the membrane, D_l is the **diffusion coefficient** of the diffusing substance in the membrane, and K is the **partition coefficient** for the diffusing material between membrane lipid and water (i.e., the ratio of solubilities of the material in the lipid and water phases). For ions and other hydrophilic substances, K is a very small number, with the result that nonmediated diffusion of such substances through lipid membranes is extremely slow. There is simply not enough of the hydrophilic substance dissolved in the bilayer to provide rapid transport. In agreement with Equation 10.1, Equation 10.4 says that net transport will stop when $C_2 = C_1$. If the concentrations of C_1 and C_2 are expressed in mol/cm³ and l in cm, then D_l has the units cm²/s. D_l is not the same as the diffusion coefficient (D) that the same molecule would have in aqueous solution because it depends not only on the size and shape of the molecule but also on the viscosity of the membrane lipid.

The rate of nonmediated transport, as measured by membrane permeability, is proportional to the diffusion and partition coefficients and inversely proportional to membrane thickness.

We usually do not know either K , D_p , or the exact thickness of the membranes involved, so we often describe the rate of passive transport in terms of a **permeability coefficient, P** , which can be measured by direct experiment:

$$J = -P(C_2 - C_1) \quad (10.5)$$

By comparing equations (10.5) and (10.4), we see that P is given by

$$P = \frac{KD_l}{l} \quad (10.6)$$

with units of cm/s.

Table 10.6 lists permeability coefficients for a number of small molecules and ions in membranes. The low P values of the ions are as expected because ions have low values of K . However, the relatively large permeability value for water is surprising. Despite their hydrophobicity, biological membranes are not, in fact, very good barriers against water. Although the reasons for this are not entirely clear, it is probably fortunate for life, for it allows cells to exchange water, albeit slowly, with their surroundings. When water loss is to be strenuously avoided, as in the leaves of desert plants, waxy substances, with their much more hydrophobic structures, provide a nearly impermeable barrier. In some cells very rapid transport of water is required. As described below, such rapid transport of water is achieved by specific membrane-spanning channels called **aquaporins**.

Facilitated Transport: Accelerated Diffusion

For many substances, the slow transport provided by nonmediated diffusion is insufficient for the functional and metabolic needs of cells, and means must be found to increase transport rates. For example, exchange of Cl^- and HCO_3^- is essential to erythrocyte function. If we examine the permeability of erythrocyte membranes to chloride or bicarbonate ions, we find permeability coefficients of about 10^{-4} cm/s. This value is about 10 million times greater than the permeability coefficient for ions in pure lipid bilayers like the artificial phosphatidylserine membrane listed in Table 10.6. Clearly, some special mechanism is required to account for this difference. Three general types of **facilitated transport**, or **facilitated diffusion**, are known to occur: transport through pores or channels formed by transmembrane proteins (Figure 10.31a); transport by carrier molecules (Figure 10.31b); and transport by **permeases** (Figure 10.31c).

Facilitated transport, via pores, permeases, or carriers, can increase the rate of diffusion across a membrane by many orders of magnitude.

Carriers

Ionophores increase the permeability of a cell membrane to ions. Thus, many bacteria secrete ionophores that act as chemical warfare agents, or **antibiotics**, to kill other bacteria with which they compete for nutrients. The ionophores kill the

TABLE 10.6 Permeability coefficients for some ions and molecules through membranes

Permeability Coefficient (cm/s) for	Synthetic Membrane (Phosphatidylserine)	Biological Membrane (Human Erythrocyte)
K^+	$<9 \times 10^{-13}$	2.4×10^{-10}
Na^+	$<1.6 \times 10^{-13}$	10^{-10}
Cl^-	1.5×10^{-11}	$1.4 \times 10^{-4*}$
Glucose	4×10^{-10}	$2 \times 10^{-5*}$
Water	5×10^{-3}	5×10^{-3}

neighboring bacteria because unregulated ion transport destroys the electrochemical gradients that store free energy needed to drive vital processes in living cells. Some ionophores create ion-conducting pores in the membrane, whereas others carry ions from one side of the bilayer to the other (see Figure 10.31b). For example, *valinomycin*, produced by a *Streptomyces*, is an ion carrier and has the structure shown in Figure 10.32. When complexed with K^+ it is a cyclic polypeptide-like molecule, involving three repeats of the sequence (D-valine)–(L-lactate)–(L-valine)–(D-hydroxyisovalerate). Its folded conformation presents an outside surface rich in $-\text{CH}_3$ groups and an interior cluster of nitrogen and oxygen atoms that is well suited to chelating cations. The dimensions of the interior cavity nicely accommodate a K^+ ion but do not fit other cations as well. This structure is exactly what is needed for a cation carrier: The outer surface is hydrophobic, making the molecule soluble in the lipid bilayer, whereas the inside mimics in some ways the hydration shell that the cation would have in aqueous solution. A number of other ion-carrier antibiotics have the same kind of structure. These molecules are either cyclic, or linear chains that can fold into cage-like structures. Their relative affinities for different ions vary greatly. For example, valinomycin has nearly a 20,000-fold preference for K^+ over Na^+ , whereas the antibiotic *monensin* prefers Na^+ by only 10-fold.

A molecule like valinomycin can diffuse to one surface of a membrane, pick up an ion, and then diffuse to the other surface and release it. There is no *directed* flow, but the carrier in effect increases the solubility of the ion in the membrane. We could say that it increases the factor K in Equation 10.6. For such ion carriers, the net transport of ions will be in the direction that equalizes concentration of the ion on both sides of the membrane. Such facilitated transport is also called **passive transport** to distinguish it from **active transport**—a strictly directional process, which requires an input of free energy.

Permeases

Membrane-spanning proteins that recognize specific molecules for transport are called permeases or **transporters**. Like the carriers described above, some permeases act in a passive fashion—transporting their substrates in both directions, with a net flow toward the side of the membrane with the lower substrate concentration. The glucose transporter in erythrocytes (**GLUT1**, or band 4.5 protein) is thought to operate in this way. The small energy demands of an erythrocyte are met by glucose, which is readily available in the surrounding blood plasma. However, as Table 10.6 shows, the nonmediated transport of glucose through artificial phospholipid membranes is exceedingly slow: $P = 4 \times 10^{-10}$ cm/s. GLUT1, a 492-residue protein with 12 membrane-spanning helices, increases the glucose diffusion rate 50,000-fold. GLUT1 is quite discriminating; for example, D-glucose is transported

FIGURE 10.32

Valinomycin, an antibiotic that acts as an ion carrier. The outside of this roughly spherical cyclic polypeptide is hydrophobic. The central cavity surrounded by oxygens (red) complexes a K^+ ion. Nitrogens are shown in blue, oxygens in the polypeptide backbone are red, and carbons are gray. The surface is covered with CH_3 groups (not shown).

Facilitated transport can be passive or active. Passive transport can only achieve net transport of a substrate along its concentration gradient. Active transport can move a substrate against its concentration gradient, but this requires an input of free energy.

**FIGURE 10.33**

The channel-forming hemolysin from *Staphylococcus aureus*. Ribbon drawings of the α -hemolysin heptamer, viewed (a) looking down the sevenfold axis and (b) perpendicular to the sevenfold axis. (c) One protomer extracted from the heptamer structure. The heptamer is 10 nm in diameter and 10 nm in length, as measured along the sevenfold axis. The β -barrel stem, which penetrates the membrane, is about 6 nm long. PDB ID: 7AHL.

orders of magnitude more rapidly than L-glucose. Facilitated transport of metabolites like glucose appears to be a common feature in cells.

The key feature of permease function is shown schematically in Figure 10.31c, namely, the permease shifts between two conformations: one open only to the “outside,” and the other open only to the “inside.” Thus, the permease never forms a pore that allows unrestricted flow of the transported substrate. Transport requires both binding of the substrate and conformational change by the permease.

Some permeases couple the transport of more than one substrate or ion. When transport of the two molecules, or ions, is in the same direction, the transporter is referred to as a **symport**; when the substrates move in opposite directions, the transporter is called an **antiport**. This cotransport strategy allows the thermodynamically unfavorable transport of some substrate *against* its concentration gradient, when coupled to the favorable transport of the cosubstrate. We will return to this topic later, after we present the general features of active transport.

Pore-Facilitated Transport

Many pathogenic bacteria synthesize and secrete protein toxins that act as ionophores by creating pores in the plasma membranes of cells of the host organism. An example, shown in Figure 10.33 (and Figure 10.15), is α -hemolysin from *Staphylococcus aureus*. This protein is made up of seven subunits, which associate to produce a membrane-spanning ion channel. Likewise, the toxin *gramicidin A* produced by the bacterium *Bacillus brevis* acts as a cation-specific ion pore, allowing a breakdown in the unequal ratio of $[K^+]$ and $[Na^+]$ normally maintained between the inside and outside of living cells. Gramicidin A is a 15-residue polypeptide, containing alternating L- and D-amino acids (Figure 10.34). Gramicidin adopts an open helical conformation when dissolved in the membrane, but one molecule of the antibiotic is long enough to traverse only half the thickness of the membrane. An open pore forms only when two gramicidin molecules line up to form a head-to-head dimer (Figure 10.34). Potassium ions (and, to a lesser extent, sodium ions) can then pass through the channel.

In addition to channels that do damage to cells, many channels facilitate transport processes that are critical to cell survival. We have already mentioned the apparatus responsible for facilitated transport of Cl^- and HCO_3^- in erythrocyte membranes: it is the transmembrane protein called the band 3 protein, or anion channel. The band 3 protein forms a channel through which Cl^- and HCO_3^- can pass. As explained in Chapter 7, much of the CO_2 generated in tissues is transported as HCO_3^- , which is formed in erythrocytes by the action of carbonic anhydrase on CO_2 .

Exit of the HCO_3^- is balanced by influx of Cl^- ; this both maintains charge balance and facilitates O_2 release (see Chapter 7). The band 3 protein doesn't just form a hole in the membrane for the passage of ions. Rather, the channel is a very selective antiport, exchanging HCO_3^- and Cl^- on a 1:1 basis. By contrast, such

**FIGURE 10.34**

Gramicidin A, an antibiotic that acts as an ion pore. Two molecules of gramicidin A form a pore through the membrane by adopting a helical conformation, with their hydrophobic side chains in contact with the lipid. Note the N-termini are inside and the C-termini are outside the bilayer core. The inside of the helix forms the hydrophilic pore. The hydrogen bonding in this open helical structure resembles that in β -sheet polypeptides. This is possible because of the alternating D and L residues.

facilitated transport is not necessary for O_2 . This tiny nonpolar molecule can move rapidly through the membrane by simple diffusion.

Many types of eukaryotic cells must move large amounts of water rapidly across their membranes as part of their physiological function. These include erythrocytes (which experience a wide range of solution osmolarity as they transit through lungs, capillaries, and kidneys), secretory cells in salivary glands, and epithelial cells in the kidney. Although water can cross membranes, it does so relatively slowly; thus, the inherent permeability of membranes toward water (see Table 10.6) is not sufficient to support the rapid transport observed in many cell types.

Such rapid transport is achieved by water-specific channels called **aquaporins**. The aquaporins function as tetramers of identical monomers. Each monomer contains six membrane-spanning helices and two shorter helices that contain a conserved N-terminal Asn-Pro-Ala (NPA) motif. Crystal structures of the aquaporins reveal that selectivity for water is achieved by three means (Figure 10.35). First, the channel is quite narrow (~ 0.28 nm) and excludes anything larger than a water molecule (including hydrated ions). Second, H_3O^+ is excluded by electrostatic repulsion. A conserved Arg places a (+) charge at this constriction, effectively repelling any cations. In addition, the two shorter helices are oriented with their N-termini pointing into the narrowest part of the channel; thus, the positive ends of the helical macrodipoles provide additional repulsion to H_3O^+ . Third, water molecules can only pass through the channel in single file. As they do so, main chain carbonyl groups as well as the conserved Asn72 and Asn192 side chains in the conserved NPA motifs form H-bonds with the individual water molecules, thereby reorienting the water molecules and disrupting H-bonding between the water molecules in the channel. This is a critical feature of the transport mechanism because it prevents protons from traversing the membrane via an H-bonding network of water molecules. As will become clear later in this chapter, and in subsequent chapters, many membranes must maintain ion gradients to carry out critical processes (e.g., bacterial flagellar motion, ATP synthesis, firing of neurons, etc.). The aquaporins elegantly solve the problem of maintaining the osmotic balance in a cell while not destroying critical ion gradients.

Research that has increased our understanding of transport across membranes was recognized by the 2003 Nobel Prize in Chemistry, awarded to Peter Agre for the discovery of aquaporins and to Roderick MacKinnon for his work elucidating the structure and function of potassium ion channels. We turn now to the selective transport of ions across membranes.

Ion Selectivity and Gating

Two outstanding features of ion channels that we explore here are their selectivity for a particular ion and the control of ion transport through the channel. Many protein ion channels and transporters display high selectivity for the biologically

Ion selectivity is achieved by optimal geometry of chelating groups in ion channels.

FIGURE 10.36

The structure of the potassium channel pore. The transmembrane pore region of the potassium channel KcsA (PDB ID 1BL8) from the bacterium *Streptomyces lividans* is shown in a “closed” conformation in panels (a–c). The pore region of the potassium channel MthK (PDB ID 1LNQ) from the bacterium *M. thermautotrophicus* is shown in an “open” conformation in panels (d–f). (a) A view looking along the pore axis from the extracellular face. The four transmembrane subunits are shown in different colors. The K^+ ions (purple spheres) are bound in the selectivity “filter” (highlighted in red) by amide carbonyl groups from each protein subunit. (b) A view from within the plane of the bilayer. Here, the periplasmic side is on top and the cytoplasmic side is on the bottom. Three K^+ ions (purple spheres) and one water molecule (smaller red sphere) are shown in the selectivity filter (see text and Figure 10.37b). (c) Here, two of the four subunits have been removed to show better the convergence of the pore helices that close the channel. The selectivity filter and the “hinge Gly” are highlighted in red. Bending of the helices at the hinge Gly residues opens the channel gate. The views in panels (d–f) are the same as those in (a–c), except that K^+ ions were not crystallized in the selectivity filter.

FIGURE 10.37

Selective binding of Na^+ and K^+ in ion channels. (a) Two Na^+ binding sites make up the selectivity filter in the transmembrane region of LeuT (PDB ID: 2A65). (b) Four K^+ are bound in the filter of the KcsA K^+ channel (PDB ID: 1K4C).

relevant ions K^+ , Na^+ , Ca^{2+} , or Cl^- . These include the bacterial K^+ channel, KcsA (shown in Figure 10.36a–c), and the Na^+ /Leu transporter, LeuT. It is instructive to compare and contrast the binding of K^+ and Na^+ by these two proteins to see how nature has achieved such exquisite selectivity. As shown in Figure 10.37, the Na^+ and K^+ bound in the **selectivity filter** are completely desolvated and chelated by multiple oxygen atoms. In LeuT, the two Na^+ binding sites provide either five or six chelating oxygen atoms (from main chain carbonyl or side chain carboxylate, hydroxyl, or amide groups) with a mean $Na^+ - O$ distance of 0.23 nm. In KcsA, each K^+ is bound by eight oxygen atoms (from main chain carbonyl or side chain $-OH$ groups) at a mean $K^+ - O$ distance of 0.28 nm. These chelating groups replace solvating interactions the ions would make with water molecules; thus, there is no enthalpic penalty for desolvating the ions as they transit the channel. Based on the structures shown in Figure 10.37, the major determinant of discrimination between Na^+ and K^+ appears to be the geometry of the chelating groups in the selectivity filter.

It is critical that the activity of any ion channel is regulated to maintain proper cell function; thus, there should be “open” (i.e., ion-conducting) and “closed” conformations for the channel. The switching between conductive and nonconductive conformations is called **gating**. Figure 10.36 compares open and closed conformations for the K^+ channel. Note that the K^+ channel pore structure is highly conserved and is defined by two membrane-spanning helices and the shorter selectivity filter described above. In the closed conformation, one transmembrane helix from each subunit extends into the channel cavity on the cytoplasmic side of the channel. The convergence of these four helices occludes the channel and prevents K^+ transport (Figure 10.36b,c). In response to some gating stimulus (e.g., a change in pH, or membrane potential, or binding of some ligand to the extracellular portion of the channel protein, etc.), the conformations of these helices change. Near the middle of each helix is a so-called hinge Gly (highlighted in red in Figure 10.36c,f). Bending of the transmembrane helices around this Gly moves the C-terminal ends of the helices apart, thereby opening the channel.

To understand better the mechanism of channel gating, let us consider the current model for the opening and closing of voltage-gated K^+ channels. The voltage-gated channels include six helical transmembrane segments labeled S1–S6 (Figure 10.38), where the K^+ pore is formed by the S5 and S6 helices along with the intervening selectivity filter sequence. This pore is structurally similar to the channels shown in Figure 10.36. Sequences S1–S4 make up the voltage-sensing domain, where S4 contains a sequence in which every third residue is lysine or

**FIGURE 10.38**

A model for voltage-gating in the K^+ channel. The channel portion of the voltage-gated K^+ channel is structurally homologous to the KcsA channel (compare to Figure 10.36). The Arg- and Lys-rich S4 helices are highlighted in blue. The depth of these helices in the bilayer changes as a function of the membrane potential. In the closed conformation (a), the helices are closer to the cytosolic side of the bilayer and this position seals the channel. The channel opens when the charged helices move toward the extracellular side of the bilayer (b). The red stripe in helix S6 indicates the location of the “hinge Gly” residue.

arginine, separated by two hydrophobic residues. The position of the S4 helix in the channel is thought to change as a function of the membrane potential ($\Delta\psi$). The cytoplasmic side of the membrane is more negatively charged; thus, in the resting state of the membrane, with the channel closed, the S4 helix is positioned closer to this side of the membrane. When the potential across the membrane changes, as in nerve signal conduction, the cytosolic side of the membrane becomes less negatively charged and the S4 helix moves toward the other side of the membrane. As it does so, it pulls S5 along, which in turn allows S6 to bend and open the channel. In this model S6 corresponds to the helix with the hinge Gly (Figure 10.37). The channel returns to the closed conformation upon restoration of the resting-state membrane potential by active ion transporters.

Now that we have described three different modes of facilitated transport, we will briefly contrast them to nonmediated transport, before discussing active transport.

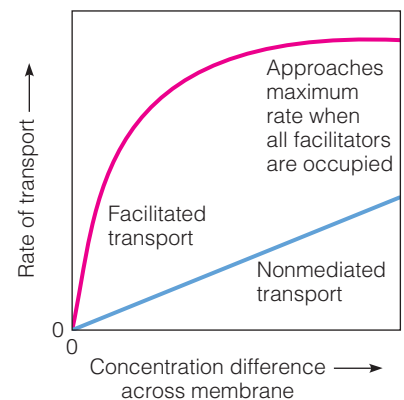

Distinguishing Facilitated from Nonmediated Transport

How can facilitated transport be distinguished from nonmediated diffusion? Aside from the generally much higher transport rate, a simple test is that facilitated transport systems are *saturable*. Any membrane has a limited number of transporters. Each carrier or permease can handle only one molecule or ion at a time; each pore can accommodate only one or a few ions or molecules at any moment. Thus, if we measure the rate of transport at increasingly higher concentration differences of the substance transported across the membrane, a limiting rate is approached when all transporters are occupied (Figure 10.39). The rate of nonmediated transport, on the other hand, increases linearly with the concentration difference, as predicted by Equation 10.4 or 10.5, because there are no sites to saturate.

There is also an easy way to distinguish between pore-facilitated and carrier-facilitated diffusion. The latter should be extremely sensitive to membrane fluidity because the carrier must actually move in the membrane. If the temperature of a membrane is lowered below its fluid–gel transition temperature, transport by a carrier like valinomycin virtually ceases. Transport by a pore structure like gramicidin A, on the other hand, is affected little by temperature changes. A simple analogy can be made to a ferry and a bridge: If the river freezes, the ferry is stopped, but the bridge can continue to transport.

In conclusion, we must emphasize that even though facilitated transport is sometimes very fast and very selective, it is still only a special form of diffusion. Transporters effectively increase the solubility of the substance in the membrane. The equilibrium state for a system exhibiting facilitated transport is the same as that for nonmediated transport—the substance will be transported down its

The rate of facilitated diffusion approaches a maximum value when all available transporters are saturated with substrate, whereas nonmediated diffusion shows a linear increase in rate as substrate concentration increases.

**FIGURE 10.39**

Facilitated and nonmediated transport. If the rate of transport is plotted against the concentration difference driving the transport, the graphs show that the rate of facilitated transport reaches a limit at a high concentration difference, whereas the rate of nonmediated transport increases linearly.

concentration gradient until the concentrations on both sides of the membrane are equal. In living cells it is necessary to transport many substances *against* a concentration gradient. The next section describes how this is achieved.

Active Transport: Transport Against a Concentration Gradient

It is imperative that some cells or cellular compartments are able to transport substances *against* concentration gradients, even very unfavorable ones. To take an extreme example, under some circumstances a $[\text{Ca}^{2+}]$ ratio of 30,000 must be established across membranes of the sarcoplasmic reticulum in muscle fibers (see Chapter 8). According to Equation 10.1, this ratio corresponds to $\Delta G = +26.6 \text{ kJ/mol}$, a formidable barrier. Nevertheless, this ratio is built up and maintained in living cells. Such transport against a concentration gradient is called **active transport**. Clearly, to pump ions against a gradient requires a free energy source of some kind. In most cases, this energy comes from the hydrolysis of ATP. It is estimated that most cells spend 20–40% of total metabolic energy just on active transport. However, the hydrolysis of ATP can be coupled to transport in a number of different ways, some of them rather indirect. To give an idea of the range of these mechanisms, we shall now consider some specific examples.

In active transport, substances are moved across a membrane against a concentration gradient. Direct or indirect coupling of transport to ATP hydrolysis provides the required free energy.

The $\text{Na}^+ - \text{K}^+$ pump acts in all cells to maintain higher concentrations of K^+ inside and Na^+ outside.

Ion Pumps: Direct Coupling of ATP Hydrolysis to Transport

The best known physiological example of active transport is the maintenance of sodium and potassium gradients across the plasma membranes of cells. The fluid surrounding cells in most animals is about 145 mM in Na^+ and 4 mM in K^+ . Yet animal cells maintain a Na^+ concentration of about 12 mM and a K^+ concentration of about 155 mM in their cytosol.

Even though Na^+ and K^+ pass very slowly through membranes by nonmediated diffusion, such inequalities would ultimately vanish unless something were done to keep K^+ moving in and Na^+ out. This movement is accomplished by the action of the **sodium–potassium pump** or **$\text{Na}^+ - \text{K}^+$ ATPase** (Figure 10.40), first described by Jens Skou, who was awarded the 1997 Nobel Prize in Chemistry for this discovery. The sodium–potassium pump is only one member of a large class

FIGURE 10.40

The structure of the $\text{Na}^+ - \text{K}^+$ ATPase with K^+ bound. The α subunit is shown in cartoon rendering with the transmembrane domain in green, the ATP-binding domain in cyan, the phosphorylation domain in orange, and the actuator domain in purple. The actuator domain translates conformation changes in the cytoplasmic domains to the membrane-bound domain (see scheme in Figure 10.41). The β subunit is beige and the small regulatory protein (FXYP) is shown in gray. K^+ ions are shown as red spheres. Two K^+ are bound in the transmembrane helical bundle. These will be transported across the membrane. Another K^+ ion, thought to activate protein dephosphorylation, is bound in the phosphorylation domain. A phosphate ion analog, MgF_4^{2-} , is shown in green spheres at the site where reversible phosphorylation of the ATPase occurs. PDB ID: 2ZXE.

of structurally related **P-type ATPases** that function in active transport across the plasma membrane. This molecular machine consists of a large 113 kDa α subunit, a 55 kDa β subunit, and frequently includes a much smaller regulatory subunit, γ . The α subunit is directly involved in the transport process and is an enzyme that hydrolyzes ATP. The free energy change in that reaction is used to drive the transport. The α subunit traverses the membrane 10 times, forming a multihelix channel. The site for ATP binding and phosphorylation lies on the cytoplasmic side (see Figure 10.40). Facing the outside are multiple sites for binding of **cardiac glycosides**, including ouabain and **digitoxin** (digitalis). The medical importance of these is discussed below. The β subunit has a single membrane-traversing helix and carries a large (20 kDa) polysaccharide on the outer surface. The β subunit acts as a chaperone and is required to target the α subunit to the plasma membrane. It also has a role in restricting K^+ movement in the conformational cycle that results in ion transport (see below).

Two K^+ ions are pumped into the cell and three Na^+ ions are pumped out for every ATP hydrolyzed. Is this estimate reasonable from a thermodynamic point of view? To answer this, we calculate the free energy required to take 3 moles of Na^+ from 12 mM to 145 mM and 2 moles of K^+ from 4 mM to 155 mM at 37 °C. First, let us use Equation 10.2 to calculate the free energy required to transport 3 moles of Na^+ from within the cell to outside. We must take into account the membrane potential of about 0.060 volt. The inside of the membrane is more negative than the outside, so this potential opposes the flow. Per mole of Na^+ , we have

$$\Delta G = RT \ln \frac{[C_{Na^+}]_{out}}{[C_{Na^+}]_{in}} + Z_{Na^+} F \Delta \psi_{in \rightarrow out}$$

$$\Delta G = \left(0.008314 \frac{\text{kJ}}{\text{mol K}} \right) (310 \text{ K}) \left(\ln \frac{(0.145)}{(0.012)} \right) + (+1) \left(96.48 \frac{\text{kJ}}{\text{mol V}} \right) (+0.060 \text{ V})$$

$$\Delta G = \left(6.4 \frac{\text{kJ}}{\text{mol}} \right) + \left(5.8 \frac{\text{kJ}}{\text{mol}} \right) = 12.2 \frac{\text{kJ}}{\text{mol}}$$

For 3 moles, then, we have $\Delta G = 3 \text{ mol } Na^+ \times +12.2 \text{ kJ}/(\text{mol } Na^+) = +36.6 \text{ kJ}$.

When K^+ is transported inward, the membrane potential is working in favor of the flow. Per mole of K^+ , we have

$$\Delta G = \left(0.008314 \frac{\text{kJ}}{\text{mol K}} \right) (310 \text{ K}) \left(\ln \frac{(0.155)}{(0.004)} \right) + (+1) \left(96.48 \frac{\text{kJ}}{\text{mol V}} \right) (-0.060 \text{ V})$$

$$\Delta G = \left(9.4 \frac{\text{kJ}}{\text{mol}} \right) + \left(-5.8 \frac{\text{kJ}}{\text{mol}} \right) = 3.6 \frac{\text{kJ}}{\text{mol}}$$

or, for 2 moles, $\Delta G = +7.2 \text{ kJ}$. The total free energy requirement for the outward transport of 3 moles of Na^+ and the inward transport of 2 moles of K^+ is then

$$\Delta G_{total} = 36.6 \text{ kJ} + 7.2 \text{ kJ} = +43.8 \text{ kJ}$$

At first glance, it would appear that the hydrolysis of 1 mole of ATP would not provide the necessary energy, for we have stated that $\Delta G^{\circ'}$, the standard-state free energy change for ATP hydrolysis under physiological conditions, is about -30 kJ/mol . In most cells, however, ATP is in much higher concentration than ADP so the actual free energy change per mole is typically -45 to -50 kJ/mol (see Chapter 12 and Problem 5). Thus, ATP hydrolysis is sufficient to maintain these concentration gradients under the observed stoichiometry of transport, but it could not transport any more than 3 mol of Na^+ and 2 mol of K^+ per mol ATP hydrolyzed.

Despite the transport against strong electrochemical gradients, the sodium–potassium pump involves no violation of thermodynamic principles. The only requirement is that ATP hydrolysis and transport be *coupled*. This coupling is apparently accomplished in a multistep process. A schematic model for the entire process is diagrammed as a cycle in Figure 10.41. It is proposed that the pump can adopt two conformations, one open only to cytosol, the other open

FIGURE 10.41

A schematic diagram of the functional cycle of the $\text{Na}^+ - \text{K}^+$ pump. The α subunit is believed to have two states, one open only to the outside (brown), the other open only to the inside (blue). A dot (\cdot) between two symbols indicates noncovalent binding, and a line ($|$) indicates covalent attachment (as in phosphorylation).

only to the cell's surroundings. Completion of one conformational cycle requires hydrolysis of one ATP. Transition to the cytosol-open conformation, which allows K^+ release and Na^+ uptake, is triggered by binding of ATP and release of phosphate. Transition to the outside-open state, which permits Na^+ release and K^+ uptake, occurs upon phosphorylation of the α subunit and release of ADP.

The outside-open state designated E-P in Figure 10.41 has an especially high affinity for cardiotonic steroids, like digitoxin and ouabain. These agents inhibit the $\text{Na}^+ - \text{K}^+$ pump by locking it in this conformation. Such inhibition has major effects on muscles, especially in the heart. The build-up of Na^+ in cells leads to measures to reduce its concentration, including a $\text{Ca}^{2+} - \text{Na}^+$ exchange process catalyzed by another pump. The resulting increase in Ca^{2+} in the sarcoplasmic reticulum of heart muscle cells leads to much stronger contractions (see pages 293–294). This is why substances like digitoxin and ouabain are used as heart stimulants.

Because ATP hydrolysis and transport are tightly coupled, a pump driven *backward* can act as an ATP generator. That is, the same kind of molecular mechanism described above, if allowed to pass a substance down a gradient, can be used to *synthesize* ATP from ADP and P_i . In fact, this mechanism is the major way in which ATP is produced in living organisms (see Chapter 15).

Cotransport Systems

There are other kinds of active transport that do not depend directly on ATP as an energy source but employ ATP hydrolysis in an indirect way. You can imagine how this might occur, if you consider that the kind of ATP-driven ion pumps described above can generate large ion concentration gradients across membranes. These ion gradients are far from equilibrium and hence represent in themselves a potential source of free energy. The **sodium–glucose cotransport system** of the small intestine (Figure 10.42) is an example of how an ion gradient is used in driving transport of glucose from a region of low [glucose] (the intestinal lumen) to one where [glucose] is higher (inside epithelial cells of the intestine wall). The transport of each glucose molecule from within the intestinal lumen into the epithelial cells is accompanied by the simultaneous movement of one Na^+ ion in the same direction. Because a favorable Na^+ gradient is maintained by the ATP-driven $\text{Na}^+ - \text{K}^+$ pump of these cells, glucose can be transported against an unfavorable

Cardiotonic steroids inhibit the $\text{Na}^+ - \text{K}^+$ pump, resulting in increased Ca^{2+} ion concentration in heart muscle, which, in turn, leads to stronger contractions of the heart muscle.

In cotransport, the unfavorable movement of a substance through the membrane is coupled to the favorable transport of another substance.

FIGURE 10.42

A schematic model for the sodium–glucose cotransport (symport) system. As in the case of the sodium–potassium pump, the sodium–glucose cotransport channel is presumed to have two possible states—one open only to the outside, the other open only to the inside of the cell. Transition to the inside-open state is stimulated by glucose binding to $E \cdot Na^+$. Return to the outside-open state occurs upon Na^+ release to the inside of the cell. The sodium gradient from inside to outside provides the driving force for the unfavorable transport of glucose. That gradient must be maintained by the sodium–potassium pump.

gradient in glucose concentration. Glucose “piggybacks” on the thermodynamically favored Na^+ transport.

A large number of such cotransport systems are known, many of them utilized to move nutrients into cells. A few examples are listed in Table 10.7. Many use the Na^+ gradient as a driving force, but some, like the *lactose permease system* in *E. coli*, depend on an H^+ gradient. As we shall see in later chapters, generation of H^+ gradients is a central step in energy production by most cells.

Transport by Modification

One other method cells have of achieving transport against a gradient uses the following strategy: Suppose a molecule, on moving into a cell by nonmediated or facilitated transport, is chemically modified in such a way that it can no longer pass back through the membrane. The net result is that quantities of the modified molecule steadily accumulate within the cell. This method is used by many bacteria for the uptake of sugars. The sugars are phosphorylated, either during their diffusion through the membrane or as soon as they emerge into the cytosol. Membranes are impermeable to the charged, phosphorylated monosaccharides, and thus these products remain in the cell. In the best-studied example, the **phosphoenolpyruvate: glucose phosphotransferase system** of *E. coli*, transport is facilitated by a transmembrane protein. While in the pore of the transporter, the sugar molecule is apparently phosphorylated by phosphoenolpyruvate (PEP, a strong phosphoryl group donor—see Chapter 3). The process has the added convenience that phosphorylation of monosaccharides is, as discussed in Chapter 13, the first step in their metabolic utilization. Thus, the sugars taken up by *E. coli* are already primed for metabolism. Although this transport mechanism looks very different from the direct coupling in ion pumps, they are basically the same. In both cases a compound (ATP or PEP) with a very favorable free energy of phosphoryl group transfer has been hydrolyzed to accomplish the directed transport of a molecule across the membrane.

In this section we have described only a few examples of specific membrane transport. This phenomenon is encountered in later chapters on metabolism. To give an idea of how important specific transport is, Figure 10.43 illustrates some

In transport by modification, a substance that has diffused through a membrane is modified so that it cannot return.

TABLE 10.7 Some cotransport systems

Molecule Transported	Ion Gradient Used	Organism or Tissue
Glucose	Na^+	Intestine, kidney of many animals
Amino acids	Na^+	Mouse tumor cells
Glycine	Na^+	Pigeon erythrocytes
Alanine	Na^+	Mouse intestine
Lactose	H^+	<i>E. coli</i>

FIGURE 10.43

Specific transport processes. This composite plant–animal cell illustrates some of the most important specific transport processes. All of the substances shown here, and many more, are transported in specific directions across cellular membranes. Magenta dots signify known transport proteins.

of the known examples, using a hypothetical cell containing some characteristics of both plant and animal cells.

The modes of transport we have described above for small molecules or ions typically involve the action of a single protein or carrier. Larger volumes of solution can be transported across various membranes in bulk as a result of remodeling of membranes. This is achieved by the actions of proteins that bind tightly to the bilayer and deform it, forming pits or sacs that enclose the volume to be transported.

Caveolae and Coated Vesicles

Bilayer deformation is required for the normal function of membranes in processes such as endocytosis (see Chapter 17), exocytosis, and membrane trafficking (Chapter 28). Endocytosis is a process in which extracellular substances are engulfed by a small portion of the membrane and imported into the cell (exocytosis is essentially the reverse process). Membrane trafficking involves the sorting of proteins into specific cellular organelles, via carrier vesicles. This requires that spherical portions of the membrane engulf some volume containing “cargo” and then bud from the membrane, in a process called **membrane fission**, so the cargo can be delivered from one site to another. The cargo may be soluble in the enclosed fluid, or it may be attached to a receptor in the membrane that encloses it. **Coated vesicles** (~0.1 microns in diameter) and smaller **caveolae**, shown in Figure 10.44, are two examples of such structures.

The formation of coated vesicles is mediated by several molecules of the protein **clathrin**, which forms a cage around a portion of the membrane and thereby distorts the bilayer into a so-called **coated pit** (top panels Figure 10.44a; see also Figure 17.10, page 718). Eventually the coated pit seals up and buds (bottom panel Figure 10.44a). This process is described in greater detail in Chapter 17 (pages 718–720).

In the case of caveola formation, the protein **caveolin** inserts into one leaflet of the bilayer and induces extreme curvature (Figure 10.44b), which leads to bud formation. Caveolin interacts with the components of membrane rafts discussed above (see page 381); thus, rafts appear to play a role in membrane trafficking.

Bulk transport across membranes involves the formation of clathrin-coated vesicles and/or caveolae.

**FIGURE 10.44**

Bulk transport by coated vesicles and caveolae. Electron micrographs are shown in panel (a) and the top of panel (b). **(a)** Formation of a clathrin-coated vesicle initiates with formation of a coated pit (top two panels), which then buds (third panel from top), forming a free coated vesicle (bottom panel). **(b)** Caveola formation occurs at sites rich in cholesterol and sphingolipids (“lipid rafts,” see Figure 10.26) due to insertion of caveolin into one leaflet of the membrane. Budding of the caveola yields a free vesicle.

Hancock, Biogenesis of caveolae: A structural model for caveolin-induced domain formation. © 1997 The Company of Biologists Ltd.

Once the cargo is enclosed it must be delivered to its target in the cell. This is achieved by recognition of proteins on the surface of the target membrane by the vesicle/caveola. The membranes of the vesicle and target must then fuse to allow the cargo to be transferred. This process, called **membrane fusion**, is mediated by proteins called **SNAREs** and is discussed in greater detail in Chapter 28 (see Figure 28.47, page 1220).

Excitable Membranes, Action Potentials, and Neurotransmission

We close with an example that demonstrates the enormous variety of properties that membranes can exhibit, through their ability to regulate ion transport. The conduction of neural impulses in animals is a remarkable process, but it depends on very simple physical principles.

Neurons, the cells responsible for conduction of electrical impulses and thus nervous system communication, have specialized thin cell projections called dendrites and axons that act as the “wires” of the nervous system (Figure 10.45). Neurons are truly remarkable cells that must meet unusual requirements. They

**FIGURE 10.45**

Structure of a typical mammalian motor neuron. A motor neuron transmits nerve impulses to muscles. The cell body contains the nucleus and most of the cellular machinery. The dendrites receive signals from the axons of other neurons; the axon transmits signals via the synaptic termini, which communicate to the dendrites of other neurons or to muscle cells. Along the axon are Schwann cells, which envelop the axon in layers of an insulating myelin membrane. The Schwann cells are separated by nonmyelinated regions called the nodes of Ranvier.

Neurons conduct electrical impulses by membrane potential changes in regions of the plasma membrane cell.

must be able to conduct impulses over relatively long distances without significant signal loss (e.g., from the spinal cord to the tip of the toe), and they must conduct impulses on millisecond timescales to control rapid and coordinated thought and behavior. Nerve conduction is accomplished not by electron flow, as in wires, but by waves in the membrane electrical potential on the surface of the membrane. To understand how nerve signaling works, we must examine how membrane potentials are generated and how they can be changed. In the limited space here, we can give only the briefest introduction to this vast and complex field.

The Resting Potential

To understand changes in membrane potentials, we must first understand the source and nature of the cell's resting membrane potential. We begin with a simplified model, which draws on our earlier discussion of the electrochemical potential difference across a semipermeable membrane (see Equation 10.2). Suppose we have an ion (M^Z) of charge Z that is present outside the membrane at concentration $[M^Z]_{\text{out}}$ and inside at concentration $[M^Z]_{\text{in}}$.

If the system is at equilibrium, ΔG for transport will be zero. Then, from equation (10.2), we find

$$\frac{RT}{ZF} \ln \frac{[M^Z]_{\text{out}}}{[M^Z]_{\text{in}}} = \Delta\psi \quad (10.7)$$

where $\Delta\psi$ is defined as $\psi_{\text{out}} - \psi_{\text{in}}$. Equation 10.7 is one form of the **Nernst equation**. For monovalent ions ($Z = \pm 1$) at 20 °C, this form of the Nernst equation reduces to

$$\Delta\psi = \pm 59 \log_{10} \frac{[M]_{\text{out}}}{[M]_{\text{in}}} \quad (10.8)$$

when $\Delta\psi$ is expressed in millivolts (mV).

According to Equation 10.8, if we maintain an ion concentration difference across a membrane, an electrical potential difference will be produced. For example, if an ion such as K^+ ($Z = +1$) is kept 10 times as concentrated inside as outside, the membrane will be polarized, with $\Delta\psi = -59$ mV. If the single ion that is unevenly distributed in this way is chloride, the potential will be +59 mV.

The major mechanisms creating ionic imbalance across cellular membranes are the specific ion pumps (e.g., the $\text{Na}^+ - \text{K}^+$ ATPase) that continually act to concentrate certain ions on one side or the other. This imbalance gives rise to the resting potential across the membrane of a nerve axon. A much-studied example is the giant axon of the squid. This is a favorite experimental tool because squids are unusual in having axons as large as 1 mm in diameter. It is possible, as shown in Figure 10.46, to insert recording electrodes into such an axon and measure the

FIGURE 10.46

Use of squid giant axons for studies of neural transmission. Electrodes attached to a voltmeter record the potential across the axonal membrane. At the resting axon ion concentrations shown here, the voltmeter would read about -60 mV. If the axon is stimulated at point A by a depolarizing pulse, the traveling membrane potential will shortly pass point B, where it can be recorded.

potential difference across the membrane. (The figure also shows stimulating electrodes, which are used in an experiment we will describe shortly.)

In the squid axon, we have a situation more complex than can be described by the Nernst equation. Several ions are involved, each of which can pass through the membrane, at least to some degree, and which are maintained in unequal concentrations on the two sides. If we used the Nernst equation to calculate the potential from the distribution of K^+ alone, we would predict a value of -75 mV (which we will call $\Delta\psi_{K^+}$). On the other hand, using the Nernst equation with the Na^+ concentration inside and outside, we would find $\Delta\psi_{Na^+} = +55$ mV. When we measure the potential across a resting squid axonal membrane, we find a value of about -60 mV. What determines the actual potential in this case?

The key is that when several kinds of ions can pass through the membrane, the *permeability* of the membrane to different ions is important in determining $\Delta\psi$. The various ions are not at true equilibrium across the axonal membrane but are in a steady state, the position of which is determined in part by the individual permeabilities. This steady state can be described quantitatively by the **Goldman equation**. For the membrane potential determined by a collection of monovalent anions and cations, the Goldman equation gives

$$\Delta\psi = \frac{RT}{F} \ln \frac{\sum_+ P_i [M_i^+]_{out} + \sum_- P_j [X_j^-]_{in}}{\sum_+ P_i [M_i^+]_{in} + \sum_- P_j [X_j^-]_{out}} \quad (10.9)$$

Here, the sums (denoted by Σ) are taken over all cations (Σ_+) and anions (Σ_-) with significant permeability, and the P values are the relative membrane permeabilities for these ions. Note that if any one ion were to have a much greater permeability than any of the others, it would dominate in the Goldman equation, and Equation 10.9 would reduce to the Nernst equation for that ion.

The resting potential is largely determined by **K^+ leak channels**, which, unlike the gated K^+ channels discussed previously, are open under most conditions. The leak channels increase the permeability of cell membranes to K^+ , resulting in a membrane potential that is close to that predicted by the Goldman equation. The only ions that contribute appreciably to the membrane potential in this case are K^+ , Na^+ , and Cl^- , and their relative permeabilities are $P_K^+ = 1.0$, $P_{Na^+} = 0.04$, and $P_{Cl^-} = 0.45$. If these values are inserted into Equation 10.9, together with the ion concentrations given in Figure 10.46, we find $\Delta\psi = -61$ mV, in agreement with experimental observation.

The resting potential of a nerve fiber is determined by the permeabilities of the membrane to different ions, particularly K^+ , which has a high permeability due to K^+ leak channels.

The Action Potential

The action potential is a controlled and rapidly propagated change in membrane potential that is transmitted down the length of an axon. This process involves a unique set of voltage-gated potassium and voltage-gated sodium channels. Due to the biochemical properties of the ion channels, the action potential is self-propagating and travels in a single direction down an axon. We briefly describe how this unique membrane potential change is created and propagated.

An action potential is created if the changes in the membrane potential reach a critical threshold. The resting potential value of -61 mV has a vital significance. Because -61 mV lies much closer to -75 mV than to $+55$ mV, it means that at the potential existing across the squid axon membrane, K^+ is much closer to its equilibrium distribution than is Na^+ . If the membrane were to become fully permeable to Na^+ ions, the major event would be a massive influx of Na^+ ions, with an accompanying shift in the membrane potentials toward $\Delta\psi_{Na^+}$. This is just what happens when an action potential is transmitted along a nerve (Figure 10.47).

Axonal fibers have specific, voltage-gated channels for the facilitated transport of Na^+ and K^+ through the membrane. As described previously, voltage-gated channels are open or closed, depending on the membrane potential. For example, they are closed in the resting state (Figure 10.47a). Suppose we perform an experiment using electrodes placed in a squid giant axon as shown in Figure 10.46. At some distance from the recording electrodes, we place stimulating electrodes

The action potential is generated and propagated because a small depolarization of the nerve cell membrane opens voltage gated channels, allowing ions to flow through.

FIGURE 10.47

The voltage-gated channel cycles during an action potential. (a) In the resting state, K⁺ is concentrated on the inside of the axon membrane and Na⁺ on the outside. (b) Electrical stimuli cause local, partial depolarization of the membrane, which in turn causes the voltage-gated sodium channel activation gates to open, allowing a large inward rush of Na⁺. The opening of these channels causes the membrane to be primarily permeable to Na⁺ and thus the membrane potential is determined primarily by the potential of Na⁺. As Na⁺ approaches its equilibrium, the inrush slows, and Na⁺ diffuses along inside the axon. (c) The increase in membrane potential closes the Na⁺ channel h-gates, and opens the K⁺ channels. K⁺ gates open, and K⁺ flows outward. (d) The outward flow of K⁺ causes an extreme decrease in the membrane potential, which becomes temporarily more negative than the resting potential. This causes the Na⁺ m-gates to close (in addition to the h-gates). Movement of K⁺ ions restores the resting potential, but the membrane is inactivated (refractory) during this time period. This refractory period is crucial for ensuring unidirectional propagation of the action potential down the axon.

Courtesy of Gary Carlton.

connected to a voltage source. If we apply at this electrode a pulse sufficient to depolarize the membrane locally by about 20 mV—that is, to a potential of -40 mV (the threshold for opening the Na⁺ channels)—the Na⁺ channel **activation gates** (m-gates) are opened (Figure 10.47b). The permeability to Na⁺ increases about 100-fold and a flood of sodium ions rushes in, bringing the membrane potential up to about $+40$ mV within less than a millisecond (Figure 10.47c). In terms of the Goldman equation, the sudden high permeability of Na⁺ ions makes them dominate, and the membrane potential *approaches* $\Delta\psi_{\text{Na}^+}$ ($+55$ mV). It does not reach this value, however, for further changes now occur. As seen in Figure 10.47b, the stimulus also causes K⁺ channel gates to open, but more slowly, and these allow the influx of K⁺ ions into the surrounding medium. This event reverses the potential again, overshooting to about -70 mV. This change closes the Na⁺ channel **inactivation gates** (h-gates, which are separate from the activation gates), temporarily making the Na⁺ channels resistant to opening (the refractory period—Figure 10.47d). The potential and permeability changes shown in Figure 10.47b–d occur in just a few milliseconds. The same changes are depicted graphically in Figure 10.48.

These steep changes in membrane potential would be a localized effect were it not for the sequential opening and closing of gates as shown in Figure 10.47c and d. As Na⁺ ions rush in, they diffuse away from the region of stimulus and trigger the same round of depolarization in an adjacent section of the fiber. Thus a wave of depolarization can spread through the axon. Following the wave front are the reverse polarization due to K⁺ efflux, the refractory zone where K⁺ channels are open and the Na⁺ channels are inactivated, and the final return to the resting condition (Figures 10.47a and 10.49). Thus, the recording electrode in Figure 10.46 will see traveling past it, at some time after the stimulating pulse, exactly the same pattern of depolarization and reversal depicted in Figure 10.47b–d and Figure 10.48. This traveling pulse is called the *action potential*. The movement is depicted in Figure 10.49. The time required for the impulse to pass from stimulating electrode

to recording electrode is proportional to the distance between the two electrodes and is inversely proportional to the velocity of propagation of the pulse. Typical values for propagation of the action potential range from 1 to 100 meters per second.

Toxins and Neurotransmission

Many extremely toxic substances have their effect by blocking the action of the specific ion gates necessary for development of the action potential. These substances are often called **neurotoxins**. *Tetrodotoxin* is found in some organs of the puffer fish. This fish is considered a delicacy in Japan, where special chefs are trained and certified for their ability to remove the toxin-containing organs. Tetrodotoxin binds specifically to the Na^+ channel, blocking all ion movement. The same effect is produced by *saxitoxin*, contained in the marine dinoflagellates responsible for “red tide.” These microscopic algae, along with their toxin, are ingested by shellfish and can in turn be consumed by humans. These two toxins, which attack a fundamental process of the nervous system, are among the most poisonous substances known, and their accidental ingestion leads to many deaths every year. A third very poisonous substance, *veratridine*, is found in the seeds of a plant of the lily family, *Schoenocaulon officinale*. This toxin also binds to the Na^+ channels but blocks them in the “open” configuration.

These toxins have proven to be useful in studies of axonal structure and conduction, for their tight binding makes them excellent affinity labels for the channel.

We have described here only one part of the whole phenomenon of the transmission of neural impulses—the conduction along a single nerve fiber. The

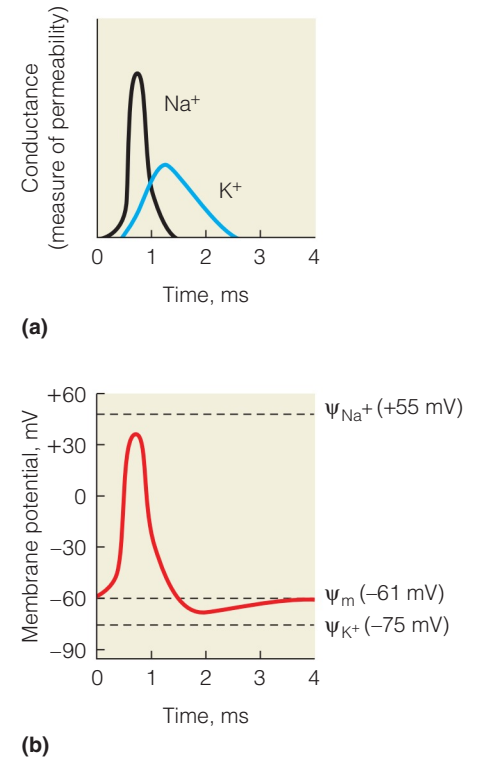

(a) Time = 0

(b) Time = 1 ms

FIGURE 10.48

The action potential. (a) Changes in membrane conductance at a point on an axon as a neural impulse passes. The membrane first becomes permeable to sodium ions, allowing a large inward rush of Na^+ . A decrease in the Na^+ permeability results and is in turn followed by an outward flow of K^+ . (b) Changes in membrane potential accompanying the permeability changes shown in (a). As Na^+ rushes in, the potential increases and becomes positive. As K^+ influx increases, the potential decreases, undershooting the resting potential, $\Delta\psi_m$, before returning to the resting potential.

Neurotoxins can act by blocking gates in the axonal membrane in closed or open states.

FIGURE 10.49

Transmission of the action potential. Shown are two “snapshots,” taken 1 ms apart, of potential along the axon. Arrows show Na^+ influx and K^+ efflux. (a) At time = 0, an action potential is occurring at the 2.5-mm position. The depolarization spreads down the axon, triggering development of the action potential downstream (to the right in this diagram). (b) At time = 1 ms, the action potential peak has moved to the 3.8-mm position. The potential can move in only one direction because after it has passed, the region behind the potential becomes refractory for a few milliseconds due to the inactivation gate (see Figure 10.47).

Courtesy of Gary Carlton.

equally important problem of how these impulses are transmitted from one cell to another is discussed in Chapter 23, where the actions of *neurotransmitter* substances are described.

SUMMARY

Many of the important properties of lipids stem from the fact that these substances are largely hydrophobic. Some are amphipathic, containing both hydrophobic and hydrophilic regions. Most naturally occurring fatty acids contain an even number of carbon atoms. When they are unsaturated, the double bonds are usually *cis*. Fatty acids are present in fats (triacylglycerols), where they serve for energy storage and insulation, and in membranes, where they are constituents of phospholipids, sphingolipids, glycosphingolipids, and glycolipids. Membranes are bilayer structures, containing proteins and lipids in a fluid mosaic. The two leaflets differ in protein and lipid composition. Peripheral proteins are confined to one face or the other, whereas integral proteins extend through the membrane, with hydrophobic α helices common in the transmembrane region.

Transport through membranes may be achieved by nonmediated diffusion; may be facilitated by pores, permeases, or carriers; or may be actively driven by exergonic reactions. Only in the last case can transport against a concentration gradient occur. An example is the $\text{Na}^+ - \text{K}^+$ pump, which maintains the ionic imbalance and membrane potential found between cells and their surroundings. Active transport may be indirect, as in cotransport or transport by modification.

Neural conduction of impulses depends upon a moving wave of depolarization (an action potential) in the membrane potential of a neural cell. This depolarization is produced by the flow of ions through voltage-gated channels in the membrane. The rate of neural transmission depends upon the dimensions of the axons and whether or not they are myelinated.

APPENDIX

Guidelines for Evaluating the Thermodynamics of Ion Transport

In biological systems the concentrations of solutes, especially ions, are usually significantly different across a membrane. Such concentration differences for ions are called “electrochemical gradients,” or “electrochemical potentials.” The free energy of ion movement through an electrochemical gradient is described by Equation 10a.1:

$$\Delta G = \Delta G^{\circ'} + RT \ln Q + nzF\Delta\psi \quad (10a.1)$$

where R = the gas constant, T = temperature in Kelvin, Q = steady-state mass action expression, n = mol of ions, z = charge on the ion, F = the Faraday constant, and $\Delta\psi$ = the membrane potential. For the movement of a solute across a membrane by diffusion, $\Delta G^{\circ'} = 0$. Note that for *active* transport, $\Delta G^{\circ'}$ will not equal zero because $\Delta G^{\circ'}$ for ATP hydrolysis is not equal to zero, and $\Delta G^{\circ'}$ for the *overall transport process* is the sum of the values of $\Delta G^{\circ'}$ for the individual steps (ion transport + ATP hydrolysis).

The term $RT \ln Q$ describes the energy required to move an ion through a concentration gradient and $nzF\Delta\psi$ describes the energy required to move an ion through an electrical potential. Given the intra- and extra-cellular concentrations of ions: $[\text{Na}^+]_{\text{in}} = 12 \text{ mM}$, $[\text{Na}^+]_{\text{out}} = 145 \text{ mM}$, $[\text{K}^+]_{\text{in}} = 155 \text{ mM}$, $[\text{K}^+]_{\text{out}} = 4 \text{ mM}$ and the potential across the membrane of 60 mV

(inside negative), one can apply basic thermodynamic principles to correctly predict the effects that the terms $RT \ln Q$ and $nzF\Delta\psi$ will have on the sign of ΔG (Equation 10a.1).

To begin, consider the simpler case of ion transport without ATP hydrolysis. Recall that changes in state functions are calculated as $\text{State}_{(\text{final})} - \text{State}_{(\text{initial})}$. In this case “final” and “initial” states more appropriately refer to final and initial *conditions* of the transported ion (i.e., the ion is either inside or outside the cell). As described in Chapter 3, the steady-state distribution of species is described by the mass-action term Q , where

$$Q = \frac{(\text{activities of species in final condition})}{(\text{activities of species in initial condition})}$$

Likewise $\Delta\psi$ is calculated as $\psi_{\text{final}} - \psi_{\text{initial}}$, where in this case “final” and “initial” refer to location:

$$\Delta\psi = \psi_{\text{final location}} - \psi_{\text{initial location}} \quad (\text{in this case “location” = “in” or “out,” depending which direction the ion is transported})$$

Putting these parameters back into Equation 10a.1:

$$\text{For the transport of } [\text{Na}^+]_{\text{in}} \rightarrow [\text{Na}^+]_{\text{out}}$$

$$\Delta G = \Delta G^{\circ'} + RT \ln Q + nzF\Delta\psi \quad (10a.2)$$

$$\Delta G = RT \ln \left(\frac{[\text{Na}^+]_{\text{out}}}{[\text{Na}^+]_{\text{in}}} \right) + nzF(\psi_{\text{out}} - \psi_{\text{in}})$$

Conversely, for the transport of $[\text{Na}^+]_{\text{out}} \rightarrow [\text{Na}^+]_{\text{in}}$

$$\Delta G = RT \ln ([\text{Na}^+]_{\text{in}}/[\text{Na}^+]_{\text{out}}) + nzF(\psi_{\text{in}} - \psi_{\text{out}}) \quad (10a.3)$$

The proper evaluation of the Q term is described in detail in Chapter 3 (see pages 79–80). Here, we describe two methods for correctly calculating the value of $\Delta\psi$.

Method 1: The conditions given above, where $\Delta\psi = 60$ mV (inside negative), indicate that the magnitude of the electrical potential difference between ψ_{in} and $\psi_{\text{out}} = 60$ mV, and that the inside is negative with respect to the outside. So ψ_{in} is a relatively negative number and ψ_{out} is a relatively positive number, thus:

For the transport of $[\text{Na}^+]_{\text{out}} \rightarrow [\text{Na}^+]_{\text{in}}$:

$$\psi_{\text{in}} - \psi_{\text{out}} = [\text{a } (-)\text{number}] \text{ minus } [\text{a } (+)\text{number}] = (-)\text{number},$$

so $\Delta\psi$ will be

$$-60 \text{ mV (or } -0.060 \text{ V)}$$

and

$$\begin{aligned} nzF\Delta\psi &= (1 \text{ mol Na}^+)(+1)(96.5 \text{ kJ mol}^{-1} \text{ V}^{-1})(-0.060 \text{ V}) \\ &= -5.79 \text{ kJ} \end{aligned} \quad (10a.4)$$

For the transport of $[\text{Na}^+]_{\text{in}} \rightarrow [\text{Na}^+]_{\text{out}}$:

$$\psi_{\text{out}} - \psi_{\text{in}} = [\text{a } (+)\text{number}] \text{ minus } [\text{a } (-)\text{number}] = (+)\text{number},$$

so $\Delta\psi$ will be

$$+60 \text{ mV (or } +0.060 \text{ V)}$$

and

$$\begin{aligned} nzF\Delta\psi &= (1 \text{ mol Na}^+)(+1)(96.5 \text{ kJ mol}^{-1} \text{ V}^{-1})(+0.060 \text{ V}) \\ &= +5.79 \text{ kJ} \end{aligned} \quad (10a.5)$$

Method 2: Check this calculation against the guiding principle given below. As seen from method 1, the *magnitude* of $nzF\Delta\psi$ is the same in either case (± 5.79 kJ/mol). The sign is different depending on which direction the ion is transported. The most common error in calculating $nzF\Delta\psi$ is incorrectly calculating the sign of $\Delta\psi$. This is where understanding a guiding principle can help.

For the transport of $[\text{Na}^+]_{\text{out}} \rightarrow [\text{Na}^+]_{\text{in}}$:

A (+) charged sodium ion is moving from an environment of relative (+) charge outside the cell to one of relative (–) charge inside the cell. *Such ion movement will decrease unfavorable repulsive interactions and increase favorable attractive interactions.* Overall, this should be a thermodynamically *favorable* process and the sign of $nzF\Delta\psi$ should be (–) to reflect that fact (see Equation 10a.4).

For the transport of $[\text{Na}^+]_{\text{in}} \rightarrow [\text{Na}^+]_{\text{out}}$:

A (+) charged sodium ion is moving from an environment of relative (–) charge inside the cell to one of relative (+) charge outside the cell. *Such ion movement will increase unfavorable repulsive interactions and decrease favorable attractive interactions.* Overall, this should be a thermodynamically *unfavorable* process and the sign of $nzF\Delta\psi$ should be (+) to reflect that fact (see Equation 10a.5).

