Until recently it was thought that lactate accumulation in skeletal muscle was largely a consequence of anaerobic metabolism, which occurs when the need for tissues to generate energy exceeds their capacity to oxidize the pyruvate produced in glycolysis. Metabolic studies, including ^{31}P NMR analyses of the levels of phosphorylated intermediates in living muscle cells during exercise, suggest that lactate is actually an intermediate and not a metabolic “dead end,” whose only fate is reconversion to pyruvate. These studies show that even in fully oxygenated muscle tissue, lactate is formed and utilized continuously. Lactate is actively oxidized by skeletal muscle mitochondria, and during exercise oxidation can account for up to 75% of lactate removal, with the remainder being used for gluconeogenesis.

Isozymes of Lactate Dehydrogenase

Lactate dehydrogenase was the first enzyme that established the structural basis for the existence of isozymes. Most tissues contain five isozymes of lactate dehydrogenase. They can be resolved electrophoretically, as shown in Figure 13.7.

Lactate dehydrogenase (LDH) is a tetrameric protein consisting of two types of subunits, called M and H, which have small differences in amino acid sequence. M subunits predominate in skeletal muscle and liver, and H subunits predominate in heart. M and H subunits combine randomly with each other, so that the five major isozymes have the compositions M_4 , M_3H , M_2H_2 , MH_3 , and H_4 . Because of random subunit reassembly, the isozymic composition of a tissue is determined primarily by the expression levels of the genes specifying the two subunits.

The physiological need for the existence of different forms of this enzyme is not yet clear. However, the tissue specificity of isozyme patterns is useful in clinical medicine. Such pathological conditions as myocardial infarction, infectious hepatitis, and muscle diseases involve cell death of affected tissue, with release of cell contents to the blood. The pattern of LDH isozymes in the blood serum is representative of the tissue that released the isozymes. This information can be used to diagnose such conditions and to monitor the progress of treatment.

Ethanol Metabolism

Pyruvate has numerous alternative fates in anaerobic microorganisms. As we have seen, lactic acid bacteria reduce pyruvate to lactate in a single step (see margin). By contrast, yeasts convert pyruvate to ethanol in a two-step pathway. This alcoholic fermentation starts with the nonoxidative decarboxylation of pyruvate to acetaldehyde, catalyzed by **pyruvate decarboxylase**. NAD^+ is regenerated in the next reaction, the NADH -dependent reduction of acetaldehyde to ethanol, catalyzed by alcohol dehydrogenase.

The first reaction requires **thiamine pyrophosphate** as a coenzyme. This coenzyme is derived from thiamine, the first of the B vitamins to be identified, and so it is also called vitamin B_1 . The vitamin is structurally complex, but its conversion to the coenzyme form, thiamine pyrophosphate, or TPP, involves simply an ATP-dependent pyrophosphorylation.

Thiamine pyrophosphate is the coenzyme for all decarboxylations of α -keto acids. Unlike β -keto acids, α -keto acids cannot stabilize the carbanion transition state that develops during decarboxylation, and they thus require the aid of a cofactor (TPP). The mechanism shown in Figure 13.8 for pyruvate decarboxylation is involved in all of these reactions. Note that TPP contains two heterocyclic rings: a substituted pyrimidine and a thiazole. Recent NMR studies have shown that both rings participate in the formation of a reactive carbanion at C-2 of the thiazole ring—the carbon atom between the nitrogen and the sulfur (step 1 in Figure 13.8). Because the thiazole ring is weakly acidic ($pK_a \sim 18$ for the ring hydrogen), a general base is required in its ionization. As shown in the following diagram, a glutamate carboxyl group in the enzyme deprotonates N-1 of the pyrimidine, which in turn increases the basicity of the amino group, facilitating the deprotonation of C-2 of the thiazole ring to give a dipolar thiazolium carbanion (or **ylid**).

The thiazole ring of TPP is the functional part of the coenzyme, allowing it to bind and transfer activated aldehydes.

This carbanion can attack the carbonyl carbon of α -keto acids, such as pyruvate, giving an addition compound (step 2 in Figure 13.8). The addition compound undergoes nonoxidative decarboxylation (step 3), with the thiazole ring acting as an electron sink in forming a resonance-stabilized carbanion. Protonation (step 4) gives a species called **active acetaldehyde** or, more accurately, **hydroxyethyl-TPP**. In pyruvate decarboxylase, this intermediate undergoes an elimination reaction to yield acetaldehyde and the TPP carbanion (step 5). In the pyruvate dehydrogenase reaction (not shown here), the activated two-carbon fragment is simultaneously oxidized and transferred to another enzyme, as discussed in Chapter 14. Thus, in general terms, TPP functions in the generation of an activated aldehyde species, which may or may not undergo oxidation as it is transferred to an acceptor. We will come across this coenzyme several times in other pathways.

Industrial production of ethanol has assumed immense importance as humanity attempts to deal with two serious problems—(1) replacement of non-renewable petroleum by renewable fuel sources and (2) utilization of biological waste materials. Efforts in these arenas involve bioengineering, to generate bacterial strains that can convert materials such as the cellulose in wood waste or straw or more complex materials in human and animal wastes to hexose sugars, and analysis of glycolytic regulation, aimed at maximizing ethanol production from such sugars. Systems-level proteomics (see Tools of Biochemistry 5D) and metabolomics (see Tools of Biochemistry 12B) approaches are revealing new engineering targets for optimizing industrial cellulosic fermentation processes. However, there are some significant downsides to the use of croplands for the production of biofuels. For example, “first generation” biofuels produced from food crops such as corn may lead to increases in the price of corn and other food

FIGURE 13.8

Thiamine pyrophosphate in the pyruvate decarboxylase reaction. Thiamine pyrophosphate (TPP) is the coenzyme for all decarboxylations of α -keto acids. The key reaction (step 2) is attack by the carbanion of TPP on the carbonyl carbon of pyruvate and is followed by nonoxidative decarboxylation of the coenzyme-bound pyruvate to give another carbanion (step 3), which is resonance-stabilized. In step 4, the two-carbon fragment (red) bound to TPP extracts a proton from the enzyme, generating a hydroxyethyl group. This fragment remains at the aldehyde oxidation level. In the final step, acetaldehyde is released and TPP carbanion is regenerated (step 5).

staples, excess fertilizer use, and soil depletion. These concerns have stimulated the development of “second generation” biofuels produced from nonfood biomass (ligno-cellulosic feedstocks), such as agricultural by-products and switchgrass. However, all of these approaches will result in increased water demand for irrigation, increased water pollution, and even increased greenhouse emissions as farmers respond to higher prices by converting forest and grassland to new cropland. Thus, many technical hurdles remain before biofuels can become commercially competitive with oil products and environmentally friendly at the same time.

Animal tissues also contain alcohol dehydrogenase, even though ethanol is not a major metabolic product in animal cells. Some of the major metabolic consequences of ethanol intoxication result from ethanol oxidation by this enzyme in the liver. First, there is massive reduction of NAD^+ to $NADH$, which depletes NAD^+ levels, thereby decreasing flux through glyceraldehyde-3-phosphate dehydrogenase, with consequent inhibition of energy generation. Second, acetaldehyde is quite toxic, and many of the unpleasant effects of hangovers result from actions of acetaldehyde and its metabolites.

Energy and Electron Balance Sheets

By writing a balanced chemical equation for glycolysis, we can compute the energy yield accompanying conversion of 1 mole of glucose. For homolactic fermentation, we can write the following balanced equation:

Similarly, we can write a balanced equation for alcoholic fermentation:

Note first that both processes involve no net change in oxidation state; NAD^+ and NADH , both of which participate in the reaction pathways, do not appear in the overall reactions. This is an example of the obligate-coupling stoichiometry that was first introduced in Chapter 12. You can see that metabolism of glucose to either lactate or ethanol represents a nonoxidative process, by comparing the empirical formulas for glucose ($\text{C}_6\text{H}_{12}\text{O}_6$) and lactate ($\text{C}_3\text{H}_6\text{O}_3$). Clearly, there is no change in the overall oxidation state of the carbons because the numbers of hydrogens and oxygens bound per carbon atom are identical for glucose and lactate. The same is true for ethanol plus CO_2 , when one counts the atoms in both. However, some individual carbon atoms of lactate, and of ethanol plus CO_2 , undergo oxidation, and some become reduced. By contrast, pyruvate is more highly oxidized than glucose, as seen from its empirical formula ($\text{C}_3\text{H}_4\text{O}_3$).

Next, note that both of these balanced equations represent an exergonic process coupled to an endergonic process. In alcoholic fermentation, for example:

Thus, the efficiency of the process, the amount of released free energy actually captured in ATP, is $61/228 = 27\%$ under standard conditions. The rest of the free energy is used to ensure that the process goes to completion. The equilibrium constant K for this process can be calculated from Equation 3.28 in Chapter 3:

$$K = e^{\left(\frac{-\Delta G^\circ}{RT}\right)} = 1.9 \times 10^{29}$$

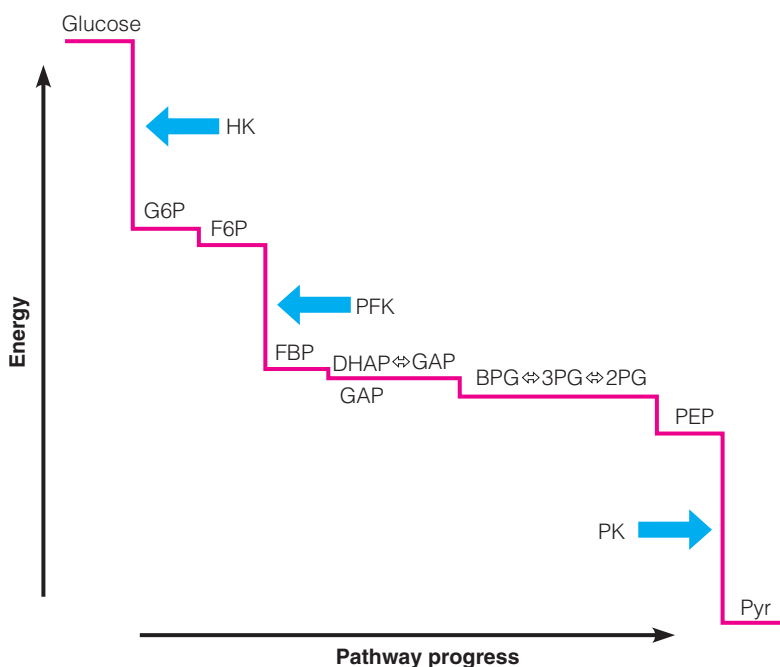

Clearly, glycolysis is highly favorable, and does indeed go to completion under standard conditions. What about physiological conditions? Table 13.1 lists ΔG values for the individual steps, estimated from the approximate intracellular concentrations of glycolytic intermediates in rabbit skeletal muscle. These estimated ΔG values are plotted in Figure 13.9 to illustrate the actual free energy changes in the pathway. All but three of the reactions function at or near equilibrium, and are freely reversible *in vivo*. The three exceptions are the reactions catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase, which take place with large decreases in free energy. These nonequilibrium reactions are irreversible *in vivo*, and they make the entire glycolytic pathway unidirectional. As we will see in the next section, these are the steps that must be bypassed in gluconeogenesis. Not coincidentally, these three nonequilibrium reactions are also the sites of regulation of glycolysis—recall from Chapter 12 that regulation can be imposed *only* on reactions displaced far from equilibrium.

This 10-step pathway is fast—anaerobic glycolysis can produce ATP at rates 100 times higher than aerobic oxidative phosphorylation. Muscle cells take advantage of this during strenuous exercise, when their oxygen supply cannot keep up with their demand for ATP. Cancer cells also take advantage of the high rate of ATP production afforded by glycolysis, supporting their high proliferation rates. Indeed, most rapidly dividing cancer cells metabolize glucose by glycolysis, producing lactate even though oxygen is abundant. This phenomenon was first noted

Glycolysis, which yields 2 ATP per glucose, is fast but releases only a small fraction of the energy available from glucose.

FIGURE 13.9

Energy profile of anaerobic glycolysis. The graph shows the change in actual free energy for each reaction in the pathway, based on estimated ΔG values calculated in Table 13.1. Metabolite and enzyme abbreviations are as defined in Table 13.1. Most of the reactions function at or near equilibrium and are freely reversible in vivo. The three enzymes that catalyze reactions so highly exergonic as to be virtually irreversible (arrows) are subject to allosteric control.

by Otto Warburg in 1925, and it is known as the “Warburg effect”—more about this in Chapter 18. Of course, this high rate of ATP production via glycolysis requires a high rate of glucose utilization, since only two ATPs are produced per glucose. This brings us to a final point about the bioenergetics of glycolysis.

Glycolysis releases but a small fraction of the potential energy stored in the glucose molecule. As noted earlier (see Chapters 3 and 12), the complete combustion of glucose to CO_2 and H_2O releases 2870 kJ/mol of free energy under standard conditions. Complete combustion of 2 moles of lactate to CO_2 and H_2O releases $2 \times 1379 \text{ kJ/mol} = 2757 \text{ kJ/mol}$ of free energy under standard conditions. Thus, in homolactic fermentation, 2757/2870, or 96%, of the free energy available in the original glucose molecule is still present in the fermentation product, lactate. Alcoholic fermentation is similarly low yield.

As we shall see in Chapter 15, about 30–32 moles of ATP are synthesized from ADP per mole of glucose carried completely through glycolysis and the citric acid cycle. Aerobic metabolism yields more energy from glucose; therefore, aerobic organisms in general are more successful and widespread than anaerobic organisms. The early evolution of aerobic metabolism made possible the large, active animals that exist today. Nevertheless, many large animals still derive a large fraction of their metabolic energy from glycolysis, under certain physiological circumstances. A good example is the crocodile—torpid (and aerobic) for much of its life, yet capable of short bursts of intensely rapid movement. In the latter circumstance glycolysis, coupled with the breakdown of carbohydrate energy stores, represents a rapid, though inefficient, way to mobilize energy.

Gluconeogenesis

Gluconeogenesis is the synthesis of glucose from noncarbohydrate precursors. Here we encounter the first instance of a principle enunciated in Chapter 12: *Biosynthetic processes are never simply the reversal of corresponding catabolic pathways.* Superficially, gluconeogenesis looks very much like glycolysis in reverse, but different enzymatic reactions are used at crucial sites. These sites are strongly exergonic reactions that are controlled largely in reciprocal fashion, so that physiological conditions that activate glycolysis inhibit gluconeogenesis and vice versa. Much the same picture will emerge from our discussion later in this chapter of glycogen synthesis as compared with glycogen mobilization.

Physiological Need for Glucose Synthesis in Animals

Most animal organs can metabolize a variety of carbon sources to generate energy—triacylglycerols, various sugars, pyruvate, amino acids, and so forth. However, the brain and central nervous system require glucose as the sole or primary carbon source. The same is true for some other tissues, such as kidney medulla, testes, and erythrocytes (Figure 13.10). Consequently, animal cells must be able to synthesize glucose from other precursors and also to maintain blood glucose levels within narrow limits—both for proper functioning of the brain and central nervous system and also for providing precursors for glycogen storage in other tissues. The glucose requirements of the human brain are relatively enormous—120 grams per day, out of about 160 grams needed by the entire body. The amount of glucose that can be generated from the body's glycogen reserves at any time is about 190 grams, and the total amount of glucose in body fluids is little more than 20 grams. Thus, the readily available glucose reserves amount to about one day's supply. During periods of fasting for more than one day, glucose must be formed from other precursors. In the overnight post-absorptive state, glycogenolysis and gluconeogenesis both contribute to overall glucose production. However, if you skip breakfast your glycogen stores become depleted and gluconeogenesis becomes the predominant process for maintaining blood glucose levels. The same occurs during intense exertion, for example, during a marathon run. Initially, hepatic glycogenolysis is the primary source of extra glucose for skeletal muscle, but hepatic gluconeogenesis becomes gradually more important as the glycogen stores deplete.

The biosynthetic process is called **gluconeogenesis**—literally, the production of new glucose. Gluconeogenesis is defined as the biosynthesis of carbohydrate from three-carbon and four-carbon precursors, generally noncarbohydrate in nature. The principal substrates for gluconeogenesis are *lactate*, produced primarily from glycolysis in skeletal muscle and erythrocytes; *amino acids*, generated from dietary protein or from the breakdown of muscle protein during starvation; the specific amino acid *alanine*, produced in muscle through the glucose–alanine cycle (see Figure 20.13, page 845); *propionate*, derived from the breakdown of fatty acids with odd-numbered carbon chains and some amino acids; and *glycerol*, derived from the catabolism of fats. The fatty acids released during lipid breakdown are mostly converted to acetyl-CoA and cannot be used for carbohydrate synthesis, except in organisms that have a functioning glyoxylate cycle (see Figure 14.21, page 620).

Gluconeogenesis occurs primarily in the cytosol, although some precursors are generated in mitochondria and must be transported to the cytosol to be utilized. The primary gluconeogenic organ in animals is the liver, with the kidney cortex contributing in a lesser but still significant way (see Figure 13.10). The major fates of glucose formed by gluconeogenesis are catabolism by nervous tissue and utilization by skeletal muscle. In addition, glucose is the primary precursor for all other carbohydrates, including amino sugars, complex polysaccharides, and the carbohydrate components of glycoproteins and glycolipids. The need for glucose as a biosynthetic intermediate means that gluconeogenesis is an important pathway in plants and microorganisms, as well as in animals, and the pathway is essentially identical in all organisms. However, the wealth of information on control of gluconeogenesis in animals leads us to concentrate on animal metabolism for the first part of this chapter.

Enzymatic Relationship of Gluconeogenesis to Glycolysis

Gluconeogenesis should be an easy pathway to learn because it closely resembles glycolysis in reverse. However, there are some important differences, which allow the pathway to run in the direction of glucose *synthesis* in the cell.

Recall that a metabolic pathway can proceed smoothly only if ΔG is strongly negative for the overall pathway in the direction written. We just saw that glycolysis from glucose to pyruvate is strongly exergonic; under typical intracellular conditions ΔG is about -103 kJ/mol (Table 13.1). How, then, can the conversion of pyruvate to

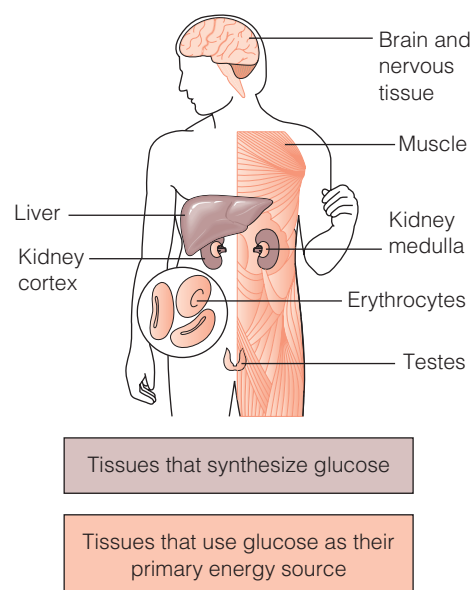

FIGURE 13.10

Synthesis and use of glucose in the human body. Liver and kidney cortex are the primary gluconeogenic tissues. Brain, skeletal muscle, kidney medulla, erythrocytes, and testes use glucose as their sole or primary energy source, but they lack the enzymatic machinery to synthesize it.

Synthesis of glucose from noncarbohydrate precursors is essential for maintenance of blood glucose levels within acceptable limits.

Gluconeogenesis uses specific enzymes to bypass three irreversible reactions of glycolysis.

Eukaryotes express two distinct isozymes of PEPCK: one in the cytosol and one in mitochondria. The cytosolic form appears to be the more important player in gluconeogenesis, as shown by the fact that its intracellular concentration is regulated by hormonal conditions known to control gluconeogenesis. However, in the livers of most mammals (including humans), at least half of the total PEPCK activity is mitochondrial. Consideration of the redox requirements and the compartmentation of gluconeogenesis suggests a metabolic explanation for the two isozymes. As shown in Figure 13.11, gluconeogenesis requires electrons in the form of NADH to reduce 1,3-bisphosphoglycerate to glyceraldehyde-3-phosphate. However, the cytosolic $[NADH]/[NAD^+]$ ratio is about 10^5 times lower than in mitochondria. In those tissues where the cytosolic PEPCK predominates, transport of malate from mitochondria to cytosol and the operation of the two malate dehydrogenase isozymes results in the transport of mitochondrial reducing equivalents to the cytosol for use in the glyceraldehyde-3-phosphate dehydrogenase reaction (Figure 13.12). However, if lactate is available as a gluconeogenic precursor, its oxidation to pyruvate by the cytoplasmic lactate dehydrogenase provides the necessary cytoplasmic reducing equivalents. Oxaloacetate produced by pyruvate carboxylase can now be converted directly to PEP by the mitochondrial PEPCK, since mitochondria possess a transporter for PEP.

The overall reaction for the bypass of pyruvate kinase is as follows:

$\Delta G^{\circ'}$ for the two reactions combined is slightly positive. However, under intracellular conditions the sequence is quite exergonic, with ΔG of about -25 kJ/mol. As shown in the summary reaction, two high-energy phosphates must be invested for the synthesis of one phosphoenolpyruvate. After this bypass, phosphoenolpyruvate is converted to fructose-1,6-bisphosphate by glycolytic enzymes acting in reverse. Note that the glyceraldehyde-3-phosphate dehydrogenase reaction requires NADH (Figure 13.11), provided by one of the alternative pathways just described (Figure 13.12).

Bypass 2: Conversion of Fructose-1,6-bisphosphate to Fructose-6-phosphate

The phosphofructokinase reaction of glycolysis is essentially irreversible, but only because it is driven by phosphate transfer from ATP. A bypass reaction in gluconeogenesis involves a simple hydrolytic reaction, catalyzed by **fructose-1,6-bisphosphatase**.

The negative $\Delta G^{\circ'}$ for this reaction favors the rightward reaction. The multi-subunit enzyme requires Mg^{2+} for activity and represents one of the major control sites regulating the overall gluconeogenic pathway. Fructose-6-phosphate formed in this reaction then undergoes isomerization by phosphoglucose isomerase to glucose-6-phosphate.

Bypass 3: Conversion of Glucose-6-phosphate to Glucose

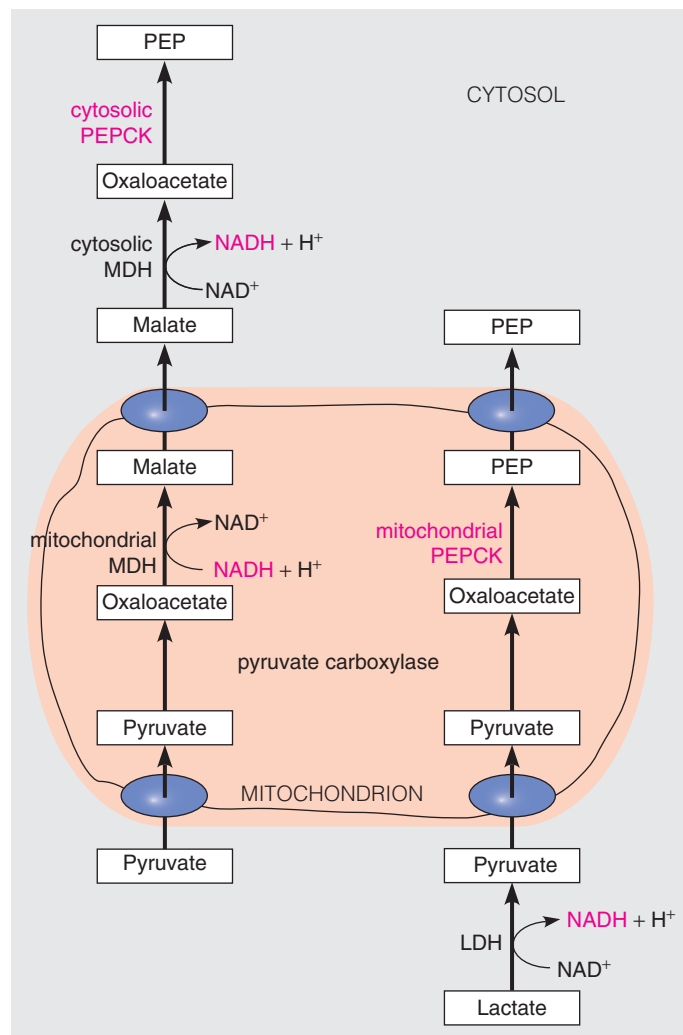

Glucose-6-phosphate cannot be converted to glucose by reverse action of hexokinase or glucokinase because of the high positive $\Delta G^{\circ'}$ of that reaction; phosphate transfer from ATP makes that reaction virtually irreversible. Another enzyme specific to gluconeogenesis, **glucose-6-phosphatase**, comes into play instead. This bypass reaction also involves a simple hydrolysis.

Glucose-6-phosphatase, which also requires Mg^{2+} , is found in the endoplasmic reticulum (ER) membrane, with its active site facing the interior space, or **lumen**, of the ER. The enzyme is part of a multiprotein complex that includes transporters to import the substrate, glucose-6-phosphate, into the ER lumen and to export the products, glucose and inorganic phosphate, back to the cytoplasm.

FIGURE 13.12

PEPCK isozymes provide alternative routes to PEP and cytoplasmic reducing equivalents. MDH, malate dehydrogenase; LDH, lactate dehydrogenase. Blue ovals indicate inner membrane transporters.

Mammals express three glucose-6-phosphatase isozymes. The major isozyme is expressed predominantly in liver and kidney, and the minor isozymes are expressed at lower levels in most other tissues, including brain, muscle, intestine, and pancreatic islets. The significance of its location in liver is that a unique function of liver is to synthesize glucose for export to the tissues via the bloodstream. The role of glucose-6-phosphatase in other tissues, especially brain and skeletal muscle, is not yet understood.

Stoichiometry and Energy Balance of Gluconeogenesis

We have emphasized that catabolic pathways generate energy, whereas anabolic pathways carry an energy cost. Let's now estimate that cost for gluconeogenesis. The overall conversion of 2 moles of pyruvate to 1 mole of glucose is quite exergonic, as shown in Table 13.2. ΔG° for the overall process is about -33 kJ/mol.

Gluconeogenesis:

But the synthesis of glucose is energetically expensive. Six high-energy phosphate groups are consumed (four ATPs and two GTPs), as well as 2 moles of NADH, which is the energetic equivalent of five more ATPs (because mitochondrial oxidation of 1 mole of NADH generates ~ 2.5 moles of ATP).

The equivalent of 11 high-energy phosphates are consumed per mole of glucose synthesized by gluconeogenesis.

TABLE 13.2 Summary of gluconeogenesis, from pyruvate to glucose

Reaction	ΔG° (kJ/mol)
Pyruvate + HCO_3^- + ATP \longrightarrow oxaloacetate + ADP + P_i	-2.1 (-4.2)
Oxaloacetate + GTP \rightleftharpoons phosphoenolpyruvate + CO_2 + GDP	+2.9 (+5.8)
Phosphoenolpyruvate + H_2O \rightleftharpoons 2-phosphoglycerate	+6.4 (+12.8)
2-Phosphoglycerate \rightleftharpoons 3-phosphoglycerate	-4.4 (-8.8)
3-Phosphoglycerate + ATP \rightleftharpoons 1,3-bisphosphoglycerate + ADP	+18.8 (+37.6)
1,3-Bisphosphoglycerate + NADH + H^+ \rightleftharpoons glyceraldehyde-3-phosphate + NAD^+ + P_i	-6.3 (-12.6)
Glyceraldehyde-3-phosphate \rightleftharpoons dihydroxyacetone phosphate	-7.6
Glyceraldehyde-3-phosphate + dihydroxyacetone phosphate \rightleftharpoons fructose-1,6-bisphosphate	-23.9
Fructose-1,6-bisphosphate + H_2O \longrightarrow fructose-6-phosphate + P_i	-16.3
Fructose-6-phosphate \rightleftharpoons glucose-6-phosphate	-1.7
Glucose-6-phosphate + H_2O \longrightarrow glucose + P_i	-13.8
Net: 2 Pyruvate + 4ATP + 2GTP + 2NADH + 2 H^+ + 4 H_2O \longrightarrow glucose + 4ADP + 2GDP + 6 P_i + 2 NAD^+	-32.7

Note: The reactions in purple type are those that bypass irreversible glycolytic reactions; the remaining reactions are reversible reactions of glycolysis. The ΔG° values in parentheses are based on doubling the first six reactions because 2 three-carbon precursors are required to make one molecule of glucose. The individual reactions are not necessarily balanced for H^+ and charge.

By contrast, if glycolysis could operate in reverse, the net equation would show far less energy input—2 moles of NADH and 2 moles of high-energy phosphate:

Reversal of Glycolysis:

This process would be highly endergonic, however, with a ΔG° of +83.1 kJ/mol. These are of course standard free energy changes, but it is clear that the investment of four extra high-energy phosphate bonds is essential if the net synthesis of glucose is to occur as an irreversible process in vivo.

Substrates for Gluconeogenesis

As indicated earlier, gluconeogenesis draws precursors from diverse sources, including lactate, amino acids, glycerol, and propionate. The pathways by which these substrates enter gluconeogenesis are shown in Figure 13.13 and are discussed in this section.

Lactate

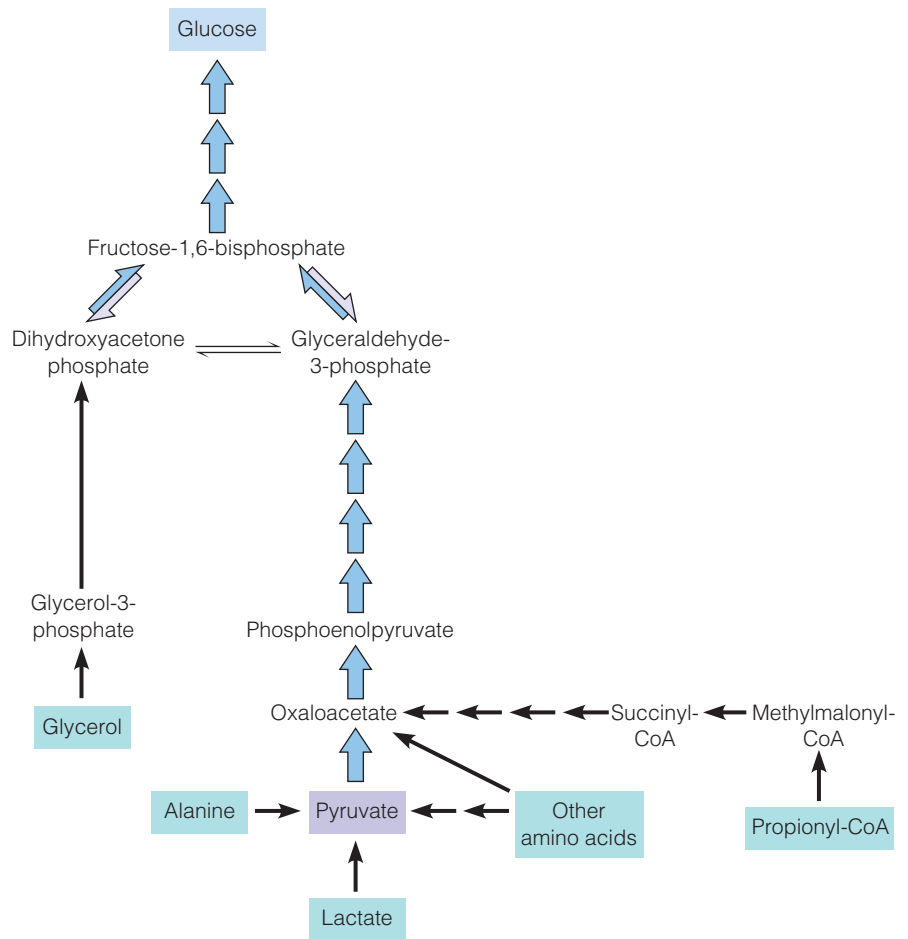

In quantitative terms, lactate is the most significant gluconeogenic precursor. Recall that skeletal muscle derives much of its energy from glycolysis, particularly during intense exertion, when respiration cannot deliver sufficient oxygen to the tissues for complete oxidation of glucose. Under these conditions, glycolysis produces pyruvate more rapidly than it can be further metabolized via the citric acid cycle. Lactate dehydrogenase is abundant in muscle, and the equilibrium strongly favors pyruvate reduction to lactate. Thus, lactate from working muscle is released to the blood, whence it is readily taken up by the heart and oxidized as fuel. The accumulation of lactate during prolonged exertion is a significant factor limiting athletic performance.

Some of the lactate produced in muscle enters the liver and is reoxidized to pyruvate by liver LDH. This pyruvate can then undergo gluconeogenesis to give glucose, which is returned to the bloodstream and taken up by muscle to regenerate the glycogen stores. This process, described originally by Carl and Gerti Cori and appropriately called the **Cori cycle**, is schematized in Figure 13.14. The pathway is particularly

The most important gluconeogenic precursors are lactate, alanine, glycerol, and propionate.

FIGURE 13.13

Outline of pathways for glucose synthesis from the major gluconeogenic precursors. Note that both glucose and lactate are carried in the blood.

active during recovery from intense muscular exercise. During this time the breathing rate is elevated, and the increased oxidative metabolism generates more ATP, much of which is used to rebuild glycogen stores via gluconeogenesis.

In a parallel process, the **glucose–alanine cycle**, pyruvate in peripheral tissues undergoes transamination to alanine, which is returned to the liver and used for gluconeogenesis. This pathway, which is presented in detail in Chapter 20, helps tissues to dispose of toxic ammonia formed during protein degradation.

Amino Acids

Like alanine, many other amino acids can readily be converted to glucose, primarily through degradative pathways that generate citric acid cycle intermediates, which can be converted to oxaloacetate (see Figure 13.13). As we will learn in Chapter 21, such amino acids are called **glucogenic** (that is, able to be converted to glucose), although *gluconeogenic* is probably a more accurate term. Among the 20 amino acids found in proteins, only the catabolic pathways for leucine and lysine do not generate gluconeogenic precursors. During fasting, when insufficient carbohydrate is ingested, the catabolism of muscle proteins is the major source of intermediates needed to maintain normal blood glucose concentrations. The same is true in the disease diabetes mellitus, as discussed further in Chapter 18.

Glycerol

In general, lipids are poor gluconeogenic precursors. Catabolism of triacylglycerols yields fatty acids and glycerol. Fatty acids undergo β -oxidation to yield acetyl-CoA (Chapter 17). In animals, acetyl-CoA cannot be converted to pyruvate or to any other gluconeogenic precursor. Hence, *fatty acids cannot undergo net conversion to carbohydrates*. Although it is true that two-carbon units from acetyl-CoA can proceed to oxaloacetate in the citric acid cycle, there is no net conversion because two carbons

Animals cannot undergo net conversion of fat to carbohydrate.

FIGURE 13.14

The Cori cycle. Lactate produced in glycolysis during muscle exertion is transported to the liver, for resynthesis of glucose by gluconeogenesis. Transport of glucose back to muscle for synthesis of glycogen, and its reutilization in glycolysis, completes the cycle.

are lost in each turn of the cycle. Therefore, aside from a minor contribution by odd-chain fatty acids (explained in the next section), the only fat breakdown product that can enter gluconeogenesis is the 3-carbon glycerol. Its utilization involves phosphorylation, followed by dehydrogenation to dihydroxyacetone phosphate (see Figure 13.13). Note that plants and bacteria *can* incorporate acetyl-CoA into carbohydrate via the glyoxylate cycle, which we will discuss in Chapter 14.

Propionate

In all organisms a three-carbon acyl-CoA, **propionyl-CoA**, is generated either from the breakdown of some amino acids or from the oxidation of fatty acids with odd numbers of carbon atoms. Propionyl-CoA enters gluconeogenesis via its conversion to succinyl-CoA and then to oxaloacetate. The process, which is detailed in Chapter 17, involves a coenzyme derived from vitamin B₁₂.

Although all organisms use propionate as a gluconeogenic substrate, it is particularly important in the metabolism of ruminant animals such as cattle. These animals display enormous rates of gluconeogenesis from a variety of substrates, owing to the great amount of bacterial fermentation occurring in their several stomach chambers. In cattle the four chambers of the stomach have a total volume as high as 70 liters. The action of various bacteria degrades plant materials, particularly cellulose, to glucose. But before the glucose can be

absorbed into the bloodstream, as in human digestion, it is fermented further to various products, notably lactate and propionate. Propionate is converted to propionyl-CoA and thence to succinyl-CoA, and lactate is simply reduced to pyruvate.

Ethanol Consumption and Gluconeogenesis

Although it is possible to visualize pathways by which ethanol could be converted to glucose, ethanol is actually a poor gluconeogenic precursor. In fact, ethanol strongly inhibits gluconeogenesis and can bring about **hypoglycemia**, a potentially dangerous decrease in blood glucose levels.

Ethanol is metabolized primarily in the liver, by reversal of the alcohol dehydrogenase reaction (page 521):

This reaction elevates the $[\text{NADH}]/[\text{NAD}^+]$ ratio in liver cytosol, which in turn shifts the equilibrium of the lactate dehydrogenase and glyceraldehyde 3-phosphate dehydrogenase reactions, inhibiting glycolysis. The same mechanism shifts the equilibrium of the cytosolic malate dehydrogenase reaction (Figure 13.12), so that oxaloacetate tends to be reduced to malate and hence becomes unavailable for gluconeogenesis. The resultant hypoglycemia can affect the parts of the brain concerned with temperature regulation. This response, in turn, can lower the body temperature by as much as 2 °C. Therefore, the time-honored practice of feeding brandy or whiskey to those rescued from cold or wet conditions is counterproductive. To be sure, alcohol creates a sense of warming through vasodilation, but this peripheral vasodilation causes further heat loss. Metabolically speaking, glucose would be far more effective in raising body temperature.

Roles of Extrahepatic Phosphoenolpyruvate Carboxykinase

In addition to its role in liver, the predominant gluconeogenic tissue, PEPCK is important in the metabolism of two other tissues. First, in kidney cortex, the other major gluconeogenic tissue, PEPCK participates in acid–base regulation. The kidney is responsible for regulating acid–base balance through the synthesis and excretion of ammonium (NH_4^+) in the urine. The primary source of ammonia is glutamine, which generates 2 moles of ammonia via the sequential action of **glutaminase** and **glutamate dehydrogenase**:

During metabolic acidosis, such as occurs in diabetes, excretion of ammonium ions into the urine facilitates the excretion of metabolically produced acids to compensate for the acidosis. The α -ketoglutarate produced in the second reaction is converted via the citric acid cycle to oxaloacetate, which generates phosphoenolpyruvate via the PEPCK reaction, for ultimate synthesis of glucose.

Second, in adipose (fatty) tissue, PEPCK participates in a process called **glyceroneogenesis**, which acts to produce sufficient glycerol-3-phosphate for triacylglycerol formation. Reesterification of free fatty acids to glycerol-3-phosphate is essential in both the fed and fasting states, in order to maintain balance between triacylglycerol breakdown and resynthesis. In adipose tissue, the phosphoenolpyruvate produced by pyruvate carboxylase and PEPCK is *not* converted to glucose. Instead, it is diverted at dihydroxyacetone phosphate for reduction to glycerol-3-phosphate, which combines with the coenzyme A derivatives of free fatty acids to produce triacylglycerols. These pathways will be discussed in more detail in Chapter 17.

Evolution of Carbohydrate Metabolic Pathways

Genome comparisons suggest that the Embden–Meyerhof–Parnas (glycolytic) pathway probably first evolved in the direction of gluconeogenesis. The earliest organisms were most likely thermophilic chemoautotrophs, living in the volcanic flows of submarine hydrothermal vents under anoxic or microaerobic conditions. It is proposed that these organisms used dissolved gases and inorganic substrates for energy production, which probably contained few carbohydrates for use as organic growth substrates. They reduced CO_2 or CO (carbon monoxide) into an activated form of acetic acid, acetyl-CoA, using electrons from H_2 as the main electron donor. This served as the starting material for the biosynthesis of more complex carbohydrates, using the primordial gluconeogenesis pathway. Only after large quantities of sugar-containing cyanobacterial and plant cell walls became available did organisms begin to use sugars as growth substrates, via the glycolytic direction of the pathway.

Coordinated Regulation of Glycolysis and Gluconeogenesis

Glycolysis and gluconeogenesis are closely coordinated with other major pathways of energy generation and utilization, notably synthesis and breakdown of glycogen (or starch), the pentose phosphate pathway (described later in this chapter), and the citric acid cycle (Chapter 14). Metabolic factors that control glycolysis tend to regulate other processes in a coordinated fashion. Thus, it is difficult to consider regulation of glycolysis in isolation from these other processes, and we return to this topic after we have presented the other major pathways in energy metabolism (see Chapter 18). However, glycolysis and gluconeogenesis provide a very useful introduction to the principles of coordinated metabolic regulation, and so we will describe here the key enzymes that serve as regulatory targets in these two opposing pathways.

The Pasteur Effect

Long before anything was known about pathways of glucose utilization, much less control mechanisms, Louis Pasteur observed that when anaerobic yeast cultures metabolizing glucose were exposed to air, the rate of glucose utilization decreased dramatically. It became clear that this phenomenon, known as the **Pasteur effect**, involves the inhibition of glycolysis by oxygen. This effect makes biological sense because far more energy is derived from complete oxidation of glucose than from glycolysis alone. What is the mechanism of this effect if oxygen is not an active participant in glycolysis? The needed insight came much later from analyses of the intracellular contents of glycolytic intermediates in aerobic and anaerobic cells. These analyses required techniques for the rapid interruption of metabolism and extraction of metabolites. One such technique is **freeze-clamping**, in which tissue is rapidly compressed between metal plates cooled to liquid nitrogen temperatures. The solid tissue can then be powdered and extracted for analysis.

Experiments of this type revealed that when oxygen is introduced to anaerobic cells, the levels of all the glycolytic intermediates from fructose-1,6-bisphosphate onward *decrease*, while all of the *earlier* intermediates accumulate at higher levels (see margin). This finding is consistent with the idea that the metabolic flux through phosphofructokinase is specifically decreased in the presence of O_2 , probably due to changes in allosteric effector levels.

FIGURE 13.15

Periodic oscillations of the levels of glycolytic intermediates in yeast cells undergoing glycolysis. The culture was shifted from aerobic to anaerobic conditions at the point labeled “Air off.” The upper tracing (blue) depicts continuous monitoring of fluorescence of the cell suspension, which is related to the intracellular concentration of NADH. The nucleotide levels (orange) were determined in a parallel experiment in which samples of culture were removed at various times, extracted, and assayed for their contents of ATP, ADP, and AMP.

Oscillations of Glycolytic Intermediates

Other important conclusions emerged from the discovery that the intracellular levels of glycolytic intermediates are not constant under many conditions but undergo periodic variations, or oscillations, as shown in Figure 13.15. These variations can be visualized most readily by following the fluorescence of a yeast cell suspension at 450 nm. The major contributor to this fluorescence is NADH, so this type of experiment monitors changes in the intracellular NADH pool with time. Oscillations are a common feature of feedback-controlled systems, and the cyclic variations in levels of glycolytic intermediates provide important clues to regulatory mechanisms affecting glycolysis.

During the time that the fluorescence of a yeast cell suspension is increasing, NADH is accumulating, through reduction of intracellular NAD^+ . Under these conditions, glycolysis is turned on and NADH is being produced by glyceraldehyde-3-phosphate dehydrogenase faster than it can be used to reduce pyruvate. Presumably, during this period one or more regulatory substances are also accumulating. Once they have accumulated sufficiently to inhibit glycolysis, the NADH level falls—until the supply of regulators is depleted to the point that the pathway is inhibited again. This cycle occurs repeatedly.

Once investigators realized that the intracellular levels of NADH were varying periodically, they began sampling extracts of oscillating cells to analyze the intracellular levels of other substrates for glycolytic enzymes. These intermediates were found to rise and fall periodically as well. Note from Figure 13.15 that the levels of ADP and AMP rise and fall precisely in phase with NADH, whereas the level of ATP is 180° out of phase. This pattern suggests that the activity of glycolysis depends in some way on the adenylate energy charge (see Chapter 12): When the charge is high, the pathway is turned off; when it is low, the pathway is activated. These and other observations suggested an enzyme regulated by energy charge as the major point of regulation. Phosphofructokinase is such an enzyme.

Regulation of glycolysis is crucial for many physiological functions. It is important to recognize that glycolysis not only generates ATP and provides pyruvate for oxidation via the citric acid cycle but also is a biosynthetic pathway. Intermediates in glycolysis are precursors to a number of compounds, particularly lipids and amino acids. These processes are discussed throughout the book, but Figure 13.16 summarizes some of the major biosynthetic roles of glycolytic intermediates. This figure illustrates why glycolysis is considered a major metabolic thoroughfare. Many pathways lead into glycolysis, and many pathways diverge from it, creating a substantial flux through the pathway.

Regulation of gluconeogenesis is also crucial for many physiological functions, but particularly so for proper functioning of nervous tissue. Although other organs can use a variety of energy sources, the well-being of the central nervous system demands maintenance of blood glucose levels within narrow limits. Gluconeogenic control is important also as an animal adjusts to muscular exertion or to cycles of feeding and fasting. Flux through the pathway must increase and decrease, based on the availability of lactate produced by the muscles, of glucose from the diet, or of other gluconeogenic precursors.

Gluconeogenesis is controlled in large part by the diet. Animals fed a high-carbohydrate diet show low rates of gluconeogenesis, whereas fasted animals or those fed carbohydrate-poor diets show high flux through this pathway. As we introduced in Chapter 12, these hormonal effects, mediated primarily through insulin and glucagon, involve both control of the synthesis of phosphoenolpyruvate carboxykinase and regulation effected through control of cyclic AMP levels. Our discussion here focuses upon these cAMP-mediated effects as well as other mechanisms affecting enzyme activities. We return to discussion of hormonal effects upon enzyme synthesis in Chapter 23, when we present hormone action in detail.

Gluconeogenic flux rates are inversely related to the carbohydrate content of the diet. This effect is mediated hormonally.

The regulatory demands placed on the cell are too complex to meet with a single rate-controlling reaction, and thus both glycolysis and gluconeogenesis are controlled at multiple points.

Reciprocal Regulation of Glycolysis and Gluconeogenesis

Gluconeogenesis and glycolysis both proceed largely in the cytosol. Because gluconeogenesis synthesizes glucose and glycolysis catabolizes glucose, it is evident that *gluconeogenesis and glycolysis must be controlled in reciprocal fashion*. In other words, intracellular conditions that activate one pathway tend to inhibit the other. If it were not for reciprocal control, glycolysis and gluconeogenesis would operate together as a giant futile cycle. Reciprocal regulation is related in large part to the adenylate energy charge. Conditions of low energy charge tend to activate the rate-controlling steps in glycolysis while inhibiting carbon flux through gluconeogenesis. Conversely, gluconeogenesis is stimulated at high energy charge, under conditions where catabolic flux rates are low, but are adequate to maintain sufficient ATP levels.

Glycolysis is controlled primarily by regulation of the three strongly exergonic, nonequilibrium reactions of the pathway—those catalyzed by hexokinase, phosphofructokinase, and pyruvate kinase (see Figure 13.9). The opposed reactions in gluconeogenesis—those catalyzed by glucose-6-phosphatase, fructose-1,6-bisphosphatase, and the combination of pyruvate carboxylase and phosphoenolpyruvate carboxykinase—are also strongly exergonic and represent the chief targets for control of this pathway. In other words, the three substrate cycles that differentiate glycolysis from gluconeogenesis (Figure 13.17) represent the primary sites for reciprocal regulation of these pathways. This illustrates the principles introduced in Chapter 12: Regulation can be imposed *only* on reactions displaced far from equilibrium, such as those that comprise these three substrate cycles. Figure 13.18 identifies the major allosteric activators and inhibitors of the key exergonic reactions in glycolysis and gluconeogenesis.

Regulation at the Phosphofructokinase/ Fructose-1,6-Bisphosphatase Substrate Cycle

Phosphofructokinase is the primary flux-controlling enzyme in glycolysis. Energy charge affects the control of glycolysis and gluconeogenesis by regulating the interconversion of fructose-6-phosphate and fructose-1,6-bisphosphate. In mammals, PFK is activated by AMP and ADP, whereas the opposing enzyme, fructose-1,6-bisphosphatase, is inhibited by AMP (Figure 13.18). Thus, as energy charge decreases, glycolysis is activated and gluconeogenesis inhibited by the opposing effects of AMP on phosphofructokinase and fructose-1,6-bisphosphatase. Although intracellular adenine nucleotide levels do vary in parallel with changes in flux through glycolysis and gluconeogenesis, as expected if energy charge is a major regulatory factor, the correspondence is not absolute. These observations suggested additional control mechanisms and led to the discovery of the much more important physiological regulator, **fructose-2,6-bisphosphate**.

Fructose-2,6-bisphosphate and the Control of Glycolysis and Gluconeogenesis

Phosphofructokinase is a homotetramer that interconverts between two conformational states, R and T (recall the discussion of R and T states in Chapter 11, page 456). In addition to the catalytic sites that bind substrates (ATP, fructose-6-phosphate), mammalian PFK has binding sites for several allosteric effectors, including AMP, ADP, ATP, citrate, and fructose-2,6-bisphosphate. Bacterial PFKs have only a single allosteric site that can bind either an inhibitor (phosphoenolpyruvate) or an activator (ADP). Fructose-2,6-bisphosphate is considered to

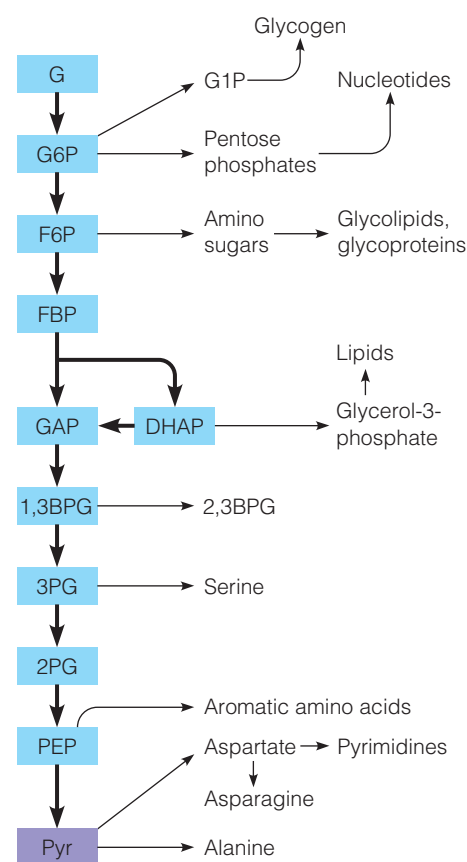

FIGURE 13.16

Alternative fates of glycolytic intermediates in biosynthetic pathways. G1P is glucose-1-phosphate.

FIGURE 13.17

Substrate cycles in glycolysis/gluconeogenesis.

FIGURE 13.18

Major control mechanisms affecting glycolysis and gluconeogenesis. The figure shows the strongly exergonic reactions of glycolysis and gluconeogenesis and the major activators and inhibitors of these reactions.

Conditions that promote glycolysis inhibit gluconeogenesis, and vice versa.

be the major regulator controlling carbon flux through glycolysis and gluconeogenesis in mammalian liver—it is active at much lower concentrations than the other physiological regulators we have discussed. As shown in Figure 13.19a, a very low concentration of fructose-2,6-bisphosphate *activates* phosphofruktokinase. AMP and ADP also activate PFK. The most significant *inhibitors* of mammalian phosphofruktokinase, from a biological standpoint, are ATP (Figure 13.19b) and citrate. The effect of ATP may seem anomalous because ATP is a substrate and hence essential for the reaction. As an inhibitor, ATP binds to a site on the enzyme separate from the catalytic site, and with lower affinity (Figure 13.19c). At low ATP concentrations, the substrate saturation curve for fructose-6-phosphate is nearly hyperbolic because the regulatory site is not occupied, and the enzyme is almost all in the R state. At high ATP levels the T state predominates, causing the curve to become sigmoidal and shift far to the right (Figure 13.19b). Thus, inhibition is achieved because the apparent affinity for fructose-6-phosphate is greatly reduced. Activators such as AMP, ADP, and fructose-2,6-bisphosphate stabilize the R state, thus increasing the apparent affinity for the substrate fructose-6-phosphate.

The control of PFK by adenine nucleotides represents a way in which energy metabolism responds to the adenylate energy charge. At high energy charge, the

relative abundance of ATP signals that the energy-yielding glycolytic pathway should diminish in activity; the signal effects inhibition of PFK. Conversely, a high AMP or ADP level signals that energy charge is low and that flux through glycolysis should increase. Inhibition by citrate represents another energy level sensor. At high energy charge, flux through the citric acid cycle diminishes, via mechanisms that are discussed in Chapter 14. Under these conditions, citrate accumulates and is transported out of mitochondria. Interaction with PFK in the cytosol can signal that energy generation is adequate, and hence the production of citric acid cycle precursors via glycolysis can be diminished.

Fructose-2,6-bisphosphate also regulates the gluconeogenic side of this substrate cycle. But here it is a potent inhibitor of fructose-1,6-bisphosphatase, at least in vitro. Thus, accumulation of the same regulatory molecule has the effect of simultaneously activating glycolysis and inhibiting gluconeogenesis (Figure 13.18).

Fructose-2,6-bisphosphate is formed from fructose-6-phosphate by a 6-phosphofructo-2-kinase, called PFK-2 to distinguish it from the well-known PFK of glycolysis, which we can call PFK-1 for clarity. Another enzyme activity, called **fructose-2,6-bisphosphatase**, cleaves fructose-2,6-bisphosphate back to fructose-6-phosphate. This activity is abbreviated FBPase-2 to distinguish it from the FBPase of gluconeogenesis.

These two activities are contained on separate domains of a 100-kilodalton enzyme, PFK-2/FBPase-2 (Figure 13.20). This bifunctional enzyme thus catalyzes the opposing reactions of a substrate cycle that determines the level of this important regulatory molecule. The velocities of the two reactions of this substrate cycle are in turn controlled by phosphorylation/dephosphorylation of the bifunctional enzyme. Conformational changes caused by phosphorylation increase the activity of one domain while decreasing the activity of the other domain, thereby altering the ratio of kinase to bisphosphatase activity. Mammals express several different tissue-specific PFK-2/FBPase-2 isozymes that are generated by alternative splicing from four distinct genes. Each isozyme has a characteristic kinase/bisphosphatase activity ratio, and different regulatory properties that fit the metabolic needs of that tissue.

The activities of the liver isozyme are controlled by the pancreatic hormones insulin and glucagon and by glucose. All of these regulatory molecules act through signaling cascades that lead to the reversible phosphorylation of a specific serine residue, which results in conformational changes in the protein. Phosphorylation *decreases* the activity of PFK-2 and *increases* the activity of FBPase-2 (Figure 13.21). Dephosphorylation reverses this effect.

Phosphorylation of PFK-2/FBPase-2 is catalyzed by cyclic AMP-dependent protein kinase. This important regulatory kinase, also known as protein kinase A (PKA), will be discussed in greater detail later in this chapter. As pointed out in Chapter 12, cyclic AMP (cAMP) plays numerous roles in regulating metabolism, both in eukaryotes and in prokaryotes. In eukaryotes its role is as a second messenger, receiving hormonal messages originating outside the cell and transmitting them within the cell. This transmission involves the activation of some metabolic processes and the inhibition of others. Glucagon is the primary hormone whose action raises cAMP levels in liver. Dephosphorylation of PFK-2/FBPase-2 is catalyzed by one or more specific protein phosphatases (Figure 13.21). Insulin stimulates dephosphorylation, and thus

Fructose-2,6-bisphosphate, the most important regulator of glycolysis and gluconeogenesis, is synthesized and degraded by different forms of the same enzyme.

FIGURE 13.20

Bifunctional PFK-2/FBPase-2. This figure shows the X-ray crystal structure of one subunit of the homodimeric human liver enzyme (PDB ID 1K6M). The N-terminal 6-phosphofructo-2-kinase domain is shown in yellow, and the C-terminal fructose-2,6-bisphosphatase domain is shown in green. The kinase active site is marked by a bound nonhydrolyzable ATP analog (ATP γ S). The bisphosphatase active site is marked by bound phosphates. The diagram of the primary structure of the 470 amino acid liver isozyme shows the location of the phosphorylation site (serine-32). Residues 1–38, including Ser-32, are not visible in the X-ray structure, suggesting that this segment is highly flexible.

activation of the 6-phosphofructo-2-kinase domain, but the signaling pathway is not known. The glucose signal is mediated by protein phosphatase 2A (PP2A). An increase in liver glucose concentration leads to increased synthesis of intermediates in the pentose phosphate pathway (discussed later in this chapter). One of these metabolites, xylulose-5-phosphate, is a specific activator of PP2A.

We will discuss the hormonal control of energy metabolism in much greater detail in Chapter 18, but we can begin to grasp some of the mechanistic details here. Glucagon, released by the pancreas in response to low blood glucose levels, binds to its plasma membrane receptors on liver cells. This activates the receptor, which then initiates the cAMP cascade and results in an active protein kinase A that catalyzes the phosphorylation of PFK-2/FBPase-2, stimulating its fructose-2,6-bisphosphatase activity. The resultant drop in fructose-2,6-bisphosphate levels causes this regulatory molecule to dissociate from PFK-1, thereby increasing the sensitivity of PFK-1 to allosteric inhibitors—citrate and ATP. This in turn *reduces* flux through glycolysis and *stimulates* gluconeogenesis by relieving the inhibition of fructose-1,6-bisphosphatase. This is one mechanism by which glucagon increases blood glucose concentration. Insulin, released by the pancreas

FIGURE 13.21

Regulation of the synthesis and degradation of fructose-2,6-bisphosphate in liver. The bifunctional PFK-2/FBPase-2 is controlled by reversible phosphorylation of a specific serine residue near the N-terminus of each subunit of the homodimeric protein. In the unphosphorylated form, the 6-phosphofructo-2-kinase domain (K) is active, and fructose-2,6-bisphosphate (F2,6BP) is synthesized. In the phosphorylated form, the fructose-2,6-bisphosphatase domain (B) is active, and F2,6BP is degraded. Glucagon stimulates phosphorylation by activating cAMP-dependent protein kinase (PKA). Insulin and glucose (via xylulose-5-phosphate) stimulate dephosphorylation by activating a protein phosphatase.

in response to high blood glucose levels, or glucose itself, stimulates dephosphorylation of PFK-2/FBPase-2, activating its 6-phosphofructo-2-kinase activity. The resultant rise in fructose-2,6-bisphosphate levels *stimulates* glycolysis and *inhibits* gluconeogenesis.

Regulation of PFK-2/FBPase-2 in Heart and Skeletal Muscle

Heart expresses a different isozyme of this bifunctional regulatory enzyme, and unlike in liver, phosphorylation of the heart isozyme *increases* its kinase-to-bisphosphatase activity ratio. Not surprisingly, the site of phosphorylation is different, a serine residue near the C-terminus of the heart isozyme. At least two protein kinases are known to phosphorylate heart PFK-2/FBPase-2: AMP-activated protein kinase (AMPK) and protein kinase B (PKB, also called Akt). As we will see in Chapter 18, AMPK is a master sensor and integrator of signals that control cellular energy balance in all eukaryotes. When the oxygen supply is restricted (**ischemia**), heart cells must switch to anaerobic glycolysis to supply ATP for continued muscle contraction. AMPK is activated by ischemia, whereupon it phosphorylates and activates the 6-phosphofructo-2-kinase activity of PFK-2/FBPase-2. Fructose-2,6-bisphosphate levels rise, stimulating glycolysis.

The PFK-2/FBPase-2 isozyme found in skeletal muscle is not subject to control by phosphorylation/dephosphorylation. Instead, skeletal muscle PFK-2/FBPase-2 is controlled by the intracellular concentration of fructose-6-phosphate, which is both an allosteric modifier and a substrate. The kinase-to-bisphosphatase activity ratio is increased by high fructose-6-phosphate, which signals the availability of substrate for glycolysis. Fructose-2,6-bisphosphate levels rise as a result, stimulating PFK-1 and thus glycolysis.

Fructose-2,6-bisphosphate even plays a regulatory role in plants. By inhibiting a cytosolic fructose-1,6-bisphosphatase, it controls the flow of three-carbon sugars, produced by photosynthesis, out of chloroplasts and into the pathway for sucrose synthesis in the cytosol.

Regulation at the Pyruvate Kinase/Pyruvate Carboxylase + PEPCK Substrate Cycle

Earlier, we identified pyruvate kinase as a control point for glycolysis. Like PFK, the L (liver) and R (erythrocyte) isozymes of pyruvate kinase are allosterically inhibited at high ATP concentrations (Figure 13.18), in a kinetically similar fashion: High ATP levels reduce the apparent affinity of pyruvate kinase for its other substrate, phosphoenolpyruvate. A second allosteric effect is the **feedforward activation** of pyruvate kinase by fructose-1,6-bisphosphate. This effect, the converse of feedback inhibition, ensures that carbon passing the first regulated step in the pathway (PFK) will be able to complete its passage through glycolysis and that undesirable accumulation of intermediates will not occur. A third feedback control effect is inhibition of pyruvate kinase by acetyl-CoA, the major product of fatty acid oxidation. This inhibition allows the cell to reduce glycolytic flux when ample substrates are available from fat breakdown. Finally, pyruvate kinase is inhibited by some amino acids, particularly alanine, the major gluconeogenic precursor among the amino acids. This relationship allows inhibition of glycolysis, with consequent activation of gluconeogenesis, specifically in gluconeogenic tissues, when ample energy and substrates are available. Control at the pyruvate kinase step allows conservation of high-energy phosphate in the phosphoenolpyruvate molecule.

Recall that the liver pyruvate kinase isozyme is also regulated by reversible phosphorylation/dephosphorylation, with the dephosphorylated form far more active than the phosphorylated form (page 533). Phosphorylation is stimulated by glucagon, acting through the same cAMP-dependent protein kinase pathway that phosphorylates PFK-2/FBPase-2. Thus, when blood glucose is low, glucagon

secretion leads to inactivation of pyruvate kinase in liver and inhibition of glycolysis. Phosphoenolpyruvate is diverted instead to gluconeogenesis. Muscle pyruvate kinase, by contrast, is not regulated by covalent modification, and virtually all of the phosphoenolpyruvate produced in muscle is converted to pyruvate.

Acetyl-CoA can also be seen as a reciprocal regulator of glycolysis and gluconeogenesis, acting on the enzymes that interconvert pyruvate and phosphoenolpyruvate (Figure 13.18). Acetyl-CoA is a required activator of pyruvate carboxylase and an inhibitor of pyruvate kinase. It can thus signal, when its levels rise, that adequate substrates are available to provide energy through the citric acid cycle and that more carbon can be shuttled into gluconeogenesis and ultimately stored as glycogen. However, some biochemists have questioned whether the activation of pyruvate carboxylase by acetyl-CoA represents an important regulatory mechanism because its intramitochondrial levels under most conditions are far higher than the concentration giving half-maximal stimulation. Thus, the activity of pyruvate carboxylase *in vivo* might not vary in response to changing acetyl-CoA levels.

Finally, glucagon controls levels of the key gluconeogenic enzyme phosphoenolpyruvate carboxykinase (PEPCK), by activating transcription of the structural gene for PEPCK (Figure 13.18). Insulin has the converse effect. By inhibiting PEPCK gene transcription, insulin tends to depress gluconeogenic flux rates. Glucagon has an additional action at the genetic level: It represses synthesis of pyruvate kinase, thereby contributing to increased gluconeogenic flux from pyruvate to phosphoenolpyruvate.

Regulation at the Hexokinase/Glucose-6-Phosphatase Substrate Cycle

Recall that mammals possess several different isozymes of hexokinase that differ in their kinetic and regulatory properties (page 525). The hexokinase isoenzymes expressed in most tissues (HK-I, -II, -III) are inhibited by their product, glucose-6-phosphate, a mechanism that controls the influx of substrates into the glycolytic pathway. The liver isozyme, hexokinase IV, is not subject to feedback inhibition by glucose-6-phosphate. HK-IV is instead regulated indirectly by glucose through a mechanism that involves protein–protein interactions (Figure 13.22). When intracellular glucose concentrations are low, HK-IV is sequestered in the nucleus bound to a 68-kDa glucokinase regulatory protein (GKRP), thereby preventing hepatic glycolysis under these conditions. Elevated concentrations of glucose favor dissociation of HK-IV from GKRP, and the hexokinase translocates from the nucleus into the cytoplasm, where it can initiate glycolysis. The effect of glucose may not be direct, since fructose-1-phosphate and its precursors (such as fructose and sorbitol) also induce dissociation. Fructose-6-phosphate favors HK-IV binding to GKRP (F-6-P and F-1-P compete for a common binding site

FIGURE 13.22

Regulation of liver hexokinase by protein–protein interactions. Activity of the liver hexokinase isozyme IV (HKIV) is regulated by alternative protein–protein interactions with the glucokinase regulatory protein (GKRP) in the nucleus and dephosphorylated PFK-2/FBPase-2 in the cytoplasm. Insulin binding to its plasma membrane receptor stimulates dephosphorylation of PFK-2/FBPase-2. Glut2, plasma membrane glucose transporter. See legend to Figure 13.21 and text for details.

on GKRP). When HK-IV translocates to the cytoplasm, it forms a complex with the dephosphorylated form of PFK-2/FBPase-2. HK-IV is activated in this complex, further stimulating glycolytic flux. Note that activation of HK-IV is mediated by a protein–protein interaction rather than by fructose-2,6-bisphosphate. Recall from Figure 13.21 that dephosphorylation of PFK-2/FBPase-2 is stimulated by insulin or high glucose, increasing its kinase-to-bisphosphatase activity ratio. Moreover, binding of HK-IV increases this ratio, resulting in even higher fructose-2,6-bisphosphate levels. Thus, in response to a high carbohydrate meal (containing, for example, glucose or fructose), the liver PFK-2/FBPase-2 system appears to coordinate the rapid up-regulation of glucose phosphorylation (by hexokinase) with subsequent flux through glycolysis (at the PFK-1 step).

Glucose-6-phosphatase is not known to be allosterically controlled, but its K_M for glucose-6-phosphate is far higher than intracellular concentrations of this metabolite. Thus, intracellular activity is largely controlled in first-order fashion by the concentration of this substrate.

In summary, glycolysis and gluconeogenesis are controlled in large part by the energy charge of the cell, and by fuel status. Regulation is distributed over multiple steps, and is highly coordinated so that the two pathways never operate simultaneously in the same cell. Liver has additional control systems that reflect its special role in maintaining glucose homeostasis for the entire animal. The other major control point of glucose metabolism, at least in animals, is the breakdown and synthesis of glycogen. This extremely important process will be discussed shortly.

Entry of Other Sugars into the Glycolytic Pathway

Thus far our discussion of glycolysis has focused on glucose as a source of carbon for this pathway. Many other sources of carbohydrate energy are available, whether through digestion of foodstuffs or utilization of endogenous metabolites. This section focuses on the utilization of monosaccharides other than glucose, of disaccharides, and of glycerol derived from fat metabolism. These pathways are summarized in Figure 13.23.

Monosaccharide Metabolism

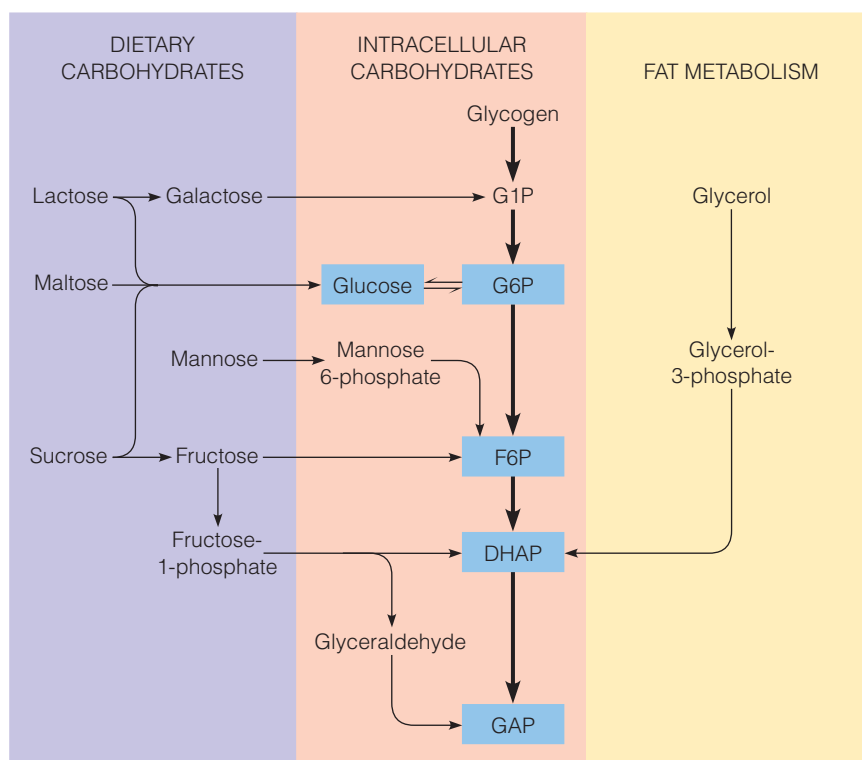

As stated earlier, hexokinases I, II, and III have broad substrate specificities. Thus, they can participate in utilization of hexoses other than glucose, particularly fructose and mannose. A separate enzyme, galactokinase, converts galactose to galactose-1-phosphate.

Galactose Utilization

D-Galactose is derived principally from hydrolysis of the disaccharide lactose [$\text{Gal}\beta(1 \rightarrow 4)\text{Glc}$], which is particularly abundant in milk. The main route for galactose utilization is conversion to glucose-6-phosphate, via the Leloir pathway, as shown in Figure 13.24. This pathway, named after Argentine biochemist Luis Leloir, begins with epimerization of β -D-galactose, released from lactose, to the α anomer (Figure 13.24, reaction 1). This step is necessary because the next reaction, an ATP-dependent phosphorylation of the hydroxyl at C-1, is catalyzed by an enzyme (**galactokinase**) that is specific for α -D-galactose (reaction 2). Transformation of galactose-1-phosphate to glucose-1-phosphate involves epimerization at carbon 4. However, before epimerization can occur, galactose-1-phosphate must be metabolically activated (reaction 3), by a transferase reaction with a nucleotide-linked sugar, **uridine diphosphate glucose**, also called UDP-glucose, or UDP-Glc. This reaction produces another nucleotide-linked sugar, **uridine diphosphate galactose**, abbreviated UDP-galactose or UDP-Gal. The UDP donor in reaction 3, UDP-Glc, is formed from glucose-1-phosphate and UTP by

FIGURE 13.23

Routes for utilizing substrates other than glucose in glycolysis. In animals, most of the carbohydrate other than glucose and glycogen comes from the diet, and most of the glycerol is derived from lipid catabolism.

UDP-Glc pyrophosphorylase. This enzyme is named from its reverse reaction, involving cleavage of the phosphoric acid anhydride bond in UDP-Glc by addition across that bond of the elements of pyrophosphoric acid.

Uridine diphosphate glucose

The glucose-1-phosphate formed in reaction 3 is then converted to glucose-6-phosphate by **phosphoglucomutase** (reaction 4), an enzyme involved also in glycogen synthesis. The final step regenerates UDP-glucose from UDP-Gal, by epimerization at C-4 (reaction 5). Details of this NAD^+ -linked reaction, catalyzed by **UDP-galactose 4-epimerase**, were shown previously in Figure 11.38 (page 448). The net stoichiometry of reactions 1–5 is:

This overlooks the critical involvement of the nucleoside diphosphate sugars UDP-Glc and UDP-Gal. As we will soon see in our discussion of glycogen biosynthesis, nucleoside diphosphate sugars are widely used intermediates in polysaccharide biosynthesis (see Chapter 9, page 328).

The enzymes on the left side of Figure 13.24 (UDP-Glc pyrophosphorylase and UDP-galactose 4-epimerase) also participate in mammary gland in the synthesis of lactose in milk. Lactose is formed from UDP-Gal plus glucose by **lactose synthase**, in the presence of the protein α -**lactalbumin** (see Figure 9.16, page 329). The endergonic synthesis of UDP-Gal in this tissue proceeds smoothly because of its high rate of conversion to lactose. As discussed in Chapters 9 and 19, UDP-Gal is also used in glycoprotein and glycolipid biosynthesis.

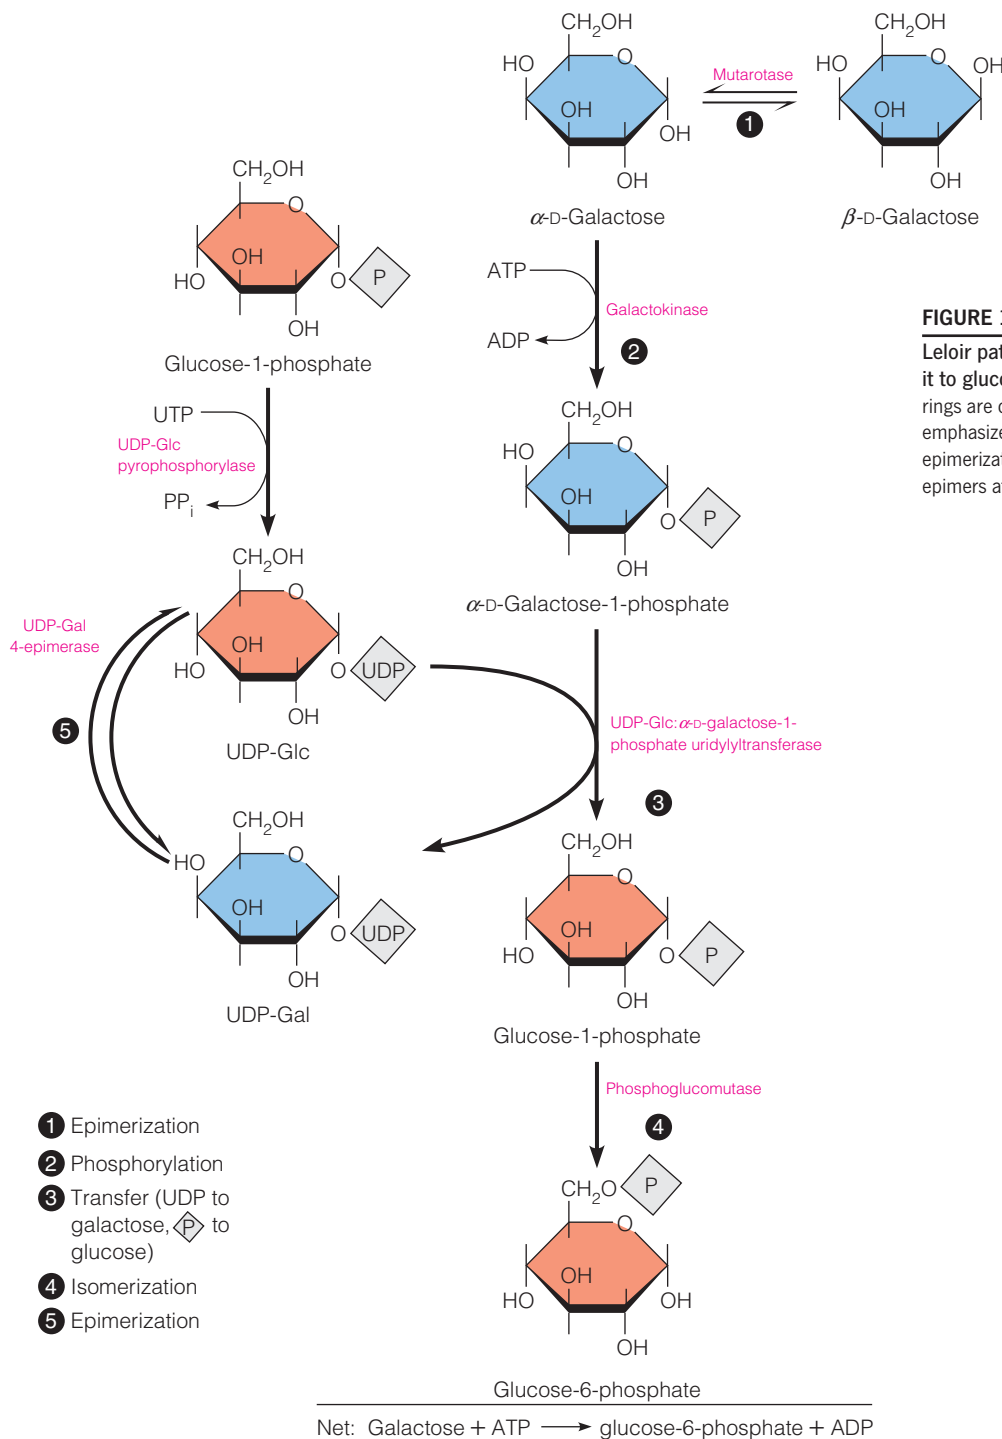

FIGURE 13.24

Leloir pathway for utilizing galactose by converting it to glucose-6-phosphate. The galactose and glucose rings are colored blue and orange, respectively, to emphasize that reaction 3 is a group transfer, not an epimerization. Recall that glucose and galactose are epimers at C-4 (see Figure 9.11).

A variety of genetic disorders in humans go by the generic name **galactosemia**. They all involve a failure to metabolize galactose, so that galactose, galactose-1-phosphate, or both accumulate in the blood and tissues. Clinical consequences include mental retardation, visual cataracts, and enlargement of the liver and other organs. These disorders result from hereditary deficiency of any one of three enzymes involved in galactose utilization. The most common form is caused by a deficiency of UDP-glucose: α -D-galactose-1-phosphate uridylyltransferase (see Figure 13.24, reaction 3). Rarer forms involve deficiencies of galactokinase or UDP-galactose 4-epimerase. Because the major dietary source of galactose is lactose in milk, the symptoms usually occur in infants. The condition can be alleviated by withholding milk and milk products from the diet.

Fructose Utilization

Fructose is present as the free sugar in many fruits, and it is also derived from hydrolysis of sucrose (see Figure 13.23). Phosphorylation of fructose in most tissues yields fructose-6-phosphate, a glycolytic intermediate. A different pathway is involved in vertebrate liver, where the enzyme **fructokinase** phosphorylates fructose to **fructose-1-phosphate** (F1P). This intermediate is then cleaved by a specific enzyme, **aldolase B**. Cleavage products are dihydroxyacetone phosphate, a glycolytic intermediate, and D-glyceraldehyde. The latter is then phosphorylated in an ATP-dependent reaction to give the glycolytic intermediate glyceraldehyde-3-phosphate. This pathway of utilization bypasses phosphofructokinase regulation and may account for the ease with which dietary sucrose is converted to fat (i.e., F1P → GAP + DHAP → glycerol-3 phosphate → triacylglycerols; see Chapter 17).

Fructose is also the major component in the “high fructose corn syrup” used to sweeten soft drinks, and there is mounting evidence linking consumption of high fructose corn syrup to increased risk of obesity and type 2 diabetes.

Mannose Utilization

Finally, among the major hexoses, mannose arises through digestion of foods containing certain polysaccharides or glycoproteins. The hexokinase-catalyzed phosphorylation of mannose to mannose-6-phosphate is followed by isomerization of the latter to fructose-6-phosphate (see Figure 13.23).

Disaccharide Metabolism

The three disaccharides most abundant in foods are maltose, lactose, and sucrose. Maltose is available primarily as an artificial sweetener, derived from starch, while lactose and sucrose are abundant natural products. In animal metabolism they are hydrolyzed in cells lining the small intestine, to give the constituent hexose sugars:

The hexose sugars pass via the portal vein to the liver, where they are catabolized as described in the previous section.

Lactase is secreted in the intestines of infants to digest the lactose in their mothers' milk. Because milk is not ingested by most mammals after weaning, lactase secretion decreases in adults as part of a normal developmental program. Humans are unusual in the animal kingdom in that many of us continue to drink milk into adulthood. Lactase deficiency in adult humans ranges from 5–20% in whites, to 75% in blacks, to almost 90% in Asians. This causes **lactose intolerance**, a condition in which ingestion of milk or lactose-containing milk products causes intestinal distress because the gut bacteria ferment the lactose that accumulates.

Plants and microorganisms have different pathways for metabolizing disaccharides. Bacteria metabolize sucrose through the action of **sucrose phosphorylase**:

The digestion of neutral fat (triacylglycerols) and most phospholipids generates glycerol as one product. In animals, glycerol first enters the glycolytic pathway by the action in liver of **glycerol kinase**.

The product is then oxidized by **glycerol-3-phosphate dehydrogenase** to yield dihydroxyacetone phosphate, which is catabolized by glycolysis (see Figure 13.23).

Polysaccharide Metabolism

In animal metabolism, two primary sources of glucose are derived from polysaccharides: (1) digestion of dietary polysaccharides, chiefly starch from plant foodstuffs and glycogen from meat; and (2) mobilization of the animal's own glycogen reserves. Recall from Chapter 9 that starch, the major nutrient polysaccharide of plants, consists of the unbranched glucose polymer amylose and the branched polymer amylopectin. Glucose residues in both polymers are linked by $\alpha(1 \rightarrow 4)$ glycosidic bonds, but amylopectin also has $\alpha(1 \rightarrow 6)$ linkages, which provide branch points in the otherwise linear polymer. Glycogen is chemically similar to amylopectin, except that it is more highly branched and is of higher molecular weight. Many microorganisms, like animals, store carbohydrate as glycogen.

Hydrolytic and Phosphorolytic Cleavages

Polysaccharide digestion and glycogen mobilization both involve sequential cleavage of monosaccharide units from nonreducing ends of glucose polymers. The first of these processes occurs via *hydrolysis* and the second via *phosphorolysis*. These processes are chemically similar, involving either water or inorganic phosphate as the nucleophile (Figure 13.25). Hydrolysis is the cleavage of a bond by addition across that bond of the elements of water, and a phosphorolytic cleavage occurs by addition of the elements of phosphoric acid. The reaction catalyzed by glyceraldehyde-3-phosphate dehydrogenase (Figure 13.6, page 530) is a good example of a phosphorolysis. An enzyme catalyzing a phosphorolysis is often called a **phosphorylase**, to be distinguished from a *phosphatase* (or, more precisely, a *phosphohydrolase*), which catalyzes the hydrolytic cleavage of a phosphate ester bond.

Energetically speaking, the advantage of a phosphorolytic mechanism is that mobilization of glycogen yields most of its monosaccharide units in the form of sugar phosphates. These units can be converted to glycolytic intermediates directly, without the investment of additional ATP. By contrast, starch digestion yields glucose plus some maltose; ATP and the hexokinase reaction are necessary to initiate glycolytic breakdown of these sugars.

The hydrolytic mechanism is useful, however, for the digestion of dietary carbohydrate, which occurs largely in the intestine. Digestion products must be absorbed and transported to the liver, where they are converted into glucose. Because sugar phosphates, like other charged compounds, are inefficiently transported across cell membranes, the hydrolytic digestion of polysaccharides to yield hexose sugars facilitates their uptake by tissues.

In plant metabolism we are not concerned with digestion because with few exceptions plants synthesize both monosaccharides and energy-storage polysaccharides via photosynthesis. However, the same enzymatic mechanisms are used to mobilize stored carbohydrate in plant metabolism as in animals—both hydrolysis and phosphorolysis of starch, with hydrolysis predominating. In the brewing of beer, the controlled germination of cereal seeds such as barley develops hydrolytic enzymes that break starch down to mono- and disaccharides for later fermentation by yeast. This process is called malting.

FIGURE 13.25

Cleavage of a glycosidic bond by hydrolysis or phosphorolysis. This formal diagram shows how the elements of water or phosphoric acid, respectively, are added across a glycosidic bond.

Dietary polysaccharides are metabolized by hydrolysis to monosaccharides. Intracellular carbohydrate stores, as glycogen, are mobilized as phosphorylated monosaccharides by phosphorylase.

FIGURE 13.26

Sequential digestion of amylopectin or glycogen by α -amylase and $\alpha(1 \rightarrow 6)$ -glucosidase.

(Top) α -Amylase in saliva cleaves 1 \rightarrow 4 bonds between the maltose units of amylopectin (or glycogen). However, it cannot cleave 1 \rightarrow 6 glycosidic bonds in the branched polymer, and a limit dextrin (gray) accumulates unless $\alpha(1 \rightarrow 6)$ -glucosidase (debranching enzyme) is present. (Bottom) $\alpha(1 \rightarrow 6)$ -Glucosidase in the intestine cleaves the branch points, exposing the amylose core to further digestion by amylase.

Starch and Glycogen Digestion

In animals, the digestion of starch and glycogen begins in the mouth, with the action of α -**amylase** secreted in saliva. This enzyme cleaves internal $\alpha(1 \rightarrow 4)$ linkages of both polymers. In the intestine, digestion continues, aided by α -amylase secreted by the pancreas. α -Amylase degrades amylose to maltose and a little glucose. However, it only partially degrades amylopectin and glycogen, as shown in Figure 13.26, because it cannot cleave the $\alpha(1 \rightarrow 6)$ linkages found at branch points. The product of exhaustive digestion of amylopectin or glycogen by α -amylase is called a **limit dextrin**; its continued degradation requires the action of a “debranching enzyme,” $\alpha(1 \rightarrow 6)$ -**glucosidase** (also called isomaltase). This action exposes a new group of $\alpha(1 \rightarrow 4)$ -linked branches, which can be attacked by α -amylase until a new set of $\alpha(1 \rightarrow 6)$ -linked branches is reached. The end result of the sequential action of these two enzymes is the complete breakdown of starch or glycogen to maltose and some glucose. Maltose is cleaved hydrolytically by **maltase**, yielding 2 molecules of glucose, which is then absorbed into the bloodstream and transported to various tissues for utilization.

Glycogen Metabolism in Muscle and Liver

Before describing the enzymology and regulation of animal glycogen metabolism, we should have some idea of the different functions of the glycogen stores in muscle and liver. Glycogen is the major energy source for contraction of skeletal muscle. Because liver derives most of its own metabolic energy from fatty acid oxidation, liver glycogen has quite a different function—as a source for blood glucose, to be transported to other tissues for catabolism. Liver serves primarily as a “glucostat,” adjusting synthesis and breakdown of glycogen to maintain appropriate blood glucose levels. As befits this role, the liver contains relatively large glycogen stores, from 2% to 8% of the weight of the organ. In liver the maximal rates of glycogen synthesis and degradation are about equal, whereas in muscle the maximal rate of glycogenolysis exceeds that of glycogen synthesis by about 300-fold. Although the enzymology of glycogen synthesis and breakdown is similar in liver and muscle, the endocrine control in liver is quite different, as we discuss here and in Chapter 18. The enzymes differ structurally as well.

Glycogen Breakdown

The principal glycogen stores in vertebrates are in skeletal muscle and liver. Breakdown of these stores into usable energy, or **mobilization** of glycogen, involves sequential phosphorylytic cleavages of $\alpha(1 \rightarrow 4)$ bonds, catalyzed by **glycogen phosphorylase**. In plants, starch is similarly mobilized by the action of **starch phosphorylase**. Both reactions release glucose-1-phosphate from nonreducing ends of the glucose polymer:

The cleavage reaction is slightly disfavored under standard conditions ($\Delta G^\circ = +3.1 \text{ kJ/mol}$), but the relatively high intracellular levels of inorganic phosphate cause this reaction to operate in vivo almost exclusively in the degradative, rather than the synthetic, direction. Note that the reaction proceeds with retention of configuration at carbon 1, i.e., the phosphate is in α linkage in the glucose-1-phosphate product.

Like α -amylase, phosphorylases cannot cleave past $\alpha(1 \rightarrow 6)$ branch points. In fact, cleavage stops four glucose residues from a branch point. The debranching process involves the action of a second enzyme, as shown in Figure 13.27. This glycogen “debranching enzyme,” ($\alpha(1,4 \rightarrow \alpha(1,4))$ glucantransferase, catalyzes two reactions. First is the transferase activity, in which the enzyme removes three of the remaining glucose residues and transfers this trisaccharide moiety intact to the end of some other outer branch via a new $\alpha(1 \rightarrow 4)$ linkage. Next, the remaining glucose residue, which is still attached to the chain by an $\alpha(1 \rightarrow 6)$ bond, is cleaved by the $\alpha(1 \rightarrow 6)$ -glucosidase activity of the same debranching enzyme. This yields one molecule of free glucose and a branch extended by three $\alpha(1 \rightarrow 4)$ -linked glucose residues. This newly exposed branch is now available for further attack by phosphorylase. The end result of the action of these two enzymes is the complete breakdown of glycogen to glucose-1-phosphate (~90%) and glucose (~10%).

At this point you might wonder why the glycogen breakdown scheme has evolved to include this complex debranching process. The importance of storing carbohydrate energy in the form of a highly branched polymer may well lie in an animal's need to generate energy very quickly following appropriate stimuli. Glycogen phosphorylase attacks *exoglycosidic* bonds—it cleaves sequentially from nonreducing ends. The more such ends that exist in a polymer, the faster the polymer can be mobilized.

To be metabolized via glycolysis, the glucose-1-phosphate produced by phosphorylase action must be converted to glucose-6-phosphate. This isomerization is accomplished by phosphoglucomutase. This reaction is also important in glycogen synthesis. The reaction is mechanistically similar to that of phosphoglycerate mutase (page 532), except that in phosphoglucomutase a phosphoserine residue on the enzyme reacts with substrate, instead of phosphohistidine:

The serine residue that carries the phosphate group is unusually reactive, as shown by the fact that phosphoglucomutase, like chymotrypsin and other serine proteases, is irreversibly inhibited by diisopropylfluorophosphate. The inhibition, like that of chymotrypsin (see Chapter 11), involves acylation of only the active site serine.

Most of the glycogen in vertebrate animals is stored as granules in cells of liver and skeletal muscle. As we learned from our discussion of gluconeogenesis, a major function of the liver is to provide glucose to other tissues for metabolism. This function is accomplished both through glycogen mobilization and through gluconeogenesis. Both processes yield phosphorylated forms of glucose, which cannot exit from liver cells. Conversion to free glucose requires the action of glucose-6-phosphatase, the same enzyme used in gluconeogenesis.

Glycogen Biosynthesis

A major fate of glucose in animals is the synthesis of glycogen. The mechanisms that are used to form glycosidic bonds in glycogen are general mechanisms used in the synthesis of all polysaccharides. For many years it was thought that reversal of the glycogen phosphorylase reaction was the major route for glycogen synthesis. However, three observations could not be reconciled with this notion. First, intracellular levels of orthophosphate are relatively high, which would make it difficult on equilibrium grounds for phosphorylase to catalyze glycogen synthesis *in vivo*. Second, although phosphorylase can synthesize glycogen *in vitro*, the product is of much lower molecular weight than natural glycogen. Third, epinephrine secretion activates glycogen metabolism only in the direction of breakdown; in

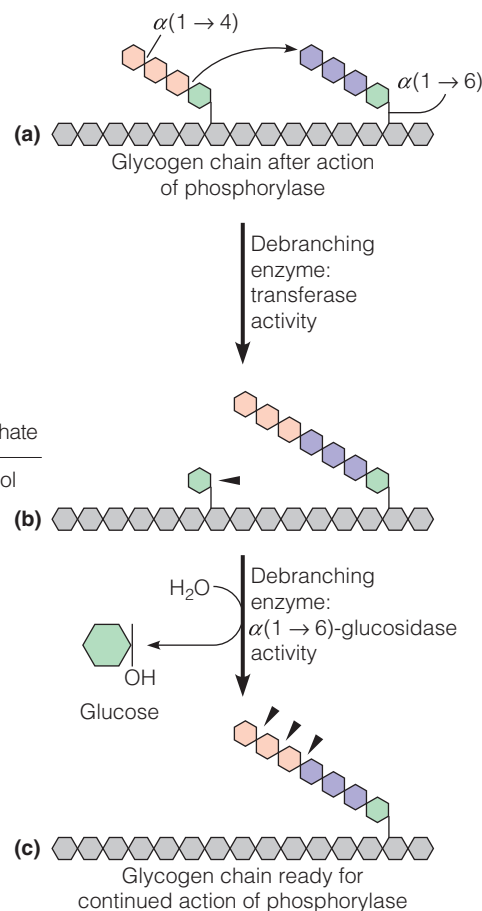

FIGURE 13.27

The debranching process in glycogen catabolism.

(a) A glycogen chain following activity by phosphorylase, which cleaves off glucose residues to within four residues of the branch point. (b) The glycogen chain following transferase activity by the debranching enzyme. The three remaining glucose residues with $\alpha(1 \rightarrow 4)$ linkage have been transferred to a nearby nonreducing end. (c) The glycogen chain following $\alpha(1 \rightarrow 6)$ -glucosidase activity by the debranching enzyme, which has removed the last remaining glucose residue of the branch. Phosphorylase will cleave off all but four glucose units of the newly elongated branch, beginning the debranching process again. The new cleavage points are indicated by wedges.

fact, epinephrine inhibits glycogen biosynthesis. All of these factors suggested that glycogen is synthesized by a different enzyme.

Glycogen Synthase and the Branching Process

In the late 1950s, Luis Leloir discovered that the substrate for glycogen biosynthesis is *uridine diphosphate glucose* (UDP-Glc, page 558). The enzyme involved, **glycogen synthase**, is bound tightly to intracellular glycogen granules.

Biosynthesis of UDP-Glucose

UDP-glucose is the metabolically activated form of glucose for glycogen synthesis.

Let us first review how the substrate UDP-Glc is synthesized from blood glucose. Glucose is transported into cells by a plasma membrane **glucose transporter**. As shown in Figure 13.28, it is then phosphorylated by hexokinase to give glucose-6-phosphate, which is isomerized to glucose-1-phosphate by phosphoglucomutase. The enzyme **UDP-glucose pyrophosphorylase** then catalyzes the synthesis of UDP-glucose. The free energy change of this phosphoanhydride exchange reaction is ~ 0 , but it is drawn forward by rapid enzymatic cleavage of pyrophosphate to orthophosphate, catalyzed by pyrophosphatase. Hydrolysis of pyrophosphate is exergonic by ~ 19 kJ/mol under standard conditions.

The Glycogen Synthase Reaction

UDP-glucose is the immediate donor of a glucosyl residue to the nonreducing end of a glycogen branch, which must be at least four glucose residues in length. Glycogen synthase is a **glycosyltransferase**—an enzyme that transfers an activated sugar unit to a nonreducing sugar hydroxyl group. The reaction, depicted in Figure 13.29, generates an $\alpha(1 \rightarrow 4)$ glycosidic linkage between C-1 of the incoming glucosyl moiety and C-4 of the glucose residue at the terminus of the glycogen chain. The reaction involves nucleophilic attack by the 4—OH of the incoming glucosyl residue on C-1 of UDP-glucose. C-1 is rendered electrophilic by elimination of UDP, an excellent leaving group, but the precise mechanism remains unsettled. The enzyme continues to add glucose residues successively to the 4-hydroxyl group at the nonreducing end. Because UDP-Glc is a high-energy compound, the glycogen synthase reaction is exergonic, with a $\Delta G^{\circ'}$ of about -13.4 kJ/mol. Glycogen synthase catalyzes the rate-limiting step of glycogen biosynthesis, and is the site of regulation of this anabolic pathway.

The primer for glycogen synthase is a short chain of glucose residues assembled by a small ($M_R = 37,000$) protein called **glycogenin**, which transfers glucose from UDP-Glc to a tyrosine residue on the protein itself. Glycogenin then transfers additional glucosyl units from UDP-Glc, to give $\alpha(1 \rightarrow 4)$ -linked primers up to eight residues long. These primers are then extended by glycogen synthase. Glycogenin thus forms the core of the mature glycogen particle that eventually consists of up to 60,000 glucose residues. These particles are stored in liver and muscle cells in granules (see Figure 9.17, page 330), which contain all of the enzymes that metabolize glycogen as well.

Formation of Branches

Glycogen biosynthesis requires glycogen synthase for polymerization and a transglycosylase to create branches.

Glycogen synthesis involves both polymerization of glucose units and branching from $\alpha(1 \rightarrow 6)$ linkages. These branches are important because they increase the solubility of the polymer and also increase the number of nonreducing ends from which glucose-1-phosphate can be derived during glycogen mobilization. However, these branches cannot be introduced by glycogen synthase. Another enzyme, called **branching enzyme** but more accurately termed **amylo-(1,4 \rightarrow 1,6)-transglycosylase**, comes into play, as shown in Figure 13.30. This branching enzyme transfers a terminal fragment, some 6 or 7 residues long, from a branch terminus at least 11 residues in length to a hydroxyl group at the 6-position of a glucose residue in the interior of the polymer. The reaction involves nucleophilic attack of the C-6 hydroxyl on C-1 of the oligosaccharide that will form the

branch. The reaction thus creates two nonreducing termini for continued action by glycogen synthase, whereas just one existed before. The branching process does not involve a large free energy change because of the chemical similarity of (1 → 4) and (1 → 6) linkages.

Coordinated Regulation of Glycogen Metabolism

In Chapter 11 we mentioned the control of glycogen breakdown, or glycogenolysis, as a particularly well-understood example of a regulatory cascade, a process in which the intensity of an initial regulatory signal is amplified manifold through a series of enzyme activations. This amplification is particularly important in the case of glycogenolysis because fright, for example, or the need to catch prey, can trigger an instantaneous requirement for increased energy generation and utilization. Glycogen represents the most immediately available *large-scale* source of metabolic energy, and hence it is important that animals be able to activate glycogen mobilization rapidly. Moreover, glycogen breakdown is the first hormone-controlled process for which the molecular action of the hormone was understood in detail (Figure 13.31).

FIGURE 13.29

The glycogen synthase reaction.

Structure of Glycogen Phosphorylase

In skeletal muscle, glycogen phosphorylase is a dimer containing two identical polypeptide chains, each of 97,400 daltons. The enzyme exists in two interconvertible forms—the relatively *active* phosphorylase *a* and the relatively *inactive* phosphorylase *b*.^{*} Phosphorylation of serine 14 on each subunit induces a conformational change that converts the relatively inactive phosphorylase *b* to the active phosphorylase *a*. Thus, phosphorylation shifts the conformational equilibrium from the less active T state to the more active R state. As shown in Figure 13.31, activation is catalyzed by a specific **phosphorylase *b* kinase**, which transfers phosphate from ATP to the two serine residues. Deactivation is brought about by a specific phosphorylase phosphatase, also called **phosphoprotein phosphatase 1 (PP1)**. As we shall see, PP1 is a ubiquitous serine/threonine protein phosphatase in eukaryotes that regulates many cellular processes through the dephosphorylation of dozens of substrates. PP1 is directed to these various functions through its association with a diverse set of targeting proteins.