Given the ion concentrations and membrane potential above, Table 10a.1 summarizes predictions for the signs on the $RT \ln Q$ and $nzF\Delta\psi$ terms in the free energy calculation based on the guiding principle above (which applies to $nzF\Delta\psi$) and another given here (which applies to $RT \ln Q$): *Transport from a location of low concentration to one of higher concentration is unfavorable; transport from a location of high concentration to one of lower concentration is favorable.*

TABLE 10a.1

	Sign on $RT \ln Q$	Sign on $nzF\Delta\psi$
For $[\text{Na}^+]_{\text{in}} \rightarrow [\text{Na}^+]_{\text{out}}$	positive (unfavorable)	positive (unfavorable)
For $[\text{Na}^+]_{\text{out}} \rightarrow [\text{Na}^+]_{\text{in}}$	negative (favorable)	negative (favorable)
For $[\text{K}^+]_{\text{in}} \rightarrow [\text{K}^+]_{\text{out}}$	negative (favorable)	positive (unfavorable)
For $[\text{K}^+]_{\text{out}} \rightarrow [\text{K}^+]_{\text{in}}$	positive (unfavorable)	negative (favorable)

PROBLEMS

- Give structures for the following, based on the data in Table 10.1.
 - cis*-9-Dodecenoic acid
 - 18:1 Δ 11
 - A saturated fatty acid that should melt below 30 °C
- Given these molecular components—glycerol, fatty acid, phosphate, long-chain alcohol, and carbohydrate—answer the following:
 - Which two are present in both waxes and sphingomyelin?
 - Which two are present in both fats and phosphatidylcholine?
 - Which are present in a ganglioside but not in a fat?

3. The classic demonstration that cell plasma membranes are composed of bilayers depends on the following kinds of data:
- The membrane lipids from 4.74×10^9 erythrocytes will form a monolayer of area 0.89 m^2 when spread on a water surface.
 - The surface of one erythrocyte is approximately $100 \mu\text{m}^2$ in area.

Show that these data can be accounted for only if the erythrocyte membrane is a bilayer.

4. The lipid portion of a typical bilayer is about 3 nm thick.
- Calculate the number of residues in an α helix that will just span this distance.
 - The epidermal growth factor receptor has a single transmembrane helix. Find it in this partial sequence:

...RGPKIPSIATGMVVGALLLVVALGIGILFMRRRH...

5. In the situations described below, what is the free energy change if 1 mole of Na^+ is transported across a membrane from a region where the concentration is $1 \mu\text{M}$ to a region where it is 100 mM ? (Assume $T = 37^\circ\text{C}$)
- In the absence of a membrane potential.
 - When the transport is opposed by a membrane potential of 70 mV .
 - In each case, will hydrolysis of 1 mole of ATP suffice to drive the transport of 1 mole of ion, assuming $\text{pH} 7.4$ and the following cytoplasmic concentrations: $\text{ATP} = 4.60 \text{ mM}$, $\text{P}_i = 5.10 \text{ mM}$, $\text{ADP} = 310 \mu\text{M}$?

- *6. Consider passive diffusion of ions across the erythrocyte membrane, as measured by the permeability coefficients in Table 10.6. Calculate the number of moles of K^+ that would diffuse across a single erythrocyte membrane in 1 min, given the following data:

$$C_{\text{K}^+}(\text{inside}) = 100 \text{ mM}$$

$$C_{\text{K}^+}(\text{outside}) = 15 \text{ mM}$$

The surface area of one erythrocyte = $100 \mu\text{m}^2$.

7. If the volume of the erythrocyte in Problem 6 is about $100 \mu\text{m}^3$, what percentage of the K^+ ions would escape by passive diffusion in 1 minute?
- *8. Assuming that the flow, J , in carrier-facilitated transport is proportional to the fraction of carriers occupied, derive an equation for J as a function of the concentration $[A]$ of the substance transported.
9. Suppose calcium ion is maintained within an organelle at a concentration 1000 times greater than outside the organelle ($T = 37^\circ\text{C}$). What is the contribution of Ca^{2+} to the membrane potential? Which side of the organelle membrane is positive, and which is negative?
10. Calculate the equilibrium membrane potentials to be expected across a membrane at 37°C , with a NaCl concentration of 0.10 M on the right and 0.01 M on the left, given the following conditions. In each case, state which side is (+) and which is (-).
- Membrane permeable only to Na^+ .
 - Membrane permeable only to Cl^- .
 - Membrane equally permeable to both ions.
11. In each of a, b, and c of Problem 10, will any appreciable transport of material take place in establishing the membrane potential?
- *12. The rod cells in the retina contain membranes that are depolarized when a photon of light is absorbed. Suppose the following concentrations exist inside and outside a retinal rod cell:

	Concentration (mM)	
	Inside	Outside
K^+	100	5
Na^+	10	140
Cl^-	10	100

(a) If the relative permeabilities of K^+ and Cl^- are 1.0 and 0.45, respectively, what must be the relative permeability for Na^+ to give a potential of 30 mV , the value found across the resting rod cell membrane? Assume $T = 37^\circ\text{C}$. [Hint: You must rearrange and solve the Goldman equation.]

(b) If the Na^+ gates were to close completely on stimulation by a photon, what value of the membrane potential would be reached?

13. Many transmembrane proteins are oligomeric, with several identical subunits. The oligomers are usually found to have some form of C_n symmetry, rather than D_n or any higher order. Suggest a reason for this observation.
14. The average human generates approximately his or her weight in ATP every day. A resting person uses about 25% of this in ion transport—mostly via the $\text{Na}^+ - \text{K}^+$ ATPase. About how many grams of Na^+ and K^+ will a sedentary 70-kg person pump across membranes in a day?
- *15. The concentration of glucose in your circulatory system is maintained near 5.0 mM by the actions of the pancreatic hormones glucagon and insulin. Glucose is imported into cells by protein transporters that are highly specific for binding glucose. Inside the liver cells the imported glucose is rapidly phosphorylated to give glucose-6-phosphate (G-6-P). This is an ATP-dependent process that consumes 1 mol ATP per mol of glucose. Given the steady-state intracellular concentrations below, calculate the theoretical maximum concentration of G-6-P inside a liver cell at 37°C , $\text{pH} = 7.2$ when the glucose concentration outside the cell (i.e., $[\text{glucose}]_{\text{outside}}$) is 5.0 mM :

$$\text{ATP} = 4.7 \text{ mM}; \text{ADP} = 0.15 \text{ mM}; \text{P}_i = 6.1 \text{ mM}$$

For: $\text{ATP} + \text{H}_2\text{O} \rightarrow \text{ADP} + \text{P}_i + \text{H}^+ \quad \Delta G^{\circ'} = -30.5 \text{ kJ/mol}$ and

$$\text{G-6-P} + \text{H}_2\text{O} \rightarrow \text{Glucose} + \text{P}_i \quad \Delta G^{\circ'} = -13.8 \text{ kJ/mol}$$

The glucose phosphorylation reaction is

- *16. ATP is synthesized from ADP, P_i , and a proton on the *matrix side* of the inner mitochondrial membrane. We will refer to the matrix side as the “inside” of the inner mitochondrial membrane (IMM).
- (a) H^+ transport from the outside of the IMM into the matrix drives this process. The pH inside the matrix is 8.2 and the outside is more acidic by 0.8 pH units. Assuming the IMM membrane potential is 168 mV (inside negative), calculate ΔG for the transport of 1 mol of H^+ across the IMM into the matrix at 37°C : $\text{H}^+_{(\text{outside})} \rightarrow \text{H}^+_{(\text{inside})}$.
- (b) Assume three mol H^+ must be translocated to synthesize one mol ATP by coupling of the following reactions:

Write the overall reaction for ATP synthesis coupled to H^+ transport [and use this equation for part (c)]:

(c) Assume three mol H^+ must be translocated to synthesize one mol ATP as described in part (b) above. Given the following steady-state concentrations: $\text{ATP} = 2.70 \text{ mM}$ and $\text{P}_i = 5.20 \text{ mM}$, the membrane potential $\Delta\psi = 168 \text{ mV}$ (inside negative), and the pH values in part (a), calculate the steady-state concentration of ADP at 37°C when $\Delta G = -11.7 \text{ kJ/mol}$.

TOOLS OF BIOCHEMISTRY 10A

TECHNIQUES FOR THE STUDY OF MEMBRANES

Electron Microscopic Methods

Examination of membrane structure as it exists within cells depends heavily on electron microscopy (EM), and virtually all of the variants of that method mentioned in Tools of Biochemistry 1A have been employed at one time or another. For example, transmission EM of thin sections of cells embedded in a plastic matrix reveals cellular membranes in cross-section (see Figure 1.2 for examples), whereas scanning EM can show surface details. An especially useful variant of this method is the freeze fracture technique. If a membrane is frozen quickly and then broken by a sharp blow from a microtome knife, it frequently splits along the plane between the bilayer leaflets (Figure 10A.1). One layer is thus peeled back, revealing the internal structure. The sample can then be metal-shadowed and studied by scanning EM. In a variant called freeze-etching, some of the ice is sublimed off before shadowing, revealing surface and subsurface details.

Although electron microscopy has revealed much of the elaborate architecture of natural membranes, investigators often need to use simplified systems to study specific membrane properties. For these purposes, synthetic bilayers and vesicles are frequently used.

Preparation of Bilayers and Vesicles

Membranes from individual types of cells or purified organelles can usually be obtained by lysis of the cell or organelle, followed by differential centrifugation.

If, as shown in Figure 10A.2, a membrane is extracted with organic solvents (a chloroform–ethanol mixture, for example),

the soluble lipid constituents can be separated from insoluble protein and oligosaccharides. The lipid mixture can then be fractionated by methods such as high-performance liquid chromatography (HPLC) to yield pure lipid components and an analysis of the lipid content. Alternatively, the investigator may wish to use the entire lipid mixture from a membrane.

If the organic solvent in such a preparation is removed by evaporation, and the membrane lipids are dispersed in aqueous solution, they will form vesicles (also called *liposomes*)—small spherical bilayer structures. Alternatively, a bilayer may be spread across a small hole in a partition between two compartments. Such preparations are often used to study permeability across membranes.

The vesicles can be used for many kinds of studies. For example, it is possible to reconstitute specific transport systems by isolating the transport proteins through detergent solubilization and then adding them to a vesicle-forming system. In the presence of ATP, properly reconstituted systems will display active transport. Figure 10A.3 demonstrates reconstitution of the Ca^{2+} pump of muscle cells. Vesicles made with specific mixtures of lipids and other components are also excellent objects for the study of such processes as the phase transition or diffusion in membranes.

In other kinds of experiments, it is desirable to retain all of the natural components in the membrane. This can often be done by carefully lysing cells or organelles, isolating the intact membranes, and then dispersing them in a solution in which they will reseal to form vesicles. In some cases, as shown with an erythrocyte in Figure 10A.4, it is possible to adjust conditions so that the vesicles reseal preferentially either right side out or inside out.

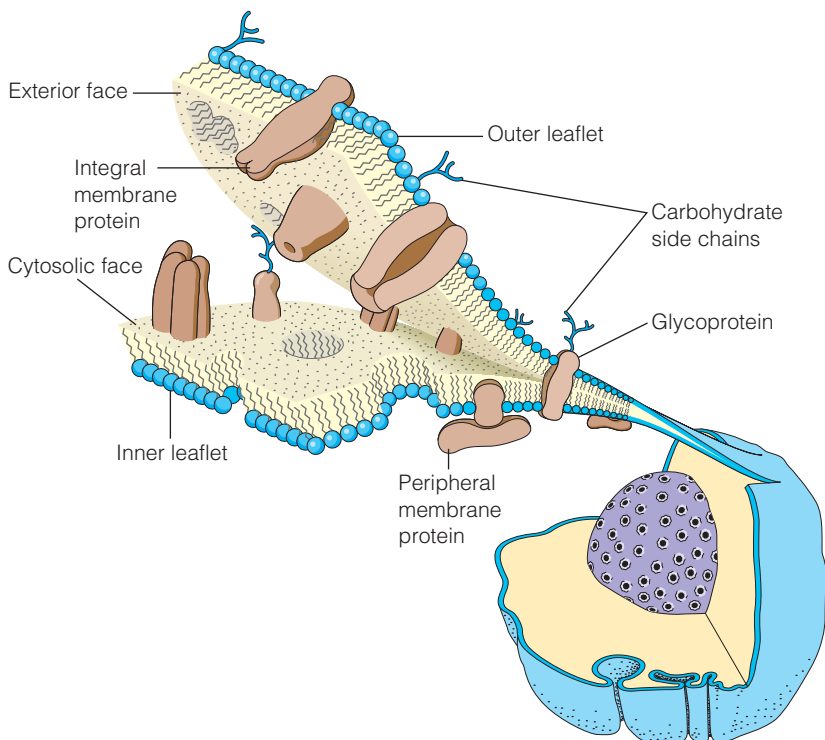

FIGURE 10A.1

**FIGURE 10A.2**

Preparation of vesicles and bilayers.

Such preparations have provided much of our information concerning membrane asymmetry.

Physical Techniques

Much of our information concerning structural transitions in membranes has come from differential scanning calorimetry (DSC). This technique was described in Tools of Biochemistry 6C for the study of protein unfolding, which is a process of phase change. Likewise, DSC is a useful technique for the study of phase transitions (e.g., from semi-crystalline to fluid) in membranes.

A simplified diagram of a DSC instrument is shown in Figure 6C.1 (page 230). To carry out a DSC experiment, samples of a lipid vesicle suspension and a buffer blank are heated in parallel, and the difference in energy input required to keep them at the same temperature is carefully monitored. As the transition temperature (T_m) is passed, more heat has to be put into the lipid sample in order to melt the membrane structure. This transition shows up as the kind of spike illustrated in Figure 10.12b. The experiment reveals the transition temperature, the sharpness of the transition, and the total energy required.

**FIGURE 10A.3**Reconstitution of the Ca^{2+} pump.

FIGURE 10A.4
Preparation and resealing of erythrocyte ghosts.

To study membrane fluidity more directly, and to examine the motion of individual kinds of molecules in the membrane, a number of other techniques are employed. Electron spin resonance (ESR) has been of major importance. Electron spin resonance bears similarities to nuclear magnetic resonance (see Tools of Biochemistry 6A) but involves changes in the spin of unpaired electrons rather than nuclei. The resonance spectrum is sensitive, in both absorption line spacing and sharpness, to the environment of the unpaired electron. As in NMR, narrow spectral lines are characteristic of a fluid environment with rapid molecular motion, and broadened lines are observed when molecular motion is sluggish.

Most compounds in natural membranes do not have unpaired electrons, but certain nitroxide compounds, such as *tempocholine*, contain an unpaired electron in an N—O bond. Tempocholine has been substituted for choline in phosphatidylcholine to act as a “reporter group,” sensing the freedom of motion of the head groups in membranes. Other reporter groups or molecules can probe the fluidity of the inside of membranes, or the mobility of membrane proteins.

Tempocholine

Another powerful technique is called fluorescence recovery after photobleaching or **FRAP** (Figure 10A.5). Selected molecules in cell membranes are given a fluorescent label. Then a tiny spot on the membrane surface is exposed to a high-intensity laser beam. This “bleaches” the fluorescent label, forming a nonfluorescent spot on the cell surface. The cell is then observed under a fluorescence microscope. As bleached molecules diffuse out of the spot and unbleached molecules diffuse in, the spot gradually recovers its original fluorescence intensity. This procedure provides a direct way to measure the lateral movement of selected molecules in membranes.

11 Enzymes: Biological Catalysts

12 Chemical Logic of Metabolism

CHAPTER 11

Enzymes: Biological Catalysts

In earlier chapters we have alluded to the importance of specific catalysts called **enzymes** in regulating the chemistry of cells and organisms. Catalysis is essential to make most critical biochemical reactions proceed at useful rates under physiological conditions. A reaction that takes many hours to approach completion cannot be metabolically useful to a bacterium that must reproduce in 20 minutes or to a human nerve cell that must respond instantly to a stimulus.

In fact, most reactions in cells must be catalyzed to proceed at rates that can support the living state. In the complex milieu of the cell, countless thermodynamically favorable reactions are possible. The cell employs specific catalysis to direct reactive substances into useful pathways rather than into unproductive side reactions. Furthermore, enzymes are regulated—in almost all cases, the activities of enzymes can be controlled to modulate the production of different substances in response to cellular and organismal needs.

The rest of this book elaborates on this theme. Each of the hundreds of reactions we will encounter is catalyzed by a specific enzyme, optimized by evolution to perform its required task. What are the special properties of enzymes that make them such efficient catalysts? That is what we will explore in this chapter.

The Role of Enzymes

Catalysts increase the velocity of chemical reactions. Enzymes are biological catalysts.

In general terms, a **catalyst** is a substance that increases the rate, or velocity, of a chemical reaction without itself being changed in the overall process. Enzymes are biological catalysts, most of which are proteins. We have already encountered a few enzymes in earlier chapters. For example, the protein trypsin catalyzes hydrolysis of peptide bonds in proteins and polypeptides. The substance that is acted on by an enzyme is called the **substrate** of that enzyme. Thus, polypeptides are the natural substrates for trypsin.

We can see the power of enzyme catalysis in a familiar example—the decomposition of hydrogen peroxide into water and oxygen:

This reaction, although strongly favored thermodynamically, is very slow unless catalyzed. A bottle of H_2O_2 (hydrogen peroxide) solution can be kept for many months before it breaks down. If, however, a bit of Fe^{3+} ion (as FeCl_3 , for example) is added, the reaction rate increases about 1000-fold. The iron-containing protein hemoglobin is even better at increasing the rate of this reaction. When hydrogen peroxide solution is applied to a cut finger, bubbles from released O_2 appear immediately—the reaction is now proceeding about 1 million times faster than the uncatalyzed process. However, even higher rates can be achieved with an enzyme specific for this reaction; *catalase*, an enzyme present in many cells, increases the rate of H_2O_2 decomposition about 1 billion-fold over the uncatalyzed rate. Hydrogen peroxide is produced in some cellular reactions and is a dangerous oxidant (see Chapter 15); thus, selective pressures have resulted in the evolution of catalase to defend cells against the damaging effects of H_2O_2 . This example shows that the rate of a favorable reaction depends greatly on whether a catalyst is present and upon the nature of the catalyst. Enzymes are among the most efficient and specific catalysts known.

Two facts deserve emphasis. First, although a true catalyst participates in the reaction process, it is unchanged by the process. For example, after catalyzing the decomposition of an H_2O_2 molecule, catalase is found again in exactly the same state as before, ready for another round. In contrast, although hemoglobin accelerates the rate of H_2O_2 decomposition, it is oxidized in the process, from the active Fe^{2+} to the inactive Fe^{3+} form; thus, hemoglobin is not a true catalyst for this reaction. Second, catalysts change *rates* of processes but do not affect the position of equilibrium for a reaction. A thermodynamically favorable process is not made more favorable, nor is an unfavorable process made favorable, by the presence of a catalyst. The equilibrium state is just approached more quickly.

Chemical Reaction Rates and the Effects of Catalysts: A Review

Reaction Rates, Rate Constants, and Reaction Order

First-Order Reactions: The Rate Constant

To understand what is meant by a reaction rate and how it might be measured, let us first consider the simplest possible reaction, the *irreversible* conversion of substance A to substance B:

The single arrow here means that the reverse reaction ($\text{B} \rightarrow \text{A}$) proceeds to only an infinitesimal extent; that is, the equilibrium state lies far to the right.

We can define the **reaction rate**, or **velocity** (v), at any instant as the rate of formation of the product, in this case B:

$$v = \frac{d[\text{B}]}{dt} \quad (11.1)$$

The units of v are *concentration per unit time* (e.g., *molar per second*: $\text{M} \cdot \text{s}^{-1}$, where $[\text{B}]$ symbolizes molar concentration of B). If we note that, for every B molecule formed, an A molecule must disappear, it is clear that v can equally well be written as

$$v = -\frac{d[\text{A}]}{dt} \quad (11.2)$$

where the negative sign indicates $[\text{A}]$ is decreasing with time. The change of each molecule of A into B is an independent event. Therefore, as molecules of A are consumed, the number of molecules left to change is diminished, and the rate

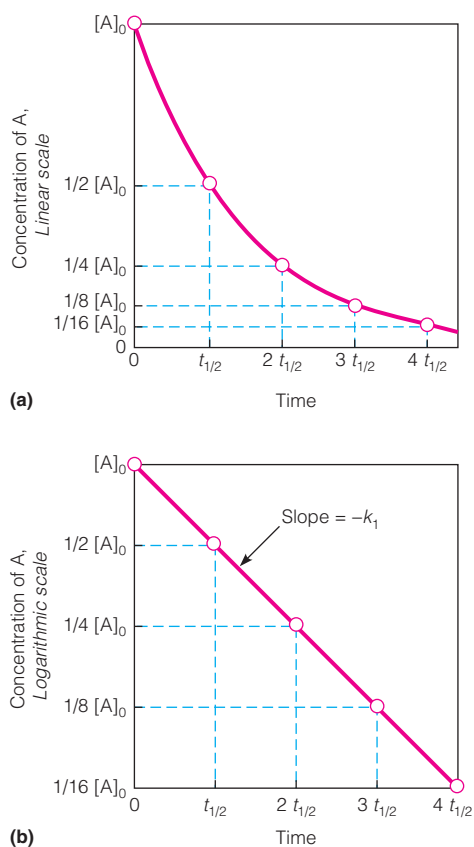

FIGURE 11.1

Determining the order and rate constant of an irreversible first-order reaction. Graphs (a) and (b) analyze the rate of a single reaction, with time expressed as multiples of the half-life ($t_{1/2}$) of the reactant. Note that for each interval of $t_{1/2}$ the reactant concentration is halved. (a) A graph of $[A]$ versus t shows that the rate, defined as the slope of the curve, decreases as the reaction continues. (b) A graph of $\ln[A]$ versus t , when linear, indicates that the reaction follows equation (11.4d) and is first-order. The slope of this line ($d \ln[A]/dt$) is equal to $-k_1$.

A first-order reaction is one whose rate is directly proportional to the first power of the reactant concentration.

A first-order reaction is characterized by single exponential decay of the reactant.

decreases as the reaction proceeds (see Figure 11.1a). Mathematically, we state this by saying that the rate is proportional to $[A]$:

$$v = \frac{d[B]}{dt} = -\frac{d[A]}{dt} = k_1[A]^n \quad (11.3)$$

The factor n in Equation 11.3 describes the dependence of the observed rate on the concentration of A. In the case where $n = 1$, the reaction rate depends on the first power of the reactant concentration and the reaction is called a **first-order reaction**. The constant k_1 is called the **rate constant** and for a first-order reaction has units of 1/(time) (typically, s^{-1} or min^{-1}). The rate constant provides a direct measure of how fast this reaction is. The larger the value of k_1 , the more rapid the rate, and vice versa. The most common example of a first-order reaction is the decay of radioactive elements (see Tools of Biochemistry 12A).

Initially, the value of n is not known. It may be 1 (first-order), or 2 (second-order), or 3 (third-order), and so on. The order of a reaction is determined experimentally by comparing the kinetic data (i.e., $[A]$ vs. time) to mathematical models, which describe the predicted change in $[A]$ for each type of reaction. We illustrate this idea for a first-order reaction.

Let us begin with an equation that describes how the concentration of A changes with time during a first-order reaction. This description can be obtained by rearranging, then integrating Equation 11.3, where $n = 1$:

$$\frac{d[A]}{[A]} = -k_1 dt \quad (11.4a)$$

$$\int_{[A]_0}^{[A]_t} \frac{d[A]}{[A]} = -k_1 \int_0^t dt \quad (11.4b)$$

In equation 11.4b we integrate both sides of the equation over limits from time = 0 (where $[A]$ equals the initial concentration " $[A]_0$ ") to time = t (where $[A] = [A]_t$), yielding:

$$\ln \frac{[A]_t}{[A]_0} = -k_1 t \quad (11.4c)$$

or

$$\ln [A]_t = \ln [A]_0 - k_1 t \quad (11.4d)$$

or

$$[A]_t = [A]_0 e^{-k_1 t} \quad (11.4e)$$

Equation 11.4e tells us that the concentration of A decreases exponentially with time, as shown in Figure 11.1a. A characteristic of such an exponential decay is the **half-life** ($t_{1/2}$), which is the time needed for $[A]$ to decrease by one half. For a first-order reaction, the half-life is inversely proportional to k_1 (see Problem 1 at the end of this chapter). To test whether a reaction is first-order, we need only make a graph of $\ln[A]$ versus t , as shown in Figure 11.1b. A straight line with a slope of $-k_1$ and an intercept of $[A]_0$, as predicted by Equation 11.4d, is consistent with a first-order reaction.

Most biochemical processes cannot be described over their full course by equations as simple as Equation 11.4c. One reason is that many of the reactions and processes we encounter are *reversible*, and as product accumulates, the reverse reaction becomes important. For example, we may have a reaction like the following:

Because A is being consumed in the reaction to the right and formed by the reaction to the left, the corresponding rate equation is

$$v = -\frac{d[A]}{dt} = k_1[A]^n - k_{-1}[B]^m = \frac{d[B]}{dt} \quad (11.5)$$

In the case where n and m both equal 1, k_1 and k_{-1} are, respectively, the rate constants for the first-order forward and reverse reactions. Such a reaction approaches a state of equilibrium, at which point the rates of the forward and reverse reactions become equal, and so the observed rate becomes zero (i.e., there is no apparent change in $[A]$ or $[B]$ over time). Thus, at equilibrium

$$k_1[A] = k_{-1}[B] \quad (11.6a)$$

Recall from the discussion of reversible ligand binding in Chapter 7 (Equation 7.7, page 240), that the equilibrium constant, K , for a reversible reaction can be written as the ratio of the forward and reverse rate constants:

$$K = \frac{[B]}{[A]} = \frac{k_1}{k_{-1}} \quad (11.6b)$$

Second-Order Reactions

The reactions we have described so far are first-order—they involve changes happening in individual molecules; but, many biochemical reactions are more complex, involving encounters between molecules. A **second-order reaction** occurs typically when two molecules must come together to form products:

This is illustrated by the binding of oxygen to myoglobin:

The rate for this process is given by

$$v = -\frac{d[\text{Mb}]}{dt} = -\frac{d[\text{O}_2]}{dt} = k_1[\text{Mb}]^n[\text{O}_2]^m \quad (11.7)$$

where n and m both equal 1, and k_1 is the **second-order rate constant**, with dimensions of $\text{M}^{-1} \text{s}^{-1}$. Equation 11.7 predicts that the rate of formation of the product, MbO_2 , is dependent on both the concentration of free Mb *and* the concentration of free O_2 . In this case we say the reaction is first order in $[\text{Mb}]$ ($n = 1$) and first order in $[\text{O}_2]$ ($m = 1$), and second order overall ($n + m = 2$). The binding of substrate (S) to an enzyme to form an **enzyme-substrate complex** is formally a second-order process:

Later in this chapter we will explore this further when we consider simple kinetic models for enzyme-catalyzed reactions.

Many more complicated kinds of reactions occur, including complex, multi-step processes. We shall not be concerned with their kinetics at this point, although we shall see that enzyme-catalyzed reactions, when analyzed in detail, are generally more complicated than those described above. Often, however, the analysis of complex multistep reaction schemes can be simplified by the recognition of a **rate-limiting step**. The rate-limiting step is the slowest step in a multistep process. As such, it determines the experimentally observed rate for the entire process.

Transition States and Reaction Rates

What determines the rate of a chemical reaction? That is, what makes a rate constant large or small? The thermodynamic concepts we have presented in earlier chapters allow us to determine whether or not a reaction is favorable. However, such information, on its own, does not explain reaction rates. A free energy diagram for a favorable reaction, drawn on the basis of thermodynamics alone, will look like Figure 11.2a. It shows the free energy of the system versus the **reaction coordinate**, a generalized measure of the progress of the reaction through intermediate

A first-order rate constant has units of $(\text{time})^{-1}$, whereas a second-order rate constant has units of $(\text{concentration})^{-1} (\text{time})^{-1}$.

FIGURE 11.2

Free energy diagrams for the simple reaction $A \rightarrow B$. **(a)** Information provided by thermodynamic studies of the equilibrium: Only the free energy difference between the initial state and the final state is revealed. G°_A and G°_B represent the standard free energies per mole, respectively, of A and B molecules. ΔG° is the standard state free energy change for the reaction. **(b)** Free energy diagram filled in to include the transition state through which the molecule must pass to go from A to B or vice versa. ΔG_1^{\ddagger} is the energy of activation for the $A \rightarrow B$ transition, and ΔG_{-1}^{\ddagger} is for the $B \rightarrow A$ transition. **(c)** A reasonable path for the transition of a pyranose (such as glucose) from boat (1) to chair (3) conformation. The highest energy state—the transition state—will look something like (2).

states. Its physical meaning will differ from one reaction to another (as discussed below). For a favorable reaction, the standard-state free energy of the products is lower than that of the reactants. However, what may be most important in determining the reaction rate is what happens in the *transition* from reactants to product. Equilibrium measurements, which pertain to final and initial states, do not reveal any information about the transition between these states or the energetic barrier that the transition presents.

A molecule in a first-order reaction must only *occasionally* reach an energy state in which the process can occur; otherwise, all molecules would already have reacted. This observation suggests that only a fraction of the molecules—those that are sufficiently energetic—can undergo reaction. Similarly, in a second-order reaction not all encounters between reactants can be productive because some collisions may not be sufficiently energetic, or the colliding molecules may not be properly oriented with respect to each other to react. Such considerations have given rise to the idea of a **free energy barrier** to reaction and the concept of an **activated state**, or **transition state** (symbolized by \ddagger). The transition state is thought of as a stage through which the reacting molecule or molecules must pass, often one in which a molecule is strained or distorted or has a particular electronic structure, or in which molecules collide productively. To make concrete the idea of a transition state, we diagram in Figure 11.2b the free energy as a function

Barriers to chemical reactions occur because a reactant molecule must pass through a high-energy transition state to form products. This free energy barrier is called the activation energy.

of the reaction coordinate. This concept is somewhat abstract, but we give a simple, concrete example in Figure 11.2c, the boat \rightarrow chair conversion of a pyranose ring (see Chapter 9, page 319). The reaction coordinate in this case is just the angle θ . Both the initial state (boat) and the final state (chair) are of lower energy than the most strained, flattened state (the half-chair state). To make the conversion, the ring must go through the half-chair state, which represents the high-energy transition state in this example.

We now consider two strategies for increasing reaction rates: (1) raising the temperature of the reaction, and (2) lowering the free energy of the transition state. The **standard free energy of activation**, ΔG^{\ddagger} , represents the additional free energy (above the average free energy of reactant molecules) that molecules must have to attain the transition state. If the activation barrier to the reaction is high, only a small fraction of the molecules will have enough energy to surmount it, or only a small fraction of collisions will be energetic enough for the reaction to occur. We know that in any sample or solution, not all molecules have the same energy at any instant. As shown in Figure 11.3a, at a given temperature some molecules will have lower kinetic energies and others will have much higher kinetic energies. As temperature increases the average kinetic energy of the molecules in a sample increases; thus, as the temperature of a sample increases we expect more molecules to have sufficient energy to attain the transition state (compare the shaded portions of Figure 11.3a), and the rate of the reaction should increase. Except for the organisms that have adapted to extreme environments (e.g., hydrothermal vents in the ocean), most organisms are sensitive to even small increases in temperature; thus, raising the temperature inside a cell beyond 2–3 °C is not generally tolerated. For example, many laboratory strains of *E. coli* grow well at 37 °C but do not survive at 42 °C. In humans, a body temperature above 41 °C is considered a medical emergency. There is another reason that raising reaction temperature is not necessarily beneficial—exothermic reactions become less favorable at elevated temperature.

Nature's response to the need to increase reaction rates in cells has been not to increase the temperature inside the cells but rather to use enzymes to lower the activation energy for the reaction. We can use the thermodynamic principles discussed in Chapter 3 to describe this effect in qualitative terms.

If we consider the simple reaction $A \rightleftharpoons B$, and assume that molecules of the reactant A are in equilibrium between the initial state and the activated state, the concentration of activated molecules at any instant will be given by Equation 3.28, introduced on page 73, for a reaction at equilibrium ($K = e^{-\Delta G^{\circ}/RT}$). It is important to recognize that a true thermal equilibrium is not possible between the reactant state and something as fleeting and dynamic as the transition state. Instead we will assume that A^{\ddagger} represents an average structure that is a reasonable approximation of the transition state. With that caveat in mind, if we let $[A^{\ddagger}]$ represent the fraction of molecules with sufficient energy to attain the transition state and $[A]$ the fraction of A that remains in the reactant state, we can use Equation 3.28 to describe the ratio $[A^{\ddagger}]/[A]$ as a function of the activation energy, ΔG^{\ddagger} :

$$\frac{[A^{\ddagger}]}{[A]} = e^{\left(\frac{-\Delta G^{\ddagger}}{RT}\right)} \quad (11.8)$$

where T is temperature and R is the gas constant. Equation 11.8 and Figure 11.3b provide us with a framework to understand the most important feature of enzyme catalysis: Enzymes achieve faster rates by lowering the activation energy for a reaction. As ΔG^{\ddagger} decreases, a larger fraction of molecules will possess sufficient energy to attain the transition state, and the rate of reaction will increase (compare the shaded portions of Figure 11.3b).

In 1921 Michael Polanyi proposed that a reaction catalyst preferentially binds the transition state structure and thereby stabilizes it, relative to the ground state, leading to a reduction in activation energy. Twenty-five years later, Linus Pauling

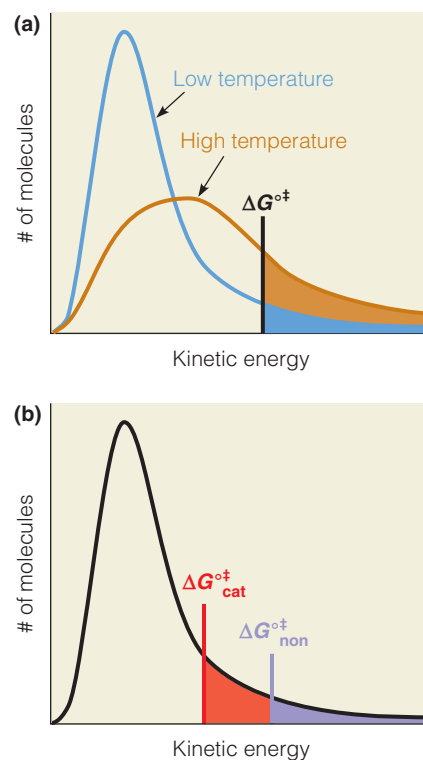

FIGURE 11.3

Effect of increasing temperature or lowering ΔG^{\ddagger} on the rates of reactions. The rates of reactions are proportional to the number of molecules with sufficient energy to overcome the activation barrier ΔG^{\ddagger} . (a) At higher temperature more molecules have this energy (compare the shaded area under the light blue curve vs. the shaded area under the orange curve). (b) Lowering the value of ΔG^{\ddagger} also increases the number of molecules with sufficient energy to attain the transition state (compare shaded areas under the curve for each value of ΔG^{\ddagger}). The subscripts “cat” and “non” indicate, respectively, the catalyzed and noncatalyzed processes.

Catalysts increase reaction rates by lowering the activation energy.

extended this idea to biological catalysts, suggesting that specific, complementary binding interactions between the transition-state structure and the enzyme active site would account for the extraordinary rate enhancements achieved by enzymes. Indeed, **transition state theory** has proved to be widely applicable to the study of enzyme catalysts, both in the laboratory and in computer simulations.

Transition State Theory Applied to Catalysis

In its simplest formulation, transition state theory assumes that a reactant molecule that attains the transition state rapidly decomposes to a lower energy state such as the product state, or to an intermediate state (see below). Because bonds are in the process of breaking and/or forming in the transition state, the lifetime of the transition state is similar to the vibrational frequencies of covalent bonds—on the order of a picosecond (10^{-12} s). These concepts are summarized in the following general expression for the rate constant, k :

$$k = \gamma \left(\frac{k_B T}{h} \right) e^{\left(\frac{-\Delta G^\ddagger}{RT} \right)} \quad (11.9)$$

where k_B is the Boltzmann constant, h is Planck's constant, T is temperature, R is the gas constant, and γ is called the “transmission coefficient.” The term $(k_B T/h)$ is a factor that accounts for the vibrational frequency of bonds in the transition state. At 310 K (37 °C), $(k_B T/h)$ has a value of $\sim 6.4 \times 10^{12} \text{ s}^{-1}$. The transmission coefficient γ takes into account several factors that we will not discuss here because, in many cases, they make relatively minor contributions to the overall value of the rate constant. The value of γ for various enzyme reactions has been calculated from quantum mechanical principles and is often very close to 1 but may be as large as $\sim 10^3$ for some hydrogen transfer reactions where quantum tunneling* is significant. Let us define the term **rate enhancement** (or **rate acceleration**) before making comparisons between the different parameters in Equation 11.9.

The rate enhancement is the ratio of the rate constants for the catalyzed (k_{cat}) and the noncatalyzed (k_{non}) reactions for a given set of conditions (e.g., temperature, pH, etc.). The rate enhancement indicates how much faster the reaction occurs in the presence of the enzyme. For example, we can compare the rate of amide bond hydrolysis by the enzyme *carboxypeptidase A* vs. the noncatalyzed rate at pH = 8 and 23 °C:

$$\text{rate enhancement} = \frac{k_{\text{cat}}}{k_{\text{non}}} = \frac{238 \text{ s}^{-1}}{1.8 \times 10^{-11} \text{ s}^{-1}} = 1.3 \times 10^{13} \quad (11.10)$$

How significant is this rate enhancement? The noncatalyzed peptide-bond hydrolysis has a half-life of ~ 2500 years, whereas the enzyme-catalyzed reaction has a half-life of ~ 0.005 second! Without the catalyst, this reaction would not occur on a physiologically useful timescale. Figure 11.4 illustrates the enormous rate enhancements that are characteristic of enzyme-catalyzed reactions.

We can combine Equations 11.9 and 11.10 to evaluate by how much an enzyme must stabilize the transition state to achieve these observed rate enhancements:

$$\text{rate enhancement} = \frac{k_{\text{cat}}}{k_{\text{non}}} = \frac{\gamma_{\text{cat}} \left(\frac{k_B T}{h} \right) e^{\left(\frac{-\Delta G_{\text{cat}}^\ddagger}{RT} \right)}}{\gamma_{\text{non}} \left(\frac{k_B T}{h} \right) e^{\left(\frac{-\Delta G_{\text{non}}^\ddagger}{RT} \right)}} = \left(\frac{\gamma_{\text{cat}}}{\gamma_{\text{non}}} \right) e^{\left(\frac{\Delta \Delta G^\ddagger}{RT} \right)} \quad (11.11)$$

*Some reactions occur much faster than would be predicted by the height of the activation barrier (ΔG^\ddagger); thus, the reaction coordinate appears to “tunnel” through the barrier. This is allowed by quantum mechanics for particles, such as electrons and protons, with small masses.

The rate enhancement for an enzyme-catalyzed reaction is the ratio of the rate constants for the catalyzed (k_{cat}) and the noncatalyzed (k_{non}) reactions. The rate enhancement indicates how much faster the reaction occurs in the presence of the enzyme.

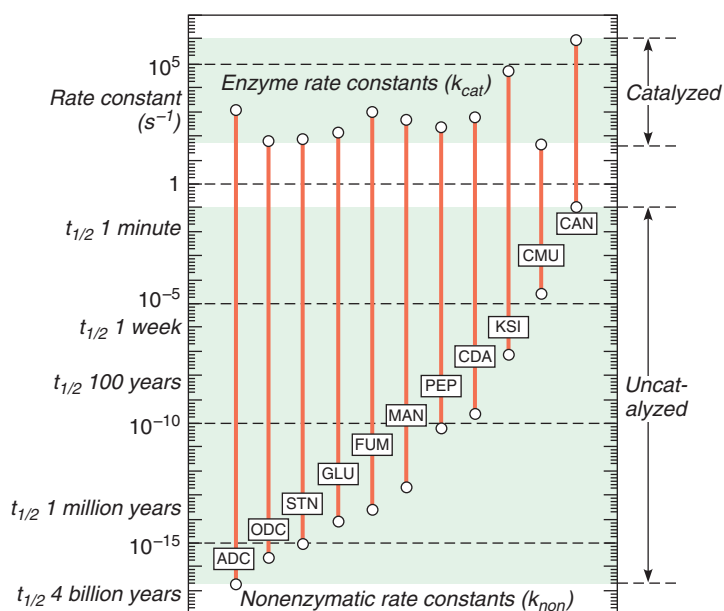

FIGURE 11.4

Enzymatic rate enhancements. Logarithmic scale of k_{cat} and k_{non} values (white circles) for some representative reactions at 25 °C. The length of each vertical bar represents the rate enhancement achieved by the enzyme. ADC = arginine decarboxylase; ODC = orotidine 5'-phosphate decarboxylase; STN = staphylococcal nuclease; GLU = sweet potato α -amylase; FUM = fumarase; MAN = mandelate racemase; PEP = carboxypeptidase B; CDA = *E. coli* cytidine deaminase; KSI = ketosteroid isomerase; CMU = chorismate mutase; CAN = carbonic anhydrase.

where $\Delta\Delta G^{\ddagger} = (\Delta G_{\text{non}}^{\ddagger} - \Delta G_{\text{cat}}^{\ddagger})$, or the difference in activation energies between the noncatalyzed and catalyzed reactions (see Figure 11.5). $\Delta\Delta G^{\ddagger}$ indicates by how many kJ/mol the transition state is stabilized in the catalyzed reaction. As is described below, the value of $\Delta\Delta G^{\ddagger}$ is often modest—equivalent to the energy gained by formation of a few noncovalent bonds (~ 30 – 90 kJ/mol).

Figure 11.5 illustrates an important point—that a catalyst lowers the activation energy barrier in *both* directions to the same extent. Thus, the rate accelerations for the forward and reverse reactions are identical (i.e., $\Delta\Delta G^{\ddagger}$ is the same in both directions). This is the basis for the earlier statement that a catalyst accelerates the approach to equilibrium (from either direction) but not its position.

In summary, a catalyst lowers the energy barrier to a reaction, thereby increasing the fraction of molecules that have enough energy to attain the transition state, and it makes the reaction go faster in both directions. However, the presence of a catalyst has no effect on the position of equilibrium because ΔG° is the same whether a catalyst is present or not. Thus, K , which equals k_1/k_{-1} , is unchanged by a catalyst, even though k_1 and k_{-1} may each be thousands or millions of times larger than they were for the noncatalyzed process.

How does a catalyst lower the activation energy barrier for a reaction such that $\Delta G_{\text{cat}}^{\ddagger} < \Delta G_{\text{non}}^{\ddagger}$? To answer this question, let us examine ΔG^{\ddagger} a bit more closely. Since $\Delta G^{\ddagger} = \Delta H^{\ddagger} - T\Delta S^{\ddagger}$, we can imagine two possibilities for making $\Delta G_{\text{cat}}^{\ddagger} < \Delta G_{\text{non}}^{\ddagger}$: either reduce ΔH^{\ddagger} (such that $\Delta H_{\text{cat}}^{\ddagger} < \Delta H_{\text{non}}^{\ddagger}$), or increase

The presence of a catalyst increases forward and reverse rates for a reaction, but does not affect the equilibrium composition of reactants and products.

FIGURE 11.5

Effect of a catalyst on activation energy. A free energy diagram (blue curve) similar to that in Figure 11.2b is shown, along with an alternative catalyzed path (red curve) for the reaction. The catalyst lowers the standard free energy of activation, ΔG^{\ddagger} , and thereby accelerates the rate because more of the reactant molecules have the energy needed to reach this lowered transition state. The rate enhancement is related to $\Delta\Delta G^{\ddagger}$ (see text). Note that the values of $\Delta G^{\circ}_{A \rightarrow B}$ for both the catalyzed and noncatalyzed reactions are the same; thus, the reaction equilibrium is not perturbed by the presence of the catalyst.

FIGURE 11.6

Entropic and enthalpic factors in catalysis. In this example, two reactants are bound to sites on the catalyst, which ensures their correct mutual orientation and proximity, and binds them most strongly when they are in the transition state conformation.

An enzyme active site is complementary in shape, charge, and polarity to the transition state for the reaction, and to a lesser extent, its substrate. Enzyme-substrate complementarity is the basis for the specificity of enzyme-catalyzed reactions.

FIGURE 11.7

Importance of intermediate states. An enzyme may alter the reaction pathway to one that includes one or more intermediate states that resemble the transition state but have a lower free energy (red curve). In the case of a single intermediate, the activation energies for formation of the intermediate state and for conversion of the intermediate to product (ΔG_1^{\ddagger} and ΔG_2^{\ddagger} , respectively) are lower than the activation energy for the uncatalyzed reaction (blue curve). In this figure, only activation energies for the enzyme-catalyzed forward reaction ($A \rightarrow B$) are shown.

ΔS^{\ddagger} (such that $\Delta S_{\text{cat}}^{\ddagger} > \Delta S_{\text{non}}^{\ddagger}$). ΔH^{\ddagger} can be lowered by increasing the number of bonding interactions between the catalyst and the transition state. As described below, this appears to be the dominant effect in most enzyme-catalyzed reactions. The ΔS^{\ddagger} term reflects the fact that a particular *orientation* between reactants or parts of a molecule may be necessary to achieve the transition state. For example, when collisions between molecules occur (as in a second-order reaction), most encounters are unproductive just because the molecules happen to be pointed the wrong way when they hit. A catalyst that can bind two reacting molecules in proper mutual orientation will increase their reactivity by making the entropy of activation less negative (Figure 11.6). In a first-order reaction, which involves something happening *within* a single molecule, parts of the molecule must often be re-oriented properly to allow the transition state to be reached. Such re-orientation is sometimes referred to as *strain*. In the case of enzymes, which are structurally dynamic catalysts, it is not always clear whether conformational strain between the enzyme and substrate induces a larger change in the conformation of the enzyme or in the substrate. The thermodynamic cost of making ΔS^{\ddagger} more positive is paid by favorable enthalpic interactions between the catalyst and substrate.

In some cases the catalyst can reduce the activation energy requirement by altering the reaction pathway and stabilizing an **intermediate** state that resembles the transition state but is of lower energy (Figure 11.7). The result is that two lower activation energy barriers replace the single higher barrier. We distinguish such an intermediate state from a transition state by the fact that the former corresponds to a local free energy minimum, and the latter to a free energy maximum.

How Enzymes Act as Catalysts: Principles and Examples

General Principles: The Induced Fit Model

We have seen that the role of a catalyst is to decrease ΔG^{\ddagger} by facilitating the formation of the transition state. An enzyme binds a molecule of substrate (or in some cases several substrates) into a region of the enzyme called the **active site**, as shown schematically in Figure 11.8. The active site is often a pocket or cleft surrounded by amino acid residues that help bind the substrate and by other residues that play a role in catalysis. The extraordinary specificity of enzyme catalysis is due in part to the complex tertiary structure of an enzyme, which enables the active site to recognize the substrate through *complementary* binding interactions (like those we described for the binding between an antibody and its cognate antigen in Chapter 7). This possibility was realized as early as 1894 by the great German biochemist Emil Fischer, who proposed a *lock-and-key hypothesis* for enzyme action. According to this model, the enzyme accommodates the specific substrate as a lock does its specific key (Figure 11.8a). Although the lock-and-key

model explained enzyme specificity, it did not increase our understanding of the catalysis itself because a lock does nothing to its key. This understanding came from an elaboration of Fischer's idea: What fits the enzyme active site best is a substrate molecule induced to take up a configuration approximating the transition state. In other words, the enzyme does not simply accept the substrate—the enzyme also demands that the substrate be distorted into something close to the transition state. This *induced fit hypothesis*, proposed by Daniel Koshland in 1958, is still an important model for enzymatic catalysis; however, it has been extended to include the idea that the substrate can also induce conformational changes in the enzyme that lead to stabilization of the transition state.

The structural changes induced upon substrate binding may be local distortions or may involve major changes in enzyme conformation (Figure 11.8b). A conformational change of this kind can be seen when substrate binds the enzyme *hexokinase*, which catalyzes the phosphorylation of glucose to glucose-6-phosphate in the first step in the metabolic pathway called **glycolysis** (see Chapter 13). The structure of this enzyme has been determined by X-ray diffraction both in the presence and absence of bound glucose. As Figure 11.9 shows, the binding of glucose causes two domains of the enzyme to fold toward each other, closing the binding-site cleft about the substrate.

But enzymes do more than simply distort or position their substrates. Often, we find specific amino acid side chains poised in exactly the right places to aid in the catalytic process itself. In many cases, these side chains are acidic or basic groups that can promote the addition or removal of protons. In other instances, the enzyme holds a metal ion in exactly the right position to participate in catalysis. Thus, an enzyme (1) binds the substrate or substrates, (2) lowers the energy of the transition state, and (3) directly promotes the catalytic event. When the catalytic process has been completed, the enzyme must be able to release the product or products and return to its original state, ready for another round of catalysis. For an enzyme (E) that catalyzes the conversion of a single substrate (S) into a single product (P), the expression for the reaction includes three steps:

Here ES represents the **enzyme–substrate complex**, and EP represents the enzyme bound to the product. For many enzyme-catalyzed reactions the first step, binding of substrate, is reversible (i.e., k_1 and $k_{-1} \gg k_2$); the second step, conversion of ES to EP, lies far to the right (i.e., $k_2 \gg k_{-2}$); and the third step, release of product, is rapid compared to the catalytic step (i.e., $k_3 \gg k_2$). We shall see later that much more complex representations are possible, with one or more intermediate states, but the equations above illustrate the basic model of enzymatic catalysis. Later in this chapter, we will develop a rate expression based on this model and the three assumptions described above.

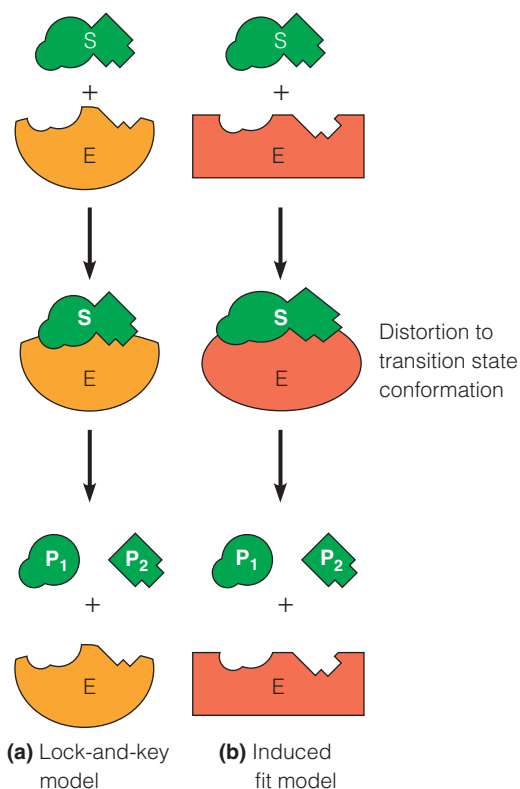

FIGURE 11.8

Two models for enzyme–substrate interaction.

In this example, the enzyme catalyzes a cleavage reaction. **(a)** The lock-and-key model. In this early model, the active site of the enzyme fits the substrate as a lock does a key. **(b)** The induced fit model. In this elaboration of the lock-and-key model, both enzyme and substrate are distorted on binding. The substrate is forced into a conformation approximating the transition state; the enzyme keeps the substrate under strain.

FIGURE 11.9

The induced conformational change in hexokinase. The binding of glucose to hexokinase induces a significant conformational change in the enzyme. The enzyme is a single polypeptide chain, with two major domains. A surface representation is shown with rainbow coloring (N-terminus is blue; C-terminus is red). Notice how the obvious cleft between the domains (panel a) closes around the glucose molecule (magenta spheres in panel b). PDB IDs: panel **(a)** 2YHX; panel **(b)** 3B8A.

FIGURE 11.11

The effect on $\Delta G_{\text{cat}}^{\ddagger}$ of differential binding to ES and the transition state. A rate enhancement is seen only for the case where $\Delta G_{\text{cat}}^{\ddagger} < \Delta G_{\text{non}}^{\ddagger}$ (top panel).

FIGURE 11.10

Reaction coordinate diagram for a simple enzyme-catalyzed reaction. The blue curve shows the free energy profile for the noncatalyzed reaction; the red curve shows the free energy profile for a simple enzyme-catalyzed reaction that follows the scheme shown in Equation 11.12.

A reaction coordinate diagram based on Equation 11.12 is shown by the red curve in Figure 11.10. This figure illustrates several important points. First, formation of the ES complex tends to be thermodynamically favorable, due to complementary binding interactions between the enzyme and substrate. Second, for maximum efficiency, binding to product should be less favorable than its release from the active site. Third, the enzyme active site must bind the transition state more favorably than it binds the substrate to achieve $\Delta G_{\text{cat}}^{\ddagger} < \Delta G_{\text{non}}^{\ddagger}$. It is critical to distinguish the ES complex (a stable intermediate state) from the transition state (an unstable state) in this analysis—they represent *different* states on the reaction coordinate.

As shown in the top panel of Figure 11.11, rate enhancement is achieved only when the enzyme binds the transition state with an affinity that is *greater than* its binding affinity for the substrate. In this case, $\Delta G_{\text{cat}}^{\ddagger} < \Delta G_{\text{non}}^{\ddagger}$. If the enzyme bound the reaction transition state with an affinity *equal to* its binding affinity for the substrate (Figure 11.11 middle panel), the activation barrier would be the same for both the catalyzed and noncatalyzed processes (i.e., $\Delta G_{\text{cat}}^{\ddagger} = \Delta G_{\text{non}}^{\ddagger}$). Finally, if some hypothetical enzyme bound the reaction transition state with an affinity *less than* its binding affinity for the substrate (Figure 11.11 bottom panel), the activation barrier would be the greater for the “catalyzed” processes (i.e., $\Delta G_{\text{cat}}^{\ddagger} > \Delta G_{\text{non}}^{\ddagger}$). Thus, an efficient catalyst will stabilize the transition state and thereby lower its free energy relative to the other states along the reaction coordinate.

As shown in Figure 11.4, rate enhancements reported for enzyme-catalyzed reactions range from 10^7 to 10^{19} . If we consider these observations in terms of transition state theory, assuming 10^3 as an upper limit for the value of $(\gamma_{\text{cat}}/\gamma_{\text{non}})$, we expect $e^{(\Delta\Delta G^\ddagger/RT)}$ to contribute at least 10^4 to 10^{16} to the rate enhancement (see Equation 11.11). This means the enzyme must provide a reduction in the activation energy (i.e., $\Delta\Delta G^\ddagger$) on the order of 24–95 kJ/mol at 37 °C (see Table 11.1). This is equivalent to the energy of a few noncovalent bonds; thus, it is reasonable to propose that specific noncovalent interactions between the enzyme active site and the transition state can account for the stabilization that gives rise to the observed rate enhancements.

We have discussed several means by which an enzyme might achieve such significant rate enhancements:

1. Preferential binding to the transition state through complementary noncovalent bonding interactions (H-bonds, charge–charge interactions, etc.).

Recall from Chapter 2 that noncovalent bonds are electrostatic in nature; thus, this is referred to as **electrostatic catalysis**.

- Distortion of the substrate and/or active site, which promotes reduction of the activation energy (induced fit).
- Binding of substrates to optimize proximity and orientation (making ΔS^\ddagger more favorable).
- Altering the reaction pathway to include intermediate states (see Figure 11.7). This is typical of **covalent catalysis**.

In addition to these, we will add two other prevalent mechanisms: **general acid/base catalysis** and **metal ion catalysis**.

General acid/base catalysis (**GABC**) is important in reactions involving proton transfer. An active-site amino acid residue is classified as a **general acid** if it donates an H^+ to an atom that develops negative charge in the transition state (Figure 11.12). A **general base** removes an H^+ from an atom that develops positive charge in the transition state. Thus, GABC may be viewed as a specialized case of electrostatic catalysis involving the transfer of a positive charge (H^+).

In general, the catalytically important residues in the enzyme active site are polar. Histidine is a very common GABC catalyst in active sites, due to its ability to accept or donate protons at physiological pH. Residues like Glu, Asp, Lys, and Arg are also common participants in proton transfers, as well as frequently serving to make electrostatic bonds with substrate molecules. A number of other residues, such as Ser, Tyr, and Cys, are also found to play important roles in the active sites of enzymes, either as H-bond donors/acceptors or as nucleophiles.

Over one third of enzymes characterized to-date contain metal ions in their active sites; thus, **metalloenzymes** are an important class of enzymes and much

Enzyme-catalyzed ester cleavage

Stabilizing interactions in transition state

Electrostatic stabilization

General acid/base catalysis

FIGURE 11.12

Enthalpic stabilization of the transition state in an enzyme-catalyzed reaction.

The upper panel shows the transition state and tetrahedral intermediate for an enzyme-catalyzed ester cleavage. This transition state might be stabilized by electrostatic interactions with active site amino acids and/or metal ions (lower left panel), or it might be stabilized by general acids or bases (lower right panel). The direction of proton transfer from the proton donor to the proton acceptor is indicated by the placement of the wide end of the dashed bond near the proton acceptor. The GAC is a proton donor and the GBC is a proton acceptor.

current research is devoted to understanding the roles of the metal ions in catalysis. If the metal ion behaves as a Lewis acid, by accepting electron density from an electron-rich atom (e.g., an atom that develops negative charge in the transition state), it is acting as an electrostatic catalyst. Metal ions can also promote the formation of hydroxide ion (OH^-) in the enzyme active site. This species is an important nucleophile in many hydrolytic reactions, such as the cleavage of peptide bonds in proteins or phosphodiester bonds in DNA and RNA.

To illustrate these general principles in a more concrete way, we consider the mechanisms of two specific enzyme-catalyzed reactions, for which details of the catalysis are well understood.

Lysozyme

Lysozyme was briefly described in Chapter 9 as an enzyme that cleaves the peptidoglycan layer of gram-positive bacteria (Figure 9.25), resulting in lysis of the bacterial cell. As such, it defends against bacterial infection, and it is found in the secretions of tissues that contact the external environment, such as tears, saliva, and mucus. The first X-ray crystal structure of an enzyme was that of lysozyme from hen egg white, reported in 1965 by the laboratory of David Phillips at the Royal Institution in London.

The active site of lysozyme is located in a deep cleft (Figure 11.13) where six glycosyl residues bind in subsites labeled A–F. The glycosidic bond cleavage occurs between residues D and E, with retention of configuration at the anomeric carbon (i.e., C1 of the pyranose in the D subsite). Based on the crystal structure of the enzyme, Phillips proposed a stereochemical mechanism in which glutamic acid 35 (E35) acts as a general acid and aspartate 52 (D52) acts as an electrostatic catalyst

FIGURE 11.13

The active site cleft of lysozyme. **Top:** The solvent-accessible surface of hen lysozyme (PDB ID: 2WAR) is shown in blue. The trisaccharide NAM-NAG-NAM is shown in stick representation bound to the active site. **Bottom:** A schematic drawing of $(\text{NAG-NAM})_3$ bound to the A–F subsites in lysozyme. The site of glycosidic bond cleavage, between the D and E subsites, is shown by the red dashed line.

FIGURE 11.14

The mechanism of action of lysozyme. The Phillips mechanism is illustrated by the black reaction arrows along the left side of the diagram. In the first step, E35 acts as a general acid to promote cleavage of the glycosidic bond and concomitant formation of the oxocarbenium ion (which is stabilized electrostatically by D52). In the second step, E35 acts as a general base, deprotonating a water molecule, which then attacks C1 of the substrate. The pathway that includes the covalent intermediate reported by Steve Withers follows the green reaction arrows along the right side of the diagram. In this case, the second step involves covalent bond formation between C1 of the substrate and D52. Attack of the water displaces D52 in the subsequent step.

during the generation of an oxocarbenium ion in the transition state (Figure 11.14). Phillips also proposed that the residue in the D subsite is distorted into a half-chair conformation upon binding in the active site (see Figure 11.2). This conformation approximates that of the oxocarbenium ion and is an example of the substrate distortion (“strain”) discussed above. Evidence for this distortion of the D site residue was reported in 1991 by Michael James based on the X-ray crystal structure of the trisaccharide NAM-NAG-NAM bound to the B-C-D subsites of lysozyme.

Additional experimental evidence for the proposed mechanism includes the observation of *kinetic isotope effects* (discussed in Tools of Biochemistry 11A) and the results of mutagenesis studies in which E35 and D52 were changed to nonionizing residues such as glutamine (Q), asparagine (N), and alanine (A). Amino acid mutations are often described using the single letter code and the following convention: [native amino acid][residue number][mutant amino acid]. For example, a mutant in which glutamine replaces glutamic acid at residue 35 would be “E35Q.” In kinetics experiments using defined substrates, the E35Q and D52N mutants each showed <0.1% of wild-type activity, suggesting that both residues play critical roles in catalysis. As shown in Figure 11.15, lysozyme has optimum activity at a pH of ~5 and is dependent on a base with a pK_a of ~4 and an acid with a pK_a of ~6. The pK_a s of all the Glu and Asp residues in lysozyme were determined by NMR titration (see Tools of Biochemistry 6A), and the pK_a s of E35 and D52 were found to be, respectively, 6.2 and 3.7. Thus, at values of pH between 3.7 and 6.2, E35 would be predominantly protonated and D52 would be predominantly deprotonated, as required by the Phillips mechanism.

FIGURE 11.15

The effect of pH on the activity of lysozyme. E35 must be protonated to act as a general acid catalyst in the first step of the mechanism; thus, at pH values below 6.2 (blue line) the ratio of $[\text{COOH}]/[\text{COO}^-]$ is greatest, favoring catalysis. D52 must be deprotonated to interact with the oxocarbenium ion; thus, at pH values above 3.7 (red line) the ratio of $[\text{COO}^-]/[\text{COOH}]$ is greatest, favoring catalysis. These two boundary requirements give rise to the observed pH optimum (~5) where both protonated E35 and deprotonated D52 are abundant.

The Phillips mechanism proposes that D52 stabilizes the oxocarbenium ion via electrostatic stabilization and also shields one side of the ion from attack by water, thus explaining the retention of configuration at the anomeric carbon (C1). This aspect of the mechanism was challenged by (1) the prediction that the lifetime of the oxocarbenium ion is too short to allow water to diffuse into the active site after the E and F glycosyl residues vacate the active site and (2) the observation that several other related enzymes proceed through an intermediate in which a stabilizing bond is made at C1 of the oxocarbenium ion. Daniel Koshland had proposed in 1953 that the mechanism of lysozyme includes such a stabilizing covalent intermediate, and when the crystal structure was obtained, D52 appeared well-positioned to make such a bond. This proposal was controversial for many years; however, in 2001, Steve Withers' laboratory reported a crystal structure of an enzyme-glycosyl intermediate that showed the D52 side chain covalently bound to C1 (Figure 11.16 and right side of Figure 11.14). This result was obtained using the E35Q mutant with the synthetic substrate NAG-2FGlcF. This

**FIGURE 11.16**

Evidence for the covalent intermediate in the mechanism of lysozyme.

The covalent adduct between the synthetic substrate NAG-2FGlcF and D52 in the active site of the E35Q mutant of lysozyme is shown (PDB ID 1H6M). The enzyme backbone is shown in cartoon representation (purple). The side chains of D52 and Q35 are shown in stick form (C atoms green, O atoms red, N atoms blue). The NAG-2FGlc adduct is shown in stick representation, where C1 is colored black and the F atom at C2 is light blue. The red arrow points to C1 of NAG-2FGlcF, which is the site Asp52 attacks to form the covalent intermediate.

substrate readily forms the oxocarbenium ion; however, the subsequent addition of —OH to the C1 is slowed by the E35Q mutation (Q does not act as a general base). Thus, the covalent intermediate is sufficiently long-lived that it is possible to obtain a crystal structure.

For the reaction to be catalytic the enzyme active site must be restored to its initial state; in this case, the side chain of E35 must be protonated and that of D52 must be free and deprotonated. Both of these requirements are achieved in the second half of the mechanism shown in Figure 11.14, in which a water molecule attacks the intermediate. Note that in this step E35 acts as a general base, removing a proton from the attacking water molecule.

In summary, lysozyme employs GABC, substrate distortion, and covalent catalysis to achieve its rate enhancement.

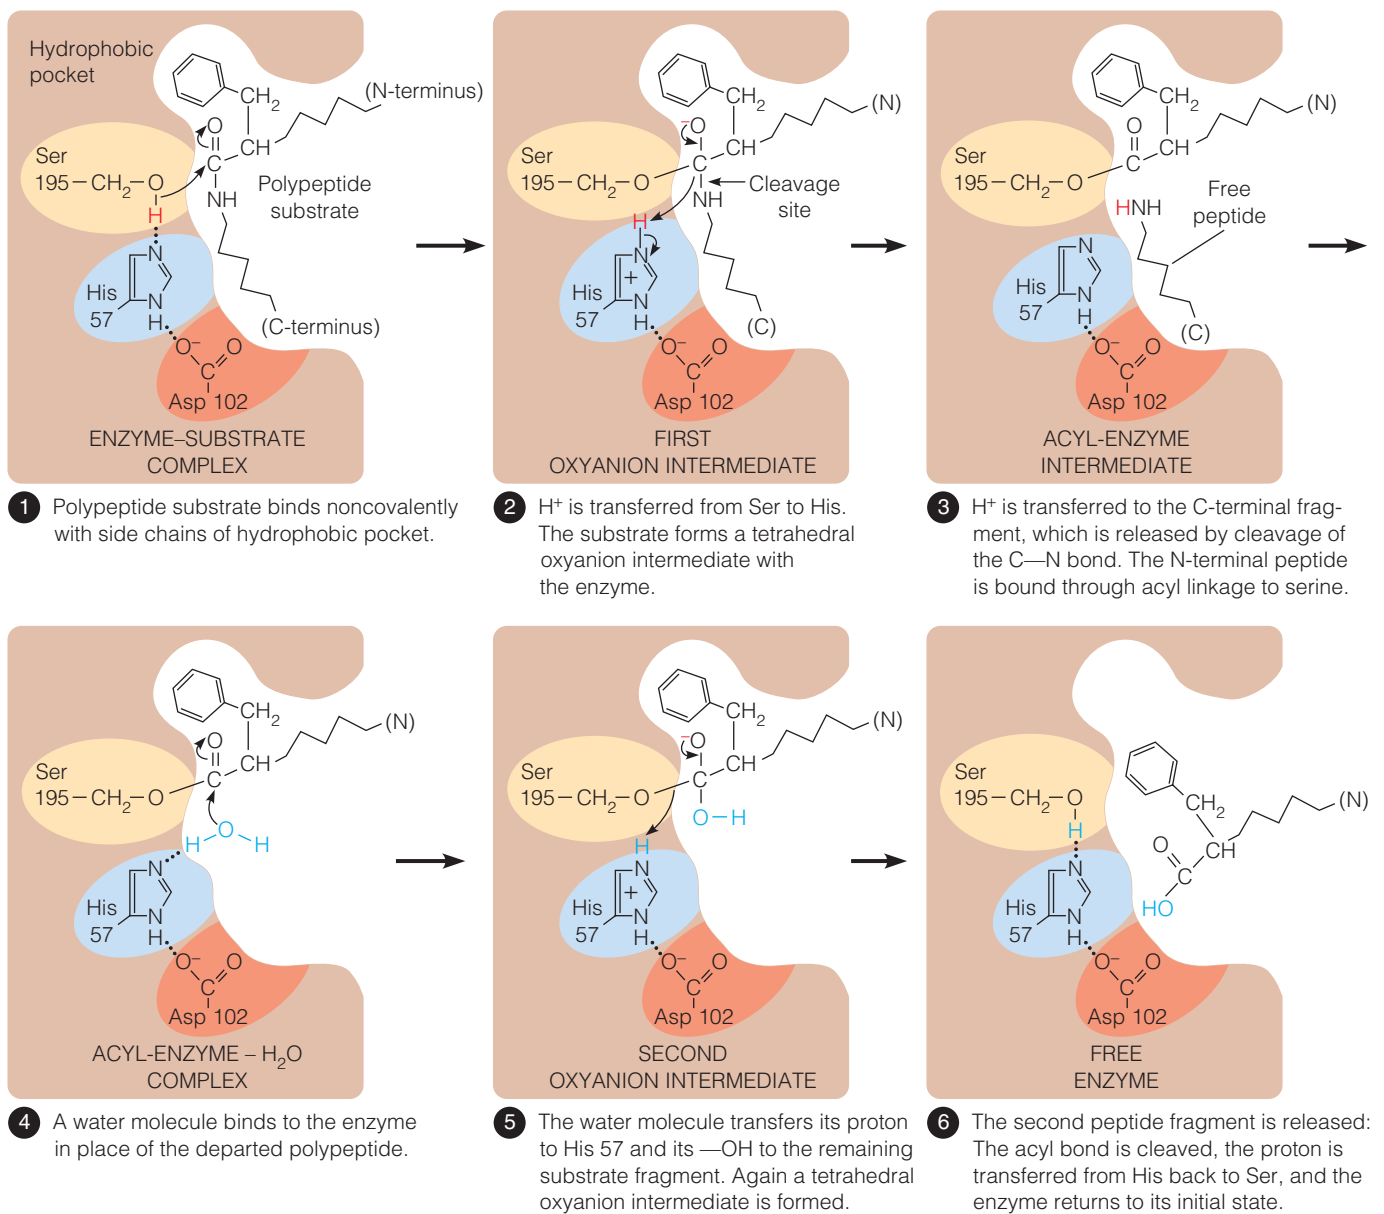

Serine Proteases

As a second example, let us consider the catalysis of peptide-bond hydrolysis by one of the **serine proteases**. This important class of enzymes includes trypsin and chymotrypsin, which we first encountered in Chapter 5. These enzymes are called proteases because they catalyze the hydrolysis of peptide bonds in polypeptides and proteins. Many kinds of proteases exist, exhibiting a wide range of substrate specificities and utilizing a variety of catalytic mechanisms. The *serine* proteases are distinct because they all have a critical serine nucleophile in the active site. The serine proteases also hydrolyze a wide variety of esters—a fact of little physiological importance, but one that biochemists make use of in kinetic studies, as described below.

Catalysis of peptide-bond hydrolysis by a serine protease (chymotrypsin, in this example) proceeds as shown in Figure 11.17. First, the polypeptide chain to be cleaved is bound to the enzyme surface. Most of the polypeptide binds non-specifically, but the side chain of the residue to the N-terminal side of the peptide bond to be cleaved must fit in the active site pocket. This pocket defines not only the position of the bond cleavage but also the *specificity* of serine proteases. Each of the serine proteases preferentially cleaves the amide bond immediately C-terminal to a specific kind of amino acid side chain. Examples of sites of preferential cleavage are shown in Table 5.4 (see page 149). For example, trypsin cleaves preferentially to the carboxylate side of basic amino acid residues like lysine or arginine, whereas chymotrypsin prefers a large hydrophobic residue like phenylalanine in this position. Chymotrypsin has a narrow specificity pocket lined with small glycine residues, which can accommodate bulky nonpolar side chains. Trypsin, on the other hand, has an aspartate side chain in the bottom of the specificity pocket. This negatively charged residue provides complementary binding interactions to the positive charge on an arginine or lysine side chain. This very specific binding of a particular type of amino acid also serves to place the active site serine very close to the carbonyl group of the bond to be cleaved—also called the **scissile bond**.

A common feature of serine proteases is the so-called **catalytic triad** of a *nucleophile*, a *general base*, and an *acid*. In many of the serine proteases that have been studied in detail, this catalytic triad is composed of serine, histidine, and aspartic acid residues presented in a similar 3-D orientation in the active site. As shown in Figure 11.18, in chymotrypsin the catalytic triad residues are Ser 195 (S195), His 57 (H57), and Asp 102 (D102). Other serine proteases have been discovered in which the triad pattern nucleophile–base–acid is conserved but the identities of the base and acid vary (e.g., Ser–His–His or Ser–Glu–Asp).

Due to the high pK_a of alcohol groups, serine side chains are usually in the protonated (i.e., —OH) form and are therefore not very reactive nucleophiles. However, S195 is in an environment that optimizes its reactivity. The S195 proton is transferred to the imidazole ring of H57, leaving a negative charge on the serine. Normally, this transfer would be unlikely (due to the

**FIGURE 11.17****Catalysis of peptide bond hydrolysis by chymotrypsin.**

The figure shows the steps in the cleavage of a polypeptide chain as catalyzed by chymotrypsin. The figure is highly schematic and does not represent the actual spatial arrangement of atoms (see Figure 11.18).

**FIGURE 11.18**

The structure of chymotrypsin and the serine protease catalytic triad. The backbone of bovine chymotrypsin determined by X-ray crystallography (PDB ID: 4CHA) is shown in cartoon representation (blue) with the side chains of the catalytic triad, S195, H57, and D102, shown in stick form within the dotted red oval. The location of the oxyanion hole (see text) is indicated by the dotted orange circle. To the left is shown a high-resolution neutron diffraction structure of the catalytic triad from porcine elastase (PDB ID: 3HGN). The neutron diffraction data show the positions of H atoms with greater resolution than do the X-ray data. Here, H57 is protonated, S195 and D102 are deprotonated, and H-bonds are shown by orange dashes.

lower pK_a of a His side chain vs. a typical Ser side chain), but it appears to be facilitated by D102, which, by its negative charge, stabilizes the protonation of the adjacent H57 side chain (see Figure 11.18). These interactions make S195 an unusually reactive nucleophile that attacks the carbonyl amide of the scissile bond.

An alternative explanation for the unusual reactivity of S195 is based on X-ray crystal and solution-phase NMR evidence for what appears to be an unusually short and strong hydrogen bond between H57 and D102. When the pK_a s of an H-bond donor and acceptor are nearly equal, the hydrogen is equally shared between them, and a so-called **low-barrier hydrogen bond** (LBHB) arises. Low-barrier hydrogen bonds are shorter (<0.25 nm), and 3–6 times stronger (~ 30 – 80 kJ/mol), with more covalent character than the typical hydrogen bonds described in Chapter 2. The proposed effect of the LBHB in chymotrypsin is to increase the pK_a of H57 to ~ 12 by stabilizing the protonated form of the imidazole side chain; thus, H57 would be better suited to deprotonate S195 (step 1 of Figure 11.17). The role of LBHBs in enzyme catalysis has been vigorously debated in the scientific literature because it remains challenging to measure directly the strength of such interactions in enzymes. Recent evidence from high-resolution crystal structure studies of the serine proteases α -lytic protease and elastin suggests that the hydrogen bond between H57 and D102 is shorter (~ 0.27 nm) than a typical hydrogen bond, but is not a LBHB. Further details of this debate can be found in the citations at the end of this chapter.

Attack by the serine nucleophile on the amide carbonyl results in the formation of a **tetrahedral oxyanion**, which then collapses to an **acyl–enzyme intermediate** (Figure 11.17). The formation of the oxyanion intermediate requires that the planar sp^2 hybridized amide carbon adopt a tetrahedral sp^3 configuration. Modeling of these species in the X-ray crystal structure of a serine protease active site led Jon Robertus and Joseph Kraut to propose the existence of an “**oxyanion hole**” that stabilizes the tetrahedral intermediate through specific H-bonding interactions to the negatively charged oxygen atom in the oxyanion (see Figure 11.19). In chymotrypsin, the H-bond donors are two backbone amido protons from residues S195 and G193. In the serine protease subtilisin, an asparagine side chain acts as an H-bond donor in the oxyanion hole. These H-bonds are stronger when the configuration of the amide carbon atom is tetrahedral rather than planar. Indeed, one of the H-bonds (from G193) appears to form only after the oxyanion is generated by attack of S195. Presumably the enzyme also stabilizes the transition state between the ES complex and this oxyanion intermediate because both states have significant negative charge on the oxygen atom and sp^3 -like geometry. The oxyanion hole is a clear example of enthalpic interactions that preferentially stabilize high-energy states along the reaction coordinate and thereby lower the overall energies of those states.

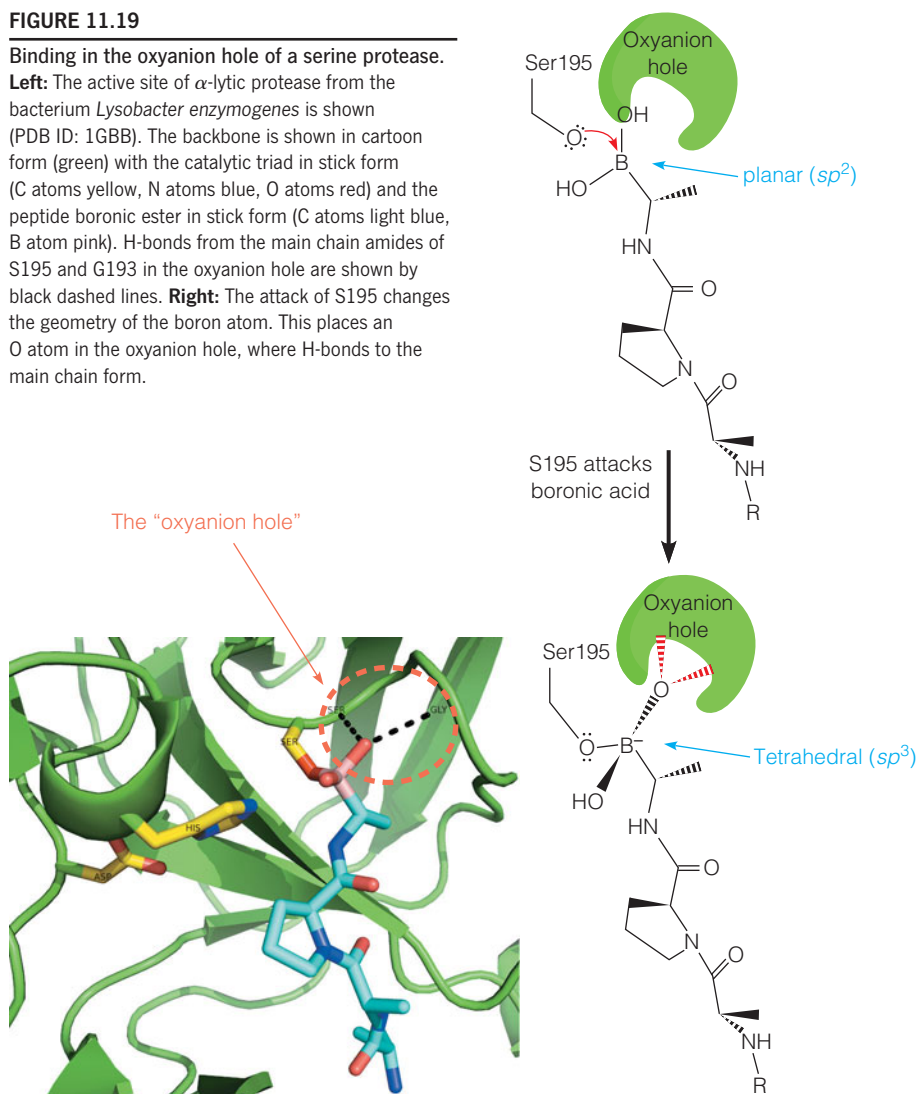

The protonated H57 acts as a general acid in the collapse of the oxyanion that yields the acyl–enzyme intermediate. This leaves the N-terminal part of the polypeptide substrate covalently bound to the enzyme and allows the C-terminal portion to diffuse from the active site. A water molecule can now enter the active site to cleave the acyl–enzyme intermediate. H57 acts as a general base, deprotonating the H_2O to make it a more potent nucleophile, which attacks the acyl–enzyme ester to form a second tetrahedral oxyanion intermediate. Finally, H57, acting as a general acid, facilitates the collapse of the oxyanion to regenerate S195 and release the remainder of the cleaved polypeptide chain. The enzyme is back in its original state, ready to catalyze the hydrolysis of another amide bond.

Mutagenesis studies have been used to confirm the critical contributions of each residue in the catalytic triad toward the $\sim 10^{10}$ rate enhancement observed for serine proteases. Working with a bacterial serine protease called subtilisin, Paul Carter and Jim Wells showed that S195A or H57A mutations reduced the rate

The catalysis of peptide-bond cleavage by serine proteases involves stabilization of transition states and tetrahedral intermediate states.

FIGURE 11.19**Binding in the oxyanion hole of a serine protease.**

Left: The active site of α -lytic protease from the bacterium *Lyso bacter enzymogenes* is shown (PDB ID: 1GGB). The backbone is shown in cartoon form (green) with the catalytic triad in stick form (C atoms yellow, N atoms blue, O atoms red) and the peptide boronic ester in stick form (C atoms light blue, B atom pink). H-bonds from the main chain amides of S195 and G193 in the oxyanion hole are shown by black dashed lines. **Right:** The attack of S195 changes the geometry of the boron atom. This places an O atom in the oxyanion hole, where H-bonds to the main chain form.

enhancement by $\sim 10^6$ compared to the wild-type enzyme, and the D102A mutant showed a reduction of $\sim 10^4$. These results indicate that S195 and H57 contribute 100-fold more to the rate enhancement than does D102. The triple mutant, S195A:H57A:D102A, also shows a $\sim 10^6$ reduction in rate enhancement, which suggests that other features of the enzyme active site, such as the oxyanion hole, contribute $\sim 10^3$ – 10^4 to the overall rate enhancement (see Problem 14 at the end of this chapter).

Additional support for the mechanism shown in Figure 11.17 comes from a large number of crystal structures of serine proteases bound to reaction intermediates as well as to **transition-state analogs**. Transition-state analogs are compounds that are designed to mimic the transition state for a reaction. As such, they are meant to possess greater shape and electrostatic complementarity to the enzyme active site than do the natural substrates. In fact, transition-state analogs typically bind to enzymes with affinities that are at least 10^2 – 10^4 greater than those of the natural substrates. In some cases the tight-binding analog is formed in the enzyme active site. An example is shown in Figure 11.19, where the tetrapeptide Ala–Ala–Pro–Ala bearing a C-terminal boronic acid is converted to a mixed borate ester following attack by S195 on the boron atom. This converts the planar boronic acid to the tetrahedral borate ester, which can then interact with the amides in the oxyanion hole.

Electrostatic		oxyanion hole
Other	strain of D ring	low-barrier H-bond?

In summary, serine proteases employ covalent catalysis and electrostatic stabilization of the transition state to achieve rate enhancement (Table 11.2).

It is important to keep in mind that there are many enzyme-catalyzed reactions that are thought to work in ways we have not discussed here, and some of these, like the proposed low-barrier H-bond in chymotrypsin, are controversial. For example, elucidating the role of protein dynamics in rate acceleration by enzymes is a matter of active research and vigorous debate. We provide a brief introduction to this topic in the next section.

The Role of Dynamics in Catalysis

Proteins are dynamic structures—a fact that is difficult to represent with static figures in the pages of a textbook, but one that should be kept in mind while considering the functional properties of biomolecules. In previous chapters we have described several examples of protein conformational changes directly related to function, such as switching between T and R states in O_2 binding in hemoglobin, the movement of myosin along an actin filament, and active transport of ions by the Na^+-K^+ pump. Such large *directed* movements in proteins occur on a timescale of μs to s; however, as shown in Table 11.3, more subtle motions in proteins (e.g., “bending” or side chain rotation) occur more rapidly and, thus, appear random in nature. Recent work suggests that the rapid conformational dynamics of proteins may not be so random, and some researchers hypothesize that the dynamic behavior of proteins has therefore *evolved* to enhance protein function.

It is logical that enzymes must be dynamic to allow substrate binding and product release, to reorganize the active site for optimal stabilization of the transition state, or to allow allosteric regulation of activity (discussed later in this chapter). However, neither the relationship between dynamic motions and observed rates nor the evolution of the dynamic features of enzymes is well understood. Even so, it seems reasonable that active site dynamics can play a critical role in those hydrogen-transfer reactions that appear to proceed via a tunneling mechanism. Quantum tunneling is exquisitely sensitive to small changes in distance (i.e., 0.1 Å) between the hydrogen donor and acceptor atoms; thus, even rapid motions such as bond rotation in the active site could dramatically affect the rate of hydrogen transfer.

Recent NMR studies on the enzyme dihydrofolate reductase (see Chapter 20) have shown that dynamic motions of several amino acids in the protein are *correlated* and biased toward the handful of conformations that are relevant to the catalytic mechanism. Furthermore, the dynamic motions observed for each intermediate in the five-step catalytic cycle of dihydrofolate reductase appear to favor the formation of conformations which resemble that of the next intermediate in the cycle.

The five intermediates in the catalytic cycle of dihydrofolate reductase are shown in Figure 11.20. Starting on the left, the catalytic cycle begins with substrate binding to the enzyme complexed with the **cofactor** *reduced* nicotinamide adenine dinucleotide phosphate (NADPH). Cofactors are small molecules that

TABLE 11.3 Timescale of protein motions related to catalysis

Motion	Approximate Time Scale (seconds)
Bond vibration	10^{-13} to 10^{-14}
Proton transfer	10^{-12}
Hydrogen bonding	10^{-11} to 10^{-12}
Elastic vibration of globular region	10^{-11} to 10^{-12}
Sugar repuckering	10^{-9} to 10^{-12}
Rotation of side chains at surface	10^{-10} to 10^{-11}
Torsional libration of buried groups	10^{-9} to 10^{-11}
Hinge bending at domain interfaces	10^{-7} to 10^{-11}
Water structure reorganization	10^{-8}
Helix-coil breakdown/formation	10^{-7} to 10^{-8}
Allosteric transitions	1 to 10^{-5}
Local denaturation	10 to 10^{-5}
Rotation of medium-sized side chains in interior	1 to 10^{-4}

The induced fit model

The conformational selection model

FIGURE 11.21

Conformational Selection vs. Induced Fit. Here *ES* represents the enzyme–substrate complex. Induced fit implies conformational homogeneity in the unbound enzyme, which is then distorted upon substrate binding. Conformational selection implies that the unbound enzyme is present in multiple conformations; but, the substrate can only bind to unbound enzyme that is in the same conformation as that of the *ES* complex. Substrate binding will perturb the conformational equilibrium of the unbound enzyme, driving more *E* into the *ES* conformation by Le Chatelier's principle (see Chapter 3).

expand the range of enzyme chemistry and are discussed in more detail later in this chapter. For example, NADPH is a source of hydride (H^-), which is commonly used in biological redox reactions. When the *E:NADPH* complex (blue) binds substrate, the *E:NADPH:S* complex (red) is formed. Hydride transfer from the NADPH to the substrate yields the product complex *E:NADP⁺:P*, shown in purple (here $NADP^+$ represents oxidized cofactor). Release of $NADP^+$ gives the *E:P* complex (green), which can then bind to NADPH to give *E:NADPH:P* (yellow). Release of the product from this complex gives *E:NADPH* and the cycle is completed.

The important finding illustrated in Figure 11.20 is that each intermediate displays dynamic motions that allow it to adopt the conformation of a neighboring intermediate state. For example, the *E:NADP⁺:P* intermediate can adopt either the *E:NADPH:S* or the *E:P* conformation. The NMR experiment used in these studies also provides information on the rates of interconversion between the conformational states (black arrows in Figure 11.20). For three of the steps in the catalytic cycle, the rates of conformational dynamics closely match the rates determined in classical kinetics studies. For example, cofactor release occurs with a rate of 200 s^{-1} , and the conformational dynamics between the *E:NADP⁺:P* and *E:P* states occur at 260 s^{-1} . This observation suggests that cofactor release occurs from the *E:P* conformation (and not from the *E:NADP⁺:P* conformation), and that cofactor is released from *E:NADP⁺:P* nearly every time the *E:NADP⁺:P* intermediate adopts the *E:P* conformation.

Compared to the induced fit model, this **conformational selection** (or **selected fit**) model is a very different description of the binding interactions between an enzyme and its substrate/cofactors. As shown in Figure 11.21, conformational selection implies that the binding of a substrate doesn't impose a conformational change on the enzyme; rather, the substrate only binds to enzyme molecules that have conformations similar to that of the *ES* complex. A corollary

is that substrate will be released when the ES complex samples conformations that are incompatible with substrate binding. This is the basis for the hypothesis that dynamic motions of enzymes, which determine the conformational state of the enzyme, have evolved due to selective pressure to optimize catalytic efficiency.

Finally, it has been suggested that dynamic conformational switching may require the *correlated* movements of several amino acid residues in the protein, and such concerted motions make up a dynamic “network.” The existence of such networks in enzymes has been proposed to explain two observations: (1) some mutations distant from the active site have significant impacts on reaction rates even though these amino acids make no direct contact to the substrate and (2) such mutations tend to affect the dynamic behavior of a larger group of amino acids. The latter observation suggests that the effect of a distant mutation can be communicated to the active site through the coordinated motions of the residues that make up the dynamic network.

The conformational selection model for enzyme catalysis suggests that free enzyme is present in multiple conformations; but, substrate binds only to an enzyme that is in a conformation similar to that of the enzyme in the ES complex.

The Kinetics of Enzymatic Catalysis

In the preceding section, we described details of the mechanisms for two well-studied enzyme-catalyzed reactions. Hundreds more are known, and such knowledge is essential in many aspects of modern medicine. A detailed understanding of the molecular basis for a disease guides the design of therapeutic drugs. For example, as discussed in Chapter 20, compounds that inhibit the activity of dihydrofolate reductase have found wide use in treating cancer and infectious diseases. Where does this mechanistic knowledge come from? X-ray crystallography and solution NMR studies have provided key structural insights into enzyme activity; however, much of our understanding of enzyme mechanisms comes from the careful mathematical analysis of enzyme kinetics. Thus, it is to that analysis that we now turn.

Reaction Rate for a Simple Enzyme-Catalyzed Reaction: Michaelis–Menten Kinetics

Earlier in this chapter we introduced Equation 11.12 as an expression for a simple reaction involving a single substrate and product:

If we analyze the **initial rate** of an enzyme-catalyzed reaction (i.e., before a significant concentration of P appears) and we assume that k_1, k_{-1} , and $k_3 \gg k_2$, Equation 11.12 simplifies to the following:

where k_{cat} is the apparent rate constant for the rate-determining conversion of substrate to product.*

We have assumed that initial reaction conditions are such that the reverse reaction between E and P is negligible. The catalytic formation of the product, with enzyme regeneration, will then be a simple first-order reaction, and its rate will be determined solely by the concentration of ES and the value of k_{cat} . Therefore, the reaction rate, or velocity, defined as the observed rate of formation of products, can be expressed as

$$v = k_{\text{cat}}[ES] \quad (11.14)$$

If v and $[ES]$ can be measured for a specific enzyme and substrate, the rate constant, k_{cat} , for that particular reaction can be derived. In practice, $[ES]$ is difficult to measure in kinetics experiments. The easily measured parameters are substrate

* k_{cat} is an aggregate rate constant = $k_2k_3/(k_2 + k_3)$. In the limiting case where $k_3 \gg k_2$, $k_{\text{cat}} \approx k_2$.

**FIGURE 11.22**

The steady state in enzyme kinetics. The figure shows how the concentrations of substrate [S], free enzyme [E], enzyme–substrate complex [ES], and product [P] vary with time for a simple enzyme-catalyzed reaction described by $E + S \rightleftharpoons ES \rightarrow E + P$. After a very brief initial period, [ES] reaches a steady state in which ES is consumed approximately as rapidly as it is formed, so $d[ES]/dt \approx 0$. The amounts of E and ES are greatly exaggerated for clarity. Note that $[E] + [ES] = [E]_t$, or total enzyme concentration, and that [ES] actually falls very slowly as substrate is consumed, while [E] accordingly rises.

(or product) concentration and the total concentration of enzyme, which must be the sum of free enzyme and enzyme bound to substrate:

$$\begin{array}{rcc} [E]_t & = & [E] + [ES] \\ \text{Total} & & \text{Free} & \text{Enzyme in} \\ \text{enzyme} & & \text{enzyme} & \text{ES complex} \end{array} \quad (11.15)$$

Thus, it is desirable to express the rate, v , in terms of the substrate concentration [S] and the total enzyme concentration $[E]_t$.

The way we have written Equation 11.13 suggests that E and S should be in equilibrium with ES, with an equilibrium dissociation constant K_S :

$$K_S = \frac{k_{-1}}{k_1} = \frac{[E][S]}{[ES]} \quad (11.16)$$

This is usually an incorrect assumption, but under certain circumstances (i.e., $k_{\text{cat}} \ll k_{-1}$), this approximation is valid. This assumption was used in early attempts to solve the problem of expressing the reaction rate. It doesn't apply in general because E, S, and ES are not truly in equilibrium; some ES is continually being drained off to make P. An analysis that avoids the assumption of equilibrium was presented by G. E. Briggs and J. B. S. Haldane in 1925. The Briggs–Haldane model is based on the following argument: The more ES that is present, the faster ES will dissociate either to products (k_{cat}) or back to reactants (k_{-1}). Therefore, when the reaction is started by mixing enzymes and substrates, the ES concentration builds up at first, but quickly reaches a **steady state**, in which it remains almost constant. This steady state will persist until almost all of the substrate has been consumed (Figure 11.22). Because the steady state accounts for nearly all the reaction time, we can calculate the reaction velocity by assuming steady-state conditions. Normally, we measure rates only after the steady state has been established and before [ES] has changed much. We can then express the velocity as follows.

In the steady state, the rates of formation and breakdown of ES are equal. Therefore,

$$\begin{array}{rcc} k_1[E][S] & = & k_{-1}[ES] + k_{\text{cat}}[ES] \\ \text{Formation of} & & \text{Dissociation} & \text{Breakdown} \\ \text{ES complex} & & \text{of ES complex} & \text{to E + P} \end{array} \quad (11.17)$$

which can be rearranged to give

$$[ES] = \left(\frac{k_1}{k_{-1} + k_{\text{cat}}} \right) [E][S] \quad (11.18)$$

Combining the ratio of rate constants in Equation 11.17 gives a single constant, K_M :

$$K_M = \frac{k_{-1} + k_{\text{cat}}}{k_1} \quad (11.19)$$

Equation 11.18 can now be rewritten as

$$K_M[ES] = [E][S] \quad (11.20)$$

At this point, [ES] is expressed in terms of [E] and [S]. To get $[E]_t$ into the equation, rather than [E], recall from Equation 11.15 that $[E] = [E]_t - [ES]$. Putting this into Equation 11.20 yields

$$K_M[ES] = [E]_t[S] - [ES][S] \quad (11.21)$$

This rearranges to

$$[ES] = \frac{[E]_t[S]}{K_M + [S]} \quad (11.22)$$

Finally, inserting this result into Equation 11.14 gives an expression for v in terms of $[E]_t$ and $[S]$:

$$v = \frac{k_{\text{cat}}[E]_t[S]}{K_M + [S]} \quad (11.23)$$

Equation 11.23 is called the **Michaelis–Menten equation**, and K_M the **Michaelis constant**, honoring two pioneers in the analysis of enzyme kinetics, Leonor Michaelis and Maude Menten. We will discuss the meaning of K_M shortly; in the meantime, there are two important points to keep in mind. First, because K_M is a ratio of the rate constants for a specific reaction (see Equation 11.19), it is a characteristic of that reaction. Thus, a given enzyme acting upon a given substrate has a defined K_M . Second, you can see from Equations 11.19 and 11.20 that K_M has units of concentration.

Now consider the graph of v versus $[S]$ shown in Figure 11.23. At high substrate concentrations, where $[S]$ is much greater than K_M , the reaction approaches a **maximum velocity**, V_{max} , because the enzyme molecules are *saturated*; every enzyme molecule is bound by substrate; thus, $[ES] = [E]_t$ and Equation 11.14 will reach its maximum value. Recall from Chapter 10 that such saturation behavior is a characteristic of transport proteins in membranes. When $[S] \gg K_M$, $K_M + [S] \approx [S]$, and Equation 11.23 simplifies to the expression for V_{max} :

$$V_{\text{max}} = k_{\text{cat}}[E]_t \quad (11.24)$$

Thus, $k_{\text{cat}}[E]_t$ in Equation 11.23 is equivalent to V_{max} , and the Michaelis–Menten rate equation is

$$v = \frac{V_{\text{max}}[S]}{K_M + [S]} \quad (11.25)$$

This is the most familiar form of the Michaelis–Menten equation.

The Significance of K_M , k_{cat} , and k_{cat}/K_M

The two quantities that characterize an enzyme obeying Michaelis–Menten kinetics are K_M and k_{cat} . What do they signify? The Michaelis constant, K_M , is often associated with the affinity of enzyme for substrate. However, this relationship is only true in the limiting case: a two-step reaction in which $k_{\text{cat}} \ll k_{-1}$, where Equation 11.19 then yields $K_M \approx k_{-1}/k_1 = K_S$, the equilibrium constant defined in Equation 11.16. It is important to note that for more complex kinetic schemes, K_M is a ratio of several rate constants. For any reaction that follows the Michaelis–Menten equation, K_M is numerically equal to the substrate concentration at which the reaction velocity has attained *half* of its maximum value (see Figure 11.23). Thus, K_M is a measure of the substrate concentration required for effective catalysis to occur. *An enzyme with a high K_M requires a higher substrate concentration to achieve a given reaction velocity than an enzyme with a low K_M but the same k_{cat} .* Table 11.4 lists K_M values for a number of important enzymes.

The second constant, k_{cat} , gives a direct measure of the rate of product formation under optimum conditions (saturated enzyme). The units of k_{cat} are usually given as s^{-1} , so the reciprocal of k_{cat} can be thought of as a time—the time required by an enzyme molecule to “turn over” one substrate molecule. Alternatively, k_{cat} measures the number of substrate molecules turned over per enzyme molecule per second. Thus, k_{cat} is sometimes called the **turnover number**. Some typical turnover numbers are listed in Table 11.4.

The enzymes listed in Table 11.4 are arranged in increasing order of the ratio k_{cat}/K_M . This ratio is often thought of as a measure of enzyme efficiency. Note that either a large value of k_{cat} (i.e., rapid turnover) or a small value of K_M (i.e., $\frac{1}{2}V_{\text{max}}$ occurs at relatively low $[S]$) will make k_{cat}/K_M large. We can gain another insight into the meaning of k_{cat}/K_M by considering the situation at very low substrate

FIGURE 11.23

Reaction velocity as a function of substrate concentration. This graph, a plot of Equation 11.25, shows the variation of reaction velocity with substrate concentration according to the Michaelis–Menten model of enzyme kinetics. The values of v plotted here are determined from the *initial rates* of the reaction (see Figure 11.24). At the point where $[S] = K_M$, the reaction has exactly half its maximum velocity. Note that V_{max} is approached asymptotically.

The steady-state assumption proposes that the concentration of enzyme–substrate complex remains nearly constant through much of the reaction.

The Michaelis constant, K_M , indicates the substrate concentration at which the reaction rate is $\frac{1}{2}V_{\text{max}}$.

The turnover number, k_{cat} , measures the rate of the catalytic process.

TABLE 11.4 Michaelis–Menten parameters for selected enzymes, arranged in order of increasing efficiency as measured by k_{cat}/K_M

Enzyme	Reaction Catalyzed	K_M (mol/L)	k_{cat} (s^{-1})	k_{cat}/K_M [$(\text{mol/L})^{-1} \text{s}^{-1}$]
Chymotrypsin	$\text{Ac-Phe-Ala} \xrightarrow{\text{H}_2\text{O}} \text{Ac-Phe} + \text{Ala}$	1.5×10^{-2}	0.14	9.3
Pepsin	$\text{Phe-Gly} \xrightarrow{\text{H}_2\text{O}} \text{Phe} + \text{Gly}$	3×10^{-4}	0.5	1.7×10^3
Tyrosyl-tRNA synthetase	$\text{Tyrosine} + \text{tRNA} \longrightarrow \text{tyrosyl-tRNA}$	9×10^{-4}	7.6	8.4×10^3
Ribonuclease	$\text{Cytidine 2', 3' cyclic phosphate} \xrightarrow{\text{H}_2\text{O}} \text{cytidine 3'-phosphate}$	7.9×10^{-3}	7.9×10^2	1.0×10^5
Carbonic anhydrase	$\text{HCO}_3^- + \text{H}^+ \longrightarrow \text{H}_2\text{O} + \text{CO}_2$	2.6×10^{-2}	4×10^5	1.5×10^7
Fumarase	$\text{Fumarate} \xrightarrow{\text{H}_2\text{O}} \text{malate}$	5×10^{-6}	8×10^2	1.6×10^8

concentrations. In this case, $[S] \ll K_M$, and most of the enzyme is free, so $[E]_t \approx [E]$. Then equation (11.23) becomes

$$v = \frac{k_{\text{cat}}}{K_M} [E][S] \quad (11.26)$$

Therefore, under these circumstances, the ratio k_{cat}/K_M behaves as a second-order rate constant for the reaction between substrate and free enzyme, and it provides a direct measure of enzyme efficiency and specificity. It shows what the enzyme and substrate can accomplish when abundant enzyme sites are available, and it allows direct comparison of the effectiveness of an enzyme toward different substrates. Suppose an enzyme has a choice of two substrates, A or B, present at equal concentrations. Then under conditions in which both substrates are dilute and are competing for the enzyme, we find

$$\frac{v_A}{v_B} = \frac{\left(\frac{k_{\text{cat}}}{K_M}\right)_A [E][A]}{\left(\frac{k_{\text{cat}}}{K_M}\right)_B [E][B]} = \frac{\left(\frac{k_{\text{cat}}}{K_M}\right)_A}{\left(\frac{k_{\text{cat}}}{K_M}\right)_B} \quad (11.27)$$

Table 11.5 lists values of k_{cat}/K_M for cleavage of various esters by chymotrypsin. Within the group shown, k_{cat}/K_M varies 1 million-fold, showing the range of preference the enzyme has for different peptide substrates. The preference to cleave next to the most hydrophobic residues is quite clear from these data.

We have just seen that the ratio k_{cat}/K_M corresponds to the second-order rate constant for enzyme–substrate combination under circumstances of low substrate concentration. Such a rate constant has a maximum possible value, which is determined

N-acetyl amino acid methyl ester

TABLE 11.5 Preferences of chymotrypsin in the hydrolysis of several N-acetyl amino acid methyl esters, as measured by k_{cat}/K_M

Amino Acid in Ester	Amino Acid Side Chain	k_{cat}/K_M [$(\text{mol/L})^{-1} \text{s}^{-1}$]
Glycine	—H	1.3×10^{-1}
Norvaline	—CH ₂ CH ₂ CH ₃	3.6×10^2
Norleucine	—CH ₂ CH ₂ CH ₂ CH ₃	3.0×10^3
Phenylalanine	—CH ₂ —	1.0×10^5

The ratio k_{cat}/K_M is a convenient measure of enzyme efficiency.

by the frequency with which enzyme and substrate molecules can collide in solution. A reaction that attains such a velocity is said to be “diffusion-limited”; every encounter leads to reaction, so nothing but the rate of molecular encounters limits the velocity. If every collision results in formation of an enzyme–substrate complex, diffusion theory predicts that k_{cat}/K_M will attain a maximum value of about 10^8 to 10^9 $(\text{mol/L})^{-1} \text{s}^{-1}$. Thus, an enzyme that approaches maximum possible efficiency will demonstrate this by having a value of k_{cat}/K_M in this range. As Table 11.4 shows, enzymes such as carbonic anhydrase and fumarase actually approach this limit. Triose phosphate isomerase (discussed in Chapter 13) is another example, having $k_{\text{cat}}/K_M = 2.4 \times 10^8$ $(\text{mol/L})^{-1} \text{s}^{-1}$. In fact, it has been argued that triose phosphate isomerase is an almost perfect enzyme, having evolved to nearly maximum efficiency. In support of this idea is the observation that triose phosphate isomerases from organisms as evolutionarily distant as yeasts and vertebrates show very little change in structure. Apparently, this enzyme (which plays a vital role in cellular ATP production from carbohydrates) reached near perfection early in evolution and has changed little since that time.

Analysis of Kinetic Data: Testing the Michaelis–Menten Equation

The measurement of reaction velocity as a function of substrate concentration is used to determine whether an enzyme-catalyzed reaction follows the Michaelis–Menten model (Equation 11.25) and, if so, to determine the constants K_M and k_{cat} .

A few analytical methods for the measurement of rates are described in Tools of Biochemistry 11A. One general point should be noted: In principle, one could simply mix enzyme and substrate and follow the change in substrate concentration with time, as shown in Figure 11.1a. As substrate is consumed, the reaction velocity decreases, until equilibrium is eventually reached. But measuring the instantaneous velocity at specific times during the reaction is difficult and usually inaccurate. It is usually easier to set up a series of experiments, all at the same enzyme concentration but at different substrate concentrations, and measure the *initial* rates (Figure 11.24). Because we know the initial $[S]$ precisely, and the change in $[S]$ versus t is almost linear in the initial stages, accurate data for v as a function of $[S]$ can be obtained. An enzyme that obeys the Michaelis–Menten kinetic model will yield a plot of initial velocity vs. substrate concentration that is hyperbolic—compare Figures 11.23 and 11.24b.

Given such data for concentrations and initial rates, how are K_M and k_{cat} calculated? In practice, modern nonlinear curve-fitting software can fit the data plotted in Figure 11.24b directly to provide these parameters. Before such data analysis became widely available, a different method was (and still is) used. Equation 11.25 can be rearranged to give the expression for a linear graph. Several kinds of graphs are possible, but it is most common to use a **double reciprocal plot**, also called a **Lineweaver–Burk plot** (Figure 11.25). A Lineweaver–Burk plot provides a quick test for adherence to Michaelis–Menten kinetics and allows easy evaluation of the critical constants. As described below, it also allows discrimination between different kinds of enzyme inhibition and regulation. Taking the reciprocal of both sides of Equation 11.25, we find

$$\frac{1}{v} = \frac{K_M + [S]}{V_{\text{max}}[S]} = \frac{K_M}{V_{\text{max}}[S]} + \frac{[S]}{V_{\text{max}}[S]} \quad (11.28a)$$

or

$$\frac{1}{v} = \left(\frac{K_M}{V_{\text{max}}} \right) \frac{1}{[S]} + \frac{1}{V_{\text{max}}} \quad (11.28b)$$

So, plotting $1/v$ versus $1/[S]$ yields a straight line. At $1/[S] = 0$, $[S]$ is infinitely large and the reaction velocity is at its maximum. Therefore, the y -intercept at

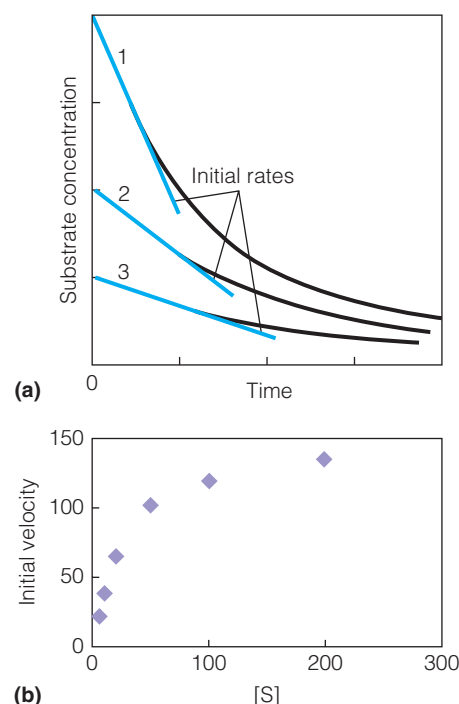

FIGURE 11.24

Analysis of initial rates. (a) Several reactions are performed with varying concentrations of substrate and the values of the initial rates are determined from the slopes of the curves in the early phase for each reaction. (b) Initial rate data, determined as described in (a), are plotted as a function of the substrate concentration. The enzyme appears to obey the Michaelis–Menten kinetic model (compare this plot to Figure 11.23).

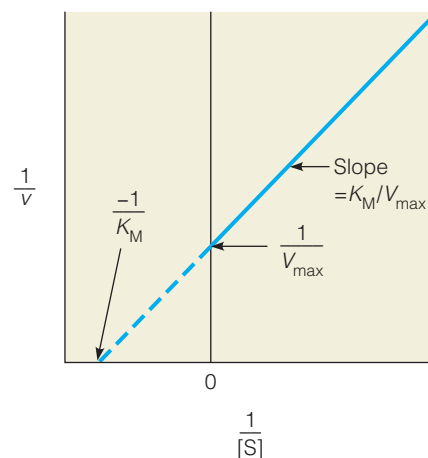

FIGURE 11.25

A Lineweaver–Burk plot. In this double reciprocal plot, $1/v$ is graphed versus $1/[S]$, according to Equation 11.28b. Note that a linear extrapolation of the data gives both V_{max} and K_M .

Lineweaver–Burk plots or Eadie–Hofstee plots provide convenient ways to determine K_M and k_{cat} from initial-rate data.

FIGURE 11.26

An Eadie–Hofstee plot. Graphing v versus $v/[S]$, we obtain V_{max} at $(v/[S]) = 0$ and K_M from the slope of the line.

The observed effects of an amino acid mutation in an enzyme active site on K_M and k_{cat} can be used to identify the role of the amino acid in substrate binding (K_M effects) and transition-state stabilization (k_{cat} effects).

Multisubstrate reactions fall into several classes, depending on the order of substrate binding: random, ordered, or ping-pong.

$1/[S] = 0$ is equal to $1/V_{\text{max}}$. Given V_{max} and $[E]_t$ (from the initial conditions of the kinetics experiment), k_{cat} can be calculated from $V_{\text{max}} = k_{\text{cat}}[E]_t$. In similar fashion, K_M is calculated using the slope of the plot, which gives K_M/V_{max} and the value of V_{max} obtained from the y -intercept. Alternatively, K_M can be calculated from the intercept of the Lineweaver–Burk plot with the x -axis where $1/v = 0$. Setting $1/v = 0$ gives

$$0 = \left(\frac{K_M}{V_{\text{max}}} \right) \frac{1}{[S]_0} + \frac{1}{V_{\text{max}}} \quad (11.29)$$

where $[S]_0$ denotes the value of $[S]$ at $1/v = 0$. We then obtain from Equation 11.29:

$$\frac{1}{[S]_0} = -\frac{1}{K_M} \quad (11.30)$$

Thus, the intercept of the Lineweaver–Burk plot with the x -axis gives $-1/K_M$ (see Figure 11.25).

A disadvantage of a Lineweaver–Burk plot is that a long extrapolation is often required to determine K_M , which introduces corresponding uncertainty in the result. Consequently, other ways of plotting the data are sometimes used. One alternative is to rearrange Equation 11.25 into the form

$$v = V_{\text{max}} - K_M \frac{v}{[S]} \quad (11.31)$$

and graph v versus $v/[S]$. This yields what is called an **Eadie–Hofstee plot** (Figure 11.26). These linear plots provide useful methods for recognizing modes of inhibition; however, they suffer from unequal weighting of the data. Performing nonlinear curve fitting to the raw data with readily available software is now preferred.

As discussed above for lysozyme and subtilisin, site-directed mutagenesis has been used extensively to test mechanistic models for most enzymes. A particular mutation may change the apparent value of k_{cat} or K_M or both. The simplest interpretation of such data is that a mutation that affects only k_{cat} changes an amino acid side chain involved solely in catalysis (e.g., the active site nucleophile, or a GABC, etc.) but not involved in binding to the substrate in the ground state. Conversely, a mutation that affects only K_M alters a side chain that binds to the substrate but is not involved in stabilizing the transition state. Frequently, both k_{cat} and K_M are affected by mutations to active site residues. This would occur for a residue that binds substrate and then makes stronger interactions with the transition state as a result of an altered geometry in the transition state that optimizes the interaction.

Multisubstrate Reactions

Our discussions of enzyme kinetics have, to this point, centered on simple reactions in which one substrate molecule is bound to an enzyme and undergoes reaction there. In fact, such reactions are in the minority. Most biochemical reactions involve two or more substrates. An example we have already discussed is proteolysis, which involves two substrates (the polypeptide and water) and two products (the two fragments of the cleaved polypeptide chain). Phosphorylation of glucose, as catalyzed by hexokinase, is another such case: The two substrates are glucose and ATP, and the products are glucose-6-phosphate and ADP.

When an enzyme binds two or more substrates and releases multiple products, the order of the steps becomes an important feature of the enzyme mechanism. Several major classes of mechanisms for multisubstrate reactions are recognized. We shall illustrate them with examples using two substrates, S1 and S2, and two products, P1 and P2.

Random Substrate Binding

In random substrate binding, either substrate can be bound first, although in many cases one substrate will be favored for initial binding, and its binding may promote the binding of the other. The general pathway is

The phosphorylation of glucose by ATP, with hexokinase as the enzyme, appears to follow such a mechanism, although there is some tendency for glucose to bind first.

Ordered Substrate Binding

In some cases, one substrate *must* bind before a second substrate can bind significantly:

This mechanism is often observed in oxidations of substrates by the cofactor NAD^+ , which is related to the cofactor NADP^+ discussed above in the dihydrofolate reductase mechanism.

The Ping-Pong Mechanism

Sometimes the sequence of events in catalysis goes like this: One substrate is bound, one product is released, a second substrate comes in, and a second product is released. This is called a “ping-pong” reaction:

Here E^* is a modified form of the enzyme, often carrying a fragment of $S1$. A good example is the cleavage of a polypeptide chain by a serine protease such as trypsin or chymotrypsin. In that case, we describe the polypeptide as $S = B-A$, where A and B designate, respectively, the C-terminal and N-terminal portions of the peptide chain on either side of the scissile bond:

Here $E^* \cdot B$ and $E^* \cdot B \cdot H_2O$ indicate the covalent intermediates described above (see Figure 11.17).

A Closer Look at Some Complex Reactions

How are the mechanism of a complex enzyme-catalyzed reaction and the rate constants for different steps determined? For example, consider the cleavage of a substrate by a serine protease such as chymotrypsin. Note that the step $E^* \cdot B + H_2O \longrightarrow E^* \cdot B \cdot H_2O$ cannot be analyzed because the concentration of water is essentially fixed in aqueous solution and is not a variable. Therefore, it will suffice to write the reaction as

FIGURE 11.27

The pre-steady-state. This plot shows the kinetics of chymotrypsin-catalyzed hydrolysis of *p*-nitrophenyl acetate. Production of the first product (*p*-nitrophenol) is followed spectrophotometrically after the enzyme and substrate are mixed. The initial burst of product formation ceases when enzyme is almost all bound in the acyl-enzyme intermediate.

In this example there are several constants to determine. Steady-state measurements will not in themselves be sufficient. It can be shown that the steady-state velocity for this reaction is given by the equation

$$v = \frac{\left(\frac{k_2 k_3}{k_2 + k_3}\right)[E]_t[S]}{[S] + \left(\frac{K_S k_3}{k_2 + k_3}\right)} \quad (11.32)$$

In other words, the enzyme obeys Michaelis–Menten kinetics, but k_{cat} and K_M are now defined as follows:

$$k_{\text{cat}} = \frac{k_2 k_3}{k_2 + k_3} \quad (11.33a)$$

$$K_M = \frac{K_S k_3}{k_2 + k_3} \quad (11.33b)$$

$$K_S = \frac{k_{-1}}{k_1} \quad (11.33c)$$

These results emphasize that the appropriate expressions for k_{cat} and K_M depend upon the reaction mechanism, even in cases where the Michaelis–Menten equation describes the velocity. To obtain the individual rate constants in such a case, measurements outside the steady-state range must be employed. One of the first indications that an enzyme-bound intermediate might be involved in proteolysis came from rapid kinetic studies of the early stages in the hydrolysis of esters by chymotrypsin. Monitoring the release of product A (*p*-nitrophenol in this example) shows that its concentration increases quickly for a few seconds, until about 1 mole has been produced per mole of enzyme. After this time, the rate is nearly constant, as expected for a reaction at steady state (Figure 11.27).

The initial rapid production of the first product, called *pre-steady-state* production, or the *burst* phase, has been explained in the following way. For ester hydrolysis, k_3 is much smaller than k_2 . Thus, the acyl intermediate forms quickly on each enzyme molecule, with accompanying release of 1 mole of product A. But after this period, more A can be formed only after each acyl intermediate breaks down and the enzyme becomes available again. The dissociation of the acyl intermediate is the rate-limiting step.

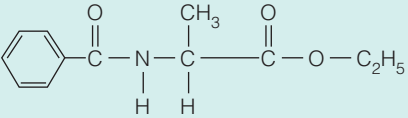

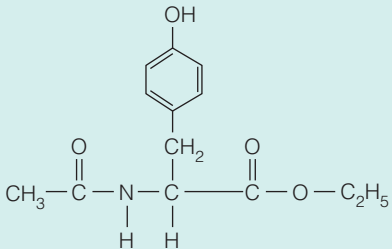

Still faster measurements, using stopped-flow techniques (see Tools of Biochemistry 11A), allow measurement of the rate of formation of the enzyme–substrate complex (ES). Measurements of the decay of the acyl intermediates after substrate is exhausted provide k_3 . By using a combination of such methods, together with steady-state studies, we can obtain all of the constants in Equation 11.32. Two examples of such detailed kinetic data are given in Table 11.6 for hydrolysis of *N*-acyl amino acid esters. In example 1, we find $k_{\text{cat}} \cong k_2$, and $K_M \cong K_S$. These are the results expected when the acylation reaction (k_2) is rate-limiting, with $k_2 < k_3$. In the second example, deacylation is rate-limiting ($k_2 > k_3$) and $k_{\text{cat}} \cong k_3$. In this situation, $K_M = K_S(k_3/k_2)$. Each of these statements can be checked by examination of how Equations 11.33a–c behave in the specific cases.

This example demonstrates that a steady-state analysis is only a first step in the study of any enzyme and that a variety of techniques must be employed to unravel the details of catalytic mechanisms.

Single-Molecule Studies of Enzyme Activity

Our discussion of enzyme kinetics so far has been based on the typical conditions used for such studies—purified proteins present in large numbers in the reaction vessel. Thus, the kinetic behavior observed is the average behavior of a huge

TABLE 11.6 Rate constants for the hydrolysis of two *N*-acyl amino acid esters by chymotrypsin

Substrate	k_{cat} (s^{-1})	k_2 (s^{-1})	k_3 (s^{-1})	K_M (mM)	K_S (mM)
	0.069	0.069	0.6	5.87	5.97
	192	5000	200	0.663	17.2

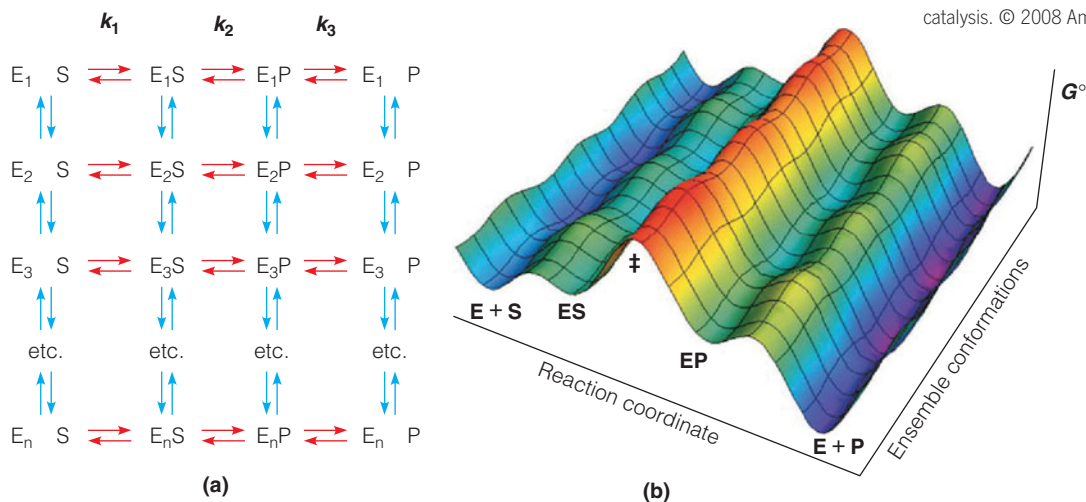

ensemble of molecules. Recently it has been possible to record the kinetics of *single enzyme molecules* tethered in place on a fluorescence microscope. Sunney Xie and coworkers studied β -galactosidase in this way. They found that the kinetic behavior of single molecules was variable—a given molecule displayed multiple turnover rates, and these rates differed between different molecules. They interpreted these results in terms of multiple conformations for each enzyme molecule (Figure 11.28a), where each conformation is associated with a different value of k_{cat} . Figure 11.28b illustrates how we might imagine variation in k_{cat} for a single enzyme molecule if we plot the reaction coordinate (i.e., the red curve in Figure 11.10) in a second dimension that describes the multiple conformations that molecules can adopt as a consequence of dynamic motions. Each state of the enzyme (e.g., E, ES, and EP) has multiple conformations and each conformation is associated with a different free energy. Energy barriers along *both* dimensions could give rise to the variations in k_{cat} observed in these experiments.