FIGURE 13.30

The branching process in glycogen synthesis.

Branching is brought about by the action of amylo-(1,4 → 1,6)-transglucosylase.

^{*}For enzymatically interconvertible enzyme systems such as glycogen phosphorylase, *a* and *b* refer to the more active and less active forms, respectively.

FIGURE 13.31

The regulatory cascade controlling glycogen breakdown. The hormonal regulation of glycogen breakdown is shown here as it might occur in a muscle cell after epinephrine stimulation or a liver cell after glucagon or epinephrine stimulation. Hormone binding to its plasma membrane receptor triggers an interaction with a G protein, which in turn interacts with and activates adenylate cyclase (see Chapter 23). Binding of cyclic AMP to the R (regulatory) subunits of the protein kinase A (PKA) R_2C_2 tetramer causes their dissociation from the C (catalytic) subunits. The active C monomer catalyzes phosphorylation of specific serine residues on inactive phosphorylase b kinase, activating phosphorylase b kinase in the process. This active kinase phosphorylates a serine residue on each of the two subunits of the homodimeric phosphorylase b. This converts the inactive phosphorylase b to the active phosphorylase a, which then catalyzes glycogen breakdown. Each reaction in the regulatory cascade amplifies the hormonal signal, so that binding of very few hormone molecules at the cell surface triggers enormous release of glucose-1-phosphate from intracellular glycogen stores. Inactivation of the pathway involves the action of protein phosphatase 1 (PP1), which removes the phosphates from phosphorylase b kinase and phosphorylase a. The activity of PP1 is also subject to hormonal control.

Control of Phosphorylase Activity

Phosphorylase b kinase is also activated by phosphorylation from an inactive to an active form (Figure 13.31). This reaction is catalyzed by the same cyclic AMP–dependent protein kinase that phosphorylates the bifunctional PFK-2/FBPase-2 in glycolysis and gluconeogenesis. In glycogenolysis, cyclic AMP exerts

Glycogen mobilization is controlled hormonally by a metabolic cascade that is activated by cAMP formation and involves successive phosphorylations of enzyme proteins.

The rapid mobilization of muscle glycogen triggered by epinephrine is one of several components of the “fight or flight” response.

a rapid and efficient activation. At the same time, it inhibits glycogen synthesis through a separate regulatory cascade, discussed below.

The primary hormone promoting glycogenolysis in muscle is epinephrine (formerly called adrenaline), which is secreted from the adrenal medulla and binds to specific receptors on muscle cell membranes. Liver glycogen mobilization is stimulated largely by the pancreatic peptide hormone glucagon, although liver can also respond to epinephrine. In both cases, as summarized in Figure 13.31, binding of the hormone at the membrane stimulates the synthesis of cAMP by membrane-bound adenylate cyclase, through the action of a G protein, G_{sa} . Cyclic AMP in turn activates protein kinase A, which catalyzes the phosphorylation of phosphorylase *b* kinase. This kinase in turn catalyzes the phosphorylation of phosphorylase *b* to *a* and, hence, the activation of glycogen breakdown, through the action of phosphorylase *a*. These events explain how the secretion of relatively few molecules of hormone, such as epinephrine, can, within just a few moments, trigger a massive conversion of glycogen to glucose-1-phosphate.

Epinephrine is the principal hormone governing the “fight or flight” response to various stimuli. In addition to stimulating glycogenolysis, the hormone triggers a variety of physiological events, such as increasing depth and frequency of heartbeats. These cardiac effects, triggered by increased intracellular Ca^{2+} concentrations, are also mediated via cAMP, as discussed further in Chapter 23. Cyclic AMP also regulates other metabolic processes, including the stimulation of fat breakdown and the inhibition of glycogen synthesis. We shall return to these effects as we proceed through metabolism.

Proteins in the Glycogenolytic Cascade

Our presentation of the glycogenolytic cascade started with the phosphorylase reaction and then worked backward, to the initial hormonal signal. Now let us start with the hormone and work forward, with emphasis on the proteins involved (again, refer to Figure 13.31). The hormone binds to a specific receptor located on the outside of the cytoplasmic membrane. This binding leads to activation of adenylate cyclase, which is bound to the inside of the membrane; the activation is mediated by a G protein, G_{sa} . (G proteins and adenylate cyclase will be discussed in great detail in Chapter 23.)

Cyclic AMP–dependent protein kinase, also called protein kinase A (PKA), is a tetramer consisting of two *catalytic* subunits, C, and two *regulatory* subunits, R (Figure 13.32a). The tetramer, R_2C_2 , is catalytically inactive. Structural analysis revealed that the catalytic subunits possess a core structure that is similar in all known protein kinases. The catalytic mechanism involves nucleophilic attack by a serine residue in the protein substrate upon the γ -phosphate of ATP. In the R_2C_2 tetramer, however, the catalytic subunits are competitively inhibited by a short inhibitor segment (IS) from the R subunit that binds in the C subunit’s active site (Figure 13.32b). Each R subunit possesses two cAMP-binding sites (domains A and B). When bound to the C subunit, the R subunit has an extended dumbbell shape, with the two cAMP-binding domains wrapped around the large lobe of the catalytic subunit (Figure 13.32b). Binding of cAMP to the R subunits causes a dramatic conformational change in the R subunits, with the two cAMP-binding domains packed together in a compact globular structure (Figure 13.32c). This conformational change causes the tetramer to dissociate, releasing the catalytically active C subunits to catalyze the phosphorylation of target proteins, including phosphorylase *b* kinase.

Phosphorylase *b* kinase is a complex multisubunit protein of ~1.3 MDa, composed of four copies each of α , β , γ , and δ subunits. The γ subunit contains the catalytic site, and the regulatory α and β subunits contain the sites of phosphorylation by PKA. The δ subunit is a protein called **calmodulin**, or **calcium-modulating protein**. Calcium ion has long been known as an important physiological regulator, particularly of processes related to nerve conduction and muscle contraction.

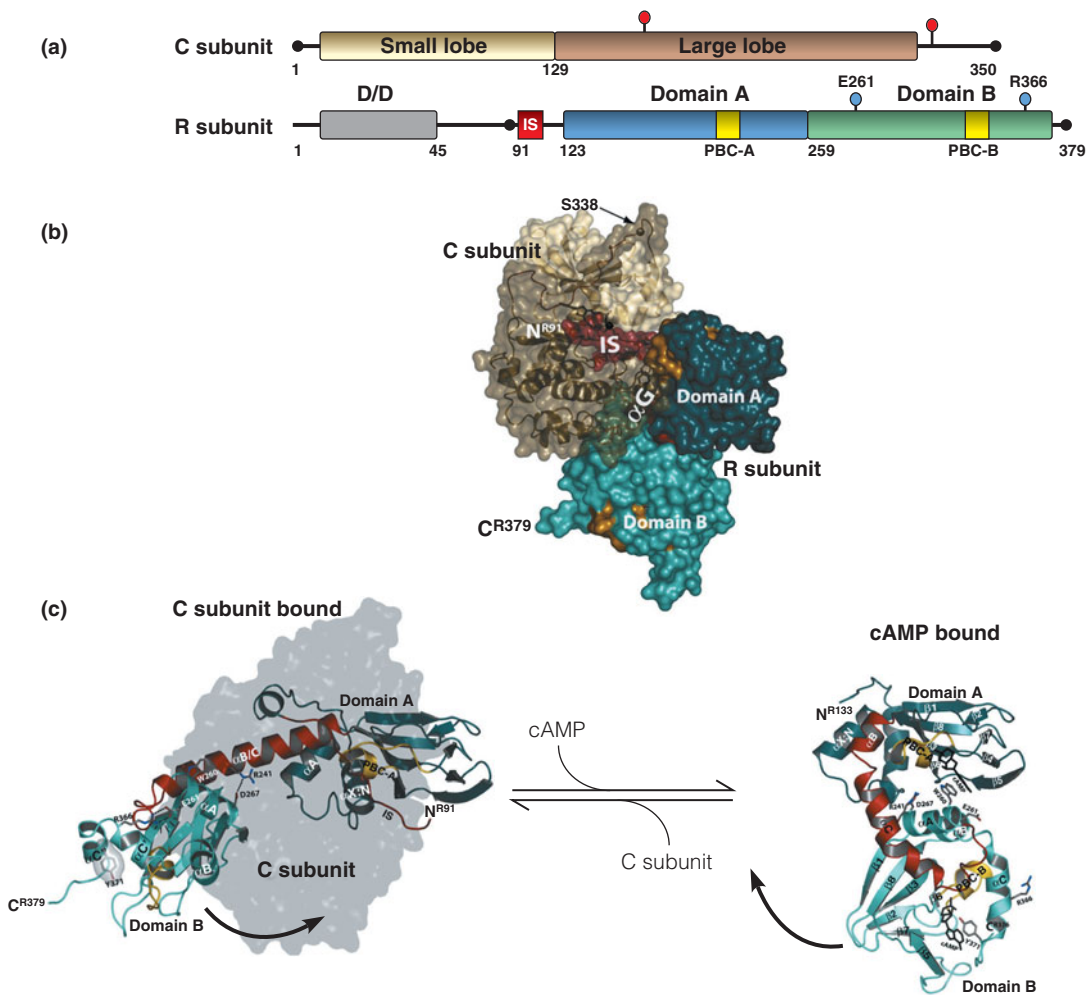

FIGURE 13.32

Structure and activation of cyclic AMP-dependent protein kinase (protein kinase A). (a) Domain structure of the catalytic (C) and regulatory (R) subunits. The two red spheres in the catalytic subunit indicate threonine or serine residues that must be phosphorylated for full activity. In the R subunit, IS indicates the inhibitor segment; PBC-A and -B indicate the locations of the cAMP binding sites. (b) Surface representation of the holoenzyme complex containing both C and R subunits. Each domain is colored with the same scheme used in panel (a). The active site of the catalytic subunit is marked by the inhibitor segment (red). (c) Conformational change of regulatory subunit upon binding cAMP. In the C subunit-bound structure (left), the R subunit has an extended dumbbell shape, with the two cAMP-binding domains wrapped around the large lobe of the catalytic subunit (gray). Upon binding cAMP, Domain B rotates $\sim 125^\circ$ toward Domain A (indicated by arrow) to adopt a compact globular structure (right), releasing the active catalytic subunits.

Most of these effects are mediated through the binding of Ca^{2+} to calmodulin, which amplifies small changes in intracellular Ca^{2+} concentration.

Calmodulin is a small protein ($M_r \sim 17,000$) of highly conserved amino acid sequence. It contains four calcium ion binding sites (Figure 13.33a). Each Ca^{2+} -binding site (Figure 13.33b) is composed of a helix-loop-helix motif known as an EF hand (Figure 13.34). This motif is found in a large number of Ca^{2+} -binding proteins. EF hand domains bind Ca^{2+} with a K_D of about 10^{-6} M, consistent with observations that calcium can effect intracellular metabolic changes in concentrations as low as $1 \mu\text{M}$. Binding stimulates a major conformational change in the protein, leading to a more compact and more highly helical structure, which augments the affinity of calmodulin for a number of regulatory target proteins (Figure 13.33c). In the case of phosphorylase *b* kinase, calmodulin plays a special role as an integral subunit of the enzyme. Hence, the glycogenolysis cascade depends on intracellular calcium concentration as well as on cyclic AMP levels. This dependence is particularly important in muscle, where contraction is stimulated by calcium release. Thus, Ca^{2+} plays a dual role, in provision of the energy substrates needed to support muscle contraction and in contraction itself.

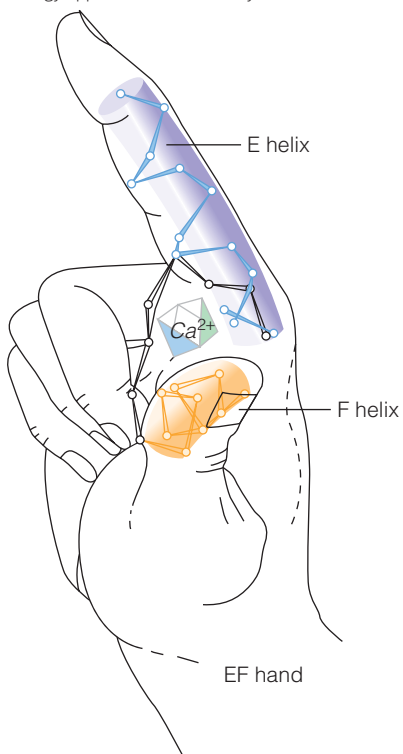

Nonhormonal Control of Glycogenolysis

Glycogen breakdown is under nonhormonal, as well as hormonal, control. Muscle and liver possess distinct isozymes of glycogen phosphorylase that differ somewhat in their allosteric properties. Recall that phosphorylase *b* is relatively inactive, existing primarily in its T state. This form of the enzyme is activated allosterically by 5'-AMP (but not by cyclic AMP). Usually this activation does not occur in the cell because

FIGURE 13.33

Calmodulin. (a) This model shows a backbone representation of bovine brain calmodulin, as determined by X-ray crystallography (PDB ID 1CLL). Ca^{2+} ions are depicted as yellow balls. The four Ca^{2+} binding domains are colored orange, violet, red, and blue, and the two ends are connected by a long central α -helix (green). (b) Each Ca^{2+} -binding domain is composed of an α -helix motif known as an EF hand. The dotted lines show the interaction between Ca^{2+} and oxygen atoms (red) on the side chains of Asp, Thr, and Glu residues. (c) The long central α -helix (green) undergoes conformational changes as a result of calcium binding. These conformational changes are responsible for changes in calmodulin's affinity for calcium-regulated targets. The structure on the left shows calmodulin (CaM) bound to the target peptide (cyan) of myosin light chain kinase (MLCK) in a "wraparound" conformation (PDB ID 1CDL). The structure on the right shows a calmodulin dimer bound to the target peptides (cyan) of a calcineurin A in an "extended" conformation (PDB ID 2W73). This illustrates the phenomenon of "domain swapping," in which each peptide is bound between the N-terminal lobe from one calmodulin monomer and the C-terminal lobe from the other calmodulin monomer.

ATP, which is far more abundant and does not activate phosphorylase *b*, competes with AMP for binding to the enzyme. However, under energy-deprived conditions, AMP may accumulate at the expense of ATP breakdown, to the extent that phosphorylase *b* and hence glycogenolysis are activated. Recent crystallographic studies show that the structural changes induced in phosphorylase *b* by AMP are remarkably similar to those induced by phosphorylation of phosphorylase *b* to *a*, even though AMP binding and phosphorylation occur at quite distant sites. Thus, AMP binding shifts the conformational equilibrium of phosphorylase *b* to the more active R state (Figure 13.35). ATP and glucose-6-phosphate, signs of adequate energy status, shift the equilibrium of phosphorylase *b* back to the less active T state. Once glycogen phosphorylase is phosphorylated, it exists primarily in the R form and is unresponsive to most metabolite effectors. However, glucose and glucose-6-phosphate act synergistically on phosphorylase *a*, shifting its equilibrium slightly back toward the T state. In the T state, the phosphoserine side chains are more accessible to phosphoprotein phosphatase 1, and the T state is more readily dephosphorylated than the R state.

Thus, the mobilization of energy reserves from glycogen can be brought about either by hormonal stimulation, reflecting a physiological need for increased ATP production, or by an allosteric mechanism triggered when the energy level is deficient for maintenance of normal functions. The nonhormonal mechanism, which does not involve a metabolic cascade, stimulates glycogenolysis in response to a low energy charge, whereas the hormonally induced cascade predominates when the need is to rapidly augment energy generation. In both cases the phosphorylation of glycogen to glucose-1-phosphate is enhanced. If, on the other hand, the cell has a high energy charge, signaled by high ATP and/or glucose-6-phosphate levels, glycogenolysis is turned off.

Control of Glycogen Synthase Activity

Earlier we noted that epinephrine secretion inhibits glycogen synthesis in muscle at the same time that it promotes glycogen mobilization. Glucagon has similar effects in liver. Control of both synthesis and degradation of glycogen is mediated by distinct

FIGURE 13.35

Control of glycogen phosphorylase activity. The enzyme exists in an equilibrium between a less active T state and a more active R state. The enzyme can be phosphorylated, in response to hormonal signals, by phosphorylase *b* kinase. Phosphorylation shifts the equilibrium largely to the R state. Dephosphorylation is catalyzed by phosphoprotein phosphatase 1 (PP1). Both T and R states can be dephosphorylated by PP1, but the T state is a better substrate because the phosphoserine side chains are more accessible in this conformation. The unphosphorylated form, phosphorylase *b*, exists largely in the T state, and its $T \rightleftharpoons R$ equilibrium is controlled by allosteric effectors AMP, ATP, and glucose-6-phosphate (G6P). Muscle phosphorylase *b* is much more sensitive to AMP and G6P than liver phosphorylase *b*. Glucose and G6P synergistically inhibit phosphorylase *a* by shifting its equilibrium to the T state, which is then rapidly dephosphorylated by PP1.

regulatory cascades involving cyclic AMP–dependent protein kinase and reversible protein phosphorylations. However, whereas the cascade controlling glycogenolysis leads to *activation* of glycogen phosphorylase (see Figure 13.31), the cascade controlling glycogen synthesis leads to *inhibition* of glycogen synthase (Figure 13.36).

Phosphorylation of Glycogen Synthase

Glycogen synthase from vertebrate tissues is a tetrameric protein comprising four identical subunits and having a total molecular weight of about 340 kilodaltons. Glycogen synthase activity is controlled by covalent modification, allosteric activation, and intracellular location. Like phosphorylase, glycogen synthase exists in phosphorylated and dephosphorylated states, with up to nine serine residues on each subunit subject to this modification. Several different protein kinases are known to act on glycogen synthase (Figure 13.36). Dephosphorylation is catalyzed by PP1, the same phosphatase that acts on glycogen phosphorylase and phosphorylase *b* kinase.

In contrast to glycogen phosphorylase, it is the unphosphorylated form, glycogen synthase *a*, that is the active form. Glycogen synthase *a* is active even in the absence of G6P, whereas the phosphorylated forms (glycogen synthase *b*) are dependent on allosteric activation by G6P. Binding of this effector overrides inhibition caused by phosphorylation (Figure 13.36). In addition, G6P binding induces a conformational change that makes the enzyme a better substrate for dephosphorylation by PP1.

Let's examine the consequences of hormone release upon glycogen synthase (see Figure 13.36). Just as depicted in Figure 13.31, the activation of adenylate cyclase by epinephrine (in muscle) or glucagon (in liver) promotes the dissociation of cAMP-dependent protein kinase (PKA) to give free catalytic C subunits. These C subunits phosphorylate active glycogen synthase *a* to inactive glycogen synthase *b*. To complicate the picture somewhat, several additional protein kinases, including AMP-activated protein kinase (AMPK), glycogen synthase kinase 3 (GSK3), and casein kinase II, can act on glycogen synthase *a*. The most important of these is GSK3. Each of these kinases phosphorylate different serine residues, but in a hierarchical manner, so that there are several different forms of glycogen synthase *b*, and it is an oversimplification to speak of just two forms. In general, as more sites are phosphorylated, the activity of the enzyme progressively decreases because of the following changes: (1) decreased affinity for the substrate, UDP-glucose; (2) decreased affinity for the allosteric activator, glucose-6-phosphate; and (3) increased affinity for ATP and P_i , both of which tend to antagonize the activation by glucose-6-phosphate. Thus, there is a graded series of responses to changing metabolic conditions, involving a series of different protein kinases. Whichever

Conditions that activate glycogen breakdown inhibit glycogen synthesis, and vice versa.

Glycogen synthase activity is controlled by phosphorylation, through mechanisms comparable to those controlling glycogen breakdown by phosphorylase but having reciprocal effects on enzyme activity.

FIGURE 13.36

Control of glycogen synthase activity. The enzyme can be phosphorylated, in response to hormonal signals, by several different protein kinases, including the catalytic subunit of cAMP-dependent protein kinase (PKA), AMP-activated protein kinase (AMPK), glycogen synthase kinase 3 (GSK3), and casein kinase II (CKII). Each subunit of the homotetramer can be phosphorylated on as many as nine serine residues. Dephosphorylation is catalyzed by phosphoprotein phosphatase 1 (PP1). Glucose-6-phosphate (G6P) can allosterically activate the phosphorylated enzyme. The conformational change also makes the enzyme a better substrate for dephosphorylation by PP1.

kinase is used, the net effect of phosphorylating glycogen synthase is inhibition of the enzyme, with consequent inhibition of glycogen synthesis.

Note that the glycogen *synthesis* cascade has one less stage than the glycogen *breakdown* cascade because PKA phosphorylates glycogen synthase directly, whereas it can act on glycogen phosphorylase only through its action on phosphorylase *b* kinase. The extra stage allows for more sensitive regulation of glycogen breakdown than of its synthesis, which is consonant with needs of animals for exceedingly rapid changes in demand for energy generation in muscle. In fact, experimental observations show that the maximum rate of muscle glycogen breakdown is some 300-fold higher than that of glycogen synthesis.

A Closer Look at Glycogen Synthase Regulation: Dephosphorylation of Glycogen Synthase *b*

As mentioned above, phosphoprotein phosphatase 1 (PP1) is the primary phosphatase that acts on glycogen synthase *b*. PP1 also dephosphorylates glycogen phosphorylase and phosphorylase *b* kinase. How is the activity and specificity of this enzyme controlled? Recall that PP1 is involved in the regulation of many cellular processes. The catalytic subunit of PP1 (PP1c) does not exist freely in the cell, but rather is associated with a host of different regulatory subunits. Indeed, PP1c has been shown to interact with as many as 100 different proteins and peptides. These regulatory subunits determine the intracellular localization, substrate specificity, and activity of PP1. One family of regulatory proteins is the glycogen-targeting subunits (G subunits). Mammals express at least 7 different G subunits, including G_M in muscle and G_L in liver, and these G subunits serve to anchor PP1 to the glycogen particle. Glycogen synthase, glycogen phosphorylase, and phosphorylase *b* kinase are also bound to the glycogen particles, and their dephosphorylation is mediated by PP1 bound to its G_M or G_L regulatory subunit. All G subunits possess a PP1-binding motif and a targeting domain with binding sites for glycogen and the PP1 substrates. G_M and G_L confer different regulatory properties onto PP1 in muscle and liver, respectively.

Let's start with muscle (see Figure 13.37). PP1c- G_M is regulated by phosphorylation of the G_M subunit, catalyzed by cAMP-dependent protein kinase (PKA). Phosphorylation of G_M leads to dissociation of PP1c, releasing it into the cytoplasm, where it is bound by a small protein called **phosphoprotein phosphatase inhibitor 1**, or **inhibitor 1**. When phosphorylated on a threonine residue, inhibitor 1 potently inhibits PP1c activity. Phosphorylation of inhibitor 1 is also carried out by PKA. Thus, as shown in Figure 13.37, cAMP exerts two effects in inhibiting glycogen synthesis: (1) phosphorylation of glycogen synthase, causing its inactivation; and (2) inhibition of phosphoprotein phosphatase 1, whose activity would tend to restore activity of glycogen synthase by catalyzing its dephosphorylation. Inhibitor 1 is

FIGURE 13.37

Regulation of phosphoprotein phosphatase 1 (PP1) in muscle. The active catalytic subunit of PP1 (PP1c) is anchored to the glycogen particle by its G subunit, G_M . Glycogen synthase *b* (GSb), phosphorylase *b* kinase (PK), and glycogen phosphorylase *a* (green) are also bound to the glycogen particle. Phosphorylation of G_M by cAMP-dependent protein kinase (PKA) leads to dissociation of PP1c, releasing it into the cytoplasm, where it is bound by inhibitor 1. Inhibitor 1 is also phosphorylated by PKA, forming a potent PP1c inhibitor. Sequestration and inhibition of PP1c increases the phosphorylation state of all the enzymes bound to the glycogen particle, resulting in inhibition of glycogen synthesis and stimulation of glycogen breakdown.

widely expressed in mammalian tissues, but is a particularly critical regulator of PP1 function in heart and in neuronal signaling. Thus, the phosphorylation cascade initiated by epinephrine binding to its receptor on the muscle cell leads to *inhibition* of glycogen synthesis (by phosphorylation of glycogen synthase and by inhibition of PP1 phosphatase activity) and *activation* of glycogen breakdown (by phosphorylation of glycogen phosphorylase and by inhibition of PP1). The net result is the flow of glucose from glycogen into glycolysis to provide ATP for muscle contraction.

Insulin has the opposite effect on muscle glycogen metabolism. In humans, skeletal muscle is the primary site for glucose storage, where up to 90% of glucose from a meal is converted to glycogen. During rest, insulin stimulates the storage of glucose as glycogen in muscle by enhancing glucose uptake and activating glycogen synthase. Glucose is imported in muscle mainly by GLUT4, a high-affinity, low-capacity glucose transporter. GLUT4 is initially localized in internal vesicles, which translocate to the plasma membrane of the muscle cell in response to insulin (see Figure 18.5, page 762). Entering glucose is phosphorylated to glucose-6-phosphate by hexokinase and then converted to glucose-1-phosphate for glycogen synthesis. Insulin binding also initiates a signaling pathway that leads to phosphorylation and inhibition of GSK3. Phosphorylation of glycogen synthase ceases, but its dephosphorylation continues. Recall that glucose-6-phosphate induces a conformational change in glycogen synthase *b* that makes it a better substrate for dephosphorylation by PP1. The net result is conversion of inactive phosphorylated glycogen synthase *b* to active dephosphorylated glycogen synthase *a*, and activation of glycogen synthesis.

Phosphoprotein phosphatase 1 is regulated differently in liver, reflecting the different roles of glycogen metabolism in liver and muscle (see Figure 13.38). Although the liver-specific G_L regulatory subunit anchors PP1 to glycogen granules in that tissue as well, G_L is not subject to reversible phosphorylation. Instead, PP1c- G_L possesses an allosteric binding site for glycogen phosphorylase *a* (the phosphorylated form), which *inhibits* the phosphatase activity of PP1c. Recall that PP1 binds both the T and R states of phosphorylase *a*, but only in the T state are the phosphoserine side chains accessible to hydrolytic activity. Thus, as long as phosphorylase *a* remains in its active R state, it sequesters PP1 from other potential substrates. If, however, glucose and glucose-6-phosphate levels rise, their binding to phosphorylase *a* shifts its equilibrium back toward the T state (Figure 13.35), exposing its phosphoserine side chains. PP1c now readily dephosphorylates the enzyme, converting it to phosphorylase *b*, which has very low affinity for PP1c- G_L . PP1c- G_L is released from the inhibited complex, where it is free to dephosphorylate other substrates in the glycogen granule, including glycogen synthase (activating it) and phosphorylase *b* kinase (inactivating it). This mechanism explains the experimental observation that activation of glycogen synthase occurs *after* inactivation of glycogen phosphorylase.

These regulatory mechanisms explain the observation that when plasma glucose levels rise after a meal, the liver gradually takes up glucose and stores it as glycogen.

The liver regulates blood glucose levels partly by control of its glycogen synthase and phosphorylase.

FIGURE 13.38

Regulation of phosphoprotein phosphatase 1 (PP1) in liver. The active catalytic subunit of PP1 (PP1c) is anchored to the glycogen particle by its G subunit, G_L . Glycogen synthase *b* (GS*b*), phosphorylase *b* kinase (PK), and glycogen phosphorylase *a* (green) are also bound to the glycogen particle. Glucose and glucose-6-phosphate (G6P) favor the T state of glycogen phosphorylase *a* (pink), which is readily dephosphorylated by PP1c, giving phosphorylase *b*. PP1c- G_L is released from the inhibited complex, where it is free to dephosphorylate other substrates in the glycogen granule, including glycogen synthase *b*, resulting in inhibition of glycogen breakdown and stimulation of glycogen synthesis.

Insulin is released from the pancreas under these conditions, stimulating glycogen synthesis. Recall from Figure 13.22 that insulin indirectly stimulates the liver isozyme of hexokinase (HK-IV), resulting in increased production of glucose-6-phosphate for incorporation into glycogen. Conversely, when blood glucose concentrations fall during fasting or exercise, glucagon secretion inhibits hepatic glycolysis (Figure 13.21) and stimulates glycogen breakdown (Figure 13.31). The liver thus maintains circulating blood glucose levels by mobilizing its glycogen stores.

Skeletal muscle, which does not carry out gluconeogenesis, relies on blood glucose supplied from the liver, as well as its own glycogen stores for fuel. Because muscle cells lack receptors for glucagon and express an isoform of pyruvate kinase (PK-M1) that is not regulated by covalent modification, muscle glycolysis is not inhibited when blood glucose concentrations are low. Muscle cells respond instead to epinephrine as part of the “fight or flight” response. Epinephrine stimulates glycogen breakdown (Figure 13.31), producing glucose-6-phosphate for ATP generation via glycolysis.

Congenital Defects of Glycogen Metabolism in Humans

A number of inherited human diseases involve mutations in genes encoding enzymes of glycogen metabolism. The clinical symptoms of these conditions, called **glycogen storage diseases**, can be quite severe and usually result from storage of abnormal quantities of glycogen or storage of glycogen with abnormal properties. Accumulation of abnormal glycogen results from its failure to be broken down. Studies on these conditions have helped identify the roles of the enzymes involved in glycogen metabolism.

Among the earliest glycogen storage diseases to be described was *von Gierke disease*, named for a German physician who studied an 8-year-old girl with a chronically enlarged liver. After her death in 1929 from influenza, her liver was found to contain 40% glycogen. The glycogen appeared normal but could not be degraded by extracts of the girl’s liver, only by extracts of other livers. Today it is recognized that these symptoms can result from deficiency of either glucose-6-phosphatase or the debranching enzyme. When the debranching enzyme is deficient, phosphorylase can degrade glycogen only until branch points are reached and no farther.

Table 13.3 provides information on several of the glycogen storage diseases that have been characterized. Among the most serious clinically is the type I disease, resulting from functional lack of glucose-6-phosphatase. Individuals with this condition can break down glycogen normally, but because they cannot cleave G6P to glucose for release from the liver to the bloodstream, they are chronically hypoglycemic. In a less severe form of this disease, blood glucose levels are normal except after stress, when the normal hyperglycemic response is inhibited. One form of this disease (type Ia) results from deficiency of glucose-6-phosphatase

Human mutations affecting enzymes of glycogen metabolism can have mild or profound clinical consequences.

TABLE 13.3 Human congenital defects of glycogen metabolism

Type	Common Name	Enzyme Deficiency	Glycogen Structure	Organ Affected
Ia	von Gierke Disease	Glucose-6-phosphatase (ER)	Normal	Liver, kidney, intestine
Ib		Glucose-6-phosphate transporter (ER)	Normal	Liver
III	Cori or Forbes Disease	Debranching enzyme	Short outer chains	Liver, heart, muscle
IV	Andersen Disease	Branching enzyme	Abnormally long unbranched chains	Liver and other organs
V	McArdle Disease	Muscle glycogen phosphorylase	Normal	Skeletal muscle
VI	Hers Disease	Liver glycogen phosphorylase	Normal	Liver, leukocytes
VII	Tarui Disease	Muscle phosphofructokinase	Normal	Muscle
IX		Liver phosphorylase kinase	Normal	Liver
-		Glycogen synthase	Normal	Liver

itself. The type Ib disease involves deficiency of the specific transporter for glucose-6-phosphate into the lumen of the endoplasmic reticulum (ER). Recall that this transporter is part of a multiprotein complex, which includes glucose-6-phosphatase itself, located on the luminal face of the ER (page 543).

Other forms of glycogen storage diseases involve abnormalities that can be easily understood in terms of the known enzymatic defect. In type III individuals, who have a defective debranching enzyme, glycogen with very short outer branches accumulates, which leads to enlargement of the liver. By contrast, type IV disease, which is associated with a defective branching enzyme, involves accumulation of glycogen with very long outer branches. Early death from liver failure is often observed in type IV individuals. Type III, V, VI, VII, and IX diseases have less severe symptoms. For instance, individuals with type V disease, with a deficiency of muscle glycogen phosphorylase, usually show no symptoms until about age 20. Once symptoms have appeared, the principal ones are severe muscle cramps upon exercising and failure of lactate to accumulate in blood after exercise. There are even some rare cases of hepatic glycogen synthase deficiency, in which affected patients have severely decreased liver glycogen stores.

Biosynthesis of Other Polysaccharides

As first discussed in Chapter 9, the synthesis of other polysaccharides involves the same mechanisms just presented for glycogen, particularly the use of nucleotide-linked sugars as activated biosynthetic intermediates and glycosyltransferase enzymes. In this section we consider briefly the synthesis of two of the most abundant and widely distributed polysaccharides—cellulose and starch.

UDP-glucose is used in plants and some bacterial species for the synthesis of cellulose, a straight-chain glucose homopolymer with $\beta(1 \rightarrow 4)$ linkages (page 332). The mechanism is identical to that of glycogen synthesis, except for the stereochemistry of glycosidic bond formation. Other nucleotide-linked sugars are also active in polysaccharide synthesis. *Adenosine* diphosphate glucose and *cytidine* diphosphate glucose are the substrates for cellulose biosynthesis in some plants. Because of the importance of cellulose in textiles and other fiber-based products, and as a potential feedstock for biofuels, there is great interest in the mechanism of cellulose biosynthesis.

Polysaccharide biosynthesis in general involves nucleotide-activated sugar intermediates and glycosyltransferase enzymes.

A Biosynthetic Pathway That Oxidizes Glucose: The Pentose Phosphate Pathway

The predominant pathway for glucose catabolism is glycolysis to yield pyruvate, followed by oxidation to CO_2 in the citric acid cycle (Chapter 14). An alternative process, the **pentose phosphate pathway**, is a remarkable, multipurpose pathway

FIGURE 13.39

Overall strategy of the pentose phosphate pathway. The pentose phosphate pathway converts glucose to various other sugars, which can be used for energy. Its most important products, however, are NADPH and ribose-5-phosphate. In **stage 1**, the oxidative phase, glucose-6-phosphate is oxidized to ribulose-5-phosphate and CO_2 , with production of NADPH. (The three reactions involved in this stage are shown in Figure 13.40.) The remaining stages constitute the nonoxidative phase of the pathway. In **stage 2**, some ribulose-5-phosphate is converted to other five-carbon sugars, including ribose-5-phosphate. The ribose phosphate may be used in nucleotide synthesis (its primary use) or in the next stage of the pentose phosphate pathway. In **stage 3**, a series of reactions converts three molecules of five-carbon sugar to two molecules of six-carbon sugar and one of three-carbon sugar. In **stage 4**, some of these sugars are converted to glucose 6-phosphate, and the cycle repeats. Figure 13.43 presents a more detailed overview of the pathway and shows how it varies under different metabolic conditions.

that operates to varying extents in different cells and tissues. The role of this pathway is primarily anabolic rather than catabolic, but we present the pathway in this chapter because it does involve catabolism of glucose. The pathway, which operates exclusively in the cytosol, is summarized in Figure 13.39.

The pentose phosphate pathway primarily generates NADPH for reductive biosynthesis and ribose-5-phosphate for nucleotide biosynthesis.

The pentose phosphate pathway has two primary functions: (1) to provide reducing equivalents (in the form of NADPH) for reductive biosynthesis and dealing with oxidative stress; and (2) to provide ribose-5-phosphate for nucleotide and nucleic acid biosynthesis. In addition, the pathway operates to metabolize dietary pentose sugars, derived primarily from the digestion of nucleic acids. In plants, a variant of the pentose phosphate pathway operates in reverse as part of the carbon fixation process of photosynthesis (see Chapter 16).

Recall from Chapter 12 that NADP^+ is identical to NAD^+ except for the additional 2' phosphate on one of the ribose moieties of NADP^+ . Metabolically, the difference between NAD^+ and NADP^+ is that nicotinamide nucleotide-linked enzymes whose primary function is to oxidize substrates use the NAD^+/NADH pair, whereas enzymes functioning primarily in a reductive direction use NADP^+ and NADPH. Because NADPH is used for fatty acid and steroid biosynthesis, tissues such as adrenal gland, liver, adipose, and mammary gland are rich in enzymes of the pentose phosphate pathway. NADPH is also the ultimate electron source for reduction of ribonucleotides to deoxyribonucleotides for DNA synthesis, so rapidly proliferating cells generally have high activity of pentose phosphate pathway enzymes, for production of both NADPH and ribose-5-phosphate.

The Oxidative Phase: Generation of Reducing Power as NADPH

It is convenient to think of the pentose phosphate pathway as operating in two phases—oxidative and nonoxidative. Two of the first three reactions in this pathway are oxidative, each involving reduction of one NADP^+ to NADPH. As shown in Figure 13.40, the first reaction, catalyzed by **glucose-6-phosphate dehydrogenase**,

**FIGURE 13.40**

Oxidative phase of the pentose phosphate pathway. The three reactions of the oxidative phase include two oxidations, which produce NADPH.

oxidizes glucose-6-phosphate to 6-phosphogluconolactone, the corresponding **lactone** (an internal ester linking carbons 1 and 5). Phosphogluconolactone is hydrolyzed by **6-phosphogluconolactonase** to **6-phosphogluconate**, which undergoes an oxidative decarboxylation to yield CO_2 , another NADPH, and **ribulose-5-phosphate** (a pentose phosphate). The net result of the oxidative phase is generation of 2 molecules of NADPH, oxidation of one carbon to CO_2 , and synthesis of 1 molecule of pentose phosphate per G6P.

The Nonoxidative Phase: Alternative Fates of Pentose Phosphates

In the nonoxidative phase, some of the ribulose-5-phosphate produced in the oxidative phase is converted to ribose-5-phosphate by **phosphopentose isomerase**.

The reaction proceeds via an enediol intermediate, just as in two different reactions of glycolysis—those catalyzed by triose phosphate isomerase (see page 529) and phosphoglucoisomerase (see page 526).

Production of Six-Carbon and Three-Carbon Sugar Phosphates

At this stage the primary functions of the pathway have been fulfilled, namely the generation of NADPH and ribose-5-phosphate. We can write a balanced equation for what has transpired thus far:

Many cells need the NADPH for reductive biosynthesis but do not need the ribose-5-phosphate in such large quantities. How, then, is this ribose-5-phosphate catabolized? The process involves a series of sugar phosphate transformations that may look complicated but that have a simple result. *The reaction sequence converts 3 five-carbon sugar phosphates to 2 six-carbon sugar phosphates and 1 three-carbon sugar phosphate.* The hexose phosphates formed can be catabolized either by recycling through the pentose phosphate pathway or by glycolysis. The triose phosphate is glyceraldehyde-3-phosphate, a glycolytic intermediate. Three enzymes are involved: **phosphopentose epimerase**, **transketolase**, and **transaldolase**.

The pathway begins with both ribulose-5-phosphate and ribose-5-phosphate, the latter having been formed by phosphopentose isomerase. Phosphopentose epimerase converts ribulose-5-phosphate to its epimer, xylulose-5-phosphate.

Recall that xylulose-5-phosphate also plays a regulatory role—it is a specific activator of protein phosphatase 2A (PP2A) in liver. PP2A dephosphorylates PFK-2/FBPase-2 (see Figure 13.21, page 554), leading to increased levels of fructose-2,6-bisphosphate, which activates the glycolytic enzyme phosphofructokinase (PFK-1). Thus, as xylulose-5-phosphate levels rise in response to excess glucose via the pentose phosphate pathway, flux through glycolysis also increases.

One mole of xylulose-5-phosphate then reacts with one mole of ribose-5-phosphate. The reaction is catalyzed by **transketolase**, which transfers a two-carbon fragment from xylulose-5-phosphate to ribose-5-phosphate to give a triose phosphate, glyceraldehyde-3-phosphate, and a seven-carbon sugar, **sedoheptulose-7-phosphate**.

The two-carbon fragment transferred is an activated **glycolaldehyde** fragment (see margin, next page). Recall that pyruvate decarboxylase transfers an activated **acetaldehyde** fragment (see Figure 13.8, page 538), with the aid of thiamine

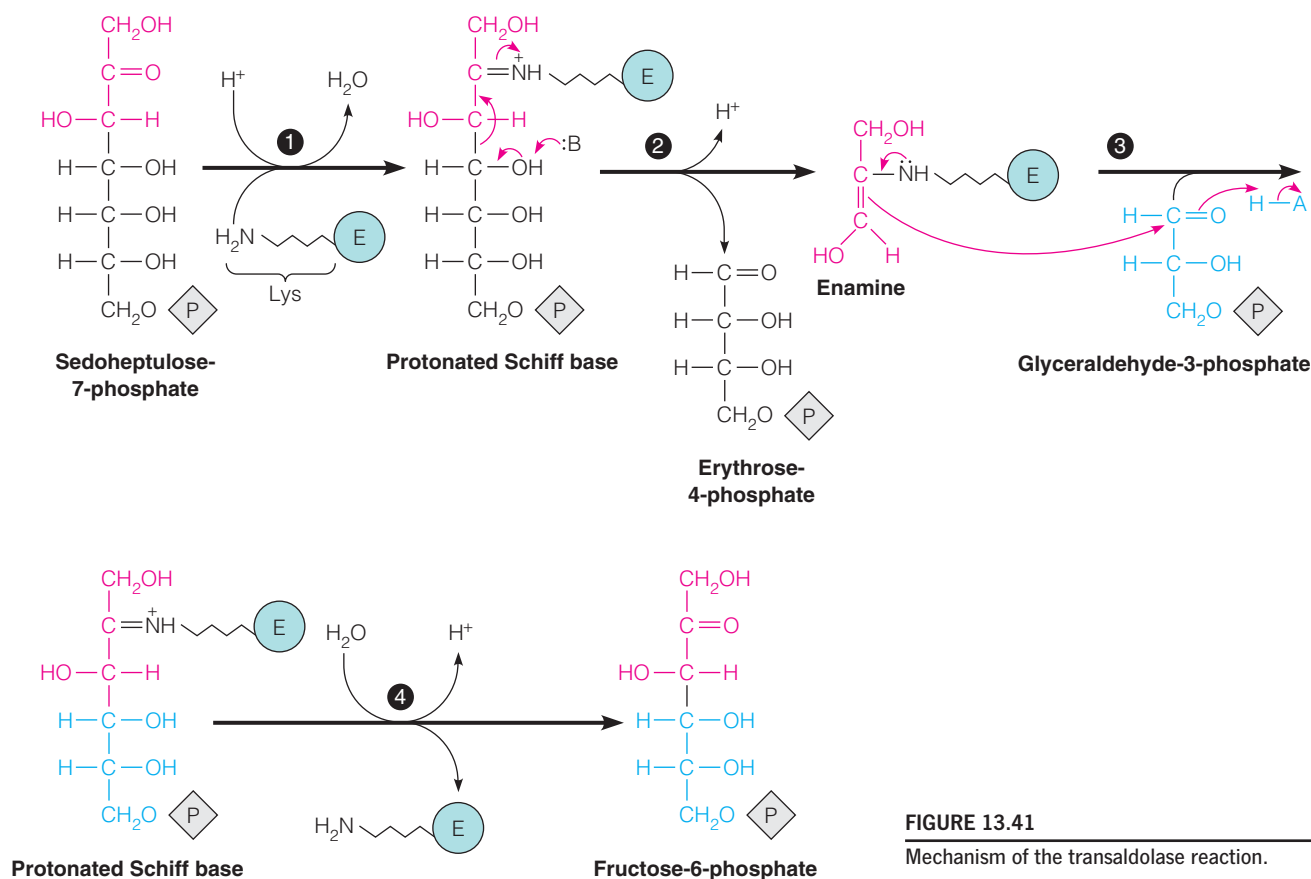

FIGURE 13.41

Mechanism of the transaldolase reaction.

pyrophosphate (TPP). Transketolase also requires TPP as a cofactor, with the two-carbon fragment bound transiently to carbon 2 of the thiazole ring of TPP. The mechanism of activation and transfer of two-carbon fragments is very similar in the reactions catalyzed by these two enzymes.

Next, transaldolase acts on the two products of the transketolase reaction, with transfer of a three-carbon **dihydroxyacetone** unit from the seven-carbon substrate to the three-carbon substrate. The products are a four-carbon sugar phosphate and a six-carbon sugar phosphate: **erythrose-4-phosphate** and **fructose-6-phosphate**, respectively. The combined actions of transketolase and transaldolase convert 2 five-carbon sugar phosphates to a four-carbon sugar phosphate and a six-carbon sugar phosphate.

Figure 13.41 shows the transaldolase reaction in more detail. The enzyme activates the ketose substrate by forming a Schiff base with a lysine residue on the enzyme (step 1). Protonation of the Schiff base leads to carbon-carbon bond cleavage, much as occurs in the fructose-bisphosphate aldolase reaction of glycolysis (see Figure 13.5, page 528), with release of a four-carbon aldose phosphate (step 2). The dihydroxyacetone unit remains bound as an enamine, which then adds to the carbonyl carbon of glyceraldehyde-3-phosphate, in an aldol condensation reaction (step 3). Hydrolysis of the protonated Schiff base yields the six-carbon product, fructose-6-phosphate (step 4).

The transketolase and transaldolase mechanisms represent two different chemical strategies to effect C—C bond cleavage (Figure 13.42). Both mechanisms use an iminium ion as an electron sink. In addition, both mechanisms involve carbanion intermediates that must be stabilized by resonance. Transketolase uses a cofactor (TPP), while transaldolase uses a protonated Schiff base with an active site lysine to solve the same problem.

FIGURE 13.42

C—C bond cleavage in transketolase and transaldolase reactions. Yellow, electron sink; green, electron source.

In the final reaction of pentose phosphate catabolism, transketolase acts on another molecule of xylulose-5-phosphate, transferring a glycolaldehyde fragment to erythrose-4-phosphate and generating a three-carbon product and a six-carbon product—glyceraldehyde-3-phosphate and fructose-6-phosphate, respectively.

So far, the pathway has required input of three pentose phosphate molecules—two for the first transketolase reaction and one for the second. Thus, to summarize the pathway to this point, we must consider three molecules of glucose-6-phosphate passing through the oxidative phase.

Now the rearrangements of the nonoxidative phase result in conversion of three pentose phosphates to 2 six-carbon and 1 three-carbon sugar phosphates.

Thus, we can write a balanced equation for the entire pathway as follows.

Tailoring the Pentose Phosphate Pathway to Specific Needs

In the equation for the overall reaction, three hexose phosphates yield two hexose phosphates, one triose phosphate, and three molecules of CO_2 . In a formal sense, therefore, the pathway can be seen as a means to oxidize the six carbons of glucose-6-phosphate to CO_2 , just as occurs in glycolysis plus the citric acid cycle.

However, as noted above, the pentose phosphate pathway is not primarily an energy-generating pathway. The actual fate of the sugar phosphates depends on the metabolic needs of the cell in which the pathway is occurring. If the primary need is for nucleotide and nucleic acid synthesis, the major product is ribose-5-phosphate, and most of the rearrangements of the nonoxidative phase do not take place (Figure 13.43a). If the primary need is for NADPH generation (for fatty acid or steroid synthesis), the nonoxidative phase generates compounds that can easily be reconverted to glucose-6-phosphate, for subsequent passage through the oxidative phase (Figure 13.43b). In this mode, repeated turns of the cycle result ultimately in the complete oxidation of glucose-6-phosphate to CO_2 and water, with maximal generation of reducing equivalents.

Finally, in a cell with moderate needs for both NADPH and pentose phosphates, the fructose-6-phosphate and glyceraldehyde-3-phosphate produced in the nonoxidative phase can be further catabolized by glycolysis and the citric acid cycle (Figure 13.43c). Because of the multiple metabolic needs of a cell for biosynthesis, it is unlikely that any one of these three modes operates exclusively in any one cell.

Regulation of the Pentose Phosphate Pathway

The pentose phosphate pathway competes with glycolysis for glucose-6-phosphate. Whereas glycolysis is regulated primarily by energy charge and fuel availability, flux through the pentose phosphate pathway is sensitive to the $\text{NADP}^+/\text{NADPH}$ ratio of the cell. The first enzyme of the pathway, glucose-6-phosphate dehydrogenase, represents the committed step, and its activity controls flux through the entire pentose phosphate pathway. Glucose-6-phosphate dehydrogenase is regulated by the availability of NADP^+ . If the $\text{NADP}^+/\text{NADPH}$ ratio is low, indicating that the cell has plenty of reducing power, glucose-6-phosphate dehydrogenase activity will be low and the pathway will not divert glucose-6-phosphate from glycolysis. If, however, the cell needs more reducing equivalents, the high $\text{NADP}^+/\text{NADPH}$ ratio will stimulate flux through glucose-6-phosphate dehydrogenase, regenerating the necessary NADPH.

Human Genetic Disorders Involving Pentose Phosphate Pathway Enzymes

The pentose phosphate pathway is particularly active in the generation of reducing power in the red blood cells of vertebrates. The importance of this activity became apparent through investigation of a fairly widespread human genetic disorder, a deficiency of glucose-6-phosphate dehydrogenase.

During World War II the antimalarial drug primaquine was prophylactically administered to members of the armed forces. As a result, a significant proportion of servicemen suffered a severe hemolytic anemia (massive destruction of red blood cells). They were also sensitive to a variety of compounds that, like primaquine, generate oxidative stress, as manifested by the appearance of hydrogen peroxide and organic peroxides in red cells. These individuals were later found to be deficient in glucose-6-phosphate dehydrogenase.

Abnormal sensitivity to antimalarial drugs was shown to result from mutations affecting glucose-6-phosphate dehydrogenase.

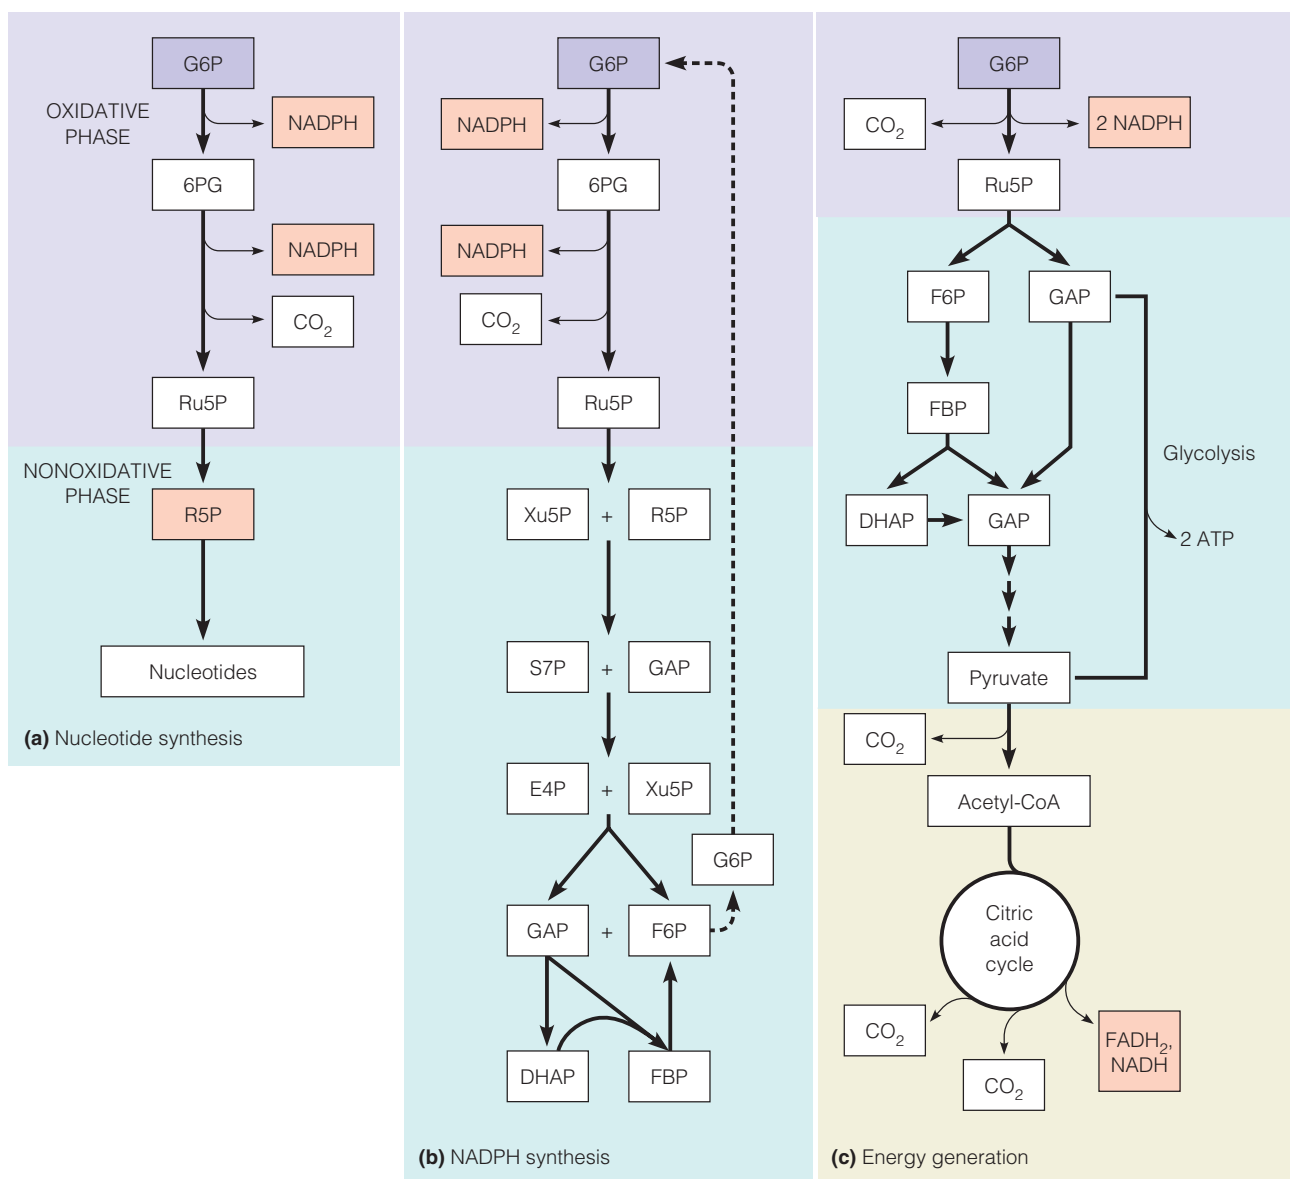

FIGURE 13.43

Alternative pentose phosphate pathway modes. The pentose phosphate pathway has different modes of operation to meet varying metabolic needs. **(a)** When the primary need is for nucleotide biosynthesis, the primary product is ribose-5-phosphate. Reducing equivalents from NADPH are used to reduce ribonucleotides to deoxyribonucleotides (Chapter 22). **(b)** When the primary need is for reducing power (NADPH), fructose phosphates are reconverted to glucose-6-phosphate for reoxidation in the oxidative phase. **(c)** When only moderate quantities of pentose phosphates and NADPH are needed, the pathway can also be used to supply energy, with the reaction products being oxidized through glycolysis and the citric acid cycle. Abbreviations: G6P = glucose-6-phosphate; 6PG = 6-phosphogluconate; R5P = ribose-5-phosphate; Ru5P = ribulose-5-phosphate; Xu5P = xylulose-5-phosphate; S7P = sedoheptulose-7-phosphate; GAP = glyceraldehyde-3-phosphate; E4P = erythrose-4-phosphate; F6P = fructose-6-phosphate; DHAP = dihydroxyacetone phosphate; FBP = fructose-1,6-bisphosphate.

Normally, peroxides are inactivated via reduction by **glutathione**, which is the tripeptide γ -glutamylcysteinylglycine.

Glutathione is abundant in most cells and, because of its free thiol group, it represents a major protective mechanism against oxidative stress. For example, it helps keep cysteine thiol groups in proteins in the reduced state. If two thiol groups become oxidized, they can be reduced nonenzymatically by glutathione.

And, as noted, glutathione also carries out the reduction of peroxides; this is an enzymatic reaction, catalyzed by **glutathione peroxidase** (see page 667).

Oxidized glutathione (GSSG) is reduced by the NADPH-dependent enzyme **glutathione reductase**.

This enzyme acts essentially unidirectionally, so that the ratio of reduced glutathione (GSH) to oxidized glutathione in most cells is about 500 to 1.

In the erythrocyte, a particularly important role of glutathione is to maintain hemoglobin in the reduced (Fe^{2+}) state; recall that methemoglobin (Fe^{3+}) cannot bind O_2 (see page 238). Therefore, the erythrocyte is especially sensitive to depletion of reduced glutathione. And because the pentose phosphate pathway is the major pathway for generation of NADPH, the erythrocyte is especially vulnerable to conditions that impair flux through this pathway and thereby lower intracellular NADPH levels. Thus, the individuals who were deficient in glucose-6-phosphate dehydrogenase were the ones most sensitive to oxidative stress caused by primaquine.

In most cases of glucose-6-phosphate dehydrogenase deficiency, the enzyme in red cells is not totally inactive but instead is decreased in activity by about 10-fold. Individuals with this deficiency are asymptomatic until stressed. That is, they are asymptomatic until primaquine or a related agent generates enough peroxides that the available GSH becomes depleted. Reduction of the resultant GSSG back to GSH is impaired because NADPH levels are inadequate to allow glutathione reductase to function. This causes methemoglobin (Fe^{3+}) to accumulate at the expense of hemoglobin, which in turn changes the structure of the cell, weakening the membrane and rendering it sensitive to rupture, or hemolysis.

Interestingly, glucose-6-phosphate dehydrogenase deficiency, like sickle-cell trait, confers resistance to malaria caused by *Plasmodium falciparum* (see Chapter 7). Thus, the deficiency has a positive survival value in tropical and subtropical regions of the world, where malaria is common. This explains the observation that glucose-6-phosphate dehydrogenase deficiency is seen most frequently among individuals of African or Mediterranean extraction.

Another genetic disorder related to the pentose phosphate pathway is the **Wernicke–Korsakoff syndrome**. This mental disorder is coupled with loss of memory and partial paralysis and develops when affected individuals suffer a moderate thiamine deficiency. The symptoms often become manifest in alcoholics, whose diets are apt to be vitamin deficient.

Glutathione, an abundant thiol-containing tripeptide, is a major intracellular reductant.

A mutation in transketolase that increases its K_M for TPP is responsible for the neurological symptoms of Wernicke–Korsakoff syndrome.

The basis for the Wernicke–Korsakoff syndrome is an alteration of transketolase that reduces its affinity for thiamine pyrophosphate by about 10-fold. Other TPP-dependent enzymes are not affected. Symptoms of the disease become manifest when TPP levels drop below the values needed to saturate the abnormal transketolase. Normal individuals contain a transketolase that binds TPP strongly enough that no change in enzyme function occurs as a result of these slight to moderate thiamine deficiencies.

Both glucose-6-phosphate dehydrogenase deficiency and the Wernicke–Korsakoff syndrome, like sickle-cell disease (Chapter 7), illustrate the interdependence of genetic and environmental factors in the onset of clinical disease. Symptoms of the hereditary change express themselves only after some kind of moderate stress that does not affect normal individuals.

SUMMARY

Glycolysis is the central pathway by which energy is extracted from carbohydrates. A 10-step pathway leads from glucose to pyruvate in respiring cells. In anaerobic microorganisms or in cells with impaired respiration, pyruvate undergoes reductive reactions, so that the overall pathway can proceed with no net change in oxidation state. Glycolysis can be viewed as occurring in two phases—first, an energy investment phase in which ATP is used to synthesize a six-carbon sugar phosphate that is split to yield two triose phosphates, and second, an energy generation phase, in which the energy of two high-energy compounds is used to drive ATP synthesis from ADP. Phosphofructokinase, pyruvate kinase, and hexokinase are the major sites for control of the pathway. Much of the control is related to the energy needs of a cell, with conditions of low energy charge stimulating the pathway and conditions of energy abundance retarding the pathway. All organisms also carry out gluconeogenesis, the synthesis of carbohydrate from noncarbohydrate three-carbon and four-carbon compounds. Gluconeogenesis uses seven glycolytic enzymes and four specific gluconeogenic enzymes, the latter to bypass the three irreversible steps in glycolysis. The four enzymes specific to gluconeogenesis are pyruvate carboxylase plus phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and glucose-6-phosphatase. Regulation occurs at the sites of these three substrate cycles. Control is supremely important in animal metabolism, requiring that blood glucose levels be maintained within narrow limits. Hormonal and allosteric mechanisms are involved, with fructose-2,6-bisphosphate being a key regulator.

Intracellular polysaccharide stores in animals are mobilized by a hormonally controlled metabolic cascade, in which cyclic AMP transmits the hormonal signal and sets in motion events that activate the breakdown of glycogen to glucose-1-phosphate. Glycogen phosphorylase is the rate-limiting step of this process. Synthesis of polysaccharides such as glycogen involves glycosyltransferases, enzymes that transfer the sugar unit from a nucleotide-linked or otherwise activated sugar to an acceptor sugar, at a nonreducing end. Glycogen synthase uses uridine diphosphate glucose as its glucosyl donor. The enzyme is regulated by hormonal and nonhormonal processes that are complementary and opposed to those that regulate glycogen breakdown by phosphorylase.

An alternative glucose oxidative pathway, the pentose phosphate pathway, generates NADPH for reductive biosynthesis and pentose phosphates for nucleotide biosynthesis.

PROBLEMS

- Intracellular concentrations in resting muscle are as follows: fructose-6-phosphate, 1.0 mM; fructose-1,6-bisphosphate, 10 mM; AMP, 0.1 mM; ADP, 0.5 mM; ATP, 5 mM; and P_i , 10 mM. Is the phosphofructokinase reaction in muscle *more* or *less* exergonic than under standard conditions? By how much?
- Methanol is highly toxic, not because of its own biological activity but because it is converted metabolically to formaldehyde, through action of alcohol dehydrogenase. Part of the medical treatment for methanol poisoning involves administration of large doses of ethanol. Explain why this treatment is effective.
- Refer to Figure 13.9, which indicates ΔG for each glycolytic reaction under intracellular conditions. Assume that glyceraldehyde-3-phosphate dehydrogenase was inhibited with iodoacetic acid. Which glycolytic intermediate would you expect to accumulate most rapidly, and why?
- In different organisms sucrose can be cleaved either by hydrolysis or by phosphorysis. Calculate the ATP yield per mole of sucrose metabolized by anaerobic glycolysis starting with (a) hydrolytic cleavage and (b) phosphorytic cleavage.
- Suppose it were possible to label glucose with ^{14}C at any position or combination of positions. For yeast fermenting glucose to ethanol, which form or forms of labeled glucose would give the *most* radioactivity in CO_2 and the *least* in ethanol?
- Write balanced chemical equations for each of the following: (a) anaerobic glycolysis of 1 mole of sucrose, cleaved initially by sucrose phosphorylase; (b) aerobic glycolysis of 1 mole of maltose; (c) fermentation of one glucose residue in starch to ethanol, with the initial cleavage involving α -amylase.
- Because of the position of arsenic in the periodic table, arsenate (AsO_4^{3-}) is chemically similar to inorganic phosphate and is used by phosphate-requiring enzymes as an alternative substrate. However, organic arsenates are quite unstable and spontaneously hydrolyze. Arsenate is known to inhibit ATP production in glycolysis. Identify the target enzyme, and explain the mechanism of inhibition.
- Suppose that you made some wine whose alcohol content was 10% w/v (i.e., 10 g of ethanol per 100 mL of wine). The initial fermentation mixture would have had to contain what molar concentration of glucose or its equivalent to generate this much ethanol? Is it likely that an initial fermentation mixture would contain that much glucose? In what other forms might the fermentable carbon appear?
- Briefly discuss why each of the three common forms of galactosemia involves impaired utilization of galactose. Which metabolic process is blocked in each condition?
- *10. Some anaerobic bacteria use an alternative pathway for glucose catabolism, shown below, that converts glucose to acetate rather than to pyruvate. The first part of this pathway (glucose to fructose-1,6-bisphosphate) is identical to the glycolytic pathway. In the second part of the alternative pathway, Enzymes 1-6 all have mechanisms/activities analogous to enzymes in glycolysis. Note that

there are two C—C bond cleavage reactions in this new pathway: $A \rightarrow B + C$ (Enzyme 1) and $C \rightarrow B + D$. All the steps where ATP is consumed or generated have been shown; however, the addition or

loss of NAD^+/NADH , P_i , H_2O , or H^+ has not been shown explicitly. Draw the structures for the intermediates B, F, G, H, and I, and include other reaction participants as needed.

- Write a pathway leading from glucose to lactose in mammary gland, and write a balanced equation for the overall pathway.
- Sketch a curve that would describe the expected behavior of phosphofruktokinase activity as a function of the adenylate energy charge.

- Explain the basis for the following statement. For efficient conversion of galactose to glucose-1-phosphate, UDP-glucose need be present in catalytic amounts only.
- The muscle isozyme of lactate dehydrogenase is inhibited by lactate. Steady state kinetic analysis yielded the following data, with lactate either absent or present at a fixed concentration.

- Pyruvate is the substrate whose concentration is varied in one plot, NADH in the other. Identify each. Use an arrow and the appropriate letter (b, c, d, or e) to identify each of the following.
- Reciprocal of V_{\max} for the uninhibited enzyme.
- The line representing data obtained in the presence of lactate acting as a competitive inhibitor with respect to the variable substrate.
- The line representing data obtained in the presence of lactate acting as a mixed inhibitor with respect to the variable substrate.

- (e) Reciprocal of K_M in the presence of lactate acting as a competitive inhibitor.
- (f) If K_M for NADH is 2×10^{-5} M, which is the most appropriate NADH concentration to use when determining K_M for pyruvate? 10^{-7} M, 10^{-6} M, 10^{-5} M, 10^{-4} M, or 10^{-3} M
- How many ATP equivalents are consumed in the conversion of each of the following to a glucosyl residue in glycogen?
 - Dihydroxyacetone phosphate
 - Fructose-1,6-bisphosphate
 - Pyruvate
 - Glucose-6-phosphate
 - How many high-energy phosphates are generated or consumed in
 - converting 1 mole of glucose to lactate?
 - converting 2 moles of lactate to glucose?
 - Avidin is a protein that binds extremely tightly to biotin. Therefore, it is a potent inhibitor of biotin-requiring enzyme reactions. Consider glucose biosynthesis from each of the following substrates and predict which of these pathways would be inhibited by avidin.
 - Lactate
 - Oxaloacetate
 - Malate
 - Fructose-6-phosphate
 - Phosphoenolpyruvate
 - $^{14}\text{CO}_2$ was bubbled through a suspension of liver cells that was undergoing gluconeogenesis from lactate to glucose. Which carbons in the glucose molecule would become radioactive?
 - Write a balanced equation for each of the following reactions or reaction sequences.
 - The reaction catalyzed by PFK-2
 - The conversion of 2 moles of oxaloacetate to glucose
 - The conversion of glucose to UDP-Glc
 - The conversion of 2 moles of glycerol to glucose
 - The conversion of 2 moles of malate to glucose-6-phosphate
 - Sketch curves for reaction velocity vs. [fructose-6-phosphate] for the phosphorylated *and* nonphosphorylated forms of PFK-2 in liver.
 - Based on information presented on pages 570–574, sketch curves relating glycogen synthase reaction velocity to [UDP-glucose], for both the *a* and *b* forms of the enzyme, in the presence and absence of glucose-6-phosphate.
 - Glycogen synthesis and breakdown are regulated primarily at the hormonal level. However, important *nonhormonal* mechanisms also control the rates of synthesis and mobilization. Describe these non-hormonal regulatory processes.
 - Why does it make good metabolic sense for phosphoenolpyruvate carboxykinase, rather than pyruvate carboxylase, to be the primary target for regulation of gluconeogenesis at the level of control of enzyme synthesis?
 - What is the metabolic significance of the following observations? (1) Only the liver form of pyruvate kinase is inhibited by alanine, and (2) only gluconeogenic tissues contain appreciable levels of glucose-6-phosphatase.
 - Predict how phosphoprotein phosphatase 1 (PP1) and phosphoprotein phosphatase inhibitor 1 (inhibitor 1) might interact with components of the glycogenolytic cascade to effect regulation reciprocal to their effects upon glycogen synthesis.
 - Write a one-sentence explanation for each of the following statements.
 - In liver, glucagon stimulates glycogen breakdown via cyclic AMP. Although one might expect glucagon also to stimulate catabolism of the glucose formed, glucagon *inhibits* glycolysis and stimulates gluconeogenesis in liver.
 - An individual with a glucose-6-phosphatase deficiency suffers from chronic hypoglycemia.
 - The action of phosphorylase kinase simultaneously activates glycogen breakdown and inhibits glycogen synthesis.
 - The presence in liver of glucose-6-phosphatase is essential to the function of the liver in synthesizing glucose for use by other tissues.
 - Write a balanced chemical equation for the pentose phosphate pathway in the first two modes depicted in Figure 13.43, where (a) ribose-5-phosphate synthesis is maximized and (b) NADPH production is maximized, by conversion of the sugar phosphate products to glucose-6-phosphate for repeated operations of the pathway.
 - $[1-^{14}\text{C}]$ Ribose-5-phosphate is incubated with a mixture of purified transketolase, transaldolase, phosphopentose isomerase, phosphopentose epimerase, and glyceraldehyde-3-phosphate. Predict the distribution of radioactivity in the erythrose-4-phosphate and fructose-6-phosphate that are formed in this mixture.
 - Pyruvate carboxylase is thought to activate CO_2 by ATP, through formation of carboxyphosphate as an intermediate. Propose a mechanism for formation of this intermediate.

TOOLS OF BIOCHEMISTRY 13A

DETECTING AND ANALYZING PROTEIN–PROTEIN INTERACTIONS

The enzymes of glycolysis are readily isolated as soluble proteins. However, several lines of evidence support the notion that they are physically associated within living cells. For years, biochemistry students have been told, “A cell is not a bag of enzymes,” implying that enzymes are organized into functional supramolecular units in intact cells. Often these organized units are stabilized by weak, noncovalent forces that are easily disrupted when cells are broken open, as must occur if the enzymes within are to be isolated and characterized. Even when cells are gently lysed, most protein extraction processes dilute intracellular contents by several orders of magnitude, and that alone

can disrupt associations that are highly concentration-dependent. Biochemists are trying to define how the organization of functionally related enzymes facilitates the flow of metabolites and the control and coordination of metabolic pathways.

An early indication that glycolytic enzymes might interact within cells came from observations that the intracellular molar concentrations of glycolytic intermediates are actually lower than the concentrations of the enzymes that act upon those intermediates. This finding suggested that most of the supply of an intermediate is enzyme-bound within cells and this, in turn, led to the

idea that intermediates are passed directly from enzyme to enzyme, without release to the surrounding milieu, as if the glycolytic enzymes functioned as part of a multienzyme complex.

If such a complex could be isolated intact, its properties could be explored by the methods for molecular weight determination, described in Tools of Biochemistry 6B. However, because of difficulties often encountered in isolating enzyme complexes held together by ephemeral forces, scientists usually use multiple approaches to demonstrate and characterize the protein-protein interactions involved. A few of those techniques are described here.

Bifunctional Cross-Linking Reagents

These are reagents containing two functional groups capable of forming covalent bonds with specific amino acid residues in closely associated proteins. For instance, *dimethylsuberimidate* (DMS) reacts with lysine ϵ -amino groups and N-terminal amino groups, cross-linking two proteins in a form that can be detected by gel electrophoresis because of the increase in molecular weight.

Some reagents have cleavable cross-links, such as a disulfide bond that can be reductively cleaved, allowing analysis of the separate cross-linked partners. Although the technique can be very informative, experimentation with many reagents is often required to find the right combination of functional groups and distance between the reactive partners for the cross-linking reaction to proceed to a measurable extent. Also, care must be taken not to overinterpret results, for even transient contacts between molecules, which may occur nonspecifically, sometimes lead to crosslinking. Chemical cross-linking is described in more detail in Tools of Biochemistry 28A.

Affinity Chromatography

In this technique, described in Tools of Biochemistry 5A, one protein is immobilized on a chromatographic support, and a mixture of proteins is passed through a column of this material. Proteins that are retained can be identified after elution, by biological activity or by electrophoretic techniques, such as immunoblotting or two-dimensional electrophoretic analysis. The chief limitations of this technique are the need to have one of the test proteins available in pure form for immobilization and the fact that interactions occur in a rather artificial environment. Again, controls are essential because of nonspecific retention of some proteins on affinity columns.

Immunoprecipitation

Antibody to a purified protein can be added to a protein mixture, often with immunoprecipitation (see Tools of Biochemistry 7A) of both the antigenic protein and any interactive proteins bound to it (co-immunoprecipitation). Although this technique is qualitative, like the approaches described above, it is simple to do, and it needs only small amounts of material. Because multiple assays can be run simultaneously, co-immunoprecipitation can be used, for example, to study the effects of the binding of small molecules (substrates or effectors) upon protein associations.

Kinetic Analysis

If enzymes catalyzing sequential reactions interact, the interactions can facilitate the flow of metabolites through multistep pathways (metabolic channeling), and this can be detected in vitro in several ways. Generally, a channeled pathway will display one or more of the following characteristics: (1) reduced *transient time*, the interval after initiating a multistep pathway needed for the formation of final product to reach its maximal rate; (2) steady-state levels of intermediates much lower than expected if they must seek the next enzyme acting on them by diffusion rather than by direct or facilitated transfer to a nearby enzyme molecule; and (3) restricted ability of an exogenous intermediate to equilibrate with the same intermediate in a channeled pathway, as determined usually by radioisotope experiments.

Library-Based Methods

These are methods that allow the screening of a large number, or library, of cloned genes. These methods allow tentative identification of interacting partners without a prior requirement for purification and identification of one of the partners. A popular method called the two-hybrid system uses a transcriptional activation system in yeast that requires two proteins to interact in order for transcription at an appropriate gene site to be initiated (see Chapters 27 and 29). One of these proteins binds at the DNA site, and the other activates transcription. Two hybrid, or fusion, proteins are generated by recombinant DNA techniques (see Tools of Biochemistry 4B); the gene for one test protein (X) is fused to the DNA-binding protein gene, and the gene for another test protein (Y), or a library of cloned genes, is fused to the gene for the

**FIGURE 13A.1**

Biacore analysis of a protein–protein association. Test protein flows past the immobilized protein in the association phase and is replaced by buffer in the dissociation phase. The height of the plateau response, as compared with standards, is related to the stoichiometry of the association.

Courtesy of Biacore Life Sciences.

transcriptional activation domain. The recombinant genes are transferred into yeast cells, where the interaction of proteins X and Y can form a fully functional transcriptional activator (assuming that the functional domains of the fusion proteins fold as they do in their native state). Transcription of the target gene is then monitored by assays for the activity of a reporter gene, a gene cloned downstream of the promoter and whose biological activity is easily assayed. Once a specific protein association has been detected, it becomes essential to isolate the interactive partners as full-length proteins and to ascertain that the interactions detected by this somewhat qualitative method are indeed biologically significant.

Biosensor Analysis

In recent years, a new kind of instrumentation has been developed that allows both qualitative and quantitative analysis of protein–protein interactions, using rather small quantities of purified proteins. One such instrument, a BIACORE, measures an optical property called *surface plasmon resonance*, which is related to minute changes in refractive index that occur when a protein in solution interacts with a protein immobilized on a chip. The signal measured is proportional to total protein concentration, over a wide range. Thus, the kinetics of a protein association reaction can

be monitored by following the increase in signal as a protein in solution passes over a chip containing immobilized protein. The amount of protein bound at equilibrium gives the affinity constant for the interaction, and the kinetics of dissociation can then be followed by passing buffer over the chip and following the decrease in signal, as indicated in Figure 13A.1. Limitations of this useful technique, which can be controlled for, include the possibility that immobilization alters the protein in a way that affects the interaction and the fact that the two interacting proteins are in different phases (solid, or immobilized, and liquid).

Finally, protein–protein interactions can be investigated using fluorescence spectroscopy methods, including fluorescence polarization and Förster Resonance Energy Transfer (FRET), as described in Tools of Biochemistry 6A.

CHAPTER 14

Citric Acid Cycle and Glyoxylate Cycle

In Chapter 13 we explored the initial, fermentative, phase of carbohydrate degradation. Here we follow the subsequent aerobic reactions by which carbohydrates are ultimately oxidized to carbon dioxide and water via the citric acid cycle (Figure 14.1). As we shall see, the citric acid cycle is the central oxidative pathway in respiration, the process by which *all* metabolic fuels—carbohydrate, lipid, and protein—are catabolized in aerobic organisms and tissues.

We saw in Chapter 13 (page 540) that a fermentation process such as glycolysis releases only a fraction of the energy available in glucose. Complete combustion of glucose to CO_2 and H_2O releases 2870 kJ/mol of free energy under standard conditions. Ethanol and lactate, like other fermentation products of carbohydrate catabolism, are at the same oxidation level as the starting material, glucose. In fact, complete combustion of ethanol to CO_2 and H_2O releases 1326 kJ/mol of free energy under standard conditions. Because 2 moles of ethanol and 2 moles of CO_2 are produced per mole of glucose, $2 \times 1326 = 2652$ kJ/mol would be released. Thus, 92% ($2652/2870$) of the free energy available in glucose is retained in the fermentation product (ethanol), meaning very little of the potential energy stored in the original glucose molecule is released by its conversion to ethanol in the fermentation process. Indeed, all fermentations are characterized by a similarly low energy yield.

Far more energy is generated if organic fuels are completely oxidized to CO_2 and H_2O by molecular oxygen in the process termed **cellular respiration**. That energy release involves dehydrogenation reactions that generate reduced electron carriers, primarily NADH. These carriers are next reoxidized in the mitochondrial respiratory (electron transport) chain. These reactions provide the energy that drives ATP synthesis, through oxidative phosphorylation. The electrons released are ultimately transferred to oxygen, which becomes reduced to water. This chapter focuses on the fates of the oxidizable substrates, and the next chapter focuses on the chain of electron carriers and the synthesis of ATP.

The citric acid cycle is a pathway for oxidizing all metabolic fuels.

Most of the energy yield from substrate oxidation in the citric acid cycle comes from subsequent reoxidation of reduced electron carriers.

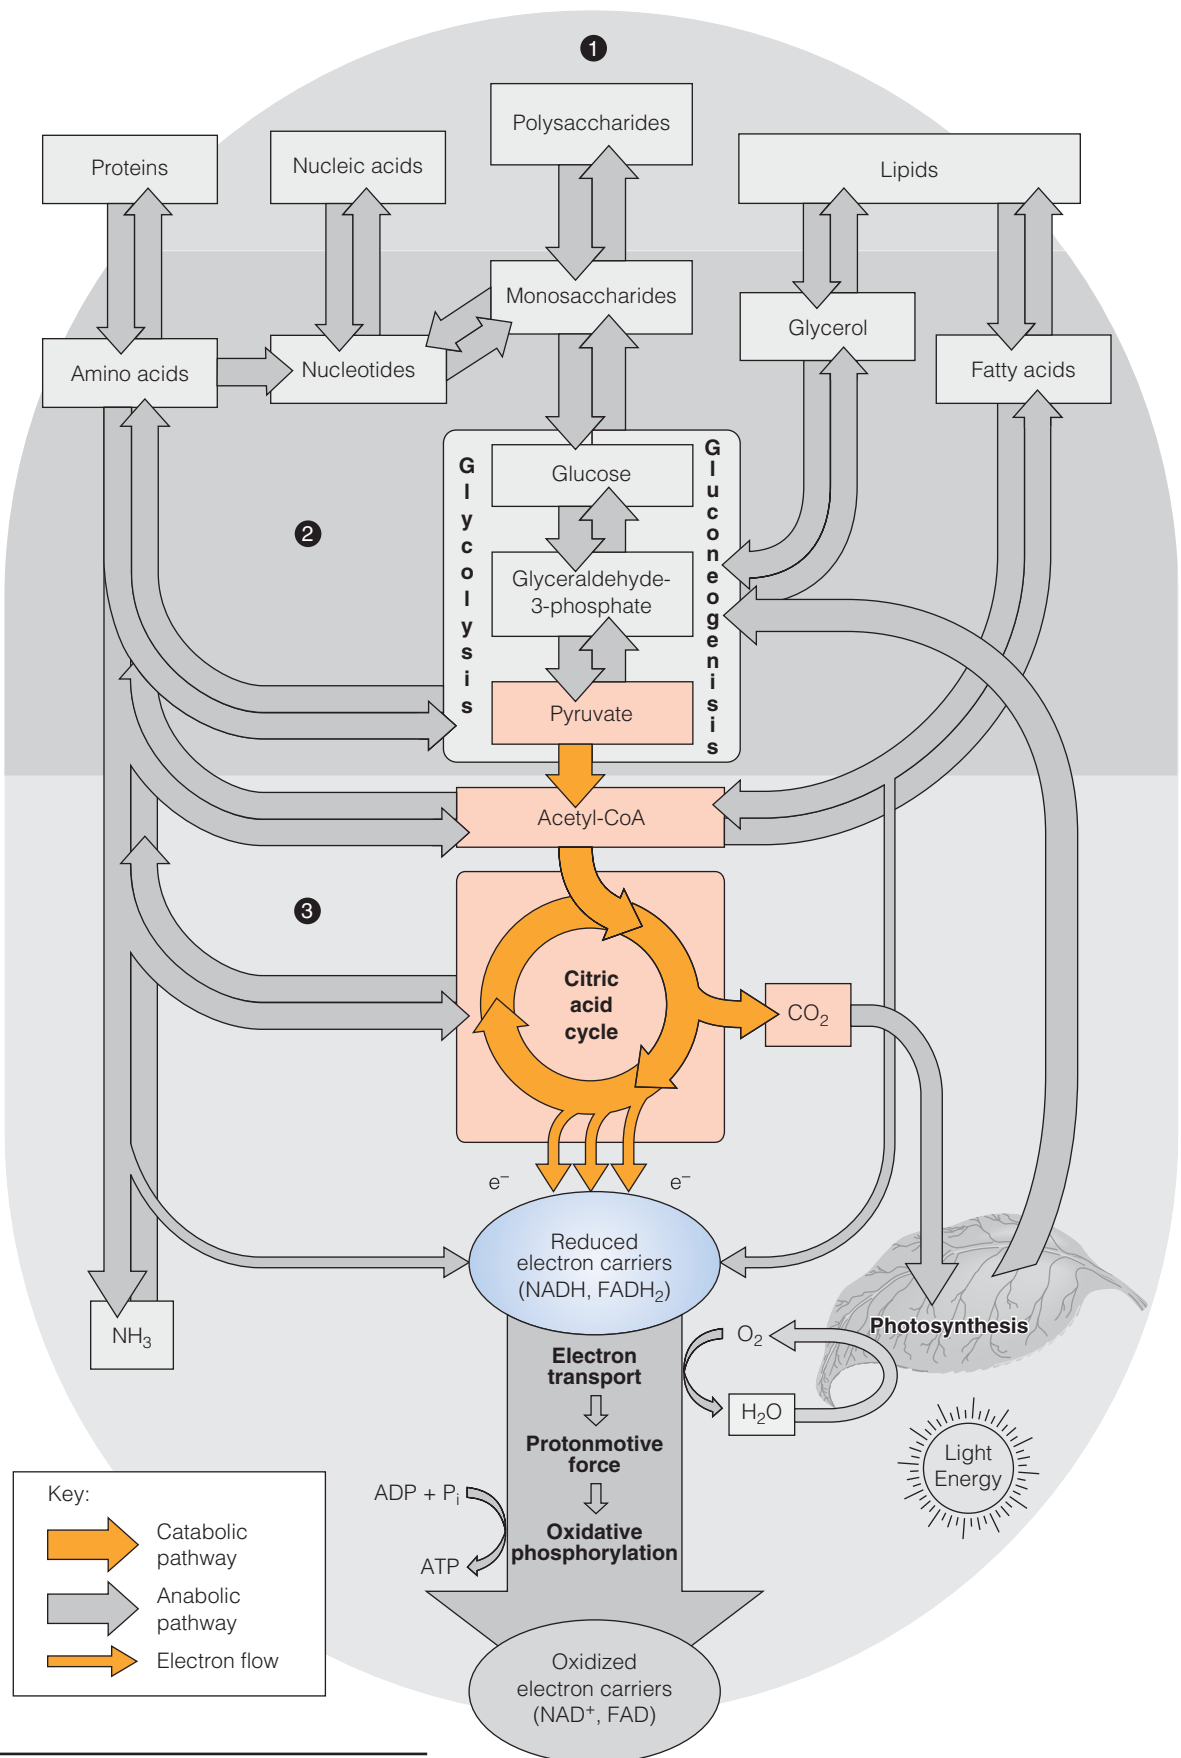

FIGURE 14.1

Oxidative processes in the generation of metabolic energy. This overview of intermediary metabolism highlights the citric acid cycle and the pathways that deliver fuel to the cycle for oxidation.

Overview of Pyruvate Oxidation and the Citric Acid Cycle

The Three Stages of Respiration

It is convenient to think of the metabolic oxidation of organic substrates as a three-stage process, schematized in Figure 14.2. Stage 1 is the generation of an activated two-carbon fragment—the acetyl group of **acetyl-coenzyme A**, or **acetyl-CoA**. (Recall from Chapter 12 that coenzyme A activates and transfers acyl groups; more about this on pages 601–602.) Stage 2 is oxidation of those two carbon atoms in the citric acid cycle to form 2 CO₂ and 4 pairs of electrons. Stage 3 is electron transport

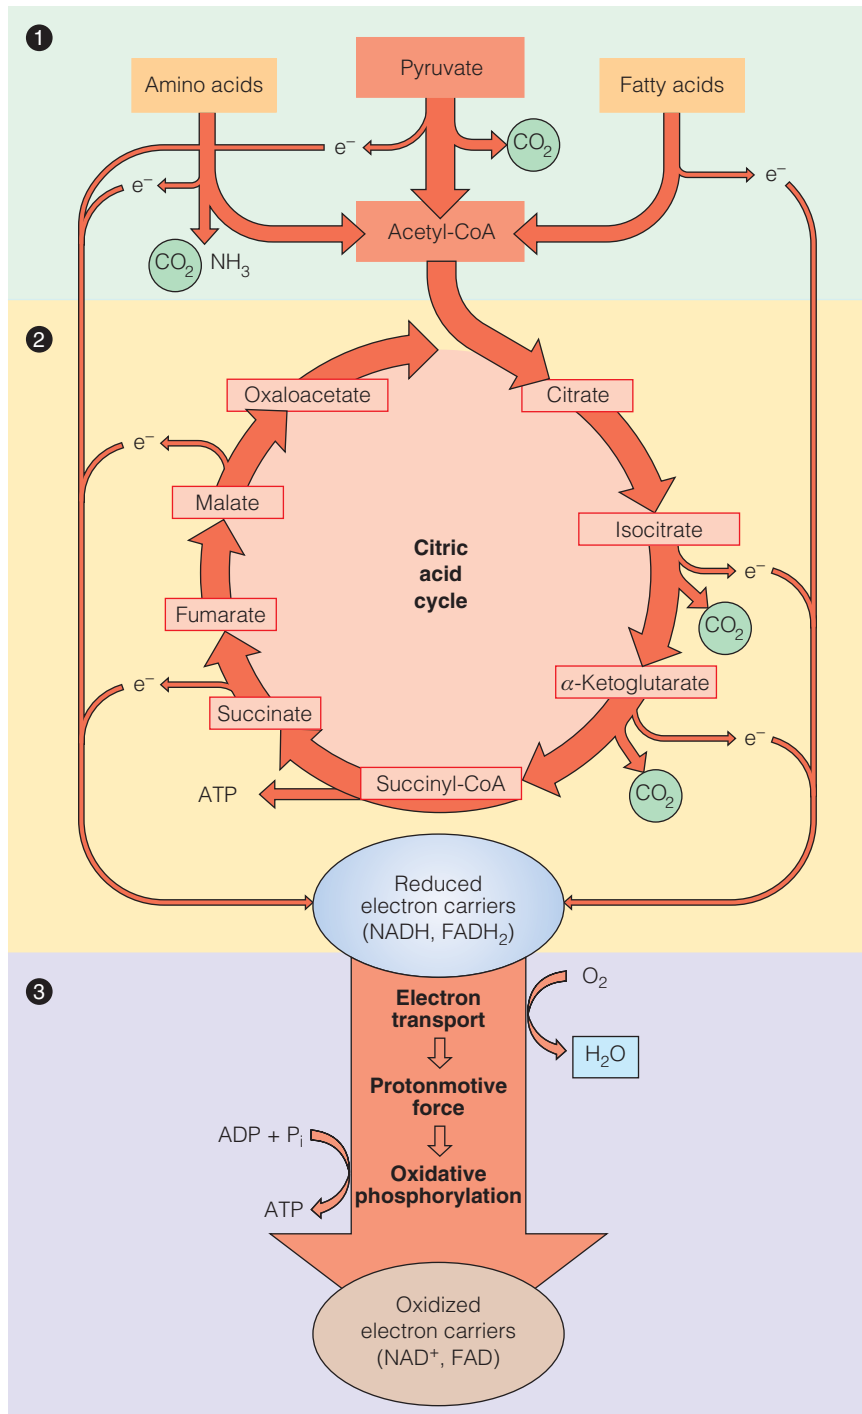

FIGURE 14.2

The three stages of respiration. In stage 1, carbon from metabolic fuels is incorporated into acetyl-CoA. In stage 2, the citric acid cycle oxidizes acetyl-CoA to produce CO₂, reduced electron carriers, and a small amount of ATP. In stage 3, the reduced electron carriers are reoxidized, providing energy for the synthesis of additional ATP.

and oxidative phosphorylation, in which the reduced electron carriers generated in the citric acid cycle become reoxidized, with concomitant synthesis of ATP. Stage 1 is a family of pathways, which operate separately on carbohydrate, fat, and protein. Carbon from carbohydrate enters stage 1 as pyruvate; oxidation of pyruvate to acetyl-CoA is described in this chapter. Fat breakdown generates acetyl-CoA primarily through β -oxidation of fatty acids (see Chapter 17), whereas several different pathways generate acetyl-CoA and citric acid cycle intermediates from amino acid catabolism (see Chapter 21).

In bacteria, the enzymes of pyruvate oxidation and the citric acid cycle are located in the cytoplasm and on the plasma membrane. In eukaryotic cells, respiration takes place in mitochondria. Reactions of the first two stages occur within the interior, **matrix** compartment of the mitochondrion, and electron transport and oxidative phosphorylation are catalyzed by membrane-bound enzymes in the inner mitochondrial membrane. The inner membrane is extensively stacked and folded into projections, called **cristae**, that greatly expand its surface area. Most of the enzymes of the citric acid cycle are soluble proteins in the matrix but one is a membrane protein bound to the matrix side of the inner membrane. These structural and biochemical relationships are discussed further when we explore the third stage of respiration in Chapter 15.

Chemical Strategy of the Citric Acid Cycle

To fully understand the chemical strategy that underlies substrate oxidation in the citric acid cycle, we first briefly review the oxidation and reduction of organic compounds. Quantitative aspects of biological oxidations are presented in Chapter 15.

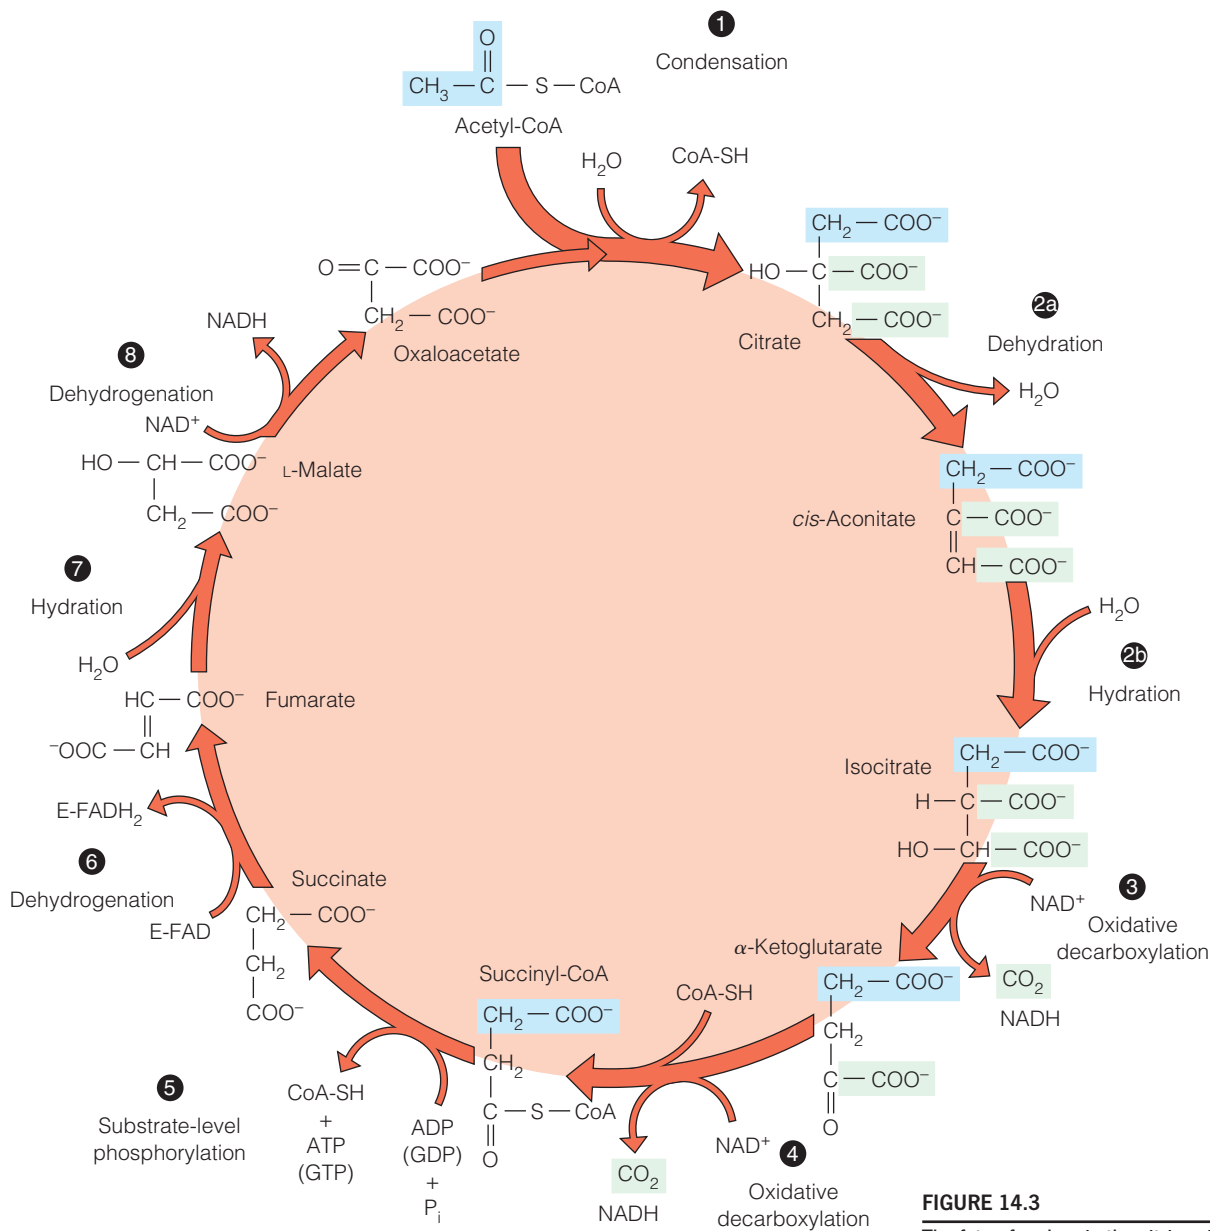

Oxidation involves the loss of electrons from a substrate; that substrate is the electron donor, and the electrons are transferred to an electron acceptor, which thereby becomes reduced. Free electrons cannot exist in the cell; electrons released in an enzyme-catalyzed oxidation must be transferred to specialized electron carriers (e.g., NAD^+ or FAD). The oxidized substrate and the electron acceptor will have different affinities for electrons—this affinity difference drives an exergonic electron flow, releasing energy that can be captured by the cell, ultimately in the form of ATP.

Carbon atoms become oxidized either through loss of a hydride ion (H^-) or through combination with oxygen. The latter process removes electrons from the shell around a carbon nucleus because the electronegativity of the oxygen draws shared electrons toward its own nucleus. Similarly, when an organic compound loses a hydride ion, it loses the electron associated with that hydrogen. Thus, either process involves a loss of electrons from the carbon atom undergoing oxidation. Formally, the two processes are equivalent.

A point of potential confusion arises in naming enzymes that catalyze oxidation reactions. Because most metabolic oxidations involve loss of hydrogen from the electron donor, we call enzymes that catalyze those reactions **dehydrogenases**. The term **oxidase** is reserved for those enzymes in which molecular oxygen itself is the electron acceptor. If oxygen combines directly with the substrate oxidized, the enzyme is called an **oxygenase**. Oxidases and oxygenases catalyze only that small proportion of oxidation reactions in which O_2 is a direct participant. Further discussion and examples are given in Chapter 15.

Referring to Figure 14.3, let's take a bird's-eye view of the citric acid cycle, focusing on the metabolic fates of the two carbons that enter the cycle. These carbons, the acetyl group of acetyl-coenzyme A, are transferred to a four-carbon dicarboxylic acid, **oxaloacetate**, to yield a six-carbon tricarboxylic acid, citrate. Citrate enters into a series of seven reactions during which two carbons are released as CO_2 and the remaining four carbons are converted to oxaloacetate, which is ready to begin the process again. Hence, the cyclic nature of the pathway: oxaloacetate is present at

Dehydrogenases catalyze substrate oxidations. Oxidases catalyze the subset of oxidations in which O_2 is the direct electron acceptor.

FIGURE 14.3

The fate of carbon in the citric acid cycle. Acetyl-CoA entering the citric acid cycle is highlighted (in blue) to show the fate of its two carbons through reaction 4. After reaction 5, the carbon atoms most recently entered are no longer highlighted because succinate and fumarate are symmetrical molecules. Thus C1 and C2 become indistinguishable from C3 and C4 beyond this point in the cycle. Carboxyl groups that leave the cycle as CO_2 in reactions 3 and 4 are shown in green. Note that these departing CO_2 groups derive from the two oxaloacetate carboxyl groups that were incorporated as acetyl-CoA in earlier turns of the cycle.

the beginning, to react with an activated two-carbon fragment, and it is present at the end, after two carbons have been oxidized to CO_2 . Thus oxaloacetate, and indeed the entire cycle, acts as a catalyst for the oxidation of acetyl-CoA to CO_2 . Note also that of the eight reactions shown in Figure 14.3, four are dehydrogenations, which together generate eight reducing equivalents (all derived from the acetyl-CoA) in the form of three NADH/H^+ and one FADH_2 .

The oxidation of acetyl-CoA to 2 CO_2 would seem to be a relatively simple transformation. Why then, is such a complicated pathway used by cells? The answer lies in the chemistry: oxidation of acetyl-CoA requires C—C bond cleavage, a difficult reaction for the two-carbon acetyl group. As discussed in Chapter 12, C—C bond cleavage is much more facile if a carbonyl group is nearby to stabilize the carbanionic transition state, for example in the retro-aldol cleavage of fructose-1,6-bisphosphate in glycolysis (Figure 13.5, page 528). The strategy used in the citric acid cycle is to metabolize acetyl-CoA through a series of β -keto acid and α -keto acid intermediates, which are readily decarboxylated in enzyme-catalyzed reactions, thereby achieving the necessary C—C bond cleavage.

Discovery of the Citric Acid Cycle

The idea that organic fuels are oxidized via a cyclic pathway was proposed in 1937 by Hans Krebs, on the basis of studies for which he later shared a Nobel Prize with Fritz Lipmann (the discoverer of coenzyme A). Beginning in 1932, Krebs tested the ability of various organic acids to be oxidized by following the rate of oxygen consumption in liver and kidney slices. He found that citrate, succinate, fumarate, malate, and acetate were readily oxidized in these tissues.

In 1935, the Hungarian biochemist Albert Szent-Györgyi, using minced pigeon breast muscle, a tissue with a very high rate of respiration, found that oxygen consumption was much greater than expected when he added small amounts of the dicarboxylic acids succinate, fumarate, or malate. Krebs recognized that these acids were somehow acting *catalytically*, rather than being used up as substrates in a linear pathway.

Then in 1937, Carl Martius and Franz Knoop discovered that citrate is converted to isocitrate and α -ketoglutarate, which was already known to undergo dehydrogenation to succinate. This linked the oxidation of citrate to that of succinate, and helped Krebs explain his earlier observation that citrate catalytically stimulated oxygen consumption. Krebs then found that malonate, an analog of succinate and a known inhibitor of succinate dehydrogenase, blocked the oxidation of pyruvate, pointing to a role for succinate dehydrogenase in pyruvate oxidation. Moreover, malonate-inhibited cells accumulated citrate, α -ketoglutarate, and succinate, suggesting that citrate and α -ketoglutarate are both normal precursors of succinate. The final piece to the puzzle was Krebs' discovery that addition of pyruvate plus oxaloacetate to this minced muscle preparation led to accumulation of citrate in the medium, suggesting that these two acids are precursors to citrate.

From these observations and a knowledge of the structures and reactivities of the organic acids that could stimulate respiration, Krebs proposed both the sequence of reactions involved and the cyclic nature of the pathway. It is worth noting that Krebs was already primed to recognize the cyclic organization of this pathway because he and Kurt Henseleit had just discovered the urea cycle (Chapter 20) in 1932.

Krebs postulated that carbohydrates entered the cycle via pyruvate, which reacted with oxaloacetate to give citrate plus CO_2 . We now know that pyruvate must first be oxidized (releasing CO_2) and that acetyl-CoA is the species that subsequently reacts with oxaloacetate to form citrate. We know also of a CoA derivative of succinate, **succinyl-CoA**. Recognition of these activated intermediates in the cycle had to await the discovery of coenzyme A by Fritz Lipmann in 1947. Except for these changes, the pathway as proposed by Krebs was correct. The reactions are outlined in Figure 14.3.

The citric acid cycle is also known by other names: the Krebs cycle, after its discoverer, and the tricarboxylic acid (TCA) cycle because it was apparent from the outset that tricarboxylic acids are involved as intermediates. It became clear only later that citrate was one of those intermediates. The following discussion of the citric acid cycle will focus on mammalian biochemistry, but essentially identical versions of this pathway are found in nearly all organisms, and it is clearly an evolutionarily ancient pathway.

Pyruvate Oxidation: A Major Entry Route for Carbon into the Citric Acid Cycle

As noted earlier, pyruvate derived from carbohydrate oxidation is but one of the major suppliers of acetyl-CoA for oxidation in the citric acid cycle. Chapters 17 and 20 focus upon oxidation of fatty acids and amino acids, respectively, to give this central metabolite. The conversion of pyruvate to acetyl-CoA, catalyzed by **pyruvate dehydrogenase complex (PDH complex)**, is an oxidative decarboxylation. In the overall reaction the carboxyl group of pyruvate is released as CO₂, while the remaining two carbons form the acetyl moiety of acetyl-CoA.

This reaction involves the decarboxylation of an α -keto acid (pyruvate). Unlike β -keto acids, α -keto acids cannot stabilize the carbanion transition state that develops during decarboxylation. To solve this problem, enzymatic decarboxylations of α -keto acid substrates all utilize the coenzyme **thiamine pyrophosphate (TPP)** to form a covalent adduct with the substrate and provide the electron delocalization required to stabilize the carbanion intermediate. We saw this same strategy used in the pyruvate decarboxylase reaction of alcohol fermentation (Chapter 13, page 538), and, indeed, the chemistry of these two decarboxylations is nearly identical.

Although the overall reaction may look straightforward, it is in fact rather complicated, involving generation of a reduced electron carrier (NADH), decarboxylation of pyruvate, and metabolic activation of the remaining two carbons of pyruvate. The reaction is highly exergonic and is essentially irreversible in vivo. Three enzymes are involved—**pyruvate dehydrogenase (E₁)**, **dihydrolipoamide transacetylase (E₂)**, and **dihydrolipoamide dehydrogenase (E₃)**—in the five-step reaction. In addition, five coenzymes are required, including the two coenzymes—NAD⁺ and coenzyme A—that appear in the overall reaction. The three enzymes (E₁, E₂, and E₃) involved are assembled into a highly organized multienzyme complex called the **pyruvate dehydrogenase complex**.

Figure 14.4 shows an electron micrograph of the complex as purified from *E. coli* and a model of the eukaryotic PDH complex, based upon cryoelectron

Pyruvate oxidation to acetyl-CoA is a virtually irreversible reaction that involves three enzymes and five coenzymes.

TABLE 14.1 Coenzymes of the pyruvate dehydrogenase reaction

Cofactor	Location	Function
Thiamine pyrophosphate (TPP)	Tightly bound to E ₁	Decarboxylates pyruvate, yielding hydroxyethyl-TPP
Lipoic acid (lipoamide)	Covalently bound to E ₂ via lysine (“swinging arm”)	Accepts hydroxyethyl carbanion from TPP as acetyl group
Coenzyme A (CoA)	Dissociable substrate for E ₂	Accepts acetyl group from lipoamide
Flavin adenine dinucleotide (FAD)	Tightly bound to E ₃	Accepts pair of electrons from reduced lipoamide
Nicotinamide adenine dinucleotide (NAD ⁺)	Dissociable substrate for E ₃	Accepts pair of electrons from reduced FADH ₂

microscopy of the yeast (*Saccharomyces cerevisiae*) complex. The *E. coli* PDH complex contains 24 polypeptide chains of E₁, 24 chains of E₂, and 12 chains of E₃. The pyruvate dehydrogenase complex as isolated from *E. coli* has a mass of about 4.6 million daltons, slightly larger than a ribosome. In mammalian mitochondria the complex is about twice that size. The eukaryotic complex (Figure 14.4b–e) is composed of a core of 60 E₂ monomers arranged as a pentagonal dodecahedron (icosahedral symmetry, see Figure 6.38, page 213). This core structure contains 12 E₃ homodimers and is surrounded by ~30–45 E₁α₂β₂ heterotetramers. In addition, the mammalian PDH complex contains ~12 copies of E₃ binding protein (E3BP) and small amounts of two regulatory enzymes as well—a kinase that phosphorylates three serine residues in E₁ and a phosphatase that removes those phosphates. We will discuss regulation of the activities of the PDH complex later in this chapter.

To understand how the three enzymes (E₁, E₂, and E₃) in the pyruvate dehydrogenase complex interact, we must understand the functions of the five coenzymes that participate in the reaction: *thiamine pyrophosphate (TPP)*, *lipoic acid*, *coenzyme A*, *flavin adenine dinucleotide (FAD)*, and *NAD⁺* (Table 14.1). TPP is tightly bound to E₁, lipoic acid is covalently bound to E₂, and FAD is tightly bound to E₃. Although we briefly introduced all five coenzymes in Chapter 11, we have discussed only NAD⁺ and TPP in detail (Chapter 13; glyceraldehyde-3-phosphate dehydrogenase and pyruvate decarboxylase reactions, respectively). Therefore, we digress here to describe the chemistry of the other three.

Coenzymes Involved in Pyruvate Oxidation and the Citric Acid Cycle

Thiamine Pyrophosphate (TPP)

The chemistry of **thiamine pyrophosphate (TPP)** was discussed in the context of its role in the pyruvate decarboxylase reaction of alcohol fermentation (Figure 13.8, page 538). As we shall see, it functions in exactly the same manner in the pyruvate dehydrogenase reaction, stabilizing a carbanion intermediate.

Lipoic Acid (Lipoamide)

In pyruvate oxidation, the acceptor of the active aldehyde (hydroxyethyl group) generated by TPP is **lipoic acid**, which is the internal disulfide of 6,8-dithiooctanoic acid. Lipoic acid was identified in 1951 by Lester J. Reed at the University of Texas and I. C. Gunsalus at the University of Illinois. With the help of Eli Lilly and Co., they processed nearly 10 tons of pork and beef liver residue to isolate ~30 mg of crystalline substance! The coenzyme is joined to E₂ via an amide bond linking the carboxyl group of lipoic acid to a lysine ε-amino group. Thus, the reactive species is an amide, called **lipoamide**, or **lipoyllysine**. Each lipoyllysine side chain is ~14 Å long, and is located within a flexible lipoyl domain of E₂ (and E₃BP),

Lipoamide is a carrier of both electrons and acyl groups.

allowing it to function as a “swinging arm” that can interact with the active sites of both the E_1 and E_3 components of the PDH complex (see below).

Transfer of the active aldehyde moiety (hydroxyethyl group) from TPP to the disulfide of lipoamide involves simultaneous oxidation of the aldehyde, coupled to reduction of the disulfide of lipoamide. This generates an acyl group, which, in pyruvate dehydrogenase, is transferred next to coenzyme A. The pair of electrons is transferred to lipoamide to form dihydrolipoamide (Figure 14.5). Thus, lipoamide is both an electron carrier and an acyl group carrier.

Flavin Adenine Dinucleotide (FAD)

Flavin adenine dinucleotide, or **FAD**, is one of two coenzymes derived from vitamin B_2 , or **riboflavin**. The other is the simpler **flavin mononucleotide (FMN)**, or riboflavin phosphate (Figure 14.6). The functional part of both coenzymes is the

FIGURE 14.6

Structures of riboflavin and the flavin coenzymes. Riboflavin and its coenzyme derivatives, FMN and FAD, all contain an isalloxazine ring system and ribitol. The figure identifies (in red) the cluster of two carbon and two nitrogen atoms within the ring system that participates in the oxidation–reduction reactions of the flavin coenzymes.

FIGURE 14.5

Oxidized and reduced forms of lipoamide. The cyclic disulfide of lipoamide can undergo a reversible two-electron reduction to form the dithiol, dihydrolipoamide. In pyruvate dehydrogenase, this reduction is coupled to the transfer of the hydroxyethyl group moiety from TPP, giving an acetyl thioester of the reduced dihydrolipoamide.

Flavin adenine dinucleotide (FAD)

isoalloxazine ring system, which serves as a two-electron acceptor. Compounds containing such a ring system are called **flavins**. In riboflavin and its derivatives the ring system is attached to **ribitol**, an open-chain version of ribose with the aldehyde carbon reduced to the alcohol level. The five-carbon of ribitol is linked to phosphate in FMN, and FAD is the adenylated dinucleotide derivative of FMN. Thus, these compounds are somewhat analogous to nicotinamide mononucleotide and nicotinamide adenine dinucleotide (NAD⁺), respectively.

Enzymes that use a flavin coenzyme are called **flavoproteins**, or **flavin dehydrogenases**. FMN and FAD undergo virtually identical electron transfer reactions. Flavoprotein enzymes preferentially bind either FMN or FAD. In a few cases, that binding is covalent. In most cases, however, the flavin is bound tightly but noncovalently, such that the coenzyme cannot easily dissociate from the enzyme. Thus flavins do not transfer electrons by diffusing from one enzyme to another, like the nicotinamide coenzymes. Instead, flavin dehydrogenases temporarily hold the electrons obtained from a reduced substrate and transfer them to a different electron acceptor. As we will see in the next chapter, another important feature of flavoproteins is that the tight binding of the flavin coenzyme to the protein (either covalently or noncovalently) confers a unique standard reduction potential (E'°) on the flavin ring.

Like the nicotinamide coenzymes, the flavins undergo two-electron oxidation and reduction reactions. The flavins, however, are distinctive in having a stable one-electron-reduced species, a **semiquinone** free radical, as shown in Figure 14.7. This free radical can be detected spectrophotometrically; whereas oxidized FAD and FMN are bright yellow, and fully reduced flavins are colorless, the semiquinone intermediate is either red or blue, depending on pH. The stability of the semiquinone intermediate gives flavins a catalytic versatility not shared by nicotinamide coenzymes, in that flavins can interact with either two-electron or one-electron donor–acceptor pairs. Also, flavoproteins can interact directly with oxygen. Thus, some, but not all, flavoproteins are oxidases.

Flavin coenzymes participate in two-electron oxidation reactions that can proceed in 2 one-electron steps.

FIGURE 14.7

Oxidation and reduction reactions involving flavin coenzymes. Flavins participate in two-electron reactions, but the existence of the stable semiquinone free radical intermediate allows these reactions to proceed one electron at a time. Thus, reduced flavins can readily be oxidized by one-electron acceptors. Spectral maxima (λ_{\max}) are indicated for the oxidized flavin and the protonated and deprotonated forms of the semiquinone intermediate. In both semiquinone forms the unpaired electron is delocalized between N-5 and C-4a.

Coenzyme A: Activation of Acyl Groups

Coenzyme A (A for acyl) participates in activation of acyl groups in general, including the acetyl group derived from pyruvate. The coenzyme is derived metabolically from ATP, the vitamin **pantothenic acid**, and β -mercaptoethylamine.

A free thiol on the β -mercaptoethylamine moiety is the business end of the coenzyme molecule; the rest of the molecule provides enzyme-binding sites. In acylated derivatives, such as acetyl-coenzyme A, the acyl group is linked to the thiol group to form an energy-rich thioester.

We designate the acylated forms of coenzyme as acyl-CoA, and the unacylated form as CoA-SH.

The energy-rich nature of thioesters, as compared with ordinary esters, is related primarily to resonance stabilization (Figure 14.8). Most esters have two resonance forms. Stabilization involves π -electron orbital overlap, giving partial double-bond character to the C—OR link. In thioesters, the larger atomic size of S (as compared with O) reduces the π -electron overlap between C and S so that the C—SR structure does not contribute significantly to resonance stabilization. Thus, the thioester is *destabilized* relative to an ester so that its ΔG of hydrolysis is increased.

Thioesters such as acetyl-CoA are energy rich because thioesters are destabilized relative to ordinary oxygen esters.

FIGURE 14.8

Comparison of free energies of hydrolysis of thioesters and oxygen esters. Lack of resonance stabilization in thioesters is the basis for the higher ΔG of hydrolysis of thioesters, relative to that of ordinary oxygen esters. The free energies of the hydrolysis products are similar for the two classes of compounds.

The lack of double-bond character in the C—SR bond of acyl-CoAs makes this bond weaker than the corresponding C—OR bond in ordinary esters, in turn making the thioalkoxide ion ($R-S^-$) a good leaving group in nucleophilic displacement reactions. Thus, the acyl group is readily transferred to other metabolites, which is what occurs in the first reaction of the citric acid cycle.

Action of the Pyruvate Dehydrogenase Complex

As noted above, the oxidation of pyruvate to acetyl-CoA involves the coenzymes TPP, lipoic acid, CoA-SH, FAD, and NAD^+ , acting in concert with three enzymes in the pyruvate dehydrogenase complex. Now we are ready to see how all of these components function together to effect the conversion of pyruvate to acetyl-CoA. The overall process is summarized in Figure 14.9.

The entire process, beginning with the decarboxylation of pyruvate, and ending with the transfer of a pair of electrons to NAD^+ , requires five steps. A central feature of this reaction sequence is that in the three middle steps, reaction intermediates are formed and transferred between active sites by covalent attachment to the lipoamide moieties on the flexible lipoyl domains of E_2 (and E_3BP). The reaction sequence begins at the active site of E_1 (**pyruvate dehydrogenase**), which catalyzes a nucleophilic addition of the TPP carbanion (ylid form of thiazolium moiety) to the ketone carbonyl group of pyruvate to form an addition product that undergoes decarboxylation to give hydroxyethyl-TPP (reaction 1, Figure 14.9). The chemistry of this step is identical to that of the pyruvate decarboxylase reaction (Figure 13.8, page 538), except that the hydroxyethyl group is not released as acetaldehyde. Instead, it is transferred to a lipoamide moiety on E_2 . This reaction, also catalyzed by E_1 , occurs by an S_N2 -like attack of the hydroxyethyl carbanion on the lipoamide disulfide, followed by elimination of TPP to form an acetyl thioester on dihydrolipoamide and regenerate E_1 (reaction 2, Figure 14.9).

FIGURE 14.9

Mechanisms of the pyruvate dehydrogenase complex. This diagram of the oxidation of pyruvate to acetyl-CoA shows the role of the swinging arms of lipoamide in the functioning of the pyruvate dehydrogenase complex. E_1 : pyruvate dehydrogenase. E_2 : dihydrolipoamide transacetylase with its lipoyl domains (LD). E_3 : dihydrolipoamide dehydrogenase. The subunit colors correspond to those in the structural model in Figure 14.4e (page 597). **Reaction 1:** Pyruvate reacts with the TPP carbanion of E_1 to form an addition product that undergoes decarboxylation, giving hydroxyethyl-TPP. **Reaction 2:** The hydroxyethyl group is transferred by E_1 to a lipoamide swinging arm on E_2 , resulting in oxidation of the 2-carbon fragment to an acetyl group, with concomitant reduction of the lipoamide disulfide to dihydrolipoamide. **Reaction 3:** The acetyl group is transferred to CoA-SH, producing acetyl-CoA and dihydrolipoamide. **Reaction 4:** E_3 reoxidizes the reduced lipoamide swinging arm by transferring two electrons to an E_3 Cys-Cys disulfide bond. **Reaction 5:** E_3 catalyzes transfer of the electrons from the Cys sulfhydryl groups to NAD^+ , regenerating the oxidized form of E_3 and releasing reduced NADH. Tightly bound FAD is used as an intermediate electron carrier in this step.

FIGURE 14.10

Mechanism of the reoxidation of dihydrolipoamide catalyzed by dihydrolipoamide dehydrogenase (E₃). This reaction (steps 4 and 5 in Figure 14.9) results in transfer of a pair of electrons from dihydrolipoamide to NAD⁺, regenerating the oxidized form of E₃ and releasing reduced NADH.

© 2005 Roberts and Company Publishers as seen in *The Organic Chemistry of Biological Pathways* by John McMurry and Tadgh Begley.

Through the combination of steps 1 and 2, pyruvate undergoes a two-electron oxidation to an acetyl group, with concomitant two-electron reduction of the lipoamide disulfide to dihydrolipoamide.

The acetyl group is now covalently bound to the active site of E₂, via the flexible lipoyllysine “swinging arm.” E₂ (**dihydrolipoamide transacetylase**) next catalyzes transfer of the acetyl group to CoA. This nucleophilic acyl substitution reaction simply exchanges one thioester for another, giving acetyl-CoA and dihydrolipoamide (reaction 3, Figure 14.9).

The last two steps of the process (reaction 4 and 5, Figure 14.9) are required to reoxidize the dihydrolipoamide of E₂, and transfer the pair of electrons to a dissociable carrier (NAD⁺). E₃ (**dihydrolipoamide dehydrogenase**) catalyzes the transfer of the electron pair from dihydrolipoamide to NAD⁺. The active site of E₃ contains a redox active Cys–Cys disulfide bond and a tightly bound FAD. The reaction involves initial formation of a mixed disulfide between dihydrolipoamide and Cys-41 of E₃ (Figure 14.10). The E₂ lipoamide disulfide is reformed by nucleophilic addition of the Cys-46 thiol to FAD to give reduced FADH₂ and reoxidized Cys–Cys disulfide on E₃. The final step (reaction 5, Figure 14.9) is transfer of the electron pair from FADH₂ to NAD⁺, regenerating the oxidized form of E₃ and releasing reduced NADH.

Physical juxtaposition of the enzymes of the complex, and covalent attachment of reaction intermediates via the lipoamide swinging arm, provides a number of advantages. The five-step reaction sequence in Figure 14.9 nicely illustrates the concept of **substrate channeling**: intermediates of a multistep pathway are “handed off” from one active site to the next without diffusing from the complex. Channeling allows the overall reaction to proceed smoothly, without unwanted side reactions or diffusion of intermediates from catalytic sites. The local concentration of substrates can be very high, allowing greater flux through the pathway. The pyruvate dehydrogenase complex represents one of the best-understood

Lipoamide is tethered to one enzyme (E₂) in the pyruvate dehydrogenase complex, but it interacts with all three enzymes via a flexible swinging arm.

examples of how cells can achieve economy of function by formation of **multienzyme complexes** catalyzing sequential reactions in a pathway. In fact, this same $E_1-E_2-E_3$ multienzyme structure is used to oxidize several other α -keto acids. Other examples include the branched-chain α -ketoacid dehydrogenase complex (Chapter 21, page 870) and the α -ketoglutarate dehydrogenase complex, which we will discuss shortly. Indeed, the E_3 subunits are identical in all three complexes from a given species. It is clear from Figure 14.9 that each complex must have a unique E_1 subunit specific to its particular α -ketoacid substrate. But once the acyl group has been transferred to CoA-SH by E_2 , the resulting dihydrolipoamide, the substrate of the E_3 subunits, is identical in each complex. Thus, as organisms evolved new α -ketoacid dehydrogenase complexes, the same E_3 subunit could be reused.

Arsenic poisoning, both intentional and unintentional, has had a long history, dating back to at least the eighth century. Trivalent As(III) compounds such as arsenite (AsO_3^{3-}) and organic arsenicals react readily with thiols, and they are especially reactive with dithiols, such as dihydrolipoamide, forming bidentate adducts:

This covalent modification of lipoamide groups inactivates $E_1-E_2-E_3$ multienzyme complexes, including the pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes of the citric acid cycle, thereby inhibiting respiration and accounting for the toxicity of these compounds. Arsenic became a favorite poison during the Middle Ages and the Renaissance, often being employed by impatient heirs to “get a jump” on their inheritances! Several prominent historical figures, including Francisco de’ Medici, George III, and Napoleon Bonaparte may have been poisoned by arsenic. Arsenic was also an ingredient in many “tonics” that were popular during the Victorian Era. Charles Darwin may in fact have suffered from chronic arsenic poisoning from his use of these tonics. Organic arsenicals were even used in the early twentieth century to treat syphilis and trypanosomiasis because these pathogens’ lipoamide-containing enzymes are often more sensitive than the host enzymes. The toxicity of these arsenic compounds led to their discontinued use once penicillin and other antibiotics were developed.

The Citric Acid Cycle

Figure 14.3 presented the entire citric acid cycle, showing the structure of each intermediate. We will now discuss the chemistry and enzymology of each reaction. The cycle is composed of eight steps, beginning with addition of a two-carbon moiety (acetyl-CoA) to a four-carbon compound (oxaloacetate) to give a six-carbon tricarboxylic acid, citrate, followed by loss of two carbons as CO_2 , and finally the regeneration of oxaloacetate. During this process, four pairs of

electrons are removed from the substrates and passed to carriers (NAD⁺ and FAD) on their way to the respiratory chain.

Step 1: Introduction of Two Carbon Atoms as Acetyl-CoA

The initial reaction, catalyzed by **citrate synthase**, is akin to an aldol condensation.

As shown in Figure 14.11, the acetyl moiety is activated by removal of an acidic α proton from the methyl carbon, and donation of a proton to the carbonyl oxygen, to give the enol (or enolate) form. A general base (side chain carboxylate of aspartate 375) abstracts the α proton and a general acid (imidazole of histidine 274) protonates the carbonyl oxygen of acetyl-CoA. The enolate then nucleophilically attacks the carbonyl carbon of oxaloacetate to give the enzyme-bound intermediate (**S**)-citroyl-CoA. This step is facilitated by a second active site histidine (His 320), acting as a general acid to protonate the aldol product. Citroyl-CoA is highly unstable, and spontaneously hydrolyzes to yield the products citrate + CoA-SH. This thioester hydrolysis makes the forward reaction highly exergonic—the K_{eq} for this reaction is about 3×10^5 , which ensures continued operation of the cycle even when the oxaloacetate concentration is low. As expected for the first committed step in a pathway, this reaction is an important site of regulation for the overall pathway (see page 612). Finally, crystallographic analysis of citrate synthase (Figure 14.12) gives excellent evidence for the induced fit model of enzyme catalysis (see Chapter 11).

Step 2: Isomerization of Citrate

The tertiary alcohol of citrate presents yet another chemical problem: Tertiary alcohols cannot be oxidized without breaking a carbon–carbon bond because the carbon atom bearing the hydroxyl group is already bonded to three other carbons and cannot form a carbon–oxygen bond. To set up the next oxidation in the pathway, citrate is converted to isocitrate, a chiral secondary alcohol, which can be more readily oxidized. This isomerization reaction, catalyzed by **aconitase**, involves successive

FIGURE 14.11

Mechanism of the citrate synthase reaction. Step 1: Asp 375 extracts a proton from the methyl group, and His 274 donates a proton to the carbonyl oxygen of acetyl-CoA, creating an enol. **Step 2:** His 274 deprotonates the acetyl-CoA enol, stabilizing the nucleophilic enolate that attacks the keto carbon of oxaloacetate. His 320 protonates the aldol product (S)-citroyl-CoA. **Step 3:** The citroyl-CoA intermediate spontaneously hydrolyzes to citrate by a nucleophilic acyl substitution reaction. Although citrate is a symmetrical molecule, the two carboxymethyl ($-\text{CH}_2\text{COO}^-$) groups occupy different positions relative to the OH and COO^- groups on C3. Thus, citrate is **prochiral**—it can become chiral by substitution of one of its carboxymethyl groups—and these two chemically equivalent groups are designated *pro-R* and *pro-S*. The two carbons derived from acetyl-CoA form the *pro-S* arm in the final product citrate. This stereospecificity arises from the fact that citrate synthase catalyzes the attack of the acetyl-CoA enolate only on the *si* face of oxaloacetate's carbonyl carbon, giving exclusively the *S* stereoisomer of citroyl-CoA (recall that a carbonyl group is trigonal planar so that it has two distinct faces, referred to as *si* and *re*, at which a nucleophile can attack). Residue numbering is based on the pig heart enzyme.

FIGURE 14.12

Three-dimensional structure of citrate synthase. The two forms of pig heart citrate synthase homodimer shown here were determined by crystallographic methods and support the induced fit model of enzyme catalysis (see Chapter 11). **(a)** In the absence of CoA-SH the enzyme crystallizes in an “open” form (PDB ID 1CTS). Citrate (red) binds at the base of large clefts in both catalytic domains of the homodimeric protein. **(b)** Binding of CoA-SH (yellow) causes the enzyme to adopt a “closed” conformation, with the clefts essentially filled (PDB ID 2CTS).

dehydration and hydration, through *cis*-aconitate as a dehydrated intermediate, which remains enzyme-bound.

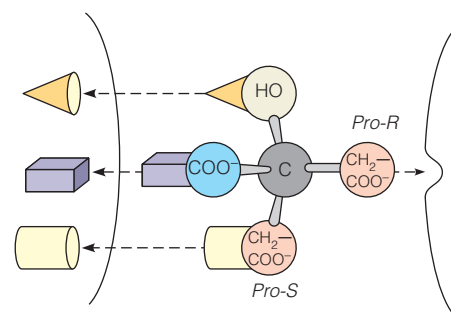

The enzyme contains nonheme iron and acid-labile sulfur in a cluster called a 4Fe-4S *iron-sulfur center*, normally associated with oxidoreductases (see Chapter 15). In aconitase this iron-sulfur cluster coordinates the hydroxyl group and one of the carboxyl groups on the citrate molecule. The dehydration occurs specifically on the *pro-R* arm, and the *pro-R* proton is removed by an active site serine acting as a base. Labeling studies showed that the —OH group added back in the hydration step is different from the one eliminated at the dehydration step, but the proton added back is the same—it is held in the active site by the serine. Furthermore, the proton removed during dehydration is added back to the *opposite* face of *cis*-aconitate during hydration. This implies that the *cis*-aconitate intermediate must flip 180° during the reaction, presumably by releasing from the enzyme, then rebind with the iron-sulfur cluster, but in the opposite orientation. Thus, of the four possible diastereomers of isocitrate, only one, the 2*R*,3*S* diastereomer, is produced.

How can citrate, a symmetric molecule, react asymmetrically with aconitase? Andrew Mesecar and Dan Koshland Jr. pointed out that if the enzyme bound the substrate at four points, then the binding site itself was asymmetric and could bind the substrate in only one way. Thus, citrate was the first substance to be recognized as **prochiral**, or symmetrical, but that becomes asymmetric upon binding to the asymmetric surface of an enzyme, or upon some similar change in one of two equivalent groups.

The aconitase reaction is freely reversible, and an equilibrium mixture of these three acids at 25 °C contains about 90% citrate, 4% *cis*-aconitate, and 6% isocitrate, but the exergonic nature of the next reaction draws the reaction to the right as written.

Aconitase is the target site for the toxic action of **fluoroacetate**, a plant product that was originally used as a rodenticide. Its use by ranchers in the West to control coyote populations also led to the death of eagles and other endangered animals. Fluoroacetate blocks the citric acid cycle by its metabolic conversion to **2-fluorocitrate**, which is a potent **mechanism-based**, or **suicide, inhibitor** of aconitase. As described in Chapter 11, a mechanism-based inhibitor undergoes the first few chemical steps of the enzymatic reaction but is then converted into a compound that binds tightly, often irreversibly, thereby inactivating the enzyme. In other words, the inhibitor requires the normal enzyme mechanism to inactivate the enzyme. Similarly, fluoroacetate can be considered a **suicide substrate**: not toxic to cells by itself, but it resembles a normal metabolite closely enough that it undergoes metabolic transformation to a product that does inhibit a crucial enzyme. The cell “commits suicide” by transforming the analog to a toxic product. In this case fluoroacetate is first converted to fluoroacetyl-CoA by acetate thiokinase (see page 621), and then to 2-fluorocitrate by citrate synthase. 2-Fluorocitrate then inhibits aconitase, halting the entire citric acid cycle.

Fundamentals of Biochemistry: Life at the Molecular Level, 3rd ed., Donald Voet, Judith G. Voet, and Charlotte W. Pratt. © 2008 John Wiley & Sons, Inc. Modified with the permission of John Wiley & Sons, Inc.

Fluoroacetate is an example of a mechanism-based, or suicide, inhibitor of aconitase.

Step 3: Generation of CO₂ by an NAD⁺-Linked Dehydrogenase

The first of two oxidative decarboxylations in the cycle is catalyzed by **isocitrate dehydrogenase**. Isocitrate is oxidized to a ketone, **oxalosuccinate**, an unstable enzyme-bound intermediate that spontaneously decarboxylates to give the product, α -ketoglutarate. The strategy here is to oxidize isocitrate's secondary alcohol to a keto group β to the carboxyl group to be removed. The β -keto group acts as an electron sink to stabilize the carbanionic transition state, facilitating decarboxylation.

This reaction occurs with a ΔG° of -11.6 kJ/mol, and under physiological conditions it is sufficiently exergonic to pull the aconitase reaction forward. A mitochondrial form of isocitrate dehydrogenase that is specific for NAD⁺ is probably the chief participant in the citric acid cycle in most cells. The NADH produced in this reaction, carrying two reducing equivalents, is the first link between

FIGURE 14.14

Covalent catalysis by the succinyl-CoA synthetase reaction. Three successive nucleophilic substitution reactions conserve the energy of the thioester of succinyl-CoA in the phosphoanhydride bond of ATP (or GTP). An active site histidine side chain is transiently phosphorylated (*N*-phosphohistidine) during the reaction.

in liver (see Chapter 17, page 735). The ATP to ADP ratio in mitochondria, on the other hand, is closer to 1, and the equilibrium of the ATP-linked reaction will lie toward succinate. An ATP-linked succinyl-CoA synthetase is thus better suited for tissues dependent on oxidative metabolism for energy production. It is also possible that some of the GTP formed by the GDP-specific isozyme could be used to drive the synthesis of ATP, through the action of **nucleoside diphosphate kinase**.

Whichever nucleotide is used, the reaction occurs via a phosphorylated enzyme intermediate (covalent catalysis). As shown in Figure 14.14, an initial mixed anhydride between phosphate and a carboxyl group of succinate is formed in a nucleophilic acyl substitution reaction, displacing CoA-SH (step 1). In a second nucleophilic substitution, an active site histidine attacks the phosphorus atom of succinyl phosphate, displacing succinate (step 2). The resulting *N*-phosphohistidine residue then transfers its phosphate to the nucleoside diphosphate substrate (ADP or GDP) in a final nucleophilic substitution reaction (step 3).

X-ray crystal structures of the *E. coli* and pig heart succinyl-CoA synthetases revealed an interesting mechanism by which the enzyme stabilizes the *N*-phosphohistidine catalytic intermediate. These enzymes are composed of α and β subunits, with the active site formed at the interface of the two subunits. Each subunit of the $\alpha\beta$ -dimer contributes an α -helix whose N-terminal end points toward the active site. Recall from Chapter 6 that α -helices possess a helical dipole moment with a partial (+) charge at their N-terminus. The positive ends of the electric dipoles of these two α -helices (termed “power” helices) stabilize the transient negatively charged phosphohistidine (Figure 14.15).

Step 6: A Flavin-Dependent Dehydrogenation

Completion of the cycle involves conversion of the four-carbon succinate to the four-carbon oxaloacetate. The first of the three reactions, catalyzed by **succinate dehydrogenase**, is the FAD-dependent dehydrogenation of two saturated carbons to a double bond.

Succinate dehydrogenase is competitively inhibited by malonate, a structural analog of succinate. Malonate inhibition of pyruvate oxidation was one of the clues that led Krebs to propose the cyclic nature of this pathway. Note that succinate

FIGURE 14.15

A charge–dipole interaction stabilizes the phosphohistidine intermediate in the succinyl-CoA synthetase reaction. In this schematic, based on the *E. coli* enzyme structure, the permanent dipoles of two α -helices (the “power” helices) are oriented such that the partial positive charges at their N-termini interact with the negative charges on the phosphate group of the active site *N*-phosphohistidine, stabilizing this transient reaction intermediate.

dehydrogenase is stereoselective, removing the *pro-S* hydrogen from one carbon and the *pro-R* hydrogen from the other, producing only the *trans* isomer, fumarate. The *cis* isomer, maleate, is not formed.

A C—C single bond is more difficult to oxidize than a C—O bond. Therefore, the redox coenzyme for succinate dehydrogenase is not NAD^+ but the more powerful oxidant FAD. The flavin is bound covalently to the enzyme protein, designated E, through a specific histidine residue.

© 2005 Roberts and Company Publishers as seen in *The Organic Chemistry of Biological Pathways* by John McMurry and Tadhg Begley.

The importance of this binding is that the reduced flavin must be reoxidized for the enzyme to act again. The two electrons from the reduced flavin are transferred, through three iron–sulfur centers in the enzyme molecule, to an electron carrier (Coenzyme Q) in the mitochondrial electron transport system. Thus the reaction catalyzed by succinate dehydrogenase can be summarized as:

In fact, succinate dehydrogenase is so tightly coupled to the other electron carriers that it is referred to as Complex II of the respiratory chain (more about this in Chapter 15). This also explains the fact that, unlike the other enzymes of the citric acid cycle, succinate dehydrogenase is an integral membrane protein, tightly bound to the mitochondrial inner membrane.

The succinate dehydrogenase reaction is followed by hydration of the fumarate double bond and dehydrogenation of the resulting α -hydroxy acid to give the α -keto acid oxaloacetate.

Step 7: Hydration of a Carbon–Carbon Double Bond

The stereospecific *trans* hydration of the carbon–carbon double bond is catalyzed by **fumarate hydratase**, more commonly called **fumarase**.

The reaction is mechanistically similar to the addition of water to *cis*-aconitate in the aconitase reaction, producing exclusively the *S* enantiomer (L-malate). The *cis* isomer of fumarate, namely maleate, is not a substrate for the forward reaction, nor can the enzyme act on D-malate in the reverse direction.

Step 8: A Dehydrogenation That Regenerates Oxaloacetate

Finally, the cycle is completed with the NAD^+ -dependent dehydrogenation of malate to oxaloacetate, catalyzed by **malate dehydrogenase**.

Despite the large positive standard free energy change ($\Delta G'^{\circ} = +29.7 \text{ kJ/mol}$), this reaction proceeds to the right in mitochondria because the highly exergonic citrate synthase reaction (the next reaction in the cycle) keeps intramitochondrial oxaloacetate levels exceedingly low (below 10^{-6} M).

Stoichiometry and Energetics of the Citric Acid Cycle

Now let us review what has been accomplished in one turn of the citric acid cycle, summarized in Table 14.2. The cycle started when a two-carbon fragment (acetyl-CoA) combined with a four-carbon acceptor (oxaloacetate). Then, two carbons were removed as CO_2 as the resultant citrate was further metabolized (but not the same two carbons that entered as acetyl-CoA). Four oxidation reactions occurred during the cycle, with NAD^+ serving as electron acceptor for three and FAD as electron acceptor for the fourth. Together, these dehydrogenations accomplish the six-electron oxidation of the methyl group and the two-electron oxidation of the carbonyl carbon of acetyl-CoA (all eight electrons derived from acetyl-CoA). High-energy phosphate was generated directly at only one reaction (catalyzed by succinyl-CoA synthetase). Finally, oxaloacetate was regenerated; it is now ready to start the cycle again by condensation with another molecule of acetyl-CoA.

TABLE 14.2 Reactions of the citric acid cycle

Reaction	Enzyme	$\Delta G'^{\circ}$ (kJ/mol)	ΔG (kJ/mol)
1. Acetyl-CoA + oxaloacetate + $\text{H}_2\text{O} \longrightarrow$ citrate + CoA-SH + H^+	Citrate synthase	-32.2	~ -55
2a. Citrate \rightleftharpoons cis-aconitate + H_2O	Aconitase	+6.3	~ 0
2b. cis-Aconitate + $\text{H}_2\text{O} \rightleftharpoons$ isocitrate	Aconitase		
3. Isocitrate + $\text{NAD}^+ \rightleftharpoons$ α -ketoglutarate + CO_2 + NADH	Isocitrate dehydrogenase	-11.6	~ -20
4. α -Ketoglutarate + NAD^+ + CoA-SH \rightleftharpoons succinyl-CoA + CO_2 + NADH	α -Ketoglutarate dehydrogenase complex	-33.5	~ -40
5. Succinyl-CoA + P_i + ADP (GDP) \rightleftharpoons succinate + ATP (GTP) + CoA-SH	Succinyl-CoA synthetase	-2.9	~ 0
6. Succinate + FAD (enzyme-bound) \rightleftharpoons fumarate + FADH_2 (enzyme-bound)	Succinate dehydrogenase	0	~ 0
7. Fumarate + $\text{H}_2\text{O} \rightleftharpoons$ L-malate	Fumarase	-3.8	~ 0
8. L-Malate + $\text{NAD}^+ \rightleftharpoons$ oxaloacetate + NADH + H^+	Malate dehydrogenase	+29.7	~ 0
	Net	-48.0	~ -115

Note: $\Delta G'^{\circ}$ value for reaction 3 was calculated from the E'° values for α -ketoglutarate/isocitrate (-0.38 V) and NAD/NADH (-0.32 V).

We can write a chemical equation representing the sum of the eight reactions involved in one turn of the cycle:

In those tissues that use a GTP-dependent isozyme of succinyl-CoA synthetase, the GTP formed in the reaction is energetically equivalent to ATP because nucleoside diphosphate kinase can convert the GTP that is formed to ATP at no net free energy cost.

Now if we take into account the pyruvate dehydrogenase reaction, and if we recall that each molecule of glucose generates two molecules of pyruvate, we can write the following equation for catabolism of glucose through glycolysis and the citric acid cycle.

Of the 10 moles of NADH produced per glucose, 2 moles are generated in the cytoplasm at the glyceraldehyde-3-phosphate dehydrogenase step. At this point the ATP yield per mole of glucose metabolized has not increased greatly over the yield from glycolysis: 2 moles of ATP per glucose in glycolysis alone to 4 moles here. Most of the ATP generated during glucose oxidation is not formed directly from reactions of glycolysis and the citric acid cycle (substrate-level phosphorylations) but is formed from the reoxidation of reduced electron carriers in the respiratory chain. These compounds, NADH and FADH₂, are themselves energy rich, in the sense that their oxidation is highly exergonic. As electrons are transferred from these reduced carriers to molecular oxygen, in a stepwise fashion, the coupled synthesis of ATP from ADP takes place, producing about 2.5 moles of ATP per mole of NADH reoxidized and about 1.5 moles of ATP per mole of FADH₂ reoxidized. As we see in Chapter 15, this coupled synthesis generates about 30–32 moles of ATP per mole of glucose oxidized to CO₂ and water.

One turn of the citric acid cycle generates one high-energy phosphate through substrate-level phosphorylation, plus three NADH and one FADH₂ for subsequent reoxidation in the electron transport chain.

Regulation of Pyruvate Dehydrogenase and the Citric Acid Cycle

Because the citric acid cycle is a source of biosynthetic intermediates, as well as a route for generating metabolic energy, regulation of the cycle is somewhat more complex than if it were just an energy-generating pathway. As in glycolysis, regulation occurs both at the level of entry into the cycle (pyruvate dehydrogenase complex and citrate synthase) and at the level of control of key reactions within the cycle (isocitrate dehydrogenase and α -ketoglutarate dehydrogenase). Figure 14.16 summarizes the major factors involved in regulation at both levels.

FIGURE 14.16

Major regulatory factors controlling pyruvate dehydrogenase and the citric acid cycle. Red brackets indicate concentration dependence. NADH can inhibit through allosteric interactions, but apparent NADH inhibition can also be a reflection of reduced NAD⁺ availability.

Control of Pyruvate Oxidation

Fuel enters the cycle primarily as acetyl-CoA, which arises from carbohydrate via pyruvate dehydrogenase and from the β -oxidation of fatty acids. Because fatty acid oxidation is discussed in Chapter 17, we concentrate here on control of pyruvate dehydrogenase. The activity of this complex is controlled by feedback inhibition and, as noted earlier, by a covalent modification that is in turn controlled by the energy state of the cell. E₂, the transacetylase component (refer to Figure 14.9), is competitively inhibited by acetyl-CoA. E₃, the dihydrolipoamide dehydrogenase component, is competitively inhibited by NADH. Thus, if the products of the reaction (acetyl-CoA and NADH) are not being continuously removed by subsequent metabolic processes, feedback inhibition by these products will shut down further pyruvate oxidation (Figure 14.17).

In the mammalian pyruvate dehydrogenase complex, however, the primary mechanism by which enzyme activity is controlled is by covalent modification of E₁, the pyruvate decarboxylase component of the complex. As shown schematically

FIGURE 14.17

Regulation of the mammalian pyruvate dehydrogenase complex by feedback inhibition and by covalent modification of E_1 . A kinase and a phosphatase inactivate and activate the first component (E_1) of the pyruvate dehydrogenase complex by phosphorylating and dephosphorylating, respectively, three specific serine residues (depicted as $-\text{CH}_2\text{OH}$). The active form of the pyruvate dehydrogenase complex is feedback inhibited by acetyl-CoA and NADH.

in Figure 14.17, this involves phosphorylation and dephosphorylation of serine residues in E_1 . Mammals express four different isozymes of **pyruvate dehydrogenase kinase**, which phosphorylate several specific E_1 serine residues, resulting in loss of activity of pyruvate dehydrogenase. Two isozymes of **pyruvate dehydrogenase phosphatase** are known that hydrolytically remove the bound phosphate and reactivate the PDH complex. These protein kinase and phosphatase isozymes are expressed in different tissues and mediate tissue-specific regulation of the PDH complex. Recall that these regulatory enzymes are both integrated within the PDH complex, and PDH activity in different tissues is a subtle balance between the relative activities of the kinases and the phosphatases. PDH kinase is *activated* by both NADH and acetyl-CoA (products of the PDH reaction) and by ATP. Thus, the kinase turns off PDH activity when products of the reaction accumulate. PDH kinase is *inhibited* by ADP and pyruvate. These inhibitors of the kinase, which indicate low energy and available substrate, respectively, result in an increase in the ratio of active to inactive PDH, increasing flux through the complex. PDH phosphatase is *activated* by Ca^{2+} and Mg^{2+} and also as a result of insulin secretion. The Ca^{2+} effect on PDH phosphatase mediates stimulation of PDH activity during muscle contraction and in response to epinephrine. Recall from Chapter 8 that Ca^{2+} is a critical signaling molecule for contraction in vertebrate muscle. Using this same signaling molecule to regulate PDH flux provides an elegant mechanism to match ATP demand to its production by the citric acid cycle and subsequent oxidative phosphorylation. The Mg^{2+} effect on PDH phosphatase regulates flux through PDH in response to the energy charge ($[\text{ATP}]/[\text{ADP}]$ ratio). Because ATP binds Mg^{2+} more tightly than does ADP, the concentration of free Mg^{2+} reflects the ATP/ADP ratio within the mitochondrion. That is, free Mg^{2+} accumulates at low $[\text{ATP}]/[\text{ADP}]$ ratios, and it increases PDH activity by stimulating PDH phosphatase activity (and thus dephosphorylation of the complex). On the other hand, when ATP is abundant and further energy production is unneeded, pyruvate dehydrogenase is turned off due to activation of PDH kinase (which phosphorylates the complex).

Together, these short-term regulatory mechanisms allow the cell to manage the utilization of fuels for entry into the citric acid cycle. As will be seen in Chapter 17,

Activity of the pyruvate dehydrogenase complex is regulated by reversible phosphorylation of the E_1 subunit.

oxidation of fatty acids is another important source of acetyl-CoA and NADH, and both of these activate the PDH kinase. Thus, when metabolic conditions favor fatty acid oxidation as the primary fuel source (e.g., during fasting or long-term exercise), carbohydrate reserves are conserved by turning off PDH activity. Once the carbohydrate supply is replenished, PDH can be quickly turned back on.

Control of the Citric Acid Cycle

Flux through the citric acid cycle is controlled by allosteric interactions, but the concentrations of substrates also play a critical role. Though details of regulation vary among different cells and tissues, the major effects are as summarized in Figure 14.16. As we saw in glycolysis, most of the reactions of a pathway operate near equilibrium under cellular conditions ($\Delta G \sim 0$; Table 14.2). Key sites for allosteric regulation are thus those enzymes that catalyze reactions that occur with large free energy decreases: citrate synthase, isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase (Table 14.2).

The most important factor controlling citric acid cycle activity is the intramitochondrial ratio of $[\text{NAD}^+]$ to $[\text{NADH}]$. NAD^+ is a substrate for three cycle enzymes (Figure 14.3) as well as for pyruvate dehydrogenase. Under conditions that decrease the $[\text{NAD}^+]/[\text{NADH}]$ ratio, such as limitation of the oxygen supply, the low concentration of NAD^+ can limit the activities of these dehydrogenases.

In some mammalian tissues, notably liver, the levels of citrate vary as much as 10-fold, and at low levels flux through the citrate synthase reaction is limited by substrate availability. Recall that in some animal tissues citrate is also a prime regulator of flux through *glycolysis* via allosteric regulation of phosphofructokinase (PFK), helping to match the rate of glycolysis to that of the citric acid cycle. This is not true for all tissues. Heart cells, for example, cannot transport citrate out of mitochondria, so interaction with cytosolic PFK probably does not occur to a significant extent. However, citrate levels still control the citric acid cycle in heart.

The other important regulatory sites are the reactions catalyzed by isocitrate dehydrogenase and α -ketoglutarate dehydrogenase. In many cells, isocitrate dehydrogenase is allosterically activated by ADP and is allosterically inhibited by NADH and ATP; this control is in addition to the indirect reduction of activity seen at low $[\text{NAD}^+]/[\text{NADH}]$ ratios. In bacteria, isocitrate dehydrogenase is also inactivated by phosphorylation at one serine residue, which prevents binding of isocitrate. α -Ketoglutarate dehydrogenase activity is inhibited by accumulation of its products succinyl-CoA and NADH. The mechanisms are comparable to the mechanisms by which levels of acetyl-CoA and NADH control pyruvate dehydrogenase activity (Figure 14.17). Finally, in vertebrates, Ca^{2+} allosterically stimulates both isocitrate dehydrogenase and α -ketoglutarate dehydrogenase. Ca^{2+} can be thought of as a second messenger in a signal transduction pathway, but one that can cross the mitochondrial inner membrane. Ca^{2+} thus allows the rate of substrate oxidation by the citric acid cycle to respond to increased ATP demand during muscle contraction.

For some time it was thought that citrate synthase represented another site for allosteric control. The enzyme is subject to inhibition by NADH, NADPH, or succinyl-CoA. However, measurements of intramitochondrial levels of oxaloacetate, acetyl-CoA, and citrate show that the enzyme is operating close to equilibrium conditions; that is, the ratio of $[\text{citrate}]$ to $([\text{acetyl-CoA}] \times [\text{oxaloacetate}])$ is close to K_{eq} for the citrate synthase reaction. On the other hand, it is evident that intramitochondrial levels of oxaloacetate, which are quite low, can exercise substrate-level control over flux through citrate synthase.

To summarize, citric acid cycle flux is responsive to the energy state of the cell, through allosteric activation of isocitrate dehydrogenase by ADP; to the redox state of the cell, through flux rate limitation caused when intramitochondrial $[\text{NAD}^+]$ decreases; and to the availability of energy-rich compounds, through inhibition of relevant enzymes by acetyl-CoA or succinyl-CoA.

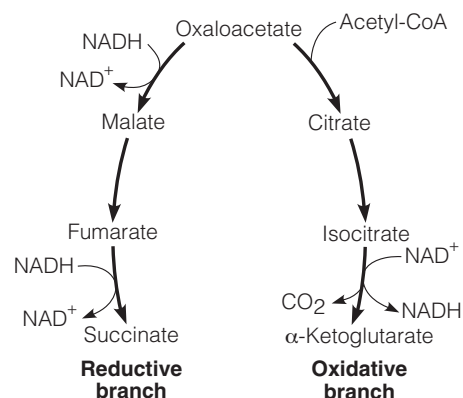

The citric acid cycle is controlled primarily by the relative intramitochondrial concentrations of NAD^+ and NADH.

Organization of the Citric Acid Cycle Enzymes

The matrix of mitochondria, where the citric acid cycle enzymes are all located, is not the simple aqueous solution we might imagine from the cartoons of mitochondria found in textbooks (including this one, see page 594). Indeed, it is estimated that the protein concentration of the mitochondrial matrix approaches *500 mg/mL or more*, and thus the matrix is more like a viscous gel. Consistent with this incredibly high protein concentration, there is now considerable evidence that the enzymes of the citric acid cycle are organized in a supramolecular multienzyme complex, or **metabolon**, that is associated with the matrix side of the inner membrane where succinate dehydrogenase is anchored. Physical association of enzymes catalyzing sequential steps in a metabolic pathway could provide significant kinetic advantages through substrate channeling, as was discussed for the pyruvate dehydrogenase complex. In fact, ^{13}C -NMR studies in the yeast *Saccharomyces cerevisiae* provide evidence for substrate channeling in the citric acid cycle. It is likely that many, if not most, multistep metabolic pathways are organized into metabolons in intact cells.

Evolution of the Citric Acid Cycle

As we discussed in Chapter 12, metabolic pathways are the products of evolution, being built from enzymes and pathways that may have had other functions initially. Indeed, as we shall see below, even the citric acid cycle as we know it in extant (currently existing) aerobic organisms is used for more than just oxidation of acetyl-CoA. Genomic analyses have revealed the existence of genes for citric acid cycle enzymes in organisms from all three domains of life (Bacteria, Archaea, and Eukarya), including anaerobic chemotrophs. These latter organisms do not harvest energy by oxidizing glucose, but rather possess an incomplete citric acid cycle as a fermentative pathway and for producing precursors for other biosynthetic processes. In the reductive branch (see margin), reversing the last four enzymes of the cycle (oxaloacetate to succinate) regenerates the oxidized cofactor NAD^+ from the NADH produced in the glyceraldehyde-3-phosphate dehydrogenase step of glycolysis (Chapter 13). In the oxidative branch, the first three steps of the citric acid cycle produce α -ketoglutarate, an important biosynthetic precursor. However, these anaerobic chemotrophs lack the enzymes necessary for conversion of α -ketoglutarate to succinate. We can imagine that these reductive and oxidative branches of an incomplete citric acid cycle existed in organisms that evolved before the appearance of atmospheric oxygen some 2.5 billion years ago. Once oxygen levels rose to a level that would support the much more efficient aerobic energy metabolism, it is not difficult to see how a complete citric acid cycle could evolve by recruitment of just a couple of new enzymes (α -ketoglutarate dehydrogenase and succinyl-CoA synthetase). Finally, phylogenetic analyses suggest that the citric acid cycle arose initially as a reductive pathway, used by early autotrophs to fix CO_2 (at the α -ketoglutarate dehydrogenase, isocitrate dehydrogenase, and pyruvate dehydrogenase steps).

Citric Acid Cycle Malfunction as a Cause of Human Disease

Given the ubiquitous nature of the citric acid cycle, and the critical role it plays in the energy metabolism of a cell, one might expect that a deficiency in any of the enzymes in the cycle would be lethal. However, we now know that defects in certain citric acid cycle enzymes, while not lethal, are linked to a number of rare neurodegenerative diseases and tumors in humans. For example, inherited deficiency of succinate dehydrogenase leads to formation of paraganglioma or pheochromocytoma tumors, depending on which subunit is defective. Mutations in the fumarase gene are linked to uterine and/or renal cell cancer. Defects in α -ketoglutarate dehydrogenase, succinate dehydrogenase, and fumarase cause neurodegenerative diseases (Leigh Syndrome or other encephalopathies). Mutations in isocitrate dehydrogenase

are found in a majority of several types of malignant gliomas, the most common type of brain tumors in humans. Although we do not fully understand the mechanisms underlying these processes, a link between organic acid accumulation and abnormal cell proliferation, resulting in tumor formation, is suspected. It is hypothesized that accumulation of certain citric acid cycle metabolites leads to activation of hypoxia-inducible factor 1 (HIF-1), a transcription factor that regulates tumor angiogenesis and tumor-cell energy metabolism. Despite the wealth of knowledge we have acquired since Krebs first elucidated the citric acid cycle, we still have a lot to learn about this pathway and its role in cellular physiology.

Anaplerotic Sequences: The Need to Replace Cycle Intermediates

Citric acid cycle intermediates used in biosynthetic pathways must be replenished to maintain flux through the cycle. Anaplerotic pathways serve this purpose.

So far, our discussion of the citric acid cycle has focused on its role in catabolism and energy generation. The cycle also serves as an important source of biosynthetic intermediates, and is thus considered an **amphibolic** pathway. Figure 14.18 summarizes the most important anabolic pathways involved. These pathways tend to draw carbon from the cycle by utilizing intermediates in the cycle. Succinyl-CoA is used in the synthesis of heme and other porphyrins. Oxaloacetate and α -ketoglutarate are the α -keto acid analogs of the amino acids aspartate and glutamate, respectively, and are used in the synthesis of these and other amino acids by transamination (see pages 618–619). In some tissues citrate is transported from mitochondria to the cytosol, where it is cleaved to provide acetyl-CoA for fatty acid biosynthesis. Because these and other reactions tend to deplete citric acid cycle intermediates by drawing carbon away, operation of the cycle would be impaired were it not for other processes that replenish the stores of citric acid cycle intermediates. These processes are called **anaplerotic** pathways, from a Greek word that means “filling up.” In most cells the flow of carbon out of the cycle is balanced by these anaplerotic reactions so that the intramitochondrial concentrations of citric acid cycle intermediates remain constant with time. The anaplerotic processes are summarized by the red arrows in Figure 14.18.

Reactions That Replenish Oxaloacetate

In animals the most important anaplerotic reaction, particularly in liver and kidney, is the reversible, ATP-dependent carboxylation of pyruvate to give oxaloacetate. This reaction is catalyzed by **pyruvate carboxylase**, which we first saw in gluconeogenesis (Chapter 13).

Recall that the enzyme is activated allosterically by acetyl-CoA; in fact, it is all but inactive in the absence of this effector (see Figure 13.18, page 552). This process represents a *feedforward* activation because the effect of acetyl-CoA accumulation is to promote its own utilization by stimulating the synthesis of oxaloacetate. The latter compound in turn reacts with acetyl-CoA, via the citrate synthase reaction. Alternatively, oxaloacetate can be used for carbohydrate synthesis, via gluconeogenesis, and acetyl-CoA accumulation can be seen as a signal that adequate carbon is available for some of it to be stored as carbohydrate.

In Chapter 11 we identified biotin as a cofactor in most carboxylation reactions involving CO_2 . Pyruvate carboxylase is a tetrameric protein with each

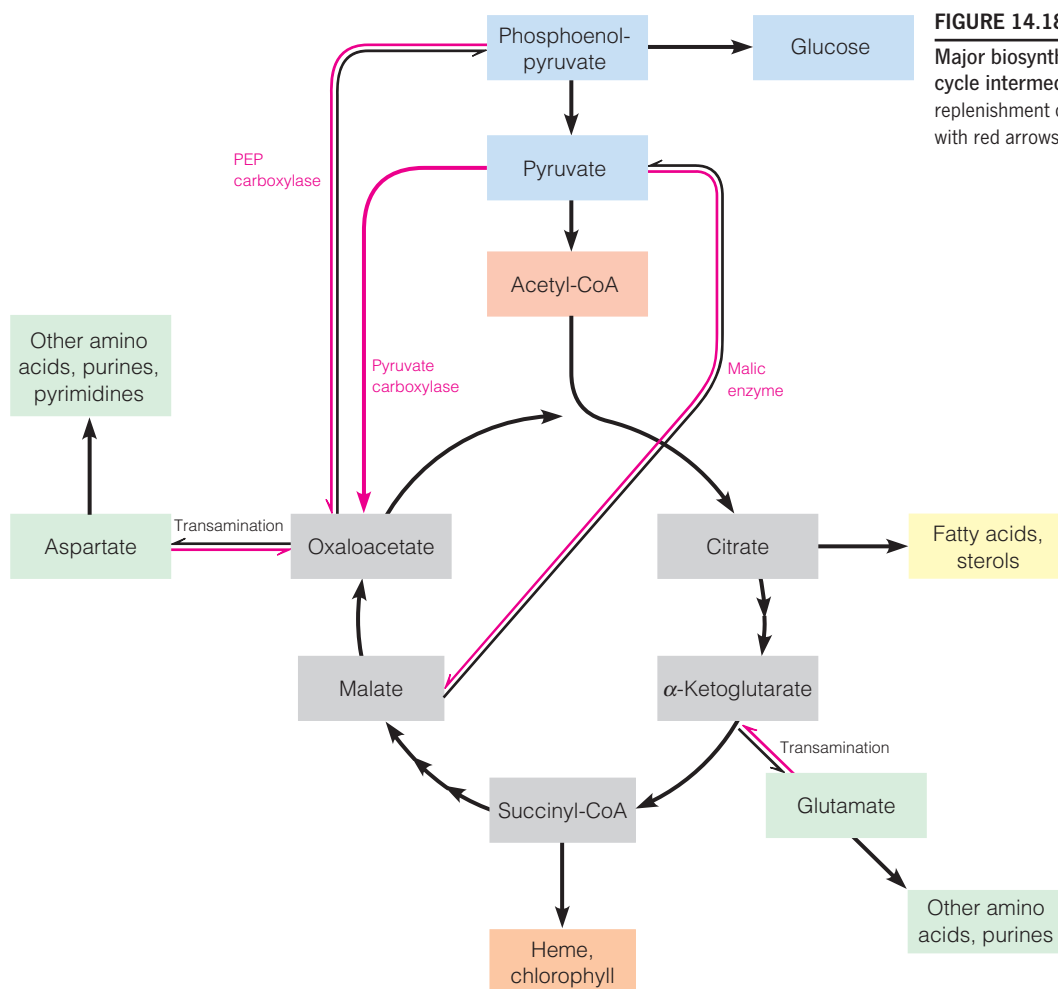

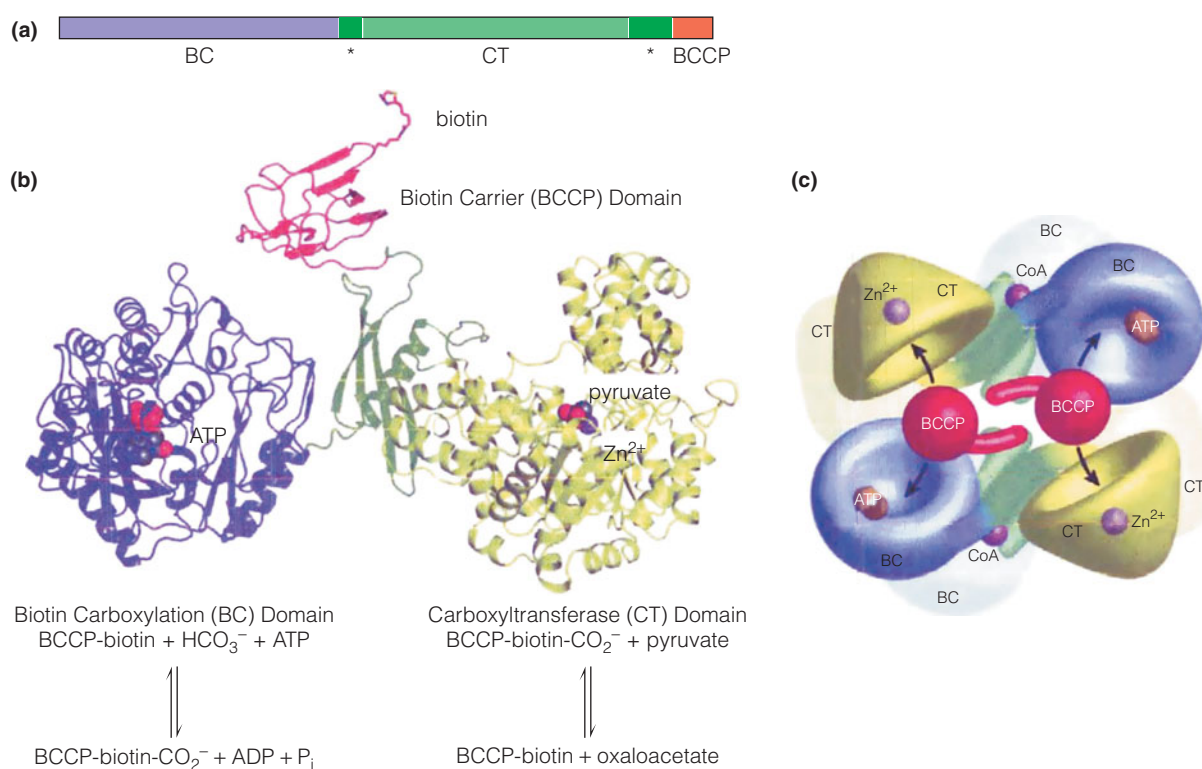

FIGURE 14.18

Major biosynthetic roles of some citric acid cycle intermediates. Anaplerotic pathways for replenishment of these intermediates are shown with red arrows.

identical subunit composed of four domains with distinct functions (Figure 14.19). A biotin carrier (BCCP) domain contains the biotin cofactor covalently bound through an amide linkage involving the ϵ -amino group of a lysine residue. The biotin carboxylation (BC) domain catalyzes an ATP-dependent carboxylation of the cofactor to give *N*-carboxybiotin (Figure 14.20). The carboxyltransferase (CT) domain catalyzes transfer of the carboxyl group from *N*-carboxybiotin to pyruvate to form the product oxaloacetate. During the reaction cycle, the BCCP domain acts as a swinging arm to transfer the biotin-bound carboxyl group between the two catalytic domains, much like the lipoamide swinging arms of α -keto acid dehydrogenase complexes we discussed earlier. The fourth domain is the regulatory domain, where the allosteric activator acetyl-CoA binds. This type of enzyme, with multiple domains carrying out multiple catalytic functions, is called a **multifunctional enzyme**.

In plants and bacteria an alternative route leads directly from phosphoenolpyruvate to oxaloacetate. Because phosphoenolpyruvate is such an energy-rich compound, this reaction, catalyzed by **phosphoenolpyruvate carboxylase**, requires neither an energy cofactor nor biotin. This reaction is important in the C_4 pathway of photosynthetic CO_2 fixation (Chapter 16).

**FIGURE 14.19****Structure of the multifunctional biotin-dependent**

pyruvate carboxylase. (a) This schematic illustrates the linear arrangement of the four domains within the primary structure of each subunit. The biotin cofactor is covalently linked to a lysine residue in the BCCP domain (red) near the C-terminus of each subunit. The dark green regions fold into the allosteric regulatory domain. (b) Shows the X-ray crystal structure of one subunit of pyruvate carboxylase from *Staphylococcus aureus*, along with the reactions catalyzed by the BC (blue) and CT (yellow) domains. Note the central allosteric domain connecting the two catalytic domains with the BCCP domain. (c) A model for the tetrameric enzyme shows how the BCCP domain swings between BC and CT active sites located on opposing polypeptide chains.

Attwood, Structure, mechanism and regulation of pyruvate carboxylase. © 2008, The Biochemical Society.

A related enzyme, phosphoenolpyruvate carboxykinase, also converts phosphoenolpyruvate to oxaloacetate. The primary role of this enzyme is in gluconeogenesis, as we discussed in Chapter 13. However, in heart and skeletal muscle, this same enzyme can be used in the anaplerotic direction to replenish oxaloacetate.

The Malic Enzyme

In addition to pyruvate carboxylase and phosphoenolpyruvate carboxylase, a third anaplerotic process is provided by an enzyme commonly known as **malic enzyme** but more officially as **malate dehydrogenase (decarboxylating:NADP⁺)**. The malic enzyme catalyzes the reductive carboxylation of pyruvate to give malate.

Note that this enzyme uses NADPH, rather than NADH, as the electron donor in this reduction. As we shall see in Chapter 17, the malic enzyme reaction, running in the opposite direction, is an important source of NADPH for fatty acid synthesis.

Reactions Involving Amino Acids

Although not usually classified as anaplerotic pathways, **transamination** reactions can be regarded that way also because they are reversible reactions that can yield citric acid cycle intermediates. In transamination an amino acid transfers its

Phase I – Biotin carboxylation (BC) domain

Phase II – Carboxyl transferase (CT) domain

FIGURE 14.20

Mechanism of the biotin-dependent pyruvate carboxylase reaction. The reaction occurs in two phases, with the first phase catalyzed by the biotin carboxylation (BC) domain and the second phase catalyzed by the carboxyltransferase (CT) domain. In phase I, bicarbonate is dehydrated via the ATP-dependent formation of carboxyphosphate. This intermediate decomposes to give free CO₂ containing sufficient free energy to carboxylate biotin, forming *N*-carboxybiotin. In phase II, the BCCP domain swings the *N*-carboxybiotin to the CT domain, where pyruvate is bound. A base (B:) in the CT active site generates the pyruvate enolate, which attacks the free CO₂ produced by elimination of biotin, to give the final product oxaloacetate.

amino group to an α -keto acid and is thereby converted itself to a keto acid. The mechanism is discussed in Chapter 20.

Glutamate and aspartate undergo transamination to generate the citric acid cycle intermediates α -ketoglutarate and oxaloacetate, respectively. Hence, cells containing amino acids in abundance can convert them via transamination to citric acid cycle intermediates. Another enzyme, **glutamate dehydrogenase**, presents an additional route for synthesis of α -ketoglutarate from glutamate.

Glutamate dehydrogenase, which we discuss in more detail in Chapter 20, uses either NAD⁺ or NADP⁺. Being reversible, transaminations and the glutamate dehydrogenase reaction can be used either for amino acid synthesis or for replenishment of citric acid cycle intermediates, depending upon the needs of the cell.

Finally, many plants and bacteria can convert two-carbon fragments to four-carbon citric acid cycle intermediates via the glyoxylate cycle, as described in the next section.

The glyoxylate cycle allows plants and bacteria to carry out net conversion of fat to carbohydrate, bypassing CO_2 -generating reactions of the citric acid cycle.

Glyoxylate Cycle: An Anabolic Variant of the Citric Acid Cycle

Metabolically, plant and animal cells differ in many important respects. Of particular concern here is that plant cells, along with some microorganisms, can carry out the net synthesis of carbohydrate from fat. This conversion is crucial to the development of seeds, in which a great deal of energy is stored in the form of triacylglycerols. (In fact, most vegetable oils available in grocery stores are mixtures of triacylglycerols derived from seeds.) When the seeds germinate, triacylglycerol is broken down and converted to sugars, which provide energy and raw material needed for growth of the plant. By contrast, animal cells cannot carry out the net synthesis of carbohydrate from fat.

Plants synthesize sugars by using the **glyoxylate cycle**, which can be considered an anabolic variant of the citric acid cycle. To understand the importance of this cycle, consider first the two primary fates of acetyl-CoA in animal metabolism—oxidation through the citric acid cycle, and the synthesis of fatty acids. Because of the virtual irreversibility of the pyruvate dehydrogenase reaction, acetyl-CoA cannot undergo net conversion to pyruvate and hence cannot participate in the *net* synthesis of carbohydrate. To be sure, the two carbons of acetyl-CoA can be incorporated into oxaloacetate, which is an efficient gluconeogenic precursor. However, because two carbons are lost in this part of the citric acid cycle, there is no *net* accumulation of carbon in carbohydrate. The glyoxylate cycle, however, permits the net synthesis of oxaloacetate by bypassing the reactions in which CO_2 is lost.

The glyoxylate cycle (Figure 14.21) is a cyclic pathway that results in the net conversion of two acetyl units, as acetyl-CoA, to one molecule of succinate. The

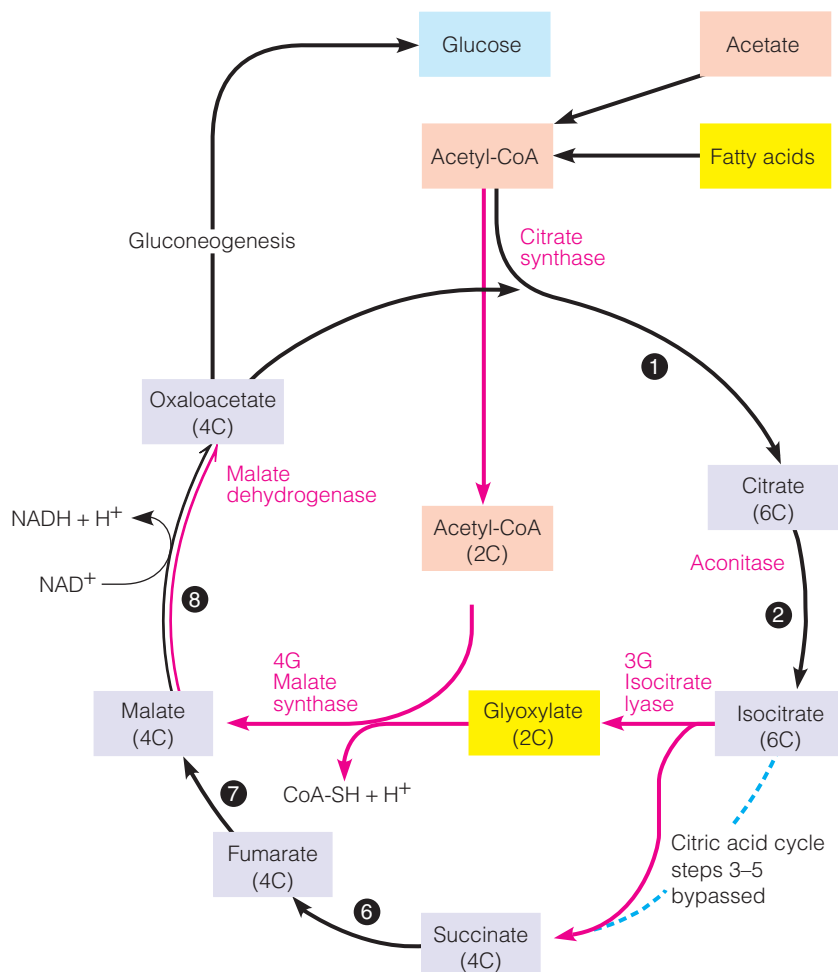

FIGURE 14.21

Reactions of the glyoxylate cycle. Two acetyl-CoA molecules enter the cycle, one at the citrate synthase step, and the second at the malate synthase step. The reactions catalyzed by isocitrate lyase and malate synthase (red arrows) bypass the three citric acid cycle steps between isocitrate and succinate (blue dashes) so that the two carbons lost in the citric acid cycle are saved, resulting in the net synthesis of oxaloacetate. The numbered reactions are identical to those in the citric acid cycle; however, reactions 1, 2, 3G, 4G, and 8 are catalyzed by unique isozymes located in the glyoxysome.

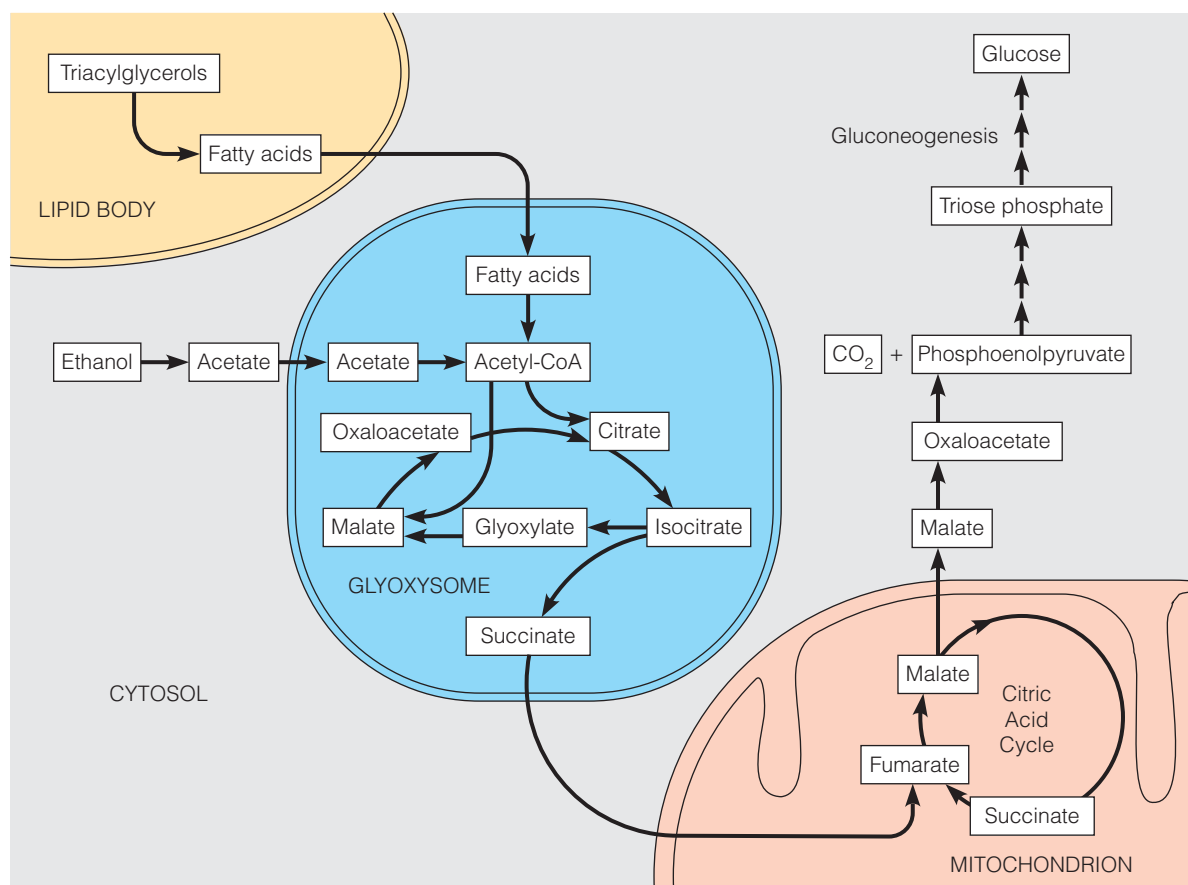

FIGURE 14.22

Intracellular relationships involving the glyoxylate cycle in plant cells. Fatty acids released in lipid bodies are oxidized in glyoxysomes to acetyl-CoA, which can also come directly from acetate. Acetyl-CoA is then converted to succinate in the glyoxylate cycle, and the succinate is transported to mitochondria. There it is converted in the citric acid cycle to oxaloacetate, which is readily converted to sugars by gluconeogenesis.

pathway uses some of the same enzymes as the citric acid cycle, but it bypasses the reactions in which carbon is lost during the citric acid cycle. The second mole of acetyl-CoA is brought in during this bypass (Figure 14.21). Thus, each turn of the cycle involves incorporation of 2 two-carbon fragments and results in the net synthesis of a four-carbon molecule. This process occurs in the **glyoxysome**, a specialized organelle that carries out both β -oxidation of fatty acids to acetyl-CoA and utilization of that acetyl-CoA in the glyoxylate cycle. Figure 14.22 illustrates the relationships of the intracellular compartments in a plant cell, and the exchange of metabolites between those compartments. The succinate generated is transported from the glyoxysome to the mitochondrion, where it is converted, via reactions 6, 7, and 8 of the citric acid cycle (see Figure 14.3), to oxaloacetate. The oxaloacetate is readily utilized for carbohydrate synthesis via gluconeogenesis.

The glyoxylate cycle also allows many microorganisms to metabolize two-carbon substrates, such as acetate. *E. coli*, for example, can grow in a medium that provides acetate as the sole carbon source, as can many fungi, protozoans, and algae. These cells synthesize acetyl-CoA, which is used both for energy production, via the citric acid cycle, and for synthesis of gluconeogenic precursors, via the glyoxylate cycle.

Now let us examine the individual reactions of the glyoxylate cycle. As noted, acetyl-CoA is provided from fatty acid oxidation. Alternatively, acetate itself is converted to acetyl-CoA by **acetate thiokinase**, an enzyme found in nearly all organisms, including those lacking the glyoxylate cycle.

Next, acetyl-CoA condenses with oxaloacetate to give citrate, just as in the citric acid cycle, and citrate reacts with aconitase to give isocitrate. At this point the

glyoxylate cycle diverges from the citric acid cycle. The next reaction, catalyzed by **isocitrate lyase**, cleaves the 6-carbon isocitrate to glyoxylate and succinate.

Glyoxylate then accepts two carbons from another acetyl-CoA, in a reaction catalyzed by **malate synthase**.

Mechanistically, this reaction is comparable to that catalyzed by citrate synthase, involving nucleophilic attack of the carbanion form of acetyl-CoA on a carbonyl carbon, in this case the aldehyde carbon of glyoxylate. The malate is then dehydrogenated to regenerate oxaloacetate. The enzyme involved here, malate dehydrogenase, is localized in glyoxysomes and is distinct from the mitochondrial form of the enzyme, which is involved in the citric acid cycle. The same is true for citrate synthase and aconitase isozymes used in the glyoxylate cycle (Figure 14.22).

As noted earlier, the glyoxylate cycle results in the net conversion of 2 two-carbon fragments, acetyl-CoA, to a four-carbon compound, succinate, as shown by the following balanced equation.

The primary fate of succinate is its entry into gluconeogenesis via its conversion to oxaloacetate.

SUMMARY

The citric acid cycle is a central pathway for oxidation of carbohydrates, lipids, and proteins. A principal entrant to this cyclic pathway is pyruvate produced in glycolysis, which undergoes oxidation to acetyl-CoA by the pyruvate dehydrogenase complex. This three-enzyme system uses five coenzymes: NAD^+ , CoA-SH, FAD, lipoamide, and thiamine pyrophosphate (TPP). Each turn of the citric acid cycle involves entry of two carbons as the acetyl group of acetyl-CoA and loss of two carbons as CO_2 . Acetyl-CoA condenses with oxaloacetate to form citrate. After one turn of the cycle, oxaloacetate is regenerated, to begin the process anew. During the cycle, reduced electron carriers, primarily NADH, are generated, and their reoxidation in mitochondria provides the energy for ATP synthesis. Regulation of the citric acid cycle occurs both at the level of entry of fuel into the cycle (at the pyruvate dehydrogenase and citrate synthase steps) and at the level of control of key reactions within the cycle (isocitrate dehydrogenase and α -ketoglutarate dehydrogenase). In mammals, activity of the pyruvate dehydrogenase complex is regulated by phosphorylation/dephosphorylation of its E_1 subunit, catalyzed by specific protein kinases and phosphatases. Anaplerotic reactions replace citric acid cycle intermediates that are consumed in biosynthetic pathways. In plants and bacteria the glyoxylate cycle bypasses the two decarboxylation reactions of the citric acid cycle, allowing acetyl-CoA to undergo net conversion to carbohydrate.

PROBLEMS

- Design a radiotracer experiment that would allow you to determine which proportion of glucose catabolism in a given tissue preparation occurs through the pentose phosphate pathway and which proportion through glycolysis and the citric acid cycle. Assume that you can synthesize glucose labeled with ^{14}C in any desired position or combination of positions. Assume also that you can trap CO_2 after administration of labeled glucose and determine its radioactivity.
- Consider the fate of pyruvate labeled with ^{14}C in each of the following positions: carbon 1 (carboxyl), carbon 2 (carbonyl), and carbon 3 (methyl). Predict the fate of each labeled carbon during one turn of the citric acid cycle.
- Suppose that aconitase did *not* bind its substrate asymmetrically. What fraction of the carbon atoms introduced in one cycle as acetyl-CoA would be released in the first turn of the cycle? What fraction of the carbon atoms that entered in the first cycle would be released in the second turn?
- [methyl- ^{14}C]Pyruvate was administered to isolated liver cells in the presence of sufficient malonate to block succinate dehydrogenase completely. After a time, isocitrate was isolated and found to contain label in both carbon 2 and carbon 5:

How do you explain this result?

- Considering the evidence that led Krebs to propose a cyclic pathway for oxidation of pyruvate, discuss the type of experimental evidence that might have led to realization of the cyclic nature of the glyoxylate pathway.
- Which carbon or carbons of glucose, if metabolized via glycolysis and the citric acid cycle, would be most rapidly lost as CO_2 ?
- In deciding which form of isocitrate dehydrogenase plays the more important role in the citric acid cycle—the NAD^+ -dependent or the NADP^+ -dependent form—what kinds of information would help you?
- Referring to Figure 14.9, write a balanced equation for the overall reaction catalyzed by each of the three enzymes in the pyruvate dehydrogenase complex— E_1 , E_2 , and E_3 .
- Briefly describe the biological rationale for each of the following allosteric phenomena: (a) activation of pyruvate carboxylase by acetyl-CoA; (b) activation of pyruvate dehydrogenase kinase by NADH ; (c) inhibition of isocitrate dehydrogenase by NADH ; (d) activation of isocitrate dehydrogenase by ADP ; (e) inhibition of α -ketoglutarate dehydrogenase by succinyl-CoA; (f) activation of pyruvate dehydrogenase phosphatase by Ca^{2+} .
- Certain microorganisms with a modified citric acid cycle decarboxylate α -ketoglutarate to produce succinate semialdehyde:

- Succinate semialdehyde is then converted to succinate, which is further metabolized by standard citric acid cycle enzymes. What kind of reaction is required to convert succinate semialdehyde to succinate? Show any coenzymes that might be involved.
 - Based on your answer in part (a), how does this pathway compare to the standard citric acid cycle in energy yield?
- Given what you know about the function of the glyoxylate cycle and the regulation of the citric acid cycle, propose control mechanisms that might regulate the glyoxylate cycle.
 - Write a balanced equation for the conversion in the glyoxylate cycle of two acetyl units, as acetyl-CoA, to oxaloacetate.
 - As discussed in Chapter 15, FAD is a stronger oxidant than NAD^+ ; FAD has a higher standard reduction potential than NAD^+ . Yet in the last reaction of the pyruvate dehydrogenase complex, FADH_2 bound to E_3 is oxidized by NAD^+ . Explain this apparent paradox.
 - Given the roles of NAD^+/NADH in dehydrogenation reactions and $\text{NADPH}/\text{NADP}^+$ in reductions, as discussed on page 488, would you expect the intracellular ratio of NAD^+ to NADH to be high or low? What about the ratio of NADP^+ to NADPH ? Explain your answers.

CHAPTER 15

Electron Transport, Oxidative Phosphorylation, and Oxygen Metabolism

The average adult human synthesizes ATP at a rate of nearly 10^{21} molecules per second, equivalent to producing his or her own weight in ATP *every day*. How is this massive amount of energy converted? As we saw in Chapters 13 and 14, glycolysis and the citric acid cycle by themselves generate relatively little ATP directly. However, under aerobic conditions, six dehydrogenation steps—one in glycolysis, another in the pyruvate dehydrogenase reaction, and four more in the citric acid cycle—collectively reduce 10 moles of NAD^+ to NADH and 2 moles of FAD to FADH_2 per mole of glucose. Reoxidation of these reduced electron carriers in the process termed **cellular respiration** generates most of the energy needed for ATP synthesis. This represents the third stage of the metabolic oxidation of substrates (Figure 15.1). In eukaryotic cells NADH and FADH_2 are reoxidized by electron transport proteins bound to the inner mitochondrial membrane. A series of linked oxidation and reduction reactions occurs, with electrons being passed along a series of electron carriers—the electron transport chain, or **respiratory chain** (Figure 15.1). The final step is reduction of O_2 to water. The overall electron transport sequence is quite exergonic. One pair of reducing equivalents, generated from 1 mole of NADH, suffices to drive the synthesis of between 2 and 3 moles of ATP from ADP and P_i by a process termed **oxidative phosphorylation**. How is the energy released from the oxidative reactions of the respiratory chain harnessed, or **coupled**, to drive the synthesis of ATP? The mechanism of this coupling will concern us throughout this chapter. In addition, we will consider a number of other important metabolic roles oxygen plays in aerobic cells.

We saw in glycolysis that the energy released during the breakdown of glucose is used to convert low-energy phosphorylated intermediates into high-energy phosphorylated intermediates, which then transfer their phosphates to form ATP. It was thus assumed that a similar mode of direct chemical coupling would underlie the formation of ATP in respiration. For many years, researchers around the world searched for a high-energy intermediate that could link electron transport to ATP synthesis. There were, however, several nagging facts that argued against a

Oxidation of 1 mole of NADH by the respiratory chain provides sufficient energy for synthesis of ~2.5 moles of ATP from ADP.

FIGURE 15.1

Overview of oxidative energy generation.

direct chemical coupling process like the phosphoglycerate kinase and pyruvate kinase reactions in glycolysis. Perhaps most troubling was the realization that the number of ATP molecules produced per glucose during respiration was not a constant: It tended to vary between 28 and 38. That is, the passage of a pair of electrons down the respiratory chain generates approximately 2.5 ATPs, not an integer, as would be predicted by a direct chemical coupling mechanism. Furthermore, respiration was shown to require a membrane. If the membrane is disrupted, the passage of electrons down the respiratory chain becomes *uncoupled* from ATP synthesis: Electrons still flow, but ATP production ceases. As we shall soon see, cells long ago evolved an elegantly simple mechanism that explains all of these observations, a mechanism that turns out to have much broader significance than just the synthesis of ATP. In short, the passage of electrons down the respiratory chain creates a proton gradient across the inner mitochondrial membrane, and the energy in this proton gradient provides the driving force for ATP synthesis.

The Mitochondrion: Scene of the Action

Our comprehension of biological oxidations requires an understanding of both the chemistry of oxidation–reduction reactions and the cell biology of the mitochondrion. Before reviewing the chemistry, let us describe the intracellular sites where these reactions occur. Cellular metabolism generates reduced compounds in all of the major compartments of a eukaryotic cell. As noted earlier, glycolysis takes place in the cytosol of eukaryotic cells, whereas pyruvate oxidation, fatty acid β -oxidation, amino acid oxidation, and the citric acid cycle occur within the mitochondrial matrix. Individual cells vary widely in the abundance and structure of their mitochondria. Most vertebrate cells contain from a few hundred to a few thousand mitochondria, but the number can be as low as 1 or as high as 100,000.

The mitochondrion consists of four distinct subregions, shown in Figure 15.2a and b—the outer membrane, the inner membrane, the intermembrane space, and the matrix, located within the inner membrane. The inner membrane is highly folded into **cristae** that project into, and often nearly through, the interior of the mitochondrion. Because respiratory proteins are embedded in the inner membrane, the density of cristae is related to the respiratory activity of a cell. For example, heart muscle cells, which have high rates of respiration, contain mitochondria with densely packed cristae. By contrast, liver cells have much lower respiration rates and mitochondria with more sparsely distributed cristae.

Whatever the compartment in which biological oxidations occur, all of these processes generate reduced electron carriers, primarily NADH. Most of this NADH is reoxidized, with concomitant ATP production, by the enzymes of the respiratory chain, firmly embedded in the inner membrane. The inner membrane itself consists of about 70% protein and 30% lipid, making it perhaps the most protein rich of all biological membranes. About half of the inner membrane protein in bovine heart mitochondria consists of proteins directly involved in electron transport and oxidative phosphorylation. Most of the remaining proteins are involved in transport of substances into and out of mitochondria. By contrast, a completely different set of proteins is bound to the outer membrane, including

FIGURE 15.2

Localization of respiratory processes in the mitochondrion. (a) A mitochondrion from a pancreatic cell, shown as a thin section in the electron micrograph. The major intramitochondrial compartments are shown, along with principal enzymes and pathways localized to each compartment. Magnification, 155,000. (b) Overview of oxidative phosphorylation. Reduced electron carriers, produced by cytosolic dehydrogenases and mitochondrial oxidative pathways, become reoxidized by enzyme complexes bound in the inner membrane. These complexes actively pump protons outward, creating an energy gradient whose discharge through complex V drives ATP synthesis.

(a)

(b)

enzymes of amino acid oxidation, fatty acid elongation, membrane phospholipid biosynthesis, and enzymatic hydroxylations.

Embedded within the inner membrane are the protein carriers that constitute the respiratory chain. They are assembled in the form of five multiprotein enzyme complexes, named I, II, III, IV, and V (Figure 15.2b). Complex I and complex II receive electrons from the oxidation of NADH and succinate, respectively, and pass them along to a lipid-soluble electron carrier, coenzyme Q (see page 631), which moves freely in the membrane. Complex III catalyzes the transfer of electrons from the reduced form of coenzyme Q to cytochrome *c*, a protein electron carrier that is also mobile within the intermembrane space. Finally, complex IV catalyzes the oxidation of cytochrome *c*, reducing O₂ to water. The energy released by these exergonic reactions creates a proton gradient across the inner membrane, with protons being pumped from the matrix into the intermembrane space. Protons then re-enter the matrix through a specific channel in complex V. The energy released by this exergonic process drives the endergonic synthesis of ATP from ADP and inorganic phosphate. Throughout this chapter we develop the structural and functional basis for our understanding of these energy coupling processes.

Most electron carriers in the respiratory chain are embedded in the mitochondrial inner membrane.

Critical to comprehension of these processes was the isolation of physiologically intact mitochondria, using differential centrifugation of cell homogenates. This feat was accomplished in the late 1940s by Eugene Kennedy and Albert Lehninger, who demonstrated that isolated mitochondria could synthesize ATP from ADP and P_i in vitro, but only if an oxidizable substrate was present as well. Much of our understanding of the sequence of electron carriers, and of the localization of specific enzymes within mitochondria, has come from fractionation and analysis of the complexes described earlier, yielding snapshots of individual parts of the overall reaction sequence of electron transport and oxidative phosphorylation.

The situation in prokaryotic cells is comparable, although different electron carriers are involved. However, because prokaryotic cells lack organelles, all of the electron carriers and enzymes of oxidative phosphorylation are bound to the inner membrane of the cell surface. Therefore, electron transport and oxidative phosphorylation occur at the cell periphery. As discussed at the end of this chapter, and in Chapter 16, there is reason to believe that mitochondria and chloroplasts, both of which contain genes and the machinery to express them, are descended from free-living primitive prokaryotic cells.

Oxidations and Energy Generation

Biological electron transport consists of a series of linked oxidations and reductions, or redox reactions. To understand the logic behind the sequence of reactions in the respiratory chain, and the mechanisms by which metabolic energy is generated from these reactions, you should recall from Chapter 3 the thermodynamics of redox reactions. We learned that the higher the value of the *standard reduction potential*, E_0' , for a redox couple, the greater is the tendency for that couple to participate in oxidation of another substrate. We can describe this tendency in quantitative terms because free energy changes are directly related to differences in reduction potential:

$$\Delta G^{\circ'} = -nF\Delta E^{\circ'} = -nF(E_{\text{acceptor}}^{\circ'} - E_{\text{donor}}^{\circ'}) \quad (15.1)$$

where n is the number of electrons transferred in the half-reactions, F is Faraday's constant (96485 J mol⁻¹V⁻¹), and $\Delta E^{\circ'}$ is the difference in standard reduction potentials between the two redox couples. $E^{\circ'}$ values for a number of biochemically important redox pairs are recorded in Table 15.1.

The values given in Table 15.1 allow calculation of free energy changes only under standard conditions (including, by convention, a pH of 7.0). For nonstandard

TABLE 15.1 Standard reduction potentials of interest in biochemistry

Oxidant	Reductant	n	E° (V)
Acetate + CO ₂ + 2H ⁺ + 2e ⁻	Pyruvate + H ₂ O	2	-0.70
Succinate + CO ₂ + 2H ⁺ + 2e ⁻	α -Ketoglutarate + H ₂ O	2	-0.67

Fumarate + 2H ⁺ + 2e ⁻	Succinate	2	0.03
Q + 2H ⁺ + 2e ⁻	QH ₂	2	0.04
Dehydroascorbate + 2H ⁺ + 2e ⁻	Ascorbate	2	0.06
Cytochrome <i>b</i> (+3) + e ⁻	Cytochrome <i>b</i> (+2)	1	0.07
Cytochrome <i>c</i> ₁ (+3) + e ⁻	Cytochrome <i>c</i> ₁ (+2)	1	0.23
Cytochrome <i>c</i> (+3) + e ⁻	Cytochrome <i>c</i> (+2)	1	0.25
Cytochrome <i>a</i> (+3) + e ⁻	Cytochrome <i>a</i> (+2)	1	0.29
O ₂ + 2H ⁺ + 2e ⁻	H ₂ O ₂	2	0.30
Ferricyanide + e ⁻	Ferrocyanide	1	0.36
NO ₃ ⁻ (Nitrate) + 2H ⁺ + 2e ⁻	NO ₂ ⁻ (Nitrite) + H ₂ O	2	0.42
Cytochrome <i>a</i> ₃ (+3) + e ⁻	Cytochrome <i>a</i> ₃ (+2)	1	0.55
Fe (+3) + e ⁻	Fe (+2)	1	0.77
$\frac{1}{2}$ O ₂ + 2H ⁺ + 2e ⁻	H ₂ O	2	0.82

Note: E° is the standard reduction potential at pH 7 and 25 °C, n is the number of electrons transferred, and each potential is for the partial reaction written as follows: Oxidant + $ne^- \rightleftharpoons$ reductant.

conditions such as those that might exist in a cell, recall that we learned in Chapter 3 to use Equation 3.23 to evaluate ΔG for a redox reaction such as

$$A_{\text{ox}} + B_{\text{red}} \rightarrow A_{\text{red}} + B_{\text{ox}}$$

$$\Delta G = \Delta G^{\circ} + RT \ln \left(\frac{[A_{\text{red}}][B_{\text{ox}}]}{[A_{\text{ox}}][B_{\text{red}}]} \right) \quad (15.2)$$

In this example A is the e⁻ acceptor and B is the donor.