This does not mean that all the enzyme kinetics presented above is invalid! The Michaelis–Menten model provides a good description of the kinetics of a large ensemble of molecules. Furthermore, Xie found that when single molecules were observed for many turnovers, their average kinetic behaviour could also be described by Michaelis–Menten kinetics. Thus, we will continue to interpret data from kinetics studies in terms of the Michaelis–Menten model.

FIGURE 11.28

Conformational dynamics and an expanded reaction coordinate landscape. (a) Studies of single molecules suggest that enzymes can adopt multiple conformations, not only along the reaction coordinate trajectory (red arrows) but also between similar states along the reaction coordinate (blue arrows between free enzyme states, ES complex, EP complex). (b) A model for the free energy landscape defined by the scheme in (a). For real enzymes this landscape is probably more rugged (i.e., higher peaks and valleys than shown here), with a few saddle points between the ES and EP states. The variability seen in observed rates for single molecules is attributed to the differences in barrier heights between the various states shown in (a).

Enzyme Inhibition

Inhibition of enzymes can be either reversible or irreversible.

Studies of enzyme inhibition can provide critical insights into the mechanisms of enzyme catalysis. Many different kinds of molecules inhibit enzymes, and they act in a variety of ways. A major distinction must be made between **reversible inhibitors** and **irreversible inhibitors**. The former involves *noncovalent* binding of the inhibitor and can always be reversed, at least in principle, by removal of the inhibitor. In some cases, noncovalent binding may be so strong as to appear irreversible under physiological conditions. Trypsin inhibitor binding to trypsin is one such example (see Figure 6.42). In irreversible inhibition, on the other hand, a molecule is *covalently* bound to the enzyme and truly incapacitates it. Irreversible inhibition is frequently encountered in the action of specific toxins and poisons, many of which kill by incapacitating key enzymes. On the other hand, the therapeutic action of many drugs depends on their acting as enzyme inhibitors, as we shall see in many examples.

Reversible Inhibition

The various modes of reversible inhibition all involve the noncovalent binding of an inhibitor to the enzyme, but they differ in the mechanisms by which they decrease the enzyme's activity and in how they affect the kinetics of the reaction.

A competitive inhibitor competes with substrate for the enzyme active site. It increases the apparent K_M .

Competitive Inhibition

Suppose a molecule exists that so closely resembles the substrate for an enzyme-catalyzed reaction that the enzyme will accept this molecule in its active site. If this molecule can also be processed by the enzyme, it is merely a competing alternative substrate. However, if the molecule binds to the active site but *cannot* undergo the catalytic step, it effectively reduces the enzyme's availability to carry out chemistry on true substrates. Such a molecule is called a **competitive inhibitor** because it competes with the substrate for binding to the same site on the enzyme (Figure 11.29).

For whatever fraction of time a competitive inhibitor molecule is occupying the active site, the enzyme is unavailable for catalysis. The overall effect is as if the enzyme cannot bind substrate as well when the inhibitor is present. Thus, the enzyme is predicted to act as if its K_M were increased by the presence of the inhibitor. These ideas can be expressed by writing the reaction scheme as

Here I stands for the inhibitory substance and K_I is a dissociation constant for inhibitor binding, defined as $K_I = [E][I]/[EI]$, where $[I]$ = concentration of free inhibitor. The rate equations can be solved as shown in the previous section, but note that now

$$[E]_t = [E] + [ES] + [EI] \quad (11.34)$$

Total enzyme
Free enzyme
Enzyme bound to substrate
Enzyme bound to inhibitor

Upon analysis of this case, the expression for v is found to be

$$v = \frac{k_{\text{cat}}[E]_t[S]}{K_M \left(1 + \frac{[I]}{K_I} \right) + [S]} \quad (11.35a)$$

FIGURE 11.29

Competitive inhibition. Both substrate and inhibitor can fit the active site. Substrate can be processed by the enzyme, but inhibitor cannot.

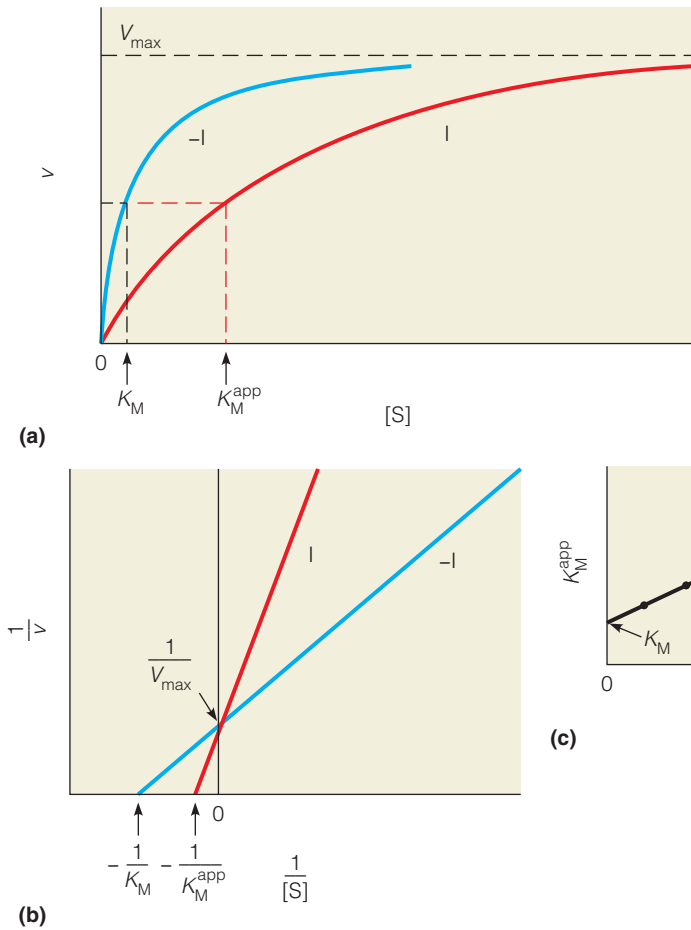

FIGURE 11.30

Effects of competitive inhibition on enzyme kinetics. (a) The effect of a competitive inhibitor (I) on reaction velocity at different substrate concentrations. Two sets of substrate-velocity experiments were carried out, one with (red line) and one without (blue line) inhibitor present. Addition of the inhibitor decreases the velocity but not the V_{\max} . The apparent K_M is higher in the presence of inhibitor. **(b)** Lineweaver–Burk plots of the reactions shown in (a). The lines cross the $1/v$ axis at the same V_{\max} , showing that I is a competitive inhibitor. **(c)** Determination of K_M and K_I . If the measurement of K_M^{app} is repeated at different concentrations of I, K_I can be determined from the slope of the line, and the true K_M from the line's intercept where $[I] = 0$ (see Equation 11.36).

or

$$v = \frac{V_{\max}[S]}{\alpha K_M + [S]} \quad (11.35b)$$

where $\alpha = (1 + [I]/K_I)$. The term αK_M may also be written as K_M^{app} , which gives

$$v = \frac{V_{\max}[S]}{K_M^{\text{app}} + [S]} \quad (11.35c)$$

This expression looks just like the Michaelis–Menten equation, with an “apparent” K_M given by $\alpha K_M = (1 + [I]/K_I)K_M$. As predicted, increasing $[I]$ causes an increase in the apparent K_M . Because the formation of EI depends on $[I]$ just as the formation of ES depends on $[S]$, the rate of a competitively inhibited reaction is strictly dependent on the relative concentrations of I and S. It is important to note that K_M for the substrate is not changing per se; rather, the presence of a competitive inhibitor increases the value of $[S]$ which gives half V_{\max} . Thus, an *apparent* K_M is measured for the inhibited reaction, which is always greater than the actual K_M for the substrate because α is always >1 .

For competitive inhibition the maximum velocity is unchanged because as $[S]$ becomes very large, v approaches V_{\max} (just as in the absence of inhibition), and $V_{\max} = k_{\text{cat}}[E]_t$. Physically, this simply means that when $[S]$ is very large at a given $[I]$, the more numerous substrate molecules will outcompete the inhibitor. The effect of competitive inhibition on a graph of v versus $[S]$ is shown in Figure 11.30a.

FIGURE 11.31

A substrate and its competitive inhibitor. The substrate UpA and the structurally similar molecule UcpA are competitors for the enzyme ribonuclease. The single difference between the substrate and the inhibitor is shown in magenta.

Because the system, at a given $[I]$, still obeys an equation of the Michaelis–Menten form, the Lineweaver–Burk plots and Eadie–Hofstee plots should be linear graphs, with K_M (but not V_{\max}) changed by the presence of inhibitor. As Figure 11.30b shows, this is exactly what happens. Both the true K_M and K_I can be determined as shown in Figure 11.30c because a plot of the K_M^{app} values obtained at different inhibitor concentrations versus $[I]$ should give a line as predicted by

$$K_M^{\text{app}} = \alpha K_M = \left(1 + \frac{[I]}{K_I}\right) K_M = K_M + \frac{K_M}{K_I} [I] \quad (11.36)$$

A clear example of a competitive inhibitor is shown in Figure 11.31. The dinucleotide UpA is an excellent substrate for the enzyme ribonuclease, which catalyzes hydrolysis of the phosphodiester bond between the two nucleotides. But if the oxygen atom at the cleavage site in UpA is replaced by a CH_2 group, the molecule becomes the *phosphonate* analog UpcA, a strong competitive inhibitor. Ribonuclease binds the analog strongly enough in the active site to allow X-ray diffraction studies of the complex, but it cannot cleave the phosphonate bond.

An uncompetitive inhibitor does not compete for the active site but affects the catalytic event. It reduces both the apparent V_{\max} and apparent K_M . These effects cannot be reversed by increasing $[S]$.

FIGURE 11.32

Uncompetitive inhibition. The inhibitor binds at a site on the enzyme surface different from that of the substrate. In this simple example, the inhibitor binds only to the ES complex and inhibits the catalytic event.

Uncompetitive Inhibition

This form of inhibition occurs when a molecule or an ion can bind to a *second* site on an enzyme surface (not the active site) in such a way that it modifies k_{cat} . It might, for example, distort the enzyme so that the catalytic process is not as efficient. The simplest case to consider is one in which the inhibitor molecule binds only to the ES complex and does not interfere in any way with substrate binding, but completely prevents the catalytic step (Figure 11.32).

Here we distinguish the equilibrium constant for inhibitor binding to free enzyme, K_I , from K'_I , the equilibrium constant for inhibitor binding to the ES complex. Because the inhibitor binding site is completely separate from the substrate binding site, such an **uncompetitive inhibitor** can be a molecule that does not resemble the substrate at all.

It can be shown (see Problem 28a) that the Michaelis–Menten equation for the uncompetitive inhibition scheme above is

$$v = \frac{V_{\max}^{\text{app}}[S]}{K_M^{\text{app}} + [S]} = \frac{V_{\max}[S]}{K_M + \alpha'[S]} \quad (11.37)$$

where $\alpha' = (1 + [I]/K'_I)$, $V_{\max}^{\text{app}} = V_{\max}/\alpha'$, and $K_M^{\text{app}} = K_M/\alpha'$. In the presence of an uncompetitive inhibitor both V_{\max} and K_M appear to be *reduced* by a factor of $1/\alpha'$ (Figure 11.33a). By binding only to the ES complex, an uncompetitive inhibitor increases the effective S binding, which reduces the apparent K_M . How can this observation be explained? At $[S] < K_M$ the effect of the inhibitor is minimal because as $[S]$ decreases, v approaches $V_{\max}[S]/K_M$. At $[S] > K_M$, the effect of the inhibitor on reducing V_{\max} is apparent because as $[S]$ increases, v approaches V_{\max}/α' . Thus, as shown in Figure 11.33a, the v vs. $[S]$ plots overlap at low $[S]$ but diverge at higher $[S]$.

Uncompetitive inhibition is distinguished from competitive inhibition by two observations: (1) uncompetitive inhibition cannot be reversed by increasing $[S]$ and (2) as shown in Figure 11.33b, the Lineweaver–Burk plot yields parallel rather

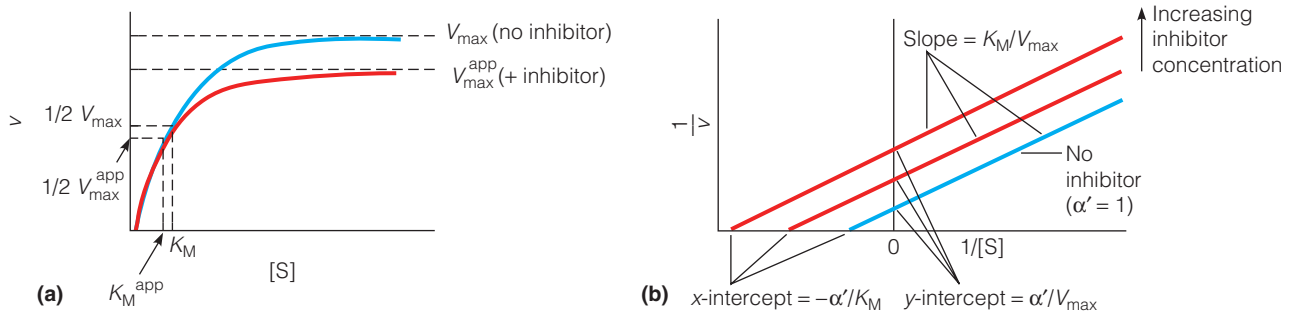

FIGURE 11.33

Effects of uncompetitive inhibition on enzyme kinetics. **(a)** The effect of an uncompetitive inhibitor (I) on reaction velocity at different substrate concentrations. In this simple example, both K_M and V_{max} are decreased by a factor of $1/\alpha'$. **(b)** Lineweaver–Burk plots of the reactions shown in (a). The lines are parallel and cross the $1/v$ axis at different points, clearly distinguishing this situation from competitive inhibition (see Figure 11.30b).

than intersecting lines (because the factor α' drops out of the ratio to give a slope $= K_M/V_{max}$ for all values of α').

This behavior is found in the inhibition of acetylcholinesterase (see Chapter 23) by tertiary amines (R_3N). Such compounds bind to the enzyme in its various forms, but the acyl–intermediate–amine complex cannot break down into enzyme plus product.

Mixed Inhibition

This form of inhibition occurs when a molecule or an ion can bind to both the free enzyme and the ES complex (see Figure 11.34):

Again, we distinguish the equilibrium constants K_I and K'_I , respectively, for inhibitor binding to E and ES. In the case where $K_I = K'_I$, the mixed mode of inhibition is also called **noncompetitive inhibition**. Substrate binding to the EI complex (green arrows in the scheme above) is typically significantly reduced compared to that for binding to free enzyme. Thus, the process $EI + S \rightleftharpoons EIS$ will not be considered here, although it is part of a complete thermodynamic analysis; in doing so, the derivation of the Michaelis–Menten equation for mixed inhibition is greatly simplified without significantly altering the conclusions of the analysis. For this simplified case:

$$v = \frac{V_{max}^{app}[S]}{K_M^{app} + [S]} = \frac{V_{max}[S]}{\alpha K_M + \alpha'[S]} \tag{11.38}$$

where α and α' are defined as above, $V_{max}^{app} = V_{max}/\alpha'$, and $K_M^{app} = \alpha K_M/\alpha'$ (see Problem 28b for the derivation of this equation). In most cases, the inhibitor has a greater affinity for the free enzyme than for the ES complex; thus, α is typically greater than α' .

This mode of inhibition is “mixed” because the denominator of Equation 11.38 contains terms found in the equations for competitive inhibition (αK_M) and uncompetitive inhibition ($\alpha'[S]$). As for competitive inhibition, K_M appears to be *increased* (by a factor of α/α'), and as for uncompetitive inhibition, V_{max} appears to be *reduced* (by a factor of $1/\alpha'$). Figure 11.35 shows that the Lineweaver–Burk plot for mixed inhibition reflects this decreased V_{max} and increased K_M , and is distinct from similar plots for competitive and uncompetitive modes of inhibition.

Finally, mixed inhibitors effectively reduce v at low and high values of $[S]$. At $[S] > K_M$, v approaches $V_{max}[S]/\alpha K_M$, and at $[S] > K_M$, v approaches V_{max}/α' . Thus, V_{max}^{app} will be less than V_{max} for all values of $[S]$.

FIGURE 11.34

A model for mixed inhibition. The inhibitor binds at a site on the enzyme surface different from that of the substrate. In this simplified example, the inhibitor binds to both free enzyme and the ES complex. EI has reduced substrate binding affinity compared to free enzyme. The EIS complex cannot carry out the catalytic event. As noted in the text, the process $EI + S \rightleftharpoons EIS$ is not considered here.

A mixed inhibitor does not compete for the active site but affects the catalytic event. It reduces the apparent V_{max} at all $[S]$ and increases the apparent K_M .

FIGURE 11.35

Lineweaver–Burk plot for mixed inhibition kinetics. V_{\max} is decreased by a factor of $1/\alpha'$ and K_M is increased by a factor of α/α' . Compare this plot with those in Figures 11.30b and 11.33b to find the features that distinguish competitive, uncompetitive, and mixed modes of inhibition.

Many irreversible inhibitors bind covalently to the active sites of enzymes.

Some substances combine *covalently* with enzymes to inactivate them irreversibly. Almost all **irreversible enzyme inhibitors** are toxic substances, either natural or synthetic. Table 11.7 lists a number of them. In most cases, such substances react with some functional group in the active site to leave it catalytically inactive or to block substrate binding.

A typical example of an irreversible competitive inhibitor is found in *diisopropyl fluorophosphate* (DFP). This compound reacts rapidly and irreversibly with serine hydroxyl groups to form a covalent *adduct*, as shown in Figure 11.36. Therefore, DFP acts as an irreversible inhibitor of enzymes that contain an essential serine in their active site. These enzymes include, among others, the serine proteases and the enzyme *acetylcholinesterase*. It is the inhibition of acetylcholinesterase that makes DFP such an exceedingly toxic substance to animals. Acetylcholinesterase is essential for nerve conduction (see Chapter 23), and its inhibition causes rapid paralysis of vital functions. Many insecticides and nerve gases resemble DFP and are potent acetylcholinesterase inhibitors (Table 11.7).

For such irreversible inhibitors to react selectively with a critical residue, they must bind strongly to the active site. Many do so because they are transition state analogs. Examples include DFP and the nerve gas *sarin*, which have a tetrahedral structure surrounding the phosphorus atom that is similar to the tetrahedral oxyanion transition state of the substrate in many hydrolytic enzymes.

Some selective irreversible inhibitors mimic the substrate of the target enzyme. An example is *N-tosyl-L-phenylalaninechloromethyl ketone* (TPCK) (see Table 11.7). TPCK is an excellent inhibitor for chymotrypsin because the phenyl group fits nicely into the active site pocket, positioning the chlorine for nucleophilic displacement by a nitrogen of the imidazole ring of His 57. The resulting covalent adduct blocks access to the enzyme active site—effectively rendering the enzyme completely inactive. A large number of such specific irreversible inhibitors have been synthesized to aid in the analysis of enzyme mechanisms and to control enzyme activity. For example, a biochemist who is using chymotrypsin to hydrolyze a protein can stop the reaction instantly at any point by simply adding TPCK. Another use for such substances is to label active site residues of an enzyme specifically to aid in their identification. When irreversible inhibitors are used in this way, they are often called **affinity labels**. In some cases an affinity label is unreactive until it is acted on by the enzyme, at which point it binds irreversibly. Such substances are called **suicide inhibitors** because the enzyme “kills” itself by processing the inhibitor from a benign to a reactive form.

Many natural toxins are irreversible enzyme inhibitors. The alkaloid *physostigmine* (see Table 11.7), which is contained in calabar beans, is toxic

FIGURE 11.36

Irreversible inhibition by adduct formation.

Diisopropyl fluorophosphate (DFP) reacts with a serine group on a protein to form a covalent adduct. The covalent bond renders the catalytically important serine ineffective in catalysis. The adduct also may block substrate binding to the active site.

TABLE 11.7 Irreversible enzyme inhibitors

Name	Formula ^a	Source	Mode of Action
Cyanide	CN ⁻	Bitter almonds	Reacts with enzyme metal ions (i.e., Fe, Zn, Cu); respiratory chain enzymes are primary targets (see Chapter 15)
Diisopropyl fluorophosphate (DFP, or DIFP)		Synthetic	Inhibits enzymes with active site serine, including acetylcholinesterase and serine proteases
Sarin		Synthetic (nerve gas)	Like DFP
Physostigmine		Calabar beans	Like DFP
Parathion		Synthetic (insecticide)	Like DFP, but especially inhibitory to insect acetylcholinesterase
N-Tosyl-L-phenylalaninechloro-methyl ketone (TPCK)		Synthetic	Reacts with His 57 of chymotrypsin
Penicillin		From <i>Penicillium</i> fungus	Inhibits enzymes in bacterial cell wall synthesis (see Chapter 9)

^aR = variable group; differs on different penicillins.

because it is a potent inhibitor of acetylcholinesterase. The *penicillin* antibiotics also act as irreversible inhibitors of serine-containing enzymes used in bacterial cell wall synthesis (see Chapter 9).

Cofactors, Vitamins, and Essential Metals

The complexity of globular protein structure and the variety of side chain structures in a protein allow the formation of many kinds of catalytic sites. This variability allows enzymes to act as efficient catalysts for many reactions. However, for some kinds of biological processes, the chemical potential of amino acid side chains alone is not sufficient. A protein may require the help of some other small molecule or ion to carry out the reaction. The ions or molecules that are bound to enzymes for this

Many enzymes use ions or small bound molecules called cofactors or coenzymes to aid in catalysis.

purpose are called **cofactors** or **coenzymes**. Like enzymes, cofactors are not irreversibly changed during catalysis; they are either unmodified or regenerated, as discussed above in the case of dihydrofolate reductase, which uses the NADPH cofactor.

Cofactors and What They Do

Many essential vitamins are constituents of enzyme cofactors.

Cofactors often have complex organic structures that cannot be synthesized by some organisms—mammals in particular. The water-soluble vitamins, those usually referred to as the vitamin-B complex, are metabolic precursors of several cofactors. This is why such vitamins are so important in metabolism. Our approach in this book is to introduce the detailed biochemistry of each cofactor as we first encounter that cofactor in discussions of metabolic pathways. Table 11.8 lists a number of important enzyme cofactors, together with their related vitamins, the kinds of reactions they are associated with, and where in this textbook you will find detailed descriptions and discussion. At this point, just to give a more concrete idea of how cofactors function, we will describe one class in some detail. These are the nicotinamide nucleotides, a major example being **nicotinamide adenine dinucleotide** (NAD^+) derived from the vitamin **niacin**.

TABLE 11.8 Some important enzyme cofactors and related vitamins

Vitamin	Cofactor	Reactions Involving These Cofactors	Page Where Cofactor Is Introduced
Thiamine (vitamin B ₁)	Thiamine pyrophosphate	Activation and transfer of aldehydes	536–538
Riboflavin (vitamin B ₂)	Flavin mononucleotide; flavin adenine dinucleotide	Oxidation–reduction	599
Niacin	Nicotinamide adenine dinucleotide; nicotinamide adenine dinucleotide phosphate	Oxidation–reduction	446, 485, 530
Pantothenic acid	Coenzyme A	Acyl group activation and transfer	601
Pyridoxine	Pyridoxal phosphate	Various reactions involving amino acid activation	845
Biotin	Biotin	CO ₂ activation and transfer	617–619
Lipoic acid	Lipoamide	Acyl group activation; oxidation–reduction	598–599
Folic acid	Tetrahydrofolate	Activation and transfer of single-carbon functional groups	848
Vitamin B ₁₂	Adenosyl cobalamin; methyl cobalamin	Isomerizations and methyl group transfers	853

The nicotinamide portion is the metabolically relevant part of NAD^+ , because it is capable of being reduced and thus can serve as an *oxidizing* agent to which two electrons and a proton are added to the nicotinamide ring: $\text{NAD}^+ + 2e^- + \text{H}^+ \rightarrow \text{NADH}$. The reaction is reversible (i.e., NADH acts as a *reducing* agent in several reactions) and is formally a **hydride ion** transfer: $\text{NAD}^+ + \text{H}^- \rightleftharpoons \text{NADH}$.

Here, R stands for the remainder of the molecule.

A typical reaction in which NAD^+ acts as an oxidizing agent is the conversion of alcohols to aldehydes or ketones (for example, by the *alcohol dehydrogenase* of liver):

It is the C-linked H, not the O-linked H, that is transferred to NAD^+ , as can be demonstrated by studies using deuterated compounds. Furthermore, these reactions are stereospecific. Even when the hydroxyl carbon has *two* hydrogens attached (as with ethanol), a particular one of the hydrogens is transferred to NAD^+ . This specificity may seem surprising because the hydroxyl carbon of ethanol is not a chiral center. How can a particular hydrogen be favored when the substrate molecule has a plane of symmetry? The answer lies in the asymmetric nature of the enzyme surface, to which both NAD^+ and the alcohol are bound. If a symmetrical molecule like ethanol is bound by at least *three* points to an asymmetric object, the two H atoms are no longer equivalent; they are said to be *prochiral* (Figure 11.37). Furthermore, although the nicotinamide ring is planar, the transfer of hydrogen in a particular reaction is always to a specific face of the ring, as the two faces are *not* equivalent in the asymmetric active site of an enzyme. Such considerations lie behind the high stereospecificity of many enzyme-catalyzed reactions, in contrast to nonenzymatic catalysis.

Sometimes it is difficult to make a clear distinction between a true cofactor and a second substrate in a reaction. The reactions we have just discussed are good examples of this problem. The dehydrogenase enzymes, such as alcohol dehydrogenase, each have a strong binding site for the oxidized form of the cofactor, NAD^+ . After oxidation of the substrate, the reduced form, NADH, leaves the enzyme and is reoxidized by other electron-acceptor systems in the cells. The NAD^+ so formed can now bind to another enzyme molecule and repeat the cycle. In such cases, NAD^+ is acting more like a second substrate than a true cofactor. Yet NAD^+ and NADH differ from most substrates in that they are continually recycled in the cell and are used over and over again. Because of this behavior, we consider them cofactors.

An example of NAD^+ behaving unambiguously as a cofactor is found in the reaction involving *UDP-galactose 4-epimerase* shown in Figure 11.38. This enzyme

FIGURE 11.37

Stereospecificity conferred by an enzyme. This figure shows how the asymmetric surface of an enzyme can confer stereospecificity in the reaction of a symmetric substrate. If the substrate molecule X_2CYZ makes at least three contacts with unique complementary groups on the enzyme, its two X atoms are no longer equivalent. Only a specific one of the two X atoms can contact the surface properly. In many cases, a minimum of *four* contacts is required to distinguish prochiral functional groups. This is discussed in greater detail in Figure 14.11 (page 605; see also page 607).

**FIGURE 11.38**

Proposed mechanism for UDP-galactose epimerase. UDP-galactose is bound to the enzyme, which carries the coenzyme NAD⁺ (step 1). Hydride is transferred to NAD⁺ from C4 of the galactose ring to produce the carbonyl intermediate (step 2) and then transferred back to C4 to give the opposite stereochemistry (step 3). The product, UDP-glucose, is then released (step 4).

facilitates synthesis of complex polysaccharides by interconverting UDP-glucose and UDP-galactose (see Chapters 9 and 13). The mechanism by which the stereochemistry of the hydroxyl at position 4 is changed involves oxidation of the hydroxyl to a carbonyl as an intermediate state. In this case, NAD⁺ is reduced to NADH (step 2), which is, in turn, reoxidized (step 3) to regenerate the NAD⁺ cofactor. This reaction provides a good example of what cofactors do and why they are necessary. The carbonyl intermediate provides an excellent intermediate state for interconversion of the sugars, but none of the normal amino acid side chains of a protein is well suited to promote this kind of redox reaction. By binding NAD⁺, the enzyme can carry out this function.

Metal Ions in Enzymes

Many enzymes contain one or more metal ions, usually held by coordinate covalent bonds from amino acid side chains, but sometimes bound by a prosthetic group like heme. Such enzymes are called **metalloenzymes**. The bound ion acts in much the same way as a coenzyme, conferring on the metalloenzyme a property it would not possess in its absence. As Table 11.9 shows, the roles these ions play are diverse. For example, the zinc ion in *carboxypeptidase A* binds the water molecule that attacks the carbonyl of the scissile bond and also acts as an electrostatic catalyst (Figure 11.39). The zinc ion stabilizes the tetrahedral oxyanion in the transition state and the intermediate state, in much the same way as the oxyanion hole serves this function in chymotrypsin (see Figure 11.19 for comparison).

In other cases, the metal in a metalloenzyme serves as a redox reagent. We have mentioned the example of the heme-iron-containing enzyme *catalase*, which catalyzes the breakdown of hydrogen peroxide, a potentially destructive agent in cells. Because the reaction involves both reduction and oxidation of H₂O₂, the Fe²⁺ is reversibly oxidized and reduced, acting as an electron exchanger. As noted previously, catalase is a very efficient enzyme; its k_{cat}/K_M value of $4 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$ approaches the theoretical diffusion limit. Hemoglobin, which also contains Fe²⁺, has weaker catalase activity because oxidation of Fe²⁺ to Fe³⁺ is largely irreversible in hemoglobin. Such redox activity requires metals like Fe or Cu with multiple oxidation states.

In many other enzymatic reactions, certain ions are necessary for catalytic efficiency, even though they may not remain permanently attached to the protein nor play a direct role in the catalytic process. For example, a number of enzymes that couple ATP hydrolysis to other processes require Mg²⁺ for efficient function. In most cases Mg²⁺ is necessary because the Mg-ATP complex (see Chapter 3) is a better substrate than ATP itself.

TABLE 11.9 Metals and trace elements important as enzymatic cofactors

Metal	Example of Enzyme	Role of Metal
Fe	Cytochrome oxidase	Oxidation–reduction
Cu	Ascorbic acid oxidase	Oxidation–reduction
Zn	Alcohol dehydrogenase	Helps bind NAD ⁺
Mn	Histidine ammonia lyase	Aids in catalysis by electron withdrawal
Co	Glutamate mutase	Co is part of cobalamin coenzyme
Ni	Urease	Catalytic site
Mo	Xanthine oxidase	Oxidation–reduction
V	Nitrate reductase	Oxidation–reduction
Se	Glutathione peroxidase	Replaces S in one cysteine in active site
Mg ²⁺	Many kinases	Helps bind ATP

The Diversity of Enzymatic Function

Classification of Protein Enzymes

By this point, it should be clear that an enormous number of different proteins act as enzymes. Many of these enzymes were given common names, especially during the earlier years of enzymology. Some enzyme names, like *triose phosphate isomerase*, are descriptive of the enzyme's function; others, like *trypsin*, are not. To reduce confusion, a rational naming and numbering system has been devised by the Enzyme Commission of the International Union of Biochemistry and Molecular Biology (IUBMB). Enzymes are divided into six major classes, with subgroups and sub-subgroups to define their functions more precisely. The major classes are as follows:

1. *Oxidoreductases* catalyze oxidation–reduction reactions.
2. *Transferases* catalyze transfer of functional groups from one molecule to another.
3. *Hydrolases* catalyze hydrolytic cleavage.
4. *Lyases* catalyze removal of a group from or addition of a group to a double bond, or other cleavages involving electron rearrangement.
5. *Isomerases* catalyze intramolecular rearrangement.
6. *Ligases* catalyze reactions in which two molecules are joined.

The IUBMB Enzyme Commission (EC) has given each enzyme a number with four parts, such as: EC 3.4.21.5. The first three numbers define major class, subclass, and sub-subclass, respectively. The last is a serial number in the sub-subclass, indicating the order in which each enzyme is added to the list, which is continually growing. Listings for almost all currently recognized enzymes, together with information on each enzyme and literature references, can be found in online databases such as BRENDA (BRAunschweig ENzyme DAtabase; <http://www.brenda-enzymes.info>) or ExPASy (Expert Protein Analysis System; <http://expasy.org/enzyme>). The 5000+ entries in these databases do not include all enzymes; more are being discovered all the time. Indeed, it has been estimated that the typical cell contains many thousands of different kinds of enzymes. Table 11.10 lists one example enzyme and reaction from each of the major classes. We will discuss each of these reactions later in this book. The main point here is the enormous diversity of enzymatic functions and how their nomenclature has been rationalized.

Molecular Engineering of New and Modified Enzymes

Despite the variety of enzymatic functions available in nature, modern biotechnology continually faces needs for substances with new catalytic abilities, or enzymes that function with different specificities or under unusual conditions. These needs have generated a field of enzyme design and engineering, which has enormous potential in the design of industrial catalysts as well as biopharmaceuticals. Several approaches are being taken to achieve the goal of generating such tailor-made catalysts. These include site-directed mutagenesis, fusion of one or more functional domains, selection of a sequence with the desired activity from a large pool of randomly generated protein sequences, generation of “catalytic antibodies,” and computational design. Tools of Biochemistry 11B provides a brief introduction to these techniques.

Nonprotein Biocatalysts: Catalytic Nucleic Acids

Throughout this chapter, we have described how the proteins called enzymes function as biocatalysts. Indeed, for many years, it was assumed that *all* biochemical catalysis was carried out by proteins. But biochemistry is full of surprises, and

Some enzymes require metal ions for their catalytic function.

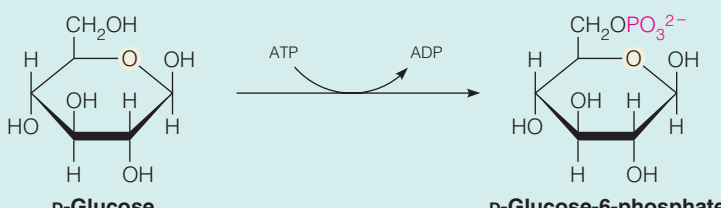

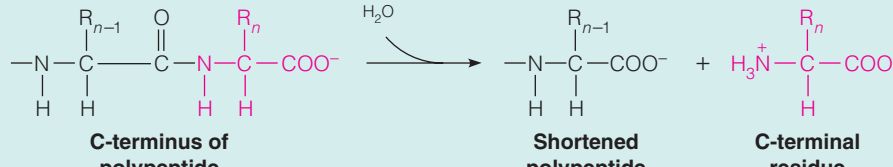

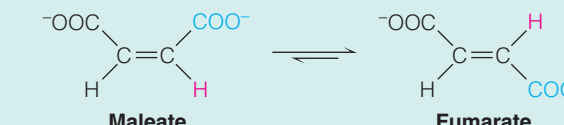

FIGURE 11.39

The mechanism of the protease carboxypeptidase A. The zinc ion (orange circle) binds a water molecule (blue) and serves as an electrostatic catalyst to promote hydrolysis of the C-terminal amino acid from a peptide substrate (green). It does so by stabilizing the negative charge on the oxygen in the tetrahedral transition state. Enzyme active site residues are indicated by black coloring. The bond cleaved is indicated by the dashed red arrow.

New or radically modified enzymes can be created by “protein engineering,” which includes a number of techniques such as site-directed mutagenesis, protein domain fusion, selection from randomly generated libraries, and computational design.

TABLE 11.10 Examples of each of the major classes of enzymes

Class	Example (reaction type)	Reaction Catalyzed
1. Oxidoreductases	Alcohol dehydrogenase (EC 1.1.1.1) (oxidation with NAD^+)	$\text{CH}_3\text{CH}_2\text{OH} \xrightarrow{\text{NAD}^+} \text{CH}_3\text{C}(=\text{O})\text{H} + \text{NADH} + \text{H}^+$ <p style="text-align: center;">Ethanol Acetaldehyde</p>
2. Transferases	Hexokinase (EC 2.7.1.2) (phosphorylation)	 <p style="text-align: center;">D-Glucose D-Glucose-6-phosphate</p>
3. Hydrolases	Carboxypeptidase A (EC 3.4.17.1) (peptide bond cleavage)	 <p style="text-align: center;">C-terminus of polypeptide Shortened polypeptide C-terminal residue</p>
4. Lyases	Pyruvate decarboxylase (EC 4.1.1.1) (decarboxylation)	$\text{CH}_3\text{C}(=\text{O})\text{COO}^- + \text{H}^+ \longrightarrow \text{CH}_3\text{C}(=\text{O})\text{H} + \text{CO}_2$ <p style="text-align: center;">Pyruvate Acetaldehyde</p>
5. Isomerases	Maleate isomerase (EC 5.2.1.1) (<i>cis-trans</i> isomerization)	 <p style="text-align: center;">Maleate Fumarate</p>
6. Ligases	Pyruvate carboxylase (EC 6.4.1.1) (carboxylation)	$\text{CH}_3\text{C}(=\text{O})\text{COO}^- + \text{CO}_2 \xrightarrow{\text{ATP}} \text{CH}_3\text{C}(=\text{O})\text{CH}_2\text{COO}^- + \text{ADP} + \text{P}_i$ <p style="text-align: center;">Pyruvate Oxaloacetate</p>

Ribozymes, a class of ribonucleic acids, function as biological catalysts.

research performed in the 1980s revealed something wholly unexpected: Some RNA molecules, called **ribozymes**, can act as enzymes.

The first hint that RNA might have catalytic activity came from studies of **ribonuclease P**, an enzyme that cleaves the precursors of tRNAs to yield the functional tRNAs (Figure 11.40 and Chapter 27). It had been known for some time that active ribonuclease P contained both a protein portion and an RNA “cofactor,” but it was widely assumed that the active site resided on the protein portion. However, careful studies of the isolated components by Sidney Altman and coworkers in 1983 revealed an astonishing fact: Whereas the protein component alone was wholly inactive, the RNA by itself, if provided with either a sufficiently high concentration of magnesium ion or a small amount of magnesium ion plus the small basic molecule spermine, was capable of catalyzing the specific cleavage of pre-tRNAs. Furthermore, the RNA acted like a true enzyme, being unchanged in the process and obeying Michaelis–Menten kinetics. Addition of the protein portion of ribonuclease P does enhance the activity (k_{cat} is markedly increased) but is in no way essential for either substrate binding or cleavage. At high salt concentrations the RNA itself becomes a very efficient catalyst; K_M becomes very low, and k_{cat}/K_M approaches $10^7 \text{ (mol/L)}^{-1} \text{ s}^{-1}$.

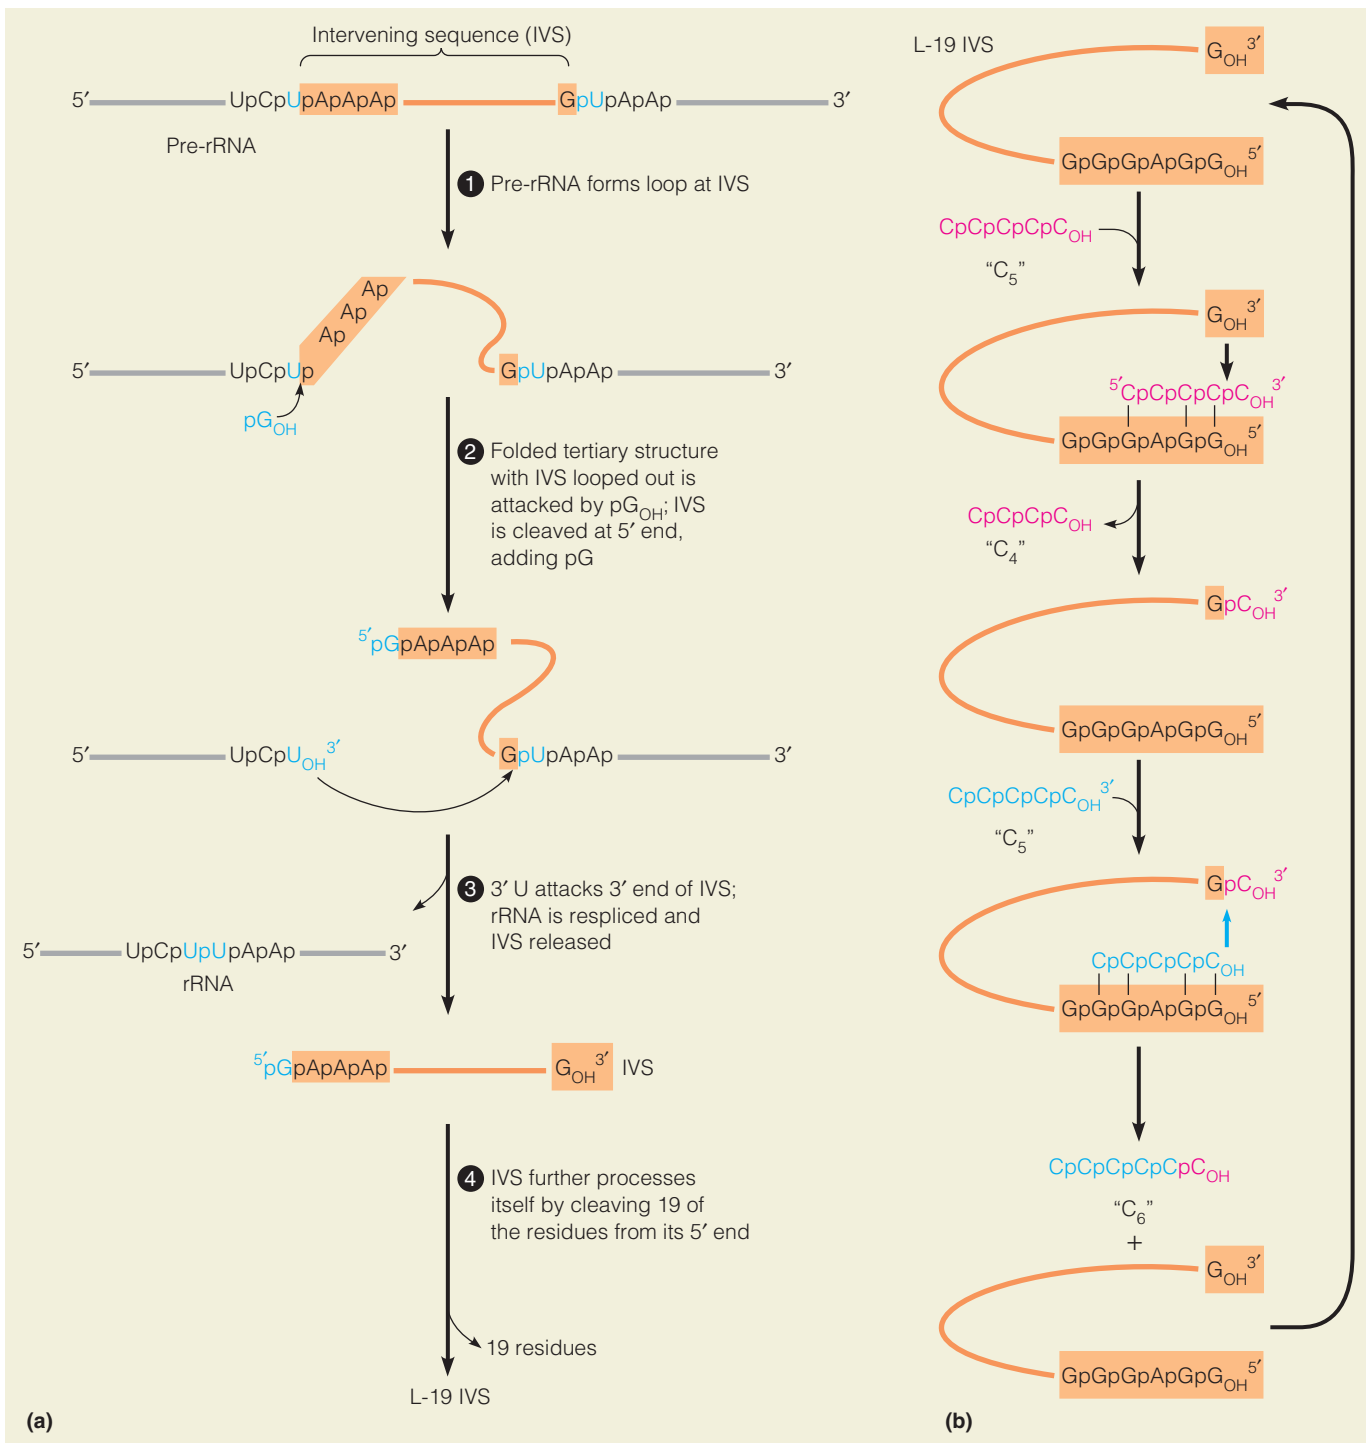

**FIGURE 11.40**

Cleavage of a typical pre-tRNA by ribonuclease P. The production of tRNA from pre-tRNA is catalyzed by an RNA–protein complex called ribonuclease P. The portion removed from tRNA is shown in black, and the resulting tRNA is in blue. The RNA portion of ribonuclease P can by itself catalyze the hydrolysis of the specific phosphodiester bond indicated by the magenta wedge. The 3' terminal —OH group is shown as a subscript to the 3'-terminal adenosine.

At about the same time, another remarkable class of RNA-catalyzed reactions was discovered by Thomas Cech and his colleagues. Examining the removal of an intron (intervening sequence, or IVS) from the preribosomal RNAs of the protist *Tetrahymena*, they found that the rRNA *itself* carried out the excision of its 413-nucleotide intron and the necessary resplicing as well (Figure 11.41a). In addition, the excised IVS went through a further series of site-specific reactions. The final product is a molecule called L-19 IVS—the intervening sequence with 19 more nucleotides removed. This activity is not regarded as true catalysis because the “catalyst” itself is modified in the reaction. However, L-19 IVS does have true catalytic abilities: It is capable of either lengthening or shortening small oligonucleotides, in the manner shown in Figure 11.41b. This example is by no means unique; we discuss other RNA-catalyzed reactions in Chapters 27 and 28.

At that time many biochemists were astounded by these discoveries, although in retrospect we can see that there is no reason why RNA molecules should not have catalytic functions. As discussed in Chapter 4, RNA molecules can adopt complex tertiary structures, just as proteins do, and such complex structure appears to be essential for enzymatic activity.

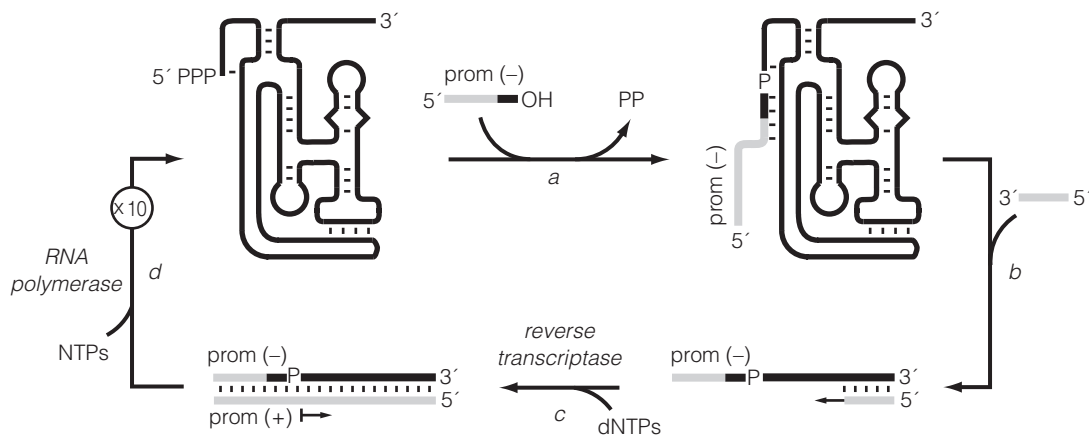

As mentioned in Chapter 4, the fact that RNA molecules possess the potential for both self-replication and catalysis has led some scientists to suggest that these molecules may well have been the primordial substances in the evolution of life. Such theorists envision an “RNA world” before proteins and DNA had evolved, where only self-replicating RNA molecules existed, capable of catalyzing a simple metabolism. Support for the idea that ribozymes could be self-replicating comes from remarkable experiments. Wright and Joyce (see References) have shown that the ribozyme depicted in Figure 11.42 is capable of self-catalyzed replication (with a little help from some protein enzymes). The RNA is capable of catalyzing the ligation of another RNA segment (in this case carrying a bacteriophage T7 promoter) to itself. In the presence of the enzymes reverse transcriptase and RNA polymerase (see, respectively, Chapters 25 and 27), a new copy of the RNA is generated. If this is supplied with an excess of the T7 promoter fragment, ligation occurs and a new copy of the ribozyme is formed. In one such experiment, the

**FIGURE 11.41**

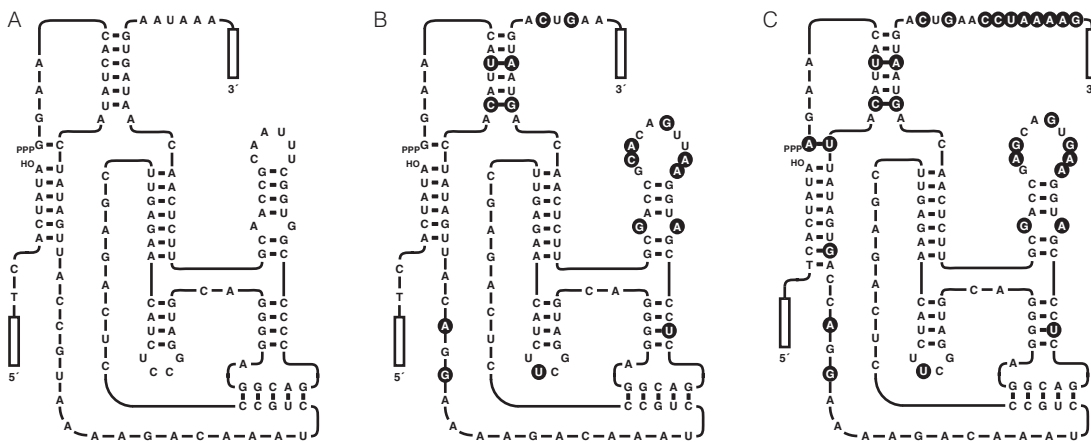

Catalysis by the intervening sequence in *Tetrahymena* preribosomal RNA. (a) Self-excision and splicing of the intervening sequence (IVS). Note that a pG_{OH} is added in the reaction. A series of further steps reduces the IVS to L-19 IVS. (b) Conversion of $2C_5$ to $C_4 + C_6$ by L-19 IVS. This oligonucleotide can itself either shorten or elongate small oligonucleotides, acting here as a true ribozyme catalyst.

system performed over 1000 doublings in a period of 2 days. During this time, the sequence evolved to a more efficient ribozyme. Such studies provide support for the “RNA-world” model for life’s origin.

Like RNA, single-stranded DNA can form complex tertiary structures, which are required for specific binding to a ligand/substrate and catalytic activity. Given the chemical similarities between DNA and RNA, it is reasonable to ask whether DNA can carry out meaningful biological catalysis. So far, no *naturally occurring* catalytic DNA, or **DNAzyme**, has been discovered in cells. However, many DNAzymes have been developed in the laboratory since the first catalytic DNA molecule was

(a)

(b)

described in 1994 by Ronald Breaker and Gerald Joyce. The DNazymes characterized to date have been obtained by selection of active sequences from large pools of randomized oligonucleotides and in vitro evolution (Figure 11.43).

Like ribozymes, DNazymes have been shown to catalyze a diverse set of reactions, with significant rate enhancements (Table 11.11). For example, the types of reactions catalyzed by DNazymes include hydrolysis (RNA and DNA cleavage), C—C bond cleavage, and photolytic repair of damaged DNA. Because DNA has greater chemical stability than do RNA and peptides, there is much current interest in developing DNazymes as therapeutics, diagnostics, and biosensors.

The Regulation of Enzyme Activity: Allosteric Enzymes

So far we have described the basic features of enzyme function. We now turn our attention to an equally important feature of enzymes: the regulation of their activity. In Chapter 1 we made an analogy between a living cell and a factory. That analogy is especially appropriate when we consider the roles that enzymes play in living cells. We note that a cell has certain raw materials available to it and must produce specific products from them. Enzymes make up the majority of the machines that facilitate these transformations in the cell. Often, as we shall see, enzymes are arranged in “assembly lines” to carry out the necessary sequential steps in a metabolic pathway.

FIGURE 11.42

Self-replication and mutation of a ribozyme.

(a) The ribozyme replication cycle, which involves repeated replication of the ribozyme, when supplied with excess T7 promoter sequence and ribonucleoside triphosphates. Reverse transcriptase and RNA polymerase are also needed. (b) Mutations that arose during ribozyme evolution. Open rectangles indicate the 5' portion of the substrate and the primer binding site at the 3' end of the ribozyme (5-CCAAUCGCAGGCUCAGC-3), both of which are immutable during evolution. Highlighted residues are those that were mutated relative to the starting ribozyme. A Prototype ribozyme used to construct the initial pool. B An individual ribozyme isolated before beginning continuous evolution. C An individual ribozyme isolated after 52 hours of continuous evolution.

Selection/*In vitro* evolution

FIGURE 11.43

Affinity selection from a random sequence library.

A large library of random sequences is applied to a chromatography matrix that displays the target ligand. Those nucleic acid sequences, or “aptamers,” that bind are selectively eluted from the column and amplified. The amplification may be performed in a manner that introduces greater variation in the selected sequences (i.e., *in vitro* evolution). The amplified sequences are re-applied to the column. This process is repeated until sequences with high affinity for the target are obtained. The clinical applications of the selected sequences include diagnostics and therapeutics.

Regulation of enzyme activity is essential for the efficient and ordered flow of metabolism.

TABLE 11.11 Examples of reaction types and rate enhancements for DNAzymes

Reaction Type	k_{cat} (min^{-1})	Rate Enhancement
Various RNA transesterifications	0.007–4.3	10^5 – 10^8
DNA cleavage	0.05–0.2	10^7 – 10^8
Porphyrin metallation	1.3	10^3
DNA ligation	0.0001–0.07	10^2 – 10^5
Adenylylation	0.005	10^{10}
N-Glycosyl cleavage	0.2	10^6
Phosphorylation	0.012	10^9

No factory operates efficiently if every machine is operating at its maximum rate. The capabilities of machines vary greatly, and if all of them were running at top speed, massive problems would soon arise. Intermediate products would pile up in some assembly lines, and certain parts of the finished product would be produced in vast excess. Different assembly lines might draw on the same raw material, and the faster ones could deplete the supplies so completely that other, equally important, lines would have to shut down. Obviously, *coordination* and *regulation* are required to run a large factory efficiently.

The same kinds of problems could occur if the enzymatic machinery of the cell were not regulated precisely. The efficiencies with which individual enzymes operate must be controlled in a manner that reflects the availability of substrates, the utilization of products, and the overall needs of the cell. In the following chapters we will see many examples of such regulation.

Substrate-Level Control

Some enzyme regulation occurs in a simple way, through direct interaction of the substrates and products of each enzyme-catalyzed reaction with the enzyme itself. This is referred to as **substrate-level control**. This is a consequence of the law of mass action (described in Chapters 2 and 3). As our analysis of kinetics has shown, the higher a substrate concentration is, the more rapidly a reaction occurs, at least until saturation of the enzyme is approached. Conversely, high levels of product, which can also bind to the enzyme, tend to inhibit the conversion of substrate to product. Insofar as the metabolically desired reaction is concerned, the product can act as an inhibitor. As an example, consider the first step in glycolysis (see Chapter 13)—the phosphorylation of glucose to yield glucose-6-phosphate (G6P):

The enzyme hexokinase, which catalyzes this reaction, is inhibited by its product, G6P. If subsequent steps in glycolysis are blocked for any reason, G6P will accumulate and bind to hexokinase. This results in inhibition of hexokinase and slows down further production of G6P from glucose. In many cases the reaction product binds the enzyme active site and therefore acts as a competitive inhibitor. Hexokinase is an interesting example because its product, G6P, can act both as a competitive inhibitor (by binding to the active site), as well as an uncompetitive inhibitor (by binding at another site).

Substrate-level control is not sufficient for the regulation of many metabolic pathways. In many instances, it is advantageous to have an enzyme regulated by some substance quite different from the substrate or immediate product. Such

regulation can be achieved with concentrations of the inhibitor that are significantly lower than those of the substrates.

Feedback Control

We have emphasized that most metabolic pathways resemble assembly lines. The simplest metabolic assembly line looks like this:

where A is the initial reactant or raw material; B, C, and D are intermediate products; and E is the final product.

The final product of this pathway, E, will probably be used in some other pathway. Similarly, the “raw material,” A, may also participate in some other set of processes. Suppose the utilization of E suddenly slows down. If everything kept going as before, E would accumulate, and consumption of A would continue. But this process is inefficient. A more efficient process would solve this problem by closely monitoring the concentration of E and, as E accumulated, sending a signal back to inhibit its production. The cell can control generation of the final product through activation (⬆️) or inhibition (⊘) of a key step in the pathway. It would be most efficient to slow the *first step*—the conversion of A to B. So the $A \rightarrow B$ “machine” should be regulated by the concentration of E.

This type of **feedback control** is called **feedback inhibition** because an *increase* in the concentration of E leads to a *decrease* in its rate of production. Note that by inhibiting the first step, we prevent both unwanted utilization of A and accumulation of E. Furthermore, because most biochemical processes are reversible to some extent, generation of a large quantity of E will tend to build up the concentration of intermediate products. The feedback control mechanism visualized above prevents accumulation of any intermediates, which might have undesired effects on metabolism.

Other metabolic situations require more complicated patterns, in which **activation** as well as inhibition may be useful. For example, consider a slightly more complex case, in which A is fed into two pathways, which lead to two products needed in roughly equivalent amounts. Then a scheme like the following emerges:

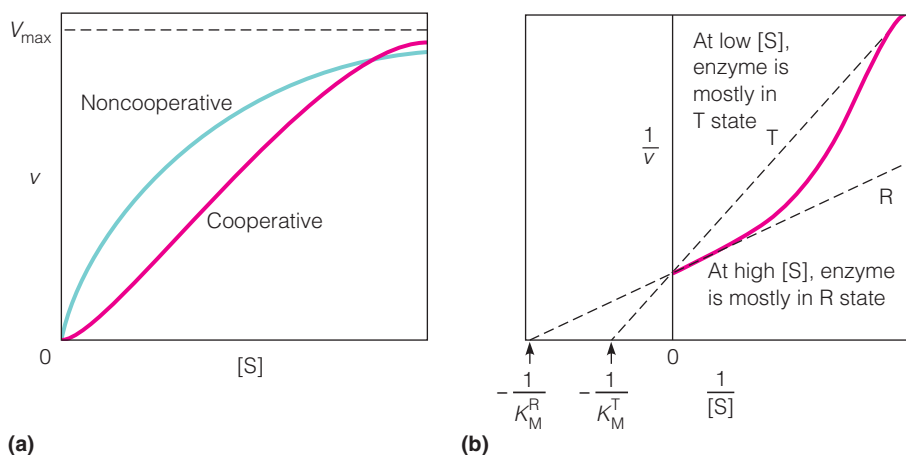

To control the pathways so that G and N keep in balance, high concentrations of G might *inhibit* the $C \rightarrow D$ enzyme and/or *activate* the $C \rightarrow K$ enzyme. Conversely, N might inhibit the $C \rightarrow K$ enzyme and/or activate the $C \rightarrow D$ enzyme. Finally, it might be useful to have G and N act *together* to inhibit the $A \rightarrow B$ enzyme, to provide overall regulation. An example of this kind of control is found in the synthesis of the purine and pyrimidine monomers that go into making DNA because approximately equal quantities of all four deoxyribonucleotides are required for DNA replication.

It is important to note that both inhibition and activation of enzymes are essential to regulate metabolism. Furthermore, control of pathways by their end products means that the necessary inhibitions and activations *must* be produced by molecules that come from far down the assembly line and therefore bear little or no resemblance to either the substrates or the direct products of the enzymes to

Feedback control is important in the efficient regulation of complex metabolic pathways.

FIGURE 11.44

Effect of cooperative substrate binding on enzyme kinetics. (a) Comparison of v vs. $[S]$ curves for a noncooperative enzyme and an allosteric enzyme with cooperative binding. The two enzymes are assumed to have the same V_{\max} . Compare this plot with the myoglobin and hemoglobin oxygen binding curves shown in Figure 7.10 (page 242). **(b)** Lineweaver–Burk Plot. Corresponding to the cooperative binding curve shown in (a). The T state has a high K_M (V_{\max} is achieved at higher $[S]$). As more S is bound, the T \rightarrow R equilibrium shifts toward the R state, which has a lower K_M .

be regulated. None of the kinds of regulation we have discussed up to this point will satisfy these needs. To attain this kind of control, organisms have evolved a special class of enzymes, capable of **allosteric regulation**. The term *allosteric* is derived from Greek words meaning “other structure,” emphasizing that structures of regulators need not resemble substrate or direct product.

Allosteric Enzymes

Allosteric enzymes are frequently multisubunit proteins, with multiple active sites. They exhibit cooperativity in substrate binding (**homoallostery**) and regulation of their activity by other, effector molecules (**heteroallostery**).

We have already studied an example of allosteric control of protein function. Hemoglobin (see Chapter 7) is a four-subunit protein that has four binding sites for its “substrate,” oxygen. The binding of oxygen is cooperative and is influenced by other molecules and ions. The basic ideas that were presented in Chapter 7 for the analysis of hemoglobin function apply equally well to allosteric enzymes.

Homoallostery

Let us first consider the homoallosteric effects (cooperative substrate binding). In Chapter 7 we contrasted O_2 binding by the single-subunit protein myoglobin with binding by the multisubunit hemoglobin. Myoglobin gives a hyperbolic binding curve (Figure 7.7); hemoglobin, with its cooperative binding, gives a sigmoidal curve (Figure 7.10d). We find *exactly the same contrast* when we compare the v vs. $[S]$ curve of a single-site enzyme obeying Michaelis–Menten kinetics with that of a multisite enzyme showing cooperative binding (Figure 11.44a). The same kind of reasoning applies: An enzyme that binds substrate cooperatively will behave, at low substrate concentration, as if it were poor at substrate binding (that is, as if it had a large K_M). But as the substrate levels are increased and more substrate is bound, the enzyme becomes more and more effective because it binds substrate more avidly in the last sites to be filled (see Figure 11.44b). We imagine this happening, as with hemoglobin, because as more substrate is bound, the enzyme undergoes a transition from a lower affinity state (T state) to a higher affinity state (R state). The kinds of models that have been used to describe O_2 binding by hemoglobin (see Figure 7.12, page 245) can account equally well for the kinetics exhibited by enzymes that show cooperative substrate binding.

What physiological function does sigmoidal kinetics fulfill? In extreme cases, enzymes obeying sigmoidal kinetics can regulate substrate levels to quite constant values. Consider a substrate that is being supplied constantly by other reactions and is acted on by an enzyme that exhibits the extreme cooperativity shown in Figure 11.45. Substrate can easily accumulate up to the critical level $[S]_c$; the enzyme is essentially inactive at lower $[S]$, allowing $[S]$ to increase up to $[S]_c$.

**FIGURE 11.45**

Effect of extreme homoallostery. The v vs. $[S]$ curve is shown for a hypothetical enzyme with extreme positive cooperativity in substrate binding. At concentrations below $[S]_c$, the enzyme is almost inactive; above this concentration, it is very active. Substrate can easily accumulate to the level $[S]_c$, but at higher concentrations it will be processed rapidly. The vertical blue line represents the homeostatic concentration range for S.

However, any further increase leads to a greatly increased enzyme activity so that the substrate will be more rapidly consumed and its concentration will be maintained near the value $[S]_c$. Although real allosteric enzymes rarely if ever exhibit curves as extremely sigmoidal as that in Figure 11.45, the principle remains: Multisubunit enzymes may help to maintain the homeostasis of a dynamic system. In other words, homoallostery enhances substrate-level control.

Heteroallostery

The major advantage of allosteric control is found in the role of **heteroallosteric effectors**, which may be either inhibitors or activators. These effectors are the analogs, in enzyme kinetics, of the CO_2 , BPG, and H^+ that so elegantly regulate O_2 binding by hemoglobin. The activation and inhibition of enzymes by allosteric effectors are the keys to the kind of complex feedback control described above. If an enzyme molecule can exist in two conformational states (T and R) that differ dramatically in the strength with which substrate is bound or in the catalytic rate, then its kinetics can be controlled by *any* other substance that, in binding to the protein, alters the $\text{T} \rightarrow \text{R}$ equilibrium. Allosteric *inhibitors* shift the equilibrium toward T, and *activators* shift it toward R (Figure 11.46). Some enzymes are regulated by multiple inhibitors and activators, allowing extremely subtle and complex patterns of metabolic control.

Aspartate Carbamoyltransferase: An Example of an Allosteric Enzyme

An excellent example of allosteric regulation is provided by the enzyme **aspartate carbamoyltransferase** (also known as aspartate transcarbamoylase, or ATCase), a key enzyme in pyrimidine synthesis (Chapter 22). As can be seen from Figure 11.47, ATCase stands at a crossroads in biosynthetic pathways. Glutamine, glutamate, and aspartate are also used in protein synthesis; but once aspartate has been carbamoylated to form ***N*-carbamoyl-L-aspartate** (CAA), the molecule is committed to pyrimidine synthesis. Thus, the enzyme that controls this step must be sensitive to pyrimidine need. In bacteria like *E. coli*, the activity of ATCase is regulated to respond to this need. This enzyme, as shown in Figure 11.48, is inhibited by cytidine triphosphate (CTP) and activated by ATP. Both responses make physiological sense; when CTP levels are already high, more pyrimidines are not needed. On the other hand, high ATP signals both a purine-rich state (signaling a need for increased pyrimidine synthesis) and an energy-rich cell condition under which DNA and RNA synthesis will be active.

Like most allosteric enzymes, ATCase is a multisubunit protein. Its quaternary structure has been examined in some detail and is depicted schematically in

FIGURE 11.46

Heteroallosteric control of an enzyme. In the absence of activation or inhibitors, the v vs. $[S]$ curve is sigmoidal. Activators shift the system toward the R state; inhibitors stabilize the T state. $[S]_c$ represents the homeostatic concentration range for S. Note that effectors significantly alter the activity of the enzyme over this range of $[S]$.

Allosteric enzymes show cooperative substrate binding and can respond to a variety of inhibitors and activators.

FIGURE 11.47

Control points in pyrimidine synthesis. This figure shows the formation of *N*-carbamoyl-L-aspartate from carbamoyl phosphate and aspartate. This reaction is the first committed step in a series of reactions that leads to synthesis of pyrimidine nucleotides, so control at or near this point is essential. In prokaryotes, the aspartate carbamoyltransferase is regulated; in most eukaryotes, regulation is on the preceding step, catalyzed by carbamoyl phosphate synthetase II.

FIGURE 11.48

Regulation of aspartate carbamoyltransferase by ATP and CTP. ATP is an activator of aspartate carbamoyltransferase, and CTP is an inhibitor. The curve marked as “control” shows the behavior of the enzyme in the absence of both regulators. *N*-Carbamoyl-L-aspartate (CAA) is the product of the reaction.

(a) ATCase: T state

(b) ATCase: R state

Figure 11.49a. There are six *catalytic* subunits, in two tiers of three, held together by six *regulatory* subunits. Pairs of regulatory subunits appear to connect catalytic subunits in the two tiers. The three-dimensional structure of ATCase has been solved to high resolution, and a detailed representation of one catalytic subunit and one regulatory subunit is shown in Figure 11.50. The catalytic subunit comprises two domains, one binding aspartate and the other carbamoyl phosphate, and the active site lies between them. The regulatory subunit is likewise of two parts; the so-called zinc domain and the allosteric domain. The former binds a structurally necessary zinc atom; the latter contains the ATP/CTP binding site. ATP and CTP thus compete for the same site so that the activity of ATCase is regulated by the *ratio* of ATP to CTP in the cell.

As in the case of hemoglobin, the allosteric regulation of ATCase involves changes in the quaternary structure of the molecule. Conformations of the R and T states have been determined by X-ray diffraction. As Figure 11.49b shows, a major rearrangement of subunit positions occurs in the T \rightarrow R transition.

Virtually every metabolic pathway we shall encounter in the following chapters is subject to complex feedback control, and in almost all cases multisubunit, allosteric enzymes are employed. The pattern of control, even in a given pathway, is not the same in every organism. To take a relevant example, whereas ATCase is the major control point in the pyrimidine pathway in bacteria, eukaryotes regulate at the preceding step—the synthesis of carbamoyl phosphate (see Figure 11.47). In mammals, the **carbamoyl phosphate synthetase II** is inhibited by UDP, UTP, CTP, dUDP, and UDP-glucose. These compounds all inhibit binding of the ATP substrate. In addition, glycine acts as a competitive inhibitor for glutamine.

Recently, examples of single subunit proteins under allosteric control have been described. Here, dynamics is thought to be of critical importance. In this model for allostery, the enzyme samples different conformational states, corresponding to higher (“R-like”) and lower (“T-like”) activities, and the effector binds to a particular conformation and stabilizes it. A positive effector binds the higher activity conformation, whereas a negative effector binds the lower activity conformation. This model suggests that any dynamic protein could, in principle, be subject to allosteric regulation.

It should be clear at this point that organisms can regulate metabolism in complex and subtle ways through allosteric enzymes; however, this kind of regulation is not sufficient for all needs. We turn now to covalent modification, an entirely different kind of regulatory mechanism.

Covalent Modifications Used to Regulate Enzyme Activity

In the factory analogy, allosteric regulation can be thought of as the feedback control of continuously running machines. But any large factory also has machinery that is used only from time to time and is left on standby until needed. The same is true for the cell. In this section, we discuss enzymes that are essentially inactive until they are changed by a **covalent modification** and then begin to function. In some cases such modification acts in the opposite direction, to inactivate otherwise active enzymes. Some such modifications can be reversed; others cannot.

FIGURE 11.49

Quaternary structure of aspartate carbamoyltransferase (ATCase). **(a)** Quaternary structure of ATCase in the T state. This schematic view of the enzyme shows the six catalytic subunits (C) and six regulatory subunits (R). Six catalytic sites (black triangles) lie in or near the grooves between the catalytic subunits. Regulatory sites (red ellipses) lie on the outer surfaces of the regulatory subunits. The molecule has 1 three-fold axis and 3 two-fold axes (D_3 symmetry). This is a side view of the molecule with the three-fold axis in the plane of the paper. **(b)** Transition of ATCase to the R state. The transition involves a rotation of the regulatory subunits, which pushes the two tiers of catalytic subunits apart and rotates them slightly about the three-fold axis.

**FIGURE 11.50**

The detailed structure of one catalytic subunit (green) and adjacent regulatory subunit (yellow) of ATCase. The view is down the three-fold axis, which is at the lower right (black triangle). The regulatory subunit lies mostly below the plane, the catalytic subunit mostly above. The location of the Zn²⁺ is shown by a red circle. PDB ID: 1ROC.

A number of kinds of covalent modification are commonly used to regulate enzyme activity (Figure 11.51). The most widespread is phosphorylation or dephosphorylation of various amino acid side chains (serine, threonine, tyrosine, and histidine, for example). Other covalent modifications include **adenylation**, the transfer of an adenylate moiety from ATP; **ADP-ribosylation**, the transfer of an ADP-ribosyl moiety from NAD⁺; and **acetylation**, the transfer of an acetyl group from acetyl-coenzyme A (see Table 11.5).

The majority of enzymes, and their associated metabolic and signaling pathways, are regulated by reversible phosphorylation. **Protein kinases** are ATP-dependent enzymes that add a phosphoryl group to the —OH group of a Tyr, Ser, or Thr on some target protein (Figure 11.52). This process is made reversible by a second class of enzymes, called **phosphatases**, which hydrolyze the resulting side chain phosphate esters, releasing P_i. In addition, several protein kinases have been found to be **oncogene** (cancer-causing gene) products. Aberrant activities of these kinases are involved in the transformation of a normal cell to a cancer cell. Much research activity has been devoted to understanding the roles of various kinases and phosphatases in cell signaling and regulation of metabolism.

Protein phosphorylation and acetylation are part of complex regulatory pathways, frequently under hormonal control. Several of these pathways are discussed in great detail in subsequent chapters, where their significance will be clearer. At this point, we shall concentrate instead on a third kind of covalent modification—the irreversible activation of certain enzymes by proteolytic cleavage of precursor forms.

Pancreatic Proteases: Activation by Cleavage

An important example of covalent enzyme activation, **proteolytic cleavage**, is found in the maturation of **pancreatic proteases**. These include a number of enzymes—for example, trypsin, chymotrypsin, elastase, and carboxypeptidase—some of which we have already discussed. All are synthesized in the pancreas. They are secreted through the pancreatic duct into the duodenum of the small intestine in response to a hormone signal generated when food passes from the stomach. They are not, however, synthesized in their final, active form because a battery of potent proteases free in the pancreas would digest the pancreatic tissue. Rather, they are made as slightly longer, catalytically inactive molecules, called **zymogens**. The names given to the zymogens of the enzymes mentioned above are *trypsinogen*,

FIGURE 11.51

Four types of covalent modifications that control the activities of enzymes. The target residue for phosphorylation or adenylation is usually serine, threonine, or tyrosine, whereas ADP-ribosylation can involve arginine, glutamate, aspartate, or a modified histidine residue. N-acetylation involves reaction between a lysine side chain and acetyl-coenzyme A.

chymotrypsinogen, *proelastase*, and *procarboxypeptidase*, respectively. The zymogens must be cleaved proteolytically in the intestine to yield the active enzymes. These enzymes are broken down after serving their purpose, so they do not endanger the intestinal tissue, which is also somewhat protected by its glycosylated surface. The cleavage of zymogens to active enzymes is diagrammed in Figure 11.53.

The first step is the activation of trypsin in the duodenum. A hexapeptide is removed from the N-terminal end of trypsinogen by *enteropeptidase*, a protease secreted by duodenal cells. This action yields the active trypsin, which then activates the other zymogens by specific proteolytic cleavages. In fact, once some active trypsin is present, it will activate other trypsinogen molecules to make more trypsin; thus its activation is *autocatalytic*. This is an example of the kind of **cascade** process frequently observed when enzymes are activated by covalent modification. The production of just a few trypsin molecules leads quickly to many more, as each enzyme molecule, when activated, can process many more every minute. These molecules can in turn activate the other zymogens. In effect, an enzyme cascade amplifies the original signal (e.g., hormone binding to the surface of a cell) and mounts a rapid, overwhelming response to that signal.

The activation of chymotrypsinogen to chymotrypsin is one of the most complex and best-studied examples of proteolytic activation of an enzyme; it is illustrated in Figure 11.54. In the first step, trypsin cleaves the bond between arginine 15 and isoleucine 16. The N-terminal peptide remains attached to the rest of the molecule because of the disulfide bond between residues 1 and 122. The product, called *π -chymotrypsin*, is an active enzyme.

Just how the cleavage of one peptide bond transforms an essentially inactive protein into an active one can now be understood as a result of detailed X-ray diffraction studies of the zymogen and the active enzyme. Cleavage of the peptide

FIGURE 11.52

Reversible covalent modification by kinases/phosphatases. The target residues for ATP-dependent phosphorylation by kinases are serine, threonine, or tyrosine. The phosphoprotein is dephosphorylated by a phosphatase-catalyzed hydrolysis reaction.

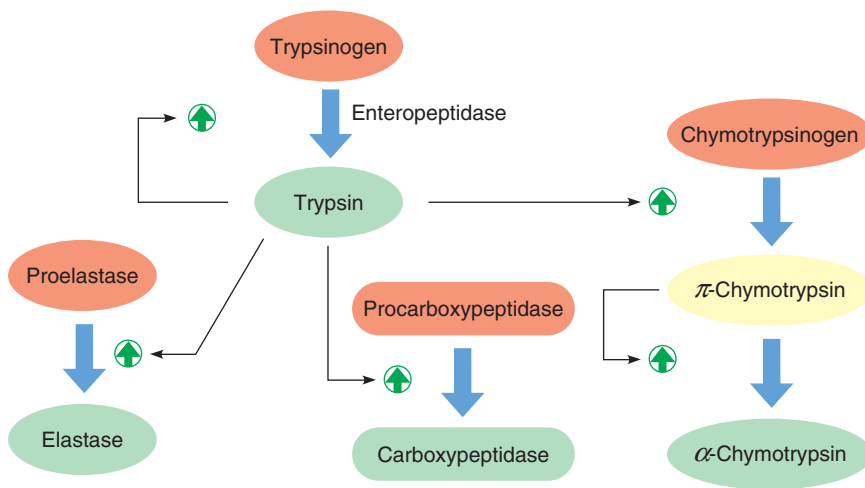

FIGURE 11.53

Zymogen activation by proteolytic cleavage. This schematic view shows the activation of pancreatic zymogens, molecules that become catalytically active when cleaved. Zymogens are shown in orange and active proteases in yellow or green. The difference between π -chymotrypsin and α -chymotrypsin is shown in Figure 11.54.

Some enzymes, such as pancreatic proteases, are irreversibly switched on by proteolytic cleavage.

bond between residues 15 and 16 creates a new, positively charged N-terminal residue at Ile 16. This residue shifts its position and forms a salt bridge with Asp 194, the neighbor of the active site Ser 195 (see Figure 11.18). This change in turn triggers further conformational rearrangements in the active site. These changes result in the formation of a catalytically competent active site pocket, including the movement of main chain amino groups of residues 193 and 195 to form the oxyanion hole. Thus, both the binding pocket and the catalytic site are formed correctly only after the peptide bond between Arg 15 and Ile 16 has been cleaved.

π -Chymotrypsin is not the most active form of chymotrypsin. More autocatalytic cleavages remove residues 14–15 and 147–148 from the molecule, to produce the final α -chymotrypsin, which is the principal and fully active form found in the digestive tract.

This battery of enzymes, trypsin, chymotrypsin, elastase, and carboxypeptidase, together with the *pepsin* of the stomach and other proteases secreted by the intestinal wall cells, is capable of ultimately digesting most ingested proteins into free amino acids, which can be absorbed by the intestinal epithelium. The enzymes themselves are continually subjected to mutual digestion and autodigestion so that high levels of these enzymes never accumulate in the intestine.

Even inactive zymogens are a potential source of danger to the pancreas. Because trypsin activation can be autocatalytic, the presence of even a single active trypsin molecule could set the activation cascade in motion prematurely. Therefore the pancreas protects itself further by synthesizing a protein called the *secretory pancreatic trypsin inhibitor* (to be distinguished from the pancreatic trypsin inhibitor shown in Figure 6.42, which is an intracellular protein found only in ruminants). This competitive inhibitor binds so tightly to the active site of trypsin that it effectively inactivates it even at very low concentration. The bonding between trypsin and its inhibitor is among the strongest noncovalent associations known in biochemistry. Only a tiny amount of trypsin inhibitor is present—far less than needed to inhibit all of the potential trypsin in the pancreas. Thus, only a fraction of the trypsin generated in the duodenum is inhibited, and the rest can be activated. Because protection is limited, zymogen activation can sometimes be triggered in the pancreas—for example, if the pancreatic duct is blocked. The active enzymes then begin to digest the pancreatic tissue itself. This condition, called *acute pancreatitis*, is extremely painful and sometimes fatal.

The first well-understood regulatory cascade was the one controlling glycogen breakdown in animal cells, a critical process that provides carbohydrate substrates for energy generation. This regulatory cascade, involving enzyme phosphorylation and dephosphorylation, is described in detail in Chapter 13. Another spectacular example of an enzyme cascade occurs in blood clotting, which we describe in the next section.

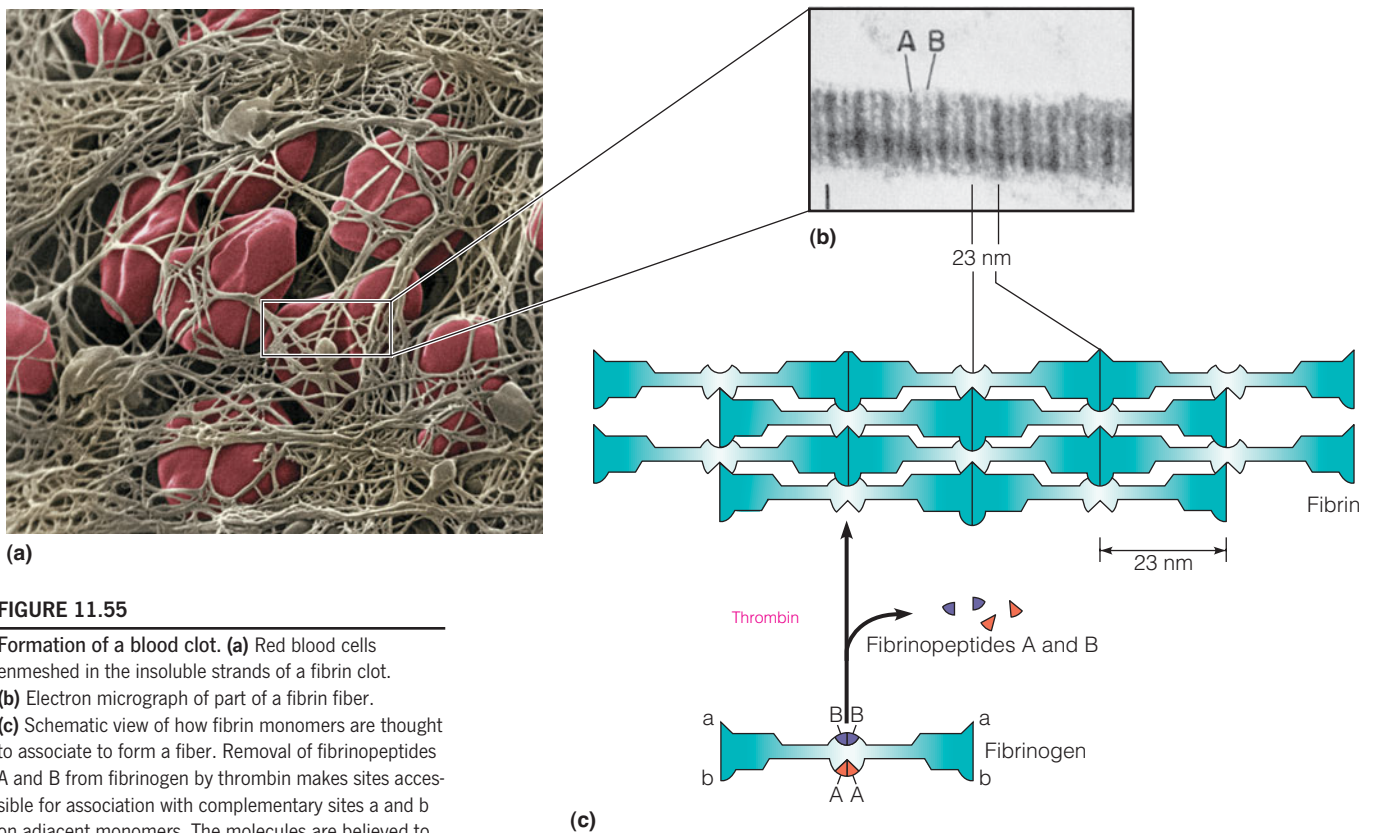

FIGURE 11.54

Activation of chymotrypsinogen. The figure is a schematic rendition of the chymotrypsinogen molecule. A series of cleavages produces the enzyme chymotrypsin, with the disulfide bonds continuing to hold the structure together. The initial cleavage between amino acids 15 and 16 (arrow) results in the formation of π -chymotrypsin. Subsequent removal of the segments shown in black yields α -chymotrypsin.

**FIGURE 11.55**

Formation of a blood clot. (a) Red blood cells enmeshed in the insoluble strands of a fibrin clot. (b) Electron micrograph of part of a fibrin fiber. (c) Schematic view of how fibrin monomers are thought to associate to form a fiber. Removal of fibrinopeptides A and B from fibrinogen by thrombin makes sites accessible for association with complementary sites a and b on adjacent monomers. The molecules are believed to overlap as shown because the striations seen in the fibers are 23 nm wide, exactly half the length of the fibrinogen molecule.

Blood clotting involves a cascade of proteolytic activation of specific proteases, culminating in the transition of fibrinogen to fibrin.

A Further Look at Activation by Cleavage: Blood Clotting

Activation of zymogens is the key to another biologically important process—the clotting of vertebrate blood. If a blood clot is examined in the electron microscope, it is found to be composed of striated fibers of a protein called **fibrin** (Figure 11.55a). The fibrin monomers are elongated molecules, about 46 nm long, that stick together in a staggered array as shown in Figure 11.55c. Fibrin monomers are derived from a precursor, **fibrinogen**, by proteolytic cleavages that release small *fibrinopeptides* (A and B in Figure 11.55c). Loss of these peptides uncovers positions at which the fibrin molecules can stick together. After the clot is formed, it is further stabilized by covalent cross-links between glutamine and lysine residues.

The proteolysis of fibrinogen to fibrin is catalyzed by the serine protease **thrombin**. Thrombin has sequence and structural similarities to trypsin, but as a protease with a very specific function it cleaves only a few types of bonds, mainly Arg–Gly. Thrombin itself is produced from **prothrombin** by another specific protease; in fact, as Figure 11.56 shows, a whole cascade of proteolytic activation reactions leads ultimately to the formation of a fibrin clot. Involved are a series of proteases referred to as *factors*. In damaged tissues, the proteins *kininogen* and *kallikrein* activate factor XII (also called *Hageman factor*), which in turn activates factor XI—and the cascade of reactions proceeds as shown. This set of initial reactions is called the **intrinsic pathway**. Alternatively, damage to blood vessels leads to the release of *tissue factor* and activation of factor VII, starting the **extrinsic pathway**. The two pathways merge in the activation of factor X, which will proteolyze and thereby activate prothrombin.

Some of the activation steps require auxiliary proteins. For example, activation of factor X in the intrinsic pathway by factor IX (*Christmas factor*) requires a 330-kilodalton protein called *antihemophilic factor* (factor VIII). The partial or complete absence of factor VIII activity is the cause of classic **hemophilia**. The gene for factor VIII is carried on the X chromosome, so women, who have two

FIGURE 11.56

The cascade process in blood clotting. Each factor (protease) in the pathway can exist in an inactive form (orange) or an active form (green). The cascade of proteolytic activations can start from exposure of blood at damaged tissue surfaces (intrinsic pathway) or from internal trauma to blood vessels (extrinsic pathway). The common result is activation of fibrinogen to clotting fibrin. Auxiliary factors that aid some steps are also shown. Asterisk (*) denotes serine proteases.

copies of this chromosome, can be heterozygous carriers of the trait but will exhibit the symptoms only if they are homozygous. However, a male descendent who receives on his single X chromosome the damaged copy of the factor VIII gene will experience more or less severe difficulty in blood clotting. The condition can now be treated by frequent transfusions of a blood serum fraction concentrated in factor VIII. The gene for this protein has recently been cloned and expressed in bacteria, and the availability of this synthetic factor VIII may allow such patients to avoid the need for frequent transfusions.

As wounds heal, or tissue damage is repaired, it is essential that blood clots be dissolved. The principal agent for clot dissolution is an enzyme called **plasmin**, which cleaves fibrin. Plasmin itself is derived by proteolytic cleavage of an inactive precursor, **plasminogen**. Activation of plasminogen is catalyzed by a number of proteases, the most important being tissue-type **plasminogen activator (t-PA)**. In addition to its normal function, t-PA can be extremely effective in initiating the cascade to dissolve the unwanted blood clot involved in stroke or heart attack.

The mechanisms of regulation we have mentioned here by no means describe the cell's whole repertoire. In addition to regulation of enzyme *performance*, cells and organisms can regulate both the synthesis and degradation of enzymes, as well as the compartmentalization of enzymes within specific organelles or multi-enzyme complexes. However, description of these processes is more appropriate in the broader framework of Chapter 12.

SUMMARY

The rate of a chemical reaction is determined by reactant concentrations and by the rate constant. The rate constant in turn depends upon the activation energy needed to reach the transition state. All catalysts function by lowering the activation energy for a reaction. In doing so, they do not affect chemical equilibrium but only increase rates.

Enzymes are biological catalysts that increase the rates of biochemical processes but are themselves unchanged. Most (but not all) enzymes are proteins. In enzyme catalysis, one or more substrates are bound at the active site of an enzyme, to form the enzyme–substrate complex; products are then released.

The induced fit hypothesis states that enzymes induce bound substrates to adopt conformations close to the transition state, though binding may also bring about conformational change in the enzyme. The role of dynamic motions in enzyme catalysis is not well understood, but may be critical for achieving high rate accelerations—particularly in reactions involving hydrogen transfer.

Most simple enzymatic reactions can be described by the Michaelis–Menten equation, with two parameters, the Michaelis constant, K_M , and the turnover number, k_{cat} . Enzymes can be inhibited reversibly or irreversibly. Reversible inhibition can be competitive, uncompetitive, or mixed. Competitive inhibition increases the apparent K_M , uncompetitive inhibition reduces the apparent V_{max} and apparent K_M , and mixed inhibition reduces the apparent V_{max} and increases the apparent K_M . Irreversible inhibition usually involves covalent binding to the active site.

Many enzymes utilize cofactors in their function; others require specific metal ions. A number of enzyme cofactors are closely related to vitamins required in the human diet.

It is possible to create new or modified enzymes by molecular engineering or in vitro evolution. A common method involves selection of active molecules from a large library of candidate clones, as in the case of the generation of catalytic antibodies. Computational approaches allow for the evaluation of candidate enzymes from even larger libraries of possible structures. In addition, it has been found that some nucleic acid molecules function as enzymes; they are called ribozymes or DNAzymes.

Regulation of enzymatic activity takes many forms. Substrate-level regulation simply depends on ambient concentrations of reactants and products. Allosteric regulation provides sensitive feedback control for complex metabolic pathways. For more drastic changes in activity, some enzymes are switched on or off (or both) by covalent modification.

PROBLEMS

1. Show that the half-life for a first-order reaction is inversely proportional to the rate constant, and determine the constant of proportionality.
2. A substance A is consumed by a reaction of unknown order. The initial concentration is 2 mM, and concentrations at later times are as shown:

Time (min)	[A] (mM)
1	1.66
2	1.44
4	1.12
8	0.76
16	0.48

Test whether or not a first-order reaction fits the data.

3. The enzyme urease catalyzes the hydrolysis of urea to ammonia plus carbon dioxide. At 21 °C the uncatalyzed reaction has an activation energy of about 125 kJ/mol, whereas in the presence of urease the activation energy is lowered to about 46 kJ/mol. By what factor does urease increase the velocity of the reaction?
4. An enzyme contains an active site aspartic acid with a $pK_a = 5.0$, which acts as a *general acid catalyst*. On the template below, draw the curve of enzyme activity (reaction rate) vs. pH for the enzyme (assume the protein is stably folded between pH 2–12 and that the active site Asp is the only ionizable residue involved in catalysis). Briefly explain the shape of your curve.

12. The catalytic efficiency of many enzymes depends on pH. Chymotrypsin shows a maximum value of k_{cat}/K_M at pH 8. Detailed analysis shows that k_{cat} increases rapidly between pH 6 and 7 and remains constant at higher pH. K_M increases rapidly between pH 8 and 10. Suggest explanations for these observations.
13. The following data describe the catalysis of cleavage of peptide bonds in small peptides by the enzyme elastase.

Substrate	K_M (mM)	k_{cat} (s^{-1})
P A P A ↓ G	4.0	26
P A P A ↓ A	1.5	37
P A P A ↓ F	0.64	18

The arrow indicates the peptide bond cleaved in each case.

- (a) If a mixture of these three substrates was presented to elastase with the concentration of each peptide equal to 0.5 mM, which would be digested most rapidly? Which most slowly? (Assume enzyme is present in excess.)
- (b) On the basis of these data, suggest what features of amino acid sequence dictate the specificity of proteolytic cleavage by elastase.
- (c) Elastase is closely related to chymotrypsin. Suggest two kinds of amino acid residues you might expect to find in or near the active site.
14. At 37 °C, the serine protease subtilisin has $k_{\text{cat}} = 50 \text{ s}^{-1}$ and $K_M = 1.4 \times 10^{-4} \text{ M}$. It is proposed that the N155 side chain contributes a hydrogen bond to the oxyanion hole of subtilisin. J. A. Wells and colleagues reported (1986, *Phil. Trans. R. Soc. Lond. A* 317:415–423) the following kinetic parameters for the N155T mutant of subtilisin: $k_{\text{cat}} = 0.02 \text{ s}^{-1}$ and $K_M = 2 \times 10^{-4} \text{ M}$.
- (a) Subtilisin is used in some laundry detergents to help remove protein-type stains. What unusual kind of stability does this suggest for subtilisin?
- (b) Subtilisin does have a problem, in that it becomes inactivated by oxidation of a methionine close to the active site. Suggest a way to make a better subtilisin.
- (c) Is the effect of the N155T mutation what you would expect for a residue that makes up part of the oxyanion hole? How do the reported values of k_{cat} and K_M support your answer?
- (d) Assuming that the T155 side chain cannot H-bond to the oxyanion intermediate, by how much (in kJ/mol) does N155 appear to stabilize the transition state at 37 °C?
- (e) The value you calculated in part (d) represents the strength of the H-bond between N155 and the oxyanion in the transition state. This value is higher than typical H-bonds in water. How might this observation be rationalized? Hint: consider Equation 2.2 (Coulomb's Law).
15. The steady-state kinetics of an enzyme are studied in the absence and presence of an inhibitor (inhibitor A). The initial rate is given as a function of substrate concentration in the following table:

[S] (mmol/L)	v [(mmol/L)min ⁻¹]	
	No inhibitor	Inhibitor A
1.25	1.72	0.98
1.67	2.04	1.17
2.50	2.63	1.47
5.00	3.33	1.96
10.00	4.17	2.38

- (a) What kind of inhibition (competitive, uncompetitive, or mixed) is involved?
- (b) Determine V_{max} and K_M in the absence and presence of inhibitor.

- *5. In some reactions, in which a protein molecule is binding to a specific site on DNA, a rate *greater* than that predicted by the diffusion limit is observed. Suggest an explanation. [Hint: The protein molecule can also bind weakly and nonspecifically to *any* DNA site.]
- *6. Derive an expression for the change of concentration of reactant with time for a reversible first-order reaction (Equation 11.5), assuming $[B] = 0$ at $t = 0$. [Warning: This is much more difficult than it looks.]
7. (a) Derive an expression for the concentration of reactant as a function of time for the second-order reaction $2A \rightarrow B$.
- (b) On the basis of your answer to (a), show how a linear graph could be obtained for a second-order reaction.
- (c) Test the data given in Problem 2 with your method.
8. The initial rate for an enzyme-catalyzed reaction has been determined at a number of substrate concentrations. Data are as follows:

[S] ($\mu\text{mol/L}$)	v ($\mu\text{mol/L min}^{-1}$)
5	22
10	39
20	65
50	102
100	120
200	135

- (a) Estimate V_{max} and K_M from a direct graph of v versus [S] (these data are plotted in Figure 11.24b). Do you find difficulties in getting clear answers?
- (b) Now use a Lineweaver–Burk plot to analyze the same data. Does this work better?
- (c) Finally, try an Eadie–Hofstee plot of the same data.
9. (a) If the total enzyme concentration in Problem 8 was 1 nmol/L, how many molecules of substrate can a molecule of enzyme process in each minute?
- (b) Calculate k_{cat}/K_M for the enzyme reaction in Problem 8. Is this a fairly efficient enzyme? (See Table 11.4.)
- *10. (a) If we write the Michaelis–Menten equation as

$$\frac{d[S]}{dt} = -\frac{d[P]}{dt} = -\frac{V_{\text{max}}[S]}{K_M + [S]}$$

it should be possible to integrate it and obtain an expression for substrate concentration as a function of time. Do so, calling $[S]_0$ the initial substrate concentration at $t = 0$.

- (b) Show from the result in (a) that under conditions where $[S]_0 \gg K_M$, the decrease in substrate concentration with time is approximately linear. Interpret this result.
11. Figure 11.39 shows a proposed mechanism for carboxypeptidase A.
- (a) What is the role of Glu 270 in catalysis?
- (b) What is the role of Arg 145 in catalysis?

16. The same enzyme as in Problem 15 is studied in the presence of a different inhibitor (inhibitor B). In this case, two different concentrations of inhibitor are used. Data are as follows:

[S] (mmol/L)	v [(mmol/L) min ⁻¹]		
	No inhibitor	3 mM inhibitor B	5 mM inhibitor B
1.25	1.72	1.25	1.01
1.67	2.04	1.54	1.26
2.50	2.63	2.00	1.72
5.00	3.33	2.86	2.56
10.00	4.17	3.70	3.49

- (a) What kind of inhibitor is inhibitor B?
 (b) Determine the apparent V_{\max} and K_M at each inhibitor concentration.
 (c) Estimate K_I from these data.
17. We have mentioned Eadie–Hofstee plots as an alternative to Lineweaver–Burk plots for expression of kinetic data. Sketch what Eadie–Hofstee plots would look like for a series of experiments at different concentrations of
 (a) a competitive inhibitor
 (b) a mixed inhibitor
18. We have discussed the role of TPCK as an irreversible inhibitor of chymotrypsin. Design a comparable inhibitor for trypsin.
19. The folding and unfolding rate constants for a myoglobin mutant have been determined. The unfolding rate constant $k_{F \rightarrow U} = 3.62 \times 10^{-5} \text{ s}^{-1}$ and the folding rate constant $k_{U \rightarrow F} = 255 \text{ s}^{-1}$, where F is the folded protein and U is the unfolded (denatured) protein. For wild-type myoglobin, $\Delta G_{F \rightarrow U}^\circ = +37.4 \text{ kJ/mol}$. Which myoglobin is more thermodynamically stable, the mutant or the wild-type?
20. The following data are found for the steady state kinetics of a multi-subunit enzyme:

[S] (mmol/L)	Initial Rate [(mmol/L)s ⁻¹]
0.25	0.26
0.33	0.45
0.50	0.92
0.75	1.80
1.00	2.50
2.00	4.10
4.00	4.80

- (a) Does this enzyme follow Michaelis–Menten kinetics?
 (b) Estimate V_{\max} .
- *21. Derive an equation expressing $\left(\frac{v/V_{\max}}{1-v/V_{\max}}\right)$ as a function of $\log[S]$ for an enzyme that obeys the Michaelis–Menten equation. For an *allosteric* enzyme, show how you could use this equation to obtain K_M^T and K_M^R (the K_M values for T and R states) from a Hill plot of kinetic data (see Figure 7.9).
- *22. In a few instances, multisubunit enzymes have been demonstrated to exhibit *negative cooperativity*; that is, the binding of the first substrate molecule markedly decreases the affinity for binding of subsequent molecules. Show what a Hill plot would look like for an enzyme exhibiting negative cooperativity. [Hint: Consult Problem 21a.]
23. The MWC theory (see pages 245–246 in Chapter 7) cannot account for negative cooperativity, but the KNF theory can. Explain.
- *24. Although the MWC theory describing binding to a multisite protein is quite complicated, we can easily derive equations for a simple case. Assume a dimeric enzyme, with two active sites and two conforma-

tional states: T and R. For simplicity, assume that the R state can bind one or two molecules of substrate, but the T state cannot bind. We then have the equations

The factor 2 appears because there are two equivalent sites on each R to bind S.

(a) From this information, show that the fraction of sites occupied at substrate concentration [S] is

$$Y = \frac{[S]}{K} \left(\frac{1 + \frac{[S]}{K}}{L + \left(1 + \frac{[S]}{K}\right)^2} \right) = \frac{v}{V_{\max}}$$

(b) Picking a large value of L (say 10^5), and with $K = 10^{-6} \text{ M}$, show that a sigmoidal curve is obtained for v/V_{\max} versus [S].

25. Suggest the effects of each of the following mutations on the physiological role of chymotrypsinogen:
 (a) R15S
 (b) C1S
 (c) T147S
26. Suppose you had available a sample of the ribozyme IVS-19 from *Tetrahymena*. Describe the protocol for a simple experiment that would demonstrate the reaction shown in Figure 11.41b.
27. Read Tools of Biochemistry 11B before answering this question. From the example shown Figure 11.B2, suggest the design of an antigen that might produce a catalytic antibody capable of amide bond hydrolysis.
28. (a) Derive the Michaelis–Menten expression for uncompetitive inhibition under steady-state conditions.
 (b) Derive the Michaelis–Menten expression for the simple case of mixed inhibition (described on pages 443–444) under steady-state conditions. [Hint: In each case, start with the appropriate expression for $[E]_T$, and recall that under steady-state conditions, $K_M = [E][S]/[ES]$.]
29. Enalapril is an anti-hypertension “prodrug” (i.e., a drug precursor) that is inactive until the ethyl ester (arrow in figure) is hydrolyzed by esterases present in blood plasma. The active drug is the dicarboxylic acid (“enalaprilat”) that results from this hydrolysis reaction.
 (a) Enalapril is administered in pill form, but enalaprilat must be administered intravenously. Why do you suppose enalapril works as a pill, but enalaprilat does not?

(b) Enalaprilat is a *competitive* inhibitor of the angiotensin-converting enzyme (ACE), which cleaves the blood-pressure regulating peptide angiotensin. ACE has a $K_M = 12 \mu\text{M}$ for angiotensin, which is present in plasma at a concentration of $75 \mu\text{M}$. When enalaprilat is present at 2.4 nM , the activity of ACE in plasma is 10% of its uninhibited activity. What is the value of K_I for enalaprilat?

TOOLS OF BIOCHEMISTRY 11A

HOW TO MEASURE THE RATES OF ENZYME-CATALYZED REACTIONS

There are essentially two approaches to enzyme kinetic analysis. The first and simplest is to make measurements of rates under conditions in which the steady-state approximation holds (see page 432). Under these conditions, the Michaelis–Menten equation is often applicable, and determination of the reaction velocity as a function of substrate and enzyme concentrations will yield K_M and k_{cat} . Almost all enzymatic studies at least start in this way. But if the experimenter wishes to learn more of the details of the mechanism, it is often important to carry out studies before the steady state has been attained. Such *pre-steady-state* experiments require the use of special fast techniques. On pages 437–438 we described how a combination of such approaches can be used to dissect a complex enzymatic process and to understand it in detail. Here we describe some of the experimental techniques that can be employed.

Analysis in the Steady State

The steady state in most enzymatic reactions is established within seconds or a few minutes and persists for many minutes or even hours thereafter. Therefore, extreme rapidity of measurement is not important, and many techniques are available to the experimenter wishing to follow the reaction. Descriptions of the most commonly used techniques follow.

Spectrophotometry

Spectrophotometric methods are simple and accurate (see Tools of Biochemistry 6A). However, an obvious requirement is that either a substrate or a product of the reaction must absorb light in a spectral region where other substrates or products do not. Classic examples are reactions that generate or consume NADH. NADH absorbs quite strongly at 340 nm, but NAD^+ does not absorb in this region. Thus we could, for example, follow the oxidation of ethanol to acetaldehyde, as catalyzed by alcohol dehydrogenase, by measuring the formation of NADH spectrophotometrically. Even if the reaction being studied does not involve a light-absorbing substance, it may be possible to couple this reaction to another, very rapid reaction that does.

Fluorescence

The applications of fluorescence are similar to those of spectrophotometry, and the problems are similar: A substrate or a product must have a distinctive fluorescence emission spectrum (see Tools of Biochemistry 6A). However, fluorescence often has the advantage of high sensitivity, so extremely dilute solutions may be employed, enabling an experimenter to greatly extend the concentration range (i.e., $[S]$) over which studies are practicable.

Automatic Titration

If the reaction produces or consumes acid or base, it can be followed by using a device called a *pH-stat*. A glass electrode senses

the pH of the solution, and its signal is used to actuate a motor-driven syringe that titrates acid or base into the reaction vessel to keep the pH constant. The time-based record of acid or base consumed is then a record of the progress of the enzymatically catalyzed reaction.

Radioactivity Assays

If a substrate is labeled with a radioactive isotope that will be lost or transferred during the reaction to be studied, measurement of changes in radioactivity can be an extremely sensitive kinetic method. This procedure requires that the labeled compound can be separated quickly at different, precisely defined times during the reaction. An example is a method often used with radioactive ATP. The ATP can be adsorbed on charcoal-impregnated filter disks by very fast filtration of aliquots from the reaction mixture. The radioactivity can then be measured in a scintillation counter (see Tools of Biochemistry 12A). Another example of the use of radioisotopes comes from measuring the rates of peptide-bond cleavage (by a protease), or protein biosynthesis (e.g., ribosomal protein synthesis). Peptides are most commonly labeled with radioactive amino acids that contain ^3H , ^{14}C , or ^{35}S . The rate of a peptide cleavage or synthesis reaction can be monitored by rapidly precipitating the peptide (or peptide fragments) from the reaction solution using cold trichloroacetic acid and collecting the precipitate on filter paper. As described above, the radioactivity present on the filter paper can be quantitated using a scintillation counter.

Analysis of Very Fast Reactions

Reactions that are extremely rapid require special techniques to investigate the pre-steady-state processes. Two major methods are currently employed to cover the rapid time scales shown in Figure 11A.1.

Stopped Flow

Figure 11A.2 shows a **stopped-flow apparatus**, first described by Quentin Gibson in the 1950s. Enzyme and substrate are initially in separate syringes. The syringes are driven, within a few milliseconds, to deliver their contents through a mixing chamber and into a third, “stopping” syringe. This step triggers a detector to begin observing (for example, by light absorption or fluorometry) the solution in the tube connecting the mixer to the stopping syringe. Flow rates can easily be made as high as 1000 cm/s. If the mixture was moving at this rate when the flow was stopped, and if the observation point is 1 cm from the mixer, the detection system first sees a mixture that is 1 ms “old.” The reaction can then be followed for as long as desired—often for a period of only a few seconds. The limitations of the method are imposed only by the initial “dead time” (i.e., the time it takes the mixed solutions

FIGURE 11A.1

Time scales for kinetic techniques described here.

FIGURE 11A.2

Typical stopped-flow apparatus.

to arrive at the detector—in the example above, 1 ms) and the rapidity of the detection system.

Stopped-flow is used to measure rates of rapid enzymatic reactions as well as ligand binding events, such as O_2 binding to, or release from, hemoglobin (see Chapter 7).

Temperature Jump

Some processes are so fast that they are essentially completed in the dead time of a stopped-flow apparatus. The experimenter may then turn to temperature jump (T-jump) methods. The basic apparatus and principle of the method are shown in Figure 11A.3a and b, respectively. A reaction mixture that is at equilibrium at a temperature T_1 is suddenly jumped to a temperature T_2 . Because chemical equilibria are typically temperature-dependent, the position of equilibrium will shift, and the system must now react to attain this new equilibrium. A rapid jump in temperature (5–10 °C in 1 μ s) can be obtained by passing a large burst of electrical current between electrodes immersed in the reaction mixture. Even more rapid jumps (10–100 ns) can be obtained if a pulsed infrared laser is used to heat the mixture. The relaxation (approach) to a

new equilibrium, monitored by absorption or fluorescence measurements, is an exponential process. For a simple reaction, the change in reactant concentration is given by

$$\Delta[A] = (\Delta[A]_{\text{total}}) e^{-t/\tau} \quad (11.A1)$$

where τ is called the *relaxation time* and can be related to the rate constants for the reaction. For example, for the simple reversible reaction

we have

$$\frac{1}{\tau} = k_1 + k_{-1} \quad (11.A2)$$

More complex reactions involve multiple relaxation times and more complex curves than expressed by equation (11A.1). T-jump experiments are appropriate for reactions with τ values as low as about 10^{-5} s.

Although a number of other techniques are employed for even faster reactions, including some newly developed NMR

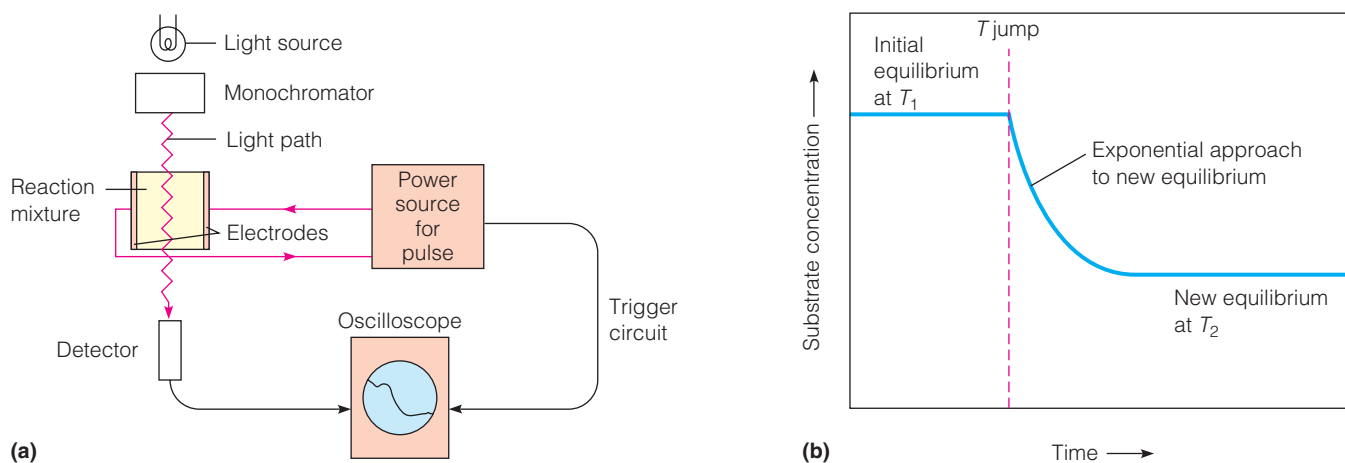

FIGURE 11A.3

The temperature jump method.

methods and pulsed laser techniques, the methods described here are widely used. If we consider the variety of techniques available to the experimenter, we can see that they cover a wide time range. Altogether, times from nanoseconds to hours can be studied.

Relating Kinetics to a Mechanism: Kinetic Isotope Effects

Kinetic data are the basis for proposing a detailed chemical mechanism such as those illustrated in Figures 11.14, 11.17, 11.38, and 11.39. The determinations of rates for the turnover of isotopically-labeled substrates are among the more useful data for distinguishing one possible mechanism from another (e.g., see the discussion of the lysozyme mechanism).

The rates of bond formation/cleavage depend on the masses of the atoms involved because the vibrational frequencies of bonds are sensitive to the masses of the bonded atoms. Bond

cleavage/formation reactions involving heavier isotopes proceed with slower rates, and this effect is known as a **kinetic isotope effect** (or KIE). Synthetic chemists have developed methods to synthesize substrates for enzyme-catalyzed reactions with atom-specific isotopic substitutions. In other words, at some specific location in the substrate molecule a deuterium (^2H or D) or a tritium (^3H or T) might be substituted for the common isotope of hydrogen, ^1H (sometimes referred to as “protium”). The KIE is largest for hydrogen isotopes because the change in mass is more significant for ^1H vs. ^2H (or ^3H), than it is for heavier elements (e.g., ^{12}C vs. ^{13}C , or ^{16}O vs. ^{18}O).

A so-called primary KIE is observed when the bond including the atom in question is broken/formed in the rate-determining step, whereas a secondary KIE is observed when the bond adjacent to the atom in question is broken/formed (Figure 11A.4). The KIE is recorded as the ratio of rates for the reactions of a substrate

FIGURE 11A.4

Examples of primary and secondary kinetic isotope effects.

labeled with two different isotopes, for example k_H/k_D . For primary KIE, the range of observed values for hydrogen transfer reactions is 2–15. For secondary KIE the range is closer to 1 (1.05–1.12). These differences in magnitude allow us to distinguish primary and secondary KIEs.

If a researcher suspects that a particular bond is broken during the slow step of a reaction she/he can synthesize a labeled substrate and compare the kinetics of the reaction with unlabeled and labeled substrates. If the expected KIE is observed, the proposed mechanism may be correct. If the expected KIE is not observed, the proposed mechanism is likely incorrect, or the bond cleavage/formation is more rapid than some other rate-determining step in the mechanism. In this way, KIEs are useful

tools for the elucidation of mechanistic detail in enzyme-catalyzed reactions.

TOOLS OF BIOCHEMISTRY 11B

INTRODUCTION TO PROTEIN ENGINEERING OF ENZYMES

The search for catalysts with “tailor-made” function has led to the development of many strategies to generate novel protein structures that possess the desired function. These fall broadly into two general categories: “rational design” methods, which are based on application of fundamental principles of protein folding, stability, and function as described in Chapters 5–7, and “directed evolution” methods, which are based on the generation of large pools of protein variants (“libraries”), followed by stringent selection for the desired function. Often, these methods are combined, such that a candidate catalyst with modest activity will be used as a starting template to generate a large library of variants, which is then screened to identify those variants with improved activity. Although we illustrate these principles with examples of protein catalysts, these same strategies are applied in the design/selection of nucleic acid catalysts (see Figure 11.43).

We begin this brief survey with a reminder that the manipulation of gene sequence allows for changes in amino acid sequence in both site-specific (“rational”) and random (“directed evolution”) strategies.

Site-Directed Mutagenesis

It is now routine to clone the genes for enzymes and to make specific mutations at particular sites in the sequence (as described in Tools of Biochemistry 5A and 25E). The method has proved extremely powerful in the elucidation of enzyme mechanisms, as described previously for lysozyme and the serine proteases (see pages 425–429); however, it can also be employed to change enzyme specificities. For example, a study of the protease *subtilisin* by James Wells and coworkers focused on mutations at a specific site (residue 166) in the specificity pocket. This site is normally occupied by Gly, and the enzyme preferentially

cleaves polypeptide chains next to a bulky hydrophobic residue. Activity toward polypeptides containing glutamic acid in the same position is very low. Replacing Gly 166 by Lys increases by 500-fold the frequency of cleavage next to glutamic acid.

Although some attempts at protein engineering for industrial purposes have aimed at tailoring enzymes for new reactions, more have focused on developing tolerance to extreme environmental conditions (heat, acidity, salinity) typical of industrial or specialized agricultural operations. However, to date, nature (evolution) appears to have been a better designer than humans; the most interesting enzymes capable of tolerating extreme environments have been found in bacteria that inhabit hot springs, deserts, and undersea thermal vents. It is now clear that there exist in nature enzymes capable of efficient function at temperatures as high as 100 °C.

Domain Fusion: Chimeric Enzymes

The rearrangement of genes that is possible with modern molecular biology techniques allows production of **fusion proteins**—proteins coded for by genes that have been spliced together in vitro from two or more sources. Such gene fusion makes it possible to join proteins, or specific protein domains, in novel ways. As a simple example of this approach, consider the problem of digesting cereal β -glucans, as found in barley. These polysaccharides involve both $\beta(1 \rightarrow 4)$ and $\beta(1 \rightarrow 3)$ linkages between glucose residues. In brewing practice, a glucanase and a microbial cellulase are used, but the latter is often ineffective in industrial conditions, leading to viscous products that interfere with beer manufacture. A hybrid enzyme has been constructed that possesses the capability of cleaving both kinds of bonds and thereby digesting the glucan to glucose in one step.

FIGURE 11B.1

Generating novel chemical structures by engineering of polyketide synthases. In this simplified example, a PKS containing 6 domains yields the erythromycin core structure (leftmost figure). Deletion of domain 4 or domain 5 (right side of figure) alters the structure of the final product (see areas highlighted in blue).

Transition state analog for carbonate hydrolysis

FIGURE 11B.2

Modeling the transition state for carbonate hydrolysis with a phosphonate ester. **Top:** The hydrolysis of a carbonate at alkaline pH involves the attack of a hydroxide ion on the carbonate carbon. **Middle:** A model of the transition state for this reaction. **Bottom:** A transition state analog for the alkaline hydrolysis reaction. This analog is relatively stable; thus, it can be used for affinity purification of candidate catalysts from a large pool of clones.

In addition to creating novel enzymes through domain fusion, it is also possible to modify the sequences of multidomain proteins to alter their function. For example, polyketide synthases (PKS) are very large multidomain enzymes that carry out the multistep synthesis of complex natural products, such as erythromycin. PKS are of great interest because the molecular engineering of these enzymes may lead to new antibiotics that could be effective in the treatment of patients infected with antibiotic-resistant strains of bacteria. Each domain in a PKS performs a specific chemical transformation on the substrate, and the *specific arrangement* of the domains within the primary sequence of the PKS dictates the chemical structure and stereochemistry of the final product (Figure 11B.1). Different products can be obtained by selectively rearranging, or deleting, gene sequences encoding PKS domains. The chemistry performed by PKS is described in greater detail in Chapter 17 (e.g., see Figure 17.37, page 747).

Selection from Random Libraries: Catalytic Antibodies

Recall from Chapter 7 that antibodies show remarkably high specificity in binding to their target antigens. Enzymes bind most strongly to the transition state in a reaction. What happens if we make antibodies against molecules that are transition-state analogs for a particular reaction? The answer is that these antibodies act like enzymes: They show specificity for a particular substrate and rate enhancement for the reaction of interest. One

of the first examples of antibody-mediated catalysis was for the carbonate ester hydrolysis shown in Figure 11B.2. Just as in the hydrolysis of amides, a tetrahedral transition state is generated in ester hydrolysis. A tetrahedral phosphonate ester was used to mimic the transition state for the carbonate hydrolysis reaction. Because the phosphonate is stable, it was also used to make an affinity column (Tools of Biochemistry 5A) that was, in turn, used to purify antibodies that bind tightly to the phosphonate. The antibodies purified in this fashion bound the analogous carbonate and catalyzed its hydrolysis with a rate enhancement of $\sim 10^3$.

Using various kinds of molecules as antigens, it has been possible to produce catalytic antibodies for a number of the classes of reactions shown in Table 11.10. In some cases, rate enhancements as much as 10^7 have been obtained; however, the majority of catalytic antibodies reported to date show rate enhancements in the range of 10^4 – 10^5 . Some researchers in this field have speculated that this value may represent the practical upper limit for rate enhancements achievable with catalytic antibodies.

For many years, the major difficulty in generating catalytic antibodies directed toward specific compounds or functional groups was the necessity of using the immune system of some animal to make the selection. Systems have been developed recently that circumvent this requirement. The basic idea is that libraries of F_{ab} or F_v fragments (see Chapter 7) with random complementarity determining regions are cloned and expressed on the surface of bacteriophage particles. The collection of phage particles is called a “library,” which typically contains 10^6 – 10^8 different clones. This library is then subjected to affinity chromatography to select for those clones that display an F_{ab} or F_v that can bind the desired molecule or structure. Such techniques have allowed the development of catalytic antibodies directed toward synthetic molecule substrates that would be very difficult to present as antigens to an *in vivo* system because of toxic effects or chemical instability of the antigen.