Free Energy Changes in Biological Oxidations

Each of the coupled redox reactions in biological electron transport involves the transfer of electrons from one redox couple to another couple of higher

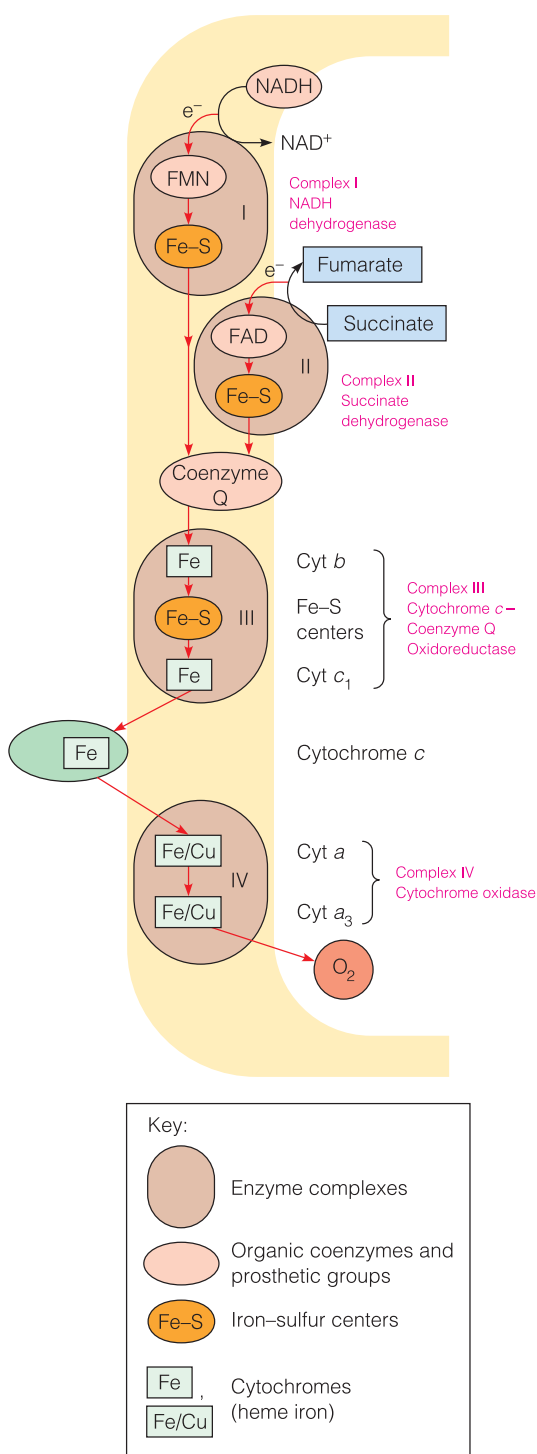

FIGURE 15.3

Respiratory electron carriers in the mitochondrion. This figure shows the sequence of electron carriers that oxidize succinate and NAD⁺-linked substrates in the inner membrane.

The respiratory chain catalyzes the transport of electrons from low-potential carriers to high-potential carriers.

(more positive) reduction potential. Thus, each individual redox reaction in the sequence is exergonic under standard conditions. For electrons entering the respiratory chain as NADH, the overall reaction sequence is given by the following equation:

This sequence is strongly exergonic under standard conditions:

$$\Delta G^{\circ'} = -nF \Delta E^{\circ'} = -2(96485 \text{ J mol}^{-1} \text{V}^{-1})(0.82 \text{ V} - (-0.32 \text{ V})) = -220 \text{ kJ/mol} \quad (15.3)$$

As discussed later in this chapter, the oxidation of 1 mole of NADH in the respiratory chain proceeds concomitantly with synthesis of about 2.5 moles of ATP from ADP and P_i. Because $\Delta G^{\circ'}$ for ATP hydrolysis is -30.5 kJ/mol , synthesis of 2.5 ATPs requires 76 kJ under standard conditions, giving an efficiency for oxidative phosphorylation of about 35%. In Chapter 3 (pages 84–85), we calculated the ΔG for this process using estimates of substrate and product concentrations that might exist in the mitochondrion. We arrived at a value for $\Delta G = -381 \text{ kJ/mol O}_2$, or -190 kJ per pair of electrons. Because ΔG for ATP hydrolysis under intracellular conditions is -50 kJ/mol or more, the efficiency of oxidative phosphorylation probably approaches 60 or 70% in vivo.

Electron Transport

Electron Carriers in the Respiratory Chain

If you compare the sequence of respiratory electron carriers (Figure 15.3) with the standard reduction potentials of those carriers (Table 15.1), you will see that $E^{\circ'}$ for each carrier increases in the same order as the sequence of their use in electron transport. This order suggests that each individual oxidoreduction reaction in electron transport is exergonic under standard conditions and that electrons flow in continuous fashion from low-potential to high-potential carriers. Very neat, but is it real? After all, we have seen that glycolysis and the citric acid cycle both proceed smoothly despite the involvement of some reactions with large positive $\Delta G^{\circ'}$ values. We shall explore some of the lines of evidence by which the currently accepted pathway of electron transport was determined. First, however, let us become better acquainted with the participants—the electron carriers involved.

Flavoproteins

Flavoproteins, introduced in Chapter 14 (page 600), contain tightly bound FMN or FAD as redox cofactors. Each flavoprotein provides a different microenvironment for the isoalloxazine ring, conferring a unique standard reduction potential on the flavin. Flavin nucleotides can act as transformers between two-electron and one-electron processes due to their ability to exist as stable one-electron reduced semiquinone intermediates.

Iron–Sulfur Proteins

Iron–sulfur clusters consist of nonheme iron complexed to sulfur in four known ways (Figure 15.4). These clusters function as the prosthetic groups of **iron–sulfur proteins**. The simplest form, designated **FeS**, involves one iron tetrahedrally complexed with the thiol sulfurs of four cysteine residues. The second form, denoted **Fe₂S₂**, contains two irons, each complexed with two cysteine residues and two inorganic sulfides. The most complicated form (**Fe₄S₄**) contains four irons, four sulfides, and four cysteine residues. Not all iron–sulfur clusters contain equal numbers of iron and sulfide ions—the **Fe₃S₄** cluster has the same geometry as the **Fe₄S₄** cluster but lacks one Fe atom and one Cys ligand. NADH dehydrogenase contains both **Fe₂S₂** and **Fe₄S₄** centers. In all of these centers the iron can undergo cyclic one-electron oxidoreduction between ferrous and ferric states. The standard reduction potential of the iron in these iron–sulfur clusters varies dramatically depending on the type of cluster and the microenvironment provided by the protein to which it is attached.

Coenzyme Q

The respiratory electron carrier coenzyme Q was discovered when treatment of isolated mitochondria with an organic solvent such as isoctane was observed to completely abolish the ability of the mitochondria to oxidize substrates. Addition of the material extracted by isoctane completely restored the oxidative capacities of the mitochondria, suggesting the presence of an extremely lipophilic electron carrier that was only loosely linked to protein. This carrier was found to be a benzoquinone linked to a number of isoprene units, usually 10 in mammalian cells and 6 in bacteria. Because the substance is ubiquitous in living cells, one group of researchers named it *ubiquinone*, while another called it **coenzyme Q**, or **Q**. The term Q_{10} is used to specify the form of Q containing 10 isoprene units. The isoprenoid tail gives the molecule its hydrophobic character, which allows Q to diffuse rapidly through the inner mitochondrial membrane. Like the flavins (FMN and FAD), Q oxidoreduction proceeds one electron at a time through a stable semiquinone intermediate so that Q provides another interface between two-electron carriers such as NADH and the one-electron carriers such as the cytochromes.

Cytochromes

Finally, we come to the cytochromes, a group of red or brown heme proteins having distinctive visible-light spectra. These proteins were first characterized and their role in respiration demonstrated by the Englishman David Keilin in 1925. Using a hand spectroscope, Keilin observed red-brown pigments in the flight muscles of insects. During muscular exertion (when an immobilized fly tried to free itself), the spectra of these pigments underwent marked changes. This observation led Keilin to postulate a role for these substances in carrying electrons from biological fuels to oxygen.

The major respiratory cytochromes are classified as *b*, *c*, or *a*, depending on the wavelengths of the spectral absorption peaks. Figure 15.5 shows the spectral characteristics of typical *b*-, *c*-, and *a*-type cytochromes. The unique spectra of each class result from differences in heme substitution and ligation. Within each class (*b*, *c*, or *a*), the cytochromes are distinguished by smaller spectral differences. For example, cytochrome *c*₁ has a spectrum similar to that of cytochrome *c*, but the α and γ absorption peaks are slightly red-shifted (i.e., shifted to longer wavelengths).

Among the respiratory electron carriers are three *b*-type cytochromes, cytochromes *c* and *c*₁, and cytochromes *a* and *a*₃. Cytochromes *b*, *c*, and *c*₁ all contain the same heme found in hemoglobin and myoglobin—iron complexed with protoporphyrin IX. In cytochromes *c* and *c*₁, but not *b*, this heme is covalently linked to the protein component, via thioether bonds formed between two of the vinyl side chains and two cysteine residues (Figure 15.6a). Cytochromes *a* and *a*₃ contain a modified form of heme, called heme A, in which one of the side chains is modified with a hydrophobic tail composed of three isoprene units (Figure 15.6b). Cytochromes *a* and *a*₃ represent two identical heme A moieties, attached to the same polypeptide chain, but within different environments in the inner membrane and, hence, having different reduction potentials. In cytochromes *a* and *a*₃, each of the hemes is associated with a copper ion, located close to the heme iron. The axial ligands of the heme iron also vary with the cytochrome type. Figure 15.6c shows a *b*-type heme bound in a four-helix bundle, a common structural motif for many cytochromes. Nature uses these differences in heme environments to access a wide range of standard reduction potentials for the cytochromes. Cytochromes undergo oxidation-reduction through the complexed metal, which cycles between +2 and +3 states of heme iron and +1 and +2 states for the copper in cytochromes *a* and *a*₃. Thus, the cytochromes are one-electron carriers.

Cytochrome *c* is a small protein (~100 amino acids), which is associated with the inner membrane but is readily extracted in soluble form. Because it is small and relatively abundant, detailed structural studies have been carried out with this protein. Recall from Chapter 5 that the amino acid sequence of cytochrome *c* has been highly conserved in evolution, with nearly 50% identity between residues at corresponding positions of cytochromes *c* in organisms as diverse as yeast and human. The other cytochromes are integral membrane proteins and are exceedingly difficult to dissociate from the membrane. Accordingly, we know less about their structures.

Determining the Sequence of Respiratory Electron Carriers

To comprehend the mechanism by which energy from biological oxidations is captured to drive ATP synthesis, we must understand the oxidation reactions of electron transport, both the sequence in which electrons are carried from reduced substrates to oxygen and the energetics of individual reactions. Figure 15.7 shows E'_0 values for the major respiratory electron carriers. If this figure accurately represents the sequence, then we can visualize respiratory electron transport as a series of coupled exergonic reactions in which the total energy available from oxidation of NADH by O₂ is released in a series of small steps, some of which are sufficiently exergonic to generate the 30.5 kJ/mol needed to drive ATP synthesis.

(c) 4-Helix bundle of cyt *b*₅₆₂

However, the data of Figure 15.7 involve standard conditions, and conditions are much different within the mitochondrion. In particular, the hydrophobic nature of the membrane environment changes *E* values in ways that are difficult to predict or to measure. We shall outline here three experimental techniques that were used to identify both the actual order of electron carriers and the specific reactions that drive ATP synthesis. We focus first on three approaches used to identify the order of electron carriers: (1) spectrophotometric techniques to measure the redox status of electron carriers in intact mitochondria; (2) use of specific respiratory inhibitors and artificial electron acceptors; and (3) fractionation of mitochondria into respiratory subassemblies, each capable of catalyzing specific portions of the overall sequence.

**FIGURE 15.7**

Standard reduction potentials of the major respiratory electron carriers. Three reactions in the respiratory chain have ΔG° values greater than -30.5 kJ/mol, the ΔG° for ATP hydrolysis: FMN \rightarrow Q; cyt *b* \rightarrow cyt *c*₁; and cyt *a* \rightarrow O_2 .

(a) Difference spectra for wavelengths below 500 nm

(b) Difference spectra continued with extended scale

FIGURE 15.8

Difference spectra of mitochondria. These difference spectra of rat liver mitochondria were recorded in a double-beam spectrophotometer. The black line shows the difference spectrum of fully reduced versus fully oxidized mitochondria. Mitochondria reduced with substrate under anaerobic conditions were in the sample chamber, and oxygenated mitochondria in the reference chamber. The peaks and shoulders refer to NADH, flavin, and the α and γ absorption bands, as indicated, for cytochromes a , a_3 , b , and c . The red line shows the effect of adding a respiratory inhibitor, antimycin A, which blocks electron flow from cytochrome b to c_1 . The inhibitor causes all of the carriers beyond cytochrome b to become fully oxidized, while NADH, flavin, and cytochrome b are in the reduced state. Note the expanded absorbance scale beyond 500 nm.

Difference Spectra

For nicotinamide nucleotides, flavin nucleotides, and cytochromes, the absorption spectrum for the reduced carrier differs from that of its oxidized counterpart. We should, therefore, be able to scan the absorption spectrum of a mixture of these carriers and ascertain the proportions of each in the oxidized and reduced states. The sensitivity of the technique is increased if a **difference spectrum** is obtained. Here the sample cuvette contains the mixture of electron carriers under study, and the reference cuvette contains not a blank but an equimolar mixture of carriers in a known state, for instance, entirely oxidized. Thus, any small absorbance changes, either positive or negative, result from reduction of a portion of the carriers in the test sample.

When these carriers are embedded in the mitochondrion, however, the task becomes quite difficult. Mitochondrial suspensions are turbid, and the resultant light scattering makes it impossible to measure difference spectra with ordinary spectrophotometers. Britton Chance greatly improved this technique in the mid-1950s when he developed a dual-wavelength, double-beam spectrophotometer that allowed him to obtain difference spectra with intact mitochondria. In the example shown by the black lines in Figure 15.8, the reference cuvette contains mitochondria saturated with oxygen so that all carriers are oxidized, while the sample cuvette contains anaerobic mitochondria plus an oxidizable substrate so that all of the carriers are reduced. The difference spectrum identifies wavelengths of maximal and minimal absorbance differences. Absorbance readings at these wavelengths allow determinations of the concentrations of the reduced and oxidized forms of an electron carrier that absorbs light in these ranges. For example, the higher the absorbance at 340 nm, the greater the proportion of the NAD^+/NADH couple that is present as NADH; and the lower the negative absorbance at 460 nm, the greater the proportion of flavin nucleotide that is in the oxidized form.

Two important observations were made soon after the introduction of this technique. First, in actively respiring mitochondria, NADH predominated over NAD^+ , whereas cytochrome a_3 was largely oxidized. For the intermediate carriers, the proportion in the oxidized state increased in the same order as the order of their presumed function in respiration (Figure 15.7). Second, when oxygen was added to anaerobic mitochondria, and difference spectra were obtained at intervals after oxygen addition, it was possible to determine the order in which each carrier went from fully reduced to partially oxidized. That order was the same as the presumed order of function in respiration.

Inhibitors and Artificial Electron Acceptors

Further information was obtained from difference spectrophotometry in conjunction with exogenous compounds that functioned either as respiratory inhibitors or as artificial electron donors or acceptors. The sites of action of several important inhibitors are shown in Figure 15.9. These inhibitors include (1) **rotenone**, a plant product from South America that is used as an insecticide and that blocks electron flow from NADH to coenzyme Q; (2) **amytal**, a barbiturate drug that acts at the same site; (3) **antimycin A**, a *Streptomyces* antibiotic that blocks electron flow from cytochrome b to c_1 ; and (4) **cyanide, azide, and carbon monoxide**. Cyanide and azide react with the oxidized form of cytochrome a_3 , and CO reacts with the reduced form.

To see the utility of respiratory inhibitors, consider what happens in actively respiring mitochondria to which antimycin A is added (refer to the red lines in Figure 15.8). Because electrons cannot flow from cytochrome b to cytochrome c_1 , all of the carriers upstream of cytochrome b become reduced, while all of the downstream carriers become fully oxidized, analogous to the accumulation of water upstream of a dam in a river. This site of inhibition is called a **crossover point**—a specific target of inhibition when an overall pathway is blocked. Crossover points in the respiratory chain can be detected by dual-beam spectrophotometry, which

FIGURE 15.9

Sites of action of some respiratory inhibitors and artificial electron acceptors. This schematic of the respiratory chain from NADH to O₂ shows the sites of action of some useful inhibitors (red) and some artificial electron acceptors (blue). Each acceptor is positioned according to its E^0 value (in parentheses), identifying the most likely site at which an acceptor will withdraw electrons from the respiratory chain when added to mitochondria.

The order of action of electron carriers in the respiratory chain was elucidated by difference spectrophotometry, analysis of respiratory inhibitors, and properties of membrane complexes.

allows identification of all the carriers preceding a site of inhibition (NAD, flavin, Q, and cytochrome *b* after antimycin treatment) and all those following that site (cytochromes *c*₁, *c*, *a*, and *a*₃).

Artificial electron donors and acceptors are compounds that can either feed in or draw off electrons from the respiratory chain in spontaneous nonenzymatic redox reactions. For example, 2,6-dichlorophenol-indophenol (DCIP) can spontaneously oxidize cytochrome *b*, but probably not *c*₁, because of the E^0 values involved (see Figure 15.9). This demonstrated that cytochrome *b* lies beyond the entry point for electrons from succinate, as well as from NADH. The key observation was that addition of DCIP to cyanide-inhibited mitochondria allows these mitochondria to oxidize both NAD⁺-linked substrates and succinate. In this system, electrons flow from substrate to cytochrome *b* and then to the exogenous electron carrier, DCIP, which becomes reduced. Ferricyanide, with its large positive E^0 , can accept electrons from any of the carriers up to cyt *a*₃.

Respiratory Complexes

Mitochondria can be disrupted by mechanical treatment, such as sonication, or by low concentrations of nonionic detergents such as *digitonin*, which preferentially solubilizes the outer membrane but leaves many protein–protein associations intact. By combinations of these techniques, one can fractionate the mitochondrial respiratory chain into four separate enzyme complexes (complexes I, II, III, and IV—see Figure 15.2b), each of which contains part of the entire respiratory sequence, plus a fifth (complex V), which catalyzes ATP synthesis from ADP. The electron-transfer activity of these multisubunit complexes is retained during solubilization and fractionation, revealing that complexes I, II, III, and IV are membrane-embedded enzymes that catalyze the transfer of electrons from a relatively mobile electron carrier (one that is not tightly membrane-bound) to another mobile carrier. These mobile carriers are NADH, succinate, coenzyme Q, cytochrome *c*, and oxygen. Analysis of each complex for the presence of electron carriers, as well as for reactions catalyzed, has helped to establish the currently accepted sequence of carriers. Figure 15.10 provides a summary of the protein composition and catalytic activities of each complex. We will now examine in more detail the structure and function of each complex and how they are organized in a respiratory chain.

NADH Dehydrogenase (Complex I)

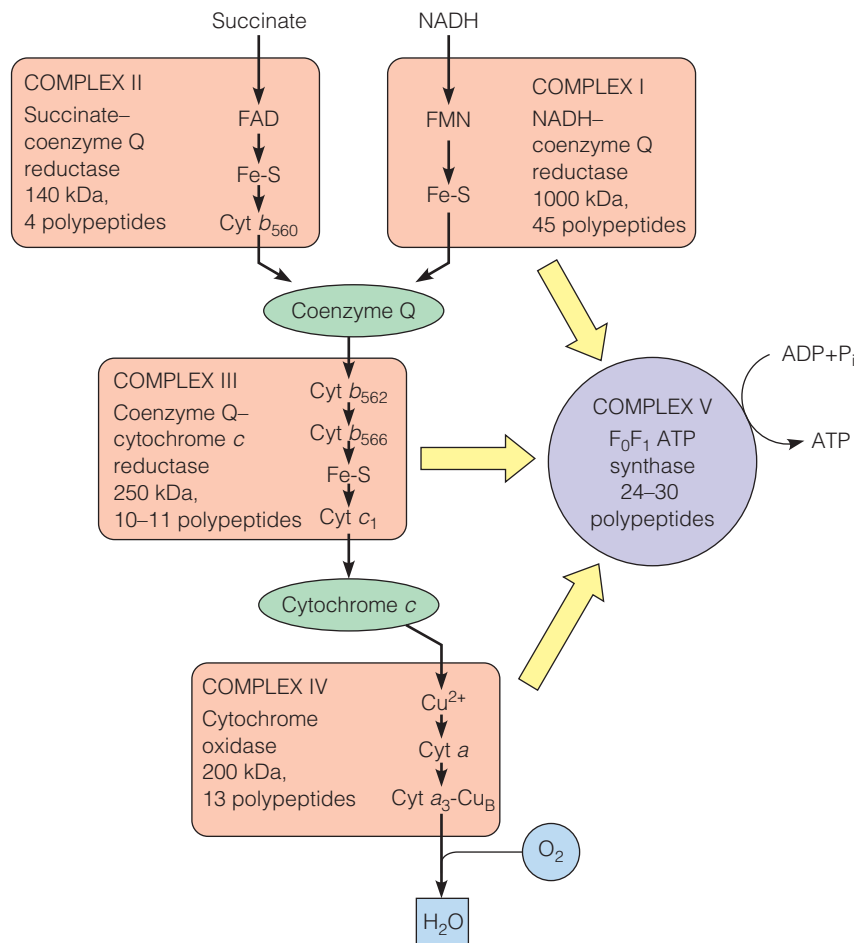

The main donor of electrons into the respiratory chain is the reduced nicotinamide nucleotide NADH. Numerous dehydrogenases in the cell catalyze the oxidation of substrates using NAD⁺ as the electron acceptor:

As described in Chapter 11, these reversible dehydrogenations involve the transfer of two electrons, in the form of a hydride ion (H⁻), from the substrate to

FIGURE 15.10

Multiprotein complexes in the mitochondrial respiratory assembly. Mobile carriers are in green. The yellow arrows denote the energy released by the actions of complexes I, III, and IV is converted into the free energy of a proton gradient which powers the synthesis of ATP by complex V (ATP synthase). The subscripts for the b cytochromes denote their spectral maxima.

NAD^+ to give NADH. The nicotinamide nucleotides readily dissociate from their enzymes and thus act as soluble redox cofactors that carry electrons between different enzymes and pathways. In mitochondrial respiration, NADH from many different dehydrogenases becomes oxidized in the first step of electron transport by complex I, or **NADH dehydrogenase**, which catalyzes the following reaction.

Mitochondrial NADH dehydrogenase is a large, membrane-embedded multisubunit complex (~1000 KDa) with about 45 separate polypeptide chains. The bacterial complex is much smaller, composed of just 14 “core” subunits which are conserved from bacteria to humans. The larger mitochondrial enzyme evolved by gradual recruitment of additional subunits to this core. The complex contains **flavin mononucleotide (FMN)** as a tightly bound prosthetic group and eight **iron-sulfur clusters**, which transfer electrons from reduced flavin to coenzyme Q (Q).

The overall reaction catalyzed by the NADH dehydrogenase complex is shown below. Because the electrons are subsequently used to reduce coenzyme Q, a more descriptive name for this complex is **NADH-coenzyme Q reductase**.

Notice that this process begins with a two-electron donor (NADH), but uses several iron–sulfur clusters, which can carry only single electrons. FMN acts as a transformer between the two-electron and one-electron carriers.

Figure 15.11 illustrates our current understanding of how these various electron carriers function in complex I. Electron microscopy of complex I from several different eukaryotic and bacterial sources reveals an L-shaped structure with two arms: a hydrophobic membrane arm embedded in the mitochondrial inner membrane (or bacterial plasma membrane), and a hydrophilic peripheral arm extending into the mitochondrial matrix (or bacterial cytoplasm) (Figure 15.11a). An X-ray crystal structure of the entire complex I from the archaea *Thermus thermophilus* reveals a 15-subunit complex with FMN and nine iron–sulfur clusters in the peripheral arm (Figure 15.11b, c). Complex I catalyzes a hydride transfer (two electrons) from NADH to FMN, which then transfers the electrons, one at a time, to the series of iron–sulfur clusters. In the final step of the reaction, Q is reduced, one electron at a time, to QH₂.

Complex I catalyzes a second important process, which is tightly coupled to the electron flow through the complex: the transfer of four protons (H⁺) from the matrix side to the intermembrane space side of the inner membrane (Figure 15.11). The X-ray structure of the *T. thermophilus* enzyme suggests a possible mechanism to explain how electron transfer drives proton pumping (Figure 15.11d). The NuoL subunit of the membrane arm possesses a long α -helix (110 Å) that projects through the adjacent membrane subunits. As electrons pass from FMN to coenzyme Q, the NuoA/J/K and H subunits undergo conformational changes that push the long α -helix toward the other membrane arm subunits. This tilts α -helices (red in Figure 15.11 c and d) in those subunits, allowing protons to pass through the channels across the membrane.

Thus complex I acts as a proton pump, using the energy released in the exergonic transfer of two electrons from NADH to Q to transport four H⁺ *against* their electrochemical gradient. To account for these four translocated protons, we can rewrite the reaction catalyzed by complex I as:

As we will see shortly, this obligately coupled process is the essence of the chemiosmotic mechanism that drives ATP synthesis.

Succinate–Coenzyme Q Reductase (Complex II)

Coenzyme Q (Q) draws electrons into the respiratory chain, not only from NADH but also from succinate, as shown in Figure 15.3, and from intermediates in fatty acid oxidation. Succinate dehydrogenase uses an FAD coenzyme, as noted in Chapter 14. Unlike the other citric acid cycle enzymes, succinate dehydrogenase is an inner membrane protein (Figure 15.12). The enzyme thus transfers electrons directly from its bound FADH₂ to the other membrane-bound respiratory carriers. Like NADH dehydrogenase (complex I), succinate dehydrogenase transfers electrons via a series of iron–sulfur centers to coenzyme Q, and it is more completely named **succinate–coenzyme Q reductase** (it is also called complex II—see Figures 15.2 and 15.3). Complex II does not pump protons, so the reaction it catalyzes can be summarized as:

At least two other flavoprotein dehydrogenases, including the **ETF:ubiquinone oxidoreductase** and **glycerol-3-phosphate dehydrogenase** also deliver electrons to Q (Figure 15.13). These enzymes transfer electrons not from citric acid cycle intermediates, but rather from other oxidation pathways. Like succinate dehydrogenase, ETF:ubiquinone oxidoreductase is bound to the matrix side of the inner membrane, and it uses FAD and an Fe₄S₄ cluster as electron carriers. **ETF (electron-transferring flavoprotein)** is a small, soluble protein in the mitochondrial matrix

Electron transport through complex I is coupled to the pumping of protons from the matrix to the intermembrane space.

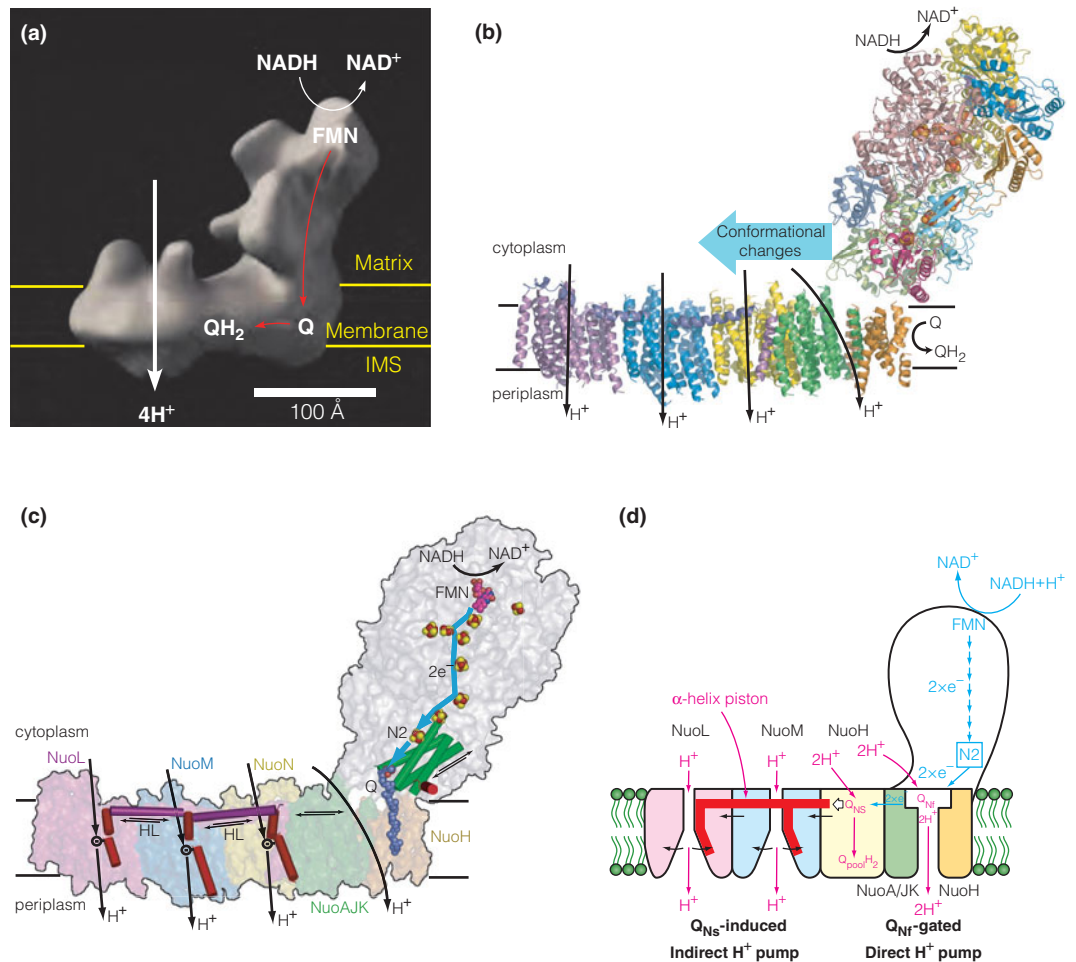

FIGURE 15.11

Structure and function of complex I (NADH-coenzyme Q reductase). (a) Model of complex I from the yeast *Yarrowia lipolytica* determined by three-dimensional electron microscopy. The membrane arm is composed of ~30 subunits, and contains the Q binding site and the proton pumping machinery. The peripheral arm is composed of eight subunits. The path of electron transport from NADH to Q, and the direction of H^+ pumping, is shown schematically. (b) X-ray structure of the entire complex I from the archaea *Thermus thermophilus*. The long α -helix of subunit NuoL that projects onto subunits NuoM (blue) and N (yellow) is dark purple. Regarding proton movement, the cytoplasm and periplasm in bacteria are equivalent to the matrix and intermembrane space (IMS), respectively, in mitochondria. (c) Proposed model of proton translocation by complex I. The subunits are named according to the *E. coli* structure, and are colored as in panel b. Locations of the FMN (pink), iron-sulfur clusters (red/yellow), and coenzyme Q (dark blue) are highlighted. The path of electron transport from FMN through the iron-sulfur clusters to Q is shown by the blue arrows. NADH binds near FMN. (d) Proposed model for coupling of electron transport to proton pumping by complex I. The long α -helix from NuoL is represented by the red horizontal bar. The vertical red bars represent proton channel α -helices that tilt in response to the conformational change in the green and orange subunits. Q_{NF} and Q_{NS} represent distinct species of coenzyme Q.

that receives electrons from at least 12 different mitochondrial FAD-containing dehydrogenases involved in fatty acid and amino acid oxidations. For example, in the first step of mitochondrial fatty acid β -oxidation (see Chapter 17), **acyl-CoA dehydrogenase** catalyzes the transfer of two electrons from the fatty acyl-CoA

FIGURE 15.12

Structure of complex II (succinate dehydrogenase) from pig heart mitochondria (PDB ID 1ZOY). The enzyme is composed of two hydrophilic subunits extending into the matrix, the FAD-binding subunit (blue) and the iron–sulfur subunit (yellow), and two transmembrane subunits (pink and gold). The path of electron transport from FAD through the three iron–sulfur clusters to coenzyme Q (UQ) is shown on the right. The enzyme also has a *b*-type heme bound by the transmembrane subunits, but its role in the electron transfer process is not yet understood. Succinate binds near FAD in the blue subunit.

substrate to ETF. ETF, with its bound FADH₂, is then reoxidized by ETF:ubiquinone oxidoreductase, transferring the electrons to Q in the respiratory chain. Glycerol-3-phosphate dehydrogenase, located on the *intermembrane face* of the inner membrane, catalyzes the oxidation of glycerol-3-phosphate to dihydroxyacetone phosphate (DHAP), reducing Q to QH₂ (Figure 15.13). We shall see later that this reaction plays an important role in shuttling electrons from cytoplasmic NADH into the mitochondrial matrix (see Figures 15.2 and 15.30). Because Q is subsequently oxidized by complex III, it can be seen as a collection point, gathering electrons from several flavoprotein dehydrogenases and passing them along the respiratory chain, ultimately to O₂ (Figure 15.10).

Coenzyme Q:cytochrome *c* Oxidoreductase (Complex III)

The oxidation of reduced coenzyme Q is mediated by another large multisubunit complex embedded in the inner membrane, complex III of the respiratory chain. This enzyme catalyzes the transfer of electrons from QH₂ to cytochrome *c*, and is thus called **coenzyme Q:cytochrome *c* oxidoreductase**. Mammalian complex III functions as a dimer, with each monomer composed of 10 or 11 protein chains (~250 kDa), including cytochrome *b*, cytochrome *c*₁, and a protein called the Rieske iron–sulfur protein. Electron transfer through this complex involves, per monomer, two *b*-type hemes, one *c*-type heme, and one Fe₂S₂ cluster, thus complex III is also referred to as **cytochrome *bc*₁ complex**. Figure 15.14 shows the X-ray crystal structure of the bovine mitochondrial complex III and the locations of the redox centers.

The path of electrons from QH₂ to cyt *c* through complex III is more complicated than indicated in Figure 15.10 because at this point, a two-electron donor,

FIGURE 15.13

Coenzyme Q collects electrons from multiple flavoproteins. This lipid-soluble mobile redox cofactor serves as the electron acceptor for at least four mitochondrial flavoprotein dehydrogenases. Electrons from NADH and succinate are delivered via complex I and complex II (succinate dehydrogenase), respectively. Electron-transferring flavoprotein (ETF):ubiquinone oxidoreductase catalyzes the transfer of electrons from reduced ETF to Q. These electrons originate in the acyl-CoA dehydrogenase step of fatty acid β oxidation. Glycerol-3-phosphate dehydrogenase, located on the intermembrane face of the inner membrane, delivers electrons from glycerol-3-phosphate to coenzyme Q. Electrons from reduced QH_2 eventually pass to complex III of the respiratory chain.

**FIGURE 15.14**

Structure of Complex III (coenzyme Q:cytochrome c oxidoreductase). (a) X-ray structure of the dimeric complex from bovine mitochondria (PDB ID 1PPJ). Cytochrome *b* subunits are yellow; each binds two *b*-type hemes (b_H and b_L), shown in red. The Rieske iron-sulfur protein (ISP) subunits are magenta, with the Fe_2S_2 iron-sulfur center shown in orange (the second ISP subunit and its iron-sulfur center are hidden behind the structure). Cytochrome c_1 subunits are blue, with their *c*-type heme in shown in green. The remaining non-core subunits are shown in silver. (b) Cartoon of the complex III dimer, with the same color scheme as in the X-ray structure, illustrating the arrangement of the subunits and redox carriers. The approximate location of the complex in the inner membrane is indicated.

QH_2 , is transferring electrons to one-electron acceptors, the cytochromes. The **Q cycle** has been proposed to account for this stoichiometry (Figure 15.15). Complex III has two binding sites for Q: Q_0 and Q_1 . QH_2 is oxidized at the Q_0 site, where the two electrons take two different paths. The first electron is passed to the iron-sulfur cluster of the Rieske iron-sulfur protein, to cytochrome c_1 and then to cytochrome *c*. The resultant QH^+ semiquinone then transfers its second electron to the low-potential b_L heme component of cytochrome *b* (also known as b_{566} because this heme has a light absorption maximum at 566 nm), and this electron next passes to the high-potential b_H heme (b_{562} , light absorption maximum at 562 nm) component. The b_H heme is located at the Q_1 site near the matrix side of the membrane, where it reduces a molecule of oxidized Q to the QH^+ semiquinone. This process is repeated, with a second molecule of QH_2 being oxidized at the Q_0 site, and one electron passing to the Rieske iron-sulfur protein and onto

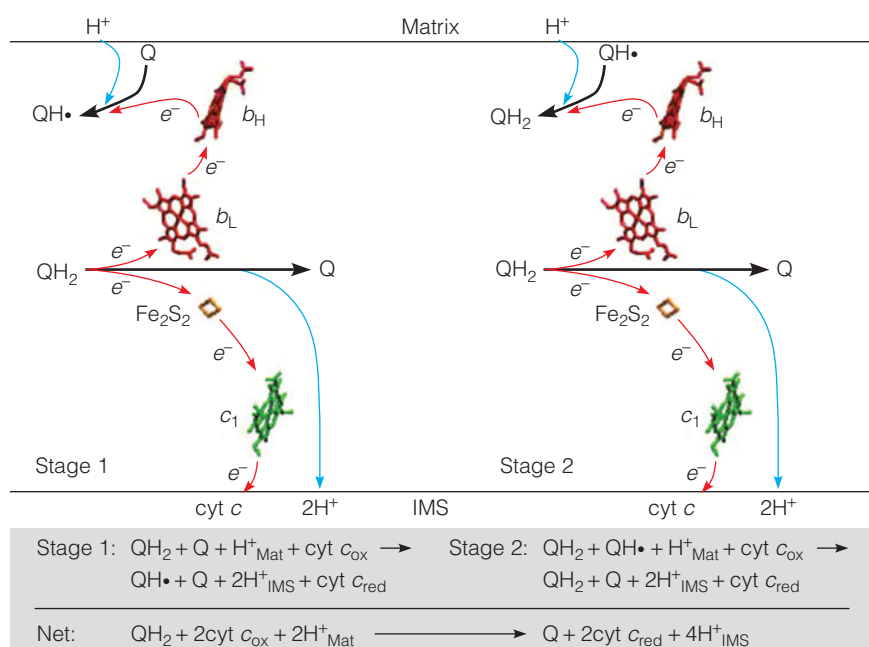

FIGURE 15.15

Q cycle. The spatial arrangement of the redox centers in one monomer of the dimeric bovine mitochondrial complex III (see Figure 15.14) is shown without the protein components (PDB ID 1PPJ). The path of electrons in each stage is indicated by red arrows, and the path of protons is indicated by blue arrows. The Q_0 site is in the middle of the diagram; the Q_1 site is at the top (matrix side of the inner membrane). The stoichiometry of each stage of the cycle is shown, as well as the net stoichiometry of the full cycle.

cytochrome *c* as before. However, this time the electron from the b_{H} heme reduces the $\text{QH}\cdot$ semiquinone to QH_2 at the Q_1 site (Figure 15.15). The result is that two molecules of QH_2 become oxidized and one molecule of Q becomes reduced, for a net transfer of two electrons to reduce two molecules of cytochrome *c*. Because the proton-consuming reactions occur within the matrix, while proton release takes place in the intermembrane space, the Q cycle contributes to the proton gradient needed to drive ATP synthesis (see page 645).

Note the location of cytochrome *c*: It is on the intermembrane space side of the inner membrane. Cytochrome *c* plays another important role in the cell besides as an electron carrier in respiration. Cytochrome *c* is a central signaling component in the **intrinsic pathway of apoptosis**, or programmed cell death. This pathway is initiated in response to oxidative damage, DNA damage, and many other chemical and physical insults that damage the cell directly. These diverse *intrinsic* stresses all trigger the same response: The mitochondrial outer membrane becomes more permeable and cytochrome *c* is released from the intermembrane space into the cytoplasm, where it binds with several other proteins in a complex (the **apoptosome**), which leads to activation of a proteolytic cascade, eventually resulting in cell death (apoptosis will be discussed in more detail in Chapter 28). Thus, this integral component of the respiratory chain is also an integral component of a cell death pathway, hinting at the relationship between mitochondria and the evolution of the eukaryotic cell (more about this at the end of this chapter).

Cytochrome *c* Oxidase (Complex IV)

The final stage of electron transport is carried out by cytochrome *c* oxidase (complex IV). The mitochondrial enzyme exists as a large homodimeric complex in the inner membrane. Each monomer is composed of 13 subunits, with 28 transmembrane helices separating hydrophilic domains facing the matrix and intermembrane space compartments (Figure 15.16). Bacterial cytochrome *c* oxidase is much simpler, composed of just four subunits. However, homologs of three of the bacterial subunits form the core of the mitochondrial complex, revealing the evolutionary origin of this enzyme. Indeed, subunits I, II, and III of cytochrome *c* oxidase are encoded by the mitochondrial genome and synthesized on mitochondrial ribosomes in the matrix. Cytochrome *c* oxidase contains two hemes, *a* and *a*₃,

Electron transport through complex III is coupled to the pumping of protons from the matrix to the intermembrane space.

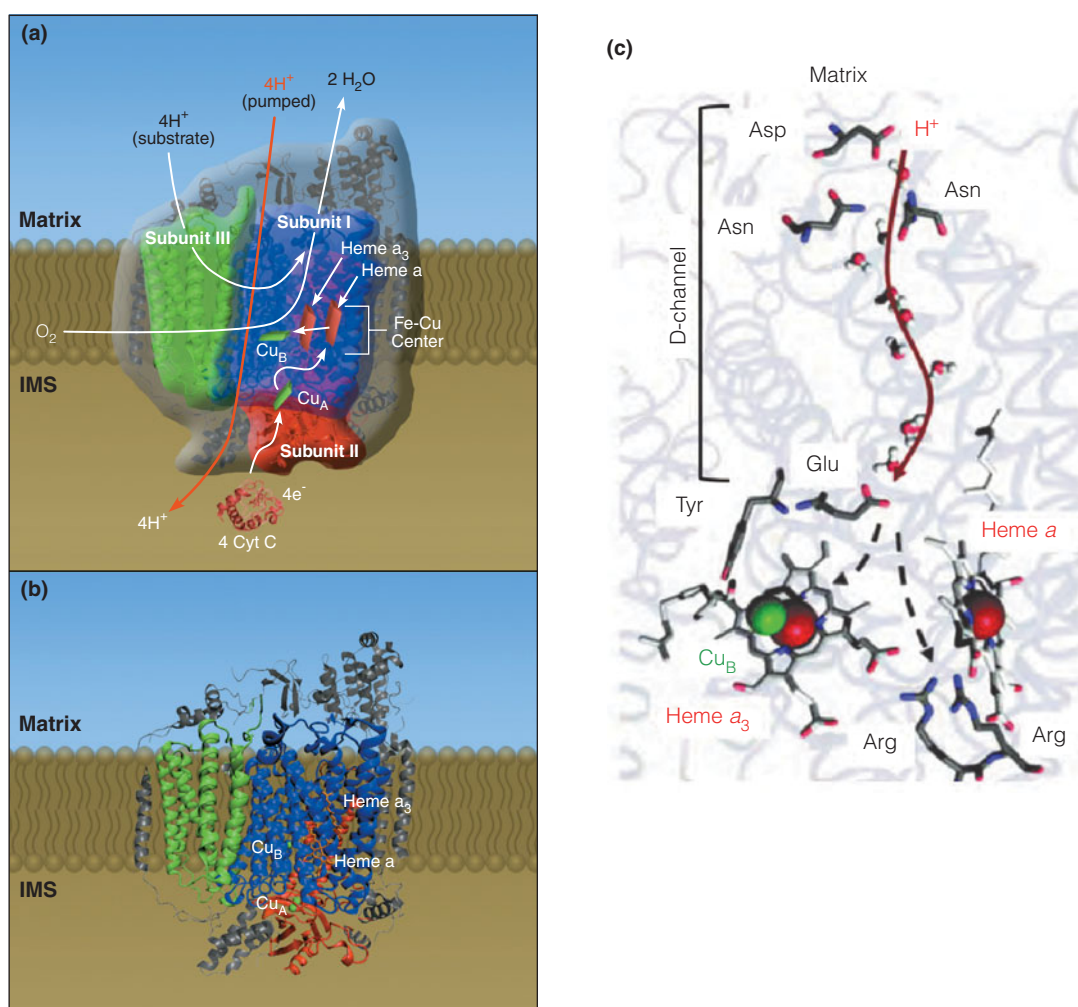

FIGURE 15.16

Structure of cytochrome c oxidase (complex IV).

(a) Cartoon of reaction catalyzed by complex IV. Four electrons are donated, one at a time, by reduced cyt *c*, to the Cu_A center, through heme *a*, and on to the catalytic site (binuclear a₃-Cu_B site) where one molecule of O₂ is reduced, yielding two molecules of H₂O. Protons are pumped from the matrix side to the intermembrane space (IMS) side of the membrane. (b) X-ray structure of one monomer of the bovine mitochondrial enzyme (PDB ID 2EIJ). Subunits I, II, and III are colored as in the cartoon in panel (a); the remaining subunits are gray. The core two hemes are orange, and the two Cu centers are green. The approximate location of the complex in the inner membrane is indicated. Cyt *c* binds near the Cu_A center of subunit II.

(c) The D-channel proton-transfer pathway in subunit I of the *R. sphaeroides* cytochrome c oxidase (PDB ID 1M57) is indicated by the red arrow and the water molecules. The dashed black arrows indicate the branching paths of protons destined for the catalytic site and the pump site.

bound by subunit I in the interior of the membrane, and two copper centers (Cu_A and Cu_B). The Cu_B atom is ligated by three histidine residues and sits within 5 Å of heme a₃ on subunit I. The iron of heme a₃ and Cu_B thus constitute a “binuclear center,” functioning as a single unit in electron transfer. The Cu_A center is composed of two Cu atoms bound by subunit II at the intermembrane space face of the membrane.

Complex IV catalyzes the transfer of electrons from reduced cytochrome *c* to oxygen. The initial oxidation of cytochrome *c* is carried out by Cu_A, with the electron transferred to heme *a*, and then to the binuclear heme a₃-Cu_B site. The binuclear center is the catalytic site where O₂ undergoes its four-electron reduction to water. The redox reaction catalyzed by complex IV is as follows:

For each electron transferred, complex IV pumps approximately one proton from the matrix side to the intermembrane space side of the membrane. Thus, the net reaction catalyzed by complex IV can be summarized as follows:

How are these four protons per molecule of oxygen reduced pumped from the matrix to the intermembrane space? X-ray structures of cytochrome *c* oxidase, such as that in Figure 15.16, reveal the existence of two distinct proton channels leading from the matrix to the catalytic center in subunit I, called the D-channel and the K-channel. The K-channel (named for an essential lysine residue)

provides two of the protons required to form water. The D-channel (named for an essential aspartate residue at the entrance to the channel; top of Figure 15.16c) provides the other two protons in the O_2 reduction to $2H_2O$, as well as all four of the pumped protons. A series of ~ 10 water molecules can be seen in the D-channel in the X-ray structures (Figure 15.16c), providing a mechanism to transfer protons through a hydrogen-bonded network (recall the proton-hopping described in Chapter 2) from the matrix to the catalytic site. How do the pumped protons move from the catalytic site, buried in the middle of the inner membrane, to the intermembrane space side? The mechanism is incompletely understood, but it probably involves conformational changes in the protein coupled to changes in redox state of the binuclear heme a_3 – Cu_B center. These conformational changes alter the pK_a s of proton-binding residues (e.g., Glu or Asp), as described for the Bohr effect in hemoglobin (see Chapter 7). One model proposes that following electron transfer to the catalytic site, a proton is transferred from a conserved glutamate residue (located at the bottom of the D-channel, near the binuclear center) to the catalytic site. Deprotonation of this Glu triggers a conformational change that raises the pK_a of a second proton acceptor such that it now has a greater affinity for protons and binds a proton from the D-channel. Reprotonation of Glu with another proton from the D-channel reverses the conformational change back to the original state, lowering the pK_a of the second proton acceptor, triggering release of the pumped proton on the other side of the membrane.

Supramolecular Organization of Mitochondrial Respiratory Chain Complexes

Recent kinetic, biochemical, and electron microscopy studies suggest that the respiratory chain complexes exist as highly organized “supercomplexes” in the inner membrane of intact mitochondria. For example, supercomplexes containing complex I, complex III, and complex IV in a 1:2:1 ratio can be isolated from rat and bovine mitochondria after solubilization with mild detergents like digitonin. Electron microscopy and 3D reconstructions show that the Q and cytochrome *c* binding sites of the individual complexes are facing each other, suggesting the possibility of substrate channeling (Figure 15.17). Indeed, kinetic studies suggest that the respiratory complexes form a series of tightly linked redox reactions, behaving much like a tiny electrical wire.

Oxidative Phosphorylation

Having discussed how the free energy of electron transport down the respiratory chain is used to pump protons out of the matrix, we turn now to the question of how that energy is made available for ATP synthesis—in short, the mechanism of oxidative phosphorylation. Mechanistically, oxidative phosphorylation is far more complex than the substrate-level phosphorylation reactions in glycolysis and the citric acid cycle, and this field of inquiry was one of the most contentious biochemical research arenas for many years. As the late Efraim Racker stated, “Anyone who is not confused about oxidative phosphorylation just doesn’t understand the situation.” As we shall see, a great deal of the needed understanding has developed in the three decades since Racker wrote these words.

The P/O Ratio: Efficiency of Oxidative Phosphorylation

Before considering the mechanism of oxidative phosphorylation, it is useful to recall the energetics of the process. We previously calculated (page 630) that for a pair of electrons entering the respiratory chain as NADH, and traversing the entire chain to O_2 , the standard free energy change, ΔG° , is -220 kJ/mol:

Electron transport through Complex IV is coupled to the pumping of protons from the matrix to the intermembrane space.

FIGURE 15.17

Model of proposed supercomplex of complexes I, III, and IV. This model is based on biochemical, X-ray structural, and electron microscopy results. Complex I is yellow, the dimer of complex III is red, and complex IV is green. Cytochrome *c* is gray. The path of electrons from NADH to O_2 is indicated, and the putative Q binding sites in complexes I and III are shown in the gray box.

How much of this free energy is actually captured as ATP in oxidative phosphorylation? This question could be answered once we could measure the quantity of ATP synthesized per mole of substrate oxidized in isolated mitochondria. What we usually measure is the **P/O ratio**, which is the number of molecules of ATP synthesized per pair of electrons carried through electron transport. ATP synthesis is quantitated as phosphate incorporation into ATP, and electron pairs are quantitated as oxygen uptake, in μmol of O atoms (not O_2 molecules) reduced to water. Oxygen uptake is determined with an oxygen electrode.

As you might imagine, precise measurements of oxygen consumption and ATP synthesis in a mitochondrial preparation are difficult to obtain, and many experimental pitfalls can lead to inaccurate estimates of the P/O ratio. Early experiments suggested that the mitochondrial oxidation of NADH proceeds with a P/O ratio of 3 and oxidation of succinate proceeds with a P/O ratio of 2. These values were consistent with older theories of oxidative phosphorylation, which postulated the existence of a high-energy intermediate directly coupled to ATP synthesis, as seen in the substrate-level phosphorylation reactions of glycolysis. However, as researchers got better at preparing intact mitochondria and measuring oxygen consumption and ATP synthesis, it became clear that the P/O ratios were *not integers*. The general consensus now is that the P/O ratio is ~ 2.5 for oxidation of NADH and ~ 1.5 for oxidation of succinate. Indeed, these noninteger P/O values contributed to the realization that phosphorylation and oxidation are *not* directly coupled. As Figure 15.2 suggests, coupling occurs indirectly. As we will see next, this mechanism does not require an integral stoichiometric relationship between reducing equivalents consumed and ATP synthesized. With this in mind, we can write a balanced equation for the mitochondrial oxidation of NADH coupled to the synthesis of ATP:

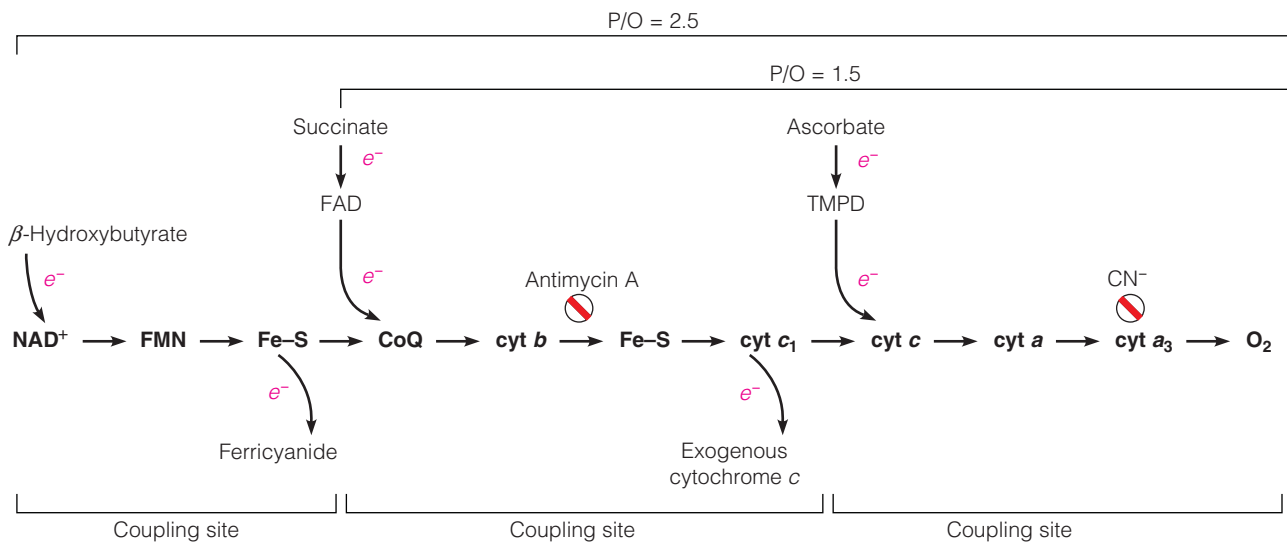

As discussed above, the oxidation of NADH by O_2 has a $\Delta G^{\circ'}$ of -220 kJ/mol . Because $\Delta G^{\circ'}$ for ATP hydrolysis is -30.5 kJ/mol , synthesis of 2.5 ATPs requires 76 kJ under standard conditions, giving an efficiency for oxidative phosphorylation of about 35% under standard conditions. Because ΔG for ATP hydrolysis under intracellular conditions is -50 kJ/mol or more, the efficiency of oxidative phosphorylation probably approaches 60% or 70% *in vivo*.

Oxidative Reactions That Drive ATP Synthesis

A glance at Figure 15.10 reveals that the transfer of reducing equivalents from an NAD^+ -oxidizable substrate to O_2 involves about a dozen consecutive, linked oxidoreduction reactions. Which of these reactions actually drive ATP synthesis? This question was of paramount concern in the early days of bioenergetics research, when it was thought that ATP synthesis was directly coupled to individual exergonic reactions, as it is in substrate-level phosphorylation. The most straightforward interpretation of the P/O ratio of 3 initially estimated for NADH oxidation was that three of the individual reactions of the respiratory chain are sufficiently exergonic to drive the synthesis of one ATP molecule each. Indeed, three of these reactions do have $\Delta G^{\circ'}$ values exceeding 30.5 kJ/mol , the minimum barrier that must be overcome (under standard conditions) to make the synthesis of each ATP exergonic (see Figure 15.7). Those three reactions are the oxidation of NADH by coenzyme Q ($\Delta G^{\circ'} = -69.5 \text{ kJ/mol}$; catalyzed by complex I), the oxidation of QH_2 by cytochrome *c* ($\Delta G^{\circ'} = -36.7 \text{ kJ/mol}$; catalyzed by complex III), and the oxidation of reduced cytochrome *c* by O_2 ($\Delta G^{\circ'} = -112 \text{ kJ/mol}$; catalyzed by cytochrome *c* oxidase). Each of these reactions was thus considered to be a “**coupling site**” for ATP synthesis; that is, each was considered to be a reaction in which ATP synthesis was driven directly by the energy released from that reaction.

Because we now know that coupling between oxidation and ATP synthesis is indirect, the concept of coupling sites is an oversimplification. Nevertheless, the concept was useful because it provided a framework for experiments identifying each of the above three reactions as individually capable of energizing the membrane for

ATP synthesis, even when the entire electron transport chain is not operating. With that in mind, let us examine this evidence, which is summarized in Figure 15.18.

First, succinate is oxidized with a P/O ratio of ~ 1.5 , not 2.5, suggesting the existence of a coupling site associated with NADH dehydrogenase (complex I). This was confirmed by blocking electron transport past cytochrome *b* with antimycin A. Ferricyanide was added as an artificial electron acceptor so that electrons could continue to flow. Under these conditions NAD^+ -linked substrates, such as β hydroxybutyrate, were oxidized with a P/O ratio of ~ 1 , confirming the existence of one site before cytochrome *b*.

Another approach involved an artificial electron donor, ascorbate. In the presence of another electron acceptor, tetramethyl-*p*-phenylene diamine (TMPD—see Figure 15.9), electrons could be supplied to the respiratory chain at cytochrome *c*. These electron carriers reduced cytochrome *c* nonenzymatically, and its oxidation via cytochrome oxidase proceeded with a P/O ratio of ~ 1 , thus localizing one coupling site beyond cytochrome *c*. Finally, purified oxidized cytochrome *c*, when added to mitochondria, can act as an electron acceptor, withdrawing electrons from the electron transport chain. The further addition of a cytochrome oxidase inhibitor, such as cyanide, forces electrons to exit from the respiratory chain at cytochrome *c*. Under these conditions succinate is oxidized with a P/O ratio of ~ 1 , which localizes a site between cytochromes *b* and *c*. However, if antimycin A is then added, no ATP is synthesized, showing that complex II (succinate dehydrogenase) is not a coupling site. In sum, these experiments demonstrate that complexes I, III, and IV are each capable of driving ATP synthesis, but that complex II is not (Figure 15.18). We now know that these three “coupling sites” indirectly drive ATP synthesis by pumping protons across the membrane as electrons flow through the complexes.

FIGURE 15.18

Experimental identification of “coupling sites.” Electron transport is restricted to particular parts of the chain by use of selected electron donors, electron acceptors, and respiratory inhibitors, as indicated. For each segment of the chain that is thus isolated, P/O ratios are determined, allowing identification of coupling sites.

Mechanism of Oxidative Phosphorylation: Chemiosmotic Coupling

What is the actual mechanism by which energy released from electron transport through the respiratory chain is harnessed to drive the synthesis of ATP? For many years, researchers around the world searched for a high-energy intermediate that could link electron transport to ATP synthesis. However, such activated intermediates have never been demonstrated in oxidative phosphorylation.

Although other models have been considered, there is now widespread acceptance of a model involving **chemiosmotic coupling**, proposed in 1961 by British biochemist Peter Mitchell. Although this model was resisted at first, overwhelming evidence has now accumulated in its support, and Mitchell’s achievements were recognized in 1978 with a Nobel Prize. In its most basic form, this model proposes that *the free energy from electron transport drives an active transport system, which pumps protons out of the*

FIGURE 15.19

Chemiosmotic coupling of electron transport and ATP synthesis. This depiction of protein complexes in the inner membrane shows the sequence of electron carriers from NADH to O_2 . Complex II is not included because it does not contribute to the proton gradient. Protons are pumped by complexes I, III, and IV as electrons flow through the complexes, generating an electrochemical gradient across the membrane (protonmotive force, pmf). Proton re-entry to the matrix, through the F_0 channel of ATP synthase (complex V), provides the energy to drive ATP synthesis.

mitochondrial matrix into the intermembrane space. This action generates an electrochemical gradient for protons. The protons on the outside have a thermodynamic tendency to flow back in, down their electrochemical gradient, and this provides the driving force for ATP synthesis. Another way to state this is that free energy must be expended to maintain the proton gradient. When protons do flow back into the matrix, that energy is dissipated, some of it being harnessed to drive the synthesis of ATP.

To understand the chemiosmotic theory in more detail, recall that some, but not all, of the reactions of electron transport transfer hydrogen ions (protons) as well as electrons. These reactions include the dehydrogenations of NADH, FMN H_2 , FAD H_2 , and reduced coenzyme Q. Mitchell proposed that the enzymes catalyzing these dehydrogenations are asymmetrically oriented in the inner membrane so that protons are always taken up from inside the matrix and released in the intermembrane space. Figure 15.19 shows how this process occurs. This **proton pumping** by respiratory proteins results in conversion of the energy of respiration to osmotic energy, in the form of an **electrochemical gradient**—or a gradient of chemical concentration that establishes an electrical potential (as discussed in detail in Chapter 10). The energy released from discharging this gradient can be coupled with the phosphorylation of ADP to ATP, with no isolatable “high energy” intermediates being formed. This process involves the ATP synthase (complex V). The F_0 portion of the complex spans the inner membrane and contains a specific channel for return of protons to the mitochondrial matrix. The free energy released as protons traverse this channel to return to the matrix is harnessed to drive the synthesis of ATP, catalyzed by the F_1 component of the complex. Before we describe the structure and function of ATP synthase, we will take a closer look at the evidence for the chemiosmotic coupling mechanism.

A Closer Look at Chemiosmotic Coupling: The Experimental Evidence

Let us now explore the experimental evidence for chemiosmotic coupling in some detail—partly because of its importance to an understanding of oxidative phosphorylation and partly because it provides insight into other biological processes, including active transport across membranes and photosynthesis. Recall from the introduction to this chapter that there were several nagging facts that argued against ATP synthesis by a direct chemical coupling process like that in glycolysis. The first was the realization that the number of ATP molecules produced per pair of electrons is approximately 2.5, not an integer as would be predicted by a direct chemical coupling mechanism. Secondly, oxidative phosphorylation was shown to require a membrane. If the membrane is disrupted, the passage of electrons down the respiratory chain becomes *uncoupled* from ATP synthesis: Electrons still flow, but ATP production ceases. These observations are nicely explained by the chemiosmotic coupling mechanism.

Chemiosmotic coupling refers to the use of a transmembrane proton gradient to drive endergonic processes like ATP synthesis.

Membranes Can Establish Proton Gradients

When it became possible to measure changes in pH and electrical potential across mitochondrial membranes, it became clear that mitochondria can pump protons from the matrix to the intermembrane space. In fact, the pH value outside an actively respiring mitochondrion is about 0.75 units lower than in the matrix. The pH gradient also generates an electrical potential of 150 to 200 millivolts (mV) across the membrane because of the net movement of positively charged protons outward across the inner membrane. The pH gradient and the membrane potential both contribute to an *electrochemical H^+ gradient*, or **protonmotive force (pmf)**, although the electrical component is by far the major contributor. An electrical charge of 150 mV across a membrane may not seem like much (1/10 the voltage of a 1.5 V flashlight battery). However, as the British biochemist Nick Lane has pointed out, considering the thickness of a biological membrane ($\sim 5 \times 10^{-9}$ m), this corresponds to 30 million volts/m, similar to the voltage of a lightning bolt! We can calculate the free energy change of this electrochemical gradient using Equation 10.2 from Chapter 10:

$$\Delta G = RT \ln\left(\frac{C_2}{C_1}\right) + ZF \Delta\psi \quad (15.4)$$

C_2 and C_1 are the concentrations of the ion in the two compartments, Z is the charge on the ion (+1 for H^+), and $\Delta\psi$ is the membrane potential, in volts. ΔG in this equation is equivalent to $\Delta\mu_{H^+}$, the proton electrochemical gradient. For a proton electrochemical gradient, because pH is a logarithmic function of $[H^+]$, Equation 15.4 can be simplified to:

$$\Delta\mu_{H^+} = 2.3 RT \Delta\text{pH} + F\Delta\psi \quad (15.5)$$

$\Delta\mu_{H^+}$ is also called Δp , the protonmotive force, or pmf. ΔpH has a positive value (+0.75) because it is defined as the pH in the matrix minus the pH in the intermembrane space (recall that $\text{pH} = -\log[H^+]$). Thus, the contribution of the pH gradient is $2.3RT(0.75) = +4.5$ kJ/mol at 37 °C (310 K). The membrane potential ($\Delta\psi$) across the inner membrane of an actively respiring mitochondrion is 0.15 to 0.20 V, so the contribution of the electrical component is +14.5 to +19.3 kJ/mol. Thus the total free energy change of transporting a proton from the matrix to the intermembrane space is on the order of +21 kJ per mole of protons. Because the formation of this protonmotive force is an endergonic process (positive ΔG), discharge of the gradient is an exergonic process: It is this free energy that is used to drive the phosphorylation of ADP. As summarized in Figure 15.19, approximately 10 protons are pumped per pair of electrons transferred from NADH to O_2 . Thus, the protonmotive force conserves approximately 210 kJ of free energy for ATP synthesis. Recall that the free energy change for the oxidation of NADH by O_2 is -220 kJ/mol under standard conditions, most of which is conserved in the electrochemical proton gradient. If we make some reasonable assumptions regarding the concentrations of reactants and products in the matrix, we can estimate that in vivo ΔG for NADH oxidation is roughly -200 kJ/mol (page 630), and ΔG for the synthesis of ATP from ADP and P_i is roughly +50 kJ/mol. Thus, electron transport provides sufficient free energy to synthesize approximately 4 moles of ATP per mole of NADH oxidized, but only about 2.5 are synthesized, reflecting the indirect, evolved coupling stoichiometry of oxidative phosphorylation.

Comparable experiments have shown that electrochemical proton gradients are used in energy transactions other than oxidative phosphorylation. Bacterial membranes use proton pumping to transduce energy both for oxidative phosphorylation and for driving flagellar motors that allow movement of the cell. Bacteria also have many membrane solute transporters that use the protonmotive force to pump solutes into or out of their cells. Proton pumping across the chloroplast thylakoid membrane drives ATP synthesis in photophosphorylation (see Chapter 17). Proton gradients also drive active transport (see Chapter 10) and heat production (see below). The existence of chemiosmotic coupling in all three domains of life, and its myriad uses, suggests an ancient evolutionary history for this energy conserving mechanism.

An Intact Inner Membrane Is Required for Oxidative Phosphorylation

When the physical continuity of the membrane is interrupted—for example, by sonication—the resultant particles can carry out electron transport but not ATP synthesis. The necessity of a structurally intact membrane for maintenance of a membrane potential is consistent with the idea that a proton gradient is essential for oxidative phosphorylation.

Key Electron Transport Proteins Span the Inner Membrane

If the respiratory proteins are to serve as proton pumps, then the electron carriers that pump protons should be in contact with both the inner and the outer sides of the membrane. Moreover, these carriers should be asymmetrically oriented in the membrane to account for proton transport in one direction—outward. Asymmetric orientation has been demonstrated by the use of agents that react with respiratory proteins but cannot themselves traverse the membrane, such as antibodies, proteolytic enzymes, or labeling reagents. Treatment of intact mitochondria with such reagents allows detection of proteins located at the outer surface of the inner membrane, whereas reaction with membrane vesicles allows access to the inner, or matrix, side. Such approaches have shown, for example, that the cytochrome oxidase complex (complex IV) binds to cytochrome *c* only on the intermembrane space side (see Figure 15.16). Moreover, 9 of the 13 subunits of the complex can be labeled from only one side or the other, indicating asymmetric placement of the complex in the membrane. Similar findings have now been made for the subunits of complexes I, II, and III.

Uncouplers Act by Dissipating the Proton Gradient

A class of compounds, exemplified by the lipophilic weak acids **2,4-dinitrophenol (DNP)** and **trifluorocarbonyl cyanide phenylhydrazone (FCCP)** are called uncoupling agents, or **uncouplers**. Uncoupling agents, when added to mitochondria, permit electron transport along the respiratory chain to O_2 to occur in the absence of ATP synthesis. That is, they *uncouple* the process of electron transport from the process of ATP synthesis. The pK_a of the phenolic hydroxyl group in DNP is such that it is normally dissociated at intracellular pH. However, a DNP molecule that approaches the inner membrane from the outside becomes protonated because of the lower pH value in this vicinity. The protonated DNP diffuses into and through the membrane by mass action. Once inside the matrix, the higher pH causes the phenolic hydroxyl to deprotonate. The deprotonated dinitrophenolate ion is still lipophilic enough to pass back across the membrane, where it can bind another proton and repeat the cycle. Thus, the uncoupler has the effect of transporting H^+ into the matrix, bypassing the F_0 proton channel and thereby preventing ATP synthesis.

Extensive data on the transport of ions other than H^+ confirm that a functionally intact membrane is essential to oxidative phosphorylation. The antibiotic *valinomycin* (see page 387 in Chapter 10) is an example of an **ionophore** (“ion carrier”). This lipid-soluble compound forms a specific complex with potassium ion. Because the complex is lipophilic and can diffuse into the membrane, just as protonated DNP does, valinomycin brings about the transport of K^+ through the inner membrane in much the same sense that DNP transports protons. Valinomycin acts by decreasing the $\Delta\psi$ (membrane potential) component of the pmf, without a direct effect on the pH gradient. Another antibiotic, **nigericin**, acts as a K^+ / H^+ **antiporter**; it carries H^+ in one direction, coupled with the reverse transport of K^+ . Thus, nigericin dissipates the pH component of the pmf, with little effect on $\Delta\psi$. Neither compound alone is a particularly effective uncoupler of oxidative phosphorylation, but in combination they collapse both elements of the pmf, and ATP synthesis is effectively inhibited.

Generation of a Proton Gradient Permits ATP Synthesis Without Electron Transport

Andre Jagendorf, while studying photosynthetic ATP production, provided important evidence for chemiosmotic coupling in the chloroplast. As presented in Chapter 16, the chloroplast couples light energy to ATP synthesis. Jagendorf showed

that ATP synthesis can proceed in the chloroplast in the absence of electron transport, so long as a proton gradient is present. Chloroplasts were incubated at pH 4 for several hours and then quickly transferred to a buffer at pH 8. Thus, like the situation in intact cells, the inside of the organelle was at a lower pH than the outside (chloroplast membranes pump protons *inward*, not outward). Addition of ADP and P_i to these chloroplasts generated a burst of ATP synthesis, simultaneous with dissipation of the pH gradient. Similar results have now been observed with mitochondria. These experiments show that the establishment of a proton gradient, even without a corresponding energy input, suffices to drive the synthesis of ATP.

A dramatic variation on Jagendorf's experiment involved a membrane protein, *bacteriorhodopsin* (Chapter 10, page 374), from the photosynthetic bacterium *Halobacterium halobium*. Bacteriorhodopsin pumps protons when the bacteria are supplied with light. Bacteriorhodopsin was isolated in a membrane-free form and then incorporated into synthetic vesicles, along with isolated liver mitochondrial F_0F_1 ATPase in the right orientation. When these vesicles were illuminated, ATP synthesis occurred, showing that phosphorylation can occur as a direct consequence of the formation of a proton gradient. This completely artificial reconstituted system, composed of bacterial and mammalian components, elegantly demonstrates the essence of chemiosmotic coupling.

Complex V: The Enzyme System for ATP Synthesis

That complexes I, III, and IV could individually drive ATP synthesis was confirmed in elegant reconstitution studies involving complex V, which catalyzes the actual synthesis of ATP from ADP. Let us review the discovery and nature of complex V and then discuss the reconstitution experiments.

When mitochondria are negatively stained with phosphotungstate, electron microscopy reveals that the cristae are covered with knoblike projections on the matrix side, each attached to the inner membrane by a short stalk (Figure 15.20). The knobs are known as **F_1 spheres**. Disruption of mitochondria by sonication generates fragments of inner membrane, which reseal in the form of closed vesicles. The membrane closes on itself inside out, so the knoblike projections are on the outside. These **submitochondrial particles** respire and synthesize ATP, just as intact mitochondria do. Efraim Racker and his colleagues showed that treatment of these vesicles with trypsin or urea caused the knobs to dissociate from the vesicles. After centrifugation to separate the “stripped” vesicles from the knobs, the vesicles could still oxidize substrates and reduce oxygen, but no ATP was synthesized. When knobs were added back to the vesicles, there was substantial reconstitution of particles that could then catalyze ATP synthesis as a result of the oxidation of exogenous substrates.

Because readdition of the knobs recoupled ATP synthesis to electron transport, the knobs were originally called **coupling factors**. Purification of the knobs attached to the underlying stalks revealed a large multiprotein aggregate consisting of more than a dozen polypeptide chains, as schematized in Figure 15.21. The entire structure, called the **F_0F_1 complex**, consists of the knob, the stalk to which it is attached, and an attached complex that is embedded in the inner membrane. The stalked knob is called F_1 , and the base is called F_0 . The F_1 complex consists of five proteins, designated α , β , γ , δ , and ϵ , with a subunit stoichiometry of $\alpha_3\beta_3\gamma\delta\epsilon$. The F_0 complex consists of an oligomer of c subunits (10 copies in yeast mitochondrial ATP synthase; 8 copies in higher eukaryotes) plus one subunit a, and single copies of subunits b, d, F6 and OSCP (oligomycin sensitivity conferral protein) that form a peripheral stalk.

The entire F_0F_1 complex has an ATP *hydrolysis* activity *in vitro*, as does factor F_1 alone; this ATPase activity was assumed to represent the reverse of the true physiological reaction, namely, ATP synthesis. The OSCP subunit in the F_0 complex is the site of binding of the ATP synthesis inhibitor **oligomycin** (discussed further on page 655). For this reason, some workers call this structure F_o (the letter o stands for oligomycin), rather than F_0 . The ATPase activity, sensitivity to oligomycin, and results of the reconstitution experiments confirm that the role of the F_0F_1 complex (also called complex V) is to synthesize ATP. The action of this

Antibiotics such as valinomycin and nigericin interfere with maintenance of the proton-motive force.

Chloroplasts use light energy to drive protons inward, establishing a proton gradient for ATP synthesis.

**FIGURE 15.21**

Structure of the F_0F_1 complex. (a) The F_0F_1 complex, also called ATP synthase or complex V, contains an F_1 knob projecting into the mitochondrial matrix and connected by a central stalk to the F_0 base. The globular F_1 knob contains three $\alpha\beta$ dimers, arranged about the central stalk, which is made up of γ , δ , and ϵ subunits. The F_0 base is composed of 10–12 c subunits (the c-ring) and one subunit a. The peripheral stalk (subunits b, d, F6, and OSCP) is attached to the F_0 base via subunit a and at least four other minor membrane-embedded subunits that are not shown. The central stalk and the c-ring compose the “rotor” of ATP synthase. The remainder of the subunits make up the “stator,” a structure that prevents the rotation of the three $\alpha\beta$ dimers of F_1 . This model is based upon the X-ray crystal structures of the yeast and bovine mitochondrial F_0F_1 complex.

(b) The yeast mitochondrial F_1F_0 X-ray structure has been docked onto cryoelectron microscopy reconstructions of the bovine complex. The 10 c subunits of the c-ring are magenta, and the γ subunit and $\alpha\beta$ dimers are colored as in panel (a). The green density represents the peripheral stalk subunits. (c) The image in (b) is rotated to highlight the peripheral stalk and its function as a stator. The approximate location of the complex in the inner membrane is indicated by the horizontal lines in each panel.

amazing structure, a molecular “rotary engine,” will be discussed after we describe its structure in more detail.

Continuing with his reconstitution experiments, Racker found that isolated submitochondrial respiratory complexes (I, II, and so on) could be reconstituted by sonication into artificial membranes (liposomes) containing purified phospholipids. When F_0F_1 complex was included in the sonication mixture, it was also incorporated into the vesicles. In this case each preparation had the electron transport properties of the original complex, plus a phosphorylation activity. For reconstituted complexes I, III, and IV, the P/O ratio was ~ 1 in each case. For example, reconstituted complex III could transfer electrons from coenzyme Q to cytochrome *c*, with concomitant synthesis of ~ 1 mole of ATP per pair of reducing equivalents. This type of evidence showed that respiratory complexes I, III, and IV each contain one coupling site. By contrast, complex II (succinate dehydrogenase) showed no ATP synthesis, confirming the absence of a coupling site in this complex.

FIGURE 15.22

Structure of the mitochondrial F_1 ATP synthase complex. (a) X-ray structure of the bovine mitochondrial F_1 complex (PDB ID 1BMF). α subunits (red) and β subunits (yellow) are arranged in a hexameric ring around the central γ subunit (blue), in the manner shown schematically in (d). The membrane would be at the bottom of the structure in this view. In (b), only one α subunit and one β subunit, from opposite sides of the hexameric ring, and the γ subunit are shown to illustrate their nearly identical tertiary structures. An ATP analog (AMP-PNP; green) can be seen bound to each subunit. (c) In this view from the matrix side of the membrane looking up, the arrangement of the α and β subunits as three $\alpha\beta$ dimers surrounding the central γ subunit is emphasized. Only the central nucleotide binding domain of each subunit is shown. The γ subunit is asymmetric, and makes unique contacts with each $\alpha\beta$ dimer. Although not obvious from this figure, each $\alpha\beta$ dimer has a slightly different conformation, especially in the central nucleotide-binding domain of each β subunit. The ATP analog AMP-PNP (green) can be seen bound in the “T” β subunit. ADP (purple) can be seen bound in the “L” β subunit and the “O” β subunit is empty.

In 1994 the publication by John Walker's group of the crystal structure of the 371-kDa F_1 component of complex V helped to clarify the mechanism by which the passage of protons through the F_0F_1 complex drives the synthesis of ATP. As was suggested in Figure 15.21, the knob of the F_1 complex contains three identical $\alpha\beta$ dimers forming a flattened sphere 90–100 Å in diameter (Figure 15.22a). Each monomer can bind an adenine nucleotide at the interfaces between the α and β subunits, but the catalytic sites are located in the β subunits. The α and β subunits have nearly identical tertiary structures, composed of an N-terminal 6-stranded β barrel, a central domain containing the nucleotide-binding site, and a C-terminal bundle of helices (Figure 15.22b). An α -helical coiled-coil domain of the γ subunit of the central stalk penetrates the interior of the three $\alpha\beta$ dimers, where it interacts with the central and C-terminal domains of the α and β subunits. Careful analysis of the crystal structure showed important structural differences among the three dimers, especially in the central nucleotide-binding domain of each β subunit. Most significant, the nucleotide-binding site of one contained ADP, while another contained AMP-PNP (a nonhydrolyzable ATP analog added during crystallization), and the third was empty (Figure 15.22c). Thus, each $\alpha\beta$ dimer exists in one of three alternative conformations. What would cause otherwise identical $\alpha\beta$ dimers to adopt different conformations? The key is the interaction of the γ subunit in the interior of the three $\alpha\beta$ dimers. Because the γ subunit is itself asymmetric, it makes unique contacts with each $\alpha\beta$ dimer. Consequently, each $\alpha\beta$ dimer assumes a different conformation.

Kinetic experiments with purified F_1 component have revealed that the equilibrium constant for formation of ATP from $ADP + P_i$ on the enzyme is close to 1. Recall that the apparent K'_{eq} for ATP hydrolysis free in solution is approximately 10^5 M (Chapter 12). Is ATP synthase violating the first law of thermodynamics, making ATP with no energy input? The key is that the enzyme is not making *free* ATP, but, rather, *bound* ATP. In fact, ATP synthase binds ATP with much, much higher affinity than ADP (~7 orders of magnitude difference). This amounts to about 40 kJ/mol of binding energy, which drives the equilibrium toward ATP on the enzyme. ATP is so tightly bound that considerable energy must be used to release it from the enzyme. The protonmotive force lowers the binding affinity of ATP by a million-fold or more, allowing its dissociation from the enzyme. The energy-dependent step is thus not ATP *synthesis* but rather its *release* from a tight-binding site. This release is brought about by the energy-dependent rotation of γ , which drives conformational changes in the $\alpha\beta$ assemblies.

All of this supported a mechanism proposed by Paul Boyer some years earlier, in which rotation of the γ subunit causes sequential conformational changes in the $\alpha\beta$ dimer assemblies. In this model, called the binding-change model, the F_1 motor functions essentially as a three-cylinder engine. As shown in Figure 15.23, the three conformations of the nucleotide-binding site are termed loose (L), tight (T), and open (O). In step 1 of Figure 15.23, rotation of γ by 120° , fueled by proton passage through channels in F_0 , opens site T, leading to ATP release, and an open O site changes to an L site, binding ADP and P_i . This same rotation causes the third site to change from an L conformation, with loosely bound ADP and P_i , to a T conformation, where the substrates are tightly bound, leading to ATP formation in step 2. Steps 3 and 4, and 5 and 6, are just repeats of steps 1 and 2, releasing two additional ATP molecules, except that the three conformations have migrated around the three $\alpha\beta$ dimers. There is now good evidence for additional conformational intermediates. For example, P_i binds to the O site before ADP. This prevents the unwanted binding of ATP instead of $P_i + ADP$ and provides an explanation for how the enzyme is able to make ATP under cellular conditions where the ATP concentration is 10 to 50 times that of ADP. The structure determination of the F_0F_1 complex and the mechanism of ATP synthesis suggested by that structure led to the recognition of Walker and Boyer as recipients of the 1997 Nobel Prize in Chemistry.

Is F_1 really a rotating engine, as implied by the model of Figure 15.23? Several experimental approaches indicate that it is. The most graphic evidence comes from

The F_0F_1 complex contains a proton channel and the enzyme that synthesizes ATP.

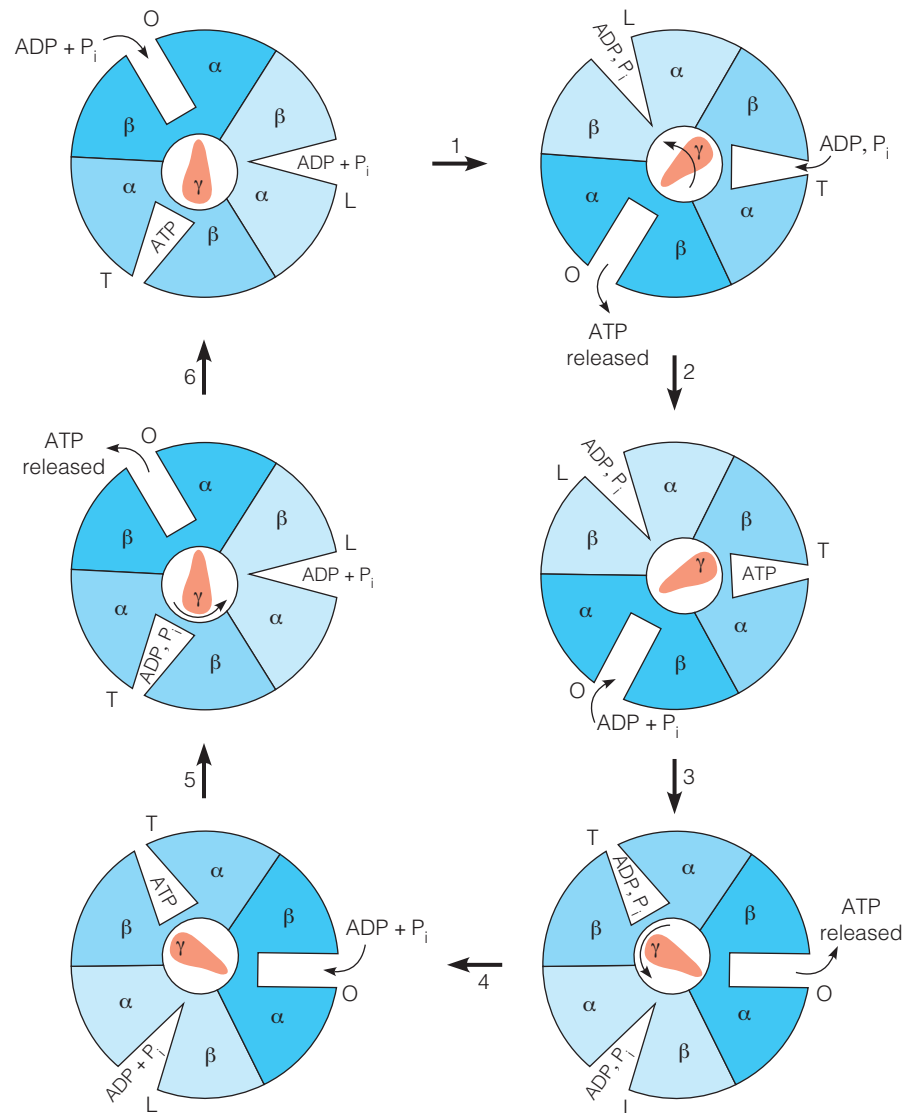

FIGURE 15.23

Binding change model for ATP synthase. The nucleotide binding site (catalytic site) of the three $\alpha\beta$ dimers exists in three different conformations, termed loose (L), tight (T), and open (O). In this scheme, the γ subunit rotates counterclockwise, driven by the passage of protons through channels in F_0 , while the $\alpha\beta$ dimer assemblies are held stationary by a stator. Each $\alpha\beta$ dimer is distinguished by a different color, with the catalytic sites shown at the interface of α and β subunits. Step 1 represents 120° rotation of the γ subunit, leading to a conformational change in all three $\alpha\beta$ dimers, such that the T site changes to an O site, leading to ATP release, and an O site changes to an L site, binding ADP and P_i . The third site changes from an L conformation, with loosely bound ADP and P_i , to a T conformation, where the substrates are tightly bound, leading to ATP formation in step 2. Steps 3 and 4, and steps 5 and 6, are just repeats of steps 1 and 2, except that the three conformations have migrated around the three $\alpha\beta$ dimers.

experiments in which the β subunits were immobilized to a glass coverslip and a fluorescent actin filament was attached to the γ protein (see Figure 15.24). α subunits were added, and F_1 complexes were allowed to assemble on the glass slide. When this structure was examined by fluorescence microscopy, the addition of ATP could be seen to stimulate the rotation of the fluorescent probe. Analysis showed the rotation to be counterclockwise (when viewed from the membrane) and to occur in discrete steps of 120°, just as predicted from the model. Rotation in a fully coupled F_1F_0 ATP synthase has now been observed in both synthesis and hydrolysis modes. The rotor turns counterclockwise in the ATP hydrolysis direction and clockwise in the ATP synthesis direction, when viewed from the membrane, and performs up to 700 revolutions per second (~100 revolutions per second in vivo).

How do protons flowing through the F_0 membrane component drive rotation of the γ subunit? As illustrated in Figure 15.21, the γ subunit is attached to the oligomer of c subunits (the c -ring) via the δ subunit. The a subunit is stationary in the membrane, anchoring the peripheral stalk stator subunits. The mechanism requires that the c -ring rotates relative to the stationary a subunit as protons flow from the intermembrane space through the complex into the matrix. Biochemical and crystallographic studies have identified putative access channels for proton movement through the a and c subunits of F_0 (Figure 15.25). Several charged residues lying in the center of the membrane are key players in the proton-transport mechanism. It was found that upon protonation of a specific acidic residue

F_1 ATP synthase functions as a three-cylinder rotary engine driven by the passage of protons through channels in F_0 .

FIGURE 15.24

The experimental system that permits observation of rotation in the F_1 component of F_0F_1 ATP synthase. (a) The cloned gene encoding the F_1 β subunit was modified by adding a sequence that encodes an oligohistidine sequence that binds to a nickel-coated bead (Ni-NTA coated bead) in the conformation shown. Thus, the F_1 complex was immobilized on the bead and attached to a glass coverslip. Streptavidin is a protein used to couple fluorescently-tagged actin to the γ subunit. (b) Fluorescence microscopic examination showed that, following addition of ATP and its subsequent hydrolysis by the $\alpha\beta$ catalytic subunits, the actin molecule was rotating, which proved that the γ subunit itself was rotating. The time interval between images is 133 ms.

FIGURE 15.26

Experimental demonstration of respiratory control.

Oxygen uptake is monitored in carefully prepared coupled mitochondria. The addition of an exogenous oxidizable substrate (glutamate) stimulates respiration only slightly, unless ADP + P_i is added as well. Both ADP additions represent limiting amounts; the second addition is twice the amount of the first, to show that the magnitude of oxygen uptake is stoichiometric. The slow oxygen uptake at the beginning results from endogenous substrates in the mitochondria. ADP stimulates respiration only until all of the ADP + P_i has been converted to ATP. Oxygen uptake is recorded in $\mu\text{moles O}$, because one pair of electrons reduces one atom of O, not one molecule of O_2 .

FIGURE 15.27

Effects of an inhibitor and an uncoupler on oxygen uptake and ATP synthesis.

The plot shows the results of an experiment in which an inhibitor and an uncoupler of oxidative phosphorylation were added to a mixture of isolated mitochondria, an oxidizable substrate (glutamate), and excess ADP + P_i . The red trace shows oxygen uptake; the blue trace represents ATP synthesis. The addition of oligomycin inhibits phosphorylation and consequently slows respiration. Dinitrophenol (DNP) uncouples respiration from phosphorylation so that O_2 uptake is stimulated even in the presence of oligomycin, but ATP synthesis remains blocked.

(glutamate in mitochondrial ATP synthase; aspartate in the bacterial enzymes), each c subunit undergoes a large rotation of its C-terminal helix, moving the protonated carboxylate to a more hydrophobic environment and generating rotation of the c-ring. As successive c subunits bind a proton, each protonated carboxylate interacts with subunit a, causing it to reionize, releasing the proton into the mitochondrial matrix. Thus, protonation/deprotonation reactions cause angular displacement of c versus a, resulting in net proton-driven c-ring rotation. Each 360° rotation produces three ATP molecules by F_1 and requires the translocation of one proton per each c subunit in the ring of F_0 .

Respiratory States and Respiratory Control

Like any metabolic process, oxidative phosphorylation can occur only in the presence of adequate quantities of its substrates. It is controlled not by allosteric mechanisms but by substrate availability and thermodynamics. Those substrates include ADP, P_i , O_2 , and an oxidizable metabolite that can generate reduced electron carriers—NADH and/or FADH_2 . Under different metabolic conditions any one of these four substrates can limit the rate of oxidative phosphorylation.

The dependence of oxidative phosphorylation on ADP reveals an important general feature of this process: *Respiration is tightly coupled to the synthesis of ATP.* Not only is ATP synthesis absolutely dependent on continued electron flow from substrates to oxygen, but electron flow in normal mitochondria occurs only when ATP is being synthesized as well. This regulatory phenomenon, called **respiratory control**, makes biological sense because it ensures that substrates will not be oxidized wastefully. Their utilization is controlled by the physiological need for ATP.

In most aerobic cells the level of ATP exceeds that of ADP by 4- to 10-fold. Thus, it is convenient to think of respiratory control as a dependence of respiration on ADP as a substrate for phosphorylation. If the energy demands on a cell cause ATP to be consumed at high rates, the resultant accumulation of ADP will stimulate respiration, with concomitant activation of ATP resynthesis. Conversely, in a relaxed and well-nourished cell, ATP accumulates at the expense of ADP, and the depletion of ADP limits the rate of both electron transport and its own phosphorylation to ATP. Thus, the energy-generating capacity of the cell is closely attuned to its energy demands.

Experimentally, respiratory control is demonstrated by following oxygen utilization in isolated mitochondria (Figure 15.26). In the absence of added substrate or ADP, oxygen uptake, caused by oxidation of endogenous substrates, is slow. Addition of an oxidizable substrate, such as glutamate or malate, has but a small effect on the respiration rate. If ADP is then added, however, oxygen uptake proceeds at an enhanced rate until all of the added ADP has been converted to ATP, and then oxygen uptake returns to the basal rate. This stimulation of respiration is stoichiometric; that is, addition of twice as much ADP causes twice the amount of oxygen uptake at the enhanced rate. If excess ADP is present instead of oxidizable substrate, the addition of substrate in limiting amounts will stimulate oxygen uptake until the substrate is exhausted.

Maintenance of respiratory control depends on the structural integrity of the mitochondrion. Disruption of the organelle causes electron transport to become uncoupled from ATP synthesis. Under these conditions, oxygen uptake proceeds at high rates even in the absence of added ADP. ATP synthesis is inhibited, even though electrons are being passed along the respiratory chain and used to reduce O_2 to water. Before carrying out experiments with freshly isolated mitochondria, biochemists usually ascertain that their mitochondria are tightly **coupled**, by determining rates of oxygen uptake in the presence and absence of added ADP. In carefully prepared mitochondria the ratio of these two O_2 uptake rates may be as high as 10. By contrast, aged or disrupted mitochondria may yield ratios as low as 1, showing an absence of coupling. Uncoupling of respiration from phosphorylation can also be achieved chemically. As noted earlier, uncouplers such as DNP or FCCP act by dissipating the proton gradient. Addition of an uncoupler to mitochondria stimulates oxygen utilization even in the absence of added ADP (Figure 15.27).

Another group of compounds, exemplified by the antibiotic oligomycin, act as inhibitors of oxidative phosphorylation. Addition of oligomycin to actively respiring, well-coupled mitochondria inhibits both oxygen uptake and ATP synthesis, as shown in Figure 15.27. However, no direct inhibition of electron transport occurs, as shown by the fact that subsequent addition of an uncoupler such as DNP greatly stimulates oxygen uptake.

Figures 15.26 and 15.27 show that blocking ATP synthesis either by depletion of substrate (ADP) or inhibition by oligomycin simultaneously blocks electron transport in coupled mitochondria. It is easy to visualize how inhibition of electron transport inhibits ATP synthesis because there is no proton gradient being formed. But how does inhibition of ATP synthesis block electron transport? Oligomycin inhibits ADP phosphorylation by binding to specific sites in the F_0 complex, blocking the flow of protons through the F_0 proton channel and thus blocking rotation of the c -ring. Likewise, depletion of ADP inhibits ATP synthesis by preventing the $\alpha\beta$ dimers from going through their catalytic cycles and the associated conformational changes. If these conformational changes are prevented, neither the γ subunit, nor the c -ring it is attached to, can rotate. Without rotation of these components, proton flow through F_0 is blocked. But why would blocking proton flow through the F_0 channel inhibit electron transport through the respiratory chain?

The answer is that these processes are *mechanically* coupled. Consider a simple hand-operated pump, like the ones our ancestors used to draw water from a well. You used your muscles to pump the handle up and down to pump water up out of the ground and out the faucet. Now what would happen if we attached a fire hose to the faucet and we used the diesel motor on the fire truck to pump water through the pump and down into the ground? What would happen to the pump handle? It would move (rapidly!) up and down because water flow (in either direction) is coupled to the mechanical movement of the pump handle. (Like ATP synthase, this pump is reversible—as mentioned earlier, ATP synthase was originally discovered as an ATPase.) What if we now held onto the pump handle, preventing it from moving? What would happen to the flow of water from the fire truck through the pump? It would stop, unless its pressure was greater than the force holding the handle (or the hose bursts!).

Using an inhibitor of ATP synthase (e.g., oligomycin) is like holding the pump handle. If we block the ATP synthase from going through its catalytic cycle, there can be no rotation of the c subunits in the F_0 complex in the membrane, and thus no flow of protons through the F_0 due to the mechanical coupling of these two processes. If there is no flow of H^+ from outside back into the matrix to dissipate the protonmotive force, the proton pressure ($\Delta\psi$) builds up on the outside of the membrane to the point where pumping protons out of the matrix is no longer favorable. That is, the thermodynamically favorable electron transport through these complexes cannot provide sufficient free energy to overcome the high opposing protonmotive force (i.e., $\Delta G_{e^- \text{ transport}} + \Delta G_{H^+ \text{ pumping}} = 0$). So

Dean Appling

The rate of electron transport is limited by the availability of ADP for conversion to ATP.

electron transport stops because it too is *mechanically* coupled to proton pumping through complexes I, III, and IV. Thus, the fundamental factor controlling the rate of respiration is the balance between ΔG for the phosphorylation of ADP (the ATP synthase reaction), ΔG for electron transport through the respiratory complexes, and ΔG for H^+ pumping (defined by the protonmotive force). If the free energy required to synthesize ATP is exactly balanced by the free energy available from the proton gradient, there will be no proton flow and no ATP synthesis (i.e., $\Delta G_{ATP\ synthesis} + \Delta G_{H^+ re-entry\ to\ matrix} = 0$). Now let's consider what happens when the cell begins to consume ATP to drive biosynthetic processes. As ATP is consumed, levels of ATP in the matrix will fall, thereby making ΔG for phosphorylation of ADP more favorable (i.e., $\Delta G_{ATP\ synthesis} + \Delta G_{H^+ re-entry\ to\ matrix} < 0$). ATP synthesis will then proceed, as will the coupled flow of protons through F_0 . This increased proton re-entry will reduce the thermodynamic barrier to electron transport (i.e., $\Delta G_{e^- transport} + \Delta G_{H^+ pumping} < 0$). This in turn leads to increased electron transport, and hence, respiration rate.

The reversibility of the ATP synthase poses a potential problem for the cell. In normally respiring mitochondria, the pmf is high, while the exchange of matrix ATP for ADP ensures that the matrix ATP/ADP ratio is held relatively low, favoring ATP synthesis (Figure 15.28a). However, when mitochondrial respiration is disturbed—for example, by hypoxia, or by proton leak across the inner membrane—the energetics can reverse. If the pmf falls below a threshold, and cytosolic ATP is available (e.g., from upregulated glycolysis), the adenine nucleotide translocase will import ATP into the matrix, increasing the ATP/ADP ratio. These conditions will favor ATP *hydrolysis*, and the ATP synthase can reverse, hydrolyzing ATP to pump protons out of the mitochondrial matrix (Figure 15.28b). If the respiratory disturbance is mild, or temporary, this reverse mode can sustain the pmf to support other processes, such as metabolite transport (see below) that require a proton gradient. However, if the loss of membrane potential is extreme, this reversal of ATP synthase will eventually deplete all cellular ATP, leading to cell death.

To prevent this potentially catastrophic outcome, operation of the F_1F_0 ATP synthase as a proton-translocating ATPase is limited by an endogenous mitochondrial F_1F_0 -ATPase inhibitor protein, IF_1 (inhibitor of F_1). IF_1 is a small (84 amino acids), highly conserved protein that inhibits the F_1F_0 -ATPase activity by binding directly to the α and β subunits of the F_1 component. IF_1 's inhibitory activity appears to be regulated by pH. During hypoxia, the cell relies mainly on homolactic fermentation for ATP production. The resulting lactic acid lowers the pH in the cytosol and mitochondria, activating the inhibitory function of IF_1 . Thus, under conditions of mild hypoxia, inhibition of F_1F_0 -ATPase by IF_1 preserves ATP at the expense of the membrane potential.

Under some natural conditions the ability to uncouple respiration from phosphorylation is highly desirable. Many mammals, particularly those that are born

FIGURE 15.28

Reversibility of F_1F_0 ATP synthase. (a) In normally respiring mitochondria, the pmf is high and ATP synthase operates in the direction of ATP synthesis. The ATP is exchanged for cytoplasmic ADP via the adenine nucleotide translocase (ant). (b) During hypoxia, the pmf falls, and the cell relies mainly on homolactic (or alcoholic) fermentation for ATP production. This ATP enters the matrix in exchange for ADP. F_1F_0 ATP synthase operates as a proton-translocating ATPase, pumping protons out of the matrix, temporarily sustaining the pmf to support other processes, such as metabolite transport.

hairless (including human infants), those that hibernate, and those that are cold-adapted, have special needs for maintenance of core body temperature. Such animals have a special tissue, called brown adipose tissue (BAT), in the neck and upper back. Mitochondria in this tissue are especially rich in respiratory electron carriers, particularly cytochromes, which give BAT its brown color. These mitochondria are specialized to generate heat from fat oxidation, metabolizing the acetyl-CoA in the citric acid cycle. The inner membranes of BAT mitochondria are rich in **uncoupling protein 1 (UCP1)**, a 33-kDa channel that allows protons to return to the matrix in a process that bypasses ATP synthase, thereby uncoupling electron transport from ATP synthesis. Thus, the energy that is derived from fat oxidation is dissipated as heat. Mammals express at least five different uncoupling proteins (UCP1–UCP5). Whereas the function and regulation of UCP1 in response to cold exposure by the sympathetic nervous system is well-understood, the physiological function of the other UCPs in other tissues, and the role of BAT in adults, remains an area of intense investigation.

A comparable phenomenon is seen in the plant world among species that emerge in early spring, often when the ground is still covered with snow. The floral spike of the skunk cabbage is a particularly dramatic example; this tissue can maintain a temperature some 10° to 25° above ambient temperature, by uncoupling oxidation from phosphorylation.

Mitochondrial Transport Systems

Whereas the mitochondrial outer membrane is freely permeable to molecules up to ~5000 Da, the permeability of the inner membrane is severely limited. The importance of this selective permeability can be seen from our discussions of electrochemical gradients and the shuttle systems used to transport reducing equivalents into the mitochondrion. We must also consider substrate transport, including the inward transport of intermediates for oxidation in the citric acid cycle, the export of intermediates used for biosynthesis in other cell compartments, and the exit of newly synthesized ATP. Properties of the principal mitochondrial transport systems are outlined in Figure 15.29. Because the matrix is negatively charged relative to the cytoplasm, it is energetically unfavorable for a negatively charged solute to enter the matrix. Consequently, mitochondrial carriers use cotransport with protons, or exchange with OH⁻, to import these metabolites. (Note: Additional systems transport fatty acids and amino acids into mitochondria for subsequent oxidation.) Most of these transporters are members of the mitochondrial carrier family (MCF).

First let us consider ATP, ADP, and P_i, the participants in oxidative phosphorylation. Two systems are involved, an **adenine nucleotide translocase (ADP/ATP carrier, or ANT)** and a **phosphate translocase**. The ADP/ATP carrier spans the inner membrane, and it binds ADP to a specific site on the outer surface of the inner membrane. The protein couples the efflux of free ATP from the matrix to the influx of an equivalent amount of free ADP from the intermembrane space (Mg-ADP and Mg-ATP are not substrates of the carrier). Because this antiporter exchanges ATP, with a charge of -4, for ADP, with a charge of -3, its action is driven by the membrane potential (outside positive). It is generally true of the mitochondrial transport systems that at least one of the participants is moving down a concentration gradient, or is coupled to the proton gradient so that no further energy source is required.

The phosphate translocase acts in either the *antiport* or the *symport* mode (see Chapter 10). As an antiporter, it transports H₂PO₄⁻ into the matrix, coupled with the efflux of a hydroxide ion. In the alternative symport mode, it transports HPO₄²⁻ into the matrix, along with two protons. Both modes of transport maintain electrical neutrality and are driven by the ΔpH component of the protonmotive force generated by electron transport. The net effect of the adenine nucleotide and phosphate transport systems is to couple the inward transport of the substrates of oxidative phosphorylation, ADP and P_i, to the efflux of the product, ATP.

FIGURE 15.29

Major inner membrane transport systems for respiratory substrates and products. The ADP/ATP carrier and the phosphate translocase move substrates for oxidative phosphorylation (ADP and P_i) into the mitochondrion and the product (ATP) out. Other transport systems move substrates and products for citric acid cycle oxidation into or out of the matrix, as dictated by the metabolic needs of the cell.

As might be expected by the critical role the ADP/ATP and phosphate carriers play in providing substrates for the ATP synthase, their deficiency in humans is usually characterized by exercise intolerance, muscular hypotonia, hypertrophic cardiomyopathy, elevated plasma lactate levels, and lactic acidosis.

Next, let us consider the substrates for oxidation. The major substrate from carbohydrate catabolism is pyruvate, which, like phosphate, is exchanged for OH^- . Dicarboxylic acid substrates—namely succinate, fumarate, and malate—can be exchanged for each other or for orthophosphate in the dicarboxylate transport system. Similarly, the tricarboxylate transport system carries either citrate or isocitrate, coupled each with the other or with a dicarboxylic acid or phosphoenolpyruvate. The influx of fatty acids for β -oxidation involves an additional transport system, which is presented in Chapter 17.

In addition to the transport systems shown in Figure 15.29, there is an important transport system for calcium ion. Ca^{2+} regulates a number of metabolic processes in the cytosol, and its release from mitochondrial stores may represent one way to change the cytosolic concentration of Ca^{2+} (see Chapter 23). Calcium is transported inward by a uniporter driven by the membrane potential, which is more negative inside. It is effluxed by exchange with Na^+ from the outside.

Shuttling Cytoplasmic Reducing Equivalents into Mitochondria

Another important role of mitochondrial carriers is to shuttle cytoplasmic reducing equivalents into the matrix for subsequent reoxidation by the respiratory chain. Recall that during aerobic glycolysis the NADH produced at the glyceraldehyde-3-phosphate dehydrogenase step is not reoxidized because pyruvate can be further oxidized in the citric acid cycle. To extract the energy from this NADH, and to regenerate oxidized NAD^+ for continued glycolysis, the reducing equivalents must be transferred into the mitochondrion. However, the NADH generated by a cytosolic NAD-linked dehydrogenase cannot itself traverse the mitochondrial membrane to be oxidized by the respiratory chain. Therefore, the reducing equivalents must be *shuttled* to respiratory assemblies in the inner mitochondrial membrane, without physical movement of the coenzyme. This process involves the reduction of a substrate by NADH in the cytoplasm, passage of the reduced substrate into the mitochondrial matrix via a specific transport system, reoxidation of that compound inside the matrix, and passage of the oxidized substrate back to the cytoplasm, where it can undergo the same cycle again.

The earliest known shuttle system is the dihydroxyacetone phosphate/glycerol-3-phosphate shuttle, which is particularly active in brain and skeletal muscle (and in the flight muscle of insects). As shown in Figure 15.30a, dihydroxyacetone phosphate (DHAP) is reduced by NADH in the cytosol, followed by reoxidation of the resultant glycerol-3-phosphate by a flavin-dependent glycerol-3-phosphate dehydrogenase, bound at the outer face of the inner mitochondrial membrane. This process involves reduction of FAD, followed by transfer of an electron pair from FADH_2 to coenzyme Q, just as intramitochondrial NADH transfers electrons to Q (see Figure 15.13). Once dihydroxyacetone phosphate has returned to the cytosol, the net effect has been to transfer two reducing equivalents from cytosolic NADH to mitochondrial FADH_2 and from there down the respiratory chain.

Electrons are transported into mitochondria by metabolic shuttles.

FIGURE 15.30

Shuttles for transfer of reducing equivalents from cytosol into mitochondria. (a) The dihydroxyacetone phosphate/glycerol-3-phosphate shuttle. (b) The malate/aspartate shuttle. Red arrows indicate flow of reducing equivalents. Glu = glutamate; Asp = aspartate; αKG = α -ketoglutarate.

A different shuttle system, particularly active in liver, kidney, and heart, is the malate/aspartate shuttle, shown in Figure 15.30b. Here, a cytosolic isozyme of malate dehydrogenase, together with NADH, reduces oxaloacetate to malate, which passes into the matrix via a specific α -ketoglutarate/malate exchanger in the inner mitochondrial membrane. The malate is reoxidized by the malate dehydrogenase of the citric acid cycle, which also uses NAD^+ . The resulting matrix NADH is then oxidized by complex I. Because oxaloacetate cannot cross the inner membrane, it is transaminated to aspartate, which is then transported out via a specific aspartate/glutamate exchanger. Once in the cytoplasm, aspartate is reconverted to oxaloacetate by transamination, to begin the cycle anew. Because of the transaminations involved, this process requires that α -ketoglutarate be continuously transported out of mitochondria and that glutamate be continuously transported in. This balance is ensured by the substrate specificity of the two exchangers.

Thus, in tissues that use the malate/aspartate shuttle, approximately 2.5 moles of ATP are generated per mole of cytoplasmic NADH. In tissues that use the dihydroxyacetone phosphate/glycerol-3-phosphate shuttle, only about 1.5 moles of ATP are generated per mole of NADH because those cytoplasmic reducing equivalents enter the respiratory chain at complex III (via QH_2), rather than at complex I.

Energy Yields from Oxidative Metabolism

Much of the past three chapters has been devoted to the pathways by which carbohydrates are oxidized to CO_2 and water. Finally, we are in a position to calculate the total energy yield and metabolic efficiency of these combined pathways. Let us review how much energy is recovered in the form of ATP from the entire oxidative catabolism of glucose. First, we present a balanced equation for each of the three pathways involved, and then we estimate the amount of ATP that can be derived through oxidative phosphorylation from the reduced electron carriers.

Glycolysis:

Pyruvate dehydrogenase complex:

Citric acid cycle (including conversion of GTP to ATP):

Net:

These three processes generate 4 moles of ATP directly, plus 10 moles of NADH and 2 moles of FADH_2 . Using P/O ratios for oxidation of NADH and FADH_2 of 2.5 and 1.5, respectively, the total realizable ATP yield is about 32 per mole of glucose oxidized [$4 + (2.5 \times 10) + (1.5 \times 2)$]. In prokaryotes and in cells using the malate/aspartate shuttle (see Figure 15.30b), the reducing equivalents from cytoplasmic glycolysis are carried into the mitochondrion with no energy cost. However, cells using the glycerol phosphate shuttle (see Figure 15.30a) must pay an energy cost because the electrons from cytosolic NADH enter the respiratory chain as FADH_2 . Therefore, the ATP yield from each of these two NADHs is ~ 1.5 , not 2.5. This decreases the overall ATP yield to 30 per mole of glucose. For the following discussion, we shall use 32 as the best estimate of total moles of ATP derived per mole of glucose oxidized. Recalling that $\Delta G^{\circ'}$ for glucose oxidation is -2870 kJ/mol (see Chapter 12, page 486) and that $\Delta G^{\circ'}$ for ATP hydrolysis is -30.5 kJ/mol , we can calculate the efficiency for operation of this biochemical machine: $(32 \times 30.5)/2870$, or $\sim 34\%$, under standard conditions. As noted earlier, ATP hydrolysis is worth 50–60 kJ/mol *in vivo*, and thus the efficiency in the cell is considerably higher.

The complete oxidation of 1 mole of glucose generates about 30–32 moles of ATP synthesized from ADP.

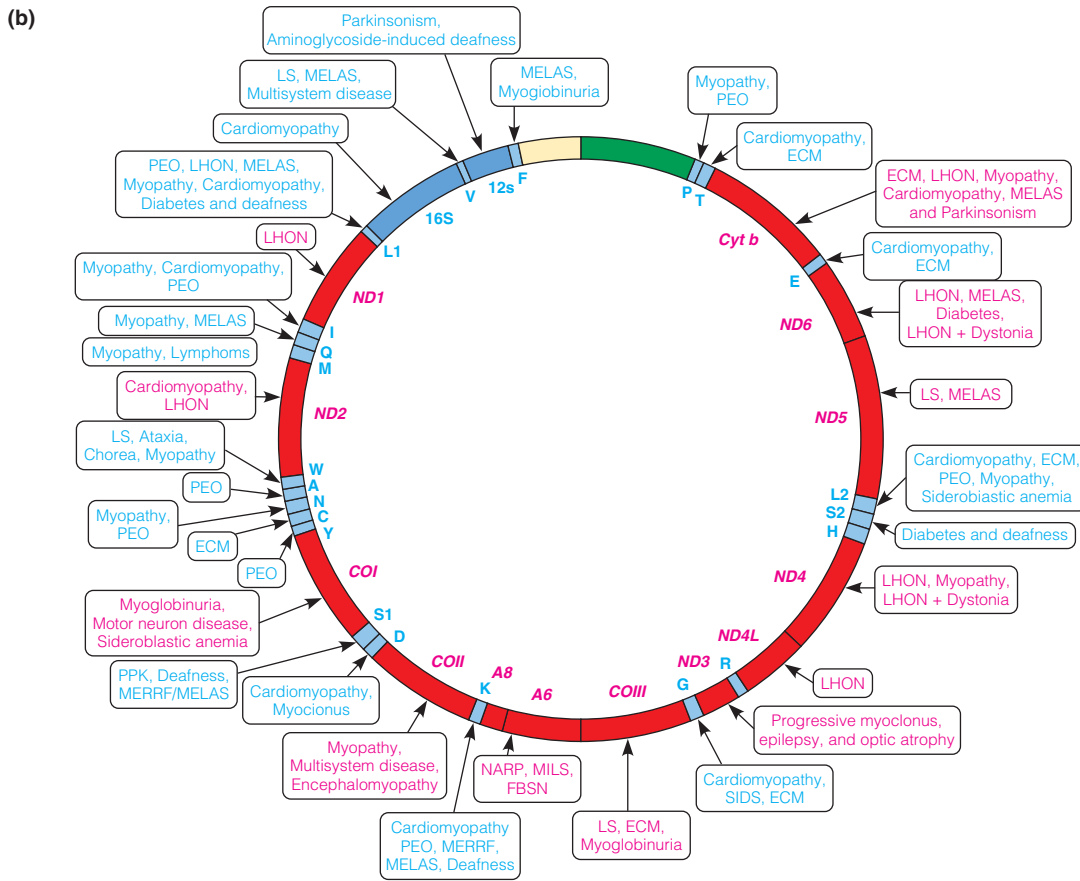

The Mitochondrial Genome and Disease

Mitochondria possess a double-stranded circular genome of approximately 16,500 bp in length. In humans, mitochondrial DNA (mtDNA) contains 37 genes that code for 13 proteins, all of which are subunits of the respiratory chain complexes (Figure 15.31a). Complexes I, III, IV, and V all contain some subunits encoded by mtDNA, whereas complex II and cytochrome *c* are encoded by nuclear DNA. The remaining mtDNA genes encode 22 tRNAs and 2 rRNAs. These tRNAs and rRNAs are part of the mitochondrial protein synthesis machinery, required to translate the 13 proteins encoded in the mtDNA. Of course, most of the proteins found in mitochondria (more than 900) are encoded by the nucleus, translated on cytoplasmic ribosomes, and then transported into the mitochondria.

FIGURE 15.31

Mitochondrial DNA and mitochondrial diseases. (a) The five multisubunit complexes of the respiratory chain are shown with mtDNA-encoded subunits in red and nuclear-encoded subunits in blue. (b) A morbidity map of the human mitochondrial genome. The 16,569-bp mtDNA shows the locations of the 13 protein-coding genes in red, the 12S and 16S ribosomal RNAs in dark blue, and the 22 transfer RNAs (identified by one-letter codes for the corresponding amino acids) in light blue. Diseases due to mutations in protein-coding genes are boxed in red; diseases due to mutations in mitochondrial protein synthesis components are boxed in blue.

Diseases that affect mitochondrial function (mitochondrial diseases) are probably quite common in humans—perhaps as much as 2% of the population has some mitochondrial defect. However, only a small number of these disorders are caused by mutations in mtDNA (~1 in 10,000 individuals). mtDNA mutations cause defects in the respiratory chain, either directly through mutations in one of the 13 structural genes (Figure 15.31a), or indirectly through mutations in a tRNA or rRNA gene. Many of these diseases involve brain and skeletal muscle, and are thus known as *mitochondrial encephalomyopathies*. A key feature of mtDNA diseases is that the tissues affected and the severity of the disease vary considerably among patients. This variability is due to the fact that each cell contains hundreds or thousands of mtDNA copies, which, at cell division, distribute randomly among daughter cells. If one of these mtDNAs becomes mutated, some daughter cells will inherit mutant mtDNA along with normal mtDNA. When a cell, tissue, or an individual has both normal and mutant mtDNA, it is said to be *heteroplasmic*. The clinical phenotype of a mtDNA mutation is largely determined by the relative proportion of normal and mutant mtDNA genomes in different tissues. A minimum number of mutant mtDNAs in a particular organ or tissue is generally required to cause mitochondrial dysfunction that is severe enough to result in disease. This is referred to as a *threshold effect*.

The “morbidity map” in Figure 15.31b shows the locations of mtDNA mutations and the mitochondrial encephalomyopathies they cause. These include LHON (Leber’s hereditary optic neuropathy), MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes), and MERRF (myoclonic epilepsy with ragged-red fibers). Although the clinical features of these disorders are quite variable, patients with mtDNA disease often exhibit progressive and disabling neurological problems, muscle weakness, chronic progressive ophthalmoplegia, and exercise-induced fatigue, all of which stem from defective respiration and ATP production.

As mentioned above, the majority of inherited mitochondrial diseases are due to mutations in nuclear genes. This is because efficient assembly and functioning of the respiratory chain requires a large number of nuclear-encoded proteins. For example, both the mitochondrial DNA polymerase and RNA polymerase are encoded by nuclear genes, as are all of the protein subunits of the mitochondrial ribosomes. More than 150 point mutations in the gene for the catalytic subunit of mitochondrial DNA polymerase (POLG) are linked with a wide variety of mitochondrial diseases, including progressive external ophthalmoplegia, Alpers’ syndrome, Parkinsonism, ataxia-neuropathy syndromes, and male infertility. In addition, there are a number of nuclear-encoded proteins required for mitochondrial dynamics (biogenesis, fission, fusion, degradation). Charcot-Marie-Tooth disease, Friedreich’s ataxia, and hereditary spastic paraplegia are examples of inherited diseases caused by mutations in genes required for these processes. Finally, there is a group of late-onset neurodegenerative diseases that all involve mitochondrial dysfunction, including Huntington’s disease, Alzheimer’s disease, and amyotrophic lateral sclerosis (ALS, also known as Lou Gehrig’s disease). The precise role of mitochondria in the pathogenesis of these hereditary neurodegenerative diseases is not yet understood, but is an area of intense investigation.

Mitochondria and Evolution

One of the biggest questions in evolutionary biology concerns the origin of mitochondria. Where did they come from? Although there are many theories, probably the most widely accepted one is the *endosymbiont hypothesis*. In this scenario, over a billion years ago an Archaea, perhaps a methanogen that used H_2 , entered into a symbiotic relationship with a facultative anaerobic α -proteobacterium, perhaps one that produced H_2 . Eventually, the Archaeal host completely engulfed the α -proteobacterium, without killing it. In this endosymbiotic relationship, the host supplied the endosymbiont with oxidizable substrates, and the endosymbiont in turn supplied the host with energy (ATP). This relationship was sealed forever as

most of the genes of the endosymbiont were transferred to the host genome, giving rise to the first eukaryotic cell, with mitochondria representing the modern descendants of the original α -proteobacterium.

Oxygen as a Substrate for Other Metabolic Reactions

In most cells, at least 90% of the molecular oxygen consumed is utilized for oxidative phosphorylation. The remaining O_2 is used in a wide variety of specialized metabolic reactions. At least 200 known enzymes use O_2 as a substrate. Because O_2 is rather unreactive, virtually all of these 200 enzymes use a metal ion to enhance the reactivity of oxygen, just as cytochrome oxidase does. In this section we briefly categorize these enzymes, and we consider the metabolism of partially reduced forms of oxygen, which arise continually in all cells and are highly toxic because of their great reactivity.

Oxidases and Oxygenases

The term **oxidase** is applied to enzymes that catalyze the oxidation of a substrate *without* incorporation of oxygen from O_2 into the product. A two-electron oxidation is usually involved, so the oxygen is converted to H_2O_2 . Most oxidases utilize either a metal or a flavin coenzyme. D-Amino acid oxidases, for example, use FAD as a cofactor.

Oxygenases are enzymes that incorporate oxygen atoms from O_2 into the oxidized products; there are two classes—monooxygenases and dioxygenases. **Dioxygenases**, which incorporate both atoms of O_2 into one substrate, are of limited distribution. An example is tryptophan 2,3-dioxygenase, which contains a heme cofactor and catalyzes the first reaction in tryptophan catabolism:

Far more widely distributed are **monooxygenases**, which incorporate one atom from O_2 into a product and reduce the other atom to water. A monooxygenase has one substrate that accepts oxygen and another that furnishes the two H atoms that reduce the other oxygen to water. Because two substrates are oxidized, enzymes of this class are also called **mixed-function oxidases**. The general reaction catalyzed by monooxygenases is as follows:

Because the substrate AH usually becomes hydroxylated by this class of enzymes, the term **hydroxylase** is also used. An example of this type of reaction is the hydroxylation of steroids. Here the reductive cofactor, NADPH, appears as BH_2 .

Several compounds other than NADPH/ H^+ function as BH_2 in monooxygenase reactions, including α -ketoglutarate, as in the hydroxylation of phytanoyl-CoA (Chapter 17) or collagen proline residues (Chapter 21).

Oxidases and oxygenases are enzymes that use O_2 as a substrate.

Cytochrome P450

Cytochromes P450 catalyze hydroxylations of numerous unreactive substrates, making them easier to metabolize.

The most numerous hydroxylation reactions involve a superfamily of heme proteins with the collective name **cytochrome P450**, found in nearly all organisms, from bacteria to mammals. The human genome contains 57 different structural genes for cytochromes P450, making this a large and diverse protein family. These proteins resemble hemoglobin and mitochondrial cytochrome oxidase in being able to bind both O_2 and carbon monoxide. Cytochromes P450 are distinctive, however, in that the reduced form of the heme, when complexed with carbon monoxide, absorbs light strongly at 450 nm. A common structural feature of cytochromes P450 is a cysteine thiolate ion, in which the sulfur occupies one of the six coordination positions with the heme iron (Figure 15.32a). The other ligands are the four pyrrole nitrogens of the protoporphyrin IX in heme and the bound oxygen. Not all proteins with the cysteinyl-heme configuration, however, are classified as cytochromes P450. This same structural motif is used, for example, by thromboxane synthase (page 814)

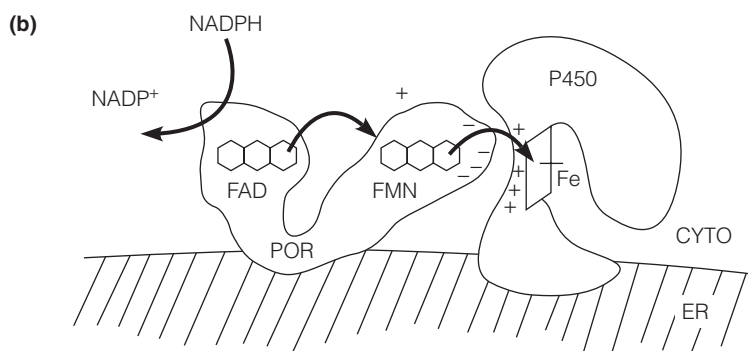

FIGURE 15.32

Cytochrome P450. (a) Active site of human cytochrome P450 2A6 in complex with the anticoagulant coumarin (PDB ID 1Z10). The Fe atom of the heme (shown edgewise) is axially liganded to Cys349. The coumarin substrate (purple) is on the opposite face of the heme. (b) The flavoprotein enzyme P450 oxidoreductase (POR) delivers electrons one at a time from NADPH to cytochrome P450.

L. Miller, Genetics of P450 oxidoreductase: Sequence variation in 842 individuals of four ethnicities and activities of 15 missense mutants.

and nitric oxide synthase (page 884). Type I cytochromes P450 are found in bacteria and mitochondria. The more common type II enzymes are found embedded in the endoplasmic reticulum membrane of eukaryotic cells.

Cytochromes P450 are involved in hydroxylating a large variety of compounds. These reactions include the hydroxylations in steroid hormone biosynthesis (see Chapter 19) and the synthesis of hydroxylated fatty acids and fatty acid epoxides. In addition, cytochromes P450 act upon thousands of **xenobiotics** (foreign compounds), including drugs such as phenobarbital and environmental carcinogens such as benzo[*a*]pyrene, a constituent of tobacco smoke, or aflatoxin B₁, a carcinogenic compound produced by a mold and found in peanuts that have not been properly screened. Hydroxylation of foreign substances usually increases their solubility and is an important step in their detoxification, or metabolism and excretion. However, some of these reactions result in activation of potentially carcinogenic substances to more reactive species, as shown for aflatoxin B₁, which is converted to more reactive species either by hydroxylation or epoxidation (see margin).

A key to the reactivity of cytochrome P450 is its ability to split O₂, with one oxygen atom binding to the cytochrome's heme iron. This bond forms a **perferryl iron–oxygen complex** (FeO³⁺). This highly reactive group can abstract a hydrogen atom, even from an unreactive substrate such as a hydrocarbon. In such a hydroxylation, reducing equivalents are typically transferred to the cytochrome from NADPH, the usual electron donor in hydroxylation reactions, via a flavoprotein, P450 oxidoreductase (POR) (Figure 15.32b).

Cytochrome P450 systems participate in a wide variety of additional reactions, including epoxidation, peroxygenation, desulfuration, dealkylation, deamination, and dehalogenation. These reactions are particularly active in liver, where a number of cytochromes P450 are inducible; that is, their synthesis is stimulated by substrates that are metabolized by these enzymes. Inducers include drugs such as phenobarbital and other barbiturates.

Reactive Oxygen Species, Antioxidant Defenses, and Human Disease

Formation of Reactive Oxygen Species

As we have seen, the terminal step in electron transport is the four-electron reduction of O₂ to water. Cytochrome oxidase, like most oxidases, transfers electrons to oxygen from metal ions that change their valence states by one electron at a time—such as the heme iron and copper in cytochrome oxidase. Because the interactions of one-electron carriers with two-electron carriers are rarely 100% efficient, oxidases often generate incompletely reduced oxygen species—**superoxide** (O₂^{•−}), formed from a one-electron reduction of O₂; hydrogen peroxide (H₂O₂), formed from a two-electron reduction; and **hydroxyl radical** (OH[•]), formed via a three-electron reduction (Figure 15.33). In addition, some enzymes, such as xanthine oxidase (Chapter 22) and amino acid oxidases (page 840), generate hydrogen peroxide as their ordinary products. Superoxide, peroxide, and hydroxyl radical are all more reactive than oxygen and are referred to collectively as **reactive oxygen species** (ROS). Hydroxyl radical is particularly reactive and is responsible for damage to other biological molecules. Hydroxyl radical damages proteins in various ways and damages membranes by initiating the oxidation of fatty acids in membrane lipids, a process termed **lipid peroxidation**. As shown in the margin on the following page, lipid peroxidation is a chain reaction because each fatty acyl moiety that undergoes peroxidation generates a radical that can initiate another peroxidation reaction. Hydroxyl radical also damages nucleic acids, both by causing polynucleotide strand breakage (double-stranded DNA breaks are lethal) and by changing the structure of DNA bases. About 20 different base changes, or DNA lesions, are known to result from reactions of hydroxyl radical with DNA. Some lesions are

Partially reduced oxygen species—superoxide, peroxide, and hydroxyl radical—are extremely toxic. Their toxicity is counteracted by both enzymatic and nonenzymatic mechanisms.

FIGURE 15.33

Reactive oxygen species (ROS). The generation and interconversion of the most common reactive oxygen species are shown. O₂^{•−}, superoxide; OH[•], hydroxyl radical; NO[•], nitric oxide; ONOO[−], peroxynitrite; Q, oxidized coenzyme Q; QH[•], semiquinone radical; H₂O₂, hydrogen peroxide.

mutagenic because the altered base created (such as **8-oxoguanine**, see margin) forms non-Watson–Crick base pairs during DNA replication. Other lesions, such as **thymine glycol**, are potentially lethal because, unless the lesion is repaired (Chapter 26), their occurrence in DNA blocks replication past that site. Hydroxyl radical is the most active mutagen derived from ionizing radiation. Hydroxyl radical is also produced from H_2O_2 in the Fenton reaction:

Superoxide per se is relatively nontoxic. However, because it contains an unpaired electron, it is a free radical, and it combines readily with another free radical, **nitric oxide** (NO^\bullet) (Figure 15.33), a biological signaling agent that is produced in many animal tissues (Chapters 7, 21, and 23). The product is **peroxynitrite** (OONO^-), also considered a reactive oxygen species. Peroxynitrite causes lipid peroxidation and also causes nitration of tyrosyl hydroxyl groups in proteins, a reaction particularly damaging to membrane proteins.

Normal cellular metabolism produces ROS, and mitochondria are an important source of these ROS. It was initially estimated that as much as 1–2% of all the electrons that start down the respiratory chain never make it to cytochrome oxidase but leak from complexes I, II, and III, and bring about one-electron reductions of oxygen to superoxide. It is now generally accepted that these in vitro experiments overestimated the in vivo production of superoxide and hydrogen peroxide by at least two orders of magnitude. Indeed, there is growing evidence that ROS constitute a second messenger system that fine tunes cellular energy metabolism in response to changes in redox status and mitochondrial function. There are even some cases where overproduction of reactive oxygen species is a normal part of the functioning of a cell. For example, certain white blood cells contribute to defense against infectious agents by **phagocytosis** (Greek, “cell eating”). Such cells can engulf a bacterial cell. This event is followed by a **respiratory burst**, a rapid increase in oxygen uptake. In a deliberate and controlled process, much of this oxygen is reduced to superoxide ion and to H_2O_2 . The hydrogen peroxide is then converted to more reactive oxidants such as hypochlorous acid (HOCl), which help to kill the engulfed bacterium.

However, uncontrolled overproduction of reactive oxygen species has the potential to inflict considerable damage on the tissues in which they are produced, a situation called **oxidative stress**. A series of elaborate mechanisms has evolved to minimize its harmful consequences.

Lipid peroxidation

8-Oxoguanine

Thymine glycol

Dealing with Oxidative Stress

As discussed in Chapter 16, the earth had an anaerobic atmosphere for its first billion years, and oxygen was intensely toxic to all life forms existing at that time. With the evolution of oxygen in our atmosphere, life forms developed both enzymatic and nonenzymatic defenses against oxidative stress. The nonenzymatic protection is afforded by **antioxidant** compounds, including glutathione (Chapter 13), vitamins C and E, and **uric acid**, an end product of purine metabolism (Chapter 22). These compounds can scavenge ROS before they can cause damage, or they can prevent oxidative damage from spreading. For example, trapping one radical can break a chain in which multiple fatty acyl moieties would otherwise be damaged in lipid peroxidation. Vitamin E, a family of compounds in which α -tocopherol is most common, is the principal lipid-soluble antioxidant compound and plays an important role in preventing membrane damage. β -Carotene and other carotenoid compounds related to vitamin A (page 808) are lipid-soluble antioxidants that also play roles in free radical trapping. Glutathione, as noted in Chapter 13, is abundant within cells and plays a particularly important role in cellular antioxidant protection. Vitamin C, or **ascorbic acid**, is an important antioxidant by virtue of its water solubility and its ready oxidation to dehydroascorbic acid. In extracellular fluids, ascorbate levels are far higher than those of glutathione,

and ascorbate probably plays the predominant role in extracellular antioxidant protection. Recent evidence suggests that a major antioxidant role of uric acid is its ability to bind and inactivate peroxynitrite.

Among enzymatic mechanisms the first line of defense is **superoxide dismutase (SOD)**, a family of metalloenzymes that catalyze a **dismutation** (a reaction in which two identical substrate molecules have different fates). Here, one molecule of superoxide is oxidized and one is reduced.

A copper- and zinc-containing form of this enzyme (SOD1) is found in the cytosol of eukaryotic cells; a manganese-containing form (MnSOD) is found in both mitochondria and bacterial cells; and a related iron-containing form is found in bacteria, cyanobacteria, and some plants. A nickel-containing bacterial SOD has recently been described.

Hydrogen peroxide is metabolized either by **peroxiredoxins**, a ubiquitous family of thiol proteins, **catalase**, another widely distributed enzyme, or by a more limited family of **peroxidases**. Peroxiredoxins are found in all domains of life, and these abundant enzymes can be located in the cytosol, in mitochondria, in chloroplasts and peroxisomes, and associated with nuclei and membranes. Peroxiredoxins play an antioxidant role through their peroxidase activity:

These enzymes can reduce and detoxify not only hydrogen peroxide, but also peroxynitrite and a wide range of organic hydroperoxides (ROOH). The catalytic mechanism involves oxidation of an active site cysteine to a sulfenic acid (S-OH) by the peroxide substrate. The sulfenic acid must then be reduced back to the thiol state by a disulfide reductase, with electrons provided by a dithiol such as thioredoxin.

Catalase is a heme protein with an extremely high turnover rate (>40,000 molecules per second). It catalyzes the following reaction:

Peroxidases, which are widely distributed in plants, reduce H_2O_2 to water at the expense of oxidation of an organic substrate. An example of a peroxidase is found in erythrocytes, which are especially sensitive to peroxide accumulation. (See pages 581–584 in Chapter 13 for a discussion of the consequences of peroxide accumulation in glucose-6-phosphate dehydrogenase deficiency.) Within erythrocytes is *glutathione peroxidase*, an enzyme that reduces H_2O_2 to water, along with the oxidation of glutathione.

Glutathione peroxidase is interesting in that it contains one residue per mole of an unusual amino acid, *selenocysteine* (Chapter 5), an analog of cysteine that contains selenium in place of sulfur (more on this in Chapter 27).

Oxygen Metabolism and Human Disease

Because oxidative stress can damage many biomolecules—lipids, proteins, and nucleic acids—the tissue injury that results can, in principle, lead to a variety of disease states. Oxidative damage has been implicated in many different human disorders, including cardiovascular disease, cancer, stroke, neurodegenerative diseases, chronic inflammatory diseases, and even aging. Determining precise cause-and-effect relationships is difficult at this stage, and it is clear that in some states, oxidative stress is not a cause but rather a result of tissue injury from some other factor, which exacerbates the original problem. However, epidemiological evidence points strongly to the value of adequate dietary intake of natural antioxidant compounds in preventing many of these diseases. The evident health-promoting effects of diets rich in fresh fruits and vegetables, particularly with respect to incidence of cardiovascular disease and cancer, probably result in large part from their high content of antioxidant compounds, particularly

vitamins C and E. Many people now take dietary supplements of vitamins C and E as a preventive measure.

Whatever the cause-and-effect relationship between oxidative damage and disease, there is little doubt that the DNA damage caused by ionizing radiation, which is known to be carcinogenic, is mediated through the mutagenic effects of hydroxyl radicals. In addition, hydroxyl radicals are generated by oxidizing agents independent of radiation effects. As discussed in Chapters 23 and 25, cancer is clearly a genetic disease, resulting from an accumulation within a precancerous cell of mutations that ultimately destroy the cell's ability to regulate its own growth and its programmed death (apoptosis). The generation of altered bases in DNA, such as 8-oxoguanine or 5-hydroxycytosine, is intensely mutagenic. Even though such lesions are usually removed by DNA repair systems (Chapter 26), the repair systems are not 100% effective, and with time the accumulation of unrepaired DNA damage can contribute to the burden of mutations that ultimately transform a normal cell to a cancer cell. Partly because cancer incidence is strongly correlated with age, many scientists also attribute normal aging to the accumulation of unrepaired mutagenic DNA lesions, and oxidative stress is implicated in what has been called the "free radical theory of aging."

SUMMARY

Most of the energy captured for ATP synthesis from oxidative reactions in cells is generated in mitochondrial oxidative phosphorylation. Reduced electron carriers, both NADH and FADH₂, shuttle reducing equivalents in the mitochondrial matrix. Enzyme complexes bound to the inner mitochondrial membrane pass these electrons through the respiratory chain, a series of electron carriers of ever-increasing reduction potential. The complexes are numbered I (NADH dehydrogenase), II (succinate-coenzyme Q oxidoreductase), III (coenzyme Q-cytochrome *c* oxidoreductase), IV (cytochrome *c* oxidase), and V (ATP synthase). Electrons are eventually transferred to O₂, which is reduced to water. The redox reactions of complexes I, III, and IV provide energy to pump protons from the matrix across the inner membrane, generating an electrochemical gradient termed the protonmotive force. Discharge of the resultant proton gradient, when protons pass back into the matrix through a specific ion channel, generates energy that is used to drive ATP synthesis. Although respiration accounts for about 90% of the total oxygen uptake in most cells, in numerous other reactions dozens of enzymes use O₂ as a substrate—oxygenases, oxidases, and hydroxylases. Some reactions generate partially reduced oxygen species—as hydroxyl radical, superoxide, and peroxide—termed reactive oxygen species, which are toxic and mutagenic. Cells possess numerous mechanisms for detoxification of these reactive oxygen species.

PROBLEMS

- Referring to Table 15.1 for E'_0 values, calculate $\Delta G'^{\circ}$ for oxidation of malate by malate dehydrogenase.
- When pure reduced cytochrome *c* is added to carefully prepared mitochondria along with ADP, P_i , antimycin A, and oxygen, the cytochrome *c* becomes oxidized, and ATP is formed, with a P/O ratio approaching 1.0.
 - Indicate the probable flow of electrons in this system.
 - Why was antimycin A added?
 - What does this experiment tell you about the location of coupling sites for oxidative phosphorylation?
 - Write a balanced equation for the overall reaction (including cytochrome *c* oxidation and ATP synthesis).
 - Calculate ΔG° , for the above reaction, using E'_0 values from Table 15.1 and a ΔG° value for ATP hydrolysis of -30.5 kJ/mol.
- Freshly prepared mitochondria were incubated with β -hydroxybutyrate, oxidized cytochrome *c*, ADP, P_i , and cyanide. β -Hydroxybutyrate is oxidized by an NAD^+ -dependent dehydrogenase.

The experimenter measured the rate of oxidation of β -hydroxybutyrate and the rate of formation of ATP.

- Indicate the probable flow of electrons in this system.
 - How many moles of ATP would you expect to be formed per mole of β -hydroxybutyrate oxidized in this system?
 - Why is β -hydroxybutyrate added rather than NADH?
 - What is the function of the cyanide?
 - Write a balanced equation for the overall reaction occurring in this system (electron transport and ATP synthesis).
 - Calculate the net standard free energy change ($\Delta G'^{\circ}$) in this system, using E'_0 values from Table 15.1 and a $\Delta G'^{\circ}$ value for ATP hydrolysis of -30.5 kJ/mol.
- If you were to determine the P/O ratio for oxidation of α -ketoglutarate, you would probably include some malonate in your reaction system. Why? Under these conditions, what P/O ratio would you expect to observe?
 - Of the various oxidation reactions in glycolysis and the citric acid cycle, the only one that does not involve NAD^+ is the succinate dehydrogenase reaction. What would $\Delta G'^{\circ}$ be for an enzyme that oxidizes succinate with NAD^+ instead of FAD? If the intramitochondrial concentration of succinate was 10-fold higher than that of fumarate, what minimum $[NAD^+]/[NADH]$ ratio in mitochondria would be needed to make this reaction exergonic at 37°C ?
 - Intramitochondrial ATP concentrations are about 5 mM, and phosphate concentration is about 10 mM. If ADP is five times more abundant than AMP, calculate the molar concentrations of ADP and AMP at an energy charge of 0.85. Calculate ΔG for ATP hydrolysis at 37°C under these conditions. The energy charge is the concentration of ATP plus half the concentration of ADP divided by the total adenine nucleotide concentration:

$$\frac{[\text{ATP}] + 1/2[\text{ADP}]}{[\text{ATP}] + [\text{ADP}] + [\text{AMP}]}$$

- From E'_0 values in Table 15.1, calculate the equilibrium constant for the glutathione peroxidase reaction at 37°C .
- In the early days of "mitochondriology," P/O ratios were determined from measurements of volume of O_2 taken up by respiring mitochondria and chemical assays for disappearance of inorganic phosphate. Now, however, it is possible to measure P/O ratios simply with a recording oxygen electrode. How might this be done?
- Years ago there was interest in using uncouplers such as dinitrophenol as weight control agents. Presumably, fat could be oxidized without concomitant ATP synthesis for re-formation of fat or carbohydrate. Why was this a bad idea?
- Referring to Figure 15.18, predict the P/O ratio for oxidation of ascorbate by isolated mitochondria.
- As a representation of the respiratory chain, what is wrong with this picture? There are four deliberate errors.

- $GSSG + NADPH + H^+ \rightarrow 2GSH + NADP^+$
 - Calculate $\Delta G'^{\circ}$ for the glutathione reductase reaction in the direction shown, using E'_0 values from Table 15.1.
 - Suppose that a cell contained an isoform of glutathione reductase that used NADH instead of NADPH as the reductive coenzyme. Would you expect $\Delta G'^{\circ}$ for this enzyme to be higher, lower, or the same as the corresponding value for the real glutathione reductase? Briefly explain your answer.
 - Given what you know about the metabolic roles and/or intracellular concentration ratios of $NAD^+ / NADH$ and $NADP^+ / NADPH$, would you expect ΔG (not $\Delta G'^{\circ}$) for this enzyme to be higher, lower, or the same as ΔG for the real enzyme under intracellular conditions? Briefly explain your answer.
- To carefully prepared mitochondria were added succinate, oxidized cytochrome *c*, ADP, orthophosphate, and sodium cyanide. Referring to Figures 15.9 and 15.18, answer the following.
 - List the sequence of electron carriers in this system.
 - Write a balanced equation for the overall reaction occurring in this system, showing oxidation of the initial electron donor, reduction of the final acceptor, and synthesis of ATP.
 - Calculate $\Delta G'^{\circ}$ for the overall reaction. $\Delta G'^{\circ}$ for ATP hydrolysis is -30.5 kJ/mol.
 - Why was cyanide added in this experiment?
 - What would the P/O ratio be if the same experiment were run with addition to the mitochondria of 2,4-dinitrophenol?
- In order to function as an oxidative phosphorylation uncoupler (page 648), 2,4-dinitrophenol must act catalytically, not stoichiometrically. What does this mean? Identify and discuss an important implication of this conclusion.

15. (a) Calculate the standard free energy change as a pair of electrons is transferred from succinate to molecular oxygen in the mitochondrial respiratory chain.

(b) Based on your answer in part (a), calculate the maximum number of protons that could be pumped out of the matrix into the intermembrane space as these electrons are passed to oxygen. Assume 25 °C, $\Delta p\text{H} = 1.4$; $\Delta\psi = 0.175 \text{ V}$ (matrix negative).

(c) At which site(s) are these protons pumped?

16. Four electron carriers, a, b, c, and d, whose reduced and oxidized forms can be distinguished spectrophotometrically, are required for respiration in a bacterial electron-transport system. In the presence of substrates and oxygen, three different inhibitors block respiration, yielding the patterns of oxidation states shown below. What is the order of the carriers in the chain from substrates to O_2 , and where do the three inhibitors act?

Inhibitor	Carriers			
	a	b	c	d
1	O	O	R	O
2	R	R	R	O
3	O	R	R	O

O and R indicate fully oxidized and fully reduced, respectively.

17. Biochemists working with isolated mitochondria recognize five energy “states” of mitochondria, depending on the presence or absence of essential substrates for respiration— O_2 , ADP, oxidizable substrates, and so forth. The characteristics of each state are:

state 1: mitochondria alone (in buffer containing P_i)

state 2: mitochondria + substrate, but respiration low due to lack of ADP

state 3: mitochondria + substrate + limited amount of ADP, allowing rapid respiration

state 4: mitochondria + substrate, but all ADP converted to ATP, so respiration slows

state 5: mitochondria + substrate + ADP, but all O_2 used up (anoxia), so respiration stops

(a) On the graph, identify the state that might predominate in each stage of the trace indicated with a letter.

(b) To determine whether isolated mitochondria exhibit respiratory control, one determines the ratio of rates of oxygen uptake in two different states. Which states?

(c) Which state probably predominates in vivo in skeletal muscle fatigued from a long and strenuous workout?

(d) Which state probably predominates in resting skeletal muscle of a well-nourished animal?

(e) Which state probably predominates in heart muscle most of the time?

CHAPTER 16

Photosynthesis

In earlier chapters, we described in considerable detail the ways in which organisms extract a substantial portion of the energy available from the oxidation of carbohydrates. Using glucose as an example, we wrote for the overall reaction:

We noted that as much as 40% of this energy could be recovered for useful biochemical work.

But life cannot depend on oxidative metabolism as its ultimate source of energy, and it cannot continue indefinitely returning organic carbon to the atmosphere as CO_2 . The reaction above is only half of the great energy–carbon cycle of nature (Figure 16.1). The reverse of the carbohydrate oxidation reaction is accomplished by plants, algae, and some microorganisms, using the energy from sunlight to provide the enormous amount of free energy required.

Photosynthesis provides carbohydrates for energy production, fixes CO_2 , and is the major source of atmospheric O_2 .

This process is called **photosynthesis**. Not only does it provide carbohydrates for energy production in plants and animals, but it is also the major path through which carbon re-enters the biosphere—that is, the principal means of carbon fixation. Furthermore, photosynthesis is the major source of oxygen in the earth's atmosphere.

Prior to the evolution of photosynthetic organisms, the earth's atmosphere was probably devoid of oxygen (though rich in carbon dioxide). Prephotosynthetic organisms must have used hydrogen/electron donors, such as H_2S , NH_3 , Fe^{2+} , and organic acids, which were in limited supply compared to water. Without the advent of photosynthesis, these energy sources would have eventually been wholly consumed, and life would have perished. Photosynthesis provided life with an unlimited supply of reducing equivalents (the oceans of water) needed to convert carbon dioxide into carbohydrates and the other organic molecules necessary for life.

FIGURE 16.1

The carbon cycle in nature. Carbon dioxide and water are combined through photosynthesis to form carbohydrates. In both photosynthetic and nonphotosynthetic organisms these carbohydrates can be reoxidized to regenerate CO_2 and H_2O . Part of the energy obtained from both photosynthesis and fuel oxidation is captured in ATP.

The fossil and geochemical records suggest that photosynthetic organisms first appeared approximately 3.4 billion to 2.3 billion years ago. Their gradual conversion of the primitive, nonoxidizing atmosphere of the earth to an oxidizing atmosphere paved the way for aerobic metabolism and the evolution of animals. Today, photosynthesis represents the ultimate source of energy for almost all life.* It is used by plants, algae, and a wide variety of prokaryotes—all of which are food sources for other organisms. A comprehensive view of the relationship of photosynthesis to other pathways we have studied is shown in Figure 16.2.

The Basic Processes of Photosynthesis

The equation we have just shown for the photosynthetic reaction is, of course, a great oversimplification. As you might expect, the actual process of photosynthesis involves many intermediate steps. Furthermore, a hexose itself is not the primary carbohydrate product. Therefore, the photosynthetic reaction is usually written in this more general form:

where $[\text{CH}_2\text{O}]$ represents a general carbohydrate.

Because the catabolism of carbohydrates to form CO_2 is an oxidative process, converting CO_2 into carbohydrate must involve a *reduction* of the carbon. The preceding reaction statement shows H_2O as the ultimate reducing agent, which is the case in plants, most algae, and cyanobacteria. However, there are photosynthetic processes in many bacteria that use other reductants. Thus, an even more general reaction can be written:

where H_2A is a general reductant and A is the oxidized product. Examples of photosynthetic reactions are given in Table 16.1. Comparison of the reactions shown in the table suggests that the source of the oxygen released in photosynthesis by plants, algae, and cyanobacteria must be H_2O , rather than CO_2 . This source was predicted in the early 1930s by C. B. van Niel, one of the pioneers in photosynthesis studies, and was confirmed in 1941 by Samuel Ruben and Martin

Photosynthesis requires a reductant, usually H_2O , to reduce CO_2 to the carbohydrate level.

*Recent developments make it necessary to qualify the statement that all life derives its energy, directly, from photosynthesis. It has been found that some bacteria, such as those associated with submarine “black smoker” hydrothermal vents, use the oxidation of substances like H_2S , formate, or H_2 as an alternate energy source, in the complete absence of light. This energy cycle represents, however, only a small fraction of the energy flow in the biosphere.

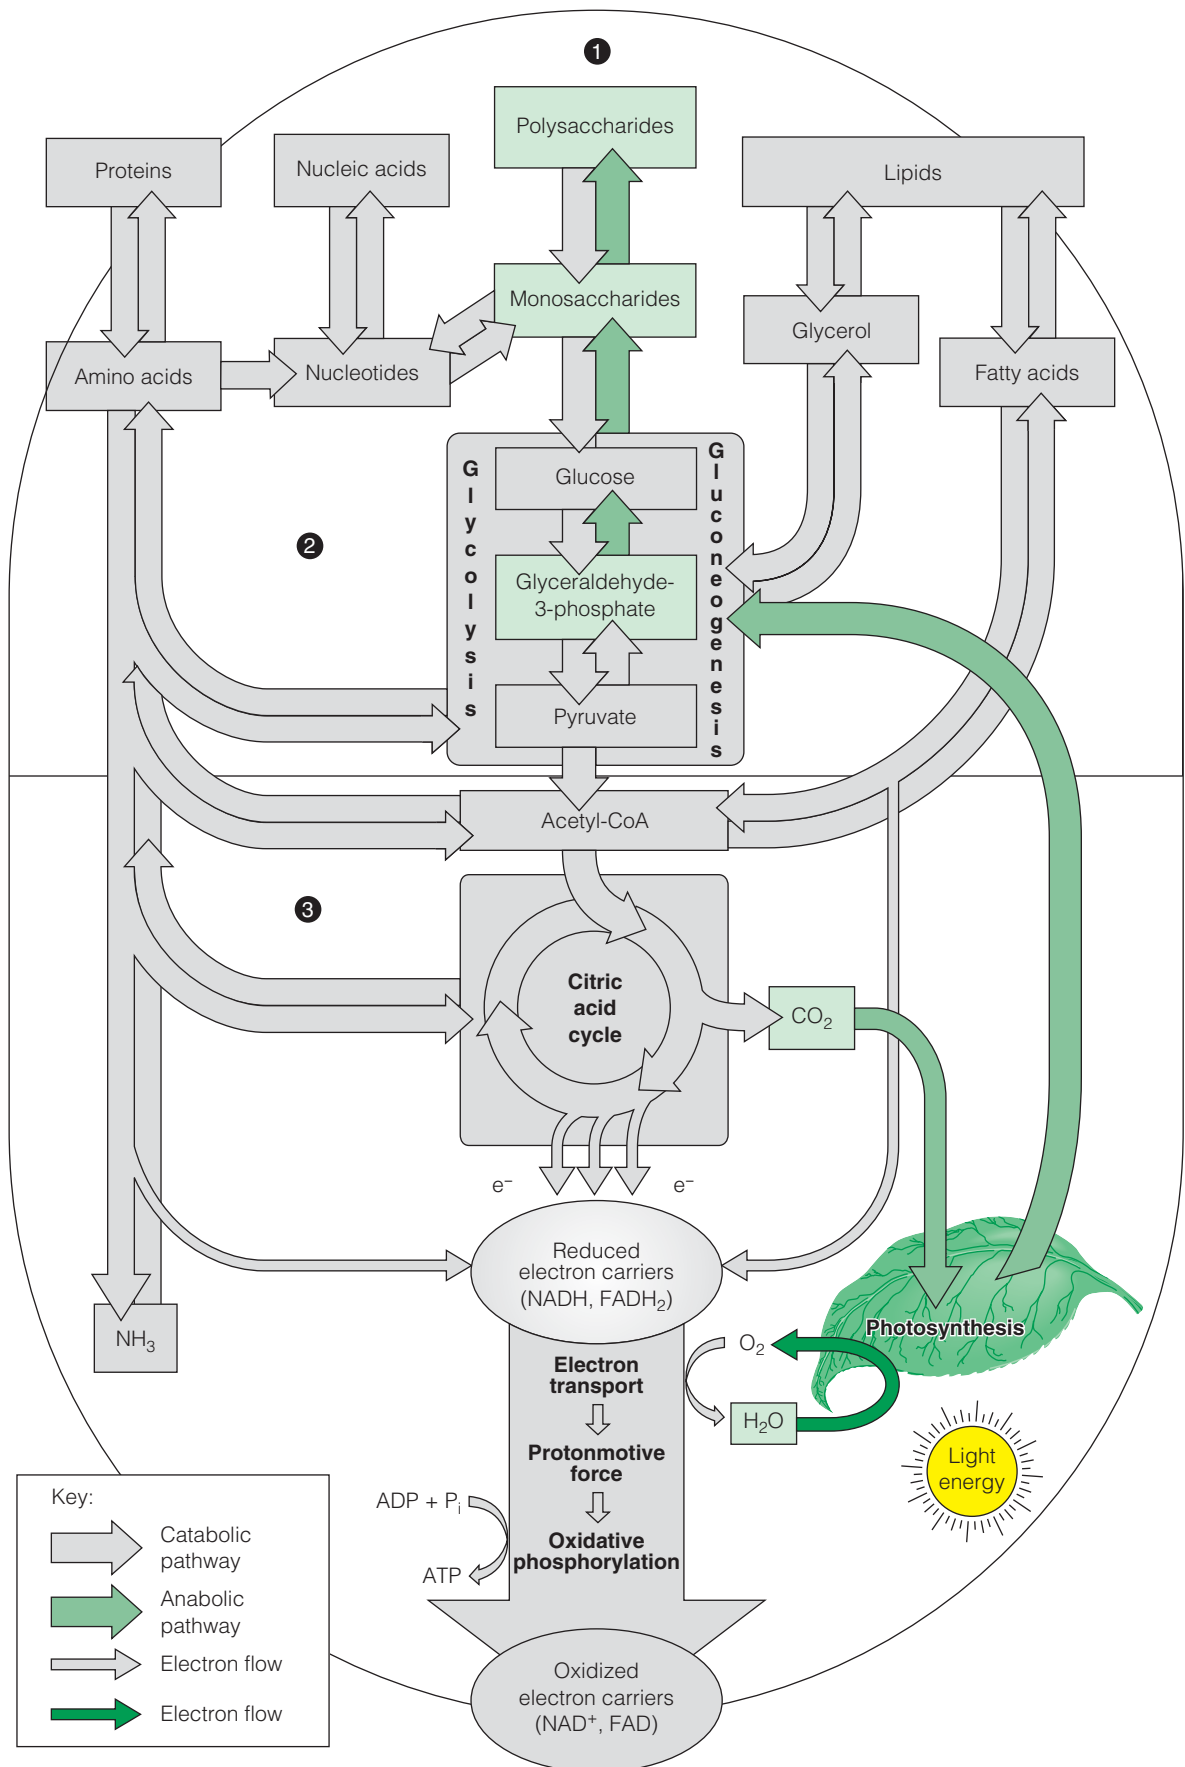

FIGURE 16.2

The role of photosynthesis in metabolism. The major biosynthetic pathways leading from carbon dioxide and water to polysaccharides are highlighted in green. Oxygen derived from the water is released as a by-product of photosynthesis.

TABLE 16.1 Examples of some photosynthetic reactions

Organisms	Reductant	Carbon Assimilation Reaction
Plants, algae, cyanobacteria	H ₂ O	CO ₂ + 2H ₂ O → [CH ₂ O] + H ₂ O + O ₂
Green sulfur bacteria	H ₂ S	CO ₂ + 2H ₂ S → [CH ₂ O] + H ₂ O + 2S
Purple bacteria	[HSO ₃ ⁻]	CO ₂ + H ₂ O + 2[HSO ₃ ⁻] → [CH ₂ O] + 2[HSO ₄ ⁻]
Nonsulfur photosynthetic bacteria	H ₂ or many other reductants such as lactate	CO ₂ + 2H ₂ → [CH ₂ O] + H ₂ O CO ₂ + 2(HC—OH) → [CH ₂ O] + H ₂ O + 2(C≡O)
		$\text{CO}_2 + 2 \begin{pmatrix} \text{CH}_3 \\ \\ \text{HC} - \text{OH} \\ \\ \text{COO}^- \\ \text{Lactate} \end{pmatrix} \longrightarrow [\text{CH}_2\text{O}] + \text{H}_2\text{O} + 2 \begin{pmatrix} \text{CH}_3 \\ \\ \text{C} = \text{O} \\ \\ \text{COO}^- \\ \text{Pyruvate} \end{pmatrix}$

Kamen in isotope labeling experiments using ¹⁸O-labeled water and unlabeled CO₂. These experiments showed that neither of the oxygen atoms in O₂ comes from CO₂. Therefore, it is more correct to write the photosynthetic reactions in the fashion shown in Table 16.1, which makes it clear that one of the oxygens from CO₂ ends up in carbohydrate, the other in water:

Light energy cannot be used *directly* to drive this reaction; in fact, H₂O does not reduce CO₂ *directly* under any known circumstances. The overall process we have just described is actually separated, both chemically and physically, into two subprocesses in all photosynthetic organisms. A slightly more sophisticated version of what actually happens is shown in Figure 16.3. In the first subprocess, in a series of steps called the **light reactions**, energy from sunlight is used to carry out the photochemical oxidation of H₂O. Two things are accomplished by this oxidation. First, the oxidizing agent NADP⁺ is reduced to NADPH and O₂ is released. Second, part of the energy from sunlight is captured by phosphorylating ADP to produce ATP. This is called **photophosphorylation**. In the second subprocess, the so-called **dark reactions** of photosynthesis, the NADPH and ATP produced by the light reactions are used in the reductive synthesis of carbohydrate from CO₂ and water. These reactions were originally termed *dark* to emphasize that they do not require the direct participation of light energy. Though this is true, the term carries the unfortunate implication that these synthetic reactions occur only in the dark. Nothing could be further from the truth. Rather, these reactions occur at all times and are actually accelerated by light. Because the term *dark reactions* is well established, we shall retain it, but you should not be misled by it.

Before considering details of either the light reactions or the dark reactions, it is appropriate to consider the sites of photosynthesis. Just as all eukaryotic cells have organelles (mitochondria) specialized for oxidative metabolism, plants and algae have organelles specialized for photosynthesis.

The Chloroplast

In all higher plants and algae, photosynthetic processes are localized in **chloroplasts**. In plants, most of these organelles are found in cells just under the leaf surface (mesophyll cells). Each cell may contain 20 to 50 chloroplasts (Figure 16.4). Eukaryotic algae also have chloroplasts, but often only one very large one is found in each cell.

FIGURE 16.3

The two subprocesses of photosynthesis. The overall process of photosynthesis is divided into light reactions and dark reactions. The light reactions, which require visible light as an energy source, produce reducing power (in the form of NADPH), ATP, and O₂. The NADPH and ATP drive the so-called dark reactions, which occur in both the presence and the absence of light and fix CO₂ into carbohydrates.

Photosynthesis can be divided into light reactions, which use sunlight energy to produce NADPH and ATP, releasing O₂ in the process, and dark reactions, which use NADPH and ATP to fix CO₂.

Photosynthesis in plants and algae occurs in chloroplasts.

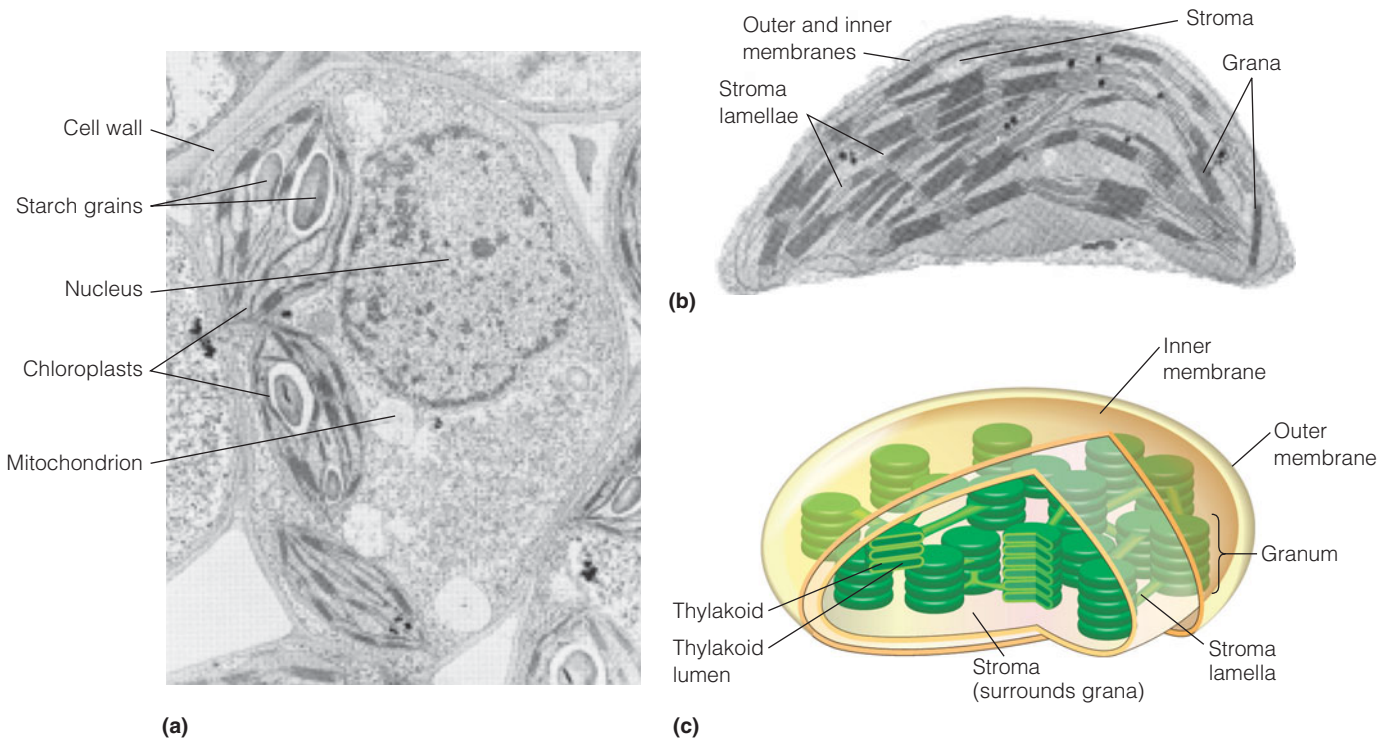

FIGURE 16.4

Chloroplasts, the photosynthetic organelles of green plants and algae. (a) Several chloroplasts are shown in a cross-section of a cell from a *Coleus* leaf. (b) Enlarged view of a single chloroplast from a leaf of timothy grass. (c) Schematic rendering of a chloroplast.

FIGURE 16.5

A photosynthetic prokaryote. This electron micrograph of a thin section of the cyanobacterium *Anabaena azollae* shows the folded membranes, which resemble the thylakoids of eukaryotic chloroplasts.

Courtesy of N. Lang, University of California, Davis/BPS.

Like mitochondria, chloroplasts are semiautonomous, carrying their own DNA to code for some of their proteins, as well as the ribosomes necessary for translation of the appropriate messenger RNAs. There is now much evidence that chloroplasts evolved from unicellular organisms similar to cyanobacteria (blue-green algae). Such prokaryotic photosynthesizers do not contain chloroplasts but have membrane structures that play the same roles as chloroplast membranes (Figure 16.5). To a certain extent, the cyanobacteria resemble free-living chloroplasts. It is believed that, early in evolution, primitive unicellular organisms took up cyanobacteria-like prokaryotes and that eventually the relationship became symbiotic: The photosynthetic organelles were no longer capable of independent life, and the algae depended upon them as energy sources. Today, some chloroplast genes are coded in the organelle genome, and some are in the cell nucleus.

The internal structure of a chloroplast, as shown in Figure 16.4b and c, bears some resemblance to that of a mitochondrion (see Figure 15.2a), except that chloroplasts have a third set of membranes. There is an outer, freely permeable membrane and an inner membrane that is selectively permeable. The inner membrane encloses a compartment called the **stroma** that is analogous to the mitochondrial matrix. Immersed in the stroma are many flat, saclike membrane structures called **thylakoids**, which are often stacked like coins to form units called **grana** (see Figure 16.4c). Individual grana are irregularly interconnected by thylakoid extensions called **stroma lamellae**. This third membrane, the thylakoid membrane, encloses an interior space, the **lumen** of the thylakoid.

The division of labor within a chloroplast is simple. Absorption of light and all of the light reactions occur within or on the thylakoid membranes. The ATP and NADPH produced by these reactions are released into the surrounding stroma where all of the synthetic dark reactions occur. Thus, there are analogies in structure and role between mitochondrial matrix and chloroplast stroma and between the inner membrane of the mitochondrion and the thylakoid membrane of the chloroplast. Indeed, we shall find that a very similar kind of chemiosmotic ATP generation is carried out across these membranes in both mitochondria and chloroplasts. To see how this ATP generation occurs, we must first examine the light reactions in detail, beginning with the process of light absorption.

The Light Reactions

Absorption of Light: The Light-Harvesting System

The Energy of Light

To understand how energy from sunlight can be captured and utilized, we must first review the nature of electromagnetic radiation. The quantum mechanical theory of radiation states that light (and all other electromagnetic radiation) has two aspects: wavelike and particle-like. We can characterize a particular kind of radiation by its wavelength (λ) or frequency (ν); these parameters characterize the *wave* aspects of the light. If waves with a length of λ are passing an observer at a velocity c , the number of waves passing per second is the frequency, ν . Thus,

$$\nu = \frac{c}{\lambda} \quad (16.1)$$

where c is the velocity of light, 2.998×10^8 m/s. The red light from a neon laser has a wavelength of 632.8 nm, or 6.328×10^{-7} m. Thus, its frequency is $4.74 \times 10^{14} \text{ s}^{-1}$. But to see how *energy* might be obtained from light, it is necessary to consider the particulate aspect of radiation. We must think of a light beam as a stream of light particles, or **photons**. Each photon has an associated unit of energy called a **quantum**. The energy value of a quantum—that is, the energy per photon—is related to the frequency of the light by one of the most basic equations in physics, Planck's law (see Tools of Biochemistry 6A)

$$E = h\nu = \frac{hc}{\lambda} \quad (16.2)$$

where h is Planck's constant, 6.626×10^{-34} J s. Thus, the neon laser in our example can deliver light energy only in packets, or quanta, of 3.14×10^{-19} J (or $[6.626 \times 10^{-34} \text{ J s}] \times [4.74 \times 10^{14} \text{ s}^{-1}]$). However, biochemists rarely deal with single photons. Because we are interested in how radiation can promote chemical or biochemical processes, which are usually expressed on a molar basis, the more appropriate quantity for our purposes is the energy of a *mole* (6.02×10^{23}) of photons. For the neon laser light, multiplying the energy per photon by 6.02×10^{23} gives 189 kJ. A mole of photons is called one **einstein**.

Figure 16.6 shows a graph of energy per mole of photons as a function of wavelength, through the infrared, visible, and ultraviolet parts of the spectrum. For comparison, the energies associated with molecular vibrations and various covalent bonds are indicated. When photons of infrared radiation are absorbed by a molecule, they can do little except stimulate molecular vibrations, which we perceive as heat. Photons of far-ultraviolet radiation, on the other hand, have energies quite capable of breaking covalent bonds. Far-ultraviolet radiation is chemically

Absorption of light and the light reactions occur in the chloroplast membranes. The dark reactions occur in the stroma.

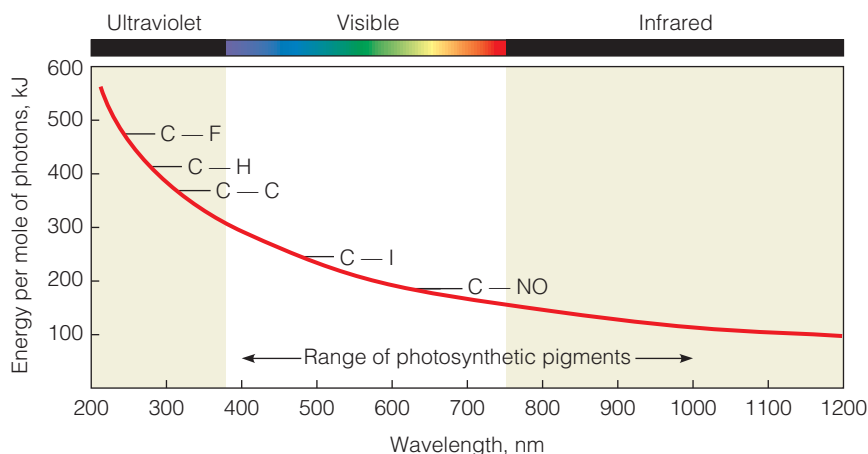

FIGURE 16.6

The energy of photons. The graph shows energy per mole of photons as a function of wavelength, compared with energies of several chemical bonds. Light in the ultraviolet range has enough energy to break many chemical bonds directly. Visible light can break some weak bonds. Light in the long-wavelength portion of infrared region of the spectrum causes only heat-producing molecular vibrations.

destructive to humans and to other organisms, but fortunately most of it is screened from the earth's surface by the ozone layer. This is one of the reasons why depletion of the ozone layer is of such serious concern.

Photosynthesis depends primarily on light in the visible and near-infrared regions of the spectrum, lying between the extremes of covalent bond-breaking and stimulating molecular vibrations. Photons in the visible and near infrared are not highly destructive, but can cause transitions in the electronic states of organic molecules that can drive reactions and thus capture the energy in a chemical form. The ability to use radiation in this range has had clear evolutionary advantages for photosynthetic organisms. Most of the sun's energy that reaches the earth's surface lies in this spectral range. The small amount of ultraviolet radiation that does get through can penetrate only a very short distance into water and thus would have been unavailable to primitive photosynthetic organisms living in the sea. The photons of far-infrared radiation have energies too low to be useful for any photochemical processes.

The Light-Absorbing Pigments

To capture the useful portion of the light energy, photosynthetic organisms have evolved a set of pigments that efficiently absorb visible and near-infrared light. The light-absorbing portions of these pigments are referred to as **chromophores**. Structures of a few of the most important photosynthetic chromophores are shown in Figure 16.7. In Figure 16.8 the absorption spectra of these photosynthetic pigments are compared with the distribution of solar radiation in the spectrum. Together, the chromophores “blanket” the visible spectrum; scarcely a photon can

FIGURE 16.7

Some photosynthetic pigments. Chlorophylls *a* and *b* are the most abundant plant and algal pigments, whereas β -carotene and phycocyanin are examples of accessory pigments. Phycocyanin and the related phycoerythrin are open-chain tetrapyrroles that are covalently attached to **phycobiloproteins** via a sulfhydryl group, and they are abundant in aquatic photosynthetic organisms. These pigments absorb strongly in the 500–600 nm range, wavelengths that can efficiently pass through water. There are also bacteriochlorophylls, which differ slightly in structure. The colored highlights indicate the extended conjugated double-bond systems.

come through that cannot be absorbed by one chromophore or another. The most abundant pigments in higher plants are chlorophyll *a* and chlorophyll *b*. As you can see by comparing Figure 16.7a with Figure 7.4b (page 236), these molecules are related to the protoporphyrin IX found in hemoglobin and myoglobin. However, the bound metal in the chlorophylls is Mg^{2+} rather than Fe^{2+} . In Figure 16.7b and c, two accessory pigments are also shown. All of these molecules absorb light in the visible region of the spectrum because they have large conjugated double-bond systems. Because chlorophylls *a* and *b* absorb strongly in both the deep blue and red, the light that is *not* absorbed but *reflected* from chloroplasts is green, the color we associate with most growing plants. The other observed colors, such as the red, brown, or purple of algae and photosynthetic bacteria, are accounted for by differing amounts of *accessory pigments*. Loss of chlorophylls in autumn leaves allows the colors of the accessory pigments, as well as nonphotosynthetic pigments, to become evident. Carotenoids are the most abundant accessory pigments in plants. These include the red-orange β -carotene (Figure 16.7b) and xanthophylls (oxygen-containing carotenoids) such as the yellow lutein. Some photosynthetic bacteria use pigments that absorb wavelengths up to about 1000 nm, in the near infrared.

The Light-Gathering Structures

Chlorophyll and some of the accessory pigments are contained in the **thylakoid membranes** of the chloroplast. The composition of these membranes is rather unusual. They contain only a small fraction of the common phospholipids but are rich in glycolipids. They also contain much protein, and some of the photosynthetic pigments are attached to certain of these proteins. Other photosynthetic pigments, including chlorophylls *a* and *b*, are not covalently bound but interact with both proteins and membrane lipids. These pigments interact with membrane lipids through their hydrophobic phytol tails (see Figure 16.7a).

The assemblies of light-harvesting pigments in the thylakoid membrane, together with their associated proteins, are organized into well-defined **photosystems**, structural units dedicated to the task of absorbing light photons and recovering some of their energy in a chemical form. As we shall see, plants use two distinct photosystems (I and II). The first part of photosynthesis takes place in what are referred to as **light-harvesting complexes (LHCs)**. Each is a multisubunit protein complex containing multiple **antenna** pigment molecules (chlorophylls and some accessory pigments) and a pair of chlorophyll molecules that act as the **reaction center**, trapping energy quanta excited by the absorption of light.

To understand how this system functions, we must look a bit more closely into what can happen when a molecule absorbs a quantum of radiant energy. Recall from Tools of Biochemistry 6A that absorption in the visible region of the spectrum excites the molecule from the ground state to a higher electronic state. In the case of the photosynthetic pigments, the excited electron occupies a π orbital in the conjugated bond system. In Tools of Biochemistry 6A we described two ways in which the energy could be lost to return the molecule to its ground state: radiationless dissipation of the energy as heat, or re-radiation as fluorescence. However, when similar absorbing molecules are packed tightly together, as in a photosystem, two other possibilities arise. First, the excitation energy may be passed from one molecule to an adjacent one—a process called **resonance transfer** or **exciton transfer** (Figure 16.9a). Alternatively, the excited electron itself may be

FIGURE 16.8

Absorption spectra and light energy. The absorption spectra of various plant pigments are compared with the spectral distribution of the sunlight that reaches the earth's surface.

(a) Resonance transfer

(b) Electron transfer

FIGURE 16.9

Two modes of energy transfer following photoexcitation. For each of the two types of energy transfer that occur in a photosystem, the left-hand illustration shows a molecule being excited to a higher energy state by absorption of a photon of radiation. The right-hand illustrations show how the energy is transferred to an adjacent molecule. **(a)** In **resonance transfer** molecule I transfers its excitation energy to an identical molecule II, which rises to its higher energy state as molecule I falls back to the ground state. Resonance transfer is extraordinarily fast. **(b)** In **electron transfer** an excited electron in molecule I is transferred to the slightly lower excited state of molecule II, making molecule I a cation and molecule II an anion.

Most chlorophyll molecules are used as antennae to catch photons and pass their energy on to reaction centers.

passed to a nearby molecule with a slightly lower excited state—an *electron transfer* reaction (Figure 16.9b). Both of these processes are important in photosynthesis.

The clue that eventually led to the recognition that resonance transfer played a role in photosynthesis came from measurements by Robert Emerson and William Arnold in the 1930s. They showed that even when the photosynthetic system of the alga *Chlorella* was operating at maximum efficiency, only one O₂ molecule was produced for every 2500 chlorophyll molecules. As we now realize, most of the chlorophyll molecules are not directly engaged in the photochemical process itself but act, instead, as antenna molecules of the light-harvesting complexes. The structure of a light-harvesting complex (LHCII) is shown in Figure 16.10. Antenna molecules absorb photons, and the energy is passed by resonance transfer to specific chlorophyll molecules in a relatively few reaction centers. In other words, the energy of a photon absorbed by any antenna molecule in a photosystem wanders about the system randomly (Figure 16.11). Eventually (meaning in about 10⁻¹⁰ s), the energy finds its way to a chlorophyll molecule in the reaction center. This molecule is like the other chlorophylls, except it is in a different protein microenvironment so that its excited state energy level is a bit lower. Thus, it acts as a trap for quanta of energy absorbed by any of the other pigment molecules. It is the excitation of this reaction center that begins the actual photochemistry of the light reactions, for it starts a series of electron transfers.

Photochemistry in Plants and Algae: Two Photosystems in Series

Our understanding of the photochemical light reactions has developed from many elegant experiments in many different laboratories. A pioneering study in 1939, by Robert Hill at the University of Cambridge, made the seminal observation that isolated chloroplasts could promote redox chemistry when illuminated

FIGURE 16.10

Three-dimensional structure of the trimeric light-harvesting complex II of plants. The X-ray structure of the pea LHCII (PDB ID 2BHW) shows that the protein exists as a homotrimer buried in the thylakoid membrane. **(a)** A top view from the luminal side of the membrane. The three monomers are in different shades of cyan. **(b)** A side view of the trimer (approximate locations of the stromal and luminal faces of the membrane are indicated). Each trimer contains 24 chlorophyll a molecules (light green), 18 chlorophyll b molecules (green), and 12 carotenoids (luteins and xanthophylls; orange), all serving as antenna molecules. Bound lipids are shown in purple.

in the presence of any of a variety of electron acceptors. For example, when ferricyanide was used, the following reaction proceeded efficiently:

A number of such reactions involving different inorganic oxidants are known and are now referred to collectively as *Hill reactions*. Such reactions, in the absence of photochemical activation, are very unfavorable. Ferricyanide, for example, is a much weaker oxidant than O_2 (refer to Table 15.1, page 629); $\Delta G^{\circ'}$ for the reaction as written is about $+178 \text{ kJ/mol O}_2$ [from eqn. 15.1; $\Delta G^{\circ'} = -4(96485 \text{ J mol}^{-1}\text{V}^{-1}) \times (0.36 \text{ V} - 0.82 \text{ V})$]; so the equilibrium should lie far to the left. Hill's discoveries showed that *chloroplasts irradiated by light are capable of driving thermodynamically unfavorable reactions*. The Hill reactions also demonstrated that the photosynthetic system can oxidize water to O_2 without any involvement of CO_2 (see Figure 16.3). This observation was the first clear indication that the light and dark reactions are separate processes, and it led ultimately to the discovery that the final electron acceptor of the light reactions in vivo is NADP^+ , yielding NADPH.

Further studies revealed that *two* kinds of photosystems must be involved in photosynthesis in plants. The first hint came from experiments that measured the quantum efficiency of photosynthesis in algae, using light of different wavelengths. The *quantum efficiency* (Q) is the ratio of oxygen molecules released to photons absorbed. As the wavelength of the monochromatic light used was raised above 680 nm (far red), an abrupt drop in Q was noted. This "red drop" was a strange observation, for chlorophylls in plants still show appreciable absorbance even at higher wavelengths. Somehow the energy was just not being used as efficiently above 680 nm. Even more remarkable was the observation that simultaneous illumination with yellow light (650 nm) produced a marked increase in the quantum efficiency from light at 700 nm. Even if the yellow light was switched off a few minutes before the measurement, the quantum efficiency remained high. The only reasonable explanation for these results is that two complementary photosystems exist, one absorbing most strongly at wavelengths around 700 nm and the other at shorter wavelengths. The action of *both* must be required for photosynthesis to proceed with maximal efficiency.

The two photosystems predicted by early experimenters have now been identified and characterized. They are both localized in the thylakoid membrane. Each photosystem is a multisubunit, transmembrane protein complex, carrying antenna and reaction center chlorophyll molecules and electron transport agents. The photosystems have been named according to the order in which they were discovered. The one showing absorbance up to 700 nm is called **photosystem I (PSI)**, and the one that absorbs only to a wavelength of about 680 nm is called **photosystem II (PSII)**. In algae, cyanobacteria, and all higher plants, these two photosystems are linked in series to carry out the complete sequence of the light reactions. The basic sequence is illustrated in Figure 16.12a, which depicts the

FIGURE 16.11

Resonance transfer of energy in a light-harvesting complex. The excitation energy originating in a photon of light wanders from one antenna molecule to another until it reaches a reaction center. There an electron is transferred to a primary electron acceptor molecule, and the energy is trapped.

FIGURE 16.12

The two-photosystem light reactions. In the two-photosystem mode of photosynthesis, the light reactions are carried out by two photosystems linked in series. **(a)** A schematic view of the path of electrons through the two photosystems. The two systems and the cytochrome complex are embedded in the thylakoid membrane. Electrons taken from water in photosystem II are transferred to photosystem I via plastoquinones (Q), the cytochrome b_6f complex, and plastocyanin (PC). In photosystem I the electrons are excited by light again, for transfer via a series of intermediates to ferredoxin. Reduced ferredoxin reduces NADP^+ . **(b)** Energetics of the two-photosystem light reactions. In each of the two reaction centers, P680 and P700, electrons are raised to an excited state by absorption of photons. In each photosystem the excited electrons are passed through an electron transport chain, which drives the pumping of protons into the thylakoid lumen. The two-photosystem mode has historically been called the Z-scheme because of the pattern of energy changes shown here, but N-scheme would be more accurate. The estimate of eight protons pumped by the cytochrome b_6f complex is based on the Q cycle translocating two protons for each electron transported.

Key: OEC = oxygen-evolving complex; Y_z = donor to P680; P680 = photosystem II reaction center chlorophyll; Ph = pheophytin acceptor; Q_A , Q_B = protein-bound plastoquinones; QH_2 = plastoquinol (reduced plastoquinone) in membrane; Cyt b_6f = cytochrome b_6f complex; PC = plastocyanin; P700 = photosystem I reaction center chlorophyll; A_0 = chlorophyll acceptor; A_1 = protein-bound phylloquinone; F_A , F_B , F_X = iron-sulfur clusters; Fd = ferredoxin; FNR = ferredoxin:NADP⁺ oxidoreductase.

(a)

(b)

path of electrons through the two systems. Figure 16.12b emphasizes the energetics of the electron flow and places the major participants in the light reactions on a scale of reduction potential.

In each of the two photosystems, the primary step is transfer of a light-excited electron from a reaction center (P680 or P700) into an electron transport chain. The ultimate source of the electrons is the water molecules shown at the left in both parts of Figure 16.12. The final destination of the electrons is the molecule of NADP^+ at the right, which is thereby reduced to NADPH. At two stages in the electron transport process, protons are released into the thylakoid lumen. Some of the protons come from the H_2O that is broken down, some come from the stroma. This transfer of protons into the lumen produces a pH gradient across the thylakoid membrane. It should not surprise you to find that this proton gradient drives ATP production, just as a proton gradient drives ATP synthesis in mitochondria (see Chapter 15). Thus, ATP and reducing power in the form of NADPH are the products of the light reactions. These compounds are exactly what is needed to drive the syntheses carried out in the dark reactions. To examine their generation in detail, we begin with photosystem II, for it is where electrons enter the scheme.

Photosystem II: The Splitting of Water

Each of the photosystems contains an electron transport chain, which extracts energy when an excited electron loses its energy of excitation in a stepwise fashion. The photosystem carries out a series of oxidation–reduction reactions. It is easiest to follow the events in a photosystem by starting with the absorption of a photon picked up by the light-harvesting system of photosystem II. The photon is funneled to a reaction center chlorophyll, designated P680 in Figure 16.12. Excitation of P680 raises the molecule from the ground state to an excited state at -0.8 volts. Thus, the excited P680 has become an excellent reducing agent, able to quickly transfer an electron from P680 to a lower-energy primary electron acceptor—*pheophytin a* (*Ph*), as shown in Figure 16.12b. The pheophytins are molecules identical to chlorophylls, except that two protons substitute for the centrally bound magnesium ion. We can consider this excited electron as a low-redox-potential electron.

The electron is then transferred to a series of *plastoquinone* molecules (Q_A and Q_B) associated with PSII proteins. Ultimately, two electrons and two protons are picked up by the plastoquinone Q_B ; the protons come from the stroma. The reduced plastoquinone, QH_2 (*plastoquinol*), is then released into the lipid portion of the thylakoid membrane. The overall reduction of plastoquinone can be written as follows:

Note the structural similarity between plastoquinone and the ubiquinone (coenzyme Q) found in respiratory chains (Chapter 15). Plastoquinol then interacts with a membrane-bound complex of cytochromes and iron–sulfur proteins, the cytochrome b_6f complex. This complex catalyzes the transfer of the electrons to a copper protein, *plastocyanin* (PC). In doing so, the b_6f complex serves two purposes. First, it transmits activated electrons from photosystem II to photosystem I. At the same time, it pumps protons from the stroma into the thylakoid lumen (2H^+ per electron). The major components of this complex are cytochrome *f* (which contains one *c*-type heme), cytochrome b_6 (which contains two *b*-type hemes), and a Rieske iron–sulfur protein (Figure 16.13a). The cytochrome b_6f

Two photosystems, linked in series, are involved in the photosynthetic light reactions in algae, cyanobacteria, and higher plants.

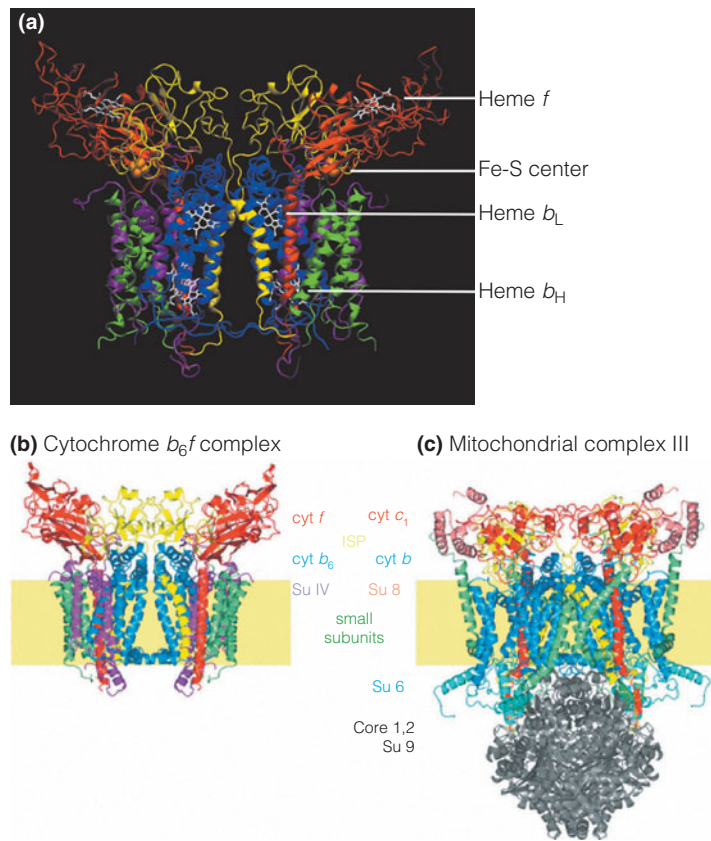

FIGURE 16.13

Structure of the cytochrome b_6f complex. (a) The X-ray structure (PDB ID 2D2C) of the complex from the thermophilic cyanobacterium, *Mastigocladus laminosus*, shows that the protein exists as a homodimer buried in the thylakoid membrane. This view is in the plane of the membrane, with the thylakoid lumen at the top. Cytochrome f subunits are red, with the c -type hemes shown in white; the Rieske iron–sulfur protein subunits are yellow, with the Fe_2S_2 iron–sulfur centers shown in orange; Cytochrome b_6 subunits are blue, with the b_H and b_L hemes shown in white; and subunits IV are purple. Four additional small subunits per monomer are shown in green. The lower panels compare the structures of the photosynthetic cytochrome b_6f complex (b) (PDB ID 2E74) and the mitochondrial complex III (c) (PDB ID 1L0L). Homologous or analogous subunits have the same colors, based on the color scheme in panel (a).

(b, c) *Photochemistry and Photobiology* 84:1349–1358, D. Baniulis, E. Yamashita, H. Zhang, S. S. Hasan, and W. A. Cramer, Structure–function of the cytochrome b_6f complex. © 2008 John Wiley & Sons, Inc. Reproduced with permission from John Wiley & Sons, Inc.

complex is thus analogous to complex III of the mitochondrial respiratory chain (Figure 16.13b, c), and catalyzes a similar Q cycle (as shown in Figure 15.15, page 641). As plastoquinol is oxidized back to plastoquinone, the two protons it has taken from the stroma are released into the thylakoid lumen. Plastocyanin, a mobile protein in the thylakoid lumen, passes the electrons on to P700 reaction centers. In this process the copper in plastocyanin is first reduced to Cu(I) and then reoxidized to Cu(II). We shall consider the fate of the electrons passed to P700 when we discuss photosystem I.

Note that the processes we have described so far have left P680 reaction centers deficient in electrons—in other words, oxidized to a strong oxidant, $P680^+$. These electrons are regained from water, which is split in the presence of an electron acceptor, releasing oxygen in the process. New insight into the mechanism of this water-splitting process has recently been provided by X-ray structures of photosystem II complexes from several cyanobacterium. Figure 16.14 shows PSII as a large multisubunit complex embedded in the thylakoid membrane. Each monomer of the homodimer comprises 20 subunits, including antenna proteins with their numerous antenna chlorophylls surrounding two subunits (D1 and D2) that contain the P680 reaction center chlorophylls and the water-splitting catalytic components. As indicated in Figure 16.12b (left), the electron acceptor is a subunit of PSII referred to as the oxygen-evolving complex (OEC). The OEC contains a cube-shaped cluster of four oxygen-bridged manganese ions and one calcium ion. This metal cluster can exist in a series of oxidation states, as indicated in Figure 16.15a; light-driven cycling through these oxidation states allows the cluster to dismantle two water molecules, passing four electrons back to P680 and releasing the four accompanying protons into the thylakoid lumen. Exactly at which points in the cycle individual electrons and protons are released is still a matter of

Photosystem II extracts electrons from water, passing them to photosystem I and releasing O_2 .

FIGURE 16.14

Structure of photosystem II. (a) The X-ray structure (PDB ID 3BZ1, 3BZ2) of PSII from the thermophilic cyanobacterium, *Thermosynechococcus elongatus*, shows that the protein exists as a homodimer buried in the thylakoid membrane. This view is in the plane of the membrane, with the thylakoid lumen at the top. Each monomer is composed of 20 subunits, including the antenna proteins CP47 (red) and CP43 (magenta), the reaction center subunits D1 (yellow) and D2 (orange), and two cytochrome b559 subunits (lime). Each monomer contains 35 chlorophyll a molecules (green) and 12 carotenoids (orange) bound to CP43 and CP47. The Mn₄Ca cluster of the oxygen-evolving center is shown in blue, bound by the D1 subunit of each monomer. (b) The structure of the Mn₄Ca cluster from the PSII of *Thermosynechococcus vulcanus* is shown in greater detail. Distances (in angstroms) between the metal atoms and oxygen atoms or water molecules are indicated.

debate, with several models proposed. In the version shown in Figure 16.15b, electrons and protons are released in pairs, which amounts to a hydrogen extraction. This idea is consistent with the observation that the electron donor returning electrons to oxidized P680 is a redox-active tyrosine in the D1 subunit of PSII. This yields a tyrosine radical (Y_2^{\cdot}) which has been observed by electron spin resonance (see Tools of Biochemistry 10A), and releases a proton. It is proposed, then,

FIGURE 16.15a

A model for the catalytic function of the oxygen-evolving complex (OEC) cluster in PSII. (a) S₀–S₄ represent the different oxidation states that the ligated metal cluster cycles through as e[−] and H⁺ are abstracted from the H₂O molecules. In the first four transitions, light energy is used to oxidize P₆₈₀ to P₆₈₀⁺, which in turn oxidizes the metal-oxo cluster of the OEC. The S₄ → S₀ transition is light-independent and releases O₂. Thus, four photons are required to oxidize two H₂O to one O₂.

FIGURE 16.15b

(b) In this proposed mechanism, Y_z represents the redox-active tyrosine residue of the D1 subunit; the oxidized form of Y_z is the neutral, deprotonated radical species, Y_z^\cdot . The two H_2O molecules are bound in the S_0Y_z state by the Ca^{2+} ion and the “dangler” Mn^{III} ion. Each transition passes through an intermediate $S_nY_z^\cdot$, in which the oxidized tyrosine is poised to oxidize the metal cluster of the OEC, but for clarity, the tyrosine radical is shown only once. In this model, only two of the Mn ions change their oxidation states. The $S_4 \rightarrow S_4'$ transition is the crucial O—O bond-forming step and involves the attack by a calcium-bound water upon the electrophilic $Mn^V=O$ oxo group. O_2 is released, and two new H_2O are bound to initiate another cycle.

that each of the steps in Figure 16.15 in which a hydrogen atom ($\text{H}^+ + \text{e}^-$) is extracted involves the following cycle:

The system has in effect stripped four electrons from the four hydrogen atoms in two water molecules. The oxygen produced diffuses out of the chloroplast. The four protons that are produced from the two water molecules are released into the thylakoid lumen, helping to generate a pH difference between the lumen and stroma. We may summarize the reaction carried out by photosystem II as follows:

The electrons produced travel through the transport chain of photosystem II and are passed on to photosystem I through the b_6f complex.

Photosystem I: Production of NADPH

We have seen that in plants, which utilize two photosystems, photosystem II accomplishes the splitting of water with evolution of O_2 and helps generate a proton gradient across the thylakoid membrane. However, the electrons from the water molecules have not yet reached their final destination in NADPH. This process is the task of photosystem I, in which electrons are again released from a reaction center by light excitation and passed through a second electron transport chain. These electrons are replaced by those passed on from photosystem II.

Photosystem I is a multiprotein complex, containing at least 19 polypeptide chains. It also contains many antenna chlorophylls and a reaction center chlorophyll, P700, which can absorb light of up to 700 nm. As shown in Figure 16.12b, excitation by a photon absorbed by antenna chlorophylls raises electrons in P700 from a ground state to an excited state at about -1.3 V —probably the most powerful reductant in nature. Each excited electron then passes through a transport chain. It is first taken up by a special chlorophyll acceptor (designated A_0), then transferred to a molecule of *phylloquinone* (A_1 , also known as vitamin K_1 —see page 811), and finally passed through a series of three iron–sulfur proteins (F_X , F_B , and F_L). These proteins contain Fe_4S_4 clusters of the kinds depicted in Figure 15.4. Finally, the electron is transferred to another iron–sulfur protein, *soluble ferredoxin* (Fd), which is present in the stroma. The enzyme ferredoxin:NADP $^+$ oxidoreductase catalyzes the transfer of electrons to NADP $^+$, after ferredoxin has been reduced by photosystem I:

In a sense, ferredoxin, rather than NADP $^+$, can be considered the *direct* recipient of electrons from the pathway. Although much of the reduced ferredoxin is used

Photosystem I receives electrons from photosystem II and transfers them to NADP^+ to make NADPH.

to reduce NADP^+ , some is used for other reductive reactions, which we discuss later. In fact, we may consider reduced ferredoxin a source of low-potential electrons for many reductive processes. The NADPH produced by ferredoxin oxidation is released into the stroma, where it will be used in dark reactions.

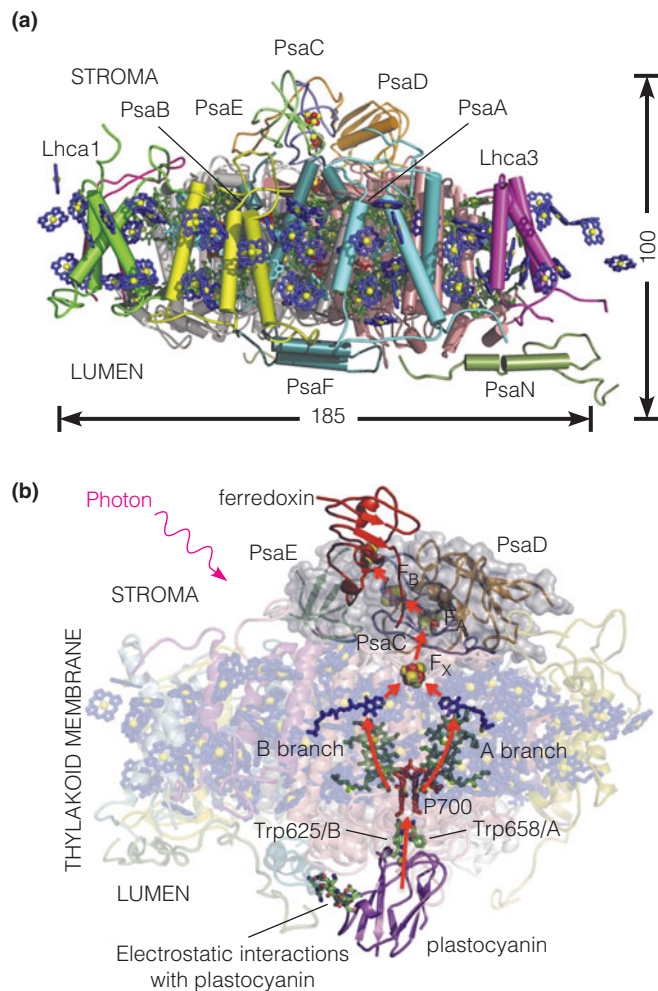

The electrons that have been driven through photosystem I originated in electron transfer from P700 reaction centers. The electron-deficient, oxidized reaction centers (P700^+) so produced must be resupplied with electrons for photosynthesis to continue. In two-system photosynthesis, these electrons are provided from photosystem II via plastocyanin.

Recently, X-ray diffraction studies have revealed structures of the entire photosystem I complex from cyanobacteria and plants (see References). The cyanobacterial complex exists as a trimer, whereas PSI in plants is a monomer. Both types of PSI consist of multiple polypeptide chains, several hundred chlorophylls (most of which are antenna molecules), and the other components of the electron transport chain in a complex that spans the thylakoid membrane. Plant PSI consists of two membrane complexes, the core complex and the light-harvesting complex I (LHCI) (Figure 16.16a). The heart of the core complex is formed by the PsaA and PsaB subunits, which bind all of the electron transport chain components, including the P700 reaction center chlorophylls, A_0 , A_1 , and the iron–sulfur clusters, as well as 80 chlorophylls that function as light-harvesting antennae. Three stromal subunits (PsaC, D, E) and one luminal subunit (PsaF) complete the core complex. LHCI is composed of four subunits (Lhca1–4) located in the

FIGURE 16.16

The structure of plant photosystem I. **(a)** A view of the pea PSI structure (PDB ID 2001) as seen from the plane of the membrane, with the thylakoid lumen at the bottom. The four LHCI subunits (Lhca1–4) are in front, and are colored green, light blue, magenta, and yellow, respectively. The core subunits PsaA (pink) and PsaB (silver) are hidden behind the LHCI subunits. Antenna chlorophylls of LHCI are blue and cyan, and antenna chlorophylls of the core are green. P700 reaction center chlorophylls are red, and the Fe_4S_4 clusters are shown as yellow-red spheres. Dimensions in Å are indicated. **(b)** Model for the electron transport chain and binding sites for plastocyanin and soluble ferredoxin. The A_0 chlorophylls are green and the A_1 phylloquinones are blue. The path of electron transport is indicated by red arrows. Amino acids involved in electrostatic and hydrophobic interactions between plastocyanin and PsaA/PsaB are also shown.

membrane on one side of the core complex. Like the LHCII described earlier, LHCI serves as an additional antenna system that collects photons and transmits the energy to the core complex. The entire plant PSI-LHCI supercomplex is ~600 kDa and contains 45 transmembrane helices and 168 antenna chlorophylls. The center-to-center distances of these antenna chlorophylls to their nearest neighbor are in the range of 7–16 Å, a favorable distance for fast excitation energy transfer.