The generation of such random sequence libraries allows for so-called **directed evolution** of protein (or nucleic acid) function in the laboratory. A diverse set of protein sequences can be generated by subjecting multiple sites in a protein gene to simultaneous random mutagenesis. The identification of the few clones within a library that possess the desired novel function is carried out using the appropriate selection or screen for that function. As we shall see in the next section, one or two rounds of directed evolution are often required to fine-tune the function of a designed protein.

Mutagenesis *in silico*: Computational Design of Enzymes

Recall from Chapter 6 that we described some modern computational methods for protein-structure prediction from amino acid sequence (see Figures 6.35 and 6.36). The reverse problem, predicting what sequence of amino acids will yield a desired tertiary structure, has also been addressed using computation. We can now bring several topics together to ask a fascinating question: Is it possible to design a protein catalyst with an active site that is complementary to the transition state for a

reaction? Protein chemists have pursued an answer to this difficult question for many years, and recent results from David Baker and colleagues suggest that the answer is “yes”—albeit, a qualified yes.

In this approach, the transition state for a reaction is modeled—we present an example for which the desired activity is that of a retro-Aldolase, which results in C—C bond cleavage (Figure 11B.3a; the retroaldol reaction is discussed in greater detail in Chapter 13). A library of model active sites is then built around the transition state (Figure 11B.3b/c). This library may have 10^{18} different models. In the next step, these model active sites are matched to the structures of known protein scaffolds that can display the critical catalytic residues in the same orientation required by the various active site models (Figure 11B.3d). This matching step is computationally intensive; however, the computer is able to evaluate many more potential active sites than is practical to clone and test in the laboratory. In the final computational design step, the specific mutations in the candidate scaffold proteins are identified and the genes for the candidate enzymes are cloned and expressed. In this example, 72 candidate sequences were cloned and evaluated and roughly half showed some catalytic activity. The best clones exhibited a rate enhancement of $\sim 10^4$ —significant, but not as large as the values for naturally occurring enzymes (see Figure 11.4).

A similar approach produced a Kemp elimination catalyst with a 10^4 rate enhancement. This could be increased to 10^6 following directed evolution of the computationally designed sequence. Two important results emerged from these studies: (1) the computational approach produced catalysts with good specificity and modest rate accelerations and (2) the crystal structures of the resulting enzymes very closely matched the structures generated during the computational design. More recently, a Diels–Alder catalyst has been generated using this methodology (see citations in the References section).

An important question remains: Why do designed catalysts typically achieve rate accelerations far below those of naturally occurring enzymes? The answer may be revealed as we gain a greater quantitative understanding of the role of protein dynamics in the function of enzymes.

CHAPTER 12

Chemical Logic of Metabolism

A chemist carrying out an organic synthesis rarely runs more than one reaction in a single reaction vessel. This procedure is essential to prevent side reactions and to optimize the yield of the desired product. Yet a living cell carries out thousands of reactions simultaneously, with each reaction sequence controlled so that unwanted accumulations or deficiencies of intermediates and products do not occur. Reactions of great mechanistic complexity and stereochemical selectivity proceed smoothly under mild conditions—1 atm pressure, moderate temperature and osmotic pressure, and a pH near neutrality. How do cells avoid metabolic chaos? A goal of the next several chapters is to understand how cells carry out and regulate these complex reaction sequences.

A First Look at Metabolism

As noted above, a principal task of the biochemist is to understand how a cell regulates its myriad reaction sequences and, in so doing, controls its internal environment. In Chapter 11 we discussed the properties of individual enzymes and control mechanisms that affect their activity. Here we consider specific reaction sequences, or **pathways**; the relationship between each pathway and cellular architecture; the biological importance of each pathway; control mechanisms that regulate **flux**, or intracellular reaction rate; and experimental methods used to investigate metabolism. Figure 12.1, a simplified view of the processes we shall consider, illustrates two important principles. First, metabolism can be subdivided into two major categories—**catabolism**, those processes in which complex substances are degraded to simpler molecules, and **anabolism**, those processes concerned primarily with the synthesis of complex organic molecules (Figure 12.1a). Catabolism is generally accompanied by the net release of chemical energy, and anabolism requires a net input of chemical energy; we will see that these two sets of reactions are coupled together by ATP. Second, both catabolic and anabolic pathways occur in three stages of complexity—stage 1, the interconversion of

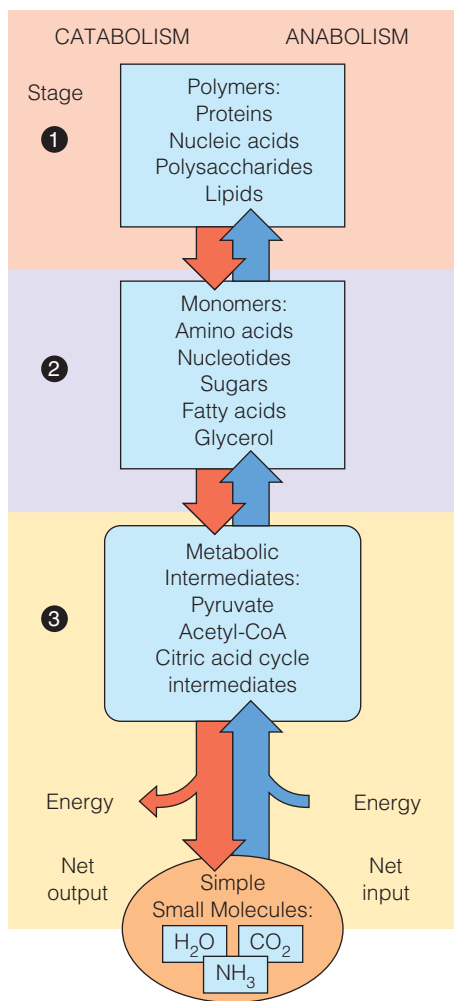

FIGURE 12.1

A brief overview of metabolism.

Intermediary metabolism refers primarily to the biosynthesis, utilization, and degradation of low-molecular-weight compounds (intermediates).

polymers and complex lipids with monomeric intermediates; stage 2, the interconversion of monomeric sugars, amino acids, and lipids with still simpler organic compounds; and stage 3, the ultimate degradation to, or synthesis from, inorganic compounds, including CO₂, H₂O, and NH₃ (Figure 12.1b). As we proceed through this chapter, we shall add detail to this figure, introducing you thereby to each major metabolic process and identifying the functions of each.

During our discussion we shall see that energy-yielding pathways also generate intermediates used in biosynthetic processes. Thus, although we will focus at first upon degradation of organic compounds to provide energy, you should be aware that metabolism is really a continuum, with many of the same reactions playing roles in both degradative and biosynthetic processes.

We shall also use the terms **intermediary metabolism**, **energy metabolism**, and **central pathways**. Intermediary metabolism comprises all reactions concerned with storing and generating metabolic energy and with using that energy in biosynthesis of low-molecular-weight compounds (intermediates) and energy-storage compounds. Not included are nucleic acid and protein biosynthesis from monomeric precursors. The reactions of intermediary metabolism can be thought of as those that do not involve a nucleic acid template because the information needed to specify each reaction is provided within the structure of the enzyme catalyzing that reaction. Energy metabolism is that part of intermediary metabolism consisting of pathways that store or generate metabolic energy. Chapters 13 through 22 present intermediary metabolism, and a major focus in Chapters 13 through 17 is on its energetic aspects. The central pathways of metabolism are substantially the same in many different organisms, and they account for relatively large amounts of mass transfer and energy generation within a cell; they are the quantitatively major pathways. Later we will identify and further discuss each central pathway, but for now let us focus on the overall process.

Most organisms derive both the raw materials and the energy for biosynthesis from organic fuel molecules such as glucose. The central pathways involve the oxidation of fuel molecules and the synthesis of small biomolecules from the resulting fragments; these pathways are found in all aerobic organisms. But a fundamental distinction among these organisms lies in the source of their fuel molecules.

Autotrophs (from Greek, “self-feeding”) synthesize glucose and all of their other organic compounds from inorganic carbon, supplied as CO₂. In contrast, **heterotrophs** (“feeding on others”) can synthesize their organic metabolites only from other organic compounds, which they must therefore consume. A primary difference between plants and animals is that plants are autotrophs and animals are heterotrophs. With the exception of rare insect-eating plants, such as the Venus flytrap, green plants obtain all of their organic carbon through photosynthetic fixation of carbon dioxide. Animals feed on plants or other animals and synthesize their metabolites by transforming the organic molecules they consume. Microorganisms exhibit a wide range of biosynthetic capabilities and sources of metabolic energy.

Microorganisms also show adaptability with respect to their ability to survive in the absence of oxygen. Virtually all multicellular organisms and many bacteria are strictly **aerobic** organisms; they depend absolutely upon **respiration**, the coupling of energy generation to the oxidation of nutrients by oxygen. By contrast, many microorganisms either can, or must, grow in **anaerobic** environments, deriving their metabolic energy from processes that do not involve molecular oxygen.

To the extent that biological molecules are synthesized ultimately from CO₂ that undergoes photosynthetic carbon fixation, the sun can be considered as the ultimate source of biological energy. However, this concept is not quite accurate because of the existence of a relatively large group of prokaryotic cells (both eubacteria and archaea) that derive their energy from other sources—for example, extremely **thermophilic** organisms, which live at temperatures as high as

100 °C or more, either in hydrothermal vents deep in the ocean or in geothermal vents in active volcanic regions. Although there is much to learn about metabolism in these organisms, it is clear that most of their metabolic energy does not come from sunlight.

Freeways on the Metabolic Road Map

Now let us return to the central pathways and their identification. Probably you have seen metabolic charts—those wall hangings like giant road maps that adorn biochemistry laboratories and offices. Figure 12.1 is a highly simplified metabolic chart. Figure 12.2 presents metabolism in more detail and is the basic road map for this section of the book. This figure will reappear in subsequent chapters, with the pathways presented in those chapters highlighted.

Faced with the thousands of individual reactions that constitute metabolism, how do we approach this vast topic? Our first concerns are with central pathways and with energy metabolism. Therefore, in the next several chapters we consider the degradative processes that are most important in energy generation—the catabolism of carbohydrates and lipids. We shall also consider how these substances are biosynthesized. These reactions are located in the middle of the metabolic charts and are illustrated with the biggest arrows—freeways, so to speak, on the metabolic road map.

The road map analogy is also useful when we consider directional flow in metabolism. Just as traffic flows from the suburbs to downtown in the morning and in the reverse direction in the evening, so also will we see that some conditions favor biosynthesis whereas others favor catabolism, and that parts of the same highways are used in both sets of processes.

Central Pathways of Energy Metabolism

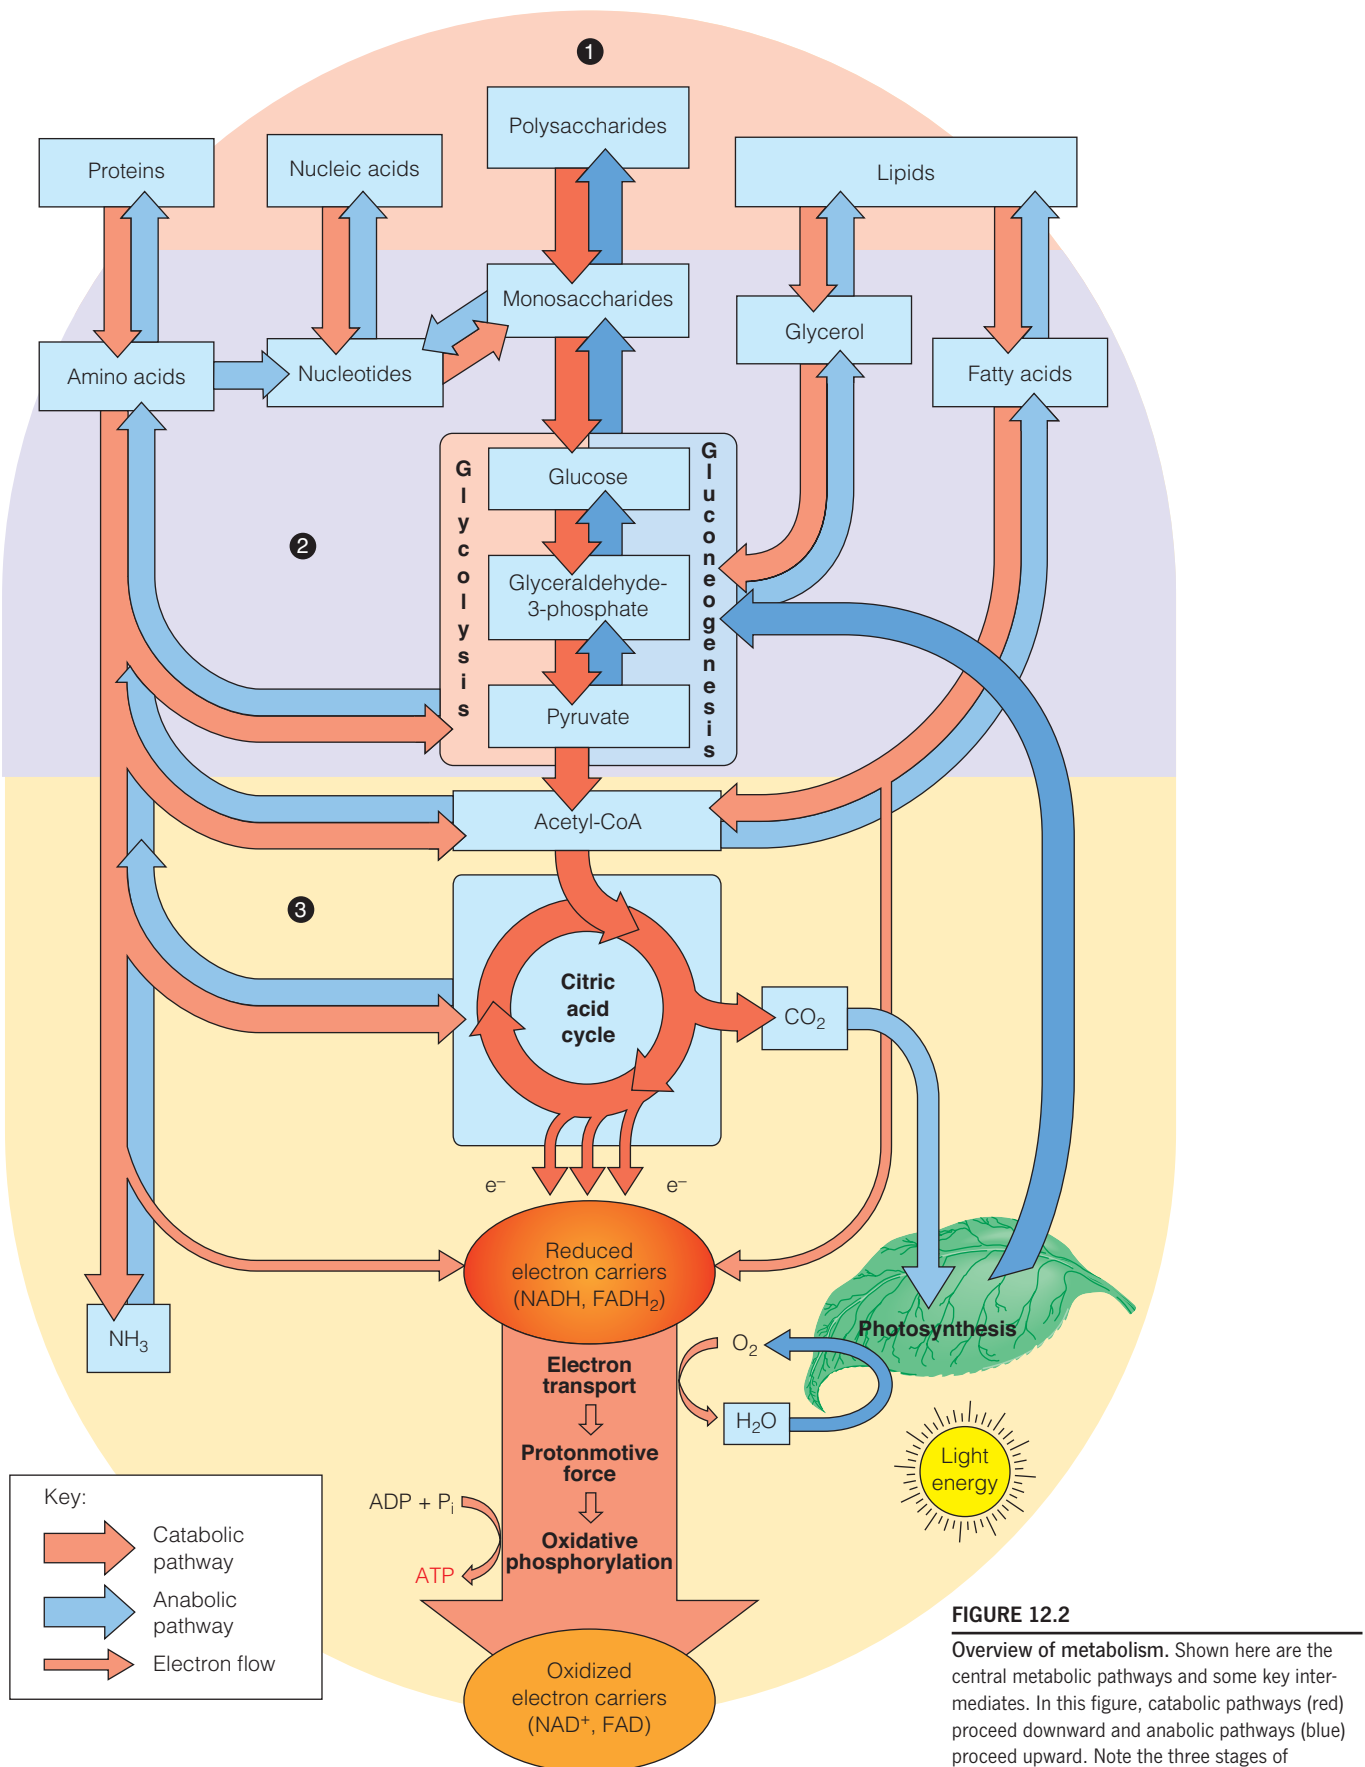

Recall from our discussion of Figure 12.1 that metabolism can be subdivided into three stages of complexity of the metabolites involved. The first pathway that we present in detail (in Chapter 13) is **glycolysis**, a stage 2 pathway for degradation of carbohydrates, in either aerobic or anaerobic cells. As schematized in Figure 12.3, the major input to glycolysis is glucose, usually derived from either energy-storage polysaccharides or dietary carbohydrates. This pathway leads to pyruvate, a three-carbon α -keto acid. Anaerobic organisms reduce pyruvate to a variety of products—for example lactate, or ethanol plus carbon dioxide. These processes are called *fermentations* (see page 487). In oxidative metabolism (respiration), the major fate of pyruvate is its oxidation to a metabolically activated two-carbon fragment, **acetyl-coenzyme A**, or acetyl-CoA (see page 601). The two carbons in the acetyl group then undergo oxidation in the **citric acid cycle** (Figure 12.4). In aerobic organisms the citric acid cycle, presented in Chapter 14, is the principal stage 3 pathway. This cyclic pathway accepts simple carbon compounds, derived not only from carbohydrate but also from lipid or protein, and oxidizes them to CO₂. Using the freeway analogy again, we will see that numerous on-ramps from the highways and byways of stage 1 and stage 2 metabolism lead to the citric acid cycle. In fact, all catabolic pathways converge at this point.

Oxidative reactions of the citric acid cycle generate reduced electron carriers whose reoxidation drives ATP biosynthesis, primarily through processes in the mitochondrial respiratory chain—**electron transport** and **oxidative phosphorylation**, shown also in Figure 12.4. As described in Chapter 15, the mitochondrial membrane uses oxidative energy to maintain a transmembrane gradient of hydrogen ion concentration (the **protonmotive force**), and discharge of this electrochemical potential energy powers the synthesis of ATP from ADP + P_i.

Stage 2 pathways other than glycolysis also deliver fuel to the citric acid cycle. Acetyl-CoA comes not only from pyruvate oxidation but also from the

The central pathways account for most of the mass transformations in metabolism.

In aerobic organisms all catabolic pathways converge at the citric acid cycle.

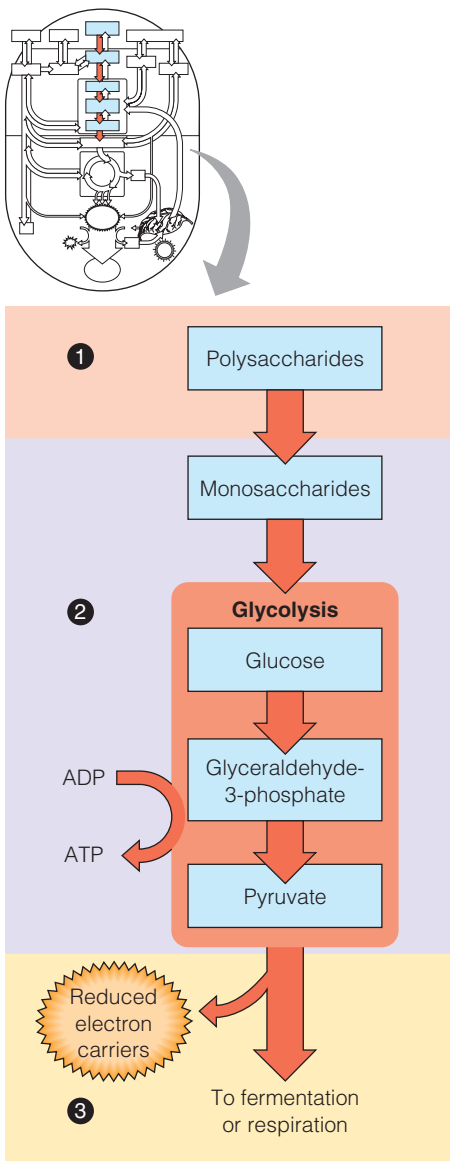

FIGURE 12.3

The initial phase of carbohydrate catabolism: glycolysis. Pyruvate either undergoes reduction in fermentation reactions or enters oxidative metabolism (respiration) via conversion to acetyl-CoA as shown in Figure 12.4.

FIGURE 12.4

breakdown of fatty acids by **β -oxidation** (presented in Chapter 17) and from some amino acid oxidation pathways (presented in Chapters 20 and 21). If the two carbons of acetyl-CoA are not oxidized in the citric acid cycle, they can go in the anabolic direction, providing substrates for synthesis of fatty acids and steroids (presented in Chapters 17 and 19). These and other biosynthetic processes use a reduced electron carrier, NADPH, which is structurally very similar to NADH (page 488).

Several important biosynthetic processes for carbohydrates will concern us in this book (Figure 12.5). Chapter 13 presents **gluconeogenesis**, the synthesis of glucose from noncarbohydrate precursors, and polysaccharide biosynthesis, particularly the biosynthesis of glycogen in animal cells. In Chapter 16 we

FIGURE 12.6

Photosynthesis.

present **photosynthesis** (Figure 12.6), the supremely important process by which green plants capture light energy to drive the generation of energy (ATP) and reducing power (NADPH), both of which are used for carbohydrate synthesis.

Distinct Pathways for Biosynthesis and Degradation

It may appear from Figure 12.2 that some pathways operate simply as the reversal of other pathways. For example, fatty acids are synthesized from acetyl-CoA, but they are also converted to acetyl-CoA by β -oxidation. Similarly, glucose-6-phosphate is synthesized from pyruvate in gluconeogenesis, which looks at first glance like a simple reversal of glycolysis. It is important to realize that in these cases the opposed pathways are quite distinct from one another. They may share some common intermediates or enzymatic reactions, but they are separate reaction sequences, regulated by distinct mechanisms and with different enzymes catalyzing their regulated reactions. They may even occur in separate cellular compartments. For example, fatty acid synthesis takes place in cytosol, whereas fatty acid oxidation takes place in mitochondria.

Biosynthetic and degradative pathways are never simple reversals of one another, even though they often begin and end with the same metabolites. The existence of separate unidirectional pathways is important for two reasons. First, to proceed in a particular direction, a pathway must be exergonic in that direction. If a pathway is strongly exergonic, then reversal of that pathway is just as strongly endergonic, and thus impossible, under the same conditions. Thus, opposed biosynthetic and degradative pathways must both be exergonic, and thus unidirectional, in their respective directions.

Second and equally important is the need to control the flow of metabolites in relation to the bioenergetic status of a cell. When ATP levels are high, there is less need for carbon to be oxidized in the citric acid cycle. At such times the cell can store carbon as fats and carbohydrates, so fatty acid synthesis, gluconeogenesis, and related pathways come into play. When ATP levels are low, the cell must mobilize stored carbon to generate substrates for the citric acid cycle, so carbohydrate and fat breakdown must occur. Using separate pathways for the biosynthetic and degradative processes is crucial for control, so conditions that activate one pathway tend to inhibit the opposed pathway and vice versa.

Consider what would happen, for example, if fatty acid synthesis and oxidation took place in the same cell compartment and in an uncontrolled fashion. Two-carbon fragments released by oxidation would be immediately used for resynthesis, a situation called a **futile cycle**. No useful work is done, and the net result is simply consumption of more ATP in the endergonic reactions of fatty acid synthesis than produced in the oxidation reactions. A similar futile cycle could result from the interconversion of fructose-6-phosphate with fructose-1,6-bisphosphate in carbohydrate metabolism.

The first reaction occurs in glycolysis, and the second participates in a biosynthetic pathway, gluconeogenesis. Both processes occur in the cytosol. The net effect of carrying out both reactions simultaneously would be the wasteful hydrolysis of ATP to ADP and P_i . However, enzymes catalyzing both of the above reactions respond to allosteric effectors, such that one enzyme is inhibited by conditions that activate the other. This reciprocal control prevents the futile cycle from occurring, even though the two enzymes occupy the same cell compartment. Therefore, it is more appropriate to call this situation—two seemingly opposed cellular reactions that are independently controlled—a **substrate cycle**.

Studies on metabolic control suggest that a substrate cycle represents an efficient regulatory mechanism because a small change in the activity of either or both enzymes can have a much larger effect on the flux of metabolites in one direction or the other. You can test this idea in Problem 6 at the end of this chapter.

Biochemical Reaction Types

There is no metaphysics in biochemistry—the chemistry of living systems follows the same chemical and physical laws as the rest of nature. The complexity of these biochemical pathways may at first glance seem overwhelming, but only five general types of chemical transformations are commonly found in cells. Although all of these transformations are catalyzed by enzymes in cells, the reactions proceed by straightforward organic chemistry mechanisms. We will discuss these reaction types only briefly here because you previously learned about them in organic chemistry. However, you should consult your organic chemistry textbook if you need a more detailed review.

Degradative and biosynthetic pathways are distinct for two reasons: A pathway can be exergonic in only one direction, and pathways must be separately regulated to avoid futile cycles.

Compartmentation and allosteric control of anabolic and catabolic processes prevent futile cycles, which simply waste energy.

**Electrophiles****Nucleophiles****Nucleophilic Substitutions**

Much of the chemistry of biological molecules is the chemistry of the carbonyl group (C=O) because the vast majority of biological molecules contain them. And most of the chemistry of carbonyl groups involves **nucleophiles** (abbreviated “Nu:”) and **electrophiles**. Recall that a nucleophile is a “nucleus-loving” substance with a negatively polarized, electron-rich atom that can form a bond by donating a pair of electrons to an electron-poor atom. An electrophile is an “electron-loving” substance with a positively polarized, electron-poor atom that can form a bond by accepting a pair of electrons from an electron-rich atom. Carbonyl groups are polar, with the electron-poor C atom bearing a partial positive charge and the electron-rich O atom bearing a partial negative charge.

Carbonyl carbons are thus very common electrophiles in biochemical reactions. Other common electrophiles are protonated imines, phosphate groups, and protons.

Oxyanions (e.g., hydroxide ion, alkoxides, or ionized carboxylates), thiolates (deprotonated sulfhydryls), carbanions, deprotonated amines, and the imidazole side chain of histidine are common nucleophiles in biochemical reactions.

In a nucleophilic substitution reaction, one nucleophile replaces a second nucleophile (the leaving group) on an sp^3 -hybridized carbon atom. The leaving group develops a partial negative charge in the transition state, and the best leaving groups are those that are stable as anions. Thus, halides and the conjugate bases of strong acids, such as the phosphate anion, are good leaving groups. Nucleophilic substitutions proceed by either S_N1 or S_N2 mechanisms. In the S_N1 (Substitution, Nucleophilic, Unimolecular) mechanism, the leaving group (Y^-) departs with the bonding electrons, generating a carbocation intermediate, *before* the attacking nucleophile (X^-) arrives. S_N1 reactions result in either retention of configuration or racemization at the reacting center.

In the S_N2 (Substitution, Nucleophilic, Bimolecular) mechanism, the attacking nucleophile approaches one side of the electrophilic center while the leaving group remains partially bonded to other side, resulting in a transient pentavalent intermediate.

In the S_N2 mechanism, departure of the leaving group from the opposite side results in a substituted product with inverted configuration.

A very important class of substitution reaction in biochemistry is the **nucleophilic acyl substitution** of carboxylic acid derivatives. Acyl substitutions occur most readily when the carbonyl carbon is bonded to an electronegative atom (such as O or N) or a highly polarizable atom (such as S) that can stabilize a negative charge and thereby act as a good leaving group. Thus, carboxylic acids and their derivatives (esters, amides, thioesters, acyl phosphates) are common substrates in acyl substitution reactions. In contrast to the S_N1 and S_N2 mechanisms of *alkyl* substitutions, *acyl* substitutions involve a tetrahedral oxyanion reaction intermediate.

The planar carbonyl group is converted to a tetrahedral geometry as the carbonyl carbon rehybridizes from sp^2 to sp^3 . As the electron pair moves from the oxyanion back toward the central carbon, the leaving group is expelled and the $C=O$ bond is regenerated. Many enzymes catalyze nucleophilic acyl substitutions, such as carboxypeptidase A, in which an activated water molecule serves as the attacking nucleophile (see Figure 11.39, page 449). This mechanism is also the basis of a variety of **group transfer reactions**, in which an acyl, glycosyl, or phosphoryl group is transferred from one nucleophile to another.

Nucleophilic Additions

Unlike carboxylic acids and their derivatives, the carbonyl carbon in aldehydes and ketones is bonded to atoms (C and H) that cannot stabilize a negative charge, and thus are not good leaving groups. These carbonyl groups typically undergo **nucleophilic addition reactions**, instead of substitution reactions. Like the nucleophilic acyl substitution mechanism, addition of a nucleophile leads to a tetrahedral oxyanion intermediate, as the electron pair from the $C=O$ bond moves onto the oxygen. Recall from Chapter 11 that an oxyanion intermediate is formed in the initial steps of peptide bond hydrolysis by the serine proteases. The oxyanion intermediate then has several fates, depending on the nucleophile (Figure 12.7). When the attacking nucleophile is a hydride ion (H^-), the oxyanion intermediate undergoes protonation to form an alcohol. Alcohols also result when the attacking nucleophile is a carbanion (R_3C^-), and this is one of the mechanisms that yield new $C-C$ bonds. When an oxygen nucleophile adds, such as an alcohol (ROH), the oxyanion intermediate undergoes proton transfer to yield a hemiacetal. This reaction is the basis of ring formation in monosaccharides (Chapter 9). Reaction with a second equivalent of alcohol gives an acetal. When the attacking nucleophile is a primary amine ($R'NH_2$), the oxyanion intermediate picks up a proton from the amino group, giving a carbinolamine, which loses water to form an **imine** ($R_2C=NR'$). Imines (called **Schiff bases**) are common reaction intermediates in many biochemical reactions due to their ability to delocalize electrons.

Carbonyl Condensations

Formation of new $C-C$ bonds is a critical element of metabolism, and the condensation of two carbonyl compounds is a common strategy used in many biosynthetic pathways. A carbonyl condensation reaction relies on the weak acidity of the carbonyl α hydrogen, producing a carbanion, which is in resonance with a nucleophilic enolate ion.

The enolate ion, stabilized by resonance, nucleophilically adds to the electrophilic carbon of a second carbonyl, forming a new C—C bond (Figure 12.8). If the second carbonyl is an aldehyde or ketone (an **aldol condensation**), this nucleophilic addition produces an oxyanion intermediate, which is protonated to give a β -hydroxy carbonyl product. If the second carbonyl is an ester (a **Claisen condensation**), the intermediate oxyanion expels the ester alkoxide (RO—) as the leaving group, giving a β -keto product. Carbonyl condensations thus result in a new bond formed between the carbonyl carbon of one reactant with the α carbon of the other. Aldol and Claisen condensations are both reversible, and such “retro-aldol” and “retro-Claisen” reactions are frequently used to cleave C—C bonds. Indeed, β -keto compounds readily undergo cleavage or decarboxylation by a retro-aldol mechanism, in which the electron-accepting carbonyl group two carbons away from the carboxylate stabilizes the formal negative charge of the carbanionic transition state.

**FIGURE 12.8**

Carbonyl condensation reactions. These reactions are initiated by deprotonation of the weakly acidic α hydrogen to give a resonance-stabilized enolate ion (top). In an aldol condensation (left side), the enolate adds to an aldehyde or ketone, yielding a β -hydroxy carbonyl product. In a Claisen condensation (right side), the enolate adds to an ester, yielding a β -keto product.

Eliminations

Eliminations of the type

are also quite common in biochemical pathways. Elimination reactions can occur by several different mechanisms, but the most common one involves a carbanion intermediate. The reactant is often a β -hydroxy carbonyl (where $\text{X}=\text{OH}$) in which the H atom to be removed is made more acidic by being adjacent to a carbonyl group. A base abstracts the proton to give a carbanion intermediate (resonance-stabilized with the enolate) that loses OH^- to form the $\text{C}=\text{C}$ double bond. β -hydroxy carbonyl compounds are readily dehydrated via these α,β -elimination reactions.

Oxidations and Reductions

Energy production in most cells involves the oxidation of fuel molecules such as glucose. Oxidation-reduction, or **redox**, chemistry thus lies at the core of metabolism. Redox reactions involve reversible electron transfer from a donor (the **reductant**) to an acceptor (the **oxidant**). Cells have evolved a number of electron carriers, such as the NAD^+ (nicotinamide adenine dinucleotide) coenzyme introduced in Chapter 11. Oxidations involving coenzymes such as NAD^+ occur by a reversible hydride (H^-) transfer mechanism, illustrated by the oxidation of an alcohol to a carbonyl compound.

A base abstracts the weakly acidic O—H proton, the electrons from that bond move to form a C=O bond, and the C—H bond is cleaved. The hydrogen *and the electron pair* (i.e., hydride, H^-) add to NAD^+ in a nucleophilic addition reaction, reducing it to NADH. The plus sign in NAD^+ reflects the charge on the pyridine ring nitrogen in the oxidized form; this charge is lost as the electron pair moves through the ring onto this nitrogen. Because the alcohol has lost a pair of electrons and two hydrogen atoms, this type of oxidation is called a **dehydrogenation**, and enzymes that catalyze this reaction are called **dehydrogenases**. Remember, however, that redox reactions are reversible, and dehydrogenases can catalyze the reductive direction as well. While two-electron oxidations exemplified by the NAD^+ -dependent dehydrogenases are the most common redox reactions in metabolism, they are certainly not the only ones. A number of redox processes involve one-electron transfers, and various electron carriers exist to handle single electrons—you'll learn more about these in Chapter 15.

There are other, less common types of reactions in biochemical pathways, such as free radical reactions, but these five represent the basic toolkit that cells use to carry out the vast majority of their chemical transformations.

Some Bioenergetic Considerations

Oxidation as a Metabolic Energy Source

Because the primary focus of the next few chapters will be on energy metabolism, we will now consider briefly how metabolic energy is generated. As we saw in Chapter 3, a thermodynamically unfavorable, or endergonic, reaction will proceed readily in the unfavored direction if it can be coupled to a thermodynamically favorable, or exergonic, reaction. In principle, any exergonic reaction can serve this purpose, provided that it releases sufficient free energy. In living systems, most of the energy needed to drive biosynthetic reactions is derived from the *oxidation* of organic substrates. Oxygen, the ultimate electron acceptor for aerobic organisms, is a strong oxidant; it has a marked tendency to attract electrons, becoming reduced in the process. Given this tendency and the abundance of oxygen in our atmosphere, it is not surprising that living systems have gained the ability to derive energy from the oxidation of organic substrates.

Biological Oxidations: Energy Release in Small Increments

In a thermodynamic sense, the biological oxidation of organic substrates is comparable to nonbiological oxidations such as the burning of wood. The free energy release is the same whether we are talking about oxidation of the glucose polymer cellulose in a wood fire, combustion of glucose in a calorimeter, or the metabolic oxidation of glucose:

This equation reveals the conservation stoichiometry, or simple **reaction stoichiometry**, of glucose combustion. Biological oxidations, however, are far more complex processes than combustion. When wood is burned, all of the energy is released as heat; useful work cannot be performed, except through the

Most biological energy derives from oxidation of reduced metabolites in a series of reactions, with oxygen as the final electron acceptor.

action of a device such as a steam engine. In biological oxidations, by contrast, oxidation reactions occur without a large increase in temperature and with capture of some of the free energy as chemical energy. This energy capture occurs largely through the synthesis of ATP, and, as discussed in Chapter 3, the hydrolysis of ATP can be coupled to many processes to provide energy for biological work. In catabolism of glucose, about 40% of the released energy is used to drive the synthesis of ATP from ADP and P_i .

Unlike the oxidation of glucose by oxygen shown in the previous equation, most biological oxidations do not involve direct transfer of electrons from a reduced substrate to oxygen (Figure 12.4). Rather, a series of coupled oxidation–reduction reactions occurs, with the electrons passed to intermediate electron carriers such as NAD^+ and FAD, and finally transferred to oxygen. We have already briefly mentioned the role of NAD^+ as an electron carrier; FAD (flavin adenine dinucleotide) will be described in detail in Chapter 14. Thus, the biological oxidation of glucose might be more accurately represented by the following coupled reactions:

The net reaction of the biological oxidation process (reaction 12.4) is identical to that of direct combustion (reaction 12.1). Reactions 12.2 and 12.3 are examples of **obligate-coupling stoichiometry**. These are stoichiometric relationships fixed by the chemical nature of the process. Thus, the complete oxidation of glucose requires the transfer of 12 pairs of electrons from glucose to molecular oxygen, whether as a direct process, as in combustion, or via intermediate electron carriers, as in the biological process. In the biological process, 12 moles of electron carriers (NAD^+ and FAD) are obligately coupled to the oxidation of 1 mole of glucose to 6 moles of CO_2 .

The transfer of electrons from these intermediate electron carriers to oxygen is catalyzed by the **electron transport chain**, or **respiratory chain**, and oxygen is called the **terminal electron acceptor**. Because the potential energy stored in the organic substrate is released in small increments, it is easier to control oxidation and capture some of the energy as it is released—small energy transfers waste less energy than a single large transfer does.

Not all metabolic energy comes from oxidation by oxygen. Substances other than oxygen can serve as terminal electron acceptors. Many microorganisms either can or must live **anaerobically** (in the absence of oxygen). For example, *Desulfovibrio* carry out anaerobic respiration using sulfate as the terminal electron acceptor:

Most anaerobic organisms, however, derive their energy from **fermentations**, which are energy-yielding catabolic pathways that proceed with no net change in the oxidation state of the products as compared with that of the substrates. A good example is the production of ethanol and CO_2 from glucose, presented in Chapter 13. Other anaerobic energy-yielding pathways are seen in some deep-sea hydrothermal vent bacteria, which reduce sulfur to sulfide as the terminal electron transfer reaction, and in other bacteria that reduce nitrite to ammonia. These organisms oxidize the substrates that sustain them, but they use terminal electron acceptors other than oxygen.

Energy Yields, Respiratory Quotients, and Reducing Equivalents

If metabolic energy comes primarily from oxidative reactions, it follows that the more highly reduced a substrate, the higher its potential for generating biological energy. We can use a calorimeter to measure the heat output (enthalpy) from oxidation of fat, carbohydrate, or protein. The combustion of fat provides more heat

energy than the combustion of an equivalent mass of carbohydrate. In other words, fat has a higher **caloric content** than carbohydrate. For illustration, compare the oxidation of glucose with the oxidation of a typical saturated fatty acid, palmitic acid:

Converting calories (the units of nutrition) to joules (the modern units of thermodynamics), we see that the oxidation of glucose yields 15.64 kJ/g, and the oxidation of palmitic acid yields 38.90 kJ/g. The carbons in fat are in general more highly reduced than those in carbohydrate; thus, they contain more protons and electrons to combine with oxygen on the path to CO_2 than do the carbons in sugar. We can see this by counting oxygen atoms. Glucose has more oxygens per carbon than does palmitic acid; each carbon in glucose is linked to at least one oxygen atom.

We can also tell that glucose is the more highly oxidized substance because its oxidation produces more moles of CO_2 per mole of O_2 consumed during oxidation, a ratio called the **respiratory quotient**, or **RQ**. The above reaction stoichiometries reveal RQ for glucose to be 1.0 ($6\text{CO}_2/6\text{O}_2$), whereas that for palmitic acid is 0.70 ($16\text{CO}_2/23\text{O}_2$). In general, the lower the RQ for a substrate, the more oxygen consumed per carbon oxidized and the greater the potential per mole of substrate for generating ATP.

Another way to express the degree of substrate oxidation is to say that more **reducing equivalents** are derived from oxidation of fat than from oxidation of carbohydrate. A reducing equivalent can be defined as 1 mole of hydrogen atoms (one proton and one electron per H atom). For example, two moles of reducing equivalents are used in the reduction of one-half mole of oxygen to water:

Whereas the breakdown of complex organic compounds yields both energy and reducing equivalents, the biosynthesis of such compounds utilizes both. For example, we know that both carbons of acetate are used for fatty acid biosynthesis:

Fifteen of the 16 carbon atoms of palmitate are highly reduced—14 at the methylene level and 1 at the methyl level. Therefore, many reducing equivalents are required to complete this biosynthesis.

The major source of electrons for reductive biosynthesis is **NADPH**, **nicotinamide adenine dinucleotide phosphate (reduced)**. NADP^+ and NADPH are identical to NAD^+ and NADH , respectively, except that the former have an additional phosphate esterified at C-2 on the adenylate moiety. NAD^+ and NADP^+ are equivalent in their thermodynamic tendency to accept electrons; they have equal standard reduction potentials (Chapter 3). However, nicotinamide nucleotide-linked enzymes that act primarily in a catabolic direction usually use the NAD^+ – NADH pair, whereas those acting primarily in anabolic pathways use NADP^+ and NADPH . In other words, as shown in Figure 12.9, nicotinamide nucleotide-linked enzymes that oxidize substrates (dehydrogenases) usually use NAD^+ , and those enzymes that reduce substrates (reductases) usually use NADPH . Of course, both dehydrogenases and reductases catalyze reversible reactions—the directions are determined by the **redox state**, or ratio of the oxidized and reduced forms of each pair that prevail in the cell. Thus, the NAD^+/NADH pair is maintained at a more oxidized level than the $\text{NADP}^+/\text{NADPH}$ pair in a healthy cell. These ratios generally drive NAD^+ -linked

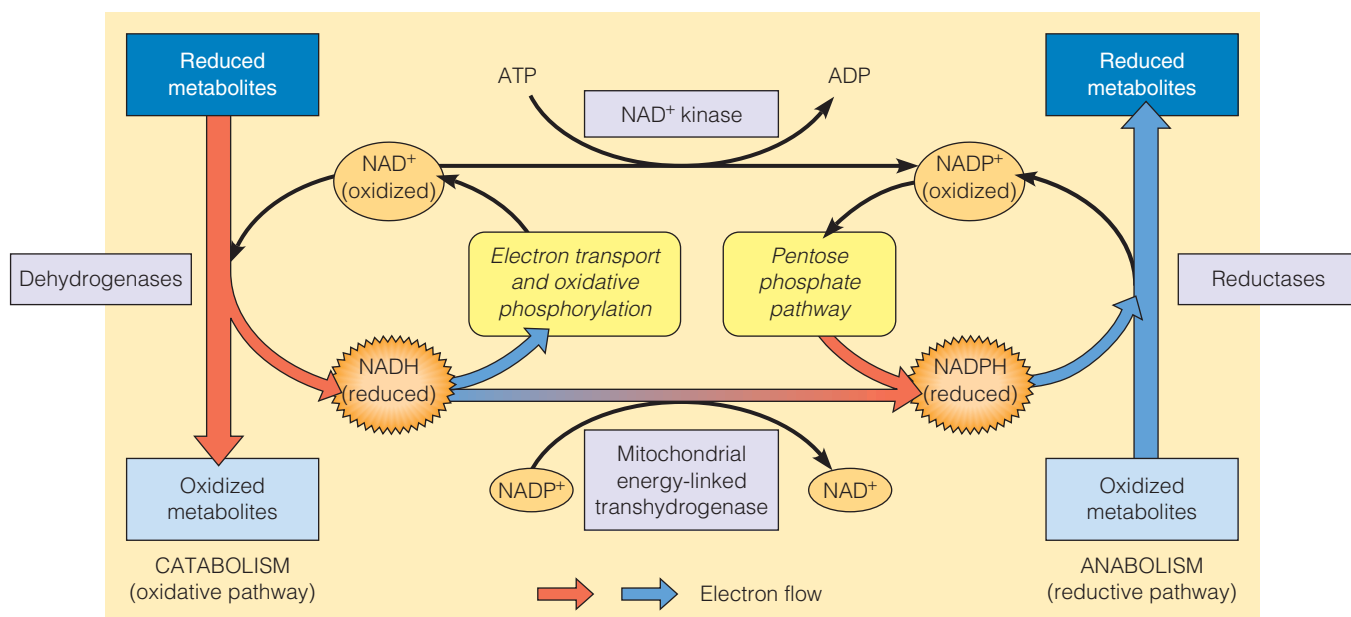

FIGURE 12.9

Nicotinamide nucleotides in catabolism and biosynthesis. NAD^+ is the cofactor for most enzymes that act in the direction of substrate oxidation (dehydrogenases), whereas NADPH usually functions as a cofactor for reductases, enzymes that catalyze substrate reduction. NADPH is regenerated either from NADP^+ in the pentose phosphate pathway (see Chapter 13) or from NADH through the action of mitochondrial energy-linked transhydrogenase (see Chapter 15). NADP^+ is synthesized from NAD^+ by an ATP-dependent kinase reaction.

NAD^+ is the cofactor for most dehydrogenases that oxidize metabolites. NADPH is the cofactor for most reductases.

reactions in the oxidative direction and NADP^+ -linked reactions in the reductive direction. An exception is two NADP^+ -linked dehydrogenases in the **pentose phosphate pathway** (see Chapter 13), which convert NADP^+ to NADPH and represent a major route for regeneration of the reduced nucleotide.

ATP as a Free Energy Currency

ATP is commonly referred to as a “free energy currency.” What does this mean? Currency is a medium of exchange. A \$20 bill has a generally recognized value that can be readily exchanged for various goods or services—for example, dinner at a moderately priced restaurant, or about a quarter-hour’s labor by a skilled auto mechanic. In the same sense, cells exchange the energy released from the breakdown of ATP to carry out essential functions, often converting the chemical energy released in ATP hydrolysis to other forms of energy—mechanical energy, for example, in muscle contraction, or electrical energy in conducting nerve impulses, or osmotic energy in transporting substances across membranes against a concentration gradient. Thus ATP serves as an immediate donor of free energy—it is continuously formed and consumed. It is estimated that a resting human turns over as much as 65 kg ATP every 24 hours, about equal to the entire body weight! (The Na^+/K^+ -ATPase you learned about in Chapter 10 accounts for approximately 25% of this resting ATP consumption.) During strenuous exercise, ATP turnover can be as high as 0.5 kg/min.

As summarized in Figures 12.3 and 12.4, regeneration of all this ATP is coupled to fermentative or oxidative processes. Thus, as we will see in Chapter 15, the oxidation of 1 mole of glucose during respiration is coupled to the phosphorylation of ~32 moles of ADP:

The stoichiometries for ADP, P_i , and ATP in this equation are fundamentally different from the simple reaction and obligate-coupling stoichiometries we have encountered thus far. There is no chemical necessity for the production of 32 moles of ATP (in fact, there is not even a direct chemical connection between glucose oxidation and ATP synthesis). We could not predict a stoichiometry of 32 ATP from chemical considerations. This is instead an **evolved-coupling**

stoichiometry. Evolved-coupling stoichiometries are biological adaptations, phenotypic traits acquired during evolution—they are the result of compromise. So why did evolution settle on a stoichiometry of ~32 ATP? Recall from Chapter 3 that the free energy changes of coupled reactions are additive. Thus equation 12.5 can be broken into its free energy yielding and free energy requiring processes:

Using estimates of the Gibbs free energy changes under physiological conditions (ΔG) of -2900 kJ/mol for glucose oxidation and -50 kJ/mol for the hydrolysis of ATP, we can see that the coupled process occurs with a net ΔG of -1300 kJ/mol glucose based on an evolved-coupling stoichiometry of 32 ATP. A ΔG of this magnitude represents such an immense driving force that respiration is emphatically favorable under virtually any physiological condition, and thus goes to completion. Because the ATP-coupling stoichiometry is an evolved trait, perhaps a different stoichiometry evolved in some ancient organism. Imagine a cell that mutated such that it ended up with an ATP-coupling stoichiometry for respiration of 58 instead of 32. Repeating the calculations above, the energy requiring process would have a ΔG of $+2900 \text{ kJ/mol}$ glucose ($58 \text{ ATP} \times +50 \text{ kJ/mol}$), giving an overall ΔG of 0 for respiration. Thus, there would be no net driving force for the reaction. Although this hypothetical cell might have a higher yield of ATP per glucose oxidized, it would come to equilibrium before very much glucose was metabolized. This cell would probably be a very poor competitor, especially if glucose concentrations were limiting, and the mutation(s) that led to this stoichiometry would likely be selected against. The ATP-coupling stoichiometry that we actually find (~32) is thus an evolved compromise between maximizing ATP yield and ensuring that the overall process is unidirectional under any conceivable conditions the cell might encounter.

The fundamental biological role of ATP as an energy-coupling compound is to convert thermodynamically unfavorable processes into favorable processes.

Of course, as emphasized in Figure 12.1, there are many biochemical pathways that consume ATP. The role of ATP in these anabolic processes is to convert a thermodynamically unfavorable process into a favorable process. Remember that biosynthetic and degradative pathways are never simple reversals of one another. In particular, opposed pathways will always have different ATP stoichiometries. That is, the number of ATP (or ATP equivalents) produced in the catabolic direction will always be different from the number of ATP (or ATP equivalents) required in the anabolic direction. We refer to these numbers as the **ATP-coupling coefficient** of the reaction or pathway. For example, in the fructose-6-phosphate/fructose-1,6-bisphosphate substrate cycle (page 481), the glycolytic reaction,

has an ATP-coupling coefficient of -1 . The gluconeogenic reaction,

has an ATP-coupling coefficient of 0. Likewise, as we will learn in Chapter 13, glycolysis has an overall ATP-coupling coefficient of $+2$, whereas gluconeogenesis has an ATP-coupling coefficient of -6 . These differences in ATP-coupling coefficients between opposed reactions or pathways are essential for the unidirectionality of both processes.

What do we really mean when we say that ATP converts a thermodynamically unfavorable process into a favorable process? Coupling ATP hydrolysis to a pathway provides a new chemical route, using different reactions with different stoichiometries, resulting in a different overall equilibrium constant for the process.

In fact, coupling ATP hydrolysis to a process changes the equilibrium ratio of certain [reactants] to [products] by a factor of 10^8 ! To illustrate this, let's consider how the equilibrium ratio of [fructose-1,6-bisphosphate] to [fructose-6-phosphate] changes when we compare a direct addition of P_i to fructose-6-phosphate vs. the reaction pathway that is coupled to ATP hydrolysis. The direct addition of P_i is simply reversal of reaction 12.7:

In this direction, the standard free energy change, $\Delta G^{\circ'}$, is +16.3 kJ/mol (see Table 13.2, page 545). Let's calculate the equilibrium constant, using Equation 3.28 from Chapter 3:

$$K = e^{\left(\frac{-\Delta G^{\circ'}}{RT}\right)} = e^{\left(\frac{-16300 \text{ J/mol}}{(8.315 \text{ J/mol} \cdot \text{K})(298 \text{ K})}\right)} = 0.0014 = \frac{[\text{fructose-1,6-bisphosphate}]}{[\text{fructose-6-phosphate}][P_i]} \quad (12.9)$$

In many cells, the normal intracellular concentration of P_i is ~1mM (10^{-3} M), so the equilibrium ratio of [fructose-1,6-bisphosphate]/[fructose-6-phosphate] achieved by this reaction would be $(0.0014)(10^{-3}) = 1.4 \times 10^{-6}$. Now let's compare that to a reaction that couples the phosphorylation of fructose-6-phosphate to ATP hydrolysis, as in reaction 12.6 above. $\Delta G^{\circ'}$ for this reaction is -14.2 kJ/mol (see Table 13.1, page 534), and thus the equilibrium constant, K , for this reaction is 308.

$$K = e^{\left(\frac{14200 \text{ J/mol}}{(8.315 \text{ J/mol} \cdot \text{K})(298 \text{ K})}\right)} = 308 = \frac{[\text{fructose-1,6-bisphosphate}][\text{ADP}]}{[\text{fructose-6-phosphate}][\text{ATP}]} \quad (12.10)$$

To compare the resulting equilibrium ratio of [fructose-1,6-bisphosphate]/[fructose-6-phosphate], we need to estimate the intracellular concentrations of ADP and ATP. In most normal, healthy cells, [ATP] is several-fold (3–10 times) higher than [ADP]. For the purposes of this calculation, let's make the simplifying assumption that the intracellular concentrations of ADP and ATP are roughly equal, that is, their concentration ratio is ~1. Thus, [ADP] and [ATP] cancel out, and the equilibrium ratio of [fructose-1,6-bisphosphate]/[fructose-6-phosphate] for this reaction is 308. This equilibrium ratio is indeed 10^8 times higher than that achieved without ATP coupling [$308/(1.4 \times 10^{-6}) = 2.2 \times 10^8$]. This effect is completely general—it depends only on the existence of a chemical mechanism that couples ATP hydrolysis to the process at hand (e.g., an enzyme like phosphofructokinase that catalyzes reaction 12.6 in glycolysis). Note that ATP is not directly hydrolyzed in this reaction, but is instead converted to ADP as its phosphate is transferred to fructose-6-phosphate. However, any process that couples the conversion of ATP to ADP gains the thermodynamic equivalent of the free energy of hydrolysis of ATP.

Metabolite Concentrations and Solvent Capacity

The use of ATP as the fundamental coupling agent in biochemical systems has had far-reaching implications for the evolutionary design of cell metabolism. Evolution has produced a complex cell metabolism comprising thousands of enzymes and metabolic intermediates each at very low individual concentrations. There are at least a couple of reasons why a cell must maintain its components at very low concentrations. Even a simple bacterial cell contains several thousand different metabolites dissolved in the aqueous compartment. This aqueous compartment has a finite capacity for the amount of dissolved substances (metabolites and macromolecules)—this is its **solvent capacity**. Thus, individual metabolites must exist at low concentrations (10^{-3} – 10^{-6} M, or even lower) to avoid exceeding the solvent capacity of the cell. Secondly, low metabolite concentrations minimize unwanted side reactions. By way of illustration, imagine two metabolites, A and B, that can react nonenzymatically to form C. Assume that this unwanted side reaction is first-order with respect to each metabolite so that the

reaction rate is directly proportional to the product of [A] and [B] ($v = k[A][B]$). We can compare the amount of C that would be produced under two different metabolite concentrations: 1 M each vs. 10^{-5} M each. Whatever the rate constant is, the velocity of the unwanted side reaction at the two different concentrations will differ by a factor of 10^{10} . Thus, the same amount of C that would be produced in 1 sec if each metabolite is at 1 M would take ~ 317 years (10^{10} sec) to produce if each metabolite is at 10^{-5} M instead.

How does ATP coupling help avoid high metabolite concentrations? It does it by activating metabolic intermediates. Let's return to our previous example, comparing the phosphorylation of fructose-6-phosphate using inorganic phosphate vs. ATP. Assume that the cell needs to maintain a [fructose-1,6-bisphosphate]/[fructose-6-phosphate] ratio of 10 to thrive. What concentration of P_i is required to ensure this nonequilibrium ratio using reaction 12.8? We can solve for the required $[P_i]$ by recognizing that ΔG for this reaction must be < 0 and rearranging the relevant form of Equation 3.23:

$$\Delta G = \Delta G^{\circ'} + RT \ln \left(\frac{[\text{F-1,6-BP}][\text{H}_2\text{O}]}{[\text{F-6-P}][P_i]} \right) < 0$$

or

$$\ln \left(\frac{[\text{F-1,6-BP}][\text{H}_2\text{O}]}{[\text{F-6-P}][P_i]} \right) < \frac{-\Delta G^{\circ'}}{RT} \quad (12.11)$$

$$\ln \left(\frac{[10][1]}{[1][P_i]} \right) < \frac{\frac{-16.3 \text{ kJ}}{\text{mol}}}{\left(\frac{0.008314 \text{ kJ}}{\text{mol K}} \right) (298 \text{ K})} \quad (12.12)$$

Solving for $[P_i]$:

$$[P_i] > \frac{10}{0.0014} = 7143 \text{ M!}$$

Of course, there is no way to fit 7000 moles of phosphate into a liter of aqueous solution. Even if the cell could survive with a [fructose-1,6-bisphosphate]/[fructose-6-phosphate] ratio of 1, it would still need a $[P_i]$ of > 714 M to make the reaction thermodynamically favorable (i.e., to make $\Delta G < 0$).

Now let us consider the process coupled to ATP hydrolysis, via the phosphofructokinase reaction (equation 12.6). Here, the relevant calculation is

$$\frac{[\text{F-1,6-BP}][\text{ADP}]}{[\text{F-6-P}][\text{ATP}]} < e^{\left(\frac{-\Delta G^{\circ'}}{RT} \right)} \quad (12.13)$$

with $\Delta G^{\circ'} = -14.2$ kJ/mol. If we assume an [ADP]/[ATP] ratio of ~ 1 under physiological conditions, we can calculate the maximum ratio of [fructose-1,6-bisphosphate]/[fructose-6-phosphate] that still makes the reaction favorable:

$$\frac{[\text{fructose-1,6-bisphosphate}]}{[\text{fructose-6-phosphate}]} < 308$$

Thus, by coupling the reaction to ATP hydrolysis the reaction will be thermodynamically favorable as long as the ratio of [F-1,6-BP] to [F-6-P] remains under 308—far above the desired 10. This scenario completely avoids the involvement of impossible concentrations of inorganic phosphate. In this example, ATP can be thought of as an activated form of phosphate. Cells have evolved a number of activated intermediates besides ATP, including acetyl-CoA, acyl-lipoate, and nucleoside diphosphate sugars (NDP-sugars). We will discuss each of these in later chapters, but suffice it to say here that they all function to allow reactions to occur under physiologically relevant concentrations of intermediates.

Activated intermediates, such as ATP, allow reactions to occur under physiologically relevant concentrations of metabolic intermediates.