PSI catalyzes the light-driven electron transfer from the soluble electron carrier plastocyanin, located at the luminal side of the thylakoid membrane, to ferredoxin, located at the stromal side of the membrane. Figure 16.16b shows the proposed binding sites for plastocyanin and ferredoxin on PSI and the locations of the electron transport chain components. The path of electrons from the first P700 iron–sulfur cluster (F_x) is branched, with the A_0 chlorophylls and A_1 phylloquinones arranged in symmetric pairs. Almost every photon absorbed by the PSI complex is used to drive electron transport. PSI is remarkably efficient, with a quantum yield of nearly 1, meaning that almost every photon absorbed by the PSI complex is captured and used to drive electron transport.

Summation of the Two Systems: The Overall Reaction and ATP Generation

We can now summarize the electron flow through the two-system light reactions. As shown in Figure 16.12, electrons are taken from water and end up in NADPH. We wrote for the overall reaction in photosystem II:

The reactions of photosystem I, if written for four electrons and with all intermediates eliminated, are

Adding these two reactions gives us the following summation of the light reactions:

The key to ATP generation is that additional protons have been pumped from the stroma into the thylakoid lumen during the passage of each electron through the electron transport chain. Current estimates of the total number of protons are somewhat uncertain because the number transported per electron by the b_6f complex is not known exactly. However, it is estimated that ~12 protons are translocated per O_2 released (corresponding to ~3 protons per electron passing from H_2O to NADP^+). The net result from the combined function of photosystem I and II is the reduction of NADP^+ and the generation of a proton gradient across the thylakoid membrane, with the lumen becoming more acidic than the stroma. Recall from Chapter 15 that the free energy available in a proton gradient ($\Delta\mu_{\text{H}}$, the protonmotive force) is composed of both a chemical component (the proton concentration gradient, ΔpH) and an electrical component (the membrane potential, $\Delta\Psi$):

$$\Delta\mu_{\text{H}} = 2.3RT\Delta\text{pH} + F\Delta\Psi \quad (16.3)$$

Unlike the mitochondrial inner membrane, the thylakoid membrane of chloroplasts is permeable to ions such as Mg^{2+} and Cl^- . Movement of these ions across the thylakoid membrane maintains electrical neutrality, dissipating most of the membrane potential. (Light-induced translocation of Mg^{2+} into the stroma also has a regulatory role, as we shall see later.) Thus, in illuminated chloroplasts, the protonmotive force is dominated by the $[\text{H}^+]$ gradient. The pH difference produced across the thylakoid membrane can become very large—as much as 3.5 pH

units in brightly illuminated chloroplasts. This pH gradient across the membrane corresponds to more than a 3000-fold difference in $[H^+]$ and a free energy change of about -20 kJ per mol of protons at 25°C . Based on the estimated stoichiometry of 12 mol H^+ per mol O_2 produced, this corresponds to roughly 240 kJ/mol O_2 energy available to drive the synthesis of ATP.

As in the case of ATP generation in mitochondria, these protons can pass back through the thylakoid membrane only through membrane-bound ATP synthase complexes. In chloroplasts these complexes are called CF_0 – CF_1 complexes, and they exhibit considerable resemblance to the F_0 – F_1 complexes of mitochondria (see Chapter 15). It has been estimated that one ATP is produced for each three protons passing through the CF_0 – CF_1 complex. Three moles of protons would supply ~ 60 kJ to drive the synthesis of 1 mole of ATP, a thermodynamically reasonable result. Because ~ 12 moles of H^+ are transported per mole of O_2 produced, $\sim 12/3 \approx 4$ moles of ATP are generated for each mole of O_2 evolved.

A summary view of the whole set of light reactions is shown in Figure 16.17. It should be noted that photosystems I and II, the cytochrome b_6f complex, and ATP synthase (CF_0 – CF_1) are all individual entities embedded in the thylakoid membrane but are not necessarily contiguous. The components that link the photosystems and the b_6f complex are mobile—plastoquinone in the lipid phase of the membrane and plastocyanin in the thylakoid lumen. Thus, electrons can be moved over long distances in this system. Such long-range transport is necessary because of the arrangement of components in the thylakoid membrane. Careful analysis of the composition of grana indicates that the interior membrane layers of the grana are rich in photosystem II; by contrast, the stroma lamellae are rich in photosystem I (Figure 16.18). This physical segregation of photosystems is possible because of the high mobilities of plastoquinone and plastocyanin. Physical separation of PSI and PSII also provides a way to optimize the quantum yield of the photosynthetic process. For maximum efficiency, the energy absorbed by each

Both photosystems transport protons from the stroma into the thylakoid lumen. The return of protons, through CF_0 – CF_1 complexes, is used to generate ATP.

FIGURE 16.17

Summary view of the light reactions as they occur in the thylakoid. Photosystems I and II and the cytochrome b_6f complex are physically separate protein complexes embedded in the thylakoid membrane. Electron transfer from PSII to cytochrome b_6f is by diffusion of reduced plastoquinone (QH_2) in the membrane lipid. Transfer from b_6f to PSI is mediated by plastocyanin (PC), soluble in the lumen. The protons added to the thylakoid lumen during the light reactions pass back across the thylakoid membrane via ATP synthase complexes (CF_0 – CF_1). The ATP synthase catalytic subunits are in the CF_1 component and face into the stroma so that ATP is generated in that compartment. Reduction of $NADP^+$ by Fd– $NADP^+$ reductase (FNR) also occurs on or near the stromal surface of the membrane.

**FIGURE 16.18**

Arrangement of components of the two photosystems on the thylakoid membrane. The membrane layers in the interior of the granum are rich in photosystem II. The stroma lamellae and the top and bottom surfaces of the granum are rich in photosystem I and ATP synthase particles, allowing $NADP^+$ reduction and ATP generation to occur at or near these stroma-facing surfaces.

photosystem should be balanced. Because the intensity and spectral quality of light can change rapidly, higher plants and green algae have evolved an elegant mechanism to modulate the excitation energy of the two photosystems. Recall that PSII and PSI have distinct maximum absorption at 680 nm (blue–green light) and 700 nm (red light), respectively. If PSII is excited in excess over PSI (referred to as State 2), the plastoquinone pool becomes over-reduced because PSII reduces Q to QH_2 faster than the cytochrome b_6f complex and PSI can oxidize it (refer to Figure 16.17). In State 1, PSI is excited in excess over PSII, and the plastoquinone pool becomes over-oxidized. To maintain an optimal excitation balance, the chloroplast can switch the light-harvesting efficiency of the two photosystems in a process called **state transitions**. This is accomplished by redistributing the LHCII antenna complexes (Figure 16.10) between PSII and PSI within the thylakoid membrane. The trigger for this switch is phosphorylation of LHCII, catalyzed by specific thylakoid-bound kinases. The kinase is activated by accumulation of reduced plastoquinone. Phosphorylated LHCII dissociates from PSII and binds to PSI, thereby redirecting the absorbed excitation energy to PSI at the expense of PSII. Once PSI activity catches up with PSII, the plastoquinone pool will become oxidized, leading to deactivation of the LHCII kinase. A constitutively active protein phosphatase catalyzes dephosphorylation of LHCII, which then redistributes back to PSII. These state transitions occur on a timescale of seconds to minutes in response to changing light conditions.

An Alternative Light Reaction Mechanism: Cyclic Electron Flow

In the two-system light reactions just described, the electrons displaced from photosystem I by excitation are replaced by photosystem II, which receives them from water. The entire process is called **noncyclic electron flow**, and generation of ATP by this process is called **noncyclic photophosphorylation**. An alternative pathway for the light reactions, called **cyclic electron flow**, utilizes the components of photosystem I, plus plastocyanin and the cytochrome b_6f complex (Figure 16.19). Whether this pathway is used or not depends on the levels of $NADP^+$ in the chloroplast stroma. When $NADP^+$ is present in only small amounts, electrons excited in the P700 center are not transferred to $NADP^+$. Instead, they are passed from ferredoxin to the cytochrome b_6f complex and from there returned via plastocyanin to the P700 ground state. One way to look at this cyclic electron flow is to consider the b_6f

FIGURE 16.19

Cyclic electron flow. When levels of NADP^+ are low and levels of NADPH are high, electrons from the P700 center are returned to it via the cytochrome b_6f complex. There is no NADP^+ reduction, but protons are pumped across the membrane and therefore ATP is generated. Symbols are as in Figure 16.12.

Cyclic electron flow, an alternative to two-system (noncyclic) electron flow, generates extra ATP when NADPH is plentiful.

complex and NADP^+ as competitors for the electrons from Fd. The b_6f complex pumps protons across the thylakoid membrane during this cyclic process, thereby ensuring the generation of ATP. Approximately one ATP is generated for every two electrons that complete the cycle, a process called **cyclic photophosphorylation**. However, in this process, no O_2 is released and no NADP^+ is reduced.

Cyclic electron flow apparently serves to generate ATP in situations when the reductant NADPH is abundant and little NADP^+ is available as an electron acceptor. It may also play a more fundamental role. As we shall see, the requirements for ATP in the photosynthetic dark reactions are substantial and may not always be fully met by noncyclic electron flow. Cyclic photophosphorylation, which produces ATP but no NADPH , helps maintain the necessary balance between ATP and NADPH production.

Reaction Center Complexes in Photosynthetic Bacteria

The light reactions just described are those that occur in plants and algae. However, some of our most precise information concerning functioning of the light reactions has come from studies of photosynthesizing bacteria, such as the purple bacteria (named for the colored bacteriochlorophyll and carotenoid pigments in their membranes). These bacteria are versatile organisms, able to obtain energy in the dark using cellular respiration, or in the light by switching on photosynthesis. Pioneering studies by Roderick Clayton showed that these organisms use only a single photosystem and that the reaction centers from these organisms could be isolated in pure form. Later, the entire molecular structure of a crystallized reaction center complex from the purple bacterium *Rhodospseudomonas viridis* was determined by Johann Deisenhofer, Hartmut Michel, and Robert Huber using X-ray diffraction. This work earned the Nobel Prize in Chemistry in 1988.

A structural model of a purple bacterial reaction center complex is shown in Figure 16.20. It is a transmembrane protein, consisting of four polypeptides. The

FIGURE 16.20

Model of a purple bacterial reaction center complex. A view of the reaction center from *Blastochloris viridis* (formally *Rhodospseudomonas viridis*) (PDB ID 3D38) as seen from the plane of the membrane (approximate locations of the periplasmic and cytoplasmic faces of the membrane are indicated). The cytochrome (yellow), carrying four heme groups (red), lies in the periplasmic space between the bacterial inner and outer membranes. Subunits M (silver) and L (tan), each with five transmembrane α -helices, span the membrane. These subunits carry four bacteriochlorophylls (green), two bacteriopheophytins (cyan), two quinones (white), and an iron atom (red)—all involved in photon harvesting and electron transfer. Two of the bacteriochlorophylls constitute the reaction center. Subunit H (orange) lies mostly on the cytosolic side of the membrane but has one membrane-spanning α -helix.

portion of the complex that lies outside the bacterial plasma membrane, in the periplasmic space, is a *c*-type cytochrome carrying four heme groups. Subunit H, on the other hand, lies largely on the cytosolic face of the membrane. Buried within the membrane are two subunits (L and M) that are largely α -helical. They carry four bacteriochlorophyll *b* molecules, two bacteriopheophytins, two quinones (designated Q_A and Q_B), and a bound iron atom. Two of the bacteriochlorophylls (the “special pair”) lie very close together; they constitute the reaction center itself. Light absorbance is maximal in the near infrared, at about 870 nm, so the center is referred to as P870.

Chemically, the purple bacterial reaction center complex most closely resembles photosystem II in plants, given that it contains pheophytins (bacteriopheophytin, or BPh) and quinones. Studies of the kinetics of the reactions in isolated type-II centers have elucidated the electron pathway (Figure 16.21). Excitation of the reaction center leads very quickly (in about 10^{-12} s) to transfer of an electron to one of the two pheophytins. The electron is then passed on to Q_A and then to Q_B . These quinones are normally bound in the complex, but on receiving a second electron (and two protons), Q_B dissociates. QH_2 is believed to then move to and reduce a cytochrome bc_1 complex (homologous to the cytochrome bc_1 complex in mitochondria). The electron is returned from the bc_1 complex to the reaction center via the cytochrome in the reaction center complex. Because the electron flow is cyclic, there is no net oxidation–reduction, and thus no need for an external reductant, such as water. Consequently, this process does not produce O_2 , and is referred to as *anoxygenic* photosynthesis.

However, the net result of this cyclic electron flow is to pump protons from the bacterial cytosol into the periplasmic space as QH_2 is oxidized by the bc_1 complex. The cytosols of such bacteria become quite alkaline as photosynthesis continues. Return of protons is through ATP synthase complexes spanning the plasma membrane, resulting in generation of ATP (Figure 16.21). The cyclic electron flow in these bacteria must be carefully distinguished from the cyclic flow that can occur via photosystem I in plants. The bacterial system is, with respect to its electron carriers, much more like photosystem II. Though no reducing power has been directly generated by the light reaction in this case, these bacteria can

Some photosynthetic bacteria use a photosystem that generates ATP in a manner analogous to that of photosystem II.

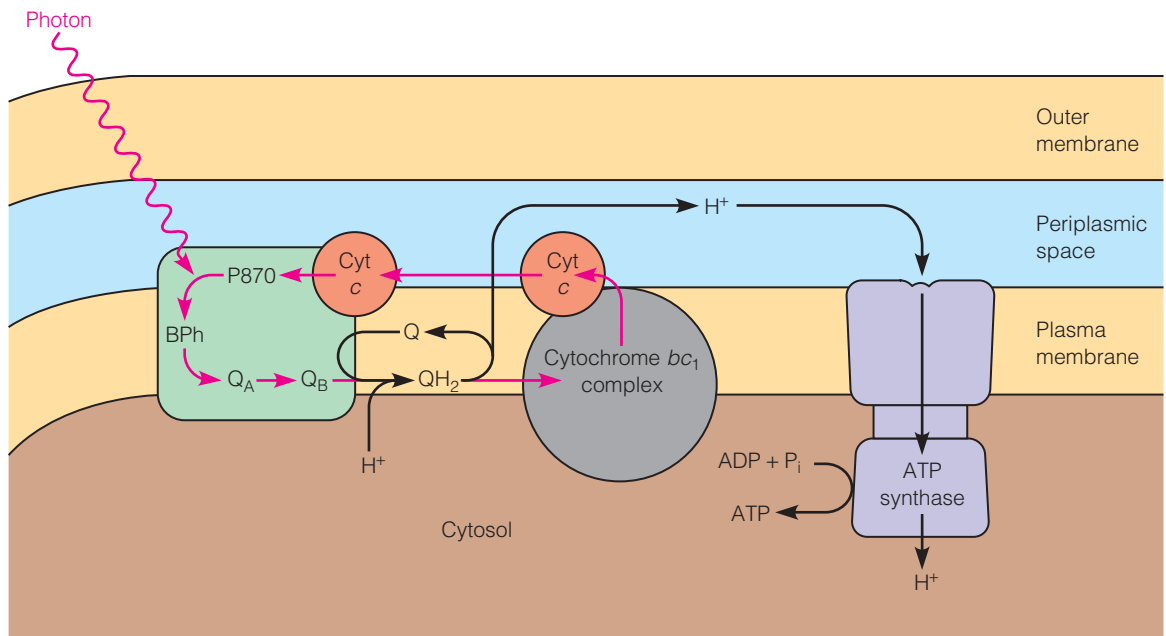

FIGURE 16.21

Postulated mechanism for purple bacterial photosynthesis. This process somewhat resembles the photosystem II reactions in the thylakoid (see Figure 16.17), with a reaction center and a membrane-bound cytochrome complex. However, there is only one kind of reaction center, water is not split, and electron flow is cyclic.

carry out the dark reactions of photosynthesis (CO_2 assimilation) by using ATP energy to transfer electrons from various substrates such as H_2S , S , $\text{S}_2\text{O}_3^{2-}$ (thio-sulfate), or H_2 to NADP^+ to produce the necessary NADPH.

Other anoxygenic photosynthetic bacteria, such as the anaerobic green bacterium *Chlorobium*, use a photosystem that more closely resembles photosystem I in plants. These type-I systems catalyze a linear light-driven electron transport process, in which electrons are extracted from H_2S to replenish the oxidized reaction center, and S_2 is released.

FIGURE 16.22

Artificial photosynthesis. In this solar cell, absorbed light energy drives the splitting of water into oxygen and protons, forming hydrogen (H_2) fuel.

Artificial Photosynthesis

The great incentive to devise new, environmentally safe energy sources has led a number of scientists to attempt to mimic the most efficient solar energy converters known—photosynthesizing plants. Although many kinds of molecules can capture photons, in most cases the energy is simply degraded to heat at low temperatures and cannot produce useful work. The trick is to produce, by capture of radiation, a long-lived excited state that can be coupled to a desired energy-saving process. Recently, researchers succeeded in incorporating a bioinspired manganese–oxygen catalyst (Mn_4O_4) into a plastic membrane that allows protons to pass in one direction (Figure 16.22). The membrane separates two electrodes. The anode is immersed in a solution containing a ruthenium dye; sunlight excites electrons in the dye that are picked up by the anode and passed into an external circuit. The Mn_4O_4 complex also absorbs photons, whereupon it catalyzes the splitting (oxidation) of H_2O to O_2 and protons (H^+). The electrons from water are passed to the electron-deficient dye molecules, and the protons pass through the membrane to the cathode. These protons then combine with electrons from the external circuit, producing hydrogen gas (H_2). Thus, like natural photosynthesis, this artificial solar cell converts sunlight into chemical fuel, although with much lower efficiency.

In what is a rapidly progressing field, a wide variety of other model systems have been developed or proposed. It may well turn out that a major energy source in the future will be patterned on that developed by nature several billion years ago.

The Dark Reactions: The Calvin Cycle

The dark reactions occur in the stroma of the chloroplast (or in the cytoplasm of photosynthetic bacteria). Their function is to fix atmospheric carbon dioxide into carbohydrates, utilizing ATP energy and reducing power (NADPH) generated by the light reactions. As noted earlier, the dark reactions can occur without light but are accelerated in the presence of light.

Carbon dioxide fixation is accomplished by adding one CO₂ at a time to an acceptor molecule and passing the molecule through a cyclic series of reactions, shown schematically in Figure 16.23. The whole series is called the **Calvin cycle**, after the biochemist Melvin Calvin, who in 1961 received the Nobel Prize for his work in this field. Calvin, working with James Bassham and Andrew Benson in the 1940s and 50s, exposed cultures of unicellular algae such as *Chlorella* and *Scenedesmus* to ¹⁴C-labeled CO₂ for a few seconds, and then rapidly killed the cells to stop all metabolism. Extracts were analyzed by the newly developed technique of two-dimensional paper chromatography and radioactive compounds were detected by exposing the chromatogram to X-ray film (autoradiography, see Tools of Biochemistry 12A). These methods allowed the researchers to discover the first product of CO₂ fixation (3-phosphoglycerate) and eventually to elucidate the entire cyclic pathway. The cycle results in the formation of hexoses and in the regeneration of the acceptor molecule. The Calvin cycle can be envisioned as divided into two stages. In stage I, the carbon dioxide is trapped as a carboxylate and reduced to the carbonyl level found in sugars, resulting in net carbohydrate synthesis. Stage II is dedicated to regenerating the acceptor molecule. Let us examine each stage in turn.

Stage I: Carbon Dioxide Fixation and Sugar Production

Incorporation of CO₂ into a Three-Carbon Sugar

Carbon dioxide is incorporated into glyceraldehyde-3-phosphate (GAP) via the intermediates shown in Figure 16.23. The acceptor molecule for CO₂ is **ribulose-1,5-bisphosphate (RuBP)**. Carbon dioxide from the air diffuses into the stroma of the chloroplast, where it is added at the carbonyl carbon of RuBP. The reaction is catalyzed by the enzyme **ribulose-1,5-bisphosphate carboxylase**, also known as ribulose-1,5-bisphosphate carboxylase/oxygenase (or **rubisco**). This enzyme is one of the most important in the biosphere and certainly the most abundant. It makes up about 15% of all chloroplast proteins, and there are an estimated 40 million tons of it in the world—about 20 pounds for every living person. There are four different forms of rubisco found in nature. Form I, found in higher plants, eukaryotic algae, and many cyanobacteria and proteobacteria, is composed of eight large (~50 kDa) catalytic subunits and eight small (~15 kDa) non-catalytic subunits. This L₈S₈ complex is arranged as a core of four homodimers of catalytic subunits capped on the top and bottom by four small subunits. The large, catalytic subunits are encoded by the chloroplast genome, whereas the small subunits are encoded by the nuclear genome. Thus, production of active rubisco in the chloroplast stroma requires coordination of nuclear and chloroplast gene expression and translocation of the cytoplasmically synthesized small subunits into the chloroplast for assembly of the holoenzyme. The other three known forms of rubisco are less widely distributed and are composed of various arrangements of large subunits only.

As its full name implies, rubisco also has an alternative oxygenase activity. We shall see the consequences of this other activity later. For the moment we will concentrate on its CO₂-fixing (carboxylase) function. The carboxylase reaction is a

FIGURE 16.23

Schematic view of the Calvin cycle. The cycle may be divided into two stages. In stage I, CO₂ is fixed and glyceraldehyde-3-phosphate (GAP) is produced. Part of this GAP is used to make hexose phosphates and eventually polysaccharides. Another fraction of the GAP is used in stage II to regenerate the acceptor molecule, ribulose-1,5-bisphosphate.

The Calvin cycle uses the ATP and NADPH generated in the light reactions to fix atmospheric CO₂ into carbohydrate.

Autoradiogram of a 2D paper chromatogram showing labeled products after a 60-sec exposure of *Scenedesmus* to ¹⁴CO₂.

Springer/*Photosynthesis Research* 73:29–49, 2002, A. A. Benson, Following the path of carbon in photosynthesis: A personal story, with kind permission from Springer Science+Business Media B.V.

The Calvin cycle has two stages. First, CO₂ is fixed by addition to ribulose-1,5-bisphosphate (RuBP) and hexoses are formed. In the second stage RuBP is regenerated.

complex series of steps in which the actual CO_2 acceptor is proposed to be the five-carbon enediolate intermediate:

FIGURE 16.24

Active site of rubisco. This model is based on the X-ray structure (PDB ID 8RUC) of spinach rubisco complexed with Mg^{2+} and the transition-state analog 2-carboxy-D-arabinitol-1,5-bisphosphate (2CABP).

Modified with permission from *Journal of the American Chemical Society* 130:15063–15080, B. Kannappan and J. E. Gready, Redefinition of rubisco carboxylase reaction reveals origin of water for hydration and new roles for active-site residues. © 2008 American Chemical Society.

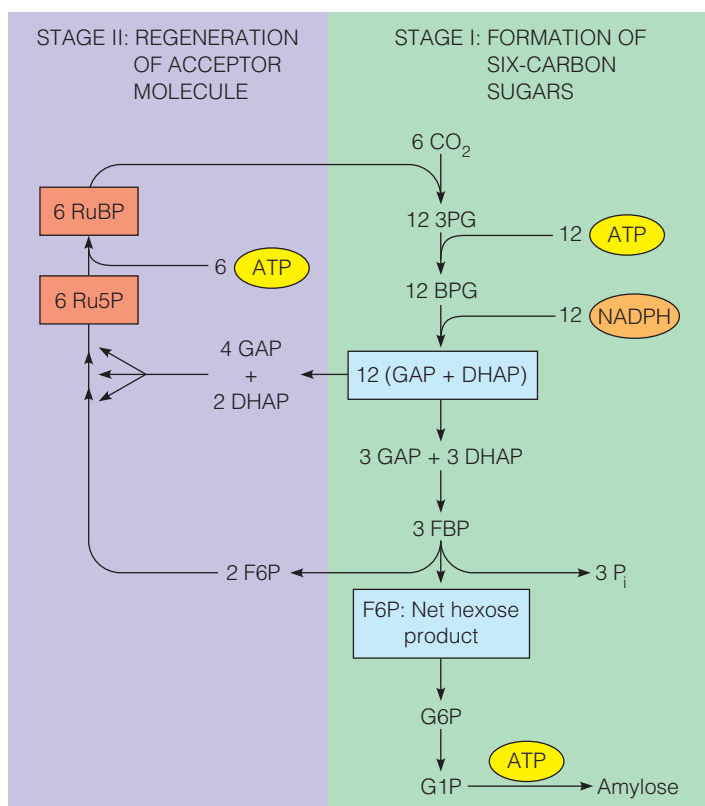

The chemistry of this reaction is the subject of intense research, and several mechanisms have been proposed. The enzyme is first activated by *carbamation* of an active site lysine residue. This carbamate, formed by nonenzymatic reaction of a nonsubstrate CO_2 with the ϵ -amino group of lysine, is analogous to the carbamates on the N-termini of hemoglobin (Chapter 7). The negatively charged carbamate forms part of the binding site for an essential Mg^{2+} ion (Figure 16.24). The Mg^{2+} ion is involved in binding RuBP and activating the H_2O molecule that hydrates the carboxy- β -keto intermediate. Once the enediolate intermediate is carboxylated, the product is hydrated and then cleaved to yield two molecules of 3-phosphoglycerate (3PG). Cleavage is facilitated by protonation by an active site acid (HB-Enz). The reaction is essentially irreversible, with $\Delta G^{\circ} = -35.1$ kJ/mol. At this point CO_2 has already been fixed into a carbohydrate. The remainder of the Calvin cycle reactions are dedicated to producing hexoses from the triose and regenerating RuBP.

Each molecule of 3PG is phosphorylated by ATP, in a reaction catalyzed by *phosphoglycerate kinase*. The 1,3-bisphosphoglycerate so produced is then reduced to glyceraldehyde-3-phosphate (GAP), with accompanying loss of one phosphate. The reducing agent is NADPH, produced in the light reaction, and the reaction is catalyzed by the enzyme *glyceraldehyde-3-phosphate dehydrogenase*:

We have encountered similar enzymes earlier, in connection with their roles in glycolysis (see Chapter 13).

At this stage of the cycle a molecule of CO_2 has been fixed into a simple (three-carbon) monosaccharide. It is useful to note the requirements in ATP and

**FIGURE 16.25**

Stoichiometry of the Calvin cycle. In six turns of the Calvin cycle, six CO_2 molecules will have entered and bound to six molecules of ribulose-1,5-bisphosphate (RuBP) to yield 12 molecules of glyceraldehyde-3-phosphate (GAP). Because GAP is in isomeric equilibrium with dihydroxyacetone phosphate (DHAP), the 12 GAP may be considered an interconvertible stock of 12 molecules of (GAP + DHAP). Of these, six are used to make three molecules of fructose-1,6-bisphosphate (FBP), of which one constitutes the net hexose product of the six turns. The other two FBPs are used, together with the six remaining molecules of (GAP + DHAP), to form six molecules of ribulose-5-phosphate (Ru5P), which are then phosphorylated to regenerate the required six molecules of RuBP.

NADPH up to this point. For each CO_2 molecule that has passed through these steps, two molecules of ATP have been hydrolyzed and two molecules of NADPH have been oxidized. However, it is more appropriate to keep accounts on a “per glucose” basis because we want to see what must happen to account for the generation of one hexose molecule from CO_2 . Figure 16.25 provides a schematic view of the stoichiometry of the whole Calvin cycle. Six molecules of CO_2 will have to enter the cycle to provide the six carbons needed for every new molecule of hexose produced. That will require formation of 12 GAP, and therefore 12 ATP and 12 NADPH will be needed.

At this point the pathway splits, so as to satisfy the two essential goals—to make hexoses and to regenerate the acceptor. Of the 12 molecules of GAP that have been produced, two will be used to make a molecule of a hexose. The remaining 10 will be utilized to regenerate the 6 molecules of ribulose bisphosphate necessary to maintain the cycle. That is, 10 three-carbon molecules will be converted to 6 five-carbon molecules.

Formation of Hexose Sugars

This is actually familiar ground, for it follows a portion of the gluconeogenic pathway described in Chapter 13. The reactions are shown schematically in Figure 16.25. Recall that glyceraldehyde-3-phosphate can be isomerized to dihydroxyacetone phosphate (DHAP) by triose phosphate isomerase (pages 528–529). Thus, the 12 molecules of GAP produced can be considered to be an interconvertible equilibrium pool of GAP and DHAP. A molecule of GAP and a molecule of DHAP can be combined, via the enzyme *fructose bisphosphate aldolase*, to yield fructose-1,6-bisphosphate (FBP). As Figure 16.25 shows, six of the GAP molecules follow this path, to yield three molecules of FBP. The FBP is dephosphorylated by fructose-1,6-bisphosphatase to yield three molecules of fructose-6-phosphate (F6P). Of these, two will be employed in the regeneration pathway, but one is available as a net product of the Calvin cycle; it is then isomerized to glucose-6-phosphate (G6P) and finally to glucose-1-phosphate (G1P).

Glucose-1-phosphate is, in plants as in animals, the precursor to oligosaccharide and polysaccharide formation. Formation of plant starch (amylose) follows a path similar to that used by animals in glycogen synthesis. However, instead of using UTP to activate the glucose monomer, as in glycogen formation, ATP is employed in the polymerization of amylose:

Amylose, which is not very soluble, is a storage carbohydrate. However, much of the saccharide synthesized in plant leaves is exported to other parts of the plant, mostly in the form of sucrose. Sucrose is synthesized in the cytosol of plant leaves by the following sequence of reactions:

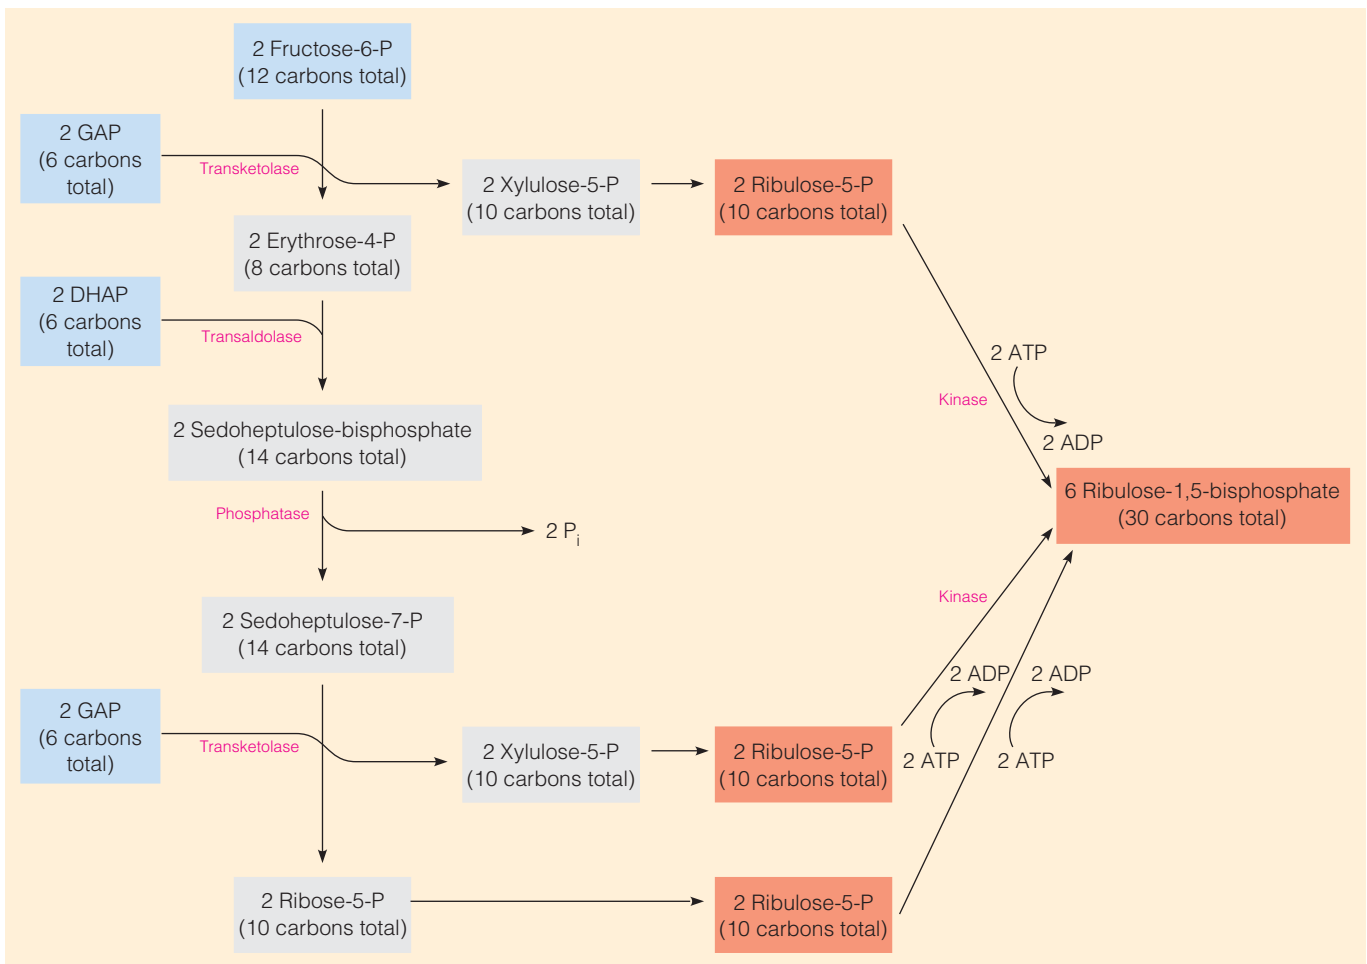

The UDP produced is then converted back to UTP by phosphate transfer from ATP.

FIGURE 16.26

Regeneration phase of the Calvin cycle. The stoichiometry here follows that in Figure 16.25. The two molecules of fructose-6-phosphate entering at the top are combined with four molecules of GAP and two molecules of DHAP to yield the required six molecules of ribulose-5-phosphate. These are then phosphorylated to produce the required RuBP. Note the similarity of this pathway to parts of the pentose phosphate pathway running in reverse (see Figure 13.39, page 576).

Stage II: Regeneration of the Acceptor

The reactions we have considered to this point can account for the introduction of one carbon into one molecule of hexose, with subsequent formation of oligosaccharides or polysaccharides. But to complete the Calvin cycle, it is necessary to regenerate enough ribulose-1,5-bisphosphate to keep the cycle going. This means we will need to regenerate 6 moles of RuBP for every 6 moles of CO_2 taken up. This is accomplished by the set of reactions shown in Figure 16.26, which constitute the

regenerative phase of the cycle schematized in Figures 16.23 and 16.25. Note that the *input* molecules in this somewhat complex reaction pathway are as follows:

1. Two molecules of DHAP and four molecules of GAP, from the six GAP that were diverted to the regeneration pathway in Figure 16.25.
2. Two of the three molecules of fructose-6-phosphate (F6P) that were produced from the remaining three GAP and three DHAP.

In order to make five-carbon molecules from six-carbon and three-carbon molecules, several rearrangements are required. They are accomplished by *transketolases* and *transaldolases*. The structures of the sugars involved in these reactions are all given in Chapter 9 and the chemistry of these reactions is discussed in Chapter 13 (pages 578–580). What is important here is the way in which two hexoses and six trioses have been rearranged and recombined to form six pentoses.

The final step in the regeneration of ribulose-1,5-bisphosphate is a phosphorylation, catalyzed by the enzyme *ribulose-5-phosphate kinase* and utilizing ATP. For six rounds of the cycle, this step will require 6 ATPs in addition to the 12 already accounted for. Therefore, the requirements for synthesizing 1 mole of hexose from CO₂ are 12 moles of NADPH and 18 moles of ATP:

[H is balanced in the second equation when the H in P_i (HPO₄²⁻) is included.] Summing these two equations, we can write the overall dark reaction as

A Summary of the Light and Dark Reactions in Two-System Photosynthesis

The Overall Reaction and the Efficiency of Photosynthesis

The ATP and NADPH needed for the dark reactions are released into the stroma by the light reactions of photosynthesis. If we recall that two photons are required for every electron to pass through photosystems I and II, and that two electrons are required to reduce each NADP⁺, then four photons are necessary for the production of each NADPH molecule. This corresponds to eight photons per O₂, a number in agreement with the quantum efficiency experimentally observed when both photosystems are operating—about 0.12 O₂ per photon. For the 12 NADPH needed in the dark reaction, as summarized in the previous section, 48 photons must be absorbed. If we assume that these photons will also pump enough protons across the thylakoid membrane to yield the 18 ATP required, we may, as an approximation, write the light reactions as

This equation differs from the third equation on page 689 because we now include the ATP generation from the proton gradient. Adding this equation for the light reaction to the overall dark reaction, we obtain

This estimate of 48 photons assumes that noncyclic photophosphorylation provides enough ATP for the dark reactions. If, as many workers in the field believe, additional ATP from cyclic photophosphorylation is required, the number of photons needed will be greater.

The overall energy efficiency of photosynthesis can approach 35%.

The photosynthetic dark reactions are regulated by the amount of light available to the organism through the activation of key enzymes.

2-carboxy-D-arabinitol-1-phosphate (CA1P)

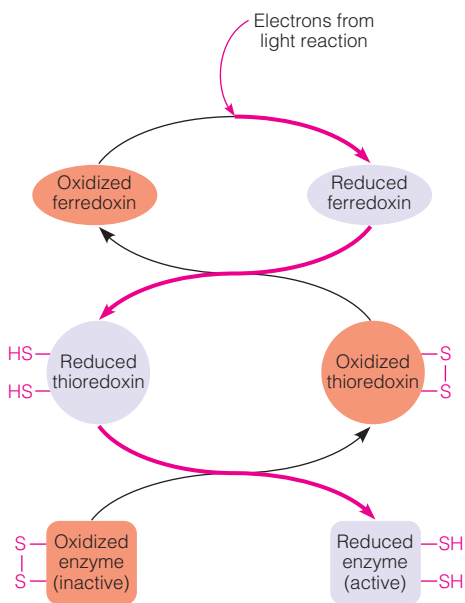

FIGURE 16.27

Light-dependent activation of dark-reaction enzymes. Some enzymes of the Calvin cycle are activated by disulfide reduction, which is mediated by reduced thioredoxin. Thioredoxin is reduced by reduced ferredoxin, which accumulates in irradiated chloroplasts. The flow of electrons from the light reactions (photosystem I) is indicated by the magenta arrows. In the dark, the enzymes are deactivated by reoxidation (reversal of the pathway). Additional functions of thioredoxin are presented in Chapter 22.

We can, on the basis of these calculations, estimate the energy efficiency of photosynthesis. Forming a mole of hexose from CO_2 and water requires, as we have seen, 2870 kJ. The energy input per photon depends on the wavelength of light used. Assuming that light of 650 nm wavelength is used, 48 einsteins of such light correspond to about 8000 kJ (see Figure 16.6). From this value, we estimate a theoretical efficiency of approximately 35%. Direct experimental measurements of the efficiency under optimal conditions give results in the same range or slightly lower. At high levels of illumination, when not all photons absorbed by the chloroplasts can be used for reaction center excitation, efficiency is much lower.

Regulation of Photosynthesis

It should be evident that the so-called dark reactions of photosynthesis, which result in the production of sugars, require careful regulation. Because the dark reactions depend on the reductive power and ATP supplied by the light reactions, it is not surprising that they are stimulated by the light reactions. There are three major ways in which this stimulation is accomplished. First, the central enzyme in the dark reactions, ribulose-1,5-bisphosphate carboxylase, is stimulated by high pH and by both CO_2 and Mg^{2+} . Recall from page 690 that the pumping of protons from the stroma into the thylakoid lumen by the light reactions increases the stromal pH; at the same time, Mg^{2+} ions enter the stroma to compensate for the positive charge of the H^+ ions that have been lost. Second, rubisco is sensitive to a number of naturally occurring sugar phosphates that act as tight-binding inhibitors, including xylulose-1,5-bisphosphate, 2-carboxy-D-arabinitol-1-phosphate (CA1P), as well as the ribulose-1,5-bisphosphate substrate itself. These inhibitors resemble transition state intermediates and cause the active site of rubisco to adopt a closed conformation, preventing carbamation and/or substrate binding. Genetic experiments with *Arabidopsis* led to the discovery of a regulatory enzyme, termed **rubisco activase**, that is required for activation and maintenance of Rubisco activity *in vivo*. Rubisco activase promotes the ATP-dependent dissociation of the inhibitor, facilitating the carbamation reaction and the binding of Mg^{2+} and substrate.

One of the most potent rubisco inhibitors, CA1P, is synthesized in chloroplasts in the dark, and is responsible for the characteristic decline in rubisco activity during darkness. When the chloroplasts are again illuminated, rubisco activase removes CA1P and reactivates rubisco. Rubisco activase is itself activated in the light by another light-dependent mechanism that will be described next.

The third way by which the dark reactions are stimulated by the light reactions depends on the redox state of critical disulfide bonds in several enzymes of the Calvin cycle. Rubisco activase, fructose-1,6-bisphosphatase (see page 697), sedoheptulose-1,7-bisphosphatase (the phosphatase shown in Figure 16.26), glyceraldehyde-3-phosphate dehydrogenase (see page 696), and ribulose-5-phosphate kinase (see Figure 16.26) are all activated by reduction of disulfides to sulfhydryls in the enzymes. Reduction is promoted by a disulfide exchange reaction with the protein *thioredoxin* (Figure 16.27). Thioredoxin, a small protein carrying two reversibly oxidizable Cys-SH groups, is used in a wide variety of redox reactions (see page 940). The reduction of thioredoxin, in turn, is promoted by oxidation of the reduced form of ferredoxin via a reaction catalyzed by the enzyme *ferredoxin-thioredoxin reductase*. In strongly irradiated chloroplasts, in which NADP^+ stores are depleted, reduced ferredoxin accumulates. High levels of reduced ferredoxin thereby lead to activation of the Calvin cycle enzymes, stimulating the Calvin cycle reactions when the light reactions are very active. The same compound, reduced thioredoxin, also stimulates the $\text{CF}_0\text{-CF}_1$ complexes, ensuring a high rate of ATP generation when illumination is intense.

In the dark, the plant “turns into an animal” in terms of its biochemistry. Although the dark reactions of photosynthesis may continue for some time, using photosynthesized ATP and NADPH, the plant must ultimately begin to draw on

its energy reserves, using pathways familiar from our studies of animal catabolism: glycolysis, the citric acid cycle, and the pentose phosphate pathway. In general, these pathways are inhibited in plants in the presence of sunlight and become more active in the dark. The key light-inhibited enzymes are phosphofruktokinase (in glycolysis) and glucose-6-phosphate dehydrogenase (in the pentose phosphate pathway). The latter is inhibited by the same reduced form of thioredoxin that *activates* Calvin cycle enzymes.

Finally, it should be mentioned that there is now evidence for regulation of chloroplast genes at the transcriptional level. Sucrose and glucose can act as corepressors, turning off expression of the photosynthetic machinery.

Photorespiration and the C₄ Cycle

Ribulose biphosphate carboxylase is a peculiar enzyme. Under normal environmental conditions, it can behave as an *oxygenase* as well as a carboxylase. In the oxygenase reaction, it is proposed that the enediolate intermediate nucleophilically attacks O₂ instead of CO₂ (compare with the carboxylase reaction on page 696):

The relative rates of the carboxylase and oxygenase reactions are determined by the concentrations of the two gases at the active site of the enzyme and its K_M values for CO₂ and O₂. Oxygenation occurs under conditions of high O₂ and low CO₂ concentrations (such as found in normal air) because the K_M for O₂ is about 10-fold higher than for CO₂. When the oxygenase reaction becomes significant, it initiates a reaction pathway known as **photorespiration**, with production of 3-phosphoglycerate and *phosphoglycolate* in the chloroplast. As Figure 16.28 shows, the phosphoglycolate is then dephosphorylated and passed to organelles called **peroxisomes**. Here, it is further oxidized, yielding glyoxylate and hydrogen peroxide. The toxic H₂O₂ is broken down by catalase, and the glyoxylate is transaminated, producing glycine. The glycine enters mitochondria, where *two* molecules are converted into *one* molecule of serine, plus one molecule each of CO₂ and NH₃. This process, involving the multiprotein glycine cleavage system and serine hydroxymethyltransferase, is described in detail in Chapter 20. The gases CO₂ and ammonia are released. The serine passes back into the peroxisome, where a series of reactions convert it to glycerate. Returning to the chloroplast, the glycerate is rephosphorylated (using ATP) to yield 3-phosphoglycerate (3PG).

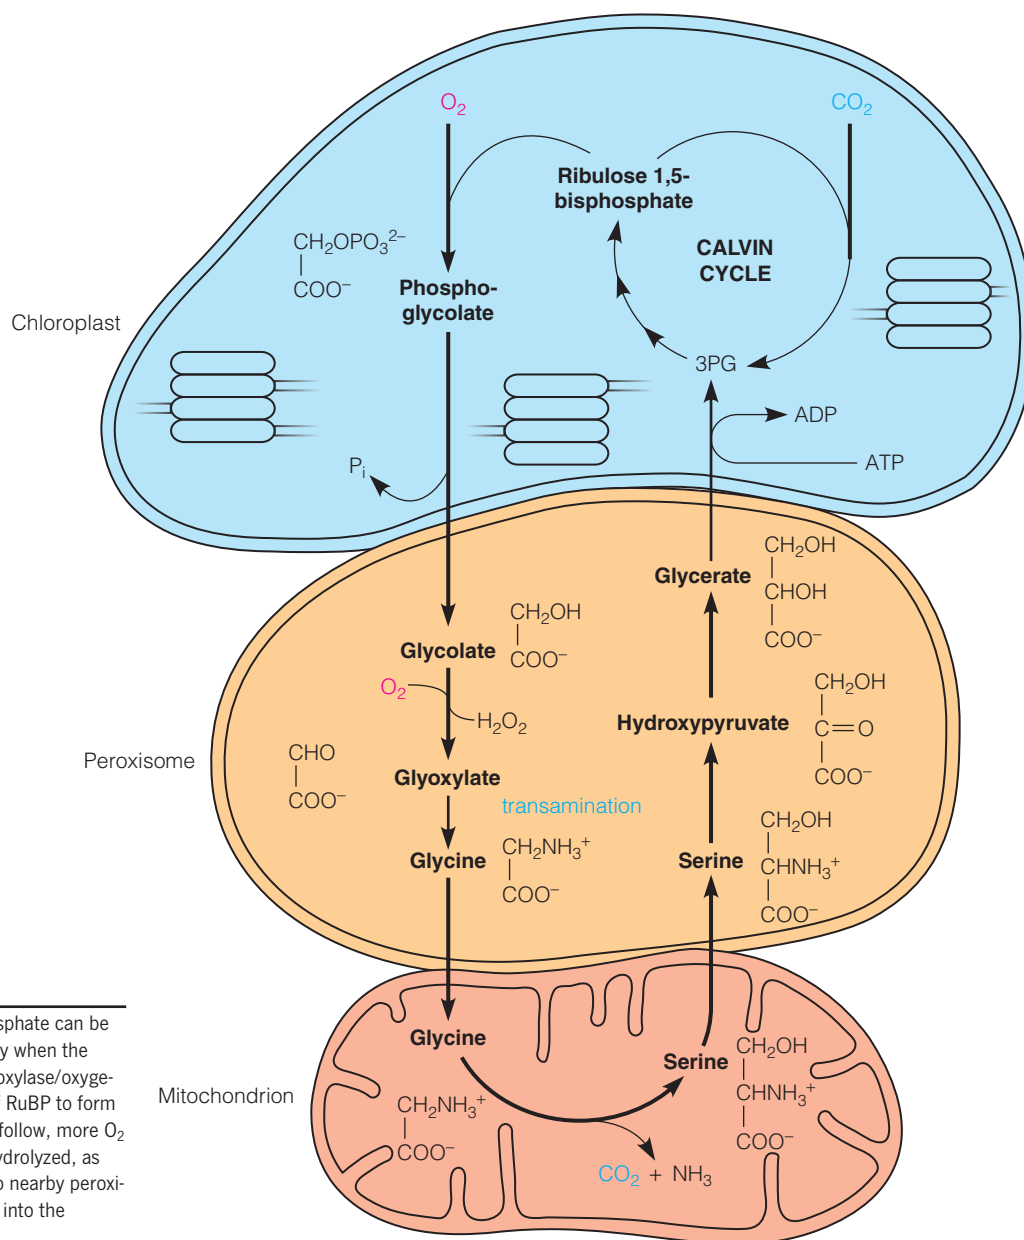

FIGURE 16.28

Photorespiration. Ribulose-1,5-bisphosphate can be diverted from the Calvin cycle, especially when the concentration of CO_2 is low. RuBP carboxylase/oxygenase (rubisco) catalyzes the oxidation of RuBP to form phosphoglycolate. In the reactions that follow, more O_2 is used, CO_2 is generated, and ATP is hydrolyzed, as metabolites pass from the chloroplast to nearby peroxisomes and mitochondria and then back into the chloroplast.

Under conditions of low CO_2 and high O_2 , plants exhibit photorespiration, in which O_2 is consumed and CO_2 released.

Photorespiration appears to be a wasteful process that costs considerable energy and limits the carbon assimilation by the plant. Note the following:

1. Ribulose-1,5-bisphosphate is lost from the Calvin cycle.
2. The fixation of CO_2 is reversed: O_2 is consumed and CO_2 is released.
3. Only a part (75%) of the carbon is returned to the chloroplast.
4. ATP is expended.

So why does photorespiration exist? It is probably a result of the fact that evolution can only work with what it has at hand. Rubisco evolved as a carboxylase ~3 billion years ago, when the atmosphere was characterized by high CO_2 and low O_2 levels. Under these conditions, the oxygenation reaction was negligible. However, as O_2 levels increased in the atmosphere, its oxygenase activity became significant. Plants then had to evolve strategies to deal with the inefficiency introduced by the oxygenase activity of rubisco. You might expect they would modify the ribulose bisphosphate carboxylase/oxygenase enzyme to suppress the oxygenase function. Surprisingly, that is not the case. This enzyme, despite (or perhaps

because of) its vital importance, has changed little over long ages. It remains a relatively inefficient catalyst (with $k_{\text{cat}} \cong 2 \text{ s}^{-1}$) and has never lost its oxygenase function. Stuck with this “design flaw” in rubisco, plants instead evolved a pathway to reclaim the two-carbon fragment (phosphoglycolate) released by the oxygenase activity. This pathway, photorespiration, can thus be thought of as an evolutionary compromise, albeit an inelegant one.

Certain plants, which are called **C₄ plants**, have evolved an additional photosynthetic pathway that helps conserve CO₂ released by photorespiration. This pathway is called the **C₄ cycle** because it involves incorporation of CO₂ into a C₄ intermediate (oxaloacetate). This cycle is distinguished from the Calvin cycle, which utilizes a three-carbon intermediate, and is hence sometimes called the C₃ cycle. The C₄ cycle is found in several crop species (maize and sugarcane, for example) and is important in tropical plants, which are exposed to intense sunlight and high temperatures. Although photorespiration occurs to some extent at all times in all plants, it is most active under conditions of high illumination, high temperature, and CO₂ depletion.

C₄ photosynthesis is really just a CO₂ concentrating mechanism, providing a higher CO₂/O₂ ratio at the active site of rubisco that favors carboxylation. C₄ plants concentrate their Calvin cycle (C₃) photosynthesis in specialized *bundle sheath cells*, which lie below a layer of mesophyll cells (Figure 16.29a). The mesophyll cells, on the other hand, which are most directly exposed to external CO₂, contain the enzymes for the C₄ cycle. This pathway, as it operates in most C₄ plants, is shown in Figure 16.29b. It is essentially a mechanism for trapping CO₂ into a four-carbon compound and passing it on to bundle sheath cells for decarboxylation and use of the resulting CO₂ in their Calvin (C₃) cycle.

The key to the efficiency of C₄ plants is that the CO₂-fixing enzyme used in this pathway, *phosphoenolpyruvate carboxylase*, lacks the oxygenase activity shown by ribulose biphosphate carboxylase, and has a much lower K_M for CO₂. Thus, even under conditions of high O₂ concentration and low CO₂ concentration in the atmosphere, the mesophyll cells continue to pump CO₂ to the photosynthesizing bundle sheath cells, where rubisco is localized. This process helps maintain high enough CO₂ levels in the bundle sheath cells that CO₂ fixation, rather than photorespiration, is favored. Furthermore, if photorespiration *does* occur, the CO₂ that is released in that process can be largely salvaged in the surrounding mesophyll cells and returned to the Calvin cycle.

As Figure 16.29 shows, the C₄ cycle costs the plant energy in the form of ATP. In fact, because ATP is hydrolyzed to AMP and inorganic phosphate in regenerating phosphoenolpyruvate, the expense is equivalent to *two* extra ATPs for every CO₂ molecule fixed.

The inefficiency of rubisco as an enzyme and its participation in photorespiration greatly reduce the efficiency of plants as food producers. Not only the very large amounts of rubisco that must be synthesized but also the energy expended in photorespiration place seemingly unnecessary demands on plant metabolism. If a more efficient enzyme could be developed, crop yields could be significantly increased and nitrogen demands reduced. There were intensive attempts to engineer a more efficient rubisco into crop plants, but these efforts were unsuccessful, and have been largely abandoned. This failure is perhaps not surprising, since evolution has had a few billion years to eliminate the oxygenase activity and has not managed to do so. An alternative approach that is currently being pursued is to introduce C₄ photosynthesis into C₃ crop plants.

Some plants (called C₄ plants) minimize the wastefulness of photorespiration by utilizing an adjunct to the Calvin cycle.

Evolution of Photosynthesis

How did photosynthesis arise? It is generally accepted that anoxygenic photosynthesis appeared first, probably soon after life began more than 3.8 billion years ago. These earliest photosynthetic bacteria possessed a single photosystem, the predecessor of modern type-I and type-II photosystems, and relied on substances like

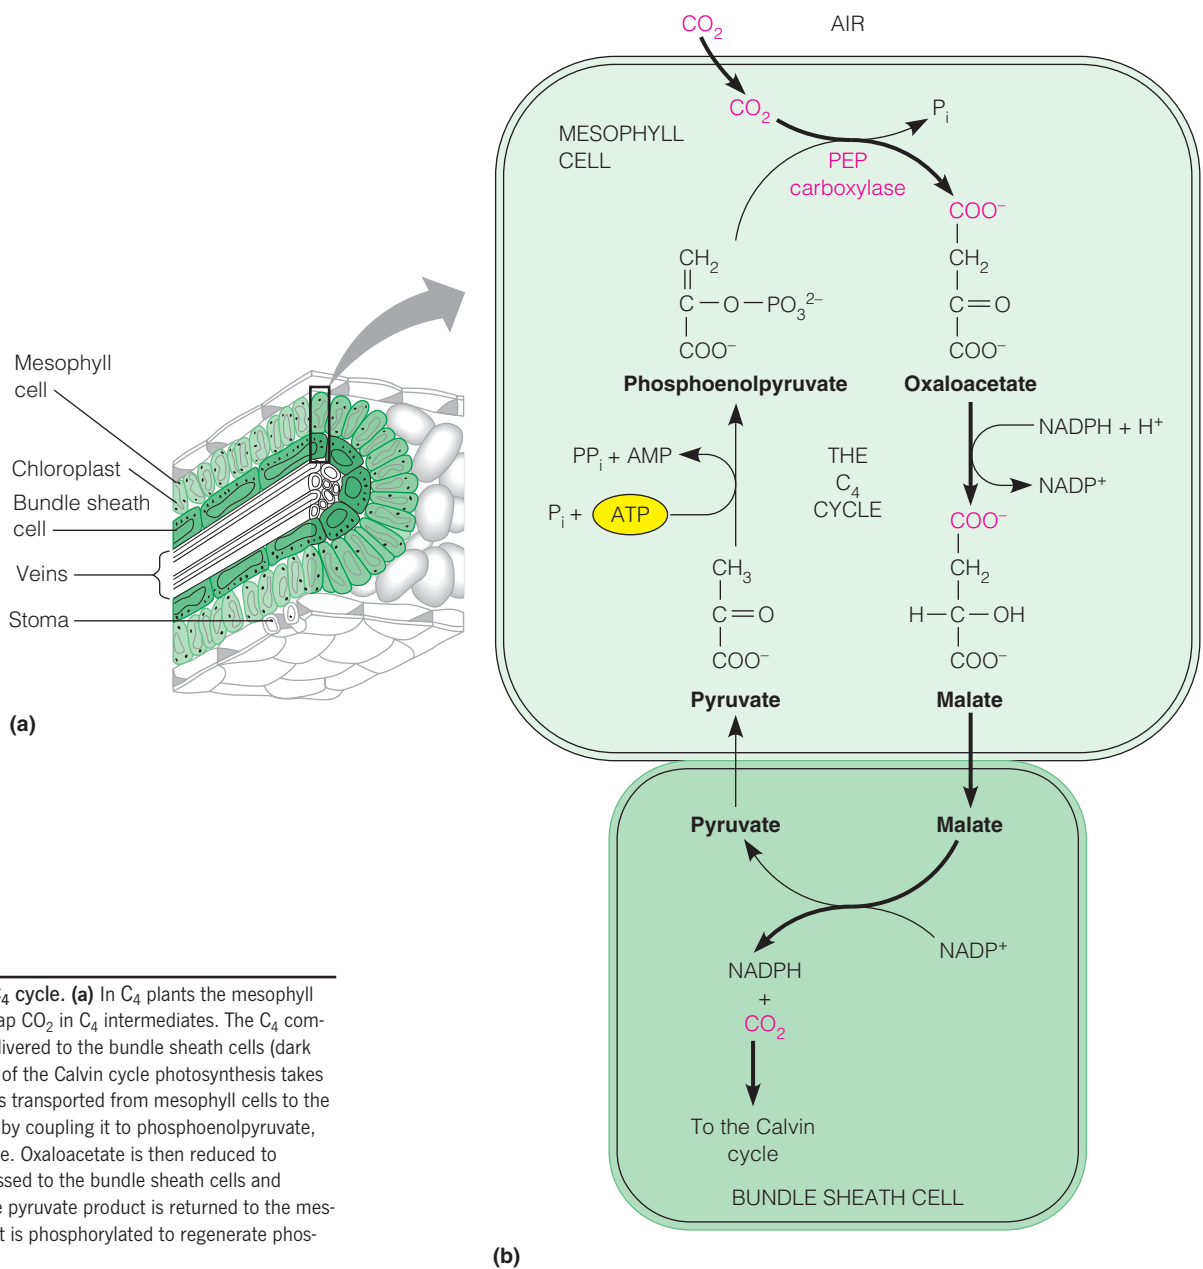

FIGURE 16.29

Reactions of the C₄ cycle. **(a)** In C₄ plants the mesophyll cells (light green) trap CO₂ in C₄ intermediates. The C₄ compounds are then delivered to the bundle sheath cells (dark green), where most of the Calvin cycle photosynthesis takes place (C₃). **(b)** CO₂ is transported from mesophyll cells to the bundle sheath cells by coupling it to phosphoenolpyruvate, forming oxaloacetate. Oxaloacetate is then reduced to malate, which is passed to the bundle sheath cells and decarboxylated. The pyruvate product is returned to the mesophyll cells, where it is phosphorylated to regenerate phosphoenolpyruvate.

hydrogen sulfide as an electron source. The modern descendants of these anoxygenic photosynthetic bacteria possess either a type-I or a type-II photosystem, but never both types in the same organism. Oxygenic photosynthesis, such as that seen in modern cyanobacteria, requires two photosystems, working in series, and a catalyst that splits water, producing O₂ and electrons—the manganese-dependent oxygen-evolving complex (OEC) of photosystem II (Figure 16.12b).

How all these components came together in one ancestral cell is the subject of much speculation. One theory, based on genomics analyses, argues that photosystem I was the ancestral prototype, from which photosystem II evolved, perhaps by a gene duplication event. An alternative theory holds that lateral gene transfer or fusion of a type-I cell with a type-II cell led to a “protocyanobacterium” possessing both photosystems (Figure 16.30). Either way, our ancient protocyanobacterium has a new problem. Recall that cyclic (type-II) photosystems supply electrons, via reduced quinones, into a proton-pumping complex (the cytochrome *bc*₁ complex) (Figure 16.21). A type-I photosystem operating in a linear fashion that uses electrons extracted from a donor such as H₂S supplies those electrons via ferredoxin to soluble electron acceptors such as NADP⁺ for net reduction of CO₂. These two

FIGURE 16.30

Proposed evolution of oxygenic photosynthesis. An ancestral anoxygenic “protocyanobacterium,” possessing genes for both type-I and type-II photosystems, expresses only one of the two photosystems at any time, depending on its environment and metabolic needs. Modern anoxygenic descendants possessing only a type-I photosystem, such as *Chlorobium* or *Heliobacillus*, evolved by loss of the type-II genes. Modern anoxygenic descendants possessing only a type-II photosystem, such as *Chloroflexus* or *Rhodospseudomonas* (renamed *Blastochloris*), evolved by loss of the type-I genes. Acquisition of a manganese-metal cluster, and loss of the regulatory switch that prevented simultaneous expression of the two photosystems, led to a cell with two photosystems linked in series to a Mn_4Ca catalyst that could extract electrons from H_2O and produce O_2 . This cell represents the ancestor of modern oxygenic Cyanobacteria.

functions would be favored under different growth conditions, but would compete with each other if expressed in the same membrane at the same time. Thus, our protocyanobacterium must have had a mechanism to switch between expression of the two photosystems, depending on its environment and metabolic state. Modern single-photosystem anoxygenic photosynthetic bacteria could have evolved from this two-system ancestor through loss of the genes encoding one photosystem (Figure 16.30). This scenario may also explain the inefficiency of modern rubisco—as mentioned above, this enzyme evolved at a time when there was little or no oxygen in the atmosphere and CO_2 levels were much higher.

Now we come to the question of the invention of oxygenic photosynthesis. Manganese ions are readily photooxidized by ultraviolet light, which would have been abundant before the ozone layer formed in the early atmosphere. Upon oxidation, a Mn ion ejects an electron, an electron that could be used to replenish an oxidized photosystem. The oxidized Mn would then grab an electron from the most abundant source available—water. If our ancestral protocyanobacterium bound a few Mn ions to the surface of its photosystem II, it could extract electrons from H_2O and pass them through the proton-pumping complex, no longer requiring a cyclic pathway. Photosystem I could now be coupled to photosystem II, taking electrons from its cytochrome bc_1 complex and passing them via ferredoxin to soluble electron acceptors (Figure 16.30). Over time, the soluble manganese ions were replaced by the more stable Mn_4Ca cluster, and the photosystems became more efficient, eventually leading to the oxygenated, green earth that exists today. There would have been substantial selective pressure for this evolutionary scenario, since oxygenic photosynthesis released our ancestral protocyanobacterium from scarce inorganic or organic electron donors. As biochemist John F. Allen of University of London has said, “Water is everywhere, so the organisms never ran out of electrons. They were unstoppable.”

SUMMARY

Photosynthesis is the source of most of the energy in the biosphere and accounts for fixation of atmospheric CO_2 and the production of most or all of the O_2 in the atmosphere. The whole process can be divided into light reactions and dark reactions. The light reactions use the energy of sunlight to extract electrons from water, producing O_2 , reductive potential, and a proton gradient that drives ATP formation. The dark reactions reduce CO_2 into carbohydrates. In plants and higher algae, both types of reactions

take place in chloroplasts. Photons for the light reaction are absorbed by antenna pigments, and the energy is transferred to reaction centers, where it enters either photosystem I or photosystem II. These two systems, working in conjunction, carry out the light reactions. Photosystem II oxidizes water, and photosystem I reduces NADP^+ . Together, the systems drive the transport of protons across chloroplast membranes to provide a pH gradient to drive ATP production. Under conditions of high NADPH concentration, photosystem I can operate independently of photosystem II in a process called cyclic photophosphorylation, where only ATP is produced. Some photosynthetic bacteria, on the other hand, use a cyclic version of photosystem II to generate ATP.

The dark reactions are largely summarized in the Calvin cycle, which may be divided into two stages. In the first stage, CO_2 is added to ribulose-1,5-bisphosphate (RuBP), which is then cleaved and reduced to form trioses that can then be combined to form hexose. The second stage of the cycle uses most of the trioses and hexoses to regenerate RuBP. A number of these dark reactions are regulated by light intensity.

Under conditions of low CO_2 and high O_2 , plants undergo an oxidative process called photorespiration. This process is essentially inefficient, and some tropical plants compensate for it via the C_4 cycle, which is less sensitive to high O_2 levels.

PROBLEMS

- According to Figure 16.12b, upon excitation the P700 reaction center is raised in potential from about +0.4 to -1.3 volts. To what value of $\Delta G^{\circ'}$ does this correspond? How does it compare with the energy in an einstein of 700 nm photons?
- In cyclic photophosphorylation, it is estimated that two electrons must be passed through the cycle to pump enough protons to generate one ATP. Assuming that the ΔG for hydrolysis of ATP under conditions existing in the chloroplast is about -50 kJ/mol, what is the corresponding percent efficiency of cyclic photophosphorylation, using light of 700 nm?
- Assume a pH gradient of 4.0 units across a thylakoid membrane, with the lumen more acidic than the stroma. What is the *longest* wavelength of light that could provide enough energy per photon to pump one proton against this gradient, assuming a 20% efficiency in photosynthesis and $T = 25^\circ\text{C}$?
- Suppose a brief pulse of $^{14}\text{CO}_2$ is taken up by a green plant.
 - Trace the ^{14}C label through the steps leading to fructose-1,6-bisphosphate synthesis, showing which carbon atoms in each compound should carry the label during the first cycle.
 - Will all molecules of fructose-1,6-bisphosphate carry two ^{14}C atoms? Explain.
- The flux of solar energy reaching the earth's surface is approximately $7\text{ J/cm}^2\text{ s}$. Assume that *all* of this energy is used by a green leaf (10 cm^2 in area), with the maximal efficiency of 35%. How many moles of hexose could the leaf theoretically generate in an hour? You may use 600 nm for an average wavelength.
- The substance dichlorophenylmethylurea (DCMU) is an herbicide that inhibits photosynthesis by blocking electron transfer between plastoquinones in photosystem II.
 - Would you expect DCMU to interfere with cyclic photophosphorylation?
 - Normally, DCMU blocks O_2 evolution, but addition of ferricyanide to chloroplasts allows O_2 evolution in the presence of DCMU. Explain.
- Suppose a researcher is carrying out studies in which she adds a nonphysiological electron donor to a suspension of chloroplasts. Illumination of the chloroplasts yields oxidation of the donor. How could she tell whether photosystem I, II, or both are involved?
- Suppose ribulose-5-phosphate, labeled with ^{14}C in carbon 1, is used as the substrate in dark reactions. In which carbon of 3PG will the label appear?
- The following data, presented by G. Bowes and W. L. Ogren in *J. Biol. Chem.* (1972) 247:2171–2176, describe the relative rates of incorporation of CO_2 by rubisco under N_2 and under pure O_2 . Decide whether O_2 is a competitive or uncompetitive inhibitor.

$[\text{CO}_2]$ (mM)	Under N_2	Under O_2
0.20	16.7	10
0.10	12.5	5.6
0.067	8.3	4.2
0.050	7.1	3.2
- J. C. Servaites, in *Plant Physiol.* (1985) 78:839–843, observed that rubisco from tobacco leaves collected before dawn had a much lower specific activity than the enzyme collected at noon. This difference persisted despite extensive dialysis, gel filtration, or heat treatment. However, precipitation of the predawn enzyme by 50% $(\text{NH}_4)_2\text{SO}_4$ restored the specific activity to the level of noon-collected enzyme. Suggest an explanation.
- It is believed that the ratio of cyclic photophosphorylation to non-cyclic photophosphorylation changes in response to metabolic demands. In each of the following situations, would you expect the ratio to increase, decrease, or remain unchanged?
 - Chloroplasts carrying out both the Calvin cycle and the reduction of nitrite (NO_2^-) to ammonia (This process does not require ATP.)
 - Chloroplasts carrying out not only the Calvin cycle but also extensive active transport
 - Chloroplasts using both the Calvin cycle and the C_4 pathway
- If a photosynthetic organism is illuminated in a closed, sealed environment, it is observed that the CO_2 and O_2 levels in the surrounding atmosphere reach a constant ratio.
 - Suggest an explanation.
 - What factor would you think primarily determines the value of this ratio?
- If algae are exposed to $^{14}\text{CO}_2$ for a brief period while illuminated, the labeled carbon is initially found almost entirely in the carboxyl group of 3-phosphoglycerate. However, if illumination is continued after the label pulse, other carbon atoms become labeled. Explain.

CHAPTER 17

Lipid Metabolism I: Fatty Acids, Triacylglycerols, and Lipoproteins

Like the carbohydrates we have discussed in previous chapters, lipids play roles in energy metabolism as well as in a variety of other processes. For lipids, those other processes include their roles as membrane constituents, hormones, fat-soluble vitamins, thermal insulators, and signaling molecules. This chapter focuses on bioenergetic aspects of lipid metabolism. We discuss the synthesis and breakdown of energy storage lipids, as well as fatty acid oxidation and biosynthesis (Figure 17.1), processes that are quite similar among plants, animals, and microorganisms. We also present topics related more directly to animal metabolism—fat digestion, absorption, storage, and mobilization. Metabolism of membrane lipids and lipids of more specialized metabolic functions is covered in Chapter 19.

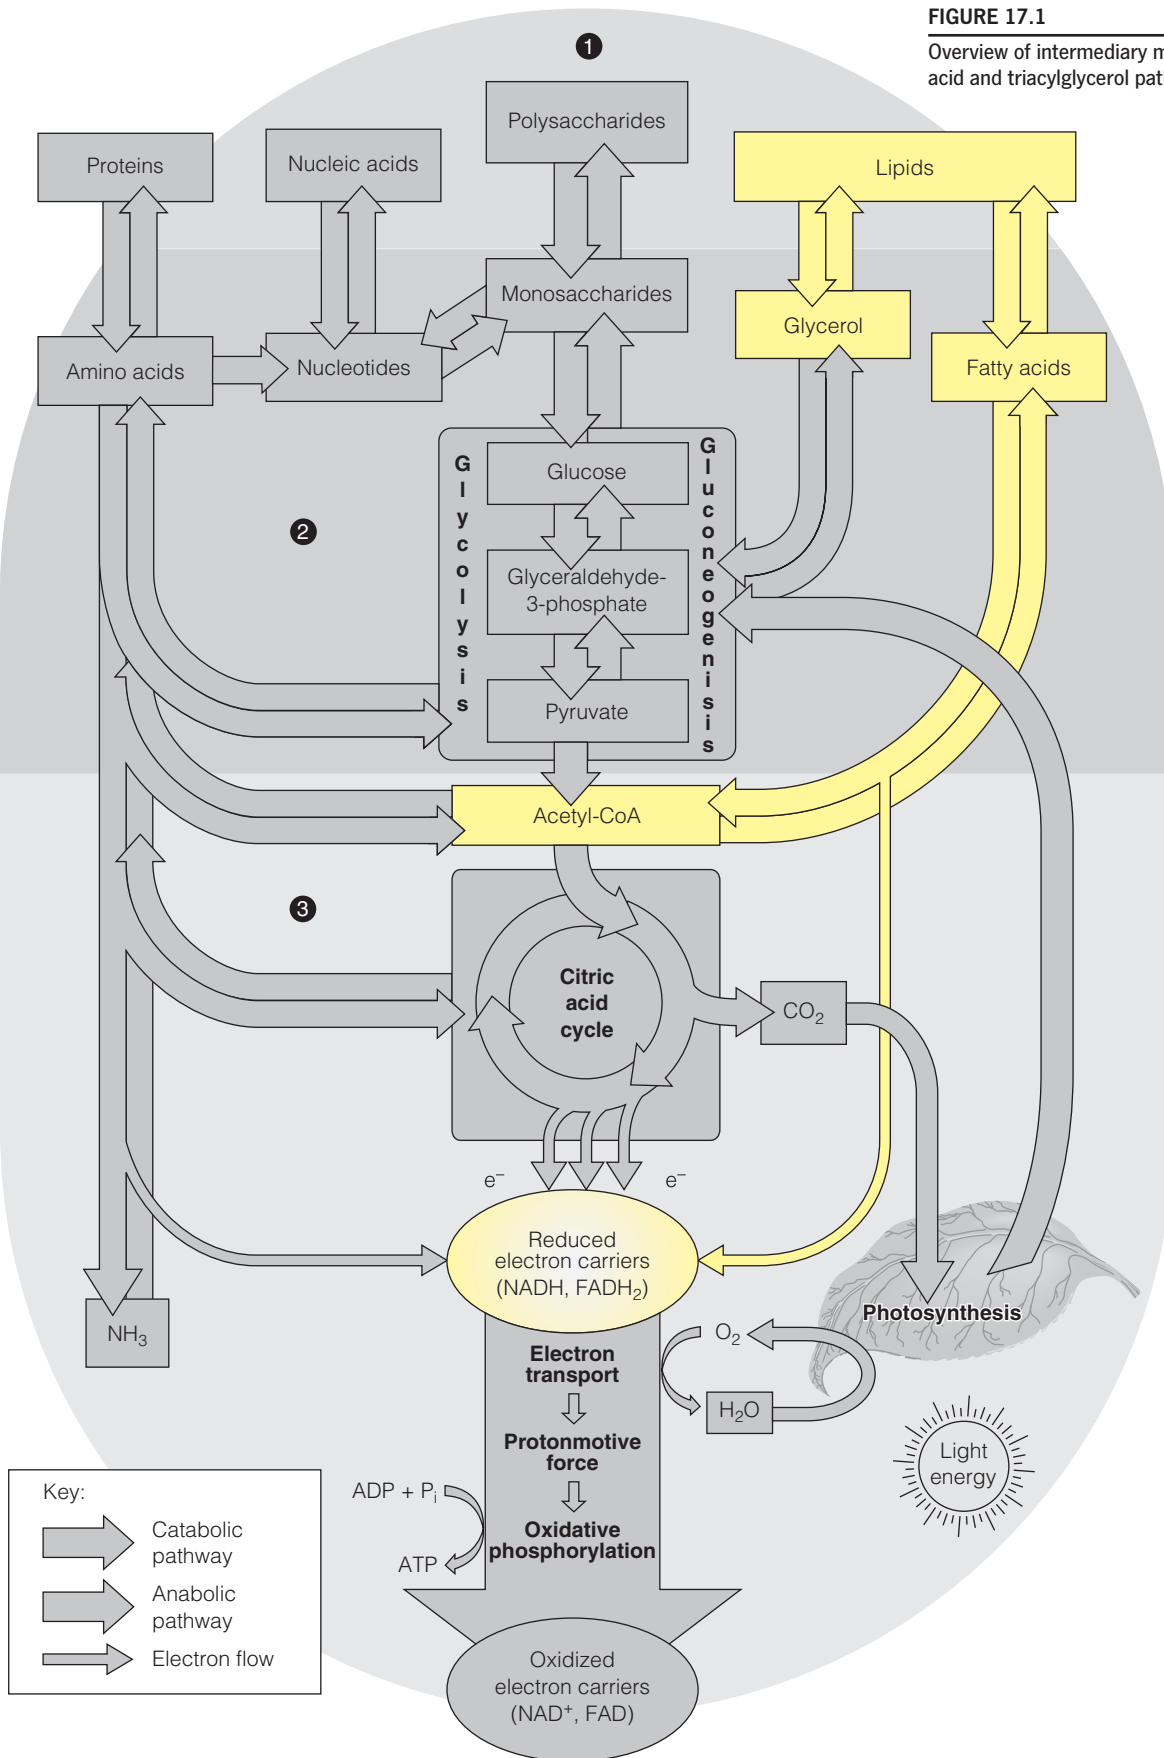

Utilization and Transport of Fat and Cholesterol

As discussed in Chapter 10, the great bulk of the lipid in most organisms is in the form of *triacylglycerols* (formerly called *triglycerides*). The term *fat*, or *neutral fat*, refers to this most abundant class of lipids. Fat utilization in animals is intertwined with lipoprotein metabolism, as is the metabolism of cholesterol. Therefore, we will consider fat and cholesterol metabolism together although cholesterol biosynthesis is presented in Chapter 19.

A mammal contains 5% to 25% or more of its body weight as lipid, with as much as 90% of this lipid in the form of triacylglycerols. Most of this fat is stored in adipose tissue and constitutes the primary energy reserve. Mammals (including humans) are “fat burners”—we eat in pulses (i.e., meals), convert the excess carbohydrate into fat, and store it. The fat is then burned at a later time as needed. Indeed, certain tissues, such as heart and liver, obtain as much as 80% of their energy needs from fat oxidation. In animal systems, fat is stored in specialized cells called *adipocytes*, where giant fat globules occupy most of the intracellular space (see Figure 10.3, page 363). Plant seeds store great quantities of fat to provide energy to the developing plant embryo

FIGURE 17.1

Overview of intermediary metabolism with fatty acid and triacylglycerol pathways highlighted.

**FIGURE 17.2**

Fat storage in a plant seedling. The electron micrograph ($\times 6500$) shows a cell from a cucumber cotyledon (seed leaf) a few days after germination. Fat stored in lipid bodies is degraded, oxidized, and converted to carbohydrate in neighboring glyoxysomes (or microbodies) to support the growth of the plant.

Courtesy of R. N. Trelease, P. J. Gruber, W. M. Becker, and E. H. Newcomb, *Plant Physiology* 48:461 (1971), Microbodies (glyoxysomes and peroxisomes) in cucumber cotyledons: Correlative biochemical and ultrastructural study in light- and dark-grown seedlings.

Fat has six times more caloric content by weight than carbohydrate because fat is more highly reduced and is anhydrous.

Tissue Fuel Stores for Average 70-kg Human

Fuel	Weight (g)	Energy Content (kJ/g)	Total Energy (kJ)
Triacylglycerols	~15,000	37	555,000
Protein	~6,000	17	100,000
Glycogen	~400	17	6,800
Glucose	~20	17	340
Total fuel stores:			662,140

(Figure 17.2). Because plant lipids contain mostly unsaturated fatty acids, the triacylglycerols of seeds are largely in the form of liquid oils.

Triacylglycerols play roles other than in energy storage. Fat serves to cushion organs against shock, and it provides an efficient thermal insulator, particularly in marine mammals, which must maintain a body temperature far higher than that of the seawater in which they live.

Fats as Energy Reserves

Recall that most of the carbon in triacylglycerols is more highly reduced than the carbon in carbohydrates. To be sure, the carboxyl carbons of fatty acids are highly oxidized, but most of the fatty acid carbons are at the reduced methyl or methylene level. Thus, metabolic oxidation of fat consumes more oxygen, on a weight basis, than oxidation of carbohydrate, with correspondingly larger metabolic energy release. The complete metabolic oxidation of triacylglycerols yields 37 kJ/g or more, whereas that of carbohydrates and proteins yields about 17 kJ/g. Adding to this difference between fat and carbohydrate is the hydrophilic nature of glucose polymers. Glycogen binds about 2 grams of water per gram of carbohydrate. Fat, being extremely nonpolar, is anhydrous. Thus, because 1 gram of intracellular glycogen contains but $\frac{1}{3}$ gram of anhydrous glucose polymer, intracellular fat contains about six times as much potential metabolic energy, on a mass basis, as intracellular glycogen. This is an obvious advantage in many situations, such as in hibernating animals, which must store several months' worth of food, or in the flight muscles of small birds, in which weight is at a premium. Incredibly, some small land birds prepare for migration by increasing their body weight about 15% per day, with all of the weight gain being triacylglycerols. Such obese birds can then fly nonstop for 60 hours or more. In addition, the insolubility of fat allows it to be stored in cells without affecting intracellular osmotic pressure.

Little wonder, then, that fat is the major energy storage form in most organisms. A typical 70-kg human may have fuel reserves of 500,000 kJ or more in total body fat and about 100,000 kJ in total protein (mostly muscle protein). By contrast, the glycogen stores amount to just 6800 kJ of available energy, and the total free glucose to about 300 kJ. Fat stores are maintained from the diet; 35%–50% of the caloric value of Western diets comes from fat. Most nutritionists recommend that this value be closer to 25%–35% for cardiovascular health. In addition, carbohydrate ingested in excess of its ability to be catabolized or stored as glycogen is readily converted to fat.

Most of the energy derived from fat breakdown comes from oxidation of the constituent fatty acids. Fatty acid oxidation provides the major energy source for many animal tissues. Brain is distinctive in being unable to use fatty acids as a significant energy supply; brain has a highly specific requirement for glucose. However, under conditions of starvation, when blood glucose levels decrease, brain can adjust to use a class of lipid-related compounds called *ketone bodies*, as discussed later in this chapter.

Fat Digestion and Absorption

The triacylglycerols that mammals use as fuel are derived from three primary sources: (1) the diet; (2) *de novo* biosynthesis, particularly in liver; and (3) storage depots in adipocytes. Processes by which these sources are utilized in animals are summarized in Figure 17.3. The major problem that animals must cope with in the digestion, absorption, and transport of dietary lipids is their insolubility in aqueous media. The action of **bile salts**, detergent substances synthesized in liver and stored in the gallbladder, is essential to the digestion of lipids and their absorption through the intestinal mucosa. The problem of transport through the blood and lymph is dealt with in part by the complexing of the lipids with proteins to form soluble aggregates called **lipoproteins**.

A bile salt molecule is made up of a **bile acid**, such as cholic acid, and an associated cation. Bile acids (discussed further in Chapter 19) are derived from cholesterol.

FIGURE 17.3

Overview of fat digestion, absorption, storage, and mobilization in the human. Triacylglycerols (fats) are ingested, synthesized in the liver, or mobilized from storage. Ingested triacylglycerols are hydrolyzed in the lumen of the small intestine by pancreatic lipase and other enzymes. Hydrolysis products absorbed by the intestinal mucosa are recombined into triacylglycerols, which combine with apoproteins to form the lipoproteins called chylomicrons. This process solubilizes the lipids and permits their transport through lymph and blood. Triacylglycerols synthesized in liver are combined with other apoproteins to form very low-density lipoproteins (VLDLs) for transport. Lipoproteins transported to peripheral tissues are hydrolyzed at the inner surfaces of capillaries. Hydrolysis products entering cells are either catabolized for energy or recombined into triacylglycerols for storage. Mobilization of stored triacylglycerols is hormonally regulated.

FIGURE 17.4

Action of bile salts in emulsifying fats in the intestine. Cholic acid, a typical bile acid, ionizes to give its cognate bile salt. The hydrophobic surface of the bile salt molecule associates with triacylglycerol, and several such complexes aggregate to form a micelle. The polar surface of the bile salts faces outward, allowing the micelle to associate with pancreatic lipase/colipase. Hydrolytic action of this enzyme frees the fatty acids to associate in a much smaller micelle that can be absorbed through the intestinal mucosa.

As shown in Figure 17.4, the bile salt molecule has both hydrophobic and hydrophilic surfaces. This amphipathic character allows bile salts to orient at an oil–water interface, with the hydrophobic surface in contact with the apolar phase and the hydrophilic surface in contact with the aqueous phase. This detergent action emulsifies lipids and yields micelles (see Chapter 10), allowing digestive attack by water-soluble enzymes and facilitating the absorption of lipid through intestinal mucosal cells. Most of the intestinal digestion occurs through action of **pancreatic lipase**, an unusual calcium-requiring enzyme that catalyzes a reaction at an oil–water interface. The substrate being cleaved is in an apolar phase, and the other substrate, of course, is water. Structural studies on pancreatic lipase show that the catalytic center is exposed as the result of a conformational change that occurs only at an oil–water interface. Pancreatic lipase also functions in a 1:1 complex with **colipase**, a 90-amino acid protein that aids in the binding to the lipid surface.

Bile salts emulsify fats, thereby promoting their hydrolysis in digestion.

The products of fat digestion comprise a mixture of glycerol, free fatty acids, monoacylglycerols, and diacylglycerols. Less than 10% of the original triacylglycerol remains unhydrolyzed. During absorption through intestinal mucosal cells, much resynthesis of triacylglycerols occurs from the hydrolysis products. This resynthesis occurs in the endoplasmic reticulum and Golgi complex of mucosal cells. Triacylglycerols emerge into the lymph system complexed with protein to form the lipoproteins called **chylomicrons**. The chylomicron is essentially an oil droplet coated with more polar lipids and a skin of protein, which help disperse and partially solubilize the fat for transport to tissues. The chylomicron is also a transport vessel for dietary cholesterol.

Transport of Fat to Tissues: Lipoproteins

Chylomicrons constitute just one class of lipoproteins found in the bloodstream. These complexes play essential roles in the transport of lipids to tissues, either for energy storage or for oxidation. Free lipids are all but undetectable in blood. The polypeptide components of lipoproteins are called **apoproteins** or **apolipoproteins**. These are synthesized mainly in the liver, though about 20% are produced in intestinal mucosal cells.

Classification and Functions of Lipoproteins

Distinct families of lipoproteins have been described, each of which plays defined roles in lipid transport. These families are classified in terms of their density, as determined by centrifugation (Table 17.1). Lipoproteins in each class contain

TABLE 17.1 Properties of major human plasma lipoprotein classes

	Chylomicron	VLDL	IDL	LDL	HDL
Density (g/mL)	<0.95	0.950–1.006	1.006–1.019	1.019–1.063	1.063–1.210
Diameter (Å)	10 ³ –10 ⁴	300–800	250–350	180–250	50–120
Components (% dry weight)					
Protein	2	8	15	22	40–55
Triacylglycerol	86	55	31	6	4
Free cholesterol	2	7	7	8	4
Cholesterol esters	3	12	23	42	12–20
Phospholipids	7	18	22	22	25–30
Apoprotein composition	A-I, A-II, A-IV, B-48, C-I, C-II, C-III, E	B-100, C-I, C-II, C-III, E	B-100, C-I, C-II, C-III, E	B-100, E	A-I, A-II, C-I, C-II, C-III, D, E

TABLE 17.2 Apoproteins of the human plasma lipoproteins

Apoprotein	Molecular Weight	Characteristics
A-I	28,300	Major protein in HDL; activates LCAT
A-II	17,400	Major protein in HDL
A-IV	44,000	Found in chylomicrons
B-48	241,100	Found exclusively in chylomicrons
B-100	513,000	Major protein in LDL
C-I	6,600	Found in chylomicrons; activates LCAT and LPL
C-II	8,900	Found primarily in VLDL and chylomicrons; activates LPL
C-III	8,800	Found primarily in chylomicrons, VLDL, and HDL; inhibits LPL
D	33,000	HDL protein, also called cholesterol ester transfer protein
E	34,000	Found in VLDL, LDL, IDL, and HDL

 Note: LCAT = lecithin:cholesterol acyltransferase, LPL = lipoprotein lipase.

characteristic apoproteins and have distinctive lipid compositions. A total of 10 major apolipoproteins are found in human lipoproteins. Their properties are summarized in Table 17.2. Each of these is encoded by a unique nuclear gene, with the interesting exception of apolipoproteins B-48 and B-100. Sequence analysis of these two proteins revealed that Apo B-48 (241,000 Da) is identical to the N-terminal portion of apo B-100. A single structural gene encodes both apo B-48 and apo B-100, which is transcribed into a 14,000-nucleotide mRNA (Figure 17.5).

FIGURE 17.5

RNA editing of the apolipoprotein B gene transcript. The APOB gene, composed of 29 exons, is transcribed to produce a ~14,000-nucleotide transcript. In liver, this mRNA is translated to give the 4536-amino acid apo B-100 product. In intestine, a cytidine deaminase converts the C residue in codon 2153 to U, changing the Gln codon to a stop codon. This edited mRNA is translated to give the 2152-amino acid apo B-48 product.

**FIGURE 17.6**

Generalized structure of a plasma lipoprotein. The spherical particle, part of which is shown, contains neutral lipids in the interior and phospholipids, cholesterol, and protein at the surface.

In liver, translation of the full-length open reading frame gives the 4536 amino acid apo B-100 (513,000 Da), which is secreted and assembled into **low-density lipoprotein (LDL)** particles. In intestine, where apo B-48 is expressed for chylomicron assembly, the apo B mRNA undergoes **RNA editing**: a cytidine deaminase found only in intestine specifically deaminates a single cytidine in the mRNA, in codon 2153, converting it to uridine. This changes the codon from CAA (Gln) to UAA, a termination codon. Translation of this edited mRNA gives the shorter apo B-48. RNA editing is fairly widespread—its mechanism and control will be discussed in Chapter 29.

Because lipids are of much lower density than proteins, the lipid content of a lipoprotein class is inversely related to its density: The higher the lipid abundance, the lower the density. The standard lipoprotein classification includes, in increasing order of density: *chylomicrons*, **very low-density lipoprotein (VLDL)**, **intermediate-density lipoprotein (IDL)**, **low-density lipoprotein (LDL)**, and **high-density lipoprotein (HDL)**. Some classification schemes recognize two classes of HDL, and in addition there is a quantitatively minor lipoprotein called very high-density lipoprotein (VHDL).

Despite their differences in lipid and protein composition, all lipoproteins share common structural features, notably a spherical shape that can be detected by electron microscopy. As shown in Figure 17.6, the hydrophobic parts, both lipid and apolar amino acid residues, form an inner core, and hydrophilic protein structures and polar head groups of phospholipids are on the outside.

Some apolipoproteins have specific biochemical activities other than their roles as passive carriers of lipid from one tissue to another. For instance, apo C-II is an activator of triacylglycerol hydrolysis by **lipoprotein lipase**, a cell surface glycoprotein that hydrolyzes triacylglycerols in lipoproteins. A human deficiency of apo C-II is associated with massive accumulation of chylomicrons and elevated triacylglycerol levels in blood. Other apoproteins target specific lipoproteins to specific cells by being recognized by receptors in the plasma membranes of these cells. Of great interest is an association of a variant form of apo E with increased risk for developing Alzheimer's disease. The mechanism underlying this association is not yet understood, but there is a solid epidemiological link between high serum cholesterol at midlife and Alzheimer's disease in later life, and apo E is the most abundant cholesterol transport protein in the central nervous system. There are three common allelic forms of apo E (E2, E3, and E4), and possessing at least one E4 allele is the major known genetic risk factor for Alzheimer's disease.

Following digestion and absorption of a meal, the lipoproteins help maintain in emulsified form some 500 mg of total lipid per 100 mL of human blood in the postabsorptive state. Of this 500 mg, typically about 120 mg is triacylglycerol, 220 mg is cholesterol (two-thirds esterified with fatty acids, one-third free), and 160 mg is phospholipids, principally phosphatidylcholine and phosphatidylethanolamine. Indeed, following a high-fat meal, chylomicrons are so abundant in blood that they give the plasma a milky appearance.

Transport and Utilization of Lipoproteins

As noted previously, chylomicrons represent the form in which dietary fat is transported from the intestine to peripheral tissues, notably heart, muscle, and adipose tissue (see Figure 17.3). VLDL plays a comparable role for triacylglycerols synthesized in liver. The triacylglycerols in both of these lipoproteins are hydrolyzed to glycerol and fatty acids at the inner surfaces of capillaries in the peripheral tissues. This hydrolysis involves activation of the extracellular enzyme lipoprotein lipase by apoprotein C-II, a component of both chylomicron and

Lipoproteins are lipid–protein complexes that allow movement of apolar lipids through aqueous environments.

**FIGURE 17.7**

Binding of a chylomicron to lipoprotein lipase on the inner surface of a capillary. The chylomicron is anchored by lipoprotein lipase, which is linked by a polysaccharide chain to the luminal surface of the endothelial cell. When activated by apoprotein C-II, the lipase hydrolyzes the triacylglycerols in the chylomicron, allowing uptake into the cell of the glycerol and the free fatty acids.

VLDL (Figure 17.7). Lipoprotein lipase is a member of the serine esterase family, which includes pancreatic lipase and **hormone sensitive lipase** (HSL, an enzyme involved in the regulated mobilization of stored fat from adipose tissue—see page 721). This family is characterized by use of a catalytic triad of serine, histidine, and aspartate and an acyl-enzyme intermediate, similar to the serine proteases described in Chapter 11. Some of the released fatty acids are absorbed by nearby cells, while others, still rather insoluble, become complexed with serum albumin for transport to more distant cells. After absorption into the cell, the fatty acids derived from lipoprotein lipase action can be either catabolized to generate energy or, in adipose cells, used to resynthesize triacylglycerols. However, because adipocytes lack glycerol kinase, glycerol-3-phosphate for resynthesis of triacylglycerols must come from glycolysis. Glycerol is returned from adipocytes to the liver, for resynthesis of glucose by gluconeogenesis. Figure 17.8 summarizes overall aspects of lipoprotein metabolism and transport.

As a consequence of triacylglycerol hydrolysis in the capillaries, both chylomicrons and VLDL are degraded to protein-rich remnants. The IDL class of lipoprotein is derived from VLDL, and chylomicrons are degraded to what are simply called chylomicron remnants. Both classes of remnants are taken up by the liver through interaction with specific receptors and further degraded in liver lysosomes. Apoprotein B-100 is reused for synthesis of LDL (via IDL). As described in the next section, LDL is the principal form in which cholesterol is transported to tissues, and HDL plays the primary role in returning excess cholesterol from tissues to the liver for metabolism or excretion. The importance of lipoproteins as transport vehicles is evident from the fact that a major consequence of chronic liver cirrhosis is fatty liver degeneration, where the liver becomes engorged with fat. Because the liver is the major site of apolipoprotein synthesis, damage to this organ causes endogenously

A major consequence of liver dysfunction is an inability to synthesize apolipoproteins and, hence, to transport fat out of the liver.

FIGURE 17.8
Overview of lipoprotein transport pathways and fates.

synthesized fat to accumulate there because it cannot be transported to peripheral tissues.

Cholesterol Transport and Utilization in Animals

Cholesterol accumulation in the blood is correlated with development of atherosclerotic plaque.

As you undoubtedly know, a primary risk factor predisposing to heart disease is an abnormally elevated level of cholesterol in the blood. Prolonged cholesterol accumulation contributes to the development of **atherosclerotic plaques**, fatty deposits that line the inner surfaces of coronary arteries.

Recall from Table 17.1 that cholesterol in plasma lipoproteins exists both as the free sterol and as cholesterol esters. Esterification occurs at the cholesterol hydroxyl position with a long-chain fatty acid, usually unsaturated. Cholesterol esters are synthesized in plasma from cholesterol and an acyl chain on phosphatidylcholine (lecithin), through the action of **lecithin:cholesterol acyltransferase (LCAT)**, an enzyme that is secreted from liver into the bloodstream, bound to HDL and LDL:

Cholesterol esters are considerably more hydrophobic than cholesterol itself.

Of the five lipoprotein classes, LDL is by far the richest in cholesterol. The amounts of cholesterol and cholesterol esters associated with LDL are typically about two-thirds of the total plasma cholesterol. In normal adults, total plasma cholesterol levels range from 3.5–6.7 mM (equivalent to 130–260 mg/100 mL of human plasma; total plasma cholesterol above 200 mg/100 mL is a major risk factor for heart disease). Approximately 40% of the weight of the LDL particle is cholesterol esters, and the total of esterified and free cholesterol approaches half the total weight. The LDL particle contains a single molecule of apoprotein B-100 as its primary protein component. Because cholesterol biosynthesis is confined primarily to the liver with some occurring also in intestine, LDL plays an important role in delivering cholesterol to other tissues.

The LDL Receptor and Cholesterol Homeostasis

The importance of understanding cholesterol homeostasis can be seen by reviewing the consequences of prolonged high plasma cholesterol levels. Excess LDL cholesterol accumulates in the inner arterial walls, forming fatty streaks, which attract white blood cells (macrophages). If cholesterol levels are too high for its subsequent removal into the bloodstream, these macrophages become engorged with fatty deposits, which then harden into plaque; this condition, called **atherosclerosis**, ultimately blocks key blood vessels and causes myocardial infarctions, or heart attacks.

To understand the relationship between elevated cholesterol levels and atherogenesis, we must know how cholesterol is taken up from LDL into cells because cholesterol esters are too hydrophobic to traverse cell membranes by themselves. The answer to this question came from the research of Michael Brown and Joseph Goldstein, who showed in the mid-1970s that cholesterol uptake by cells is a receptor-mediated process and that the quantity of receptors themselves is subject to regulation.

In 1972 Brown and Goldstein began to study a hereditary condition called **familial hypercholesterolemia**, or FH. Individuals with the rare homozygous form of this disease (about 1 in a million) have grossly elevated levels of serum cholesterol, from 650 to 1000 mg/100 mL (about five-fold over normal levels). They develop atherosclerosis early in life and usually die of heart disease before age 20. The more common heterozygous condition, characterized by one defective allele instead of two, affects about one individual in 500. These individuals have less severely elevated cholesterol levels, in the range of 350 to 500 mg/100 mL. They are at high risk to have heart attacks in their thirties and forties, although many enjoy a normal life span.

FIGURE 17.9**Feedback regulation of HMG-CoA reductase activity.**

Fibroblasts obtained from a normal subject (closed symbols) or from a patient homozygous for familial hypercholesterolemia (FH Homozygote) (open symbols) were grown in monolayer cultures. **(a)** At time zero, the medium was replaced with fresh medium depleted of lipoproteins, and HMG-CoA reductase activity was measured in extracts prepared at the indicated times. **(b)** Twenty-four hours after addition of the lipoprotein-deficient medium, human LDL was added to the cells at the indicated levels, and HMG-CoA reductase activity was measured at the indicated time.

Courtesy of Joseph L. Goldstein and Mike S. Brown.

Crucial to the success of Brown and Goldstein was their ability to demonstrate the defective FH phenotype in cell culture. Fibroblasts from FH patients synthesized cholesterol at abnormally high rates in culture, whereas normal cells showed low rates of synthesis. Figure 17.9 reproduces the results of this seminal experiment. When cultured in the presence of LDL, normal cells showed low activity of hydroxymethylglutaryl-CoA reductase (HMG-CoA reductase, the rate-limiting and major regulated enzyme in cholesterol synthesis—see page 801, Chapter 19). In the absence of LDL the same cells showed reductase activities some 50- to 100-fold higher (Figure 17.9a). This high level of enzyme activity was rapidly suppressed upon addition of LDL to normal cells (Figure 17.9b). These results suggested that cholesterol is normally transported into the cell, where it regulates its own synthesis by suppressing the activity of the rate-limiting enzyme (feedback regulation). By contrast, cells from FH individuals showed high levels of reductase activity, whether cultured in the presence or absence of LDL, suggesting that they were deficient in ability to take up cholesterol from the medium.

These observations suggested that cholesterol is taken into cells through the action of a specific receptor, which is deficient or defective in FH patients. In short order Brown and Goldstein and their colleagues demonstrated the existence of this receptor, the **LDL receptor** (see Figure 17.8), and demonstrated a new mechanism by which cells can interact with their environment—**receptor-mediated endocytosis**. By conjugating LDL with an electron-dense material and binding the conjugate to cells, the investigators were able to visualize the LDL receptor on cell surfaces (Figure 17.10). These experiments showed that the

**FIGURE 17.10**

Receptor-mediated endocytosis of LDL. Low-density lipoprotein (LDL) was conjugated with ferritin to permit electron microscopic visualization. **(a)** The LDL-ferritin (dark dots) binds to a coated pit on the surface of a cultured human fibroblast (a type of connective tissue cell). **(b)** The plasma membrane closes over the coated pit, forming an endocytotic vesicle.

Courtesy of R. G. W. Anderson, M. S. Brown, and J. L. Goldstein.

receptors are clustered in a structure called a **coated pit**, an invagination whose most abundant protein is **clathrin**, a self-interacting protein capable of forming a cage-like structure (Figure 17.11).

Endocytosis is a process by which cells take up large molecules from the extracellular environment. Although LDL uptake involves a cell surface receptor, the interaction of LDL with its receptor is unlike the interaction of hormones such as epinephrine with their receptors. As discussed in Chapters 12 and 13, the binding of epinephrine at its receptor in the plasma membrane triggers intracellular metabolic changes, but the hormone itself does not enter the cell. By contrast, when LDL binds to its receptor, through recognition of the B-100 apoprotein by the receptor, the entire LDL molecule is engulfed and taken into the cell, as schematized in Figure 17.12. The plasma membrane fuses in the vicinity of the LDL–receptor complex, and the coated pit becomes an endocytotic vesicle. Several of these clathrin-lined vesicles fuse to form an **endosome**. The endosome then fuses with a lysosome, putting the LDL–receptor complex in contact with the hydrolytic enzymes of the lysosome. The LDL apoprotein is hydrolyzed to amino acids, and the cholesterol esters are hydrolyzed to give free cholesterol. The receptor itself is recycled, moving back to the plasma membrane to pick up more LDL. About 10 minutes is required for each round trip. The discovery of the LDL receptor and receptor-mediated endocytosis earned Brown and Goldstein the Nobel Prize for Physiology or Medicine in 1985.

Much of the cholesterol released moves to the endoplasmic reticulum, where it is used for membrane synthesis. The internalized cholesterol exerts three regulatory effects. (1) As mentioned earlier, it suppresses endogenous cholesterol synthesis, by inhibiting HMG-CoA reductase and also by suppressing transcription of the gene for this enzyme and accelerating degradation of the enzyme protein. (2) It activates **acyl-CoA:cholesterol acyltransferase (ACAT)**, an intracellular enzyme that synthesizes cholesterol esters from cholesterol and a long-chain acyl-CoA. This promotes the storage of excess cholesterol in the form of droplets of cholesterol esters. (3) It regulates the synthesis of the LDL receptor itself, by decreasing transcription of the receptor gene. Decreased synthesis of the receptor ensures that cholesterol will not be taken into the cell in excess of the cell's needs, even when extracellular levels are very high. This regulatory mechanism explains why excessive dietary cholesterol leads directly to elevations of blood cholesterol levels. With intracellular cholesterol levels so well regulated, the extracellular cholesterol accumulates because it has nowhere else to go.

This regulatory structure led to the development of inhibitors of HMG-CoA reductase, on the assumption that they would depress *de novo* cholesterol biosynthesis and, hence, intracellular cholesterol levels; the production of LDL receptors was expected to increase as a consequence, thereby leading to more rapid clearance of extracellular cholesterol from the blood. Indeed, HMG-CoA reductase inhibitors, called **statins**, work in exactly this way and are currently the gold standard for therapeutic approaches to lowering cholesterol levels (more about this in Chapter 19).

Studies of many individuals with FH have given a remarkably detailed picture of the LDL receptor and its action. The receptor is a glycoprotein with an 839-residue polypeptide chain and 18 O-linked oligosaccharide chains. The LDL receptor binds specifically the apolipoproteins B-100 and E, and also participates in the uptake of chylomicron remnants and VLDL remnants by the liver.

Gene cloning and DNA sequence analysis have allowed identification of five classes of mutations affecting the receptor and its metabolism in humans. First are mutations that lead to insufficient receptor synthesis. Second, and most common, are mutations in which the receptor is synthesized but fails to migrate from the endoplasmic reticulum to the Golgi complex, for transport to the cytoplasmic membrane. Third are mutations in which receptor is synthesized and processed normally and reaches the cell surface, but fails to bind LDL. Fourth are mutations

FIGURE 17.11

Structure of a clathrin-coated pit. (a) Clathrin, the major protein in coated pits, forms triskelions (named after the symbol of three legs radiating from the center), which assemble into polyhedral lattices composed of hexagons and pentagons, such as the barrel shown in the next panel. (b) Image reconstruction from electron cryomicroscopy of a clathrin barrel formed from 36 triskelions. A single clathrin triskelion is highlighted in light blue. (c) A coated pit on the inner surface of the plasma membrane of a cultured mammalian cell is visualized by freeze-fracture electron microscopy. The cage-like structure of the pit is due to the clathrin lattice.

Uptake of cholesterol from the blood occurs at the LDL receptor via receptor-mediated endocytosis.

Intracellular cholesterol regulates its own level by controlling (1) *de novo* cholesterol biosynthesis, (2) formation and storage of cholesterol esters, and (3) LDL receptor density.

FIGURE 17.12

Involvement of LDL receptors in cholesterol uptake and metabolism. LDL receptors are synthesized in the endoplasmic reticulum **1** and mature in the Golgi complex **2**. They then migrate to the cell surface, where they cluster in clathrin-coated pits **3**. LDL, made up of cholesterol esters and apoprotein, binds to the LDL receptors **4** and is internalized in endocytotic vesicles **5**. Several such vesicles fuse to form an organelle called an endosome **6**. Proton pumping in the endosome membrane causes the pH to drop, which in turn causes LDL to dissociate from the receptors **7**. The endosome fuses with a lysosome **8** and the receptor-bearing clathrin coat dissociates and returns to the membrane **9**. The receptor-LDL complex is degraded in the lysosomes **10** and cholesterol has various fates. Regulatory actions of cholesterol are shown in red. ACAT, acyl-CoA:cholesterol acyltransferase.

that reach the cell surface and bind LDL but fail to cluster in clathrin-coated pits and thus do not internalize LDL. Finally, there is a class of mutant receptors that bind and internalize LDL in coated pits, but fail to release LDL in the endosome, and do not recycle to the cell surface.

Receptor-mediated endocytosis is now known to be a widely used pathway for internalization of extracellular substances, including other lipoproteins, cell growth factors, the iron-binding protein transferrin, some vitamins, and even viruses.

Cholesterol, LDL, and Atherosclerosis

Thanks principally to the work of Brown and Goldstein, we now know a great deal about the genetic and biochemical factors that control serum cholesterol levels, and overwhelming epidemiological evidence now links prolonged hypercholesterolemia to the development of atherosclerotic plaque. Much, however, remains to be learned. We don't know, for example, why diets rich in saturated fatty acids tend to elevate serum cholesterol levels. Nor do we know why a particular class of polyunsaturated fatty acids (PUFAs) called ω -3 (**omega-3**) fatty acids tends to depress levels of both serum cholesterol and triacylglycerols and slow the build-up of atherosclerotic plaques. But nutritionists have found that adding to a Western diet fish or fish oils, which are abundant in this class of fatty acids, does indeed have this effect. That is why we are being urged to substitute fish for red meat, which tends to be rich in both saturated fatty acids and cholesterol. The most prominent ω -3 fatty acid is linolenic acid, which is an 18:3 Δ 9,12,15 fatty acid (nutritionists number fatty acids backward from biochemists, so the term ω -3 refers to a double bond on the third carbon from the terminal methyl group, what we would call the bond between C-15 and C-16 in this 18-carbon molecule; see margin on next page).

Polyunsaturated fat (PUFA) ingestion is correlated with low plasma cholesterol levels. The mechanisms involved are not completely understood.

Linolenic acid is an essential fatty acid for humans, but we lack the enzymes to synthesize it, so it must be obtained from the diet. Two other important ω -3 PUFAs, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) can be synthesized by humans from dietary linolenic acid.

Progress is being made, however, in learning how elevated cholesterol levels lead to atherogenesis (plaque formation). LDL undergoes rather ready oxidation, both in cells and in plasma, to a mixture of molecules collectively called **oxidized LDL**. Although the specific oxidation reactions are not well defined, they include peroxidation of unsaturated fatty acids (page 666), hydroxylation of cholesterol itself, and oxidation of amino acid residues in the apoprotein. Accumulation of oxidized LDL on the vessel wall triggers an inflammation response in which the endothelial cells express adhesion molecules that recruit monocytes and T lymphocytes. Some of these cells differentiate into macrophages that take up the lipids that accumulate at sites of arterial injury. Uptake occurs through one of a family of **scavenger receptors**; these receptors take up many substances in addition to oxidized LDL. Unlike the LDL receptor, the scavenger receptor is not down-regulated by cholesterol, so cholesterol uptake into these cells is virtually unlimited, which converts these cells to a cholesterol-engorged species called a **foam cell**. These events have a chemotactic effect, causing more white cells to migrate to the site and leading them to accumulate more cholesterol, which ultimately becomes one of the chief chemical constituents of the plaque that forms at such a site.

TV advertisements talk about “bad cholesterol” and “good cholesterol.” These are actually inappropriate terms because cholesterol itself is a natural metabolite, an essential component of all membranes, and the precursor to all steroid hormones and bile acids (see Chapter 19). However, cholesterol present in LDL is considered “bad” because prolonged elevation of LDL levels is what leads to atherosclerosis. By contrast, cholesterol in HDL is called “good” because high levels of HDL counteract atherogenesis. Cholesterol cannot be metabolically degraded, and excess cholesterol is returned from peripheral cells to the liver, for passage through the bile to the intestine, for ultimate excretion (Figure 17.8). As the agent for this transport back to the liver, HDL plays a role in lowering total serum cholesterol levels, which is “good.” Recent studies have shown that cholesterol from HDL is taken up into cells not by endocytosis, as with LDL, but instead by a “docking” reaction, in which HDL interacts with another member of the scavenger cell surface receptor family (SR-BI), deposits its cholesterol for uptake, and departs as a remnant without itself being incorporated in the cell’s interior.

Mobilization of Stored Fat

In general, the capacity of animal storage depots to store fat is virtually unlimited. Whatever appears in the body from the diet is absorbed, and most of it is transported to adipose tissue for storage. The lack of control of this process is sadly evident from the prevalence of obesity among humans, in whom fat is stored in excess of its need to supply energy. By contrast, the release of fat from storage depots in adipose tissue is controlled hormonally, to meet the needs of the organism for energy generation.

The catabolism of fat (**lipolysis**) begins with the hydrolysis of triacylglycerol to yield glycerol plus free fatty acid (often abbreviated FFA). About 95% of the energy derived from subsequent oxidation of the fat comes from the fatty acids, with only 5% coming from glycerol. All of the carbons from fatty acids are catabolized to two-carbon fragments, as acetyl-coenzyme A, except for the small proportion of fatty acids that contain odd-numbered chains.

The release of metabolic energy stored in triacylglycerols is comparable to the mobilization of carbohydrate energy stored in animal glycogen, in that the first step of fat breakdown—its hydrolysis to glycerol and fatty acids—is hormonally regulated. Three lipolytic enzymes are now known to participate in this process: **triacylglycerol lipase**, also called hormone-sensitive lipase (**HSL**), **adipose triglyceride lipase** (**ATGL**), and **monoacylglycerol lipase** (**MGL**). All three of these

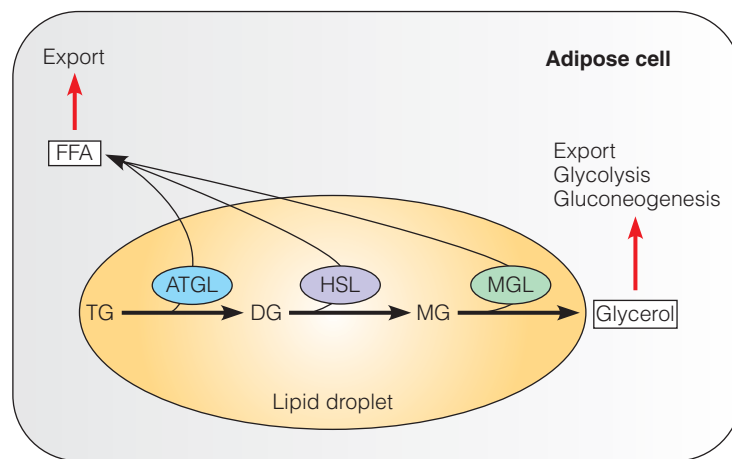

Uptake of oxidized LDL by a scavenger receptor is a key event in atherogenesis.

Fat mobilization in adipose cells is hormonally controlled, via the cyclic AMP-dependent phosphorylation of lipolytic enzymes and lipid droplet-associated proteins.

FIGURE 17.13

Mobilization of adipose cell triacylglycerols by lipolysis. Three lipases act sequentially to hydrolyze triacylglycerol (TG) to glycerol and free fatty acids (FFA). These enzymes act at the oil–water interface of the lipid droplet. FFA are exported to the blood plasma, where they are bound to albumin for transport to liver and other tissues for subsequent oxidation. Glycerol is released to the blood to be taken up by liver cells, where it serves as a gluconeogenic substrate. DG, diacylglycerol; MG, monoacylglycerol; ATGL, adipose triglyceride lipase; HSL, hormone-sensitive lipase; MGL, monoacylglycerol lipase.

The Journal of Lipid Research 50:3–21, R. Zechner, P. C. Kienesberger, G. Haemmerle, R. Zimmermann, and A. Lass, Adipose triglyceride lipase and the lipolytic catabolism of cellular fat stores. enzymes are serine esterases, catalyzing the hydrolysis of the ester linkage between the glycerol backbone and a fatty acid using a serine nucleophile to form the acyl-enzyme intermediate. HSL and MGL each possess the classic catalytic triad of serine, aspartate, and histidine, whereas ATGL has a catalytic dyad of serine and aspartate. Although these enzymes catalyze the same chemical reaction, their substrate specificities differ. HSL is capable of hydrolyzing triacylglycerol (TG), diacylglycerol (DG), monoacylglycerol (MG), and cholesteryl esters (CEs), but is 10 times more active with DG than with TG or MG. Indeed, HSL was long considered the only enzyme involved in this process. This view was overturned when HSL-knockout mice were created (see Tools of Biochemistry 26A), which totally lack HSL. To everyone's surprise, these mice did not become overweight or obese and could still release free fatty acids in response to hormonal stimulation. This result suggested that another TG hydrolase must exist, and led to the discovery of ATGL in 2004. ATGL has 10-fold higher substrate specificity for TG than for DG and does not hydrolyze MG. Recently, ATGL-knockout mice have been created. In contrast to HSL-deficient mice, ATGL-knockout mice accumulate excessive TG in all organs, whereas DG levels are normal. Thus, it appears that these three enzymes work together to convert triacylglycerol to free fatty acids and glycerol. ATGL catalyzes the first step in TG mobilization, generating DG and FFA. HSL catalyzes hydrolysis of DG, generating MG and FFA, and MGL releases the third FFA from the glycerol backbone (Figure 17.13).

How is lipolysis regulated? HSL activity is controlled by a cascade involving cyclic AMP (Figure 17.14). Depending on the physiological state, glucagon, epinephrine, parathyroid hormone, thyrotropin, or adrenocorticotropin binds to a β -adrenergic receptor on the plasma membrane, leading to activation of adenylate cyclase, as described in Chapter 13. This, in turn, activates protein kinase A (PKA), by releasing active catalytic subunits (C) from the inactive R_2C_2 tetramer. PKA phosphorylates several target proteins in the adipose cell to stimulate lipolysis. HSL activity is stimulated by phosphorylation, but only about two-fold. The major stimulatory effect is on **perilipin**, a protein that coats the cytosolic surface of adipocyte lipid droplets. Normally, perilipin blocks access of HSL to the lipid droplet. However, upon phosphorylation of perilipin by PKA, phosphorylated HSL is recruited to the lipid droplet where it can now access its DG substrate. ATGL activity also appears to be controlled by perilipin, albeit indirectly. In addition, ATGL requires a cofactor for full activity, a protein named CGI-58. In unstimulated adipocytes, CGI-58 is sequestered by perilipin A on the lipid droplet and is unavailable to activate ATGL. Following hormonal stimulation and PKA-dependent phosphorylation of perilipin, CGI-58 is released from perilipin to activate ATGL and deliver it to the lipid droplet (Figure 17.14). In adipose tissue the primary hormonal effects are mediated by epinephrine in stress situations and by glucagon during fasting.

The involvement of protein cofactors for lipases that act at an oil–water interface is quite common. We learned previously that pancreatic lipase requires colipase

**FIGURE 17.14**

Control of lipolysis in adipose cells by a cyclic AMP-mediated cascade system. Hormonal activation of a β -adrenergic G-protein coupled receptor on the plasma membrane leads to elevation of cAMP levels, which in turn, activates protein kinase A (PKA). PKA phosphorylates perlipin (PL) and HSL **1**. CGI-58 dissociates from phosphorylated perlipin, and binds ATGL **2**. Phosphorylated HSL is recruited to the lipid droplet and activated by phosphorylated perlipin **3**. Phosphorylated perlipin also recruits the ATGL/CGI-58 complex to the lipid droplet, activating this lipase **4**. Activated ATGL hydrolyzes TG to DG + FFA; activated HSL hydrolyzes DG to MG + FFA; cytoplasmic MGL hydrolyzes MG to free glycerol + FFA.

(page 712) and lipoprotein lipase requires apoC-II (page 714) for full activity. In a similar manner, the action of both HSL and ATGL depends on cofactor proteins (perilipin and CGI-58, respectively). MGL, on the other hand, appears to be a cytoplasmic lipase that hydrolyzes MG released from the lipid droplet without the requirement of any cofactor.

The free fatty acid hydrolysis products exit the adipocyte by passive diffusion and find their way to the blood plasma, where the fatty acids become bound to **albumin**. This is the most abundant plasma protein, about 50% of the total plasma protein in humans. The protein, with an M_r of 66,200, contains 17 disulfide bridges. Each molecule of albumin can bind up to 10 molecules of free fatty acid, although the actual amount bound is usually far lower. Fatty acids are released from albumin and taken up by tissues largely by passive diffusion so that fatty acid uptake into cells is driven primarily by concentration. Most of the glycerol released to the bloodstream is taken up by liver cells, where it serves as a gluconeogenic substrate, leading to the production of glucose (see Figure 17.8).

Fatty Acid Oxidation

Early Experiments

The nature of the pathway by which fatty acids are oxidized was revealed as early as 1904, in a brilliant series of experiments by a German chemist named Franz Knoop. The experiments were inspired because they involved the first known use of metabolic tracers, more than 40 years before radioactive tracers became available. Knoop fed dogs a series of fatty acids in which the terminal methyl group was derivatized with a phenyl group. The expectation was that these analogs would follow metabolic pathways similar to those used for oxidizing normal fatty acids. Knoop found that when the fed fatty acid had an even-numbered carbon chain, the final breakdown product, recovered from urine, was phenylacetic acid. When the fed fatty acid had an odd-numbered chain, the product was benzoic acid (Figure 17.15).

These results led Knoop to propose that fatty acids are oxidized in a stepwise fashion, with initial attack on carbon 3 (the β -carbon with respect to the carboxyl group). This attack would release the terminal two carbons, and the remainder of the fatty acid molecule could undergo another oxidation. Release of a two-carbon fragment would occur at each step in the oxidation. With the analogs, the process would be repeated until the remaining acid, either phenylacetic or benzoic acid, could not be further metabolized and would be excreted in the urine.

**FIGURE 17.15**

Oxidation of phenyl derivatives of fatty acids in Knoop's experiment. Red triangles represent presumed sites of cleavage of these model fatty acids.

The next major development came in the 1940s, when Luis Leloir and Albert Lehninger independently demonstrated fatty acid oxidation in cell-free liver homogenates. Lehninger showed that ATP was essential for this process, suggesting that ATP somehow activates the carboxyl group of the fatty acid. Working with Eugene Kennedy, Lehninger also showed that the process occurs in mitochondria and that it releases two-carbon fragments that are oxidized in the citric acid cycle. In Munich, Feodor Lynen demonstrated that the ATP-dependent activation esterifies the fatty acid carboxyl group with the thiol group of coenzyme A, and it was later shown that all of the intermediates in the subsequent oxidative reactions are fatty acyl-CoA thioesters. Thus, by the mid-1950s the basic outlines of the fatty acid oxidation pathway were clear. As shown in Figure 17.16, the pathway consists of activation of the carboxyl group, transport into the mitochondrial matrix, and stepwise oxidation of the carbon chain, two carbons at a time, from the end containing the carboxyl group.

Fatty Acid Activation and Transport into Mitochondria

Fatty acids are activated for oxidation by ATP-dependent acylation of coenzyme A.

For the most part, fatty acids arise in the cytosol, either through biosynthesis (as discussed later in this chapter) or through triacylglycerol or fatty acid transport from fat depots outside the cell. These fatty acids must be transported into the mitochondrial matrix for oxidation. Because the inner membrane is impermeable to free long-chain fatty acids and acyl-CoAs, a specific transport system comes into play. That transport system operates hand in hand with the metabolic activation needed to initiate the β -oxidation pathway.

A series of **acyl-CoA synthetases**, specific for short-chain, medium-chain, or long-chain fatty acids, catalyzes formation of the fatty acyl thioester conjugate with coenzyme A (steps 1 and 1' in the upper part of Figure 17.16):

The synthetase specific for long-chain acids is a membrane-bound enzyme, found in both the endoplasmic reticulum and the outer mitochondrial membrane; the short-chain and medium-chain enzymes are found primarily in the mitochondrial matrix. The long-chain enzyme, which plays the predominant role in initiating fatty acid oxidation, acts on fatty acids with chain lengths of 10 to 20 carbons; the medium-chain enzyme acts on 4- to 12-carbon chains; and the short-chain enzyme prefers acetate and propionate.

Chemically, the energy-rich thioester link in long-chain fatty acyl-CoAs is identical to that of acetyl-CoA (see Chapter 14). Recall that pyruvate oxidation provides the energy to drive acetyl-CoA formation in the pyruvate dehydrogenase reaction. The acyl-CoA synthetases, on the other hand, use a two-step mechanism involving cleavage of ATP to drive the endergonic thioester formation (Figure 17.17). First comes activation of the carboxyl group by ATP to give a **fatty acyl adenylate**, with concomitant release of pyrophosphate. Next, the activated carboxyl group is attacked by the nucleophilic thiol group of CoA, thereby displacing AMP and forming the fatty acyl-CoA derivative. Carboxyl groups of amino acids are activated for protein synthesis in very similar fashion.

Although each fatty acyl-CoA, like ATP itself, is an energy-rich compound (ΔG° of hydrolysis ~ -30 kJ/mol), cleavage of ATP to AMP ($\Delta G^{\circ} = -45.6$ kJ/mol; Figure 3.7) provides the driving force for the formation of the fatty acyl-CoA. The reaction is made essentially irreversible because of the active pyrophosphatase present in most cells:

Thus, the overall reaction (sum of the two previous reactions) proceeds far in the direction of completion, with a net ΔG° of about -35 kJ/mol.

FIGURE 17.16

Overview of the fatty acid oxidation pathway.

FIGURE 17.17

Mechanism of acyl-CoA synthetase reactions.

The figure shows reversible formation of the activated fatty acyl adenylate, nucleophilic attack by the thiol sulfur of CoA-SH on the activated carboxyl group, and the quasi-irreversible pyrophosphatase reaction, which draws the overall reaction toward fatty acyl-CoA.

Fatty acyl-CoAs are formed on the outer mitochondrial membrane. Hence, they must move through the inner mitochondrial membrane to become oxidized. This movement involves transfer of the fatty acyl moiety to a carrier called **carnitine** (step 2, upper part of Figure 17.16). The reaction is catalyzed by **carnitine acyltransferase I** (also called **carnitine palmitoyltransferase I**, or **CPT I**), embedded in the outer mitochondrial membrane with its active site facing the cytoplasm. CPT I yields a derivative, **fatty acyl-carnitine**, that traverses the inner membrane via a specific carrier, the carnitine-acylcarnitine translocase (Figure 17.18 and step 3, upper part of Figure 17.16). A second enzyme, **carnitine acyltransferase II** (also called **carnitine palmitoyltransferase II**, or **CPT II**), loosely associated with the matrix side of the inner membrane, completes the transfer process by exchanging fatty acyl-carnitine for free carnitine and producing fatty acyl-CoA within the matrix (step 4, upper part of

FIGURE 17.18

The carnitine acyltransferase system, for transport of fatty acyl-CoAs into mitochondria.

Figure 17.16). The inner membrane translocase is an antiporter, catalyzing the reversible exchange of acylcarnitine for free carnitine. Thus, the free carnitine formed in the matrix returns to the intermembrane space via the translocase and then moves to the cytoplasm through pores in the outer membrane. Although fatty acyl-carnitines are ordinary esters, the ester bond in these compounds is somewhat activated, as shown by the ready reversibility of the carnitine acyltransferase reactions.

What is the point of this rather complex shuttling process? It exists to regulate fatty acid oxidation, preventing the futile cycle that would occur if oxidation and resynthesis were taking place at the same time. Carnitine acyltransferase I is strongly inhibited by **malonyl-CoA**, the first committed intermediate in fatty acid synthesis (page 737) (CPT II is insensitive to malonyl-CoA). Indeed, entry of fatty acids into mitochondria is rate-limiting for β -oxidation and is the primary point of regulation. Thus, conditions in the cell that favor fatty acid synthesis prevent the transfer of fatty acyl moieties to their intracellular sites of oxidation and, hence, prevent that oxidation.

Carnitine transports acyl-CoAs into mitochondria for oxidation.

The β -Oxidation Pathway

Once inside the mitochondrial matrix, fatty acyl-CoAs are oxidized as predicted by Knoop, with oxidation of the β -carbon and a series of steps in which the fatty acyl chain is shortened by two carbons at a time. The two-carbon fragment is released in the form of acetyl-CoA. Each step involves four reactions (Figure 17.19 and steps 1–4, lower part of Figure 17.16). The pathway is cyclic in that each step ends with formation of an acyl-CoA, shortened by two carbons, which undergoes the same process in the next step, or cycle. For example, 1 mole of palmitoyl-CoA, derived from a 16-carbon fatty acid, undergoes seven cycles of oxidation to give 8 moles of acetyl-CoA. Each cycle releases 1 two-carbon unit, concomitant with 2 two-electron oxidation–reduction reactions. Because each cycle results in oxidation of the β -carbon (the α -carbon remains at the methylene oxidation state), the pathway is called **β -oxidation**.

FIGURE 17.19

Outline of the β -oxidation of fatty acids. In the diagram a 16-carbon saturated fatty acyl-CoA (palmitoyl-CoA) undergoes seven cycles of oxidation to yield eight molecules of acetyl-CoA. These reactions correspond to steps 1–4, lower part of Figure 17.16.

Mechanistically, this pathway is remarkably similar to that used to oxidize succinate in the citric acid cycle (compare with Figure 14.3, page 595). As shown in Figure 17.19, each cycle in the oxidation of a saturated fatty acyl-CoA involves the following reactions: (1) dehydrogenation to give an enoyl derivative; (2) hydration of the resultant double bond, with the β -carbon undergoing hydroxylation; (3) dehydrogenation of the hydroxyl group (oxidation to a ketone); and (4) cleavage by attack of a second molecule of coenzyme A on the β -carbon, to release acetyl-CoA and a fatty acyl-CoA two carbons shorter than the original substrate. Oxidation of unsaturated fatty acyl-CoAs is slightly different, as discussed on page 730.

Acetyl-CoA from β -oxidation enters the citric acid cycle, where it is oxidized to CO_2 in the same fashion as the acetyl-CoA derived from the oxidation of pyruvate. Like the citric acid cycle, β -oxidation generates reduced electron carriers, whose reoxidation in the mitochondria generates ATP via oxidative phosphorylation from ADP. Now let us describe the individual reactions in detail (refer to Figure 17.19).

Reaction 1: The Initial Dehydrogenation

The first reaction is catalyzed by an **acyl-CoA dehydrogenase**, which catalyzes the removal of two hydrogen atoms from the α - and β -carbons to give a *trans* α,β -unsaturated acyl-CoA (*trans*-2-enoyl-CoA) as the product. This oxidation introduces a conjugated double bond into a carbonyl compound, and like most enzymes that catalyze this type of oxidation, acyl-CoA dehydrogenase uses a tightly bound FAD prosthetic group. The enzyme first abstracts the acidic *pro-R* hydrogen from the α -carbon to give a thioester enolate. The *pro-R* hydrogen on the β -carbon is then transferred as a hydride equivalent to FAD to give the *trans* double bond and enzyme-bound FADH_2 .

As shown in Figure 17.20, the enzyme-bound FADH_2 contributes a pair of electrons to a shuttle protein, the **electron-transferring flavoprotein (ETF)**. These electrons are passed in turn to coenzyme Q via ETF-Q oxidoreductase, an integral membrane protein, and are then shuttled along the respiratory chain, yielding ATP via oxidative phosphorylation. In this respect, ETF-Q oxidoreductase is comparable to NADH dehydrogenase and succinate dehydrogenase. All three are flavoproteins that transfer electrons to the mobile electron carrier coenzyme Q (see Figure 15.13, page 640).

Reactions 2 and 3: Hydration and Dehydrogenation

Like succinate oxidation, an initial FAD-dependent fatty acyl-CoA oxidation is followed by hydration and an NAD^+ -dependent dehydrogenation. In β -oxidation the latter two reactions are catalyzed by **enoyl-CoA hydratase** and **3-L-hydroxyacyl-CoA dehydrogenase**, respectively (Figure 17.19). Both reactions are stereospecific. Because carbon 3 is β with respect to the carboxyl carbon, the products of these two reactions are sometimes called **L- β -hydroxyacyl-CoA** and **β -ketoacyl-CoA**, respectively. Hence the term *β -oxidation*.

FIGURE 17.20

Fate of reducing equivalents derived from fatty acyl-CoA dehydrogenation. Enzyme-bound FAD becomes reduced and then transfers its electrons to ETF, which in turn passes them to coenzyme Q, which is also a collection point for electrons from NADH dehydrogenase and succinate dehydrogenase (see Figure 15.13, page 640).

Reaction 4: Thiolitic Cleavage

The fourth and last reaction in each cycle of the β -oxidation pathway involves attack of the nucleophilic thiol sulfur of coenzyme A on the electron-poor keto (β) carbon of 3-ketoacyl-CoA, with cleavage of the α – β bond and release of acetyl-CoA. The other product is a shortened fatty acyl-CoA, ready to begin a new cycle of oxidation:

Because this reaction involves cleavage by a thiol, it is referred to as a **thiolitic cleavage**, by analogy with hydrolysis, which involves cleavage by water. The enzyme is commonly called **β -ketothiolase**, or simply **thiolase**. An essential nucleophilic cysteine thiol group on the enzyme (E-SH) attacks the substrate, with formation of an acyl-enzyme intermediate and acetyl-CoA in a retro-Claisen reaction (see Chapter 12, page 484). Free CoA-SH then attacks the intermediate in a nucleophilic acyl substitution reaction (see margin).

As noted earlier, the overall oxidation pathway as just described is applicable to the most abundant fatty acids—those that contain even numbers of carbon atoms and are fully saturated. Presently, we shall describe the variations in this pathway that permit oxidation of other fatty acids. For the saturated, even-chain fatty acyl-CoAs, oxidation simply proceeds stepwise, with two carbons lost as acetyl-CoA after each cycle. For the C_{16} palmitoyl-CoA, the example shown in Figure 17.19, the first cycle yields acetyl-CoA plus the C_{14} myristoyl-CoA. A second cycle, acting on the latter substrate, yields acetyl-CoA plus the C_{12} lauroyl-CoA. In the seventh and last cycle, the 3-hydroxyacyl-CoA dehydrogenase reaction yields acetoacetyl-CoA. Thiolitic cleavage of this substrate yields 2 moles of acetyl-CoA (see margin on next page). Thus, the oxidation of 1 mole of palmitic acid involves six successive cycles, each of which yields 1 mole of acetyl-CoA, and a seventh cycle, which yields 2 moles. Other saturated even-chain fatty acids are degraded identically. For example, stearic acid oxidation involves eight steps, with two acetyl-CoAs resulting from the last cycle.

Mitochondrial β -Oxidation Involves Multiple Isozymes

Mammalian mitochondria possess multiple isozymes for several of the steps of the β -oxidation pathway. Four isozymes of acyl-CoA dehydrogenase exist with overlapping chain length specificities for short-, medium-, long-, or very long-chain fatty acyl-CoAs (referred to as SCAD, MCAD, LCAD, and VLCAD, respectively). All of these are soluble matrix proteins, except VLCAD (very long-chain acyl-CoA

Mechanism of thiolitic cleavage

dehydrogenase), which is bound to the matrix side of the inner membrane. There are two isozymes for each of the next three enzymes in the pathway. One member of each pair is a soluble matrix enzyme, specific for shorter chain acyl-CoAs. The other isozyme of each pair is specific for longer chain substrates and is known to be an inner membrane protein. In 1992, a large protein was purified from rat and human mitochondrial inner membranes that possessed long-chain enoyl-CoA hydratase, long-chain hydroxyacyl-CoA dehydrogenase, and long-chain ketoacyl-CoA thiolase activities. This 460,000-dalton protein, an $\alpha_4\beta_4$ octamer, catalyzes the last three steps of the β -oxidation cycle and was thus named mitochondrial trifunctional protein (MTP). One hypothesis, not yet proven, is that upon entry into the mitochondrial matrix, long-chain fatty acyl-CoAs are initially metabolized by VLCAD and MTP; after several rounds of β -oxidation by the membrane-bound isozymes, the shortened acyl-CoA substrates are handed off to the soluble isozymes for completion of the pathway.

Many disorders that affect mitochondrial fatty acid oxidation in humans have been described, including inherited defects in proteins of the carnitine acyltransferase system and the β -oxidation enzymes. Deficiency of medium-chain acyl-CoA dehydrogenase (MCAD) is the most common disorder of fatty acid metabolism, with a frequency of 1 in 15,000, and has been associated with some cases of sudden infant death syndrome (SIDS). Two different disorders affect the mitochondrial trifunctional protein: either isolated long-chain hydroxyacyl-CoA dehydrogenase (LCHAD) deficiency, or complete MTP deficiency with reduced activity of all three enzymes, depending on the nature of the mutation. Children with fatty acid oxidation disorders usually present within the first year of life with recurring episodes of fatty liver (steatosis), high blood levels of fatty acid intermediates, hypoglycemia, and may also exhibit skeletal and cardiac myopathies. The episodes are induced by fasting as a result of the regulatory mechanisms that control the switch from carbohydrate fuels to lipid fuels (more about this later), and thus treatment includes avoiding fasting and consuming a low-fat, high-carbohydrate diet. Improvements in mass spectrometry (see Tools of Biochemistry 12B) have facilitated the screening of newborn infants using blood spots, allowing affected infants to be detected before the onset of symptoms. This is important because many of these disorders can be managed by relatively simple dietary means.

Energy Yield from Fatty Acid Oxidation

We can now write a balanced equation for the overall degradation of palmitoyl-CoA to 8 moles of acetyl-CoA:

Each of the products is metabolized exactly as described earlier for oxidation of carbohydrates. Acetyl-CoA is catabolized via the citric acid cycle, and FADH_2 and NADH transfer electrons to the respiratory chain through ETF (page 727) and complex I, respectively. Thus, we can easily compute the metabolic energy yield from fatty acid oxidation in terms of moles of ATP synthesized from ADP. Recall from Chapter 15 that the P/O ratios for oxidation of flavoproteins and NADH are ~ 1.5 and ~ 2.5 , respectively, and oxidation of acetyl-CoA in one turn of the citric acid cycle yields 10 ATPs. The following summation, using palmitate as an example, gives the total energy yield:

Reaction	ATP Yield
Activation of palmitate to palmitoyl-CoA	-2
Oxidation of 8 acetyl-CoA	$8 \times 10 = 80$
Oxidation of 7 FADH_2	$7 \times 1.5 = 10.5$
Oxidation of 7 NADH	$7 \times 2.5 = 17.5$
Net: Palmitate \longrightarrow $\text{CO}_2 + \text{H}_2\text{O}$	106

Fatty acids are oxidized by repeated cycles of dehydrogenation, hydration, dehydrogenation, and thiolitic cleavage, with each cycle yielding acetyl-CoA and a fatty acyl-CoA shorter by two carbons than the input acyl-CoA.

↓ Thiolase
CoA-SH

+

The final
thiolitic cleavage

From this, you can calculate the ATP yield per carbon oxidized to CO_2 as 106/16, or about 6.6. The corresponding value for glucose is 5–5.3 (30–32 ATPs formed per 6 carbons oxidized). Thus, the energy yield from fat oxidation is higher than that from oxidation of the less highly reduced carbohydrate, whether measured on a weight basis (see page 488) or a molar basis.

Oxidation of Unsaturated Fatty Acids

Two enzymes, enoyl-CoA isomerase and 2,4-dienoyl-CoA reductase, play essential roles in the oxidation of unsaturated fatty acids.

Recall from Chapter 10 that many fatty acids in natural lipids are unsaturated; that is, they contain one or more double bonds (see Table 10.1, page 361). Because these bonds are in the *cis* configuration, they cannot be hydrated by enoyl-CoA hydratase, which acts only on *trans* compounds. Two additional enzymes, **enoyl-CoA isomerase** and **2,4-dienoyl-CoA reductase**, must come into play for unsaturated fatty acids to be oxidized. The isomerase acts upon monounsaturated fatty acids, such as the 18-carbon Δ^9 compound, oleic acid, which contains a *cis* double bond between carbons 9 and 10. Oleic acid is activated, transported into mitochondria, and carried through three cycles of β -oxidation just as are the saturated fatty acids. The product of the third cycle is the CoA ester of a 12-carbon fatty acid with a *cis* double bond between carbons 3 and 4. Not only is the double bond in the wrong configuration to be hydrated, but it is also in the wrong position. The enoyl-CoA isomerase enzyme converts this *cis*-3-enoyl-CoA to the corresponding *trans*-2-enoyl-CoA, which can then be acted on by enoyl-CoA hydratase (see margin). This hydration and all subsequent reactions are identical to those already described for saturated fatty acids.

The other auxiliary enzyme, 2,4-dienoyl-CoA reductase, comes into play during the oxidation of polyunsaturated fatty acids, such as linoleic acid (18:2 $\Delta^9,12$). This 18-carbon fatty acid contains *cis* double bonds between carbons 9 and 10 and between carbons 12 and 13. As shown in Figure 17.21, linoleyl-CoA undergoes three cycles of β -oxidation, just as does oleyl-CoA, to give a C_{12} acyl-CoA with *cis* double bonds between carbons 3 and 4 and between 6 and 7. Enoyl-CoA isomerase converts the Δ^3 *cis* double bond to a Δ^2 *trans* double bond. There follow hydration, dehydrogenation, and thiolitic cleavage to give acetyl-CoA plus a 10-carbon enoyl-CoA, unsaturated between carbons 4 and 5. Action of acyl-CoA dehydrogenase yields a dienoyl-CoA, unsaturated at C_4 — C_5 and at C_2 — C_3 . The NADPH-dependent 2,4-dienoyl-CoA reductase converts this to a C_{10} *cis*- Δ^3 -enoyl-CoA. The isomerase comes into play once more, generating a *trans*- Δ^2 -enoyl-CoA, which undergoes the remaining cycles of β -oxidation normally.

By the pathways described here, both monounsaturated and diunsaturated 18-carbon fatty acids can undergo degradation to 9 moles of acetyl-CoA. There is, of course, a reduction in the overall energy yield because each double bond at an odd-numbered carbon in the original fatty acid means one less FAD reduction step in the overall process. A double bond at an even-numbered carbon must be reduced at the expense of NADPH, equivalent to the cost of ~ 2.5 ATP. The two auxiliary enzymes allow all of the even-chain polyunsaturated fatty acids to be similarly degraded, with the following exception. A significant portion of dietary lipid contains unsaturated fatty acids with double bonds in the *trans* configuration. These fatty acids arise through microbial action in the digestive systems of ruminant mammals and also chemically, through partial hydrogenation of fats and oils. Commercial vegetable oils are subjected to partial hydrogenation to protect them against oxidation by converting the double bonds to single bonds (more saturated). Unfortunately, some *cis* double bonds are isomerised to *trans* double bonds during this process, and *trans* fatty acids can thus be quite abundant in dairy products and in margarine and cooking oils. Because there is growing evidence implicating *trans* fatty acids in coronary artery disease, margarine manufacturers are beginning to remove them from their product and many cities such as New York have banned the use of *trans* fatty acids in restaurants.

**FIGURE 17.21**

β -Oxidation pathway for polyunsaturated fatty acids. This example, using linoleyl-CoA, shows sites of action of enoyl-CoA isomerase and 2,4-dienoyl-CoA reductase, enzymes specific to unsaturated fatty acid oxidation (identified with magenta type).

Oxidation of Fatty Acids with Odd-Numbered Carbon Chains

Though most of the fatty acids in natural lipids contain even-numbered carbon chains, a small proportion have odd-numbered carbon chains. The latter group presents a special metabolic problem, which is solved in a novel way. The substrate for the last cycle of

Odd-numbered fatty acid chains yield upon oxidation 1 mole of propionyl-CoA, whose conversion to succinyl-CoA involves a biotin-dependent carboxylation and a coenzyme B₁₂-dependent rearrangement.

electrons not to the respiratory electron transport chain but directly to oxygen (these enzymes are thus more properly called **acyl-CoA oxidases**; see margin). The latter is reduced to hydrogen peroxide, which in turn is acted on by catalase.

The next two steps, hydration of the enoyl-CoA and oxidation of the hydroxyacyl-CoA, are catalyzed by a multifunctional enzyme that carries two additional activities required for the processing of unsaturated fatty acids (an epimerase and isomerase). The fourth step of the cycle is catalyzed by a monofunctional thiolase. Because electrons are not shuttled into the respiratory chain, the peroxisomal pathway is not coupled to energy production, but it does generate heat. In animal peroxisomes the pathway proceeds only as far as C₄ and C₆ acyl-CoAs. However, these acyl groups can be transferred to carnitine for transport into mitochondria, where β -oxidation can be completed. By contrast, plant glyoxysomes carry the oxidation all the way to acetyl-CoA, which is used for carbohydrate synthesis via the glyoxylate pathway. The function of the peroxisomal pathway is not yet clear, but it involves initial stages in oxidizing very long-chain fatty acids (VLCFA) and other lipids. The importance of the peroxisomal pathway is revealed by two human genetic diseases. Infants born with Zellweger syndrome are unable to import any proteins into the peroxisome, including those of the β -oxidation pathway, and they accumulate high levels of VLCFA in their blood. These infants have profound neurological impairment, and they die within their first year. Individuals with X-linked adrenoleukodystrophy (X-ALD) are also unable to metabolize VLCFA (≥ 22 C). The disease is characterized by elevated plasma and tissue levels of VLCFA. X-ALD is caused by mutations in the *ABCD1* gene, which encodes an ATP-binding-cassette (ABC) transporter located in the peroxisomal membrane. Patients with mutations in this gene are unable transport the CoA derivatives of these very long-chain fatty acids into peroxisomes, and thus their oxidation is blocked. Boys born with X-ALD develop normally for the first few years, but they then suffer progressive neurological impairment and death by age 10–15 years. Dietary treatment with a mixture of glyceryl trioleate and glyceryl trierucate (referred to as Lorenzo's Oil) normalizes plasma VLCFA levels in patients, presumably by competing with the enzyme system that elongates saturated fatty acids (see page 744). This treatment was the subject of a popular 1992 film, but the clinical efficacy of Lorenzo's Oil in preventing the neurological damage of X-ALD remains controversial.

Glyceryl trierucate

α -Oxidation of Fatty Acids

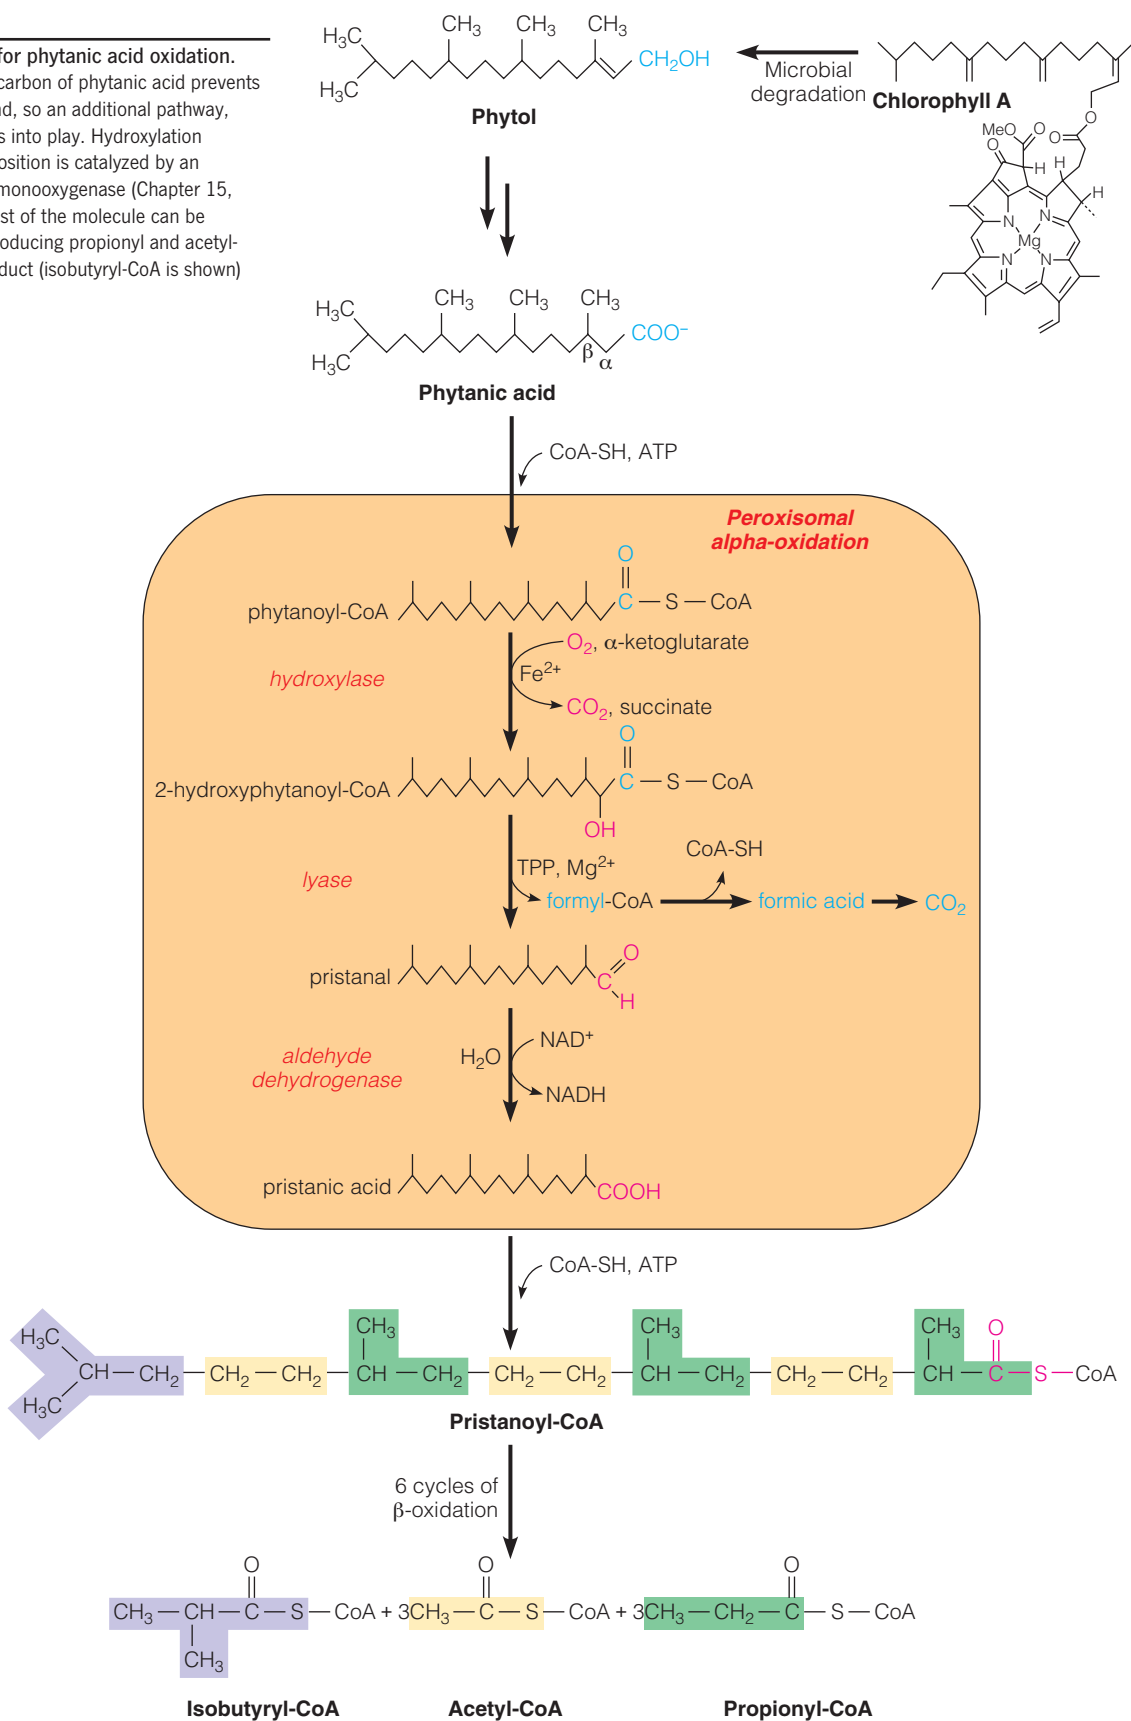

Although β -oxidation is the major pathway for fatty acid degradation, a minor pathway, also localized to peroxisomes, oxidizes certain fatty acids with initial oxidation occurring on the α -carbon rather than the β -carbon. This pathway came to light through analysis of a rare and severe congenital neurological disorder called **Refsum's disease**. Patients with this condition accumulate large amounts of an unusual fatty acid, **phytanic acid**, which is derived from **phytol**, a constituent of chlorophyll (Figure 17.23). The methyl group on carbon 3 of phytol prevents β -oxidation of this substrate. However, the α -carbon can undergo oxidation, to give **pristanic acid**, a substrate that can be further degraded by β -oxidation (Figure 17.23). In Refsum's disease the α -oxidation pathway is defective, and the phytanic acid is not converted to a compound that can be degraded. The only known treatment is to feed a diet containing little or no chlorophyll. This treatment is difficult because it rules out both leafy green vegetables and meat and milk that come from herbivorous animals—all of these foods contain substantial amounts of phytanic acid.

Ketogenesis

Thus far we have written about acetyl-CoA as though it had only two major metabolic fates, either oxidation to CO₂ in the citric acid cycle or biosynthesis of fatty acids. Another major pathway comes into play in mitochondria (primarily in

FIGURE 17.23

The α -oxidation pathway for phytanic acid oxidation. The methyl group on the β -carbon of phytanic acid prevents β -oxidation of this compound, so an additional pathway, involving α -oxidation, comes into play. Hydroxylation of phytanoyl-CoA at the α -position is catalyzed by an α -ketoglutarate-dependent monooxygenase (Chapter 15, page 663). After that, the rest of the molecule can be degraded by β -oxidation, producing propionyl and acetyl-CoA. The final oxidation product (isobutyryl-CoA) remains speculative.

liver) when acetyl-CoA accumulates beyond its capacity to be oxidized or used for fatty acid synthesis. That pathway is called **ketogenesis**, and it leads to a class of compounds called **ketone bodies**.

During fasting or starvation, when carbohydrate intake is too low, oxaloacetate levels fall so that flux through citrate synthase is impaired, causing acetyl-CoA levels to rise. Under these conditions, 2 moles of acetyl-CoA undergo a reversal of the thiolase reaction to give acetoacetyl-CoA (Figure 17.24). Acetoacetyl-CoA can react in turn with a third mole of acetyl-CoA to give **3-hydroxy-3-methylglutaryl-CoA (HMG-CoA)**, catalyzed by **HMG-CoA synthase**. When formed in cytosol, HMG-CoA is an early intermediate in cholesterol biosynthesis (see Chapter 19). In mitochondria, however, HMG-CoA is acted on by **HMG-CoA lyase** to yield **acetoacetate** plus acetyl-CoA. Acetoacetate undergoes either NADH-dependent reduction to give **D-β-hydroxybutyrate** or, in very small amounts, spontaneous decarboxylation to acetone. Collectively, acetoacetate, acetone, and β-hydroxybutyrate are called ketone bodies, even though the last compound does not contain a keto carbonyl group. Liver also produces free acetate, by direct hydrolysis of acetyl-CoA. All of these compounds can be utilized by peripheral tissues as an alternative fuel under ketogenic conditions. Extrahepatic tissues take up acetate from the blood and transport it into mitochondria, where it is converted back to acetyl-CoA in an ATP-dependent reaction catalyzed by **acetyl-CoA synthetase**:

Acetyl-CoA is then oxidized through the citric acid cycle for ATP production.

In some circumstances, ketogenesis can be considered an “overflow pathway.” As noted above, it is stimulated when acetyl-CoA accumulates because of deficient carbohydrate intake. Ketogenesis occurs primarily in liver because of the high levels of HMG-CoA synthase in that tissue. Ketone bodies are transported from liver to other tissues, where acetoacetate and β-hydroxybutyrate can be reconverted to acetyl-CoA for energy generation. The reversion involves enzymatic transfer of a CoA moiety from succinyl-CoA to acetoacetate, yielding acetoacetyl-CoA and succinate.

This enzyme, β-ketoacyl-CoA transferase, is present in all tissues except liver so that liver does not compete with the peripheral tissues for use of ketone bodies as fuel. The acetoacetyl-CoA is then converted to two acetyl-CoA by thiolase.

As discussed further in Chapter 18, ketogenesis becomes extremely important in fasting and starvation, when the brain, which normally uses glucose as its main fuel, undergoes metabolic adaptation to the use of ketone bodies. Excess ketone bodies are excreted in the urine, but because of its high volatility, acetone can be detected on the breath. Under normal conditions, certain other tissues, particularly heart, derive much of their energy by metabolizing ketone bodies produced in the liver. In untreated diabetes, where tissues are unable to efficiently use glucose, ketone bodies are produced in excess of the capacity of peripheral tissues to use them, a condition referred to as **ketosis**. Blood levels of ketone bodies in these patients can exceed 100 mg/dL and high levels of the weak acids acetoacetate and β-hydroxybutyrate lower blood pH (**acidosis**). This **ketoacidosis** is a diagnostic feature of diabetes.

FIGURE 17.24

Biosynthesis of ketone bodies in the liver. The three water-soluble compounds commonly called ketone bodies are boxed. Acetone is formed in very small quantities, by nonenzymatic decarboxylation of acetoacetate. Acetate is also produced and released by liver for utilization by peripheral tissues.

When carbohydrate catabolism is limited, acetyl-CoA is converted to ketone bodies, mainly acetoacetate and β -hydroxybutyrate—important metabolic fuels in some circumstances.

Animals readily convert carbohydrate to fat, but cannot carry out net conversion of fat to carbohydrate.

Fatty acid synthesis occurs through intermediates similar to those of fatty acid oxidation, but with differences in electron carriers, carboxyl group activation, stereochemistry, and cellular location.

Fatty Acid Biosynthesis

Relationship of Fatty Acid Synthesis to Carbohydrate Metabolism

We have noted that the vast majority of the stored fuel in most animal cells is in the form of fat. However, a large proportion of the caloric intake of many animal diets—certainly most human diets—is carbohydrate. Because carbohydrate storage reserves are strictly limited, there must be efficient mechanisms for conversion of carbohydrate to fat. In this section our primary focus is on fatty acid synthesis.

As schematized in Figure 17.25, a central metabolite is acetyl-CoA, which comes both from pyruvate in the pyruvate dehydrogenase reaction and from fatty acid β -oxidation. Acetyl-CoA is, in turn, converted in the cytosol to fatty acids. Thus, acetyl-CoA is derived from both fat breakdown and carbohydrate breakdown and is also the major fat precursor. However, in animals *acetyl-CoA cannot undergo net conversion to carbohydrate*. This is because of the virtual irreversibility of the pyruvate dehydrogenase reaction. As noted in Chapter 14, the glyoxylate cycle in plants and some microorganisms permits a bypass of this step, with net conversion of acetyl-CoA to gluconeogenic precursors. However, *in animals the conversion of carbohydrate to fat is unidirectional*. Moreover, although fatty acid synthesis is regulated, the total capacity for fat storage is not.

Early Studies of Fatty Acid Synthesis

Early in the twentieth century, when it became evident that most fatty acids in lipids contain even-numbered chains, it was reasonable to expect that the biosynthetic process would involve some stepwise addition of activated two-carbon fragments, in the same sense that oxidation proceeds two carbons at a time. Indeed, this process was demonstrated experimentally in the 1940s, in one of the first metabolic experiments using isotopic tracers. David Rittenberg and Konrad Bloch fed mice acetate labeled with the stable isotopes ^{13}C and deuterium ($^{13}\text{C}^2\text{H}_3^{13}\text{COO}^-$) and found both isotopes incorporated into fatty acids.

Once the β -oxidation pathway had been discovered, it was generally thought that fatty acid synthesis would proceed simply by a reversal of its degradation pathway. However, when biochemists began to fractionate enzyme systems capable of

FIGURE 17.25

Acetyl-CoA as a key intermediate between fat and carbohydrate metabolism. Arrows identify major routes of formation or utilization of acetyl-CoA. Citrate serves as a carrier to transport acetyl units from the mitochondrion to the cytosol for fatty acid synthesis.

synthesizing fatty acids, they found that the activities of β -oxidation were lacking from their purified fractions. The key discovery that established fatty acid synthesis as an entirely different pathway was Salih Wakil's observation in the late 1950s that fatty acid synthesis has an absolute requirement for bicarbonate. The carbon from that bicarbonate was not incorporated in the final product, however. These observations led to the discovery of a three-carbon compound, *malonyl-CoA*, as the first committed intermediate in fatty acid biosynthesis. Today we know that, although the chemistries of fatty acid synthesis and degradation are similar, the pathways differ in the enzymes involved, acyl group carriers, stereochemistry of the intermediates, electron carriers, intracellular location, and regulation. Indeed, fatty acid metabolism is one of the best examples of the statement that anabolic pathways are never the simple reversal of catabolic pathways.

The overall process of fatty acid synthesis is similar in all prokaryotic and eukaryotic systems analyzed to date. Three separate enzyme systems catalyze, respectively, (1) biosynthesis of palmitate from acetyl-CoA, (2) chain elongation starting from palmitate, and (3) desaturation. In eukaryotic cells the first pathway occurs in the cytosol, chain elongation occurs both in mitochondria and in the endoplasmic reticulum, and desaturation occurs in the endoplasmic reticulum.

Biosynthesis of Palmitate from Acetyl-CoA

As outlined in Figure 17.26, the chemistry of palmitate synthesis is remarkably similar to that of palmitate oxidation run in reverse. The synthetic process comprises stepwise additions of two-carbon units, with each step proceeding via condensation, reduction, dehydration, and another reduction. The major distinctions are (1) the need for an activated intermediate, malonyl-CoA, at each two-carbon addition step, (2) the nature of the acyl group carrier, and (3) the use of NADPH-requiring enzymes in the reductive reactions. Details of these and the other reactions follow.

Synthesis of Malonyl-CoA

The first committed step in fatty acid biosynthesis is the formation of malonyl-CoA from acetyl-CoA and bicarbonate, catalyzed by **acetyl-CoA carboxylase (ACC)**.

Like other committed steps in biosynthetic pathways, this reaction is so exergonic as to be virtually irreversible. Similar to other enzymes catalyzing carboxylation reactions (see Chapter 14, page 618), acetyl-CoA carboxylase has a biotin cofactor, covalently bound via a lysine ϵ -amino group. The reaction proceeds via a covalently bound *N*-carboxybiotin intermediate.

The prokaryotic form of this enzyme, exemplified by the enzyme purified from *E. coli*, consists of three separate proteins: (1) a small carrier protein that contains the bound biotin, (2) a **biotin carboxylase**, which catalyzes the ATP-dependent formation of *N*-carboxybiotin, and (3) a **transcarboxylase**, which transfers the activated carboxyl group from *N*-carboxybiotin to acetyl-CoA. The hydrocarbon chains in both biotin and its associated lysine residue act as a flexible swinging arm, which allows the biotin to interact with the catalytic sites of both catalytic subunits, just as we saw for pyruvate carboxylase (Figure 14.19, page 618).

FIGURE 17.26

Chemical similarities between oxidation and synthesis of a fatty acid. The figure shows a single cycle of oxidation (down) or addition (up) of a two-carbon fragment. Coenzyme A is the acyl group carrier for oxidation, and acyl carrier protein (ACP) is the carrier for synthesis.

FIGURE 17.27

The active filamentous form of eukaryotic acetyl-CoA carboxylase.

By contrast, ACC in eukaryotes consists of a single protein containing two identical polypeptide chains, each with M_r of about 265,000. The dimeric protein itself has low activity, but in the presence of citrate it polymerizes to a novel filamentous form, with M_r of $4-8 \times 10^6$, that can readily be visualized in the electron microscope (Figure 17.27). The equilibrium between inactive protein dimers and the active filamentous form, and its control by metabolic intermediates, represents an important mechanism for regulating fatty acid biosynthesis. The regulation of ACC and fatty acid synthesis will be discussed after we describe the rest of the pathway (page 745).

Malonyl-CoA to Palmitate

Recall that all of the intermediates in fatty acid oxidation are activated via their linkage to a carrier molecule, coenzyme A. A similar activation is involved in fatty acid synthesis, but the carrier is different. It is a small protein (77 residues in *E. coli*) called **acyl carrier protein (ACP)**. The chemistry of activation is identical to that in acyl-CoAs. Indeed, ACP uses an identical phosphopantetheine moiety with its reactive sulfhydryl group as that found in CoA. In ACP, the phosphopantetheine moiety is covalently linked to a serine group in the polypeptide (Figure 17.28). All of the chemistry catalyzed by fatty acid synthase occurs on substrates attached to ACP via a thioester linkage. As we shall see, the phosphopantetheine moiety acts as a swinging arm to transfer the acyl group between the active sites of the complex.

To begin the synthesis of a new palmitic acid molecule, the fatty acid synthase must first be charged with starter substrates. The acetyl moiety of acetyl-CoA is loaded onto ACP in a reaction catalyzed by **malonyl/acetyl-CoA-ACP transacylase (MAT)** (Figure 17.29, reaction 1a). The acetyl group is then transferred to a Cys-SH in the active site of the **β-ketoacyl-ACP synthase (KS)**, giving acetyl-KS (reaction 1b). The phosphopantetheine moiety of ACP is now available to be charged with the second substrate, malonyl-CoA, also catalyzed by MAT (Figure 17.29,

**FIGURE 17.28**

Phosphopantetheine as the reactive unit in ACP and CoA.

reaction 2). Because the energy-rich thioester bonds in acyl-CoAs and acyl-ACPs are identical, these transacylase reactions are readily reversible. The fatty acid synthase is now activated for the first cycle of chain elongation. In each cycle, a primer substrate (an acyl group on KS) is condensed with an extender molecule (a malonyl group on ACP). The synthetic cycle proceeds via *condensation*, *reduction*, *dehydration*, and *reduction*.

For the first cycle of synthesis (Figure 17.30, reactions 1–4), we start with 1 mole each of malonyl-ACP and acetyl-KS, and in four reactions we generate 1 mole of butyryl-ACP. These are the reactions that resemble the reactions (in reverse) of fatty acid oxidation (see Figure 17.26). The key carbon–carbon bond forming reaction is a Claisen-type condensation (see Figure 12.8, page 485) between acetyl-KS and malonyl-ACP (Figure 17.30, reaction 1). This reaction, catalyzed by KS, involves decarboxylation of the malonyl moiety to give a nucleophilic enolate ion, which attacks the electrophilic acetyl group on KS. Breakdown of the tetrahedral intermediate involves elimination of the KS cysteine thiol, freeing it for attachment of the elongated acyl group at the end of the cycle (reaction 5). The condensation product, a β -ketoacyl-ACP thioester, is next reduced to a *D*- β -hydroxyacyl-ACP in an NADPH-dependent reaction catalyzed by **β -ketoacyl-ACP reductase (KR)** (reaction 2). Dehydration of the *D*- β -hydroxyacyl-ACP, catalyzed by **β -hydroxyacyl-ACP dehydrase (DH)** (reaction 3), yields a *trans*-2-enoyl-ACP, which undergoes a second NADPH-dependent reduction, catalyzed by **enoyl-ACP reductase (ER)** (reaction 4), to yield a fatty acyl-ACP—butyryl-ACP in the first cycle of synthesis. To end the first cycle, the butyryl group is translocated from ACP to the Cys-SH of KS (reaction 5), and ACP is charged with a second malonyl-CoA. To start the second cycle, butyryl-KS reacts with another molecule of malonyl-ACP, and the product of the second cycle is hexanoyl-ACP.

FIGURE 17.29

Malonyl/acetyl-CoA-ACP transacylase (MAT) loads fatty acid synthase with substrates. The acyl groups (acetyl or malonyl) are transferred from the SH group of CoA to the SH group of the phosphopantetheine moiety of acyl carrier protein (ACP). The reactions shown here produce acetyl-KS and malonyl-ACP, which are used in the remaining reactions of the cycle.

FIGURE 17.30

Synthesis of palmitate, starting with malonyl-ACP and acetyl-KS. The first cycle of four reactions generates butyryl-ACP. Following translocation from ACP, butyryl-KS reacts with a second molecule of malonyl-ACP, leading to a second cycle of two-carbon addition. A total of seven such cycles generates palmitoyl-ACP. Hydrolysis of this product releases palmitate.

The same pattern continues until the product of the seventh cycle, palmitoyl-ACP, undergoes hydrolysis to yield palmitate and free ACP. This final step is catalyzed by **thioesterase (TE)** (reaction 6).

What is the molecular logic of using malonyl-ACP as a donor of an acetyl unit? The condensation of two activated acetyl units is normally quite endergonic. A comparable reaction in reverse—namely the thiolitic cleavage of acetoacetyl-CoA—is strongly exergonic. However, the carboxyl group of malonyl-ACP is a good leaving group because the β -carbonyl group can act as an electron acceptor during the decarboxylation. This decarboxylation makes the condensation reaction exergonic. Ultimately, it is ATP hydrolysis that drives this otherwise endergonic condensation reaction because ATP participated in the original synthesis of malonyl-CoA from acetyl-CoA (page 737). This condensation process explains the early observation that bicarbonate is not incorporated into the final product. Rather, all of the carbons in fatty acids come from acetate.

Like most biosynthetic pathways, this one requires both *energy* (as ATP) and *reducing equivalents* (as NADPH). The quantitative requirements can be seen from the stoichiometry of the complete seven-cycle process:

Although one H₂O is released in each cycle, a net of only six H₂O is produced in the complete process because one H₂O is used to hydrolyze the thioester linkage to release free palmitate (Figure 17.30, reaction 6). To see the ATP requirement, we must consider the synthesis of the 7 moles of malonyl-CoA:

Hence, the following equation describes the overall process.

Multifunctional Proteins in Fatty Acid Synthesis

The fatty acid synthesis reaction pathway is essentially identical in all known organisms, but the enzymology involved is startlingly variable. Fatty acid synthesis was first worked out in *E. coli*, and it was discovered that all the reactions are catalyzed by seven distinct monofunctional enzymes, which can be separately purified. This same organization is found in all bacteria and plants, and is referred to as **type II fatty acid synthesis**. The earliest biochemical studies of fatty acid synthesis in animals and yeast revealed seven or eight individual polypeptide species in purified fatty acid synthase (FAS) preparations. It was eventually demonstrated that the eukaryotic enzymes were exquisitely sensitive to proteolysis, and trace amounts of proteases in FAS preparations resulted in proteolysis of the native polypeptide chains into smaller species. Once this was recognized, steps were taken to avoid proteolysis, and FAS could be purified intact from animals and yeast. These studies revealed that in animals and in lower eukaryotes all of the FAS activities are associated in a multifunctional enzyme referred to as a **megasynthase**, or **type I fatty acid synthase**. Two basic megasynthase architectures have evolved. The animal enzyme is a homodimer of 273,000 Da subunits (0.54 MDa total). Each subunit of the dimeric mammalian FAS is folded into seven distinct domains, and each domain carries out a specific function in the reaction sequence. Six of these domains carry active sites for the chemical steps and the seventh is the ACP domain with its phosphopantetheine moiety—truly, a *multifunctional* protein. The order of these domains along the polypeptide chain

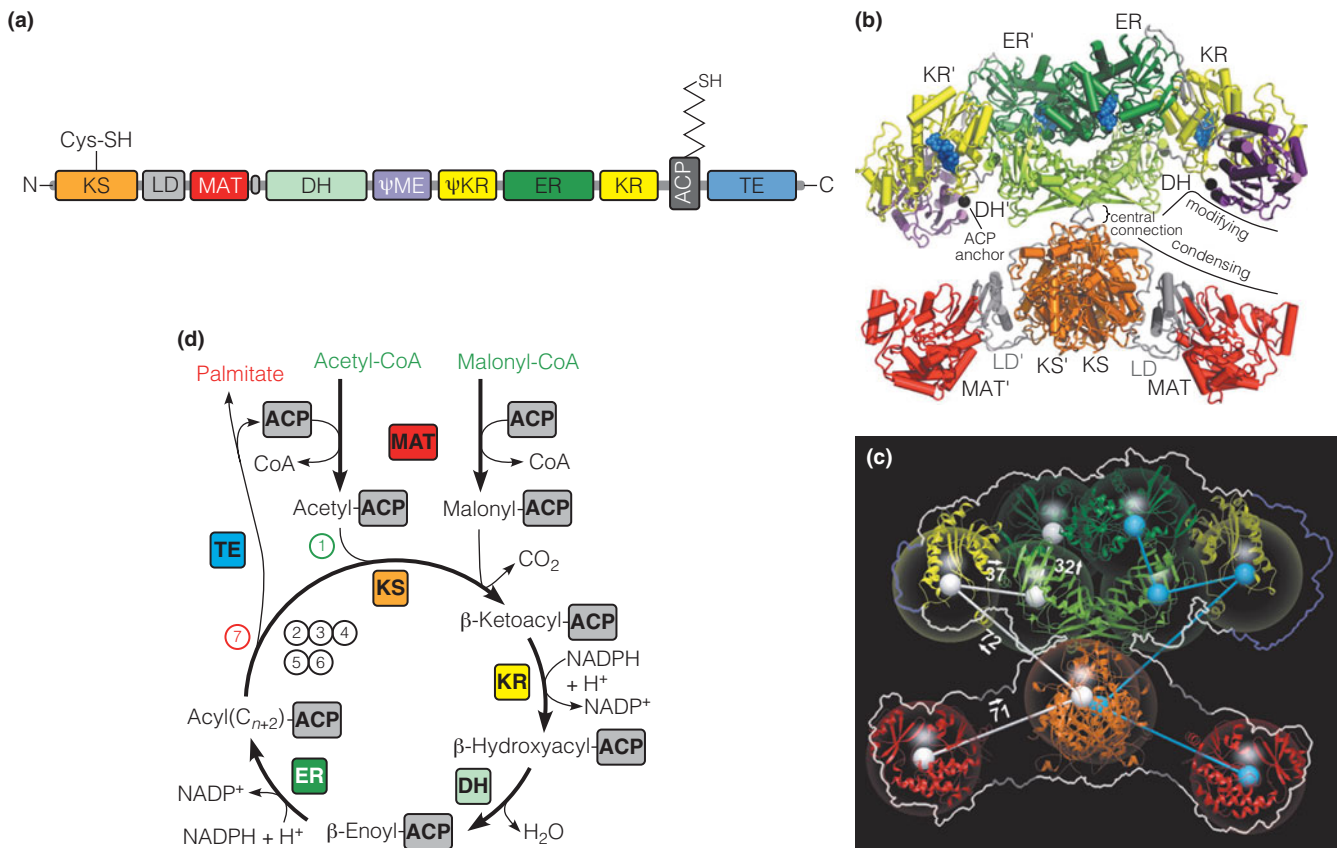

FIGURE 17.31

Structure and swinging arm mechanism in the mammalian fatty acid synthase complex. (a) Arrangement of domains on the 273,000-dalton polypeptide chain. KS = ketoacyl-ACP synthase; MAT = malonyl/acetyl transacylase; DH = hydroxyacyl-ACP dehydrase; ER = enoyl-ACP reductase; KR = ketoacyl-ACP reductase; ACP = acyl carrier protein; TE = thioesterase. The KR domain is actually composed of two discontinuous regions (ψ KR + KR) split by the ER domain. LD = linker domain; ψ ME = noncatalytic structural domain. The cysteine thiol and phosphopantetheine thiol groups are shown attached to KS and ACP, respectively. (b) A cartoon representation of the X-ray structure of the porcine FAS homodimer (PDB ID 2VZ9). Each domain is abbreviated and colored as in panel a; domains of the second subunit are indicated by a prime ('). The two subunits are approximately C-shaped and intertwine at the central connection of the X-structure. The condensing and modifying domains are located in the lower and upper arms, respectively. The ACP anchor site is indicated by a black sphere, and NADP^+ bound at the KR active sites is shown in blue. (c) The ACP-phosphopantetheine swinging arm serves as a mechanism for bringing acyl groups into contact with all of the active sites (indicated by solid white and blue spheres). The hollow spheres that surround each active site show the length of the phosphopantetheine arm, indicating how close ACP must approach the individual domains during the catalytic cycle. The active sites are connected in order of the reaction sequence. The distances between the active sites, in Å, are indicated for the left subunit. (d) Summary of catalytic cycle. The first cycle ① begins with transfer of the acetyl group from acetyl-CoA to the ACP swinging arm. The acetyl group is then transferred to the cysteine thiol group on KS, and a malonyl group is transferred to the ACP swinging arm. KS catalyzes the condensation, and KR, DH, and ER catalyze the modifying steps. At the end of the first six cycles ②–⑥, KS translocates the reduced acyl group from ACP to its own Cys-SH to begin another cycle; after the last cycle ⑦, the palmitoyl group is hydrolyzed from ACP by the TE activity.

Ban, The crystal structure of a mammalian fatty acid synthase. © 2006 and 2008. Modified with permission from AAAS and Nenad Ban.

is illustrated in Figure 17.31a. Note the locations of the ACP and KS domains—at opposite ends of the polypeptide chain. The sulfhydryl groups of these two domains must come into close proximity for the condensation step (reaction 1 in Figure 17.30). The X-ray structure of the porcine FAS (Figure 17.31b) reveals how this might occur. The two subunits form an intertwined X-structure on which two fatty acids can be synthesized simultaneously. The domains that catalyze the condensing reaction are found in the lower arms of the structure, whereas the domains catalyzing the next three reactions (the modifying reactions) are found in the upper arms. The ACP and thioesterase (TE) domains are not visible in this structure, but their attachment site (C-terminus of the KR domain) is known. During the reaction cycle, the phosphopantetheine moiety attached to the ACP domain serves as a swinging arm for bringing acyl groups into contact with all of the active sites of the complex. The order of the reaction sequence as the ACP

Malonyl-CoA represents an activated source of two-carbon fragments for fatty acid biosynthesis, with the loss of CO_2 driving C—C bond formation.

In eukaryotes, fatty acid synthesis is carried out by a megasynthase, an organized multienzyme complex that contains multifunctional proteins.

domain moves between the active sites is shown in Figure 17.31c. Figure 17.31d summarizes the catalytic cycle and the step at which each domain participates. The cycle begins with transfer of the acetyl group from acetyl-CoA to the ACP swinging arm. The acetyl group is then transferred to the cysteine thiol group on KS, and a malonyl group is transferred to the ACP swinging arm. KS catalyzes the condensation, and KR, DH, and ER catalyze the modifying steps. At the end of the first six cycles, KS translocates the reduced acyl group from ACP to its own Cys-SH to begin another cycle; after the last (seventh) cycle, the palmitoyl group is hydrolyzed from ACP by the TE activity.

Lower eukaryotes (yeast and fungi) possess a type I fatty acid synthase composed of two multifunctional polypeptide chains. This megasynthase has a mass of about 2.6 million daltons and is composed of six α subunits and six β subunits. The α subunit contains the ACP domain, the condensing enzyme (KS), and the β -ketothioester reductase (KR). The β subunit contains the remaining three activities (MAT, DH, and ER). The yeast complex lacks the thioesterase (TE) activity because the final product of fatty acid synthase activity in yeast is not palmitate but palmitoyl-CoA.

In 1988, it was discovered that mitochondria can also synthesize fatty acids. When the fungus *Neurospora crassa* was given [^{14}C]pantothenic acid, a small (125 amino acid) mitochondrial protein became labeled. This protein turned out to be a homolog of the bacterial acyl carrier protein (ACP), and this suggested that mitochondria might possess a fatty acid synthesis system. Subsequent studies have revealed that mitochondria from almost all species contain a complete type II FAS system of soluble monofunctional enzymes. One of the roles of this mitochondrial pathway is synthesis of **octanoic acid**, the precursor for the lipoic acid cofactor essential for pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes of the citric acid cycle (Chapter 14). The mitochondrial system can synthesize fatty acids up to 14 carbons in length (myristic acid), but the physiological function for these longer fatty acids is not yet known.

Although all of these fatty acid synthase systems use essentially the same chemistry to build fatty acids, differences in their enzymology provide the possibility that specific inhibitors might be developed as antimicrobial drugs. For example, triclosan is widely used as an antibacterial agent. Triclosan is a potent inhibitor of bacterial enoyl-ACP reductase (ER), closely mimicking the structure of the enolate intermediate of the substrate (Figure 17.32). Unfortunately, the widespread use of triclosan in toothpastes, underarm deodorants, antiseptic soaps, plastic kitchenware, and many other household products has led to the development of triclosan resistance in several bacterial species, including *E. coli*, *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Salmonella enterica*. Drug resistance is an increasingly common problem associated with the overuse of antibiotics.

It has long been known that intermediates between acetyl-CoA and palmitate do not accumulate in cells that are synthesizing fatty acids—the process is extremely fast. The basis for this is clear because all the intermediates are covalently bound to the ACP domain of a multifunctional protein. This arrangement ensures that substrates need not seek catalytic sites by simple diffusion. Indeed, starting from acetyl-CoA and malonyl-CoA, eukaryotic megasynthases can synthesize palmitate in less than a second. Moreover, because the genetic apparatus needs to regulate the synthesis of only one or two polypeptide chains instead of seven, this type of organization is attractive from the standpoint of coordinating the activities involved. Multifunctional proteins have now been described in most major metabolic processes, although few other enzymes carry as many as four activities on one polypeptide chain.

Transport of Acetyl Units and Reducing Equivalents into the Cytosol

Because acetyl-CoA is generated in the mitochondrial matrix, it must be transported to the cytosol for use in fatty acid synthesis. Like longer-chain acyl-CoAs,

FIGURE 17.32

Triclosan is a specific inhibitor of bacterial enoyl-ACP reductase (ER). The X-ray structure of *E. coli* ER complexed with triclosan and NADPH (PDB ID 1D8A) shows that the phenol ring of triclosan stacks on top of the nicotinamide ring of NADPH. The three residues highlighted in yellow (phenylalanine-203, methionine-159, and glycine-93) make hydrophobic and van der Waals contacts with triclosan. Single amino acid substitutions of any of these three residues confers triclosan resistance to *E. coli*.

FIGURE 17.33

Transport of acetyl units and reducing equivalents used in fatty acid synthesis. This diagram shows the shuttle mechanism for transferring acetyl units and reducing equivalents from mitochondria to the cytosol, for use in fatty acid synthesis. Citrate must be exchanged for a carrier as it moves out of the mitochondrion. Some citrate is evidently exchanged for orthophosphate and some for malate. The malate that is not exchanged generates some of the NADPH for fatty acid synthesis, through action of the malic enzyme. Purple circles represent transport systems located in the mitochondrial membrane. 1 = citrate synthase; 2 = citrate lyase; 3 = malate dehydrogenase; 4 = malic enzyme; 5 = pyruvate carboxylase.

acetyl-CoA cannot penetrate the inner membrane. A shuttle system is used, which is interesting both because it provides a control mechanism for fatty acid synthesis and because it generates much of the NADPH needed for the process. The shuttle involves citrate, which is formed in mitochondria from acetyl-CoA and oxaloacetate in the first step of the citric acid cycle (Figure 17.33, step 1). When citrate is being generated in excess of the amount needed for oxidation in the citric acid cycle, it is transported through the mitochondrial membrane to the cytosol. There it is acted on by **citrate lyase** to regenerate acetyl-CoA and oxaloacetate at the expense of one ATP (step 2):

Oxaloacetate cannot directly return to the mitochondrial matrix because the inner membrane lacks a transporter for this compound. First it is reduced by a cytosolic malate dehydrogenase to malate (step 3), and some malate is oxidatively decarboxylated by the malic enzyme to give pyruvate (step 4; the malic enzyme is working here opposite to the direction shown in Chapter 14, page 618). Some of the malate formed returns to the mitochondrion in exchange for citrate, however.

The resultant pyruvate is transported back into mitochondria, where it is reconverted to oxaloacetate by pyruvate carboxylase (step 5; see Chapter 14, page 618).

The net reaction catalyzed by these three enzymes is as follows:

For each mole of malate remaining in the cytosol, 1 mole of NADPH is generated. Much of the remainder of the 14 moles of NADPH required to synthesize 1 mole of palmitate is generated in the cytosol via the pentose phosphate pathway.

Citrate serves as a carrier of two-carbon fragments from mitochondria to cytosol for fatty acid biosynthesis.

Elongation of Fatty Acid Chains

Because fatty acid synthase action leads primarily to palmitate, we must consider the processes that lead from palmitate to give the variations observed among fatty acids in both chain length and degree of unsaturation. In eukaryotic cells, elongation occurs in both mitochondria and endoplasmic reticulum (ER). The latter, so-called microsomal, system has far greater activity and is the one described here. The chemistry is similar to the fatty acid synthase sequence that leads to palmitate, but the microsomal elongation system involves acyl-CoA derivatives and separate enzymes bound to the cytoplasmic face of the ER membrane. The first reaction is a condensation between malonyl-CoA and a long-chain fatty acyl-CoA substrate. The resultant β -ketoacyl-CoA undergoes NADPH-dependent reduction, dehydration of the resultant hydroxyacyl-CoA, and another NADPH-dependent reduction to give a saturated fatty acyl-CoA two carbons longer than the original substrate.

Multiple condensing enzymes are present in endoplasmic reticulum, one of which acts on unsaturated fatty acyl-CoAs. Apparently, a single set of enzymes carries out the remaining three reactions.

Fatty Acid Desaturation

Higher animals and fungi possess several endoplasmic reticulum-bound acyl-CoA desaturases that catalyze the production of mono- and polyunsaturated fatty acids. The first *cis*-double bond is always introduced between carbons 9 and 10, counting from the carboxyl end of the fatty acid. Additional double bonds are introduced toward the carboxyl end at three-carbon intervals so that the double bonds are separated by a methylene group, and therefore not conjugated. The most common monounsaturated fatty acids in animal lipids are oleic acid, an 18:1 Δ 9 acid, and palmitoleic acid, a 16:1 Δ 9 compound (see Table 10.1, page 361). These compounds are synthesized from stearate and palmitate, respectively, by a microsomal Δ 9 desaturating system called **stearoyl-CoA desaturase**. The overall reaction for stearoyl-CoA desaturation is as follows:

Note that both substrates, the fatty acid and the NAD(P)H, undergo two-electron oxidations in this reaction. The overall electron transfer in this reaction involves cytochrome b_5 and another enzyme, the flavin-dependent **cytochrome b_5 reductase** (Figure 17.34). The cytochrome b_5 component is found as an N-terminal domain of the desaturase. Mammalian endoplasmic reticulum also contains Δ 5 and Δ 6 desaturases which function similarly to the Δ 9 desaturating system.

Whereas plants possess Δ 12 and Δ 15 desaturases (Figure 17.35), animals are unable to introduce double bonds beyond Δ 9 (i.e., between C10 and the methyl carbon) in the fatty acid chain. Hence, they cannot synthesize either linoleic acid (18:2 Δ 9,12) or linolenic acid (18:3 Δ 9,12,15). These are called **essential fatty acids** because they are required lipid components that must be provided in the diet from plants.* After ingestion in mammals, they are in turn substrates for further desaturation and elongation reactions, as summarized in Figure 17.35. Linolenic acid is the precursor for the omega-3 PUFAs EPA (20:5 Δ 5,8,11,14,17) and DHA (22:6 Δ 4,7,10,13,16,19) (see margin, page 721). Dietary linoleic acid is the precursor for **arachidonic acid** (20:4 Δ 5,8,11,14), which serves as precursor to a class of compounds called the *eicosanoids*. As discussed in Chapter 19, eicosanoids include two important classes of metabolic regulators, the prostaglandins and the thromboxanes.

FIGURE 17.34

Fatty acid desaturation system. The black arrows indicate the path of electron flow as the two substrates are oxidized. Δ 5 and Δ 6 desaturases use the same mechanism.

*Fish are also good sources of linoleic acid and linolenic acid, but they cannot synthesize these essential fatty acids—like all animals, fish must obtain them from their diet.

Mammalian cells require specific amounts of polyunsaturated fatty acids for these signaling functions and to maintain proper membrane fluidity. Dietary PUFAs repress the expression of all three desaturase systems so that de novo production is turned off if adequate levels of these unsaturated fatty acids can be obtained from the diet.

Control of Fatty Acid Synthesis

To a large extent, fatty acid biosynthesis is controlled by hormonal mechanisms. Much of the fatty acid synthesis in animals takes place in adipose tissue, where fat is being stored for release and transport to other tissues on demand, to help meet their energy needs. As extracellular messengers, hormones are well suited to these interorgan regulatory roles.

Figure 17.36 summarizes the major effects in regulation of fatty acid synthesis in animal cells. Insulin acts in several ways to stimulate synthesis and storage of fatty acids in adipose tissue and liver. One of its effects is to increase glucose entry into cells by stimulating translocation of the glucose transporter to the plasma membrane. This effect increases flux through glycolysis and the pyruvate dehydrogenase reaction, which provides acetyl-CoA for fatty acid synthesis. Insulin also activates the pyruvate dehydrogenase complex, by stimulating its dephosphorylation to the active form (see Chapter 14, page 613).

Another site for regulation (not shown in the figure) is the transfer of acetyl units from the mitochondrial matrix to the cytosol, where fatty acid synthesis occurs. Citrate lyase, a key enzyme in this process (page 743), is activated by phosphorylation. Insulin and other growth factors stimulate this activation through the PI3K/Akt pathway (more about this in Chapter 18).

The first enzyme whose action is committed to fatty acid synthesis is acetyl-CoA carboxylase (ACC, page 737). Activities of this enzyme are quite low in starved animals, reflecting its regulation by allosteric and covalent modification mechanisms. Phosphorylation of acetyl-CoA carboxylase causes its inactivation. Two protein kinases are known to phosphorylate ACC: AMP-activated protein kinase (AMPK) and cyclic AMP-dependent protein kinase (PKA). The AMPK system acts as a sensor of cellular energy status—it is activated by increases in the cellular AMP:ATP ratio (more about this in Chapter 18). Thus, under conditions of low energy charge, such as would occur during fasting or starvation, activated AMPK switches off fatty acid synthesis by inhibiting ACC. ACC activity is also under hormonal control. Glucagon and epinephrine activate PKA, which phosphorylates and inhibits the enzyme.

Citrate and long-chain fatty acyl-CoAs are allosteric modulators of acetyl-CoA carboxylase. As noted earlier, ACC must undergo a reversible polymerization in order to be active. Long-chain fatty acyl-CoAs at low levels prevent polymerization, thereby inactivating the enzyme and providing feedback inhibition of the pathway. Citrate is an allosteric activator of ACC, stimulating its polymerization. As the carrier of acetyl units from mitochondria (see Figure 17.25, page 736), cytoplasmic citrate levels rise when mitochondrial acetyl-CoA and ATP concentrations increase. Thus the same molecule (citrate) serves as the precursor of acetyl-CoA for fatty acid biosynthesis and as an activator of the rate-limiting step for this process. The levels of fatty acyl-CoAs are lowered by insulin, another mechanism by which insulin stimulates fatty acid synthesis.

Fatty acid degradation is also regulated. Recall that malonyl-CoA, the product of the acetyl-CoA carboxylase reaction, inhibits fatty acid oxidation by blocking carnitine acyltransferase I, the first committed intermediate in fatty acid synthesis (page 726). This provides an elegant mechanism to coordinately regulate the synthesis and degradation of fatty acids.

Finally, there is evidence that fatty acid synthesis is controlled by the availability of reducing equivalents. Recall that NADPH comes from both the transport of citrate out of mitochondria (see page 743) and the pentose phosphate pathway

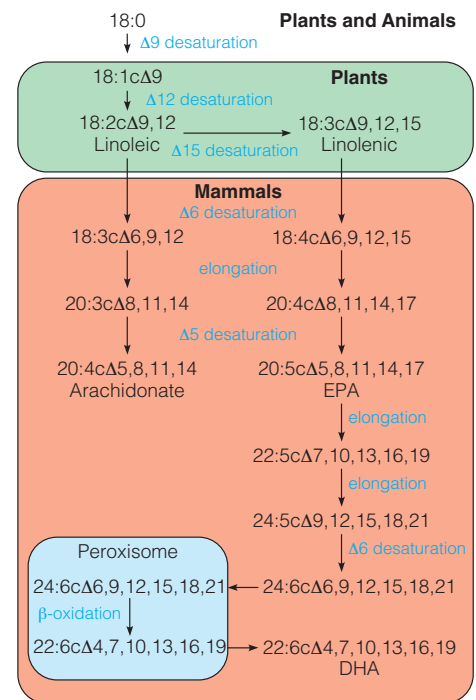

FIGURE 17.35

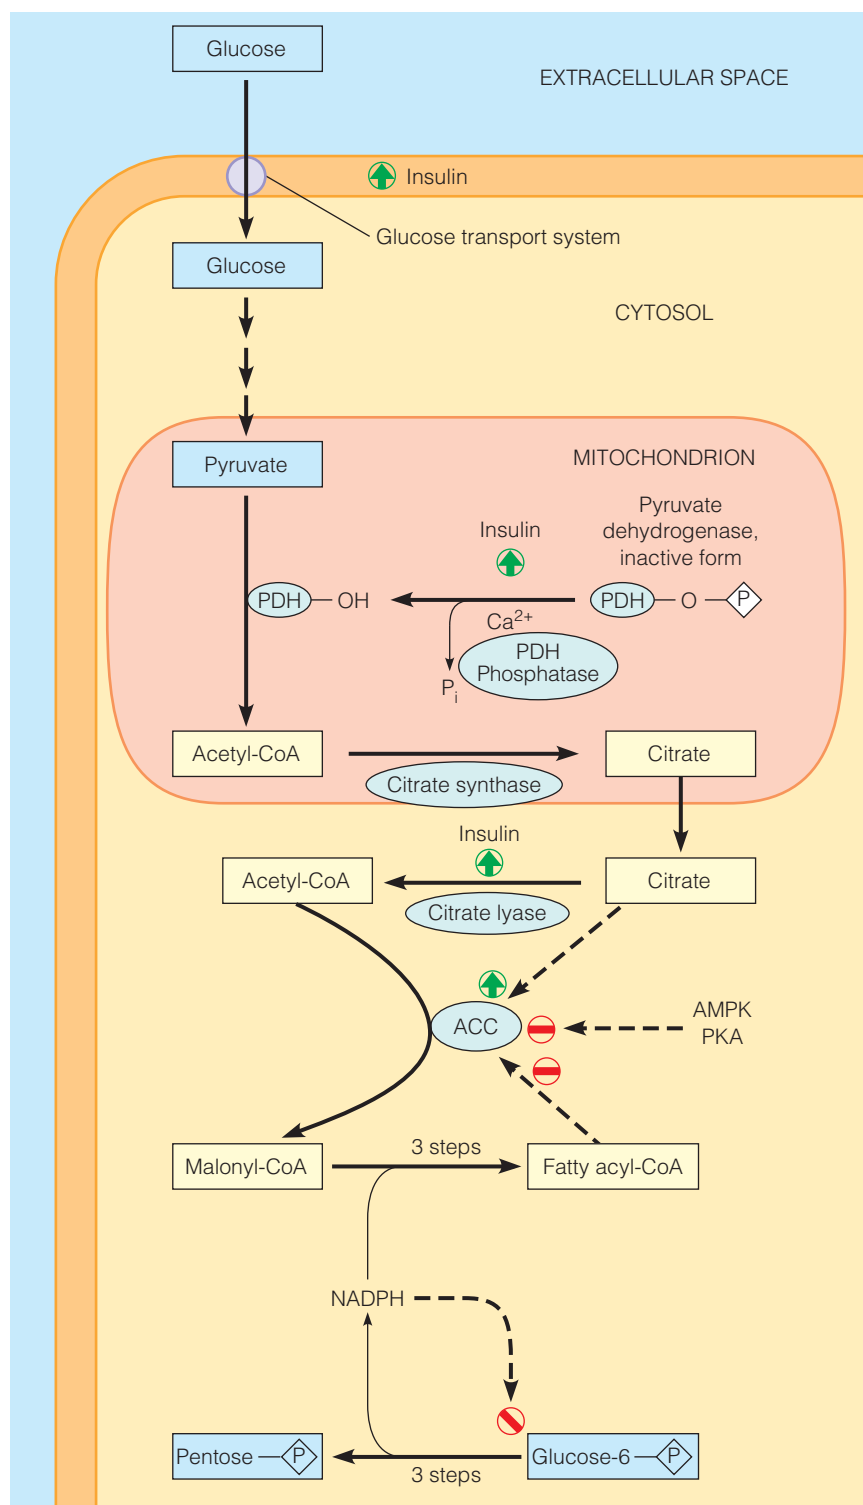

Pathway for synthesis of polyunsaturated fatty acids (PUFAs) in plants and animals. The essential fatty acids, linoleic and linolenic, are obtained in the diet. Mammals alternate $\Delta 5$ or $\Delta 6$ desaturation with two-carbon elongation cycles to produce arachidonic acid, eicosapentaenoic acid (EPA), and other PUFAs. Synthesis of docosahexaenoic acid (DHA) involves chain shortening of the 24:6 intermediate by one cycle of peroxisomal β -oxidation to give the 22:6 DHA. Although not shown, the mammalian desaturation and elongation reactions all operate on acyl-CoA derivatives, whereas the plant enzymes are specific for acyl-ACP substrates.

Acetyl-CoA carboxylase is the committed enzyme and major control point for fatty acid synthesis.

FIGURE 17.36**Regulation of fatty acid synthesis in animal cells.**

The rate-limiting enzyme, acetyl-CoA carboxylase (ACC), is controlled by both allosteric (citrate and long-chain fatty acids) and covalent modification mechanisms. Phosphorylation by AMP-activated protein kinase (AMPK) or cyclic AMP-dependent protein kinase (PKA) inactivates ACC. Insulin stimulates fatty acid synthesis by increasing glucose uptake and increasing flux through pyruvate dehydrogenase to produce acetyl-CoA. The dephosphorylated form of PDH is the enzymatically active form.

(see Chapter 13). The pentose phosphate pathway in turn is controlled through inhibition by NADPH of glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase. Typically, about 60% of the NADPH for fatty acid synthesis comes from the pentose phosphate pathway. When acetate is added to an experimental tissue preparation, that proportion can rise to 80%, indicating that flux through the pentose phosphate pathway can rise when the demand for NADPH increases.