Thermodynamic Properties of ATP

What factors equip ATP for its special role as energy currency? First, there is nothing unique about the chemistry of ATP; the phosphoanhydride bonds whose breakdown can be coupled to drive endergonic reactions are shared by all other nucleoside di- and triphosphates and by several other metabolites. When we call ATP a “high-energy compound,” as we did in Chapter 3, we use that term within a defined context; i.e., a high-energy compound is one containing at least one bond with a sufficiently favorable ΔG° of hydrolysis. ATP has two phosphoanhydride bonds. Cleavage of one yields adenosine diphosphate (ADP) and inorganic phosphate (P_i), and cleavage of the other gives adenosine monophosphate (AMP) and pyrophosphate (PP_i). Either reaction proceeds with a large negative ΔG° of hydrolysis (Figure 3.7, page 76). Note, however, that calling a substance a high-energy compound does not mean that it is chemically unstable or unusually reactive. In fact, ATP is a *kinetically* stable compound; its spontaneous hydrolysis is slow, but when hydrolysis does occur, whether spontaneously or enzyme-catalyzed, substantial free energy is released. Be aware, however, that utilization of that energy to drive endergonic reactions usually does *not* involve hydrolysis. Rather, ATP breakdown is usually coupled with a thermodynamically unfavorable reaction, such as the synthesis of glucose-6-phosphate from glucose. In this case the phosphate released from ATP does not become P_i but instead is transferred directly to glucose, forming the esterified phosphate of glucose-6-phosphate. Thus, as discussed in Chapter 3, it is more accurate to say that ATP has a “high phosphoryl group transfer potential” than to call it a high-energy compound. However, so long as you understand the context in which the term is used, the concept of a high-energy compound is quite useful.

Recall from Chapter 3 that several factors contribute to the thermodynamic stability of a hydrolyzable bond and determine whether ΔG° for hydrolysis is highly favorable, as in the phosphoric anhydride bonds of ATP, ADP, or pyrophosphate, or less favorable, as in the phosphoric ester bonds of glucose-6-phosphate or AMP. These factors include electrostatic repulsion among the negative charges in the molecule before hydrolysis, resonance stabilization of the products of hydrolysis, and the tendency of the hydrolysis products to deprotonate (see page 77). By contrast, the hydrolysis of a phosphate ester, such as AMP, generates an alcohol (the sugar 5' hydroxyl), which has almost no tendency to lose a proton.

The above mentioned factors combine to give ATP hydrolysis a ΔG° of -30.5 kJ/mol, twice the phosphate transfer potential of phosphate esters such as AMP. On the other hand, several important metabolites have ΔG° values for hydrolysis that are much more negative than that of ATP. Examples include phosphoenolpyruvate, 1,3-bisphosphoglycerate, and creatine phosphate (see Figure 3.7, page 76), with ΔG° values of -61.9 , -49.4 , and -43.1 kJ/mol, respectively. This means that ATP

Phosphoanhydride bonds are *thermodynamically* unstable, but *kinetically* stable—large free energies of activation require enzymes to lower the activation barrier.

is actually intermediate on the scale of “chemical potential.” This is important as well because it means that the breakdown of a compound such as phosphoenolpyruvate can be coupled to drive the synthesis of ATP itself from ADP and P_i . In fact, such coupled reactions, called **substrate-level phosphorylation** reactions, represent the process by which ATP is synthesized in glycolysis, as we discuss in Chapter 13.

The Important Differences Between ΔG and ΔG°

But what provides the energy for synthesis of compounds with a much higher phosphate transfer potential than that of ATP itself? Much of the answer lies in the fact that ΔG values under intracellular conditions are quite different from standard (ΔG°) values. This is mainly because intracellular concentrations are far different from the 1 M concentrations used to compute standard free energies. If you work Problem 5 at the end of this chapter, you will see that ATP hydrolysis has a considerably more negative ΔG value at intracellular concentrations of ATP, ADP, AMP, and P_i than it has under standard conditions. In fact, the physiological ratio of $[ATP]/[ADP]$ is $\sim 10^8$ times higher than the equilibrium ratio. This value is not coincidental—if the physiological $[ATP]/[ADP]$ ratio is 10^8 times larger than its equilibrium ratio, then the equilibrium ratio of any other reaction that is coupled to ATP hydrolysis will be altered by this same order of magnitude (see page 491). As we shall see, maintenance of the physiological ratio of $[ATP]/[ADP]$ so far away from equilibrium is accomplished by *kinetic* control, i.e., by regulation of enzymes. The key point is that maintaining the physiological ratio so far from equilibrium provides the thermodynamic driving force for nearly every biochemical event in the cell.

Kinetic Control of Substrate Cycles

Substrate cycles provide a beautiful illustration of the advantages of ATP as a coupling agent and the role of kinetic control over the direction, as well as the rate, of these opposing pathways. Let’s return once again to the fructose-6-phosphate/fructose-1,6-bisphosphate substrate cycle:

	ΔG°	K	ATP coupling coefficient
Fructose-6-phosphate + ATP \rightarrow fructose-1,6-bisphosphate + ADP (PFK)	-14.2	308	-1
Fructose-1,6-bisphosphate + H_2O \rightarrow fructose-6-phosphate + P_i (FBPase)	-16.3	719	0
<hr/>			
Net: ATP + H_2O \rightarrow ADP + P_i			

For the phosphofructokinase (PFK) reaction, under physiological conditions where $[ATP] \approx [ADP]$, we calculated a value of 308 for the equilibrium ratio of $[\text{fructose-1,6-bisphosphate}]/[\text{fructose-6-phosphate}]$ (equation 12.10). Thus, this reaction is favorable in the direction of fructose-1,6-bisphosphate until its concentration approaches a level 308 times that of fructose-6-phosphate. For the fructose-1,6-bisphosphatase (FBPase) reaction, using the physiological concentration of P_i ($\sim 10^{-3}$ M), we obtain a value of 719,000 for the equilibrium ratio of $[\text{fructose-6-phosphate}]/[\text{fructose-1,6-bisphosphate}]$. Thus, under virtually any likely cellular condition, the FBPase reaction is thermodynamically favorable in the direction of fructose-6-phosphate. It follows then that *both* the PFK and FBPase reactions are thermodynamically favorable in their respective directions as long as $[\text{fructose-1,6-bisphosphate}]/[\text{fructose-6-phosphate}]$ ratio is between 0.000014 ($1/719,000$) and 308. In fact, the ratio will *always* be in this wide range in a healthy cell, and thus both reactions are *always* favorable. What then prevents these two reactions from occurring simultaneously, accomplishing nothing more than the net hydrolysis of ATP (i.e., a futile cycle)? The answer, of course, is the independent, but coordinated, kinetic control of the two opposed enzymes. As we

will see in the next chapter, enzymes in substrate cycles are kinetically regulated by the levels of allosteric effectors.

Thus, substrate cycles illustrate the important metabolic design feature mentioned previously: ATP-coupling coefficients of opposing reactions or pathways always differ. This difference allows both sequences to be thermodynamically favorable at all times. The choice of which pathway operates, however, is determined entirely by the metabolic needs of the cell (via allosteric effectors), not by thermodynamics (because both pathways are favorable). Why is it so important for both pathways to be thermodynamically favorable at all times? *Because regulation can be imposed only on reactions that are displaced far from equilibrium.* Consider the following analogy:

A dam separates two bodies of water. If the water level is the same on both sides of the dam, we can say the system is at equilibrium. If we now open the floodgate, what happens? Water may move back and forth through the floodgate, but there will be no net movement of water or change in water levels. Thus, regulation (opening the floodgate) has no impact on a system at equilibrium. Now imagine a different system.

Here, the water level on the left side of the dam is much higher than that on the right side of the dam. We would say this system is far from equilibrium. If we now open the floodgate, water will rush from the left side to the right side and will continue flowing until it reaches equilibrium, or until we impose regulation (close the floodgate). This characteristic, that each pathway of an opposing pair is thermodynamically favorable (made possible by the different ATP-coupling coefficients for each), results in each pathway being unidirectional (because the reverse direction is highly thermodynamically unfavorable). These opposing pathways (e.g., glycolysis vs. gluconeogenesis) are like dams holding back high waters, each poised to flow downhill (thermodynamics), just waiting for the signal to open the floodgates (kinetics). The signal (e.g., allosteric effectors) will logically be different for each floodgate (regulatory enzyme) so that both pathways never flow at the same time (but both could if allowed).

The theoretical basis of this concept, which was developed in Chapter 3, is illustrated in Figure 12.10. It shows a plot of G (Gibbs free energy) vs. the log of the ratio of Q (the mass action ratio; page 69) to K (the equilibrium constant) for the reaction $A \rightleftharpoons B$. This plot gives a parabola and the slope at any point on the curve corresponds to ΔG . The free energy is at a minimum when the Q/K ratio = 1 (i.e., when the actual concentrations of reactants and products is equal to their equilibrium concentrations). In other words, when the system is at equilibrium, $\Delta G = 0$ (verified by the slope = 0 at this point). The magnitude of ΔG is greatest when the mass action ratio is far from equilibrium concentrations, and the further the reaction is from equilibrium, the greater the driving force. ΔG will be large and negative when $[A]$ is high and $[B]$ is low (left side of parabola; $Q/K < 1$), and the reaction will proceed to the right due to the large driving force. Conversely, when $[B]$ is high and $[A]$ is low (right side of parabola; $Q/K > 1$), the reaction will proceed to the left due to an equally large driving force.

Earlier we estimated a ΔG of approximately -1300 kJ/mol for the oxidation of one mole of glucose during respiration (page 490). We can calculate the corresponding Q/K ratio at 298 K using Equation 3.33 from Chapter 3:

$$\Delta G = RT \ln\left(\frac{Q}{K}\right)$$

$$\frac{Q}{K} = e^{\left(\frac{\Delta G}{RT}\right)} = e^{\left(\frac{-1300 \times 10^3 \text{ J/mol}}{(8.315 \text{ J/mol}) \cdot (298 \text{ K})}\right)} \approx 10^{-228}$$

This Q/K ratio, 10^{-228} , is based on approximations of ΔG and might be off by a few orders of magnitude. Whatever the actual value, however, it lies far, far up the left arm of the parabola in Figure 12.10, and thus represents an immense driving force.

Regulation can be imposed only on reactions that are displaced far from equilibrium.

FIGURE 12.10

Gibbs free energy of a reaction as a function of its displacement from equilibrium.

Other High-Energy Nucleotides

As discussed earlier, there is nothing unique about the properties endowing ATP with its special role as energy currency. All other nucleoside triphosphates, as well as more complex nucleotides, such as NAD^+ , have ΔG° values for hydrolysis close to -31 kJ/mol and could have been selected for the role played by ATP. However, evolution has created an array of enzymes that preferentially bind ATP and use its chemical potential to drive endergonic reactions. There are exceptions, such as the use of GTP as the primary energy-providing nucleotide in protein synthesis. But phosphate-bond energy is created almost exclusively at the adenine nucleotide level, through oxidative phosphorylation in aerobic cells, photosynthesis in plants, and substrate-level phosphorylation during glycolysis in virtually all organisms. As a result, ATP is usually the most abundant nucleotide.

In most cells, ATP levels, at 2–8 mM, are severalfold higher than those of the other nucleoside triphosphates and also severalfold higher than the levels of ADP or AMP. These factors give ATP a strong tendency to distribute its γ (outermost) phosphate in the synthesis of other nucleoside triphosphates. This is accomplished through the action of **nucleoside diphosphate kinase**, which synthesizes CTP from CDP in the following example.

Nucleoside diphosphate kinase is active with a wide variety of phosphate donors and acceptors. Because its equilibrium constant is close to unity and because ATP is the most abundant nucleotide within cells, the enzyme normally uses ATP to drive the synthesis of the other common ribo- and deoxyribonucleoside triphosphates from their respective diphosphates.

Some metabolic reactions, such as the activation of amino acids for protein synthesis, cleave ATP, not to ADP and P_i , but to AMP and PP_i . The conversion of AMP to ATP, allowing reuse of the nucleotide, involves another enzyme, **adenylate kinase** (also called myokinase because of its abundance in muscle).

ADP is reconverted to ATP by substrate-level phosphorylation, oxidative phosphorylation, or (in plants) photosynthetic energy. Because the reaction is readily reversible, it can also be used for resynthesis of ATP when ADP levels rise; for example, after a burst of energy consumption. This function is particularly important in muscle metabolism.

Adenylate Energy Charge

As noted above, ATP levels are normally severalfold higher than the levels of ADP and AMP in well-nourished, energy-sufficient cells. Many enzymes that participate in regulating energy-generating or storage pathways are acutely sensitive to concentrations of adenine nucleotides. In general, energy-generating pathways, such as glycolysis and the citric acid cycle, are activated at low energy states, when levels of ATP are relatively low and those of ADP and AMP are relatively high. It is useful to be able to describe the energy status of a cell in quantitative terms. In his excellent book (cited in the references at the end of this chapter), Daniel Atkinson has likened the cell to a battery. When the cellular battery is fully charged, all of the adenine ribonucleotides are present in the form of ATP. When fully discharged, all of the ATP has been broken down to AMP. Atkinson has proposed the term **adenylate energy charge**, which is defined in terms of the intracellular concentrations of ATP, ADP, and AMP.

$$\text{Adenylate energy charge} = \frac{[\text{ATP}] + 0.5[\text{ADP}]}{[\text{ATP}] + [\text{ADP}] + [\text{AMP}]} \quad (12.14)$$

The term is the proportion of total energy-rich bonds that could be present in the adenine nucleotides in a cell to those that are actually present. Note that ADP has one energy-rich bond compared with two in ATP, so it carries one-half the weight of ATP in the numerator of equation 12.14. The value of the adenylate energy charge is probably never far from 1 in well-nourished aerobic cells.

Arginine phosphate

Major Metabolic Control Mechanisms

The living cell uses a marvelous array of regulatory devices to control its functions. These mechanisms include those that act primarily to control enzyme *activity*, such as substrate concentration and allosteric control, as discussed in Chapter 11. Control of enzyme *concentration*, through regulation of enzyme synthesis and degradation, is the major focus of Chapters 27–29 and 20, respectively. In eukaryotic cells, *compartmentation* represents another regulatory mechanism, with the fate of a metabolite being controlled by the flow of that metabolite through a membrane. Overlying all of these mechanisms are the actions of *hormones*, chemical messengers that act at all levels of regulation.

Control of Enzyme Levels

If you were to prepare a cell-free extract of a particular tissue and determine intracellular concentrations of several different enzymes, you would find tremendous variations. Enzymes of the central energy-generating pathways are present at many thousands of molecules per cell, whereas enzymes that have limited or specialized functions might be present at fewer than a dozen molecules per cell. Two-dimensional gel electrophoresis of a cell extract (see Figure 1.11, page 19) gives an impression, from the varying spot intensities, of the wide variations in amounts of individual proteins in a particular cell.

The level of a single enzyme can also vary widely under different environmental conditions, in large part because of variation in the enzyme's rate of synthesis. For example, when a usable substrate is added to a bacterial culture, the abundance of the enzymes needed to process the substrate may increase, through synthesis of new protein, from less than one molecule per cell to many thousands of molecules per cell. This phenomenon is called enzyme **induction**. Similarly, the presence of the end product of a pathway may turn off the synthesis of enzymes needed to generate that end product, a process called **repression**.

For some time it was thought that controlling the intracellular level of a protein was primarily a matter of controlling the *synthesis* of that protein—in other words, through genetic regulation. We now know that intracellular protein *degradation* is also important in determining enzyme levels (see Chapter 20).

Enzyme levels in a cell may change in response to changes in metabolic needs.

Control of Enzyme Activity

The *catalytic activity* of an enzyme molecule can be controlled in two ways: by reversible interaction with ligands (substrates, products, or allosteric modifiers) and by covalent modification of the protein molecule.

Enzyme activity is most commonly controlled by low-molecular-weight ligands, principally substrates and allosteric effectors. Substrates are usually present within cells at concentrations lower than the K_M values for the enzymes that act on them, but within an order of magnitude of these values. In other words, substrate concentrations usually lie within the first-order ranges of substrate concentration–velocity curves for the enzymes that act on them. Therefore, reaction velocities respond to small changes in substrate concentration. Ligands that control enzyme activity can also be polymers. For example, protein–protein interactions can affect enzyme activity, and several enzymes of nucleic acid metabolism are activated by binding to DNA.

We saw in Chapter 11 that allosteric activation or inhibition usually acts on committed steps of a metabolic pathway, often initial reactions. The effectors function by binding at specific regulatory sites, thereby affecting subunit–subunit interactions in the enzyme. This effect, in turn, either facilitates or hinders the binding of substrates. Such a mechanism operates in an obvious way to control product formation if a pathway is unidirectional and unbranched. However, some substrates are involved in numerous pathways, so many branch points exist. Therefore, some of the allosteric enzymes that we will describe display somewhat more complicated regulation than the examples presented in Chapter 11.

Enzyme activity is regulated by interaction with substrates, products, and allosteric effectors and by covalent modification of enzyme protein.

Covalent modification of enzyme structure represents another efficient way to control enzyme activity. Chapter 11 introduced several types of covalent modification that are used to regulate enzyme activity, including **phosphorylation**, **acetylation**, **methylation**, **adenylation** (the transfer of an adenylate moiety from ATP), and **ADP-ribosylation** (the transfer of an ADP-ribosyl moiety from NAD^+). Many other less common covalent modifications are now known. However, phosphorylation is by far the most widespread covalent modification used to control enzyme activity.

Control through covalent modification is often associated with regulatory cascades. Modification activates an enzyme, which in turn acts on a second enzyme, which may activate yet a third enzyme, which finally acts on the substrate. Because enzymes act catalytically, this cascading provides an efficient way to *amplify* the original biological signal. Suppose that the original signal modifying enzyme A activates it 10-fold, that modified enzyme A then activates enzyme B 100-fold, and that B activates enzyme C 1000-fold. Thus, with the involvement of relatively few molecules of enzyme, a pathway can be activated by a million-fold ($10^1 \times 10^2 \times 10^3$).

The first well-understood regulatory cascade was the one controlling glycogen breakdown in animal cells, a critical process that provides carbohydrate substrates for energy generation. This regulatory cascade, involving enzyme phosphorylation and dephosphorylation, is described in detail in Chapter 13. Blood clotting, described in Chapter 11, is another well-understood regulatory cascade.

Compartmentation

We have already described the physical division of labor that exists in a eukaryotic cell, in the sense that enzymes participating in the same process are localized to a particular *compartment* within the cell. For example, RNA polymerases are found in the nucleus and nucleolus, where DNA transcription occurs, and the enzymes of the citric acid cycle are all found in mitochondria. Figure 12.11 presents the locations of a number of metabolic pathways within eukaryotic cells.

Compartmentation creates a division of labor within a cell, which increases the efficiency of cell function. The creatine–creatine phosphate shuttle (page 496) is a good example of this. In addition, compartmentation has an important

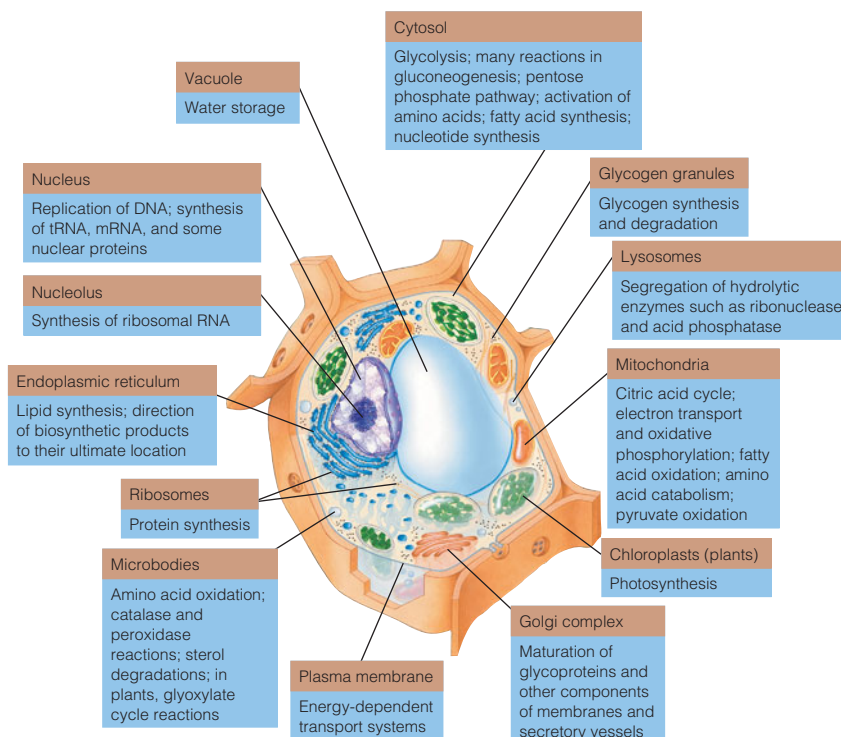

FIGURE 12.11

Locations of major metabolic pathways within a eukaryotic cell. This hypothetical cell combines features of a plant cell and an animal cell.

Biology, 5th ed., Neil A. Campbell, Jane B. Reece, and Lawrence A. Mitchell. © 1999. Reprinted by permission of Pearson Education Inc., Upper Saddle River, NJ.

regulatory function. This function derives largely from the selective permeability of membranes to different metabolites, thereby controlling the passage of intermediates from one compartment into another. Typically, intermediates of a pathway remain trapped within an organelle, while specific carriers allow substrates to enter and products to exit. The flux through a pathway, therefore, can be regulated by controlling the rate at which a substrate enters the compartment. For example, one of the ways in which the hormone insulin stimulates carbohydrate utilization is by moving glucose transporters into the plasma membrane so that glucose is more readily taken into cells for catabolism or for synthesis of glycogen.

Compartmentation is more than a matter of tucking enzymes into the proper organelles. Juxtaposition of enzymes that catalyze sequential reactions localizes substrates even in the absence of membrane-bound organelles. Opportunities for diffusion are reduced because the product of one reaction is released close to the active site of the next enzyme in a pathway. The enzymes may be bound to one another in a membrane, as are the enzymes of mitochondrial electron transport. Alternatively, they may be part of a highly organized multiprotein complex, such as the pyruvate dehydrogenase complex, a major entry point to the citric acid cycle.

Compartmentation can also result from weak interactions among enzymes that do not remain complexed when they are isolated. For example, conversion of glucose to pyruvate by glycolysis is catalyzed by enzymes that interact quite weakly in solution. However, there is evidence that these enzymes interact within the cytosol, forming a supramolecular structure that facilitates the multistep glycolytic pathway. The concept of intracellular interactions among readily solubilized enzymes developed as scientists began to realize that the cytosol is much more highly structured than was formerly thought. High-resolution electron micrographs of mammalian cytosol reveal the outlines of an organized structure that has been termed the **cytomatrix**, a model of which is shown in Figure 12.12. It is likely that such structures form as a result of the extremely high concentrations of proteins inside cells, which decrease the concentration of water and drive weakly interacting proteins to associate. It has been proposed that soluble enzymes are bound within the cell to the structural elements of the cytomatrix.

Whether highly structured or loosely associated, multienzyme complexes allow for efficient control of reaction pathways. Enzyme complexes restrict diffusion of intermediates, thereby keeping the average concentrations of intermediates low (but their local concentrations high, at enzyme catalytic sites). This complexing reduces *transient time*, the average time needed for a molecule to traverse a pathway. Thus, the flux through a pathway can change quickly in response to a change in the concentration of the first substrate for that pathway.

Enzymes catalyzing sequential reactions are often associated, even in the cytosol, where organized structures are difficult to visualize.

Hormonal Regulation

Overlaid and interspersed with the regulatory mechanisms operating within a eukaryotic cell are messages dispatched from other tissues and organs. The process of transmitting these messages and bringing about metabolic changes is called **signal transduction**. The extracellular messengers include hormones, growth factors, neurotransmitters, and pheromones, which interact with specific receptors, resulting in specific metabolic changes in the target cell.

Metabolic responses to hormones can involve changes in gene expression, leading to changes in enzyme levels. This type of response typically operates on a timescale of hours to days, resulting in a reprogramming of the metabolic capability of the cell. On a shorter timescale (seconds to hours), some hormones stimulate the synthesis of intracellular **second messengers** that control metabolic reactions. One of the most important second messengers is **adenosine 3',5'-cyclic monophosphate**, more commonly called **cyclic AMP**, or simply **cAMP**. The hormone (the first messenger) acts extracellularly, by binding to receptors in the plasma membrane. Because the receptor protein traverses the membrane, it can, on the intracellular side, stimulate the formation of a second messenger in response to extracellular

binding of the first messenger. These signal transduction systems can effect precise control over metabolic pathways, often through reversible covalent modification of critical enzymes in the pathway.

Signal transduction systems are modular in nature, allowing for a diversity of metabolic responses based on the same operating principles. Thus, secretion of one hormone can have quite diverse effects in different tissues, depending upon the nature of the receptor and other components and second messenger systems in different target cells. Moreover, a single second messenger may have diverse effects within a single cell. For example, cyclic AMP, which activates glycogen degradation, also activates a cascade that inhibits the synthesis of glycogen. This dual effect is an example of a coordinated metabolic response: Glycogen synthesis is *inhibited* under the same physiological conditions that *promote* glycogen breakdown. These signal transduction systems will be described in great detail in Chapters 13, 18, and 23.

Adenosine-3',5'-cyclic monophosphate
(cyclic AMP)

Second messengers transmit information from hormones bound at the cell surface, thereby controlling intracellular metabolic processes.

Distributive Control of Metabolism

In recent years, an important principle of metabolic regulation has emerged. With the discovery in the 1950s and 1960s of allosterically regulated enzymes, the concept arose that metabolic pathway flux is regulated primarily through control of the intracellular activity of one or a few key enzymes in that pathway. When it was realized that allosteric enzymes often catalyze committed reactions, i.e., the first reaction in a pathway that leads to an intermediate with no other known function, the concept arose that these enzymes catalyze the “rate-limiting reactions” in metabolic pathways. Taken literally, the term *rate-limiting reaction* implies that the flux rate of the pathway is identical to the intracellular activity of the rate-limiting step. However, because in a metabolic steady state all of the steps along a linear pathway are proceeding at the same rate, it is difficult or impossible to establish that the rate is controlled by a single enzymatic step. In other words, the concept of a rate-limiting enzyme is seriously flawed.

We now realize that metabolic regulation is more complex and that all of the enzymes in a pathway contribute toward control of pathway flux. An approach called **metabolic control analysis** assigns to each enzyme in a pathway a **flux control coefficient**, C^J , a value that can vary between zero and one. Consider a metabolic pathway where substrate A is converted to product D in several steps. The **flux** through the pathway, J , is equal to the rate of the forward process, v_f , minus the rate of the reverse process, v_r :

$$J = v_f - v_r$$

For a given enzyme, the flux control coefficient is the relative increase in flux, divided by the relative increase in enzyme activity that brought about that flux increase. For a true rate-limiting enzyme, the flux control coefficient is 1; a 20% increase in the activity of that enzyme would increase that flux rate by 20%. But metabolic control theory predicts that all enzymes in a pathway contribute toward regulation, meaning that all enzymes have flux-control coefficients greater than zero (but none has a value as high as 1, which would be the case if flux were truly controlled solely by one rate-limiting enzyme). Flux-control coefficients are properties of the pathway or metabolic system, and thus all the flux-control coefficients in the pathway must sum to 1:

$$C_1^J + C_2^J + \dots + C_n^J = 1$$

In the hypothetical pathway in the margin, intermediate C has two alternative fates. Because reaction 4 draws C away from the pathway $A \rightarrow D$, it decreases flux through the pathway, and the enzyme that catalyzes step 4 has a negative flux control coefficient. The sum of the four flux control coefficients in the pathway still equals 1.

The predictions of metabolic control theory can be tested, for example, by using mutations affecting a specific enzyme to bring about defined changes in the activity of that enzyme in vivo, and then measuring the change in flux rate of a pathway in which that enzyme is involved. Such analyses confirm that enzymes catalyzing committed

reactions do play large roles in regulation (i.e., they have high flux-control coefficients). More important, however, these analyses confirm that *every* enzyme in a pathway contributes toward control of that pathway; in other words, every enzyme has a flux-control coefficient greater than zero. Thus, regulation of a pathway is *distributed* among all of the enzymes involved in the pathway, giving rise to the concept of **distributive control of metabolism**. In retrospect, this concept should have been predicted simply from the long-understood complexity of metabolism. Many intermediates participate in more than one pathway, making different pathways interdependent and interlocking. Regulatory schemes that depend on control of just one or two enzymes in each pathway lack the flexibility and subtlety to account for the ability of cells to maintain homeostasis under widely varying nutritional and energetic conditions. To be sure, for each pathway or process, one or a few regulatory enzymes of primary importance have been identified, and these will be pointed out as we present the individual pathways involved.

Experimental Analysis of Metabolism

Goals of the Study of Metabolism

Given that metabolism consists of all the chemical reactions in living matter, how does a biochemist approach metabolism in the laboratory? To subdivide a particular metabolic process into experimentally attainable goals, the biochemist seeks (1) to identify reactants, products, and cofactors, plus the stoichiometry, for each reaction involved; (2) to understand how the rate of each reaction is controlled in the tissue of origin; and (3) to identify the physiological function of each reaction and control mechanism. These goals necessitate isolating and characterizing the enzyme catalyzing each reaction in a pathway. This latter task—extrapolating from test tube biochemistry to the intact cell—is especially challenging. For instance, given that most enzymes catalyze reactions that can proceed in either direction, what is the direction of an enzymatic reaction *in vivo*? Many reactions originally found to proceed one way *in vitro* have been shown to proceed in the opposite direction *in vivo*. The mitochondrial enzyme that synthesizes ATP from ADP, for example, was originally isolated as an ATPase—an enzyme that hydrolyzes ATP to ADP and P_i . Therefore, it is not enough to isolate an enzyme and to demonstrate that it catalyzes a particular reaction in the test tube. We must show also that the same enzyme catalyzes the same reaction in intact tissue, usually a more difficult task.

To achieve the stated goals, a biochemist must perform analyses at several levels of biological organization, from living organisms and intact cells to broken-cell preparations and, ultimately, to purified components. Cell-free, or *in vitro*, preparations can be manipulated in ways that intact cells cannot—for example, by addition of substrates and cofactors that will not pass through cell membranes. The researcher attempts to duplicate *in vitro* the process that is known to occur *in vivo*.

Preparation of cell-free components usually destroys biological organization. Cells can be broken open by sonication, shear forces, or enzymatic digestion of cell walls. These harsh treatments lead to mixing of components that were in separate compartments in the intact cell, making it possible to misinterpret data obtained from *in vitro* systems. An example comes from studies of protein biosynthesis. The existence of messenger RNA as a template for protein synthesis was predicted in 1961 from the behavior of bacterial mutants altered in genetic regulation. However, it was difficult to demonstrate the existence of messenger RNA *in vitro* because the putative template was present in very small amounts and was rapidly degraded by enzymes in cell-free extracts. Only when investigators learned how to prevent this degradation could they prove the existence of messenger RNA.

The foregoing discussion reveals the necessity of studying metabolism at various levels of biological organization, from intact organism to purified chemical components. Here we discuss what can be learned at each level.

Levels of Organization at Which Metabolism Is Studied

Whole Organism

Biochemists must investigate metabolism in whole organisms because our ultimate aim is to understand chemical processes in intact living systems. Radioisotopic tracers are widely used to characterize metabolic pathways, as described in Tools of Biochemistry 12A. A classic example, described in Chapter 19, is the elucidation of cholesterol synthesis in the 1940s. Konrad Bloch injected ^{14}C -labeled acetate into rats and followed the flow of label into intermediates by sacrificing rats at intervals and analyzing the radioactive compounds in their livers. In designing experiments of this type, the investigator must pay attention to the efficiency of transport of the labeled precursor to the organs of interest, uptake of the precursor into cells, and competition of exogenous precursors with preexisting pools of unlabeled intermediates.

Many diagnostic tests in clinical medicine are *in vivo* metabolic experiments. Instead of using radioisotopes, we sample tissue at intervals and carry out biochemical assays. In the **glucose tolerance test**, for example, a subject consumes a large oral dose of glucose, and its level in the blood is then determined at intervals over several hours. The glucose tolerance test is used to diagnose diabetes and other disorders of carbohydrate metabolism.

In recent years, *nuclear magnetic resonance* (NMR) spectroscopy has become widely available for noninvasive monitoring of intact cells and organs. As explained in Tools of Biochemistry 6A, compounds containing certain atomic nuclei can be identified from an NMR spectrum, which measures shifts in the frequency of absorbed electromagnetic radiation. A researcher can determine an NMR spectrum of whole cells, or of organs or tissues in an intact plant or animal. NMR has even become a powerful noninvasive diagnostic tool, referred to as magnetic resonance imaging (MRI) in the medical arena. For the most part, macromolecular components do not contribute to the spectrum, nor do compounds that are present at less than about 0.5 mM. The nuclei most commonly used in this *in vivo* technique are ^1H , ^{31}P , and ^{13}C . Figure 12.13 shows ^{31}P NMR spectra that represent components in the human forearm muscle. The five major peaks correspond to the phosphorus nuclei in orthophosphate (P_i), creatine phosphate, and the three phosphates of ATP. Because peak area is proportional to concentration, the energy status of intact cells can be determined. For example, an energy-rich muscle has lots of creatine phosphate, whereas a fatigued muscle uses up most of its creatine phosphate in order to maintain ATP levels (note also the accumulation of AMP—peak 6—in the third scan). NMR is finding wide applicability in monitoring recovery from heart attacks, in which cellular ischemia (insufficient oxygenation) damages cells by reducing ATP content. NMR can also be used to study metabolite compartmentation, flux rates through major metabolic pathways, and intracellular pH.

Isolated or Perfused Organ

Some of the difficulties in transporting a precursor or inhibitor to the desired organ can be circumvented by using an isolated organ. A researcher usually **perfuses** the isolated organ during the experimental manipulations. This procedure involves pumping a buffered isotonic solution containing nutrients, drugs, or hormones through the organ. The solution partly takes the place of the normal circulation, delivering nutrients and removing waste products. The researcher can also perfuse an organ within a living animal, following appropriate surgical procedures. Of course, perfusion is much less efficient than circulation; thus, experiments at this level must be of limited duration.

FIGURE 12.13

Effect of anaerobic exercise on ^{31}P NMR spectra of human forearm muscle. (a) Before exercise. (b) One minute into a 19-minute exercise period. (c) The 19th minute. (d) Ten minutes after exercise. Peak areas are proportional to intracellular concentrations. Peak 1 = P_i ; 2 = creatine phosphate; 3 = ATP γ -phosphate; 4 = ATP α -phosphate; 5 = ATP β -phosphate; 6 = phosphomonoesters. See Tools of Biochemistry 6A for interpretation of NMR spectra.

The circulation problem can be partly overcome by cutting the tissue into thin slices before the experimental manipulations begin. The structural integrity of the organ is lost, but most of the cells remain intact, and they are in better contact with the fluid that bathes the tissue. The cells may be better oxygenated and supplied with substrates than in a whole organ. The elucidation of the citric acid cycle resulted largely from experiments with slices of liver and heart.

Whole Cells

Tissue slices are not now widely used, partly because methods are now available for disaggregating an organ or a tissue into its component cells. Liver, kidney, and heart cells can be prepared by treatment of the organ with trypsin or collagenase, to break down the extracellular matrix that holds the organ together. For plant cells, enzymes such as cellulase or pectinase, which attack the cell wall, can be used to make comparable preparations.

Any plant or animal organ contains a complex mixture of different cell types. Several means of fractionating the cells after disaggregation of an organ are used to obtain preparations enriched in one cell type. One method is centrifugation to separate cells on the basis of size. In recent years the **fluorescence-activated cell sorter** has come into widespread use. In a typical application a cell suspension is treated with a fluorescent-tagged antibody to a cell surface antigen, which is present in varying amounts among different cell types. Cells pass in single file through a laser beam and are physically separated according to the amount of fluorescence recorded from each cell. Such machines, which can sort several thousand cells per second, result in fractionation based on the abundance of the selected surface antigen.

Uniformity in a cell population is often achieved by growth of cells in **tissue culture**. Disaggregated cells of an organ or a tissue can, with special care, be induced to grow in a medium containing cell nutrients and protein growth factors. The cells grow and divide independently of one another, much like the cells in a bacterial culture. Although animal cells usually cease growth after a certain number of divisions in culture, variant lines arise that are capable of indefinite growth, as long as they are adequately nourished. In such cultures, **clonal** cell lines can be generated in which all of the cells in a line are derived from a single cell so that they are genetically and metabolically uniform. This uniformity is a boon for many biochemical investigations. For example, much of our understanding of virus replication depends upon the ability to infect a large number of identical cells in culture simultaneously and then follow the metabolic changes by sampling the cell culture at various times after infection.

One problem with tissue culture is that cells adapted to long-term growth in culture take on characteristics different from those of their parent cells, which were originally embedded in plant or animal tissue. Maintaining specialized cell characteristics in culture always presents a challenge.

Cell-Free Systems

Problems of transport through membranes are obviated by working with broken-cell preparations. Animal cells are easily lysed (ruptured) by mild shear forces, suspension in hypotonic medium, or freezing and thawing. Bacterial cells have a rigid cell wall that requires vigorous treatment such as sonication (using ultrasound energy to agitate particles). Enzymatic digestion with lysozyme is often used to open bacterial cells under relatively mild conditions. Breaking the especially tough cell walls of yeasts and plants usually requires combinations of enzymatic and mechanical treatments.

Initial metabolic experiments are usually carried out in unfractionated cell-free homogenates. However, localizing a metabolic pathway within a particular cell compartment requires fractionating the homogenate to separate the organelles, usually by **differential centrifugation**. Lysis is carried out in isotonic sucrose solutions and generally yields morphologically intact organelles. These components can be pelleted by centrifugation at different speeds and for different lengths of time. Typically, nuclei, mitochondria, chloroplasts, lysosomes, and **microsomes** (artificial membrane vesicles formed from disrupted endoplasmic reticulum) can all be at

least partially separated from each other. The contents of the cytosol remain in the supernatant after the final centrifugation step. Much of our understanding of DNA replication and transcription in eukaryotic cells comes from investigations with isolated nuclei, whereas purified mitochondria have yielded much of our understanding of respiratory electron transport and oxidative phosphorylation.

Purified Components

To understand a biological process at the molecular level, the investigator must purify to homogeneity all of the factors thought to be involved and determine their interactions. Often, as with the citric acid cycle, this process is simply a matter of purifying the individual enzymes involved, determining the substrate and cofactor requirements of each, recombining the purified enzymes, and showing that the entire process can be catalyzed by purified components. This process is called **reconstitution**. Some pathways require cell constituents other than enzymes, such as the ribosomes and transfer RNAs needed for protein synthesis.

In purifying individual components, the biochemist continually risks losing factors that are essential for normal control or for some other aspect of the process under study. Avoiding such pitfalls requires painstaking experiments in which the researcher defines criteria for biological activity and continually examines fractions to ensure that each activity is retained through each fractionation step. A good example of this approach is presented in Chapter 25, in which we discuss the several enzymes and proteins that must function at a DNA replication fork.

Metabolic Probes

An invaluable biochemical aid is the use of metabolic probes, agents that allow a researcher to interfere specifically with one or a small number of reactions in a pathway. The consequences of such interference can be extremely informative. Two kinds of probes are most widely used—*metabolic inhibitors* and *mutations*. By blocking a specific reaction *in vivo* and determining the results of the blockade, such probes help identify the metabolic role of a reaction. For example, respiratory poisons such as carbon monoxide and cyanide block specific steps in respiration, and metabolic inhibitors helped identify the order of electron carriers in the respiratory electron transport chain (see Chapter 15).

Inhibitors can present difficulties for the researcher, such as poor transport into cells or multiple sites of action. It is often easier to interfere with a pathway by selecting mutant strains deficient in the enzyme of interest. In the 1940s George Beadle and Edward Tatum were the first to use mutations as biochemical probes, in their work with the bread mold *Neurospora crassa*. Beadle and Tatum isolated a number of X-ray-induced mutants that required arginine for growth, in addition to the constituents of minimal medium. Furthermore, different mutations affected different enzymes in the arginine biosynthetic pathway, with each mutant accumulating in the culture medium the intermediate that was the substrate for the deficient enzyme. This observation allowed Beadle and Tatum to order the enzymes according to the reactions they controlled, by the rationale illustrated in Figure 12.14. If a culture filtrate (containing an accumulated intermediate) from one mutant allowed a second mutant to grow without arginine, the researchers concluded that the first mutation blocked an enzymatic step *later* in the pathway than the step blocked by the second mutation. Ultimately, the accumulating intermediates were identified and the pathway was elucidated. The impact of this “biochemical genetics” approach was much wider than simply working out the details of a metabolic pathway. Beadle and Tatum recognized that there was a one-to-one correspondence between a genetic mutation and the loss of a specific enzyme, leading them to propose the **one gene—one enzyme hypothesis**, years before the chemical nature of the gene was known.

In addition to identifying pathways, mutants have been used to elucidate regulatory mechanisms. The earliest successes came from studies in Paris by François Jacob and Jacques Monod, who isolated dozens of *Escherichia coli* mutants with

By inactivating individual enzymes, mutations and enzyme inhibitors help identify the metabolic roles of enzymes.

A mutant defective in enzyme:	Accumulates metabolite in culture medium:	Requires an external source of:	Culture filtrate allows the growth of another mutant, defective in enzyme:
I	A	B, C, D, or E	—
II	B	C, D, or E	I
III	C	D or E	I or II
IV	D	E	I, II, or III

Analysis of mutants

**FIGURE 12.14**

Using mutations as biochemical probes. The steps of a hypothetical metabolic pathway are identified by analysis of mutants defective in individual steps of the pathway. For example, we can identify metabolite C as the substrate for enzyme III by the absence of this enzyme in mutants that accumulate C. We know that D and E follow C in the pathway because feeding either D or E to mutants defective in enzyme III bypasses the genetic block and allows the cells to grow.

defects in regulation of lactose catabolism or with abnormalities in virus–host relationships. These data led ultimately to the discovery of mRNA and the repressor–operator mechanism of genetic regulation, which we discuss in Chapter 27. Recombinant DNA technologies (see Tools of Biochemistry 4B) have allowed even more sophisticated perturbations of metabolic regulatory systems. For example, a researcher might use site-directed mutagenesis to disable the allosteric regulatory sites on an enzyme in a particular substrate cycle. The mutated enzyme is then introduced back into the cell, replacing the wild-type version, and the effects of loss of regulation can be examined *in vivo*.

A single investigation can use both metabolic inhibitors and mutations. This combined approach helped to elucidate the function of DNA gyrase, one of the DNA topoisomerases mentioned in Chapter 4. This enzyme is inhibited by nalidixic acid. When nalidixic acid is administered to bacteria, DNA replication is inhibited, suggesting that DNA gyrase plays an essential role in DNA replication. However, because nalidixic acid *could* inhibit DNA replication by blocking some other enzyme, stronger evidence is needed. Such evidence was obtained when mutants resistant to nalidixic acid were found to contain an altered form of DNA gyrase that was resistant to nalidixic acid. Thus, a single mutation abolished nalidixic acid sensitivity for both the enzyme and the ability of the cells to replicate their DNA, strongly supporting an essential role for DNA gyrase in DNA replication.

Finally, **systems biology** approaches are now being applied to the study of metabolism. Systems biologists try to catalog the full set of components in a system, and then study the interactions between these components and how these interactions give rise to the specific function and behavior of that system. Metabolic profiling (see Tools of Biochemistry 12B) is an example of this kind of approach.

In this chapter we have described the general strategy of metabolism, identified the major pathways, outlined how pathways are regulated, and identified experimental approaches to understanding metabolism. We are now prepared for detailed descriptions of metabolic pathways, which we begin in Chapter 13 with carbohydrates.

SUMMARY

Metabolism is the totality of chemical reactions occurring within a cell. Catabolic pathways break down substrates to provide energy, largely through oxidative reactions, whereas anabolic pathways synthesize complex biomolecules from small molecules, often from intermediates in catabolic pathways. Catabolic and anabolic pathways with the same end points are actually different pathways, not simple reversals of each other, so that both pathways are thermodynamically favorable. Regulation can be imposed only on reactions that are displaced far from equilibrium. Most metabolic energy comes from oxidation of substrates, with energy release coming in a series of small steps as the electrons released are transferred ultimately to oxygen. The more highly reduced a substrate, the more energy is released through its catabolism.

Flux through metabolic pathways is controlled by regulation of enzyme concentration (through control of enzyme synthesis and degradation), enzyme activity (through concentrations of substrates, products, and allosteric effectors, and covalent modification of enzymes), compartmentation, and hormonal control. Hormonal regulation may involve control of enzyme synthesis at the genetic level or regulation of enzyme activity. In the latter case, intracellular second messengers are formed in response to hormonal signals.

The understanding of metabolic processes requires identification of each reaction in a pathway and a knowledge of the reaction's function and control. This understanding requires experimentation at all levels of biological organization, from living organism to purified enzyme. The ability to block specific enzymes, either with inhibitors or mutations, is of great value in identifying the functions of those enzymes.

PROBLEMS

1. Write a balanced equation for the complete oxidation of each of the following, and calculate the respiratory quotient for each substance.

- Ethanol
- Acetic acid
- Stearic acid
- Oleic acid
- Linoleic acid

2. Given what you know about the involvement of nicotinamide nucleotides in oxidative and reductive metabolic reactions, predict whether the following intracellular concentration ratios should be (1) unity, (2) greater than unity, or (3) less than unity. Explain your answers.

- $[\text{NAD}^+]/[\text{NADH}]$
- $[\text{NADP}^+]/[\text{NADPH}]$

Because NAD^+ and NADP^+ are essentially equivalent in their tendency to attract electrons, discuss how the two concentration ratios might be maintained inside cells at greatly differing values.

- NAD^+ kinase catalyzes the ATP-dependent conversion of NAD^+ to NADP^+ . How many reducing equivalents are involved in this reaction?
 - How many reducing equivalents are involved in the conversion of ferric to ferrous ion?
 - How many reducing equivalents are involved in reducing one molecule of oxygen gas to water?

4. On page 488 we showed that the oxidation of glucose and palmitic acid yields 15.64 kJ/g and 38.90 kJ/g, respectively. Calculate these values in terms of kJ/mol and kJ per carbon atom oxidized for both glucose and palmitic acid.

5. Free energy changes under intracellular conditions differ markedly from those determined under standard conditions. $\Delta G^{\circ\prime}$ for ATP hydrolysis to ADP and P_i is -30.5 kJ/mol. Calculate ΔG for ATP hydrolysis in a cell at 37°C that contains ATP at 3 mM, ADP at 1 mM, and P_i at 1 mM.

6. Consider the following hypothetical metabolic pathway:

(a) Under intracellular conditions, the activity of enzyme X is $100 \text{ pmol}/10^6 \text{ cells/sec}$. Calculate the effect on metabolic flux rate ($\text{pmol}/10^6 \text{ cells/sec}$) of $\text{B} \rightarrow \text{C}$ of the following treatments. Calculate as % change (increase or decrease).

Treatment	% Change in flux
Inhibitor that reduces activity of X by 10%	
Activator that increases activity of X by 10%	

(b) Now consider a substrate cycle operating with enzymes X and Y in the same hypothetical metabolic pathway:

Under intracellular conditions, the activity of enzyme X is 100 pmol/10⁶ cells/sec, and that of enzyme Y is 80 pmol/10⁶ cells/sec. What are the direction and rate (pmol/10⁶ cells/sec) of metabolic flux between B and C?

(c) Calculate the effect on direction and metabolic flux rate of the following treatments. Calculate as % change (increase or decrease).

Treatment	Direction of flux (B → C or C → B)	% Change in flux
Inhibitor that reduces activity of X by 10%		
Activator that increases activity of X by 10%		
Doubling the activity of enzyme Y		

(d) Briefly summarize the regulatory advantage(s) of a substrate cycle in a pathway.

7. The glucose/glucose-6-phosphate substrate cycle involves distinct reactions of glycolysis and gluconeogenesis that interconvert these two metabolites. Assume that under physiological conditions, [ATP] = [ADP]; [P_i] = 1 mM.

Consider the glycolytic reaction catalyzed by hexokinase:

(a) Calculate the equilibrium constant (*K*) for this reaction at 298°K, and from that, calculate the maximum [glucose-6-phosphate]/[glucose] ratio that would exist under conditions where the reaction is still thermodynamically favorable.

(b) Reversal of this interconversion in gluconeogenesis is catalyzed by glucose-6-phosphatase:

K for this reaction is 262. Calculate the maximum ratio of [glucose]/[glucose-6-phosphate] that would exist under conditions where the reaction is still thermodynamically favorable.

(c) Under what cellular conditions would both directions in the substrate cycle be strongly favored?

(d) What ultimately controls the direction of net conversion of a substrate cycle such as this in the cell?

Read Tools of Biochemistry 12A before attempting to work Problems 8–10.

- *8. Two-dimensional gel electrophoresis of proteins in a cell extract provides a qualitative way to compare proteins with respect to intracellular abundance. Describe a quantitative approach to the determination of number of molecules of an enzyme per cell.
- *9. Mammalian cells growing in culture were labeled for a long time in [³H]thymidine to estimate the rate of DNA synthesis. The thymidine administered had a specific activity of 3000 cpm/pmol. At intervals, samples of culture were taken and acidified to precipitate nucleic acids. The rate of incorporation of isotope into DNA was 1500 cpm/10⁶ cells/min. A portion of culture was taken for determination of specific activity of the intracellular dTTP pool, which was found to be 600 cpm/pmol.
- (a) What fraction of the intracellular dTTP is synthesized from the exogenous precursor?
- (b) What is the rate of DNA synthesis, in molecules per minute per cell of thymine nucleotides incorporated into DNA?
- (c) How might you determine the specific activity of the dTTP pool?
- *10. Suppliers of radioisotopically labeled compounds usually provide each product as a mixture of labeled and unlabeled material. Unlabeled material is added deliberately as a **carrier**, partly because the specific activity of the carrier-free product is too high to be useful and partly because the product is more stable at lower specific activities. Using the radioactive decay law, calculate the following.
- (a) The specific activity of carrier-free [³²P]orthophosphate, in mCi/mmol.
- (b) In a preparation of uniform-label [³H]leucine, provided at 10 mCi/mmol, the fraction of H atoms that are radioactive.

TOOLS OF BIOCHEMISTRY 12A

RADIOISOTOPES AND THE LIQUID SCINTILLATION COUNTER

Radioisotopes revolutionized biochemistry when they became available to investigators shortly after World War II. Radioisotopes extend by orders of magnitude the sensitivity with which chemical species can be detected. Traditional chemical analysis can detect and quantify molecules in the micromole or nanomole range (i.e., 10⁻⁶ to 10⁻⁹ mole). A compound that is “labeled,” containing one or more atoms of a radioisotope, can be detected in picomole or even femtomole amounts (i.e., 10⁻¹² or 10⁻¹⁵ mole). Radiolabeled compounds are called **tracers** because they allow an investigator to follow specific chemical or

biochemical transformations in the presence of a huge excess of nonradioactive material.

Recall that isotopes are different forms of the same element. They have different atomic weights but the same atomic number. Thus, the chemical properties of the different isotopes of a particular element are virtually identical. Isotopic forms of an element exist naturally, and substances enriched for rare isotopes can be isolated and purified from natural sources. Most of the isotopes used in biochemistry, however, are produced in nuclear reactors. Simple chemical compounds produced in such

reactors are then converted to radiolabeled biochemicals by chemical and enzymatic synthesis.

Stable Isotopes

Although radioisotopes are widely used in biochemistry, stable isotopes are also used as tracers, particularly when convenient radioisotopes are not available. For example, the two rare isotopes of hydrogen include a stable isotope ($^2\text{H}_1$, or **deuterium**) and a radioactive isotope ($^3\text{H}_1$, or **tritium**). Of the many uses of stable isotopes in biochemical research, we mention three applications here. First, incorporation of a stable isotope often increases the density of a material because the rare isotopes usually have higher atomic weights than their more abundant counterparts. This difference presents a way to separate labeled from nonlabeled compounds physically, as in the Meselson–Stahl experiment on DNA replication (see Chapter 4). Second, compounds labeled with stable isotopes, particularly ^{13}C , are widely used in nuclear magnetic resonance studies of molecular structure and dynamics (see Tools of Biochemistry 6A). Third, stable isotopes are used to study reaction mechanisms. The “kinetic isotope effect” refers to the effect on reaction rate of substitution of an atom by a heavy isotope. As discussed in Chapter 11, such an effect helps to identify rate-limiting steps in enzyme-catalyzed reactions. Table 12A.1 gives information about the isotopes, both stable and radioactive, that have found the greatest use in biochemistry.

The Nature of Radioactive Decay

The atomic nucleus of an unstable element can decay, giving rise to one or more of the three types of ionizing radiation: α -, β -, or γ -rays. Only β - and γ -emitting radioisotopes are used in biochemical research; the most useful are shown in Table 12A.1. A β -ray is an emitted electron, and a γ -ray is a high-energy photon.

γ -Ray detectors have found wide use in immunological research because γ -emitting isotopes of iodine are available, and antibodies, like many proteins, can easily be iodinated without substantial changes in their biological properties. Most biochemical uses of radioisotopes, however, involve β -emitters.

Radioactive decay is a first-order kinetic process. The probability that a given atomic nucleus will decay is affected neither by the number of preceding decay events that have occurred nor by interaction with other radioactive nuclei. Rather, it is an intrinsic property of that nucleus. Thus, the number of decay events occurring in a given time interval is related only to the number of radioactive atoms present. This phenomenon gives rise to the **law of radioactive decay**:

$$N = N_0 e^{-\lambda t}$$

where N_0 is the number of radioactive atoms at time zero, N is the number remaining at time t , and λ is a radioactive decay constant for a particular isotope, related to the intrinsic instability of that isotope. This equation states that the *fraction* of nuclei in a population that decays within a given time interval is constant. For this reason, a more convenient parameter than the decay constant λ is the **half-life**, $t_{1/2}$, the time required for half of the nuclei in a sample to decay. The half-life is equal to $-\ln 0.5/\lambda$, or $+0.693/\lambda$. The half-life, like λ , is an intrinsic property of a given radioisotope (see Table 12A.1).

The basic unit of radioactive decay is the **curie** (Ci). This unit is defined as an amount of radioactivity equivalent to that in 1 g of radium, namely 2.22×10^{12} disintegrations per minute (dpm). Biochemists usually work with far smaller amounts of radioactive material—the **millicurie** (mCi) and the **microcurie** (μCi), which correspond, respectively, to 2.2×10^9 and 2.2×10^6 dpm. Because detectors of radioactivity rarely record every decay event in a sample—that is, they are not 100% efficient—we often speak of radioactivity in terms of the decay events actually recorded: counts per minute, or cpm. Counting efficiency is the percentage of decay events actually recorded, as determined, for example, by reference to standards. A counter that is 50% efficient for a given isotope would show a count rate of 1.1×10^5 cpm for a $0.1 \mu\text{Ci}$ sample.

TABLE 12A.1 Some useful isotopes in biochemistry

Isotope	Stable or Radioactive	Emission	Half-Life	Maximum Energy (MeV ^a)
^2H	Stable			
^3H	Radioactive	β	12.1 years	0.018
^{13}C	Stable			
^{14}C	Radioactive	β	5568 years	0.155
^{15}N	Stable			
^{18}O	Stable			
^{24}Na	Radioactive	β (and γ)	15 hours	1.39
^{32}P	Radioactive	β	14.2 days	1.71
^{35}S	Radioactive	β	87 days	0.167
^{45}Ca	Radioactive	β	164 days	0.254
^{59}Fe	Radioactive	β (and γ)	45 days	0.46, 0.27
^{131}I	Radioactive	β (and γ)	8.1 days	0.335, 0.608

^aMeV = million electron volts.

Detection of Radioactivity: The Liquid Scintillation Counter

In scintillation counting, the most widely used method for measuring β -emissions, the sample is dissolved or suspended in an organic solvent, although aqueous mixtures are available as well. Also present are one or two fluorescent organic compounds, or **fluors**. A β -particle emitted from the sample has a high probability of hitting a molecule of the solvent; this contact excites the solvent molecule, driving an electron into a higher-energy orbital. When that electron returns to the ground state, a photon of light is emitted. The photon is absorbed by a molecule of the fluor, which in turn becomes excited. Fluorescence involves the absorption of light at a given energy, followed by emission of that light at lower energy, or longer wavelength. A photomultiplier detects the fluorescence and for each disintegration converts it to an electrical signal, which is recorded and counted.

FIGURE 12A.1

Energy spectra for some β -emitting isotopes. Shown here are spectra for the three β -emitters most widely used in biochemistry— ^3H , ^{14}C , and ^{32}P .

Whereas γ -rays are emitted at distinct and characteristic energy values, a β -emitting isotope will display a range of energy values among its emissions. Each β -emitter shows a characteristic **energy spectrum**—that is, a plot of energy (in millions of electron volts, or MeV) against the probability of an individual emission having that energy. Figure 12A.1 shows the energy spectra for three widely used radioisotopes— ^3H , ^{14}C , and ^{32}P .

These differences in emission energies are exploited in the liquid scintillation counter so that two isotopes in the same sample can be simultaneously quantified (a dual-label experiment). A strong β -emission excites more fluor molecules than a weak emission does, so a brighter light flash is produced. This flash level can be detected by setting electronic discriminators so that energy values falling only within a desired range are recorded—that is, setting a “window” that is optimized for detection of a particular isotope. This restriction reduces counting efficiency because only a fraction of the emissions from the higher-energy isotope are counted, but it does permit great selectivity. Most scintillation counters have three different sets of discriminators, or **counting channels**. Thus, isotopes can be counted simultaneously in three different windows.

Because radioactive decay is a random process, the more counts observed during the analysis of a sample, the more closely the measured radioactivity will approach the true decay rate. In practice, therefore, a researcher wants to count a sample for enough time to accumulate several thousand counts. Also, the researcher must consider the signal-to-noise ratio and design an experiment so that the measured radioactivity of the samples of interest will be many times higher than **background radioactivity**, or the counts recorded in the absence of a radioactive sample.

Some Uses of Radioisotopes in Biochemistry

Radioisotopes have many uses in metabolic investigations. Here we describe a few examples. Tracer experiments can be categorized in terms of the time of exposure of the biological system to the radioisotope and include (1) equilibrium labeling, (2) pulse labeling, and (3) pulse-chase labeling.

In **equilibrium labeling** the exposure to the tracer is relatively long so that each labeled species reaches a constant **specific radioactivity**, or **specific activity**. The specific activity is a measure of the relative abundance of radioactive molecules in a labeled sample and is reported as radioactivity per unit mass—for example, cpm/mol. Experiments to identify metabolic precursors often involve equilibrium labeling conditions. The investigator administers a radiolabeled precursor so as to maximize the chance of detecting label in the product. A good example, mentioned in Chapter 19, is Konrad Bloch’s study of cholesterol biosynthesis, in which ^{14}C -labeled acetate was administered to rats. Bloch then isolated cholesterol from the liver and determined, by chemical degradation, the specific carbon atoms in cholesterol that had incorporated radioactivity.

Another use of equilibrium labeling is to measure rates of biological processes from the rates of labeling by low-molecular-weight precursors. An example is the widespread use of radiolabeled thymidine to follow rates of DNA synthesis, either in cell cultures or in intact organisms. Incorporation of thymidine into macromolecules other than DNA is negligible, so the investigator merely samples the population with time and observes the incorporation into acid-insoluble material. However, this measurement alone does not give the true rate of DNA replication. The investigator must also consider the metabolism of the labeled precursor en route to its ultimate destination. If intracellular metabolism is producing dTTP, that nucleotide will be nonradioactive, and its mixing with the labeled pool will dilute the specific radioactivity incorporated into DNA. The labeling experiment gives only a rate of DNA labeling, in cpm incorporated per cell per unit time. To get a true rate, in molecules incorporated per cell per unit time, the initial result must be divided by the specific activity of the immediate precursor, in this case, dTTP. Calculating that specific activity requires isolation of dTTP in sufficient amount and purity to allow determination of both its mass and radioactivity.

Pulse labeling involves administration of an isotopic precursor for an interval that is short relative to the process under study. Radiolabel accumulates preferentially in the shortest-lived species—that is, the earliest intermediates in a metabolic pathway—because the shorter the labeling interval is, the less time is available for loss of radioactivity from a labeled pool through breakdown of rapidly labeled and short-lived metabolites. Melvin Calvin identified the pathway of photosynthetic carbon fixation by labeling green algae with $^{14}\text{CO}_2$ for just a few seconds. If labeling was carried out for 10 s, a dozen or more radioactive compounds could be detected. After a 5-s pulse of radioactivity, only a single compound was labeled, namely 3-phosphoglycerate. This finding led ultimately to the discovery of ribulose-1,5-bisphosphate carboxylase as the first enzyme in the photosynthetic carbon fixation pathway (see page 695 in Chapter 16).

In a **pulse-chase** experiment, the investigator administers label for a short time (the pulse) and then rapidly reduces the specific activity of the isotopic precursor to prevent further incorporation. This reduction can be done by adding unlabeled precursor at a molar excess of about 1000-fold, which greatly

dilutes the radioisotope still present (the chase). The investigator samples at various times afterward to determine the metabolic fate of the material labeled during the pulse. Messenger RNA was originally detected by pulse-labeling bacterial cultures (see Chapter 27). Traditional analytical methods could not detect mRNA because of its low abundance and its metabolic instability in bacterial cells. When label incorporated into mRNA by a pulse of [^{32}P]orthophosphate or labeled uridine was chased out, the label was ultimately found to be distributed uniformly in all cellular RNA species. This finding showed that the metabolic instability of mRNA involves its degradation to nucleotides, which can then be used for synthesis of other RNA species.

A final application of radioisotopes is **radioautography**, in which the investigator incorporates an isotopic precursor into a biomolecule and prepares an image of the radiolabeled molecule on a sheet of photographic film. Chapter 25 shows several

radioautographs of individual DNA molecules made radioactive by growth of *E. coli* in the presence of [^3H]thymidine. The two-dimensional gel shown in Figure 1.11 (page 19) is a radioautograph because the radiolabeled proteins were detected by their ability to darken photosensitive film. Film radioautography has been largely replaced by **phosphorimaging**, in which the photographic film is replaced by an imaging plate coated with photostimulable phosphors. Phosphorimaging is much more accurate than film radioautography in quantifying the amount of radioactivity in the sample because its response to radioactivity is far more linear than that of X-ray film. Moreover, the imaging plate can be erased and reused indefinitely.

TOOLS OF BIOCHEMISTRY 12B

METABOLOMICS

Virtually all the facts in this textbook came from experiments in which a biochemist measured something in a cell extract: the level of a particular mRNA or protein, the activity of a particular enzyme, or the concentration of a particular metabolite. Indeed, a large part of experimental biochemistry involves the development of specific and sensitive *assays* for a particular cellular component. For example, Hans Krebs's elucidation of the citric acid cycle (see Chapter 14) depended on his ability to accurately measure the concentrations of potential substrates such as pyruvate, citrate, succinate, or oxaloacetate in muscle or liver slices. A specific assay had to be developed to measure each metabolite. To fully analyze a pathway such as the citric acid cycle or glycolysis might require 10 or more separate metabolite assays on each sample. Furthermore, these assays could only measure already known metabolites—they were not very useful for discovering new or missing metabolic intermediates.

In recent years, however, new technologies have made it possible to move beyond the measurement of single mRNAs, single proteins, or single metabolites. The development of these new technologies has driven the “-omics” revolution—genomics, transcriptomics, proteomics, and metabolomics—where hundreds or even thousands of specific components are measured simultaneously in a biological sample. Thus, it is now feasible to measure the full set of transcripts (transcriptome), proteins (proteome), or metabolites (metabolome) in a particular cell or tissue. The metabolome represents the ultimate molecular phenotype of a cell under a given set of conditions because all the changes in gene expression and enzyme activity eventually lead to

changes in cellular metabolite levels (the metabolic state or profile). The metabolic state of a cell or a whole organism is a sensitive indicator of the physiological status of the organism. Changes in metabolic state can be used to understand and diagnose disease, study effects of drugs, and even predict the effectiveness of a drug in a particular patient. There are many analytical approaches to determining the metabolic state of a cell (metabolic profiling), but they all follow the same basic process (Figure 12B.1): sample extraction; metabolite identification and quantitation; and data analysis (informatics).

Metabolic Profiling

Sample Collection and Extraction

Samples of interest are collected—for example drug-treated vs. untreated cells, serum from a patient, or a tissue biopsy from a tumor. The small molecules are extracted from the samples by methods that are matched to the analytical technique to be used. No single method will extract all metabolites from a sample. Different extraction procedures can be used to select specific subsets of the metabolome (e.g., lipophilic metabolites, amino acids, or carbohydrates).

Metabolite Identification and Quantitation

While the number of distinct metabolites in a cell is not known, it is certainly on the order of a few thousand. Therefore, the analytical method must have both a separation component and a detection

Data Analysis (Informatics)

The third critical step in metabolic profiling is data analysis. Because the datasets are generally quite large, and sophisticated statistical methods are required to visualize and compare metabolic profiles, data analysis uses modern informatics tools. These informatics algorithms attempt to identify patterns in the data that are reproducibly characteristic of a particular metabolic state. These patterns, or fingerprints, can then be compared between samples. The most common informatics methods for analyzing and comparing metabolome data are hierarchical clustering (the partitioning of a data set into subsets or clusters) (Figure 12B.1b) and principal component analysis (PCA) (Figure 12B.1c). PCA is used to reduce multidimensional data sets to lower dimensions (principal components). PCA can often reveal the internal

structure of the data in a way which best explains the variance in the data.

Applications

Biomarker Discovery

The identification of new biomarkers to predict or diagnose disease is a major goal of biomedical research. Although there are some useful single molecule biomarkers known, for many diseases a pattern of several metabolites will be a more informative biomarker. The following example illustrates the power of metabolic profiling to discover new biomarkers. Acetaminophen (e.g., Tylenol) is a widely used over-the-counter analgesic. Excess acetaminophen is toxic to the liver because it causes oxidative stress, but individuals vary in their

FIGURE 12B.2

Differential metabolic profile from livers of control mice and livers from mice 2 h after treatment with acetaminophen. The 2D plot (m/z vs. elution time) shows cations detected by CE-MS analysis. The arrow points to the metabolite subsequently identified as ophthalmate whose level significantly increased in treated mice. The color bar indicates the increase (red) or the decrease (blue) of metabolite level after drug treatment.

susceptibility to liver damage. To identify potential biomarkers for the oxidative stress caused by acetaminophen, CE-MS was used to study changes in liver metabolites in mice treated with excess acetaminophen. Metabolic profiling identified 132 compounds, including a new metabolite (ophthalmate) (Figure 12B.2). This compound is not a metabolite of acetaminophen, but its levels rise in response to the drug. This new metabolite may serve as a useful biomarker for acetaminophen-induced hepatotoxicity in humans.

Disease Diagnosis

The incidence of diabetes has increased so rapidly in the United States that it is now considered an epidemic. Today, more than 21 million Americans have diabetes, and it is estimated that 54 million have prediabetes—they have elevated blood sugar levels, but not high enough to be classified as diabetes. Prediabetics are at high risk of developing type 2 diabetes. If detected early enough, diabetes is a manageable disease. Insulin resistance, traditionally defined as the reduced ability of insulin to promote glucose uptake, is a characteristic feature of type 2 diabetes. However, insulin regulates many other metabolic processes, and metabolic profiling can be used to look beyond glucose metabolism. LC-MS has been used to quantify changes in 191 metabolites in human

plasma following glucose ingestion. Eighteen of these were observed to change reproducibly in healthy individuals, reflecting four distinct arms of insulin function (Figure 12B.3). In prediabetic patients, however, a subset of these metabolites showed blunted responses to glucose ingestion, providing a strong indicator of loss of insulin sensitivity. This application of metabolic profiling holds great promise in early diagnosis of diabetes.

Predicting Drug Response

One of the most serious problems with therapeutic drugs is that patients can vary considerably in their response to the drug and in their susceptibility to side effects. For example, the tyrosine kinase inhibitor imatinib is a highly effective drug for treatment of chronic myeloid leukemia (CML). Unfortunately, some patients develop resistance to this drug, and treatment fails. To try to understand the mechanisms underlying this individual variation in drug response, blood plasma metabolites were profiled in CML patients previously determined to be either sensitive or resistant to imatinib. Principal component analysis (PCA) revealed metabolic profiles that differed between those patients who were sensitive to drug treatment from those who were resistant (Figure 12B.4). Thus metabolic profiling can be used to predict whether a drug will be effective in a particular patient.

**FIGURE 12B.4**

Principal component analysis of blood plasma metabolites in chronic myeloid leukemia (CML) patients. 3D scatter plot of the first three principal components (PC1 vs. PC2 vs. PC3). Green squares are patients who are sensitive to drug treatment (SCML). Black diamonds are patients who are resistant to drug treatment (RCML). Red triangles are untreated CML patients (UCML). Blue circles are healthy controls (HC).

CHAPTER 13

Carbohydrate Metabolism: Glycolysis, Gluconeogenesis, Glycogen Metabolism, and the Pentose Phosphate Pathway

Our detailed study of metabolism begins with the anaerobic phases of carbohydrate metabolism (Figure 13.1). Much of this chapter is devoted to glycolysis, the initial pathway in the catabolism of carbohydrates. The term *glycolysis* is derived from Greek words meaning “sweet” and “splitting.” These words are literally correct terms, for glycolysis is the pathway by which six-carbon sugars are split, yielding a three-carbon compound, pyruvate. During glycolysis, some of the potential energy stored in the hexose structure is used to drive the synthesis of ATP from ADP. Glycolysis can proceed under anaerobic conditions, with no net oxidation of the sugar substrates taking place. **Anaerobes**, microorganisms that live in oxygen-free environments, can derive all of their metabolic energy from this process. Indeed, carbohydrate is the only fuel whose catabolism can produce ATP in the absence of oxygen. However, aerobic cells also use glycolysis. In these cells, glycolysis is the initial, anaerobic part of an overall degradation pathway that ultimately involves considerable oxygen consumption and the complete oxidation of carbohydrates to CO_2 and H_2O .

This chapter will also introduce *gluconeogenesis*, the synthesis of glucose from noncarbohydrate precursors, as well as the synthesis of storage polysaccharides, primarily glycogen in animals. We discuss these two energy-requiring biosynthetic processes here because their regulation is so intimately coordinated with that of glycolysis. We will end the chapter with the *pentose phosphate pathway*, a multipurpose pathway that represents an alternative process for the catabolism of glucose.

FIGURE 13.1

Catabolic and anabolic processes in anaerobic carbohydrate metabolism. The gold arrows show the glycolytic pathway and the breakdown of polysaccharides that supply this pathway. Glycolysis generates ATP anaerobically and provides fuel for the aerobic energy-generating pathways. The green arrows show the gluconeogenesis pathway, the synthesis of polysaccharides such as glycogen. The blue arrow shows the pentose phosphate pathway, an alternative carbohydrate oxidation pathway needed for nucleotide synthesis. The numbers 1, 2, and 3 identify the three stages of metabolism (see Chapter 12).

Glycolysis is an appropriate point to begin a detailed study of metabolism, for several reasons. First, it was the earliest metabolic pathway to be understood in detail. Second, the pathway is nearly universal in living cells. Third, the regulation of glycolysis is particularly well understood. Last, but not least, is the central metabolic role this pathway plays in generating both energy and metabolic intermediates for other pathways. It is one of the busiest freeways on the metabolic road map, but it is also connected to many less traveled roads.

Although cells can metabolize a variety of hexose sugars via glycolysis, glucose is the major carbohydrate fuel for many cells. Indeed, some animal tissues, such as brain, normally use glucose as the sole energy source, and all energy generation in such cells begins with glycolysis. Most cells, however, can utilize other sugars, and we shall explore how those sugars are converted to intermediates in glycolysis. In addition, we will consider processes by which stored carbohydrate in the form of polysaccharides is made available for use in glycolysis.

The 10 reactions of glycolysis occur in two phases: energy investment (first five reactions) and energy generation (last five reactions).

Glycolysis: An Overview

Relation of Glycolysis to Other Pathways

Glycolysis is a 10-step pathway that converts one molecule of glucose to two molecules of pyruvate, with the concomitant generation of two molecules of ATP. The breakdown of storage polysaccharides and the metabolism of oligosaccharides yield glucose, related hexoses, and sugar phosphates, all of which find their way into the glycolytic pathway. We will focus initially on the pathway as it begins with glucose and then discuss the routes for entry of other carbohydrates.

The 10 reactions between glucose and pyruvate can be considered as two distinct phases, schematized in Figure 13.2. The first five reactions constitute an **energy investment phase**, in which sugar phosphates are synthesized at the expense of 2 equivalents of ATP (converted to ADP), and the six-carbon substrate is split into 2 three-carbon sugar phosphates. The last five reactions represent an **energy generation phase**, in which the two triose phosphates are converted to energy-rich compounds. These transfer 4 moles of phosphate to ADP, leading to 4 moles of ATP. The net yield, per mole of glucose metabolized, is 2 moles of ATP and 2 moles of pyruvate. Note that 2 reducing equivalents are generated as well, in the form of NADH.

In aerobic organisms, glycolysis is the first step in the complete oxidation of glucose to CO_2 and water. The second step is oxidation of pyruvate to acetyl-CoA, and the final process is oxidation of the acetyl group carbons in the citric acid cycle (see Figure 13.1). Chapter 14 presents the latter processes in detail. Glycolysis also provides biosynthetic intermediates. Thus, glycolysis is both an anabolic and a catabolic pathway, with an importance that extends beyond the synthesis of ATP and substrates for the citric acid cycle.

Anaerobic and Aerobic Glycolysis

Glycolysis is an ancient metabolic pathway that probably evolved before the earliest known photosynthetic organisms began contributing O_2 to the earth's atmosphere. Thus glycolysis had to function initially under anaerobic conditions—with no net change in the oxidation state as substrates are converted to products. Recall from Chapter 12 that oxidation involves the loss of electrons from a substrate, and the electrons are transferred to an electron acceptor, which thereby becomes reduced. However, note in Figure 13.2 that the conversion of glucose to pyruvate, which does oxidize the carbons of glucose, involves the concomitant reduction of 2 equivalents of NAD^+ to NADH. For the pathway to operate anaerobically, NADH must be reoxidized to NAD^+ by transferring its electrons to an **electron acceptor** so that a *steady-state concentration of NAD^+ is maintained*. Some microorganisms growing anaerobically can generate additional energy by transferring the electrons to inorganic substances such as sulfate ion or nitrate ion, and some microorganisms

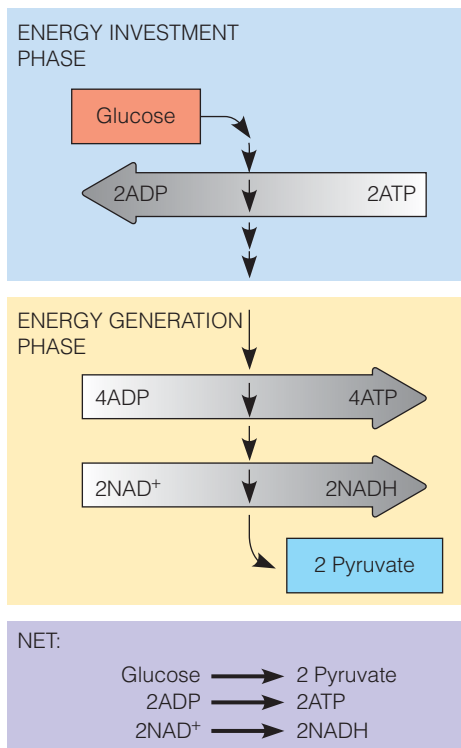

FIGURE 13.2

The two phases of glycolysis and the products of glycolysis.

reduce organic substrates. Most straightforward is the route used by lactic acid bacteria, which simply use NADH to reduce pyruvate to lactate, via the enzyme **lactate dehydrogenase**.

Lactate formation is strongly favored under standard conditions, as indicated by the large negative standard free energy change.

Glycolysis is therefore part of a *fermentation*, which we defined as an energy-yielding metabolic pathway that involves no net change in oxidation state of the carbon substrate (page 487). This **homolactic fermentation** (conversion of all six carbons of glucose to lactate*) is also important in the manufacture of cheese. **Alcoholic fermentation** involves cleavage of pyruvate to acetaldehyde and CO₂ (see page 536), with the acetaldehyde then reduced to ethanol by **alcohol dehydrogenase**:

As carried out by yeasts, this fermentation generates the ethanol in alcoholic beverages. Yeasts used in baking also carry out the alcoholic fermentation; the CO₂ produced by pyruvate decarboxylation causes bread to rise, and the ethanol produced evaporates during baking. Among the dozens of other useful fermentations are those leading to acetic acid (manufacture of vinegar) and propionic acid (manufacture of Swiss cheese). All of these fermentations are simply variations on the same theme: The NADH produced earlier in the pathway must be reoxidized to NAD⁺ by transferring its electrons to some abundant electron acceptor. The simplest way to ensure that there is enough electron acceptor available is for the cell to use the same carbon skeleton that the electrons came from in the first place, that is, pyruvate, or a derivative of pyruvate. Thus, the large diversity of fermentations found in nature are distinguished really only by the final fermentation product. Figure 13.3 illustrates the common strategy used by virtually all fermentations.

Animal cells, like lactic acid bacteria, can reduce pyruvate to lactate, and they do so when pyruvate is produced faster than it can be oxidized through the citric acid cycle. During strenuous exertion, skeletal muscle cells derive most of their energy from **anaerobic glycolysis**—glycolysis occurring under anaerobic conditions.

By contrast, consider a cell undergoing active *respiration*, the oxidative breakdown and release of energy from nutrient molecules by reaction with oxygen. In these cells, pyruvate is oxidized to acetyl-CoA, which enters the citric acid cycle. The NADH produced during glycolysis is reoxidized through the mitochondrial electron transport chain for additional energy production (see Chapter 15), with the electrons transferred ultimately to O₂, the terminal electron acceptor. The conversion of glucose to pyruvate in a respiring cell is called **aerobic glycolysis**.

A fermentation is an energy-yielding metabolic pathway with no net change in the oxidation state of products compared to substrates.

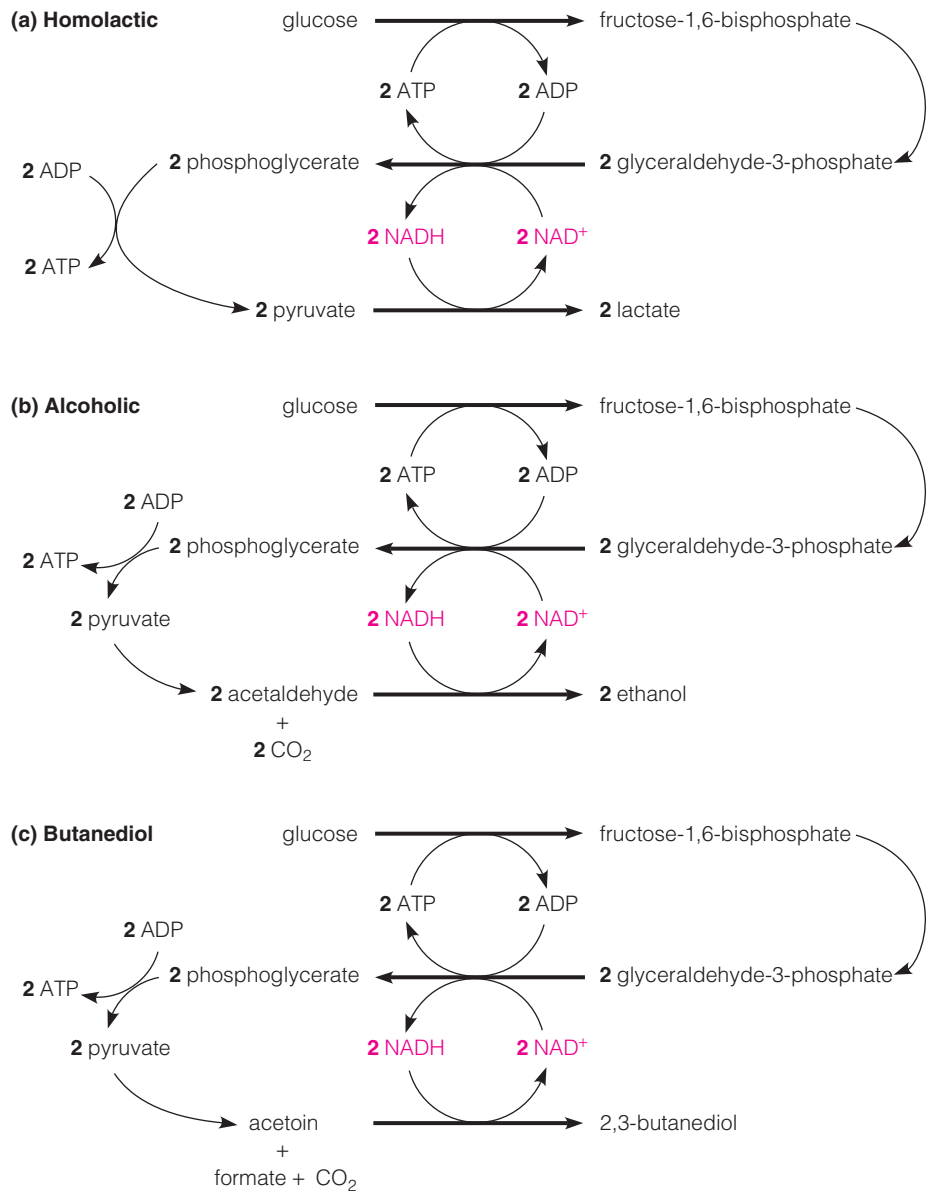

Anaerobic glycolysis (like aerobic glycolysis) leads to pyruvate, but the pyruvate is then reduced, so no net oxidation of glucose occurs.

*Some organisms carry out a **heterolactic fermentation**, in which only one lactate is produced, with the other three carbons converted to one ethanol plus one CO₂.

FIGURE 13.3

Fermentations use a common strategy to regenerate oxidized NAD^+ . (a) Homolactic (b) Alcoholic (c) Butanediol.

The Crucial Early Experiments

For as long as humans have used yeasts in baking and in brewing, fermentation has been exploited, even though the biochemical process was not understood until the last century. (The early definition of *fermentation* was “a chemical change with effervescence.”) Louis Pasteur’s demonstration in 1856 that fermentations are carried out by microorganisms ranks as a milestone in the history of science. The dominant viewpoint of the time was that a process such as the fermentation of glucose to ethanol was so complex that it could not be reconstituted outside a living cell. As we saw in Chapter 1, however, Eduard and Hans Büchner showed in 1897 that fermentation could occur under cell-free conditions.

In 1905 Arthur Harden and William Young found that inorganic phosphate, when added to yeast extract, stimulated and prolonged the fermentation of glucose. During fermentation the inorganic phosphate disappeared from the reaction medium, which led Harden and Young to suggest that fermentation was functioning via the formation of one or more sugar phosphate esters.

This observation opened the door to dissection of the individual chemical reactions involved in fermentation, a feat accomplished in Germany in the 1930s, largely by G. Embden, O. Meyerhof, Jacob Parnas, and O. Warburg. In fact, glycolysis is

often referred to as the **Embden–Meyerhof–Parnas pathway**. These scientists identified 10 different reactions, virtually identical in a wide range of organisms, leading from glucose to pyruvate. Glycolysis is the first metabolic pathway to have been elucidated as a series of defined chemical reactions. Extensive information is now available about the structure and mechanism of action of each enzyme involved.

Strategy of Glycolysis

Glycolysis is such an important pathway that we shall examine each of its 10 reactions in some detail. Before doing so, let us look at the pathway as a whole. First, recall from Chapter 12 that in eukaryotic cells glycolysis occurs in the cytosol, and the further oxidation of pyruvate occurs in mitochondria. (Certain trypanosomes, the parasitic protozoans that cause African sleeping sickness, present an interesting exception. They carry out the first seven reactions of glycolysis in an organized cytoplasmic organelle called the **glycosome**.)

The chemical strategy of glycolysis can be condensed into three processes:

1. Add phosphoryl groups to glucose, yielding compounds with low phosphate group–transfer potential = priming.
2. Chemically convert these low phosphate group–transfer potential intermediates into compounds with high phosphate group–transfer potential.
3. Chemically couple the energy–yielding hydrolysis of these high phosphate group–transfer potential compounds to the synthesis of ATP by transfer of the phosphate group to ADP.

Figure 13.4 presents an abbreviated look at the conversion of glucose to pyruvate. In the energy investment phase (the first five reactions), the sugar is metabolically activated by phosphorylation. This priming process yields a six-carbon doubly phosphorylated sugar, **fructose-1,6-bisphosphate**, which undergoes cleavage to yield 2 equivalents of triose phosphate: **glyceraldehyde-3-phosphate** and **dihydroxyacetone phosphate**. Both of these compounds have a lower phosphate transfer potential than that of ATP.

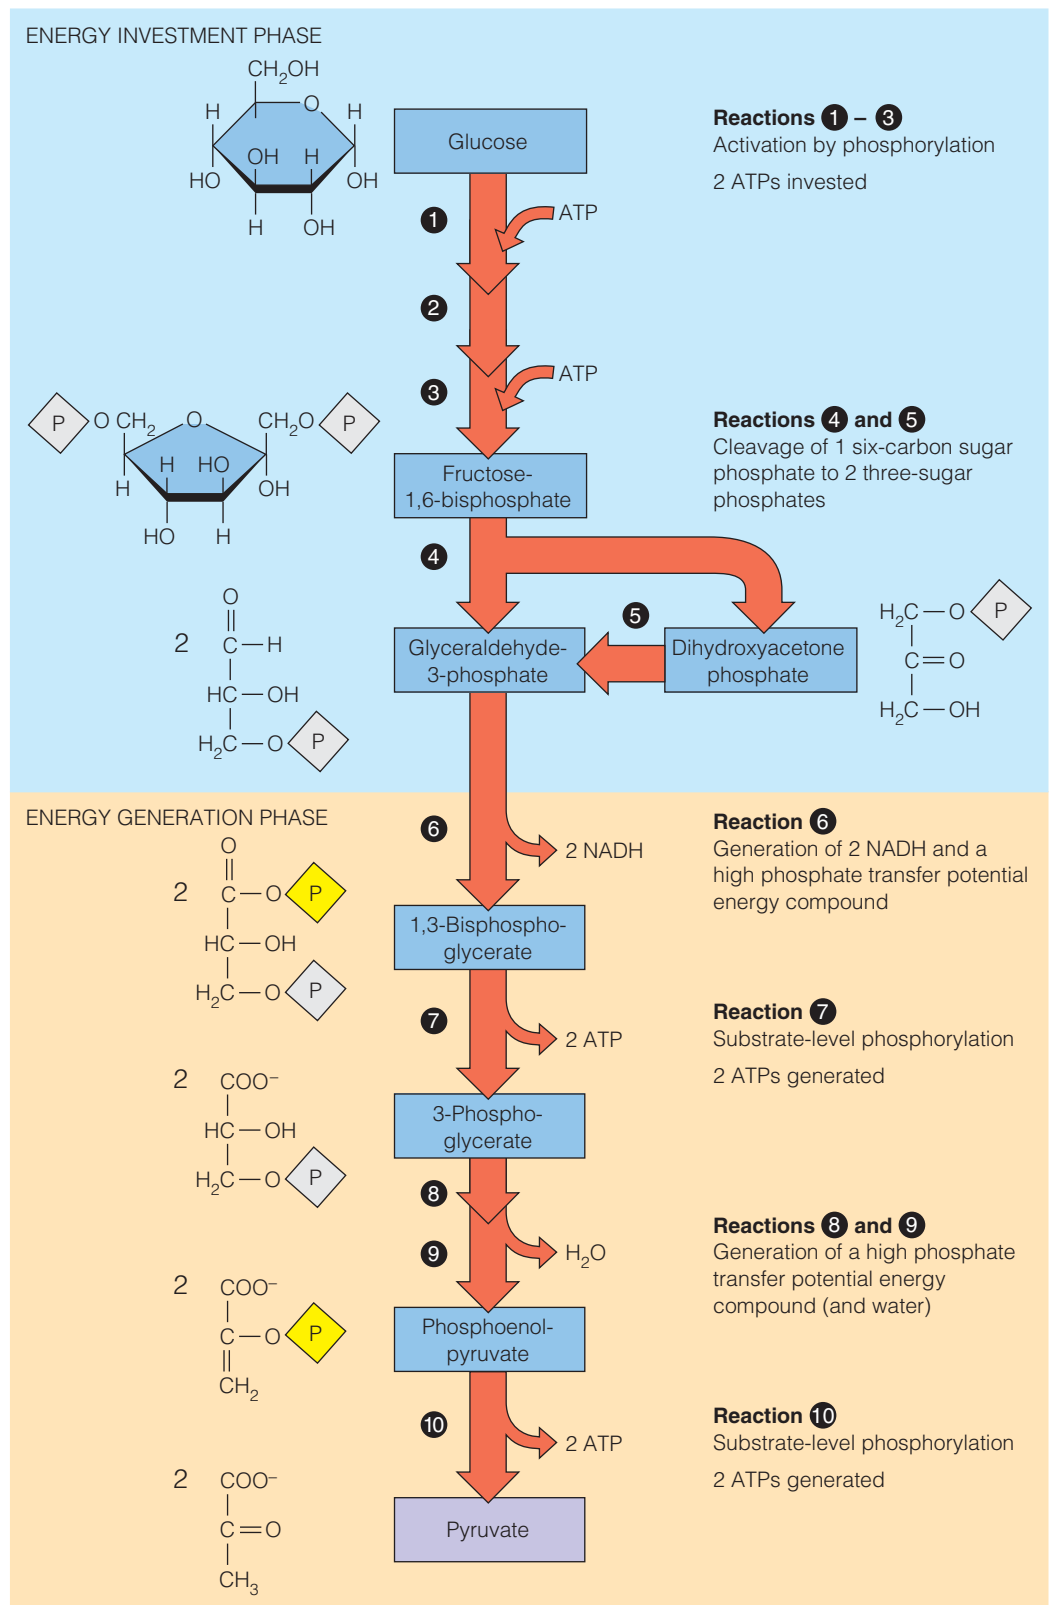

In the energy generation phase (reactions 6 through 10), the triose phosphates undergo further activation to yield two compounds containing high phosphate transfer potential—first **1,3-bisphosphoglycerate** and then **phosphoenolpyruvate**. Recall from Figure 3.7 (page 76) that each of these compounds has a higher ΔG^{or} of hydrolysis than ATP. The energy used to boost the phosphate transfer potential of these compounds comes from oxidation reactions. During the energy generation phase, the high phosphate transfer potential of these compounds drives the phosphorylation of ADP, yielding ATP. This process is called **substrate-level phosphorylation**—the direct transfer of a phosphoryl group from a donor compound to ADP, yielding ATP. Substrate-level phosphorylation is distinguished from **oxidative phosphorylation**, the indirect synthesis of ATP driven by the transmembrane gradient of hydrogen ion concentration (the **protonmotive force**, see Chapter 15), and **photophosphorylation**, the utilization of photosynthetic light energy to generate a protonmotive force that drives ATP synthesis (see Chapter 16).

Because 2 moles of triose phosphate are metabolized per mole of glucose, the yield from the two substrate-level phosphorylations of glycolysis is 4 moles of ATP per mole of glucose. Subtracting the 2 moles of ATP invested in the first, priming phase (reactions 1–5), we see a net gain of two ATP molecules synthesized per molecule of glucose converted to pyruvate (see Figures 13.2 and 13.3).

ATP is synthesized by three major routes—substrate-level phosphorylation, oxidative phosphorylation, and photophosphorylation.

Reactions of Glycolysis

Now let us consider in sequence the 10 reactions leading from glucose to pyruvate, numbering each reaction as indicated in Figure 13.4. The complete names of substrates and products are given when each reaction is presented, but in the text

**FIGURE 13.4**

An overview of glycolysis. This condensed view of glycolysis shows the key intermediates and reactions in each of the two major phases. In the energy-generating phase, two ATPs are produced for each ATP utilized in the energy-investment phase. Here and elsewhere, the phosphate groups of high phosphate transfer potential compounds are highlighted in yellow.

these names are shortened for simplicity. Thus, glucose-6-phosphate is the same as α -D-glucose-6-phosphate.

Reactions 1–5: The Energy Investment Phase

The first five reactions, which constitute the energy investment phase, are summarized in the margin.

Reaction 1: The First ATP Investment

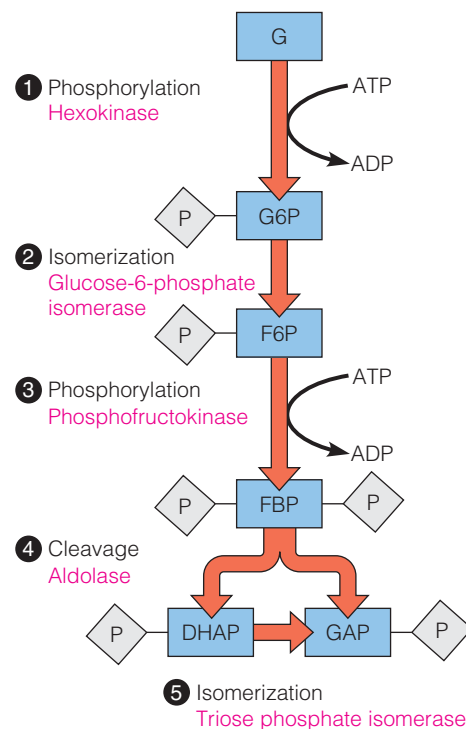

We begin with the ATP-dependent phosphorylation of glucose, catalyzed by **hexokinase**. (To simplify the ring structures used throughout this and subsequent chapters, hydrogens have been omitted. An empty vertical bond in a furanose or pyranose ring implies an H.)

The reaction involves a nucleophilic attack of the C6—OH of glucose on the electrophilic γ -phosphate of ATP. Magnesium ion is required because the reactive form of ATP is its chelated complex with Mg^{2+} (see page 496). This is true for virtually all ATP-requiring enzymes. Mg^{2+} partially neutralizes the negative charges on the oxygen atoms, making $\text{Mg}^{2+} \cdot \text{ATP}$ more susceptible to nucleophilic attack, that is, making it a better electrophile. Hexokinase exists in various forms in different organisms but is generally characterized by broad specificity for sugars and low K_M for the sugar substrate (0.01 to 0.1 mM). The broad specificity allows phosphorylation of various hexose sugars, including fructose and mannose, leading to their utilization via glycolysis. The low K_M allows glycolysis to proceed even when the blood glucose concentration is in the lowest part of its normal range (4 mM or less; see margin). As noted in Chapter 11, hexokinase is inhibited by its product, glucose-6-phosphate, a mechanism that controls the influx of substrates into the glycolytic pathway. Besides serving the priming function, phosphorylation of glucose aids in its retention in the cell—phosphorylated compounds cross the plasma membrane very poorly. Recall also that the structure of hexokinase provides striking evidence for the induced fit model of enzyme catalysis (see page 419).

Mammals possess several molecular forms of hexokinase. Different molecular forms of an enzyme catalyzing the same reaction are called **isoenzymes**, **isozymes**, or **isoforms**. Most tissues express hexokinase I, II, or III, all low K_M enzymes. Because intracellular glucose levels (2–15 mM) are usually far higher than the K_M value for hexokinase, the enzyme often functions *in vivo* at saturating substrate concentrations. Vertebrate liver expresses a distinctive isozyme, hexokinase IV, characterized by a much lower affinity for glucose, and an insensitivity to inhibition by physiological concentrations of glucose-6-phosphate. More important, hexokinase IV exhibits a sigmoidal concentration dependence on glucose (see margin), requiring 5–10 mM glucose for half-saturation. This special hexokinase isozyme, previously called glucokinase, allows the liver to adjust its rate of glucose utilization in response to variations in blood glucose levels. In fact, as discussed in Chapter 18, a major role of liver is to regulate blood glucose levels, and this enzyme represents one of the principal mechanisms by which it does so.

Although most bacteria contain a hexokinase, the usual route for glucose uptake and phosphorylation is the phosphoenolpyruvate:glucose phosphotransferase system. This system, introduced in Chapter 10 as an example of transport by modification

A low affinity isozyme of hexokinase in liver with a sigmoidal dependence on glucose concentration permits that organ to adjust glucose utilization to glucose supply at high blood glucose levels.

(page 395), couples the phosphorylation of glucose to its translocation across the cytoplasmic membrane. The energy to drive these two coupled processes is provided by phosphoenolpyruvate (PEP), one of the high energy compounds produced in the energy generation phase of glycolysis. The phosphoenolpyruvate:glucose phosphotransferase system catalyzes the following overall process:

Glucose-6-phosphate, now in the cytoplasm, directly enters glycolysis at reaction 2. Bacteria possess a parallel set of phosphotransferase systems to allow transport and phosphorylation of numerous monosaccharides, disaccharides, and other sugar derivatives.

Reaction 2: Isomerization of Glucose-6-phosphate

The next reaction, catalyzed by **glucose-6-phosphate isomerase** (also called phosphoglucosomerase), is the readily reversible isomerization of the aldose, glucose-6-phosphate (G6P), to the corresponding ketose, **fructose-6-phosphate** (F6P).

This reaction proceeds via an enediolate intermediate: B: and B-H represent active-site amino acid residues acting as bases and acids, respectively.

Transferring the carbonyl oxygen from carbon 1 to carbon 2 has two important effects. The hydroxyl group generated at carbon 1 can be readily phosphorylated in the reaction 3. It also sets up the sugar for a symmetric aldol cleavage in reaction 4. We shall encounter other aldose–ketose isomerizations that proceed by a similar mechanism.

Reaction 3: The Second Investment of ATP

In reaction 3, **phosphofructokinase** catalyzes a second ATP-dependent phosphorylation, to give a hexose derivative, fructose-1,6-bisphosphate (FBP), phosphorylated at both carbons 1 and 6.

The reaction involves the same chemistry we saw in step 1—nucleophilic substitution. Here, however, the C1—OH of fructose-6-phosphate is the nucleophile that attacks the electrophilic γ -phosphate of ATP. Like phosphorylation at the 6 position, this reaction is sufficiently exergonic to be essentially irreversible *in vivo*. Irreversibility is important because phosphofructokinase (PFK) represents the primary site for regulation of the flow of carbon through glycolysis. PFK is an allosteric enzyme whose activity is acutely sensitive to the energy status of the cell, as well as to the levels of various other intermediates, particularly citrate and fatty acids. Interactions with allosteric effectors, which are discussed later in this chapter, activate or inhibit PFK. This allosteric regulation increases carbon flux through glycolysis when there is a need to generate more ATP and inhibits it when the cell contains ample stores of ATP or oxidizable substrates.

Higher plants and a number of prokaryotes contain two different PFKs—the ATP-dependent enzyme and a unique form, which uses pyrophosphate (PP_i) instead of ATP as the phosphorylating agent.

Whereas phosphorylation of fructose-6-phosphate by the ATP-dependent PFK is virtually irreversible *in vivo*, the pyrophosphate-dependent enzyme catalyzes a near-equilibrium reversible reaction. The pyrophosphate-dependent enzyme has been proposed to be involved in adaptation of plants to nonoptimal conditions, such as phosphate deficiency or low oxygen stress.

Reaction 4: Cleavage to Two Triose Phosphates

Reaction 4 is catalyzed by **fructose-1,6-bisphosphate aldolase**, usually called **aldolase**, because its reaction is similar to the reverse of an aldol condensation. In this reaction the “splitting of sugar” that is connoted by the term *glycolysis* occurs because the six-carbon compound fructose-1,6-bisphosphate is cleaved to give 2 three-carbon intermediates, glyceraldehyde-3-phosphate and dihydroxyacetone phosphate (DHAP).

This reaction illustrates an important metabolic principle. Note that the reaction is strongly endergonic under standard conditions, such that formation of fructose-1,6-bisphosphate is highly favored. However, from the actual intracellular concentrations of the reactant and products, as determined in rabbit skeletal muscle, a ΔG of -1.3 kJ/mol is calculated, consistent with the observation that the reaction proceeds as written *in vivo*. As was emphasized in Chapter 3, this example illustrates the importance of considering conditions *in the cell* (ΔG), rather than standard state conditions ($\Delta G^{\circ'}$) in deciding which direction of a reaction is favored.

Aldolase from most vertebrate sources is a tetrameric protein. The enzyme activates the substrate for cleavage by nucleophilic attack on the keto carbon at position 2 with a lysine ϵ -amino group in the active site, as shown in Figure 13.5.

The phosphofructokinase reaction is the primary step at which glycolysis is regulated.

Aldolase cleaves fructose-1,6-bisphosphate under intracellular conditions, even though the equilibrium lies far toward fructose-1,6-bisphosphate under standard conditions.

FIGURE 13.5

Reaction mechanism for fructose-1,6-bisphosphate aldolase. The figure shows the protonated Schiff base intermediate (iminium ion) between the substrate and an active site lysine residue. An aspartate residue facilitates the reaction via general acid–base catalysis. See text for details.

This is facilitated by protonation of the carbonyl oxygen by an active site acid (aspartate) (step 1). The resulting carbinolamine undergoes dehydration to give a protonated **Schiff base** (iminium ion) (step 2). A Schiff base is a nucleophilic addition product between an amino group and a carbonyl group. A retro-aldol reaction then cleaves the protonated Schiff base into an enamine plus glyceraldehyde-3-phosphate (step 3). The enamine is protonated to give another iminium ion (protonated Schiff base) (step 4), which is then hydrolyzed off the enzyme to give the second product, DHAP (step 5).

The advantage of the Schiff base intermediate derives from its ability to delocalize electrons. The positively charged iminium ion is thus a better electron acceptor than a ketone carbonyl, facilitating retro-aldol reactions like this one and, as we shall see, many other biological conversions. This mechanism also reveals the importance of the earlier glucose-6-phosphate isomerase reaction in setting the symmetry of the aldolase reaction. If glucose had not been isomerized to fructose (moving the carbonyl to C-2 instead of C-1), the aldolase reaction would have given two- and four-carbon fragments, instead of the metabolically equivalent three-carbon fragments.

Reaction 5: Isomerization of Dihydroxyacetone Phosphate

As noted above, the symmetrical aldolase reaction yields 2 three-carbon sugar phosphates. The function of reaction 5, catalyzed by **triose phosphate isomerase**, is conversion of one of these products, dihydroxyacetone phosphate (DHAP), to the other, glyceraldehyde-3-phosphate (GAP). Because GAP is the substrate for the next glycolytic reaction, this reaction permits use of all six carbon atoms of

glucose: C-1 and C-6 of glucose become C-3 of glyceraldehyde-3-phosphate; C-2 and C-5 become C-2; and C-3 and C-4 become C-1 of glyceraldehyde-3-phosphate.

This reaction is also weakly endergonic under standard conditions, but the intracellular concentration of glyceraldehyde-3-phosphate is low (because it is consumed in subsequent reactions), drawing the reaction toward the right. The isomerization of dihydroxyacetone phosphate proceeds via an enediol intermediate.

At this point, glycolysis has expended two ATP molecules and converted one hexose sugar to two molecules of glyceraldehyde-3-phosphate, each of which will next be metabolized to give compounds with high phosphate transfer potential that can drive the synthesis of ATP. The energy investment phase of the cycle is complete, and the energy generation phase is about to begin.

Reactions 6–10: The Energy Generation Phase

The five reactions of the energy generation phase are summarized in the margin.

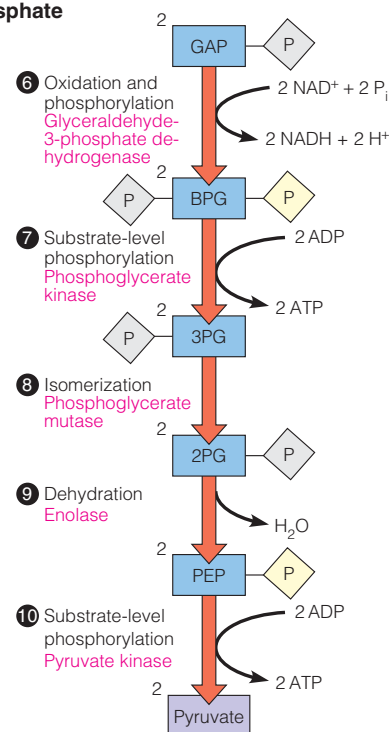

Reaction 6: Generation of the First Energy-Rich Compound

This reaction, catalyzed by **glyceraldehyde-3-phosphate dehydrogenase**, is among the most important in glycolysis, partly because it generates the first intermediate with high phosphate transfer potential and partly because it generates a pair of reducing equivalents (see Figure 13.6). The overall reaction is as follows:

Reaction 6 involves a two-electron oxidation of the carbonyl carbon of glyceraldehyde-3-phosphate to the carboxyl level, a reaction that is normally quite exergonic. However, the overall reaction is slightly *endergonic* (under *standard* conditions) because the enzyme utilizes most of the energy released by the oxidation to drive the synthesis of a compound with high phosphate transfer potential, 1,3-bisphosphoglycerate (BPG). This compound contains a carboxylic–phosphoric acid mixed anhydride, or an **acyl-phosphate group**, at position 1, a functional group with a very high standard free energy of hydrolysis, -49.4 kJ/mol . This enzyme also requires a coenzyme, NAD^+ , to accept electrons from the substrate being oxidized.

Because the acyl-phosphate group is much more energy rich than the phosphate anhydride of ATP, 1,3-bisphosphoglycerate can drive the synthesis of ATP

Glyceraldehyde-3-phosphate dehydrogenase creates a high-energy compound and generates a pair of reducing equivalents.

FIGURE 13.6

Reaction mechanism for glyceraldehyde-3-phosphate dehydrogenase. **Step 1:** Formation of the initial thiohemiacetal intermediate between glyceraldehyde-3-phosphate and the enzyme. **Step 2:** Oxidation of the initial intermediate by NAD^+ to give an acyl-thioester enzyme intermediate.

Steps 3, 4: Phosphorolytic cleavage of the thioester bond in the acyl-enzyme intermediate. B: represents an active site histidine acting as a general base.

from ADP. Indeed, it does so in the next reaction in the sequence, the first of two substrate-level phosphorylations in glycolysis. Because of the importance of understanding how ATP is synthesized, much attention has focused on understanding how the high phosphate transfer potential compounds in substrate-level phosphorylation are synthesized.

For glyceraldehyde-3-phosphate dehydrogenase, that understanding derived in large part from an old observation that glycolysis is inhibited by iodoacetate and by heavy metals such as mercury. Both compounds react with free sulfhydryl groups, as the following shows for iodoacetate:

The finding that these compounds inhibit glycolysis specifically by inhibition of glyceraldehyde-3-phosphate dehydrogenase strongly implied that the enzyme contains one or more essential thiol groups. We now know that the reaction proceeds as outlined in Figure 13.6, starting with formation of a **thiohemiacetal** group involving the substrate carbonyl group and a cysteine thiol group on the enzyme. The thiohemiacetal is next oxidized by NAD^+ to give an acyl-enzyme intermediate, or thioester. Thioesters are high-energy compounds (see Figure 14.8, page 601); cleavage of this thioester by P_i preserves much of the energy as the acyl phosphate, which is the product.

This mechanism conserves the energy of oxidation by coupling an exergonic reaction to an endergonic reaction:

The reaction is slightly endergonic under standard conditions. However, the intracellular level of 3-phosphoglycerate is high relative to that of 2-phosphoglycerate (2PG), so that in vivo the reaction proceeds to the right without difficulty. The enzyme contains a phosphohistidine residue in the active site. In the first step of the reaction, the phosphate is transferred from the enzyme to the substrate to give an intermediate, 2,3-bisphosphoglycerate. Transfer of the phosphate from C-3 to the active site of the enzyme regenerates the phosphorylated enzyme and forms the product, which is released.

Moving the phosphate from the 3 position to the 2 position sets up the next energy-conserving step in glycolysis, again by conversion of a compound with low phosphate transfer potential to one with very high phosphate transfer potential.

Reaction 9: Synthesis of the Second High-Energy Compound

Reaction 9, catalyzed by **enolase**, generates phosphoenolpyruvate (PEP), another compound with very high phosphate transfer potential. PEP participates in the second substrate-level phosphorylation of glycolysis.

Like most β -hydroxy carbonyl compounds, 2-phosphoglycerate is readily dehydrated via an α,β -elimination reaction. An active site Lys, acting as a general base, abstracts a proton from C-2 (α carbon) of 2PG, generating a carbanionic intermediate. An active site Glu facilitates the elimination, protonating the leaving group (OH^-) by general acid catalysis. Product formation is also favored by the stability of the conjugated double bond system in PEP. Enolase requires two Mg^{2+} ions, which neutralize the negative charges on the substrate and lower the $\text{p}K_a$ of the C-2 proton, making it easier to abstract. Despite its small overall free energy change, this seemingly simple transformation increases enormously the standard free energy of hydrolysis of the phosphate bond—from -15.6 kJ/mol for 2-phosphoglycerate to -61.9 kJ/mol for phosphoenolpyruvate. Phosphorylation of the C2—OH prevents the otherwise highly favorable tautomerization to the keto form. When the phosphate is transferred to ADP, the enol to keto tautomerization can take place, driving the reaction forward. As discussed in Chapter 3 (page 79), the great thermodynamic instability of enolpyruvate is chiefly responsible for the large negative free energy of hydrolysis of phosphoenolpyruvate.

Reaction 10: The Second Substrate-Level Phosphorylation

In the last reaction, catalyzed by **pyruvate kinase**, phosphoenolpyruvate transfers its phosphoryl group to ADP in another substrate-level phosphorylation. Note that the enzyme is named as if it were acting leftward in the reaction shown below, even though it is strongly exergonic in the rightward direction. Many enzymes were named before the function or direction of intracellular catalysis had been identified.

Phosphoenolpyruvate

Pyruvate

The enzyme requires Mg^{2+} and K^+ . Even though the reaction involves the endergonic synthesis of ATP, the overall reaction is strongly exergonic because, as noted in Chapter 3, the spontaneous tautomerization of the product, enolpyruvate, to the highly favored keto form provides a strong thermodynamic drive ($\Delta G^{\circ'} = -46 \text{ kJ/mol}$) in the forward direction.

The pyruvate kinase (PK) reaction is another site for metabolic regulation. PK, like many enzymes, exists in animal tissues as multiple isozymes. Mammals carry two paralogous pyruvate kinase genes, which, through alternative splicing, produce four different PK isozymes. As we will see in Chapter 27, alternative splicing is a common mechanism used by eukaryotes to greatly expand the number of different protein products produced from a single gene. The PK-L and PK-R isozymes, both encoded by the *PKLR* gene, are expressed specifically in liver and red blood cells, respectively. The M1 and M2 isozymes are encoded by the *PKM2* gene. PK-M1 is expressed in muscle and brain and other terminally differentiated tissues. PK-M2 is expressed during embryonic development, but also in tumor cells, where it appears to confer a selective proliferation advantage to the tumor cells—more about this later. All four PK isozymes are homotetramers of ~60 kDa subunits, and except for the M1 isozyme, require allosteric activation by fructose-1,6-bisphosphate for full activity. The L and R isozymes are allosterically inhibited at high ATP concentrations. The M1 isozyme, on the other hand, is constitutively active. On top of these allosteric mechanisms, the synthesis of the liver enzyme is also under dietary control; intracellular activity may increase as much as 10-fold from increased enzyme synthesis, or induction, as a result of high carbohydrate ingestion.

The liver pyruvate kinase isozyme (PK-L) is also regulated by phosphorylation and dephosphorylation. The dephosphorylated form is far more active than the phosphorylated form. Phosphorylation, which is under hormonal control, diverts phosphoenolpyruvate to gluconeogenesis (see below) when fatty acid oxidation and the citric acid cycle are already operating at rates sufficient to meet the energy needs of the cell. By contrast, virtually all of the phosphoenolpyruvate produced in muscle is converted to pyruvate.

Human genetic deficiencies of erythrocyte pyruvate kinase (PK-R) reveal an interesting link between glycolysis and hemoglobin function. Accumulation of phosphoenolpyruvate leads to excessive levels in blood of other glycolytic intermediates and three-carbon metabolites, including 2,3-bisphosphoglycerate (2,3-BPG). 2,3-BPG was introduced in Chapter 7 as an allosteric inhibitor of oxygen binding to hemoglobin, and its accumulation leads to decreased affinity of hemoglobin for oxygen in PK-R-deficient patients. However, the anemia associated

Pyruvate kinase catalyzes the second glycolytic reaction that forms ATP.

Dietary carbohydrate induces the biosynthesis of pyruvate kinase and increases the ability of the body to obtain energy from glycolysis.

TABLE 13.1 Summary of glycolysis

Reaction	Enzyme	ATP yield	$\Delta G^{\circ'}$	ΔG
Glucose (G) ↓ ATP ① ↓ ADP Glucose-6-phosphate (G6P)	HK	-1	-16.7	-33.5
Glucose-6-phosphate (G6P) ↓ ② Fructose-6-phosphate (F6P)	PGI		+1.7	-2.5
Fructose-6-phosphate (F6P) ↓ ATP ③ ↓ ADP Fructose-1,6-bisphosphate (FBP)	PFK	-1	-14.2	-22.2
Fructose-1,6-bisphosphate (FBP) ↓ ④ Glyceraldehyde-3-phosphate (GAP) + dihydroxyacetone phosphate (DHAP)	ALD		+23.9	-1.3
Glyceraldehyde-3-phosphate (GAP) + dihydroxyacetone phosphate (DHAP) ↓ ⑤ Two glyceraldehyde-3-phosphate (GAP)	TPI		+7.6	~0
Two glyceraldehyde-3-phosphate (GAP) ↓ NAD ⁺ + P _i ⑥ ↓ NADH + 2H ⁺ 1,3-Bisphosphoglycerate (BPG)	GAPDH		+6.3 (+12.6)	-1.7 (-3.4)
1,3-Bisphosphoglycerate (BPG) ↓ ADP ⑦ ↓ ATP 3-Phosphoglycerate (3PG)	PGK	+1 (+2)	-18.8 (-37.6)	~0
3-Phosphoglycerate (3PG) ↓ ⑧ 2-Phosphoglycerate (2PG)	PGM		+4.4 (+8.8)	~0
2-Phosphoglycerate (2PG) ↓ ⑨ ↓ H ₂ O Phosphoenolpyruvate (PEP)	ENO		-3.2 (-6.4)	-3.3 (-6.6)
Phosphoenolpyruvate (PEP) ↓ ADP ⑩ ↓ ATP Pyruvate (Pyr)	PK	+1 (+2)	-31.4 (-62.8)	-16.7 (-33.4)
Net: Glucose + 2ADP + 2P _i + 2NAD ⁺ → 2 pyruvate + 2ATP + 2NADH + 2H ⁺ + 2H ₂ O		+2	-83.1	-102.9

Note: $\Delta G^{\circ'}$ and ΔG values in kJ/mol. The values in parentheses are based on doubling all the reactions past reaction 5, since the energy generation phase involves 2 three-carbon substrates per glucose molecule. ΔG values are estimated from the approximate intracellular concentrations of glycolytic intermediates in rabbit skeletal muscle.

with this enzyme deficiency is generally well tolerated because reduced O_2 binding in the lungs is compensated by increased O_2 release in the tissues (see Figures 7.10 and 7.24).

The pyruvate kinase reaction converts the overall glycolytic pathway from an energy-neutral process to one that involves net synthesis of ATP. Two high-energy phosphates (i.e., ATP) per hexose are generated here, to go with the two generated by phosphoglycerate kinase (see Figure 13.3). Subtracting the two ATPs invested at hexokinase and phosphofructokinase gives a net yield of 2 moles of high-energy phosphates per mole of glucose—not a high yield, to be sure, but the process is fast and can meet the energy requirements of many anaerobes. Moreover, subsequent metabolism of pyruvate through aerobic pathways generates much additional high-energy phosphate.

Table 13.1 summarizes the reactions of glycolysis, showing free energy changes and ATP yields at each step. Note the difference between standard (ΔG°) and estimated (ΔG) Gibbs free energy changes, and the three values in red—we will discuss the importance of these shortly.

Metabolic Fates of Pyruvate

Pyruvate represents a central metabolic branch point. Its fate depends crucially on the oxidation state of the cell, which is related to the reaction catalyzed by glyceraldehyde-3-phosphate dehydrogenase (reaction 6). Recall that this reaction converts 1 mole of NAD^+ per mole of triose phosphate to NADH. The cytoplasm has a finite supply of NAD^+ , so *this NADH must be reoxidized to NAD^+* for glycolysis to continue. During aerobic glycolysis, as noted earlier, this NADH is oxidized by the mitochondrial electron transport chain, with the electrons transferred ultimately to molecular oxygen. This oxidation of NADH, which we consider in detail in Chapter 15, yields additional energy, with about 2.5 moles of ATP synthesized from ADP per mole of NADH oxidized. Because 2 moles of NADH are produced per mole of glucose entering the pathway, aerobic glycolysis yields considerably more ATP than anaerobic glycolysis. In addition, the oxidation of pyruvate through the citric acid cycle generates much more energy, via respiration.

Lactate Metabolism

In aerobic cells that are undergoing very high rates of glycolysis, the NADH generated in glycolysis cannot all be reoxidized at comparable rates in the mitochondrion. In such cases, or in anaerobic cells, which lack mitochondria, NADH must be used to drive the reduction of an organic substrate in order to maintain redox homeostasis. As noted earlier, that substrate is pyruvate itself, both in eukaryotic cells and in lactic acid bacteria, and the product is lactate. The enzyme catalyzing this reaction is lactate dehydrogenase (see page 521). The equilibrium for this reaction lies far toward lactate. As illustrated in Figure 13.3a, the NADH produced in the oxidation of glyceraldehyde-3-phosphate is used to reduce pyruvate to lactate. Thus, during anaerobic glycolysis, an overall electron balance is maintained.

Even in aerobic vertebrates, some tissues such as red blood cells derive most of their energy from anaerobic metabolism. Skeletal muscle, which derives most of its energy from respiration when at rest, relies heavily on anaerobic glycolysis during exertion, when glycogen stores are rapidly broken down, or mobilized, to provide glucose for glycolysis. Normally the lactate produced diffuses from the tissue and is transported through the bloodstream to highly aerobic tissues, such as heart and liver. The aerobic tissue can catabolize lactate further, through respiration, or can convert it back to glucose, through gluconeogenesis. However, if lactate is produced in large quantities, it cannot be readily consumed. Then, as we

Pyruvate must be reduced to lactate when tissues are insufficiently aerobic to oxidize all of the NADH formed in glycolysis.

FIGURE 13.7

Structural basis for the existence of isozymes of lactate dehydrogenase. Preparations were subjected to electrophoresis in a starch gel, which was then treated to reveal bands containing enzymatically active protein. LDH-1 is a tetramer containing only the H subunit, whereas LDH-5 contains only M subunits. The middle lane depicts an experiment in which equal amounts of LDH-1 and LDH-5 were mixed. The subunits were dissociated and then allowed to reassociate. The presence of five different enzyme forms and their relative amounts show that individual M and H subunits can associate randomly to form tetramers of mixed-subunit composition.