Variant Fatty Acid Synthesis Pathways That Lead to Antibiotics

We digress from lipid metabolism to introduce a related series of pathways in bacteria and fungi, involved in the biosynthesis of a class of antibiotics called **polyketides**. Erythromycin, which is synthesized by the bacterium *Saccharopolyspora erythraea*, is an example of this class. Another example, shown in the margin, is oxytetracycline, produced by *Streptomyces rimosus*. These polyketide antibiotics are potent inhibitors of bacterial protein synthesis (Chapter 28). Other polyketides, such as lovastatin and simvastatin (Chapter 19, page 803) have found clinical use as cholesterol-lowering drugs. Polyketides are synthesized in assembly-line fashion by giant enzyme megasynthases that consist of individual modules for rounds of carbon addition, with each module closely resembling the process whereby two carbons are added in a cycle of the fatty acid synthesis pathway. However, one or more of the modifying activities of fatty acid synthesis are missing in some of the modules, a factor that leads to great structural diversity among the products. For example, the synthesis of 6-deoxyerythronolide B, the aglycone precursor of erythromycin A, is shown in Figure 17.37a. 6-Deoxyerythronolide B synthase (DEBS) is composed of three large subunits that carry 28 active sites. Each subunit contains two modules, with each module responsible for one round of chain extension and modification. Figure 17.37b shows a model of the DEBS3 subunit, containing modules

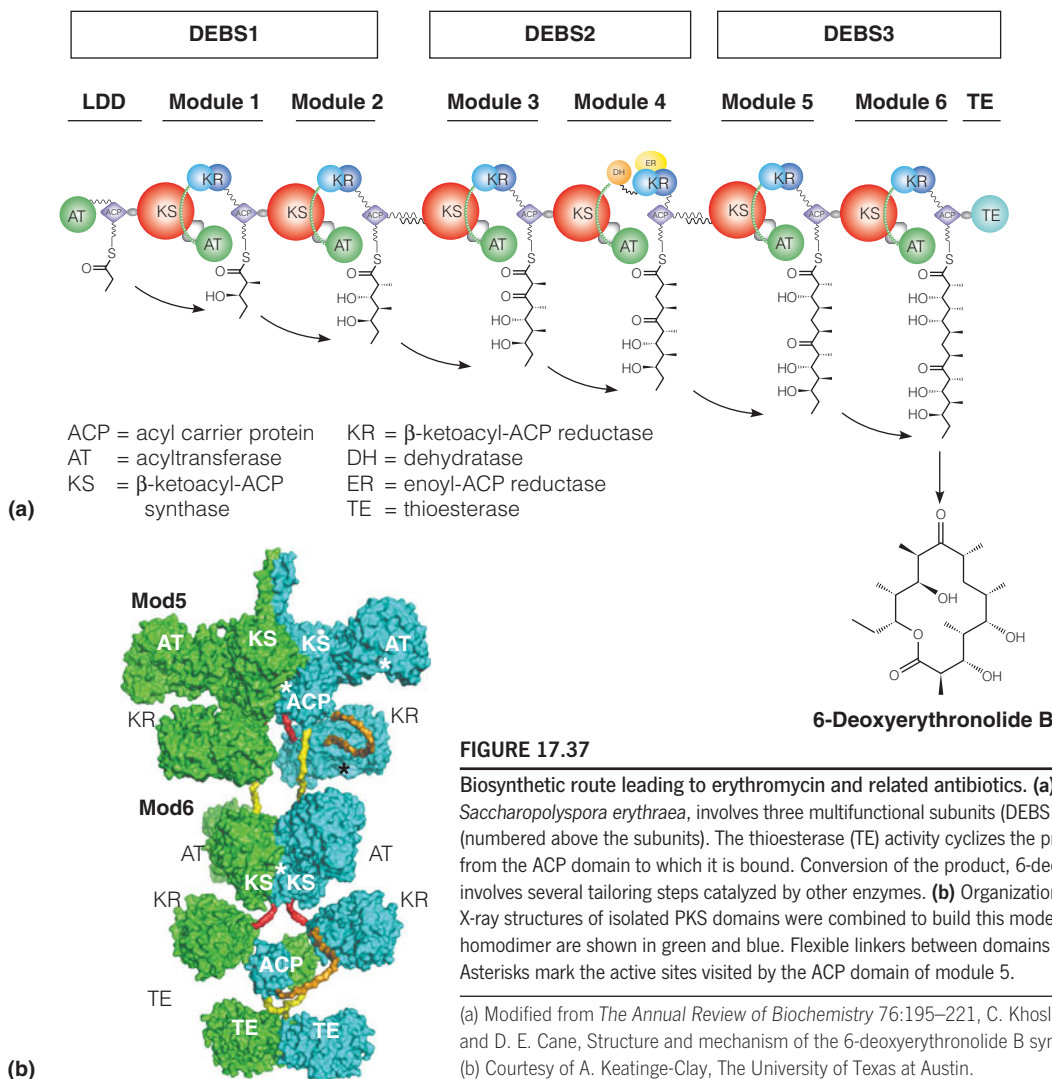

FIGURE 17.37

Biosynthetic route leading to erythromycin and related antibiotics. (a) This process, as it occurs in *Saccharopolyspora erythraea*, involves three multifunctional subunits (DEBS1–3). Each subunit houses two modules (numbered above the subunits). The thioesterase (TE) activity cyclizes the product in the process of removing it from the ACP domain to which it is bound. Conversion of the product, 6-deoxyerythronolide B, to erythromycin A involves several tailoring steps catalyzed by other enzymes. (b) Organization of the homodimeric DEBS3 subunit. X-ray structures of isolated PKS domains were combined to build this model. The two identical subunits of the homodimer are shown in green and blue. Flexible linkers between domains are in red, yellow, and orange. Asterisks mark the active sites visited by the ACP domain of module 5.

Erythromycin A

Oxytetracycline

5 and 6 plus the terminal thioesterase domain. Beginning with propionyl-CoA (instead of acetyl-CoA) and malonyl-CoA, this pathway involves seven two-carbon addition cycles, just like the synthesis of palmitoyl-ACP. However, only one of the seven modules contains a dehydratase domain, and two of the modules lack the ketoacyl reductase domain. Thus, the product, unlike fatty acids, contains both keto and hydroxyl oxygen atoms. Much current excitement involves protein engineering to modify and rearrange the individual modules, to further diversify the pathways involved, possibly leading to novel and useful antibiotics.

Biosynthesis of Triacylglycerols

Fatty acyl-CoAs and glycerol-3-phosphate serve as the major precursors to triacylglycerols and, as we shall see in Chapter 19, to the glycerophospholipids used to build membranes. In many cases, the glycerol backbone is the limiting substrate. Glycerol-3-phosphate is derived either from the reduction of the glycolytic intermediate dihydroxyacetone phosphate (DHAP), catalyzed by **glycerol-3-phosphate dehydrogenase**, or from the ATP-dependent phosphorylation of glycerol by **glycerol kinase** (see margin, page 749). The pathway involving DHAP predominates in adipose tissue because adipocytes lack glycerol kinase. During fasting or starvation conditions when glycolysis is reduced, adipocytes, hepatocytes, and cancer cells can synthesize glycerol-3-phosphate from pyruvate. This pathway, termed **glyceroneogenesis**, is an abbreviated version of gluconeogenesis (Chapter 13) that uses pyruvate carboxylase and phosphoenolpyruvate carboxykinase (PEPCK) to produce DHAP (Figure 17.38), which is then reduced to glycerol-3-phosphate by glycerol-3-phosphate dehydrogenase.

FIGURE 17.38

Glycerolipid/free fatty acid cycle and glyceroneogenesis. Mammals hydrolyze and resynthesize triacylglycerols (TG) in a glycerolipid/free fatty acid (GL/FFA) cycle. FFA are released from TG by lipases acting on lipid droplets. ATGL, adipose triglyceride lipase; HSL, hormone-sensitive lipase; MGL, monoacylglycerol lipase (see Figure 17.13). Some of the FFAs are released into the blood for transport and oxidation, but ~75% are reesterified back to TG. ATP hydrolysis in this futile cycle is shown in red. The glycerol backbone is produced via glyceroneogenesis, involving reactions catalyzed by pyruvate carboxylase and phosphoenolpyruvate carboxykinase (PEPCK), and reversal of glycolytic steps to give dihydroxyacetone phosphate (DHAP). DHAP is reduced to glycerol-3-phosphate, as shown in the margin on page 749. AMP-activated protein kinase (AMPK)-dependent phosphorylation of GPAT and HSL inhibits these steps of the cycle. The lysophosphatidic acid (LPA), phosphatidic acid (PA), and *sn*-1,2-diacylglycerol (DAG) intermediates in the TG resynthesis pathway are also important lipid signaling molecules.

Whatever the source, glycerol-3-phosphate undergoes two successive enzymatic esterifications with fatty acyl-CoAs to yield **diacylglycerol-3-phosphate**. The first esterification is catalyzed by **glycerophosphate acyltransferase (GPAT)**, and as the first committed step of the cycle, is an important site of regulation (see below). Diacylglycerol-3-phosphate, also called **phosphatidic acid**, is a precursor both to phospholipids and to triacylglycerols. The pathway to triacylglycerols involves hydrolytic removal of the phosphate, followed by transfer of another fatty acyl moiety from an acyl-CoA.

Careful studies on the release of glycerol and free fatty acids (FFA) during hormone-stimulated lipolysis of adipose tissue triacylglycerols (TG) in both rats and humans showed that nearly 40% of the FFAs were rapidly recycled back to TG. Some of the FFA and glycerol were released into the circulation and taken up by tissues such as heart and skeletal muscle for oxidation, but a substantial portion was taken up again and reesterified to TG. This recycling is now known to occur not only in adipose tissue but also in liver and skeletal muscle, and it is part of the **glycerolipid/free fatty acid cycle (GL/FFA cycle)**. It is estimated that about 75% of the total FFA released during adipose lipolysis is reesterified back to TG either in the adipose tissue itself or in other tissues. GL/FFA cycling can occur within a single cell, or between different organs in the body.

As can be seen from Figure 17.38, the glycerolipid/free fatty acid cycle is a classic example of a futile cycle (Chapter 12), continuously forming and hydrolyzing triacylglycerols at the expense of ATP and releasing the energy as heat. Indeed, one of the important roles of the GL/FFA cycle is heat production (thermogenesis) and body temperature maintenance. Excessive futile cycling can be suppressed by inhibition of two enzymes in the cycle. Both GPAT, catalyzing the first committed step of the cycle, and hormone-sensitive lipase (HSL), catalyzing triacylglycerol hydrolysis, are inhibited by AMPK-dependent phosphorylation in response to low energy charge (more about this in Chapter 18).

It is likely that another important function of this cycle is the production of lipid-signaling molecules, including ***sn*-1,2-diacylglycerol (DAG)**, **lysophosphatidic acid (LPA)**, and **phosphatidic acid (PA)** (more about these in Chapter 23). Finally, recent work suggests a role for the GL/FFA cycle in diabetes. Insulin resistance, the fundamental defect in type 2 diabetes, is associated with elevated levels of FFAs in the blood. These elevated FFAs lead to increased accumulation of fat inside muscle cells. GL/FFA cycling within the muscle cell leads to a buildup of intracellular DAG, which somehow shuts down the insulin-signaling pathway, making the muscle cells resistant to insulin. One class of antidiabetic drugs called thiazolidinediones (see margin, page 750) increases insulin sensitivity, in part by reducing FFA levels in the blood. The mechanism by which these drugs reduce circulating FFAs involves stimulation of the expression of genes involved in fatty acid uptake, transport, and storage in adipose tissue. Up-regulated genes include lipoprotein lipase, acyl-CoA synthetase, PEPCK, and glycerol kinase. As we will see in Chapter 18, these drugs act through **peroxisome proliferator-activated receptor- γ (PPAR- γ)**, a transcription factor essential for fat cell differentiation and maintenance of normal adipocyte function and a master regulator of cellular metabolism.

As we have noted, triacylglycerols represent the major form in which energy can be stored. Normally in an adult animal, synthesis and degradation are balanced so that there is no net change in the total body amount of triacylglycerols. If dietary intake exceeds caloric needs, then proteins, carbohydrate, or fat can each readily provide acetyl-CoA to drive the synthesis of fatty acids and triacylglycerols. On the other hand, fat reserves allow animals to go for rather long times without eating and still maintain adequate energy levels. Such fasting does generate some metabolic stresses, though, as we describe further in Chapter 18.

Thiazolidinediones

Rosiglitazone (Avandia)

Pioglitazone (Actos)

Hibernating animals have adapted remarkably well to cope with such stresses. For example, bears store huge amounts of fat just before beginning a hibernation that may last as long as seven months. During this period all of the bear's energy comes from breakdown of the stored fat. Moreover, the bear excretes so little water that the water released from fat oxidation meets the animal's needs. Similarly, the glycerol released from triacylglycerols provides a source of gluconeogenic precursors.

Biochemical Insights into Obesity

About one-third of Americans are classified as seriously overweight, making obesity one of our most significant public health problems. Until recently, obesity was usually considered simply a consequence of overeating, leading to excessive triacylglycerol deposition in adipocytes. It is becoming clear that biochemical factors lead some individuals to be far more prone to obesity than others. In 1995 the product of the *OB* gene in mice (*OB*, for *obese*) was identified. Mice bearing two defective alleles of the *OB* gene (*ob/ob*) grow to body weights as much as three times normal. The *OB* gene specifies a 16-kDa protein called **leptin**, an **adipokine** synthesized in adipocytes which acts as a hormone, binding to a specific receptor (product of the *DB* gene) in neurons in the **arcuate nucleus** of the hypothalamus, where food intake is controlled. Mice with two defective alleles of the *DB* gene (*db/db*) are obese and develop diabetes. Leptin evidently functions as a "lipostat," sensing the amount of fat stored in the adipocytes. When fat stores are adequate, leptin levels are high, and the signaling system controls feeding behavior to limit fat deposition. Leptin also stimulates mitochondrial uncoupling in adipose tissue by increasing the synthesis of uncoupling proteins (UCP 1; Chapter 15, page 657). During starvation, leptin levels decline, which promotes feeding and fat storage within the adipocyte. *ob/ob* mice, lacking functional leptin, act as if perpetually starved, and their overeating makes them obese; injections of leptin lower their feeding rates and cause them to lose weight dramatically. Obese humans are different from obese mice, however, in that they contain high levels of leptin. Current research is aimed at the premise that these individuals are somehow unresponsive to normal leptin signaling. We will discuss the pathways through which leptin and other adipokines act in more detail in Chapter 18.

Evidence is accumulating for other biochemical factors as significant elements in weight control. A number of hormones, including **serotonin** (page 895), control satiety, the feeling of fullness after eating. The antiobesity drug **fenfluramine**, which acts by increasing serotonin levels and affecting the appetite, was becoming quite popular until it was found to do serious damage to the heart and was withdrawn from the market. Current biochemical attention is focused upon UCPs, which by uncoupling oxidative phosphorylation, decrease the amount of ATP synthesized during oxidative metabolism. Attention is also focused upon other hormonal factors and upon fatty acid-binding proteins, which evidently participate in the transport of fatty acids to different locations within the cell. Biochemical research on obesity is one of the most active current research frontiers.

SUMMARY

Triacylglycerols are the main form for storage of biological energy. In animals, dietary triacylglycerols are digested and then resynthesized as they are complexed with proteins to form chylomicrons, for transport to tissues. Triacylglycerols synthesized in liver are transported to peripheral tissues as very low-density lipoproteins. Low-density lipoproteins represent the major vehicle for transport of cholesterol to peripheral tissues. Cholesterol levels in blood are regulated through control of synthesis of LDL receptors, involved in cellular uptake of LDL by endocytosis. Faulty control of LDL levels contributes toward the development of atherosclerotic plaque.

Fat depots are mobilized by enzymatic hydrolysis of triacylglycerols to fatty acids plus glycerol. The process is hormonally controlled via cyclic AMP. Most fatty acid degradation occurs through β -oxidation, a mitochondrial process that involves stepwise oxidation and removal of two-carbon fragments as acetyl-CoA. Processing unsaturated fatty acids is a bit more complicated because of the stereochemistry involved, but the pathways are straightforward. Under conditions in which further oxidation of acetyl-CoA through the citric acid cycle is limited, acetyl-CoA is used to synthesize ketone bodies, which are excellent energy substrates for brain and heart.

Fatty acid biosynthesis occurs via the stepwise addition of two-carbon fragments, in a process that superficially resembles a reversal of β -oxidation. Metabolic activation involves acyl carrier protein, and the reductive power comes from NADPH. In eukaryotic cells the seven enzyme activities are linked covalently on multifunctional enzymes or multienzyme complexes called megasynthases. Fatty acid elongation beyond the C₁₆ stage is mechanistically similar, but CoA derivatives are involved instead of acyl carrier protein. Elegant mechanisms have evolved to coordinately regulate the synthesis and degradation of fatty acids. Unsaturated fatty acids are formed primarily by an ER-associated desaturating system. Triacylglycerols are synthesized by straightforward pathways in which acyl groups in fatty acyl-CoAs are transferred to the hydroxyl groups of glycerol-3-phosphate and diacylglycerol. Faulty hormone control of triacylglycerol deposition, along with excess dietary intake, can be responsible for obesity.

PROBLEMS

- Calculate the ATP yield from oxidation of palmitic acid, taking into account the energy needed to activate the fatty acid and transport it into mitochondria. Do the same for stearic acid, linoleic acid, and oleic acid.
- If palmitic acid is subjected to complete combustion in a bomb calorimeter, one can calculate a standard free energy of combustion of 9788 kJ/mol. From the ATP yield of palmitate oxidation, what is the metabolic efficiency of the biological oxidation, in terms of kilojoules saved as ATP per kilojoule released? (Ignore the cost of fatty acid activation.)
- Calculate the number of ATPs generated by the complete metabolic oxidation of tripalmitin (tripalmitoylglycerol). Hydrolysis of the triacylglycerol occurs at the cell surface. Consider the energy yield from catabolism of glycerol, as well as from the fatty acids. Calculate the ATP yield per carbon atom oxidized, and compare it with the energy yield from glucose.
- Write a balanced equation for the *complete* metabolic oxidation of each of the following. Include O_2 , ADP, and P_i as reactants and ATP, CO_2 , and H_2O as products.
 - Stearic acid
 - Oleic acid
 - Palmitic acid
 - Linoleic acid
- Calculate the number of ATPs generated from the metabolic oxidation of the four carbons of acetoacetyl-CoA to CO_2 . Now consider the homolog derived from oxidation of an odd-numbered carbon chain, namely propionoacetyl-CoA. Calculate the net ATP yield from oxidation of the five carbons of this compound to CO_2 .
- 2-Bromopalmitoyl-CoA inhibits the oxidation of palmitoyl-CoA by isolated mitochondria but has no effect on the oxidation of palmitoylcarnitine. What is the most likely site of inhibition by 2-bromopalmitoyl-CoA?

- When the identical subunits of chicken liver fatty acid synthase are dissociated *in vitro*, all of the activities can be detected in the separated subunits except for the β -ketoacyl synthase reaction and the overall synthesis of palmitate. Explain these observations.
- Mammals cannot undergo *net* synthesis of carbohydrate from acetyl-CoA, but the carbons of acetyl-CoA can be incorporated into glucose and amino acids. Present pathways by which this could come about.
- Describe a pathway whereby some of the carbon from a fatty acid with an odd-numbered carbon chain could undergo a net conversion to carbohydrate.
- How many tritium atoms (3H) are incorporated into palmitate when fatty acid synthesis is carried out *in vitro* with the following labeled substrate?

- What would be the effect on fatty acid synthesis of an increase in intramitochondrial oxaloacetate level? Briefly explain your answer.
- Glucagon secretion causes inhibition of intracellular acetyl-CoA carboxylase activity by several mechanisms. Name all you can think of.
- Identify and briefly discuss each mechanism ensuring against simultaneous fatty acid synthesis and oxidation in the same cell.
- Discuss the metabolic rationale for phosphorylation of acetyl-CoA carboxylase by AMP-activated protein kinase (AMPK) and cyclic AMP-dependent protein kinase (PKA).
- Describe the probable effect in adipocytes of insulin-stimulated uptake of glucose into these cells.

CHAPTER 18

Interorgan and Intracellular Coordination of Energy Metabolism in Vertebrates

Our presentation of intermediary metabolism in earlier chapters has placed primary emphasis on the cell, its reactions, its individual enzymes, and its other components. In this chapter we integrate these individual pathways in two ways. First, we review the metabolic profiles of the major organs in vertebrates: which fuels they use, which fuels they generate, and how the organs interact under stress to maintain appropriate energy balance. Second, we describe how these interactions are controlled in large part by hormonal signals, some of which have already been introduced. The molecular mechanisms of hormonal signal transduction will be discussed in detail in Chapter 23.

As we consider metabolic integration, keep in mind that metabolism is controlled to a great extent by the availability of substrates for specific metabolic pathways. In general, substrate concentrations within cells fall below saturating levels for the enzymes that metabolize them. Therefore, fluxes through particular enzymes vary as the concentrations of the substrate vary. A good example is the metabolic adaptation that occurs during a marathon run. Once the glycogen stores in liver and muscle are exhausted, flux through glycolysis decreases in muscle, not for any hormonal reason but simply because glucose phosphates are less available. Hormonal adjustments then occur to allow increased use of fatty acids in muscle, but the primary factor determining which metabolic pathway becomes functional in the cell—and thus which substrates are catabolized for energy—is the concentration of each of the usable substrates.

Metabolite concentrations represent a significant intracellular control mechanism.

Interdependence of the Major Organs in Vertebrate Fuel Metabolism

In this section we look at metabolism not as the activities in just one cell but as the totality of chemical reactions in a complex multicellular animal. We emphasize the specialized roles that each of the major organs plays in fuel metabolism—brain, muscle, liver, adipose tissue, and heart—and we describe the varying relationships among these organs as the animal encounters different physiological conditions.

Fuel Inputs and Outputs

In a differentiated organism, each tissue must be provided with fuels that it can use, in amounts sufficient to meet its own energy needs and to perform its specialized roles. The kidney, for example, must generate ATP for the osmotic work of transporting solutes against a concentration gradient for excretion. Muscle must generate ATP for the mechanical work of contraction, and in heart muscle the energy supply must be continuous. The liver generates ATP for biosynthetic purposes, whether for plasma protein synthesis, cholesterol generation, fatty acid synthesis, gluconeogenesis, or the production of urea for nitrogen excretion. Energy production must meet needs that vary widely, depending on level of exertion, composition of fuel molecules in the diet, time since last feeding, and so forth. For example, in humans the daily caloric intake may vary by four-fold, depending in part on the level of exertion—from 1500 to 6000 kcal/day in an average-sized human (1 kcal is equal to 1 **large calorie**, or **Cal**, the unit favored by nutritionists and found on our food labels). In the SI units used in this book, caloric intake ranges from 6000 to 25,000 kJ/day.

The major fuel depots are triacylglycerols (adipose tissue), protein (muscle), and glycogen (muscle and liver).

The major organs involved in fuel metabolism vary in their levels of specific enzymes so that each organ is specialized for the storage, use, and generation of different fuels. The major fuel depots are *triacylglycerols*, stored primarily in adipose tissue; *protein*, most of which exists in skeletal muscle; and *glycogen*, which is stored in both liver and muscle. In general, an organ specialized to *produce* a particular fuel lacks the enzymes to *use* that fuel. For example, liver is a major producer of ketone bodies, but little catabolism of ketone bodies occurs in the liver. Now let us review how the mobilization of each depot is controlled, and how the organs involved communicate with each other, to meet the energy needs of the animal. This information is summarized in Figure 18.1 and Table 18.1.

Metabolic Division of Labor Among the Major Organs

Brain

The brain is the most fastidious, and one of the most voracious, of the organs. It must generate ATP in large quantities to maintain the membrane potentials essential for transmission of nerve impulses. Under normal conditions the brain uses only glucose to meet its prodigious energy requirement, which amounts to about 60% of the glucose utilization of a human at rest. The brain's need for about 120 grams of glucose per day is equivalent to 1760 kJ—about 15% of the total energy consumed by one person. The brain's quantitative requirement for glucose remains quite constant, even when an animal is at rest or asleep. The brain is a highly aerobic organ, and its metabolism demands some 20% of the total oxygen consumed by a human. Because the brain has no significant glycogen or other fuel reserves, the supply of both oxygen and glucose cannot be interrupted, even for a short time. Otherwise, irreversible brain damage results. However, the brain can adapt during fasting or starvation to use ketone bodies (see Chapter 17) instead of glucose as a major fuel.

Muscle

Muscle can utilize a variety of fuels—glucose, fatty acids, and ketone bodies. Skeletal muscle varies widely in its energy demands and the fuels it consumes, in line with its wide variations in activity. In resting muscle, fatty acids represent the major energy source; during exertion, glucose is the primary source. Early in a period of exertion, that glucose comes from mobilization of the muscle's glycogen reserves. Later, as glycogen reserves are depleted, fatty acids become the dominant fuel. Skeletal muscle stores about three-fourths of the total glycogen in humans, with most of the rest being stored in the liver. However, glucose produced from muscle glycogen cannot be released for use by other tissues. Muscle lacks the

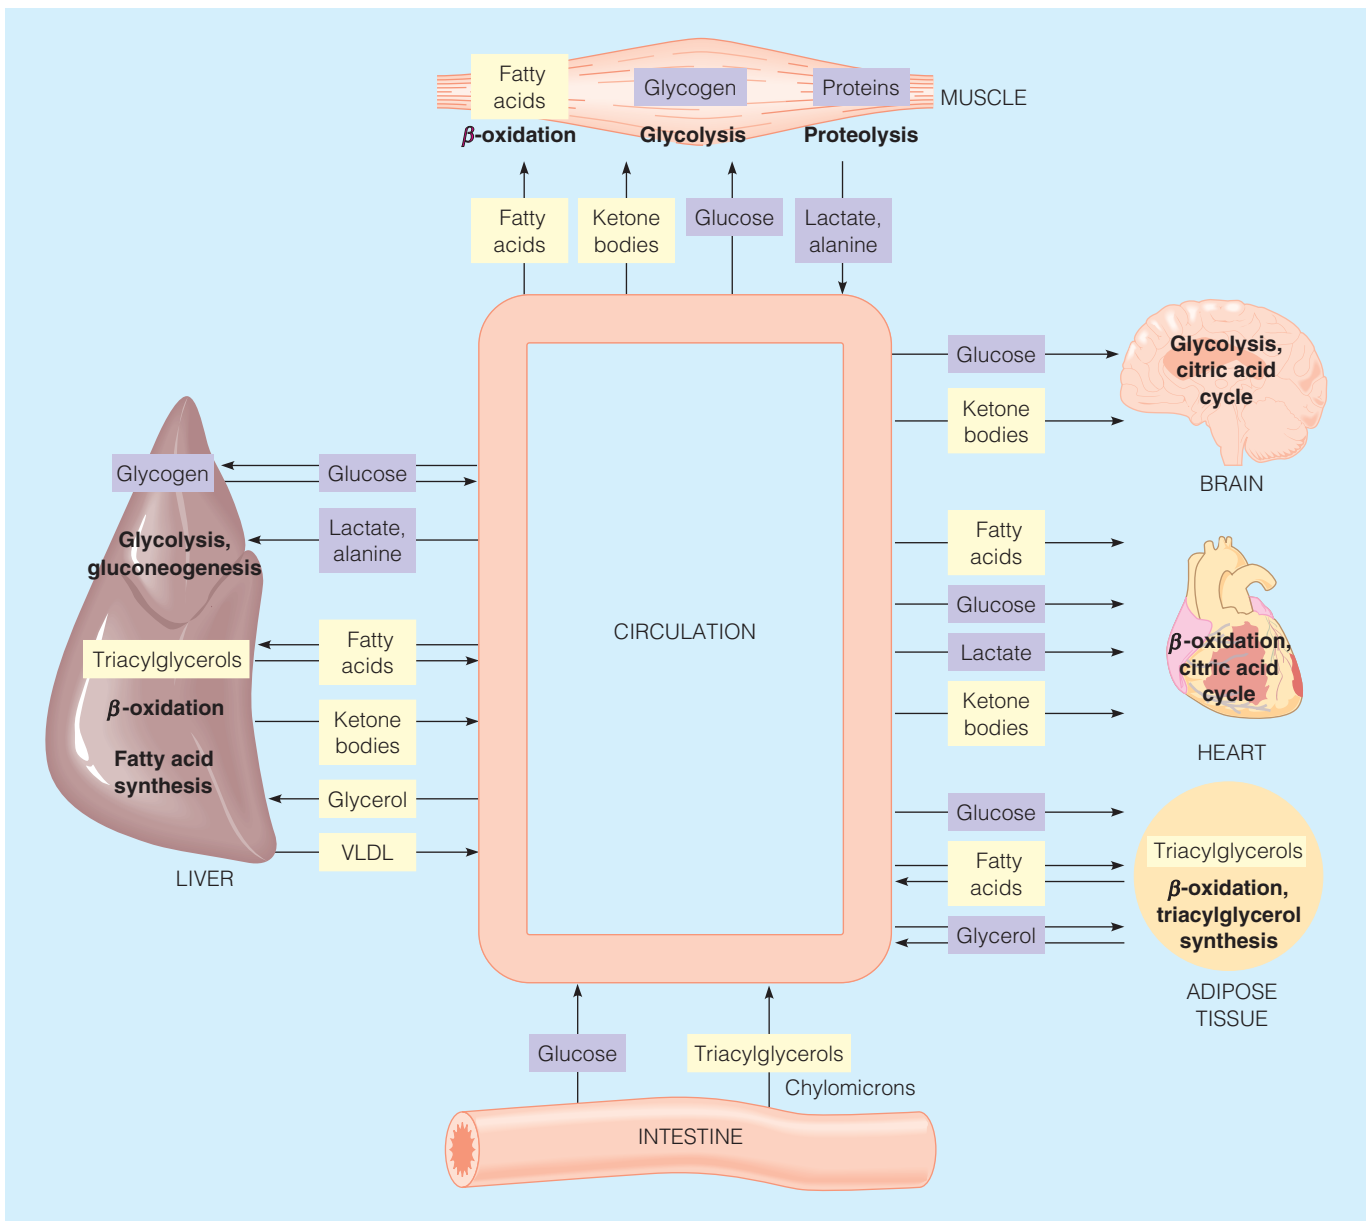

FIGURE 18.1

Metabolic interactions among the major fuel-metabolizing organs. The major fuel metabolites imported and exported by each organ are shown, along with the major energy pathways and fuel reserves in each organ. Lipid-derived metabolites are highlighted in yellow; carbohydrate-derived metabolites are highlighted in blue. VLDL, very low density lipoprotein.

TABLE 18.1 Profiles of the major vertebrate organs in fuel metabolism

Tissue	Fuel Store	Preferred Fuel	Fuel Sources Exported
Brain	None	Glucose (ketone bodies during starvation)	None
Skeletal muscle (resting)	Glycogen	Fatty acids	None
Skeletal muscle (during exertion)	None	Glucose	Lactate, alanine
Heart muscle	None	Fatty acids	None
Adipose tissue	Triacylglycerols	Fatty acids	Fatty acids, glycerol
Liver	Glycogen, triacylglycerols	Amino acids, glucose, fatty acids	Fatty acids, glucose, ketone bodies

enzyme glucose-6-phosphatase, so glucose phosphates derived from glycogen cannot be converted to free glucose for export—they are retained for use by the muscle cells.

During exertion, the flux rate through glycolysis exceeds that through the citric acid cycle, so lactate accumulates and is released. Another metabolic product is alanine, produced via transamination from pyruvate in the glucose–alanine cycle (see page 844 in Chapter 20). Both lactate and alanine are transported through the bloodstream to the liver, where they are reconverted through gluconeogenesis to glucose, for return to the muscle and other tissues by the Cori cycle (see Figure 13.14, page 547). However, the major fate of lactate during exertion is uptake by the heart for use as fuel, via oxidation to CO_2 (Chapter 13).

Muscle contains another readily mobilizable source of energy—its own protein. However, the breakdown of muscle protein to meet energy needs is both energetically wasteful and harmful to an animal, which needs its muscles to move about in order to survive. Protein breakdown is regulated so as to minimize amino acid catabolism except in starvation.

Finally, recall that muscle has an additional energy reserve in creatine phosphate, which generates ATP without the need for metabolizing fuels (see Chapter 12, page 496). This reserve is exhausted early in a period of exertion and must be replenished, along with glycogen stores, as muscle rests after prolonged exertion.

Heart

The metabolism of heart muscle differs from that of skeletal muscle in three important respects. First, work output is far less variable than in skeletal muscle. Second, the heart is a completely aerobic tissue, whereas skeletal muscle can function anaerobically for limited periods. Mitochondria are much more densely packed in heart than in other cells, making up nearly half the volume of a heart cell. Third, the heart contains negligible energy reserves as glycogen or lipid, although there is a small amount of creatine phosphate. Therefore, the supply of both oxygen and fuels from the blood must be continuous to meet the unending energy demands of the heart. The heart uses a variety of fuels—mainly fatty acids but also glucose, lactate, and ketone bodies.

Adipose Tissue

Adipose tissue represents the major fuel depot for an animal. The total stored triacylglycerols amount to some 555,000 kJ (133,000 Cal) in an average-sized human (see Chapter 17, page 710). This is enough fuel, metabolic complications aside, to sustain life for a couple of months in the absence of further caloric intake.

The adipocyte, or fat cell, is designed for continuous synthesis and breakdown of triacylglycerols, with breakdown controlled largely via the activation of hormone-sensitive triglyceride lipases (see Figure 17.13, page 722). Because adipocytes lack the enzyme glycerol kinase, some glucose catabolism must occur for triacylglycerol synthesis to take place—specifically, the formation of dihydroxyacetone phosphate, for reduction to glycerol-3-phosphate (see Chapter 17, page 749). Glucose acts as a sensor in adipose tissue metabolism. When glucose levels are adequate, continuing production of dihydroxyacetone phosphate generates enough glycerol-3-phosphate for resynthesis of triacylglycerols from the released fatty acids. When intracellular glucose levels fall, the concentration of glycerol-3-phosphate falls also, and fatty acids are released from the adipocyte for export as the albumin complex to other tissues.

Liver

A primary role of liver is the synthesis of fuel components for use by other organs. In fact, most of the low-molecular-weight metabolites that appear in the blood through digestion are taken up by the liver for this metabolic processing. The liver

is a major site for fatty acid synthesis. It also produces glucose, both from its own glycogen stores and from gluconeogenesis, the latter using lactate and alanine from muscle, glycerol from adipose tissue, and the amino acids not needed for protein synthesis. Ketone bodies are also manufactured largely in the liver. In liver the level of malonyl-CoA, which is related to the energy status of the cell, is a determinant of the fate of fatty acyl-CoAs. When fuel is abundant, malonyl-CoA accumulates and inhibits carnitine acyltransferase I, preventing the transport of fatty acyl-CoAs into mitochondria for β -oxidation and ketogenesis. On the other hand, shrinking malonyl-CoA pools signal the cells to transport fatty acids into the mitochondria, for generation of energy and fuels.

An important role of liver is to buffer the level of blood glucose. It does this largely through the action of hexokinase IV (previously called glucokinase), an enzyme specific to liver, with a high $K_{0.5}$ (about 7.5 mM) for glucose, and partly through a high- K_M transport protein, the **glucose transporter (GLUT2)**, one member of a family of membrane proteins that carry out facilitated diffusion of glucose. Thus, liver is unique in being able to respond to high blood glucose levels by increasing the uptake and phosphorylation of glucose, which results eventually in its deposition as glycogen. Glucose-6-phosphate accumulation activates the *b* form of glycogen synthase (see Figure 13.36, page 572). In addition, glucose itself binds to glycogen phosphorylase *a*, increasing the susceptibility of phosphorylase *a* to dephosphorylation (see Figure 13.35, page 571), with consequent inactivation. Thus, in addition to hormonal effects, described shortly, liver senses the fed state and acts to store fuel derived from glucose. Liver also senses the fasted state and increases the synthesis and export of glucose when blood glucose levels are low. (Other organs also sense the fed state, notably the pancreas, which adjusts its glucagon and insulin outputs accordingly.)

To meet its internal energy needs, the liver can use a variety of fuel sources, including glucose, fatty acids, and amino acids.

Blood

All of the organs we have discussed are connected by the bloodstream, which transports what may be one organ's waste product but another organ's fuel (for example, alanine from muscle to liver). Blood also transports oxygen from lungs to tissues, enabling exergonic oxidative pathways to occur, followed by transport of the resultant CO_2 back to the lungs for exhalation, as described in Chapter 7. And, as described in Chapter 17, the lipoprotein components of blood plasma (e.g., chylomicrons and very low-density lipoproteins) play indispensable roles in transporting lipids. Of course, blood is also the medium of transport of hormonal signals from one tissue to another, and of exit for metabolic end products, such as urea, via the kidneys.

In terms of the blood's own energy metabolism, the most prominent pathway is glycolysis in the erythrocyte. Blood cells constitute nearly half the volume of blood, and erythrocytes constitute more than 99% of blood cells. Mammalian erythrocytes contain no mitochondria and depend exclusively upon anaerobic glycolysis to meet their limited energy needs.

Hormonal Regulation of Fuel Metabolism

In animals, it is supremely important to maintain blood glucose levels within rather narrow limits, particularly for proper functioning of the nervous system. Of course, blood glucose levels vary, depending on nutritional status. Several hours after a meal, the normal level in humans is about 80 mg per 100 mL of blood, or 4.4 mM. Shortly after a meal, that level might rise to 120 mg per 100 mL (6.6 mM). In response, homeostatic mechanisms come into play to promote uptake of glucose into cells and its use by tissues. Similarly, when glucose levels

One of the most important roles of liver is to serve as a "glucostat," monitoring and stabilizing blood glucose levels.

Maintenance of blood glucose within narrow limits is critical to brain function.

fall, several hours after a meal, other mechanisms promote both glucose release, from liver glycogen stores, and gluconeogenesis so that the normal level is maintained. Some of the homeostatic mechanisms were mentioned in the previous section; others involve hormonal regulation. Though we discuss molecular mechanisms of hormone action in detail in Chapter 23, it is appropriate here to discuss at the physiological level some of the hormones involved in fuel metabolism.

Actions of the Major Hormones

The most important hormone promoting glucose uptake and use is insulin, whereas both glucagon and epinephrine have the opposite effect, to increase blood glucose levels. The major effects of these agents are summarized in Table 18.2. Figure 18.2 illustrates the interplay between the two pancreatic hormones, insulin and glucagon.

Insulin

Insulin is a 5.8-kilodalton protein (see page 151) that is synthesized in the pancreas. The pancreas has both **endocrine cells**, which secrete hormones directly into the bloodstream, and **exocrine cells**, which secrete zymogen precursors of digestive enzymes into the upper small intestine. The endocrine tissue, which takes the form of cell clusters known as islets of Langerhans, contains at least five

The key hormones regulating fuel metabolism are insulin, which promotes glucose use, and glucagon and epinephrine, which increase blood glucose.

TABLE 18.2 Major hormones controlling fuel metabolism in mammals

Hormone	Biochemical Actions	Enzyme Target	Physiological Actions
Insulin	↑ Glucose uptake (muscle, adipose tissue)	GLUT4	Signals fed state: ↓ Blood glucose level
	↑ Glycolysis (liver, muscle)	PFK-1 (via PFK-2/FBPase-2)	↑ Fuel storage
	↑ Acetyl-CoA production (liver, muscle)	Pyruvate dehydrogenase complex	↑ Cell growth and differentiation
	↑ Glycogen synthesis (liver, muscle)	Glycogen synthase	
	↑ Triacylglycerol synthesis (liver)	Acetyl-CoA carboxylase	
	↓ Gluconeogenesis (liver)	FBPase-1 (via PFK-2/FBPase-2)	
	↓ Lipolysis		
	↓ Protein degradation		
	↑ Protein, DNA, RNA synthesis		
Glucagon	↑ cAMP level (liver, adipose tissue)		Signals fasting state: ↑ Glucose release from liver
	↑ Glycogenolysis (liver)	Glycogen phosphorylase	↑ Blood glucose level
	↓ Glycogen synthesis (liver)	Glycogen synthase	↑ Ketone bodies as alternative fuel for brain
	↑ Triacylglycerol hydrolysis and mobilization (adipose tissue)	Hormone-sensitive lipase, perilipin, adipose triglyceride lipase	
	↑ Gluconeogenesis (liver)	FBPase-1 (via PFK-2/FBPase-2), pyruvate kinase, PEPCK	
	↓ Glycolysis (liver)	PFK-1 (via PFK-2/FBPase-2)	
	↑ Ketogenesis (liver)	Acetyl-CoA carboxylase	
Epinephrine	↑ cAMP level (muscle)		Signals stress: ↑ Glucose release from liver
	↑ Triacylglycerol mobilization (adipose tissue)	Hormone-sensitive lipase, perilipin, adipose triglyceride lipase	↑ Blood glucose level
	↑ Glycogenolysis (liver, muscle)	Glycogen phosphorylase	
	↓ Glycogen synthesis (liver, muscle)	Glycogen synthase	
	↑ Glycolysis (muscle)	Glycogen phosphorylase, providing increased glucose	

FIGURE 18.2

Aspects of the control of blood glucose levels by pancreatic secretion of insulin and glucagon. Conditions resulting from high glucose levels are shown in blue, and those from low glucose levels in pink. Green arrows indicate stimulatory responses.

different cell types, each specialized for synthesis of one hormone. The α (or A) cells produce glucagon; the δ (or D) cells, **somatostatin**; the ϵ cells, **ghrelin**; and the F cells, **pancreatic polypeptide**. Insulin is synthesized in the β (or B) cells, which sense glucose levels and secrete insulin in response to increased levels of blood glucose. The β cells take up and catabolize glucose, resulting in increased intracellular ATP levels, which causes closure of ATP-gated K^+ channels and depolarization of the plasma membrane (see Chapter 10). Voltage-gated Ca^{2+} channels open in response to this membrane depolarization, leading to increased cytosolic $[Ca^{2+}]$, which finally triggers exocytosis of insulin granules.

The simplest way to describe the several actions of insulin is to say that *insulin signals the fed state* and thereby promotes (1) uptake of fuel substrates into some cells, (2) storage of fuels (lipids and glycogen), and (3) biosynthesis of macromolecules (nucleic acids and protein). Specific effects include increased uptake of glucose in muscle and adipose tissue; activation of glycolysis in liver; increased synthesis of fatty acids and triacylglycerols in liver and adipose tissue; inhibition of gluconeogenesis in liver; increased glycogen synthesis in liver and muscle; increased uptake of amino acids into muscle with consequent activation of muscle protein synthesis; and inhibition of protein degradation. Because of its promotion of biosynthesis, it is appropriate to consider insulin a growth hormone.

The mechanism by which insulin stimulates glucose uptake into muscle and adipose cells is an area of intense investigation. One important action involves the glucose transporter, GLUT4 (see Figure 18.5). Before stimulation by insulin, this transporter is not present on the cell surface; rather, it is localized in vesicles in the cytosol. The protein is translocated to the cell surface in response to insulin, where it facilitates glucose uptake. An important consequence of glucose uptake in adipocytes is its conversion to glycerol-3-phosphate, which combines with fatty acids to stimulate triacylglycerol synthesis.

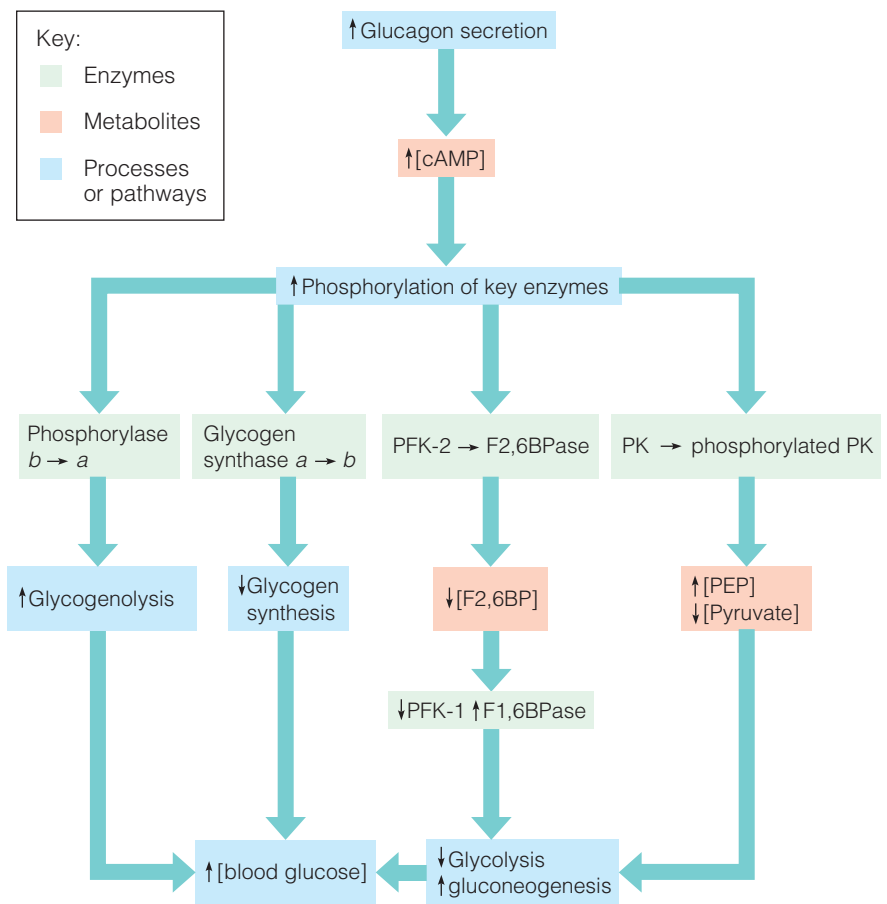

Glucagon

A 3.5-kilodalton polypeptide, glucagon is synthesized by α cells of the islets of Langerhans in the pancreas. These endocrine cells sense the blood glucose concentration and release the hormone in response to low levels (see Figure 18.2). Both synthesis and release of glucagon are controlled by insulin.

The primary target of glucagon is the liver, and its principal effect is to increase cyclic AMP levels in liver cells, as schematized in Figure 18.3. The resultant metabolic cascades, discussed in Chapter 13, promote glycogenolysis and

FIGURE 18.3

Actions of glucagon in liver that lead to a rise in blood glucose. Brackets indicate concentration; \uparrow and \downarrow indicate increase or decrease, respectively, in enzyme activity, pathway flux, or metabolite level.

inhibit glycogen synthesis. In addition, by activating the hydrolysis of fructose-2, 6-bisphosphate, cAMP inhibits glycolysis and activates gluconeogenesis. Glucagon also brings about inhibition of pyruvate kinase (PK) in the liver, causing phosphoenolpyruvate (PEP) to accumulate. The level of pyruvate decreases, both because its synthesis from PEP is blocked and because it continues to be converted to PEP, via the pyruvate carboxylase and phosphoenolpyruvate carboxykinase reactions. Although accumulation of PEP is slight, it suffices to promote gluconeogenesis, while inhibition of pyruvate kinase diminishes the glycolytic flux rate.

Glucagon also raises cAMP levels in adipose tissue. There the chief effect of cAMP is to promote triacylglycerol mobilization via phosphorylation of hormone-sensitive lipase and perilipin, yielding glycerol and fatty acids (see Figure 17.14, page 723).

Epinephrine

The catecholamines epinephrine and norepinephrine, when released from presynaptic nerve endings, function as neurotransmitters (see Chapter 23). When released from adrenal medulla in response to low blood glucose levels, epinephrine interacts with second-messenger systems in many tissues, with varied effects. In muscle, epinephrine activates adenylate cyclase, with concomitant activation of glycogenolysis and inhibition of glycogen synthesis (see Chapter 13). Triacylglycerol breakdown in adipose tissue is also stimulated, providing fuel for the muscle tissue. Epinephrine also inhibits insulin secretion and stimulates glucagon secretion. These effects tend to increase glucose production and release

by the liver. The net result is to increase blood glucose levels. Unlike glucagon, the catecholamines have short-lived metabolic effects. As discussed in Chapter 13, epinephrine action on skeletal and heart muscle cells is a crucial part of the “fight or flight” response.

Coordination of Energy Homeostasis

All organisms, indeed all cells, must balance the ingestion and absorption of fuel molecules with the metabolism and storage of these nutrients to meet immediate, as well as long-term, energy needs. Maintenance of this balance is termed **energy homeostasis**, and a complex regulatory system has evolved to coordinate and integrate these processes. This regulatory system comprises a bewildering number of components, but two protein kinases, AMPK and **mTOR**, play central roles in orchestrating the metabolic activity of mammalian cells. A third highly conserved family of enzymes, the **sirtuins**, are also emerging as important regulators of energy metabolism.

AMP-Activated Protein Kinase

We have seen AMPK (AMP-activated protein kinase) several times in the preceding chapters. This serine/threonine protein kinase, found in all eukaryotes, is activated when the energy charge of the cell is low (i.e., high AMP:ATP ratio), such as occurs during nutrient starvation or hypoxia. Once activated, AMPK initiates a signaling process that conserves cellular energy by stimulating pathways that lead to ATP production while inhibiting pathways that utilize ATP. AMPK is a heterotrimer, composed of a catalytic subunit (α) and two regulatory subunits (β and γ). Activation of the catalytic α subunit involves the binding of AMP to four nucleotide-binding sites in the γ subunit (Figure 18.4). Activation of AMPK also requires phosphorylation of a specific threonine residue in the α subunit, and AMP binding to the γ subunit allosterically protects against dephosphorylation of this residue in the α subunit. Two upstream kinases, **LKB1** and Ca^{2+} /calmodulin-dependent protein kinase kinase β (**CaMKK β**), are known to phosphorylate the critical Thr residue.

AMPK phosphorylates multiple substrates that enhance energy-producing pathways, including targets that stimulate glucose uptake (via translocation of GLUT4 to the plasma membrane), glycolysis in heart (via stimulation of the kinase activity of the heart-specific PFK-2/FBPase-2; see Chapter 13, page 555), and mitochondrial biogenesis. At the same time, other AMPK targets inhibit energy-requiring pathways, including hepatic gluconeogenesis (via decreased transcription of gluconeogenic enzymes), fatty acid synthesis (via acetyl-CoA carboxylase; see Figure 17.36, page 746), triacylglycerol synthesis (via glycerophosphate acyltransferase and hormone-sensitive lipase; see Figure 17.38, page 748), and cholesterol synthesis (via HMG-CoA reductase; Chapter 19, page 802). These effects are summarized in Figure 18.5.

Mammalian Target of Rapamycin

mTOR (mammalian target of rapamycin) is the other main player in the regulation of energy homeostasis. Like AMPK, mTOR is a highly conserved serine/threonine protein kinase found in all eukaryotes. In contrast to AMPK, mTOR is active under nutrient-rich conditions and inactive under nutrient-poor conditions. Activated mTOR promotes anabolic processes, including cell proliferation, protein synthesis, and biosynthesis, but inhibits catabolic processes. mTOR exists as two distinct multiprotein complexes: a rapamycin-sensitive complex (mTORC1) composed of mTOR, mLST8, raptor, and PRAS40; and a rapamycin-insensitive complex (mTORC2) composed of mTOR, mLST8, rictor, Sin1, and

AMPK and mTOR protein kinases play central roles in orchestrating the metabolic activity of mammalian cells.

AMPK is activated when the energy charge of the cell is low.

FIGURE 18.4

Mammalian AMP-activated protein kinase (AMPK). This figure shows the X-ray crystal structure of the heterotrimeric enzyme (PDB ID 2Y94). The α subunit, shown in cyan, is composed of two domains, an N-terminal kinase domain (dark cyan) and a C-terminal regulatory domain (light cyan). The kinase active site is marked by a bound inhibitor, staurosporine (orange). Phosphorylated threonine 172 is shown in space-filling representation. The regulatory β subunit (green) is normally 272 amino acids long, but only its C-terminal 85 residues are included in this structure. The regulatory γ subunit (red) is composed of four nucleotide-binding sites (CBS motifs, named after related sequences in cystathionine β synthase). Two of these sites are filled with AMP molecules (yellow); two are empty. In this structure of active AMPK, a loop of the α -subunit (blue) interacts with bound AMP in one of the CBS motifs of the γ -subunit. This interaction stabilizes the binding of the catalytic domain to the β -subunit, thereby inhibiting dephosphorylation of Thr 172 by phosphatase. This explains how AMP binding to the γ subunit allosterically protects against dephosphorylation of this residue in the catalytic subunit.

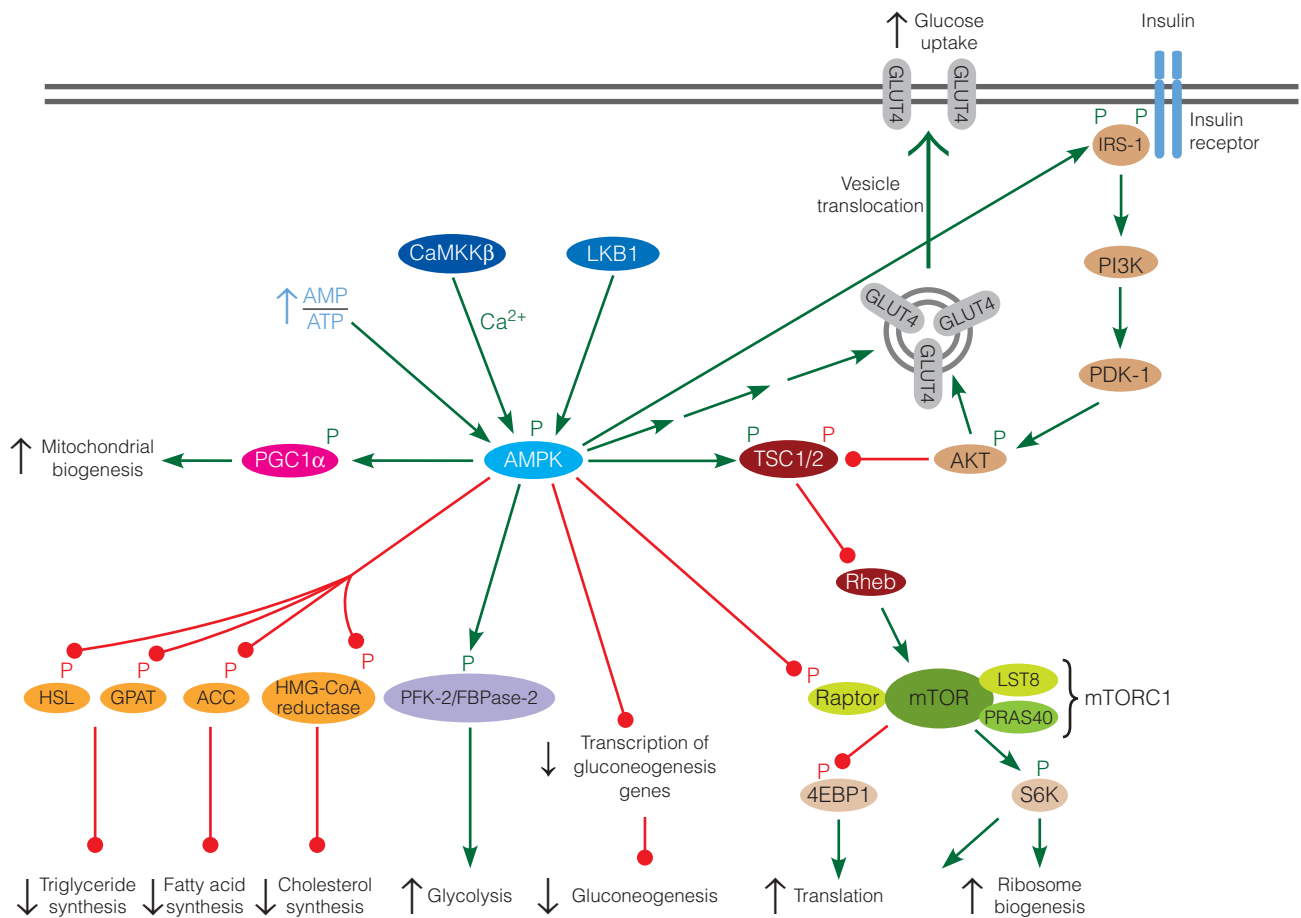

FIGURE 18.5

AMPK and mTOR signaling pathways. Green arrows indicate activation; red balls indicate inhibition. P indicates phosphorylation, causing either activation (P) or inhibition (P) of the phosphorylated target protein. For example, phosphorylation of TSC1/2 by AKT inhibits TSC1/2; phosphorylation by AMPK, at a different site, activates TSC1/2. Some of the metabolic responses mediated by AMPK and mTOR are tissue-specific. Refer to text for details. 4EBP1, eIF4E-binding protein 1; ACC, acetyl-CoA carboxylase; CaMKK β , Ca²⁺/calmodulin-dependent protein kinase kinase β ; GLUT4, glucose transporter; GPAT, glycerophosphate acyltransferase; HSL, hormone-sensitive lipase; IRS, insulin receptor substrate; PI3K, phosphoinositide 3-kinase; PGC-1 α , PPAR γ coactivator 1 α ; S6K, ribosomal protein S6 kinase; TSC1/2, tuberous sclerosis complex.

PRR5/Protor. mTOR was discovered during biochemical studies with the bacterial macrolide, **rapamycin**, a potent immunosuppressant. Rapamycin binds to a small cellular protein, FKBP12, and this FKBP12-rapamycin complex allosterically inhibits mTORC1, but has no effect on mTORC2.

The two best-characterized substrates of mTORC1 are **4EBP1** (eukaryotic initiation factor **4E-binding protein 1**) and **S6K** (ribosomal protein **S6 kinase**) (Figure 18.5). Raptor acts as a scaffold to recruit these downstream substrates to the mTORC1 complex. 4EBP1 normally inhibits the translation initiation factor eIF4E (see Chapter 28); phosphorylation of 4EBP1 by mTORC1 suppresses its ability to bind eIF4E and inhibit translation. Phosphorylation of S6K activates this downstream protein kinase, which phosphorylates a number of proteins involved in translational control. The net effect of phosphorylation of 4EBP1 and S6K by mTORC1 is thus stimulation of protein synthesis and ribosome biogenesis.

mTORC1 activity is regulated by a number of upstream inputs, most of which are transmitted through the tuberous sclerosis complex (TSC) (Figure 18.5). This complex, first discovered as a tumor suppressor (see Chapter 23), is composed of TSC1 (hamartin) and TSC2 (tuberin). TSC2 contains a GTPase activating protein (GAP) domain that inactivates the small Ras-like GTPase **Rheb**. Rheb normally activates mTORC1, thus loss of TSC1 or TSC2 leads to hyperactivation of mTORC1. TSC serves as an integration point for regulation of mTORC1, receiving inputs from a wide variety of environmental signals, including growth factors (e.g., insulin and epidermal growth factor), energy status, and nutrient availability. Insulin signaling begins with phosphorylation of an **insulin receptor substrate** (IRS) protein by the tyrosine kinase activity of the plasma membrane insulin receptor. IRS proteins (humans express three isoforms, IRS-1, -2, and -4) integrate the activated insulin receptor to downstream adaptor proteins and

mTOR, in contrast to AMPK, is active under nutrient-rich conditions, and inactive under nutrient-poor conditions.

enzymes. Thus, phosphorylated IRS activates **phosphoinositide 3-kinase** (PI3K), which converts membrane phosphatidylinositol 4,5-bisphosphate (PIP_2) to phosphatidylinositol 3,4,5-trisphosphate (PIP_3), a second messenger with a variety of intracellular targets. PIP_3 activates yet another protein kinase (PDK-1), which then activates a third protein kinase, Akt (also called PKB). Akt then phosphorylates TSC, inactivating the complex, resulting in activation of mTORC1. Activated Akt also stimulates GLUT4 translocation to the plasma membrane, accounting for insulin-stimulated glucose transport in muscle cells. We will discuss the insulin signal transduction pathway in more detail in Chapter 23.

Let's look more closely at the mechanism by which mTORC1 senses energy status because it involves AMPK. Recall that AMPK is activated during nutrient starvation, directly sensing the adenylate energy charge (AMP/ATP ratio). Activated AMPK then phosphorylates the TSC complex, which suppresses mTORC1 function by inhibiting Rheb. Activated AMPK can directly inhibit mTORC1 by phosphorylation of the raptor subunit of the complex. AMPK also modulates the insulin signaling pathway by phosphorylating IRS, thereby increasing the sensitivity of the cell to insulin (Figure 18.5).

In summary, AMPK and mTOR play opposing roles in controlling the metabolic activity of cells in response to intracellular and extracellular signals that report on the energy status of the individual cell and the organism as a whole. These two protein kinases, and the nutrient signaling pathways they control, are evolutionarily conserved from yeast to humans.

Sirtuins

Sirtuins are a highly conserved family of protein deacetylases. These enzymes catalyze the deacetylation of acetylated lysine residues in target proteins. Recall from Chapter 11 that acetylation of lysine residues is a common covalent modification of proteins, catalyzed by a family of protein acetyltransferases. Reversal of this modification requires an enzyme-catalyzed deacetylation. Of the three types of protein deacetylases found in nature, sirtuins are unique in that they require NAD^+ for their deacetylation activity. NAD^+ functions not as a redox cofactor in this complex reaction, but rather as a substrate that is cleaved to nicotinamide and 2'-O-acetyl-ADP-ribose (OAADPr).

Sirtuins are named after the founding member of the family, yeast Sir2 (silent information regulator 2), which deacetylates histones to regulate gene expression (silencing) of the mating type locus in yeast. Sirtuins are now known to act on many proteins besides histones, and they are structurally conserved from bacteria to humans (Figure 18.6). Mammals possess seven sirtuins (SIRT1-7), which differ in their cellular localization (nucleus, mitochondria, cytoplasm) and protein targets. For most protein targets, deacetylation increases the activity of the target protein. The deacetylase activity of sirtuins is sensitive to changes in the cellular NAD^+ levels, being enhanced at high NAD^+/NADH ratios. Thus, sirtuins act as metabolic sensors of the cellular redox state.

Sirtuins are a highly conserved family of NAD^+ -dependent protein deacetylases.

FIGURE 18.6

Catalytic core of sirtuins is evolutionarily conserved. X-ray crystal structures of the catalytic cores of sirtuins from (a) yeast (PDB ID 1Q14), (b) an archaea (PDB ID 1IC1), (c) a eubacterium (PDB ID 1S5P), and (d) human (PDB ID 2B4Y) show a high degree of structural similarity. The Rossmann-fold domain, characteristic of NAD⁺/NADP-binding proteins, is magenta, the small zinc-binding domain is blue. The Zn ion is red. Disordered regions are indicated with dashed lines. Panel e shows the yeast Hst2 sirtuin with bound acetylated peptide substrate (green) and carba-NAD⁺, a substrate analog (cyan).

Modified from *Biochimica et Biophysica Acta* 1804:1604–1616, B. D. Sanders, B. Jackson, and R. Marmorstein, Structural basis for sirtuin function: What we know and what we don't. © 2010, with permission from Elsevier.

Sirtuins are part of an intricate regulatory system that controls flux through fuel utilization pathways in response to the dietary availability of alternative fuels. For example, we will see in the next section that under fasting conditions, mammals initiate a reprogramming of their metabolic systems across several tissue types. This response includes increasing the rate of glucose synthesis in the liver and kidney and increasing the utilization of fatty acids as a fuel source in peripheral tissues. One of the most important participants in this metabolic reprogramming is the **peroxisome proliferator-activated receptor- γ coactivator 1 α** (**PGC-1 α**). PGC-1 α was initially discovered as a co-activator of the transcription factor peroxisome proliferator-activated receptor- γ (PPAR γ), but PGC-1 α binds to and stimulates the transcriptional activity of several transcription factors, including p53, nuclear respiratory factors 1 and 2 (NRF-1, NRF-2), and forkhead box O (FOXO).

The transcriptional coactivator function of PGC-1 α is sensitive to its acetylation status, and PGC-1 α can be deacetylated by SIRT1. Fasting (low nutrients) results in a higher NAD⁺/NADH ratio, activating the sirtuins. Deacetylation of PGC-1 α causes upregulation of its coactivator function (Figure 18.7). In liver, upregulation of PGC-1 α function stimulates gluconeogenesis by activating the transcription of the phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase genes. In skeletal muscle and heart, the transcriptional responses mediated by PGC-1 α lead to increased oxidation of fatty acids and decreased utilization of glucose. Deacetylated PGC-1 α also coactivates the transcription of nuclear-encoded genes that encode subunits of the mitochondrial respiratory chain (Chapter 15) as well as genes that encode components of the mitochondrial gene expression machinery. This enhanced mitochondrial biogenesis increases the capacity of the cell for fatty acid oxidation and is a critical part of the PGC-1 α -dependent metabolic reprogramming that occurs in heart and skeletal muscle.

PGC-1 α is capable of integrating multiple signals that monitor the cellular energy state. Recall that AMPK also stimulates mitochondrial biogenesis. AMPK phosphorylates PGC-1 α , which also causes its activation (see Figure 18.5). It appears that phosphorylation primes PGC-1 α for subsequent deacetylation by SIRT1. Thus, PGC-1 α senses both the AMP/ATP ratio (via AMPK) and the NAD⁺/NADH ratio (via SIRT1).

More than 2000 proteins have been found to be acetylated in mammalian cells, and the list of pathways known to be regulated by SIRT-mediated deacetylation is expanding rapidly. Table 18.3 summarizes our current understanding of this important family of regulatory enzymes.

The three mitochondrial sirtuins (SIRT3–5) are involved in the regulation of several metabolic processes, including the urea cycle and respiration. Deacetylation of their target proteins (Table 18.3) activates these pathways.

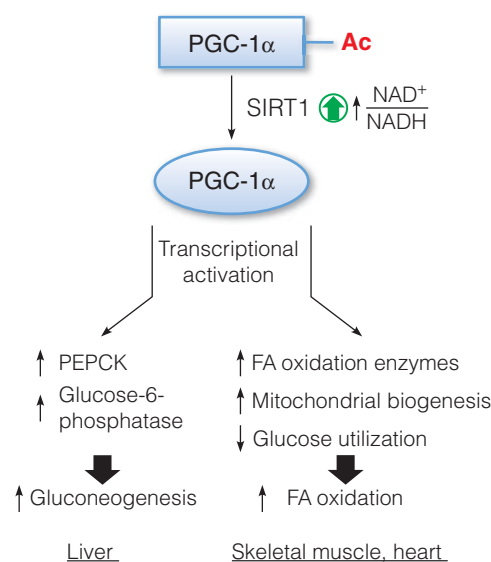

FIGURE 18.7

PGC-1 α and SIRT1 control the reprogramming of fuel utilization pathways in response to fasting. A high NAD⁺/NADH ratio, in response to low nutrients (fasting), activates SIRT1 to deacetylate PGC-1 α , upregulating its transcriptional coactivator function. Tissue-specific transcriptional activation programs result in increased gluconeogenesis (liver) and increased fatty acid oxidation (skeletal and heart muscle).

TABLE 18.3 Substrates and cellular locations of mammalian sirtuins

	Subcellular Location	Deacetylation Substrates
SIRT1	Nucleus, cytoplasm	Histones PGC-1 α , FOXO, and many other transcription factors IRS-2
SIRT2	Nucleus, cytoplasm	Histones FOXO and other transcription factors
SIRT3	Mitochondrial matrix	Acetyl-CoA synthetase 2 (Chapter 17) Long-chain acyl-CoA dehydrogenase (Chapter 17) Complex I of electron transport chain (Chapter 15) Glutamate dehydrogenase (Chapter 20) Ornithine transcarbamoylase (Chapter 20) NADP ⁺ -dependent isocitrate dehydrogenase (Chapter 14) Superoxide dismutase (Chapter 15)
SIRT4^a	Mitochondrial matrix	Glutamate dehydrogenase ^b (Chapter 20)
SIRT5	Mitochondrial matrix	Carbamoyl phosphate synthetase I (Chapter 20)
SIRT6	Nucleus	Histones
SIRT7	Nucleolus	RNA polymerase I ^c

^aSIRT4 catalyzes ADP ribosylation, rather than deacetylation, of its targets.

^bADP ribosylation of glutamate dehydrogenase decreases its activity.

^cThe specific RNA polymerase I target has yet to be identified.

SIRT4 does not appear to be a true protein deacetylase because it does not exhibit NAD^+ -dependent deacetylation activity *in vitro*. Rather, SIRT4 catalyzes **ADP-ribosylation**, the transfer of ADP-ribose from NAD^+ to target proteins (see Figure 11.51, page 460).

Finally, in addition to regulating energy homeostasis, sirtuins play important roles in cellular stress responses, genomic stability, and tumorigenesis. In fact, sirtuins control lifespan in lower organisms, and evidence is accumulating that these evolutionarily conserved enzymes regulate the aging process in mammals as well. The first clue that sirtuins might influence the aging process came from studies on calorie restriction in laboratory rodents. Calorie restriction (CR), a reduction in food intake of 30–40%, can extend lifespan by up to 50% and delays the onset of age-associated disease. Moreover, CR extends lifespan in organisms ranging from yeast to rodents to primates. In a 20-year-long study of rhesus monkeys, CR reduced the incidence of diabetes, cancer, cardiovascular disease, and brain atrophy. Genetic studies in yeast led to the realization that sirtuins are important mediators of the CR response in most organisms, including mammals. For example, SIRT1 knockout mice do not exhibit the longevity normally associated with calorie restriction. Conversely, transgenic mice that overexpress SIRT1 exhibit many CR responses even when fed *ad libitum* (no food restriction). Enticed by the possibility that sirtuins might extend life, a virtual Gold Rush took place to find small molecules that could activate SIRT1. Resveratrol was the first of these compounds to be discovered by screening for activators of the NAD^+ -dependent deacetylation activity of SIRT1. Resveratrol is a polyphenolic compound found in red grapes (and thus red wine), berries, and many other plants and has previously been associated with health benefits in humans. Although resveratrol and newer classes of SIRT1 activators do indeed confer many phenotypes of CR on fed animals, they are not likely to represent a simple “fountain of youth.” Nonetheless, pharmacological manipulation of sirtuin function holds great promise for treatment of aging-related diseases.

Calorie restriction extends lifespan in organisms ranging from yeast to primates. The mechanisms are not fully understood, but sirtuins are important mediators of this response.

Endocrine Regulation of Energy Homeostasis

AMPK, mTOR, and sirtuins all evolved in unicellular organisms as part of a control system that sensed the nutrient supply and initiated appropriate metabolic responses. If nutrients are abundant, the cells take up the fuels and metabolize them via glycolysis, a rapid, but relatively inefficient process (Figure 18.8, left panel). This *proliferative metabolism* provides the building blocks and free energy needed to produce biomass (new cells) during exponential growth. When nutrients are scarce, the cells adapt to a *starvation metabolism*. Biomass production ceases, and the cells switch to a slower, but more efficient, oxidative metabolism in order to extract maximum energy from the limiting nutrients. During the evolution of metazoans (multicellular organisms), this control system grew in complexity, responding to new inputs and developing new outputs. In contrast to unicellular organisms, most of the cells in multicellular organisms are bathed in a relatively constant supply of nutrients via the circulatory system, and this supply often exceeds the levels needed to support cell growth and replication. Growth control in metazoans thus evolved to occur at the levels of nutrient intake, transport, and utilization (metabolism). Thus, most mammalian cells exhibit a strict dependence on growth factors (hormones) to switch from a quiescent, differentiated state to a proliferative state. Nondividing, differentiated mammalian cells typically use oxidative metabolism (aerobic glycolysis + citric acid cycle) to metabolize glucose, as in the starvation metabolism of unicellular organisms (Figure 18.8, right panel). Upon stimulation by growth factors (e.g., insulin), differentiated cells switch to the faster glycolysis.

In 1925, Otto Warburg noted that, unlike nondividing, differentiated mammalian cells, most rapidly dividing cancer cells metabolize glucose by aerobic glycolysis, producing lactate even when oxygen is abundant. In this phenomenon, known as the “Warburg effect,” the cancer cells have overcome their normal strict

**FIGURE 18.8**

Proliferating and nonproliferating cells use different metabolic strategies to generate energy. Proliferative metabolism, in both unicellular and multicellular organisms, relies on glycolysis, a rapid but relatively inefficient process for generating ATP. This “fermentative” metabolism requires abundant nutrients. When nutrients are scarce, unicellular organisms adapt to a starvation metabolism, characterized by the slower, but more efficient, oxidative metabolism. This same efficient oxidative metabolism is used by nondividing, differentiated mammalian cells. Nutrient abundance is rarely an issue in multicellular organisms so that the switch between proliferative and quiescent metabolism is determined by the presence or absence of appropriate growth factors, rather than by nutrient availability.

From *Science* 324:1029–1033, M. G. Vander Heiden, L. C. Cantley, and C. B. Thompson, *Understanding the Warburg effect: The metabolic requirements of cell proliferation*. © 2009. Reprinted with permission from AAAS.

dependence on growth factors, and they switch to a proliferative metabolism. We now know that in most cases, cancer cells have acquired genetic mutations in components of the growth factor signaling pathways that normally control proliferation. For example, mutations that alter the signaling activity of PI3K are the most common genetic mutations found in cancer cells. We will see several other examples in Chapter 23.

In mammals, the brain coordinates whole body energy homeostasis. The brain receives information about the quality and quantity of nutrients being consumed, the levels of fuels already present in the blood, and the amounts of energy present in various storage depots in the body. These fuel and hormonal signals converge in neurons in the **arcuate nucleus** of the hypothalamus, where food intake is controlled. Not surprisingly, AMPK and mTOR play central roles in integrating these signals in the hypothalamus, where activation of AMPK promotes food intake (Figure 18.9). Hypothalamic AMPK is activated in response to low levels of nutrients such as glucose, branched-chain amino acids, and free fatty acids. The most important endocrine regulators of food intake are insulin and leptin (inhibit intake), and **ghrelin** and **adiponectin** (promote intake). Each of these act via specific receptors on particular cells in the arcuate nucleus to initiate signaling pathways that converge on AMPK and mTOR.

**FIGURE 18.9**

Fuel and hormonal control of food intake in the arcuate nucleus of the hypothalamus. Activation of AMPK promotes food intake; inhibition suppresses food intake. Green arrows indicate stimulatory effects; red bars indicate inhibitory effects. Insulin acts through the phosphoinositide 3-kinase (PI3K) cascade to inhibit food intake. Leptin has both direct and indirect effects (through PI3K and AMPK) on mTOR. Adiponectin and ghrelin stimulate food intake by activating AMPK. S6K, ribosomal protein S6 kinase; BCAA, branched-chain amino acids; FFA, free fatty acids.

Insulin inhibits food intake through its activation of mTOR. As discussed at the end of Chapter 17, leptin is a peptide hormone released by adipocytes (an **adipokine**) when fat stores are adequate. Leptin activates mTOR and inhibits AMPK function in hypothalamus, suppressing food intake. Ghrelin, a small peptide hormone (28 amino acids) produced in cells lining the stomach, promotes food intake by activating hypothalamic AMPK. Adiponectin, another adipokine produced by adipocytes, is normally abundant in plasma, but decreases in obese individuals or people with type 2 diabetes. Adiponectin stimulates food intake by activating AMPK in hypothalamus. These effects are summarized in Figure 18.9.

Of course, all of these hormones have effects on tissues outside of the brain as well. Thus, leptin and adiponectin both activate AMPK signaling in skeletal muscle, leading to increased fatty acid oxidation, glucose uptake, and mitochondrial biogenesis (Figure 18.10). In liver, AMPK activation suppresses gluconeogenesis and lipogenesis. Ghrelin and insulin both suppress AMPK activity in liver, opposing the effects of leptin. Adiponectin has insulin-sensitizing effects on liver and other tissues. Finally, both leptin and adiponectin have autocrine activity, activating AMPK in adipocytes, leading to increased fatty acid oxidation, glucose uptake, and decreased lipogenesis.

Responses to Metabolic Stress: Starvation, Diabetes

An excellent way to understand how the interorgan and hormonal relationships we have discussed actually integrate fuel metabolism is to examine the effects of metabolic stress. In this section we consider two examples—prolonged fasting, in which the intake of fuel substrates is inadequate; and **diabetes mellitus**, in which a functional insufficiency of insulin impairs the ability of the body to use glucose, even when the sugar is present in abundance.

First let us review how glucose levels are maintained during normal feeding cycles (Figure 18.11). The blood glucose elevation occurring shortly after a carbohydrate-containing meal stimulates the secretion of insulin and suppresses the secretion of glucagon. Together these effects promote uptake of glucose into the liver, stimulate glycogen synthesis, and suppress glycogen breakdown. Flux through hexokinase IV increases in response to elevated glucose levels, providing substrates for glycogen synthesis. In addition, activation of acetyl-CoA carboxylase in the liver stimulates fatty acid synthesis, with subsequent transport to adipose tissue as triacylglycerols in very low-density lipoproteins. There, the increased levels of glycolytic intermediates and fatty acids stimulate triacylglycerol synthesis. Finally, increased glucose uptake into muscle increases levels of substrates for glycogen synthesis in that tissue as well.

Several hours later, when blood glucose levels begin to fall, the above events are reversed. Insulin secretion slows and glucagon secretion increases. This promotes glycogen mobilization in liver via the cAMP-dependent cascade mechanisms that activate glycogen phosphorylase and inactivate glycogen synthase. Triacylglycerol breakdown in adipocytes is activated as well, via the action of hormone-sensitive lipase, generating fatty acids for use as fuel by liver and muscle. At the same time, the decrease in insulin levels reduces glucose use by muscle, liver, and adipose tissue. Consequently, nearly all the glucose produced in the liver is exported to the blood and is available for use by the brain.

Starvation

Suppose that food intake is denied not just for a few hours, as just described, but for many days. Given that a 70-kg human can store at most the equivalent of 6700 kJ of energy as glycogen, this source of blood glucose will be exhausted in just a few hours. Because it is critical for brain function that blood glucose levels be

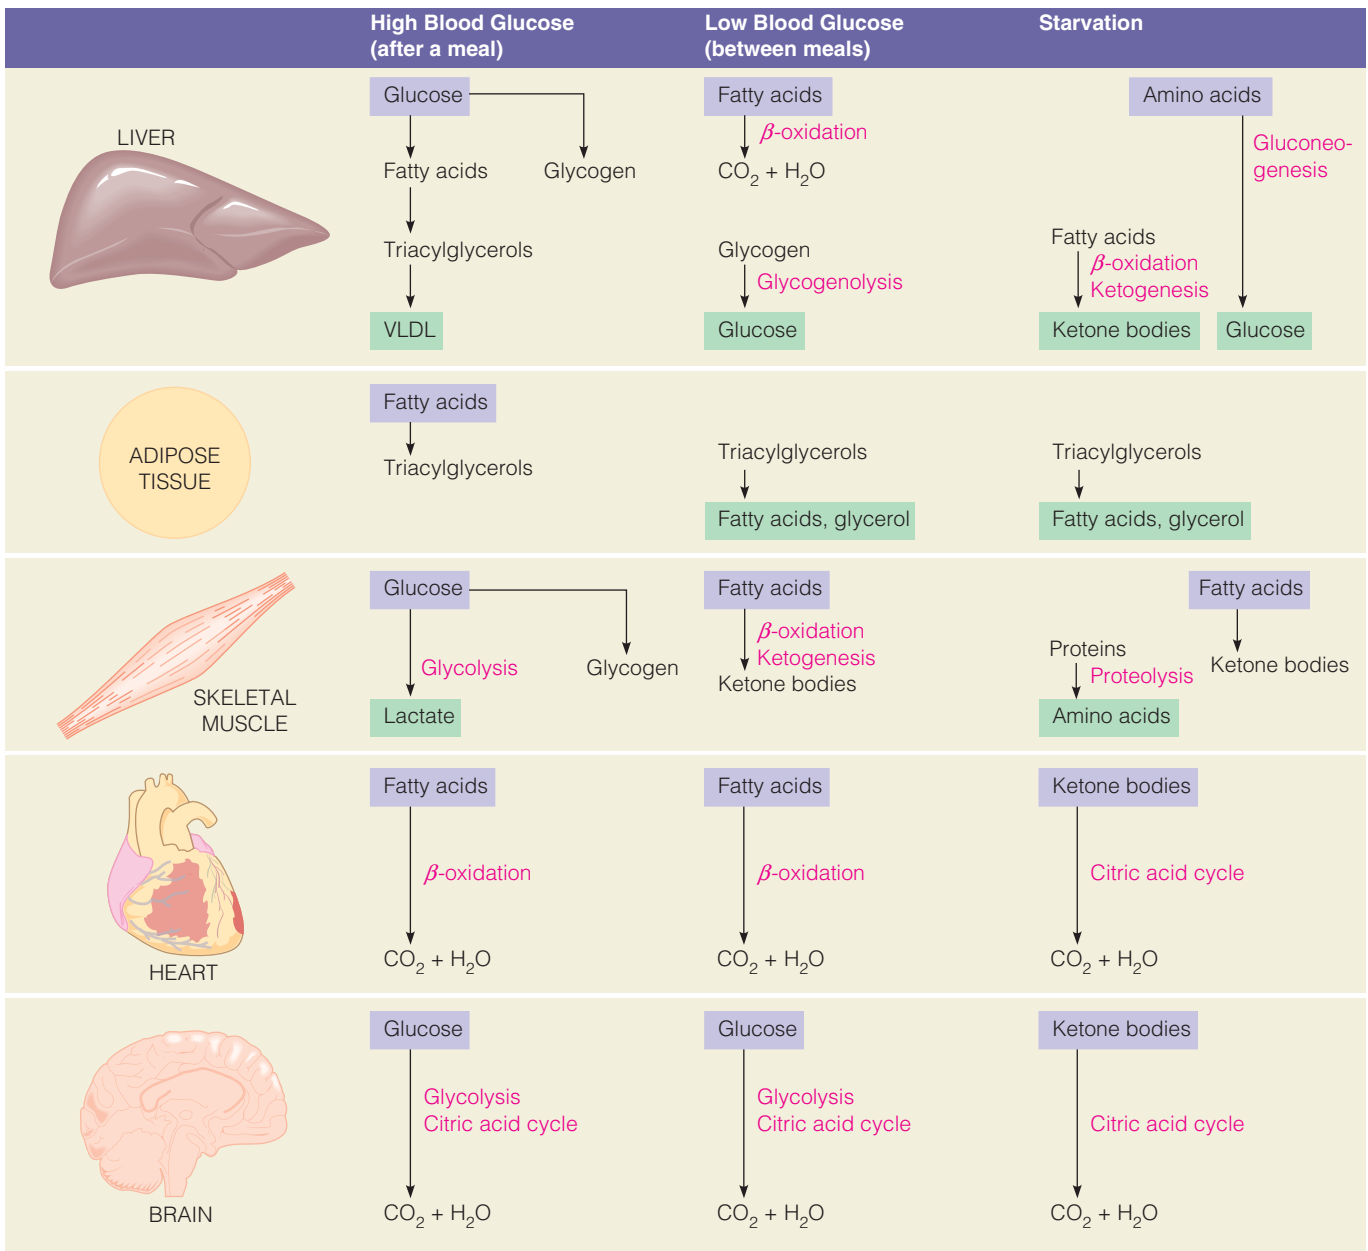

FIGURE 18.11

Major events in the storage, retrieval, and use of fuels in the fed and unfed states and in early starvation. Purple indicates fuels imported into the tissue; green indicates fuels exported from tissue.

maintained near 4.4 mM, the organism adapts metabolically to increase the use of fuels other than carbohydrate, primarily fat.

Before we discuss the metabolic adjustments involved, let us consider the other major energy stores: about 565,000 kJ as triacylglycerol, largely in adipose tissue, and 100,000 kJ as mobilizable proteins, largely in muscle. These stores provide sufficient energy to permit survival for up to several months. However, use of these stores presents problems. Triacylglycerol mobilization generates metabolic fuel largely in the form of acetyl-CoA, whose further oxidation in the citric acid cycle requires oxaloacetate. Recall from Chapter 14 that oxaloacetate and other citric acid cycle intermediates are used in other metabolic reactions and must be replenished via anaplerotic pathways. The most important of these processes is the pyruvate carboxylase reaction, with most of the pyruvate coming from carbohydrate catabolism. When carbohydrate availability is limited, the resupply of citric acid cycle intermediates is limited, and flux through the cycle may be reduced.

Metabolic adaptations promote alternative fuel use during starvation so that glucose homeostasis is maintained for several weeks.

During carbohydrate limitation, citric acid cycle intermediates can be provided from other sources. For example, the glycerol released from lipolysis can be used, but it is not produced in amounts adequate to maintain levels of citric acid cycle intermediates. Alternatively, these intermediates can be produced from protein catabolism and transamination. However, this process is energetically wasteful and has the undesirable effect of wasting the muscle and weakening the fasting subject. Nevertheless, proteolysis is accelerated during the first few days of starvation because amino acids for protein synthesis are not present in sufficient amounts to counterbalance protein breakdown, which continues at normal rates. A major fate of the released amino acids is gluconeogenesis, as the body attempts to cope with the absence of glycogen stores by synthesizing its own glucose. During this time, the liver and muscle are shifting to fatty acids as the dominant fuels for their own use.

Meanwhile, the increased use of carbon for gluconeogenesis diminishes the amount of oxaloacetate available to combine with acetyl-CoA in the citric acid cycle. Because fat breakdown has been activated, both acetyl-CoA and reduced electron carriers accumulate in the liver to the point that the acetyl-CoA cannot all be oxidized, and ketone bodies begin to accumulate. Accumulation of acetoacetate and β -hydroxybutyrate increases flux through the reactions that catabolize these ketone bodies. Thus, the brain adapts to reduced glucose levels by increasing the use of ketone bodies as alternative energy substrates. This trend continues for the duration of starvation. On the third day, the brain derives about one-third of its energy needs from ketone bodies; by day 40, that usage has increased to two-thirds. This adaptation reduces the need for gluconeogenesis and spares the mobilization of muscle protein. In fact, the loss of muscle protein *decreases* by about four-fold late in starvation—from about 75 grams consumed per day on day 3 to about 20 grams per day on day 40. The metabolic changes accompanying starvation compromise the organism's abilities to respond to further stresses, such as extreme cold or infection. However, the adaptations do allow life to continue for many weeks without food intake, the total period being determined largely by the size of the fat deposits.

Diabetes

In starvation, glucose utilization is abnormally low because of inadequate glucose supplies. In **diabetes mellitus**, glucose utilization is similarly low, but the reason in this case is that the hormonal stimulus to glucose utilization—namely, insulin—is defective. As a result, glucose is actually present in excessive amounts. The consequences of insulin deficiency are comparable to those of starvation in revealing important aspects of interorgan metabolic relationships.

Diabetes is a major public health issue, having reached epidemic proportions in the United States and around the world. It is estimated that more than 12% of the adult population in the United States is afflicted with this disease. Diabetes is not a single disease but rather a family of diseases. **Type 1 diabetes**, formerly called insulin-dependent diabetes, or juvenile diabetes because of its typical early onset, often involves autoimmune destruction of the β cells of the pancreas, which can be caused by various factors, including viral infection. Some forms of type 1 diabetes have a genetic origin. Mutations in insulin structure can render the hormone inactive, and other mutations cause defects in the conversion of preproinsulin or proinsulin to the active hormone (see Chapter 5). Either way, type 1 diabetes is characterized by insulin deficiency, and can be treated by administration of insulin. **Type 2 diabetes**, formerly called adult-onset diabetes, obesity-related diabetes, or non-insulin-dependent diabetes mellitus, is characterized by insulin resistance—patients cannot respond to therapeutic doses of insulin. Type 2 diabetes accounts for more than 95% of people with diabetes.

Diabetes results either from insulin deficiency or from defects in the insulin response mechanism.

The specific defects that lead to insulin resistance in type 2 diabetes are not known, but several clues are beginning to shed some light on the disease. The first

is that most people with type 2 diabetes are also obese. In fact, obesity is so closely associated with insulin resistance that there must be a mechanistic link. Like diabetes, the prevalence of obesity has increased dramatically in the United States since the 1970s, with 34% of adults classified as obese in 2010. The second clue comes from the close relationship between type 2 diabetes and **metabolic syndrome**. Metabolic syndrome, which afflicts some 50 million Americans, is defined by abdominal obesity, hypertension, high blood sugar, and, most importantly, insulin resistance. These metabolic abnormalities often precede both cardiovascular disease and diabetes. Common to both obesity and metabolic syndrome is excess fuel intake and abnormal accumulation of lipid in “ectopic sites,” primarily liver and skeletal muscle. Excess lipids initially accumulate in adipose cells, increasing their size. Eventually, fuel intake exceeds the storage capacity of adipose tissue, and excess lipids are shunted to ectopic sites. There is growing evidence that this abnormal lipid accumulation causes the insulin resistance by affecting downstream signaling pathways. Two related mechanisms have gained wide support as potential causes of the disease. The **lipid overload** hypothesis states that when fat accumulates in muscle cells, it blocks the insulin signaling pathway that normally stimulates translocation of GLUT4 (the major glucose transporter in muscle) to the plasma membrane (see Figure 18.5). Thus, insulin no longer efficiently stimulates glucose transport, that is, the cell is insulin resistant. The **inflammation** hypothesis states that as adipose cells increase in size with excess lipids, they secrete inflammatory adipokines and cytokines, including TNF- α , interleukins, and resistin. These cytokines bind their receptors in peripheral tissues such as muscle and stimulate an inhibitory phosphorylation of IRS, making it a poor substrate for the insulin receptor tyrosine kinase (see Figure 18.5). Once again, insulin signaling is shut down, and the cell becomes insulin resistant. Thus, although type 2 diabetes has long been characterized by defects in carbohydrate metabolism, abnormal lipid metabolism may be at the root of the disease.

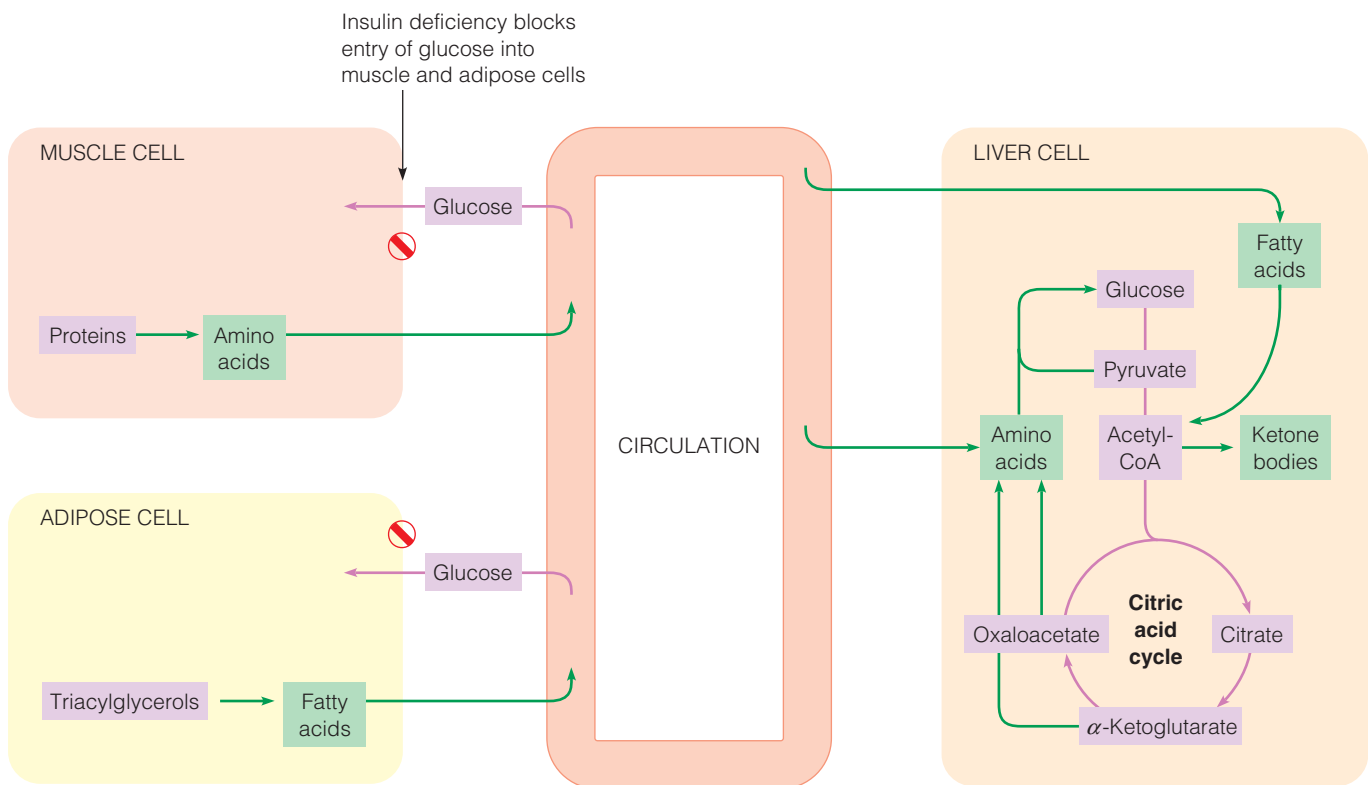

The antidiabetic drugs mentioned in Chapter 17 (the thiazolidinediones; page 750) increase the insulin sensitivity of people with type 2 diabetes by decreasing the expression of inflammatory adipokines that induce insulin resistance and by increasing production of adiponectin, which has insulin-sensitizing effects. These drugs act through PPAR γ , the same transcription factor that PGC-1 α coactivates. PPAR γ is essential for fat cell differentiation and maintenance of normal adipocyte function and is a master regulator of cellular metabolism. Unfortunately, due to the pleiotropic roles of PPAR γ , this class of drugs has serious side effects, including weight gain, osteoporosis, and heart failure. Recent studies have led to a better understanding of the mechanism by which these drugs activate PPAR γ and provide an opportunity to develop new antidiabetic drugs with fewer side effects.

Whatever the cause of the functional insulin deficiency, diabetes can truly be called “starvation in the midst of plenty.” The insufficient production of insulin or the failure of insulin to act normally in promoting glucose utilization, with resultant glucose accumulation in the blood, starves the cells of nutrients and promotes metabolic responses similar to those of fasting (Figure 18.12). Liver cells attempt to generate more glucose by stimulating gluconeogenesis. Most of the substrates come from amino acids, which in turn come largely from degradation of muscle proteins. Glucose cannot be reused for resynthesis of amino acids or of fatty acids, so a person with diabetes may lose weight even while consuming what would normally be adequate calories in the diet.

As cells attempt to generate usable energy sources, triacylglycerol depots are mobilized in response to the abnormally low insulin-to-glucagon ratio. Fatty acid oxidation is elevated, with concomitant generation of acetyl-CoA. Flux through the citric acid cycle may decrease because of the accumulation of reduced electron carriers and/or oxaloacetate limitation. In liver, both effects accelerate ketone body formation, generating increased levels of organic acids in the blood

Two related mechanisms have been proposed as causes of type 2 diabetes: the lipid overload hypothesis and the inflammation hypothesis.

Diabetes can be thought of as “starvation in the midst of plenty” because cells are unable to utilize the glucose that accumulates in the blood.

**FIGURE 18.12**

The metabolic abnormalities in diabetes. The insulin deficiency blocks the uptake of glucose into muscle and adipose tissue and reduces glucose catabolism in all tissues. Proteolysis in muscle and lipolysis in adipose tissue are enhanced. In the liver, gluconeogenesis from amino acids and citric acid cycle intermediates is stimulated as the cells attempt to remedy the perceived lack of usable glucose, and fatty acid oxidation and ketogenesis are also increased. Green indicates pathways activated; pink indicates pathways diminished.

(ketosis). These acids can lower the blood pH from the normal value of 7.4 to 6.8 or lower (ketoacidosis). Decarboxylation of acetoacetate, which is stimulated at low pH, generates acetone, which can be smelled on the breath of patients with severe ketoacidosis. A special danger is that such people may lose consciousness, and this, coupled with a sweet organic odor on the breath, may give the impression that they are intoxicated, when in fact their lives are in jeopardy.

The excessive concentrations of glucose in body fluids generate other metabolic problems, quite different from anything seen in starvation. At blood glucose levels above 10 mM, the kidney can no longer reabsorb all of the glucose out of the blood filtrate, and glucose is spilled into the urine, sometimes in amounts approaching 100 grams per day. In fact, the Latin name *diabetes mellitus* literally means “honey-sweet urine.” Glucose excretion creates an osmotic load, which causes large amounts of water to be excreted as well, and under these conditions the kidney cannot reabsorb most of this water. In fact, the earliest indications of diabetes are often frequent and excessive urination, coupled with excessive thirst. Long before biochemistry was a science, the loss of nutrients, excessive urination, and breakdown of fat and protein were recognized as hallmarks of diabetes. As early as the first century A.D., diabetes was described as “the flesh and bones running together into urine.” It took another 1800 years or so before Israel Kleiner in New York, and Frederick Banting, Charles Best, James Collip, and John Macleod in Toronto discovered that extracts of dog pancreas possessed the ability to lower glucose levels and restore health to children and young adults suffering from diabetes. These studies culminated in the identification of insulin as the active component in 1922.

In type 1 diabetes, the metabolic imbalance is usually more severe and difficult to control than in the milder and more common type 2 diabetes. The latter can often be controlled by exercise and dietary restriction of carbohydrate, whereas treatment for type 1 diabetes involves daily self-injection of insulin. For many years this insulin was purified from bovine pancreas, and its high cost, coupled

with occasional problems resulting from the minor structural differences between human and bovine insulin, led the fledgling biotechnology industry to attempt to produce human insulin through recombinant DNA techniques. In the late 1970s the gene for human insulin was cloned into *E. coli* in a form that allowed it to be expressed, and in 1982 cloned human insulin became the first recombinant DNA product to be approved for human use.

SUMMARY

Each organ or tissue of a multicellular organism has a distinctive profile of metabolic activities that allow it to serve its specialized functions. Remote tissues must remain in constant communication to maintain homeostasis. In vertebrates the most essential element of this homeostasis is maintenance of constant blood glucose levels, primarily for proper brain function. The actions of three hormones—insulin, glucagon, and epinephrine—play the dominant roles in contributing to glucose homeostasis. Insulin signals the fed state and promotes glucose utilization and synthesis of energy storage compounds. Glucagon acts primarily upon liver cells, increasing blood glucose by several mechanisms involving cyclic AMP. Epinephrine has similar effects on muscle cells. Energy homeostasis, maintaining the balance of fuel intake with the metabolism and storage of nutrients to meet energy needs, is coordinated by a complex intracellular regulatory system. Two protein kinases, AMPK and mTOR, play central roles in orchestrating the metabolic activity of mammalian cells. The sirtuins, a highly conserved family of NAD⁺-dependent protein deacetylases, act as metabolic sensors of the cellular redox state. The response to metabolic stresses such as starvation and diabetes reveals the interorgan and hormonal relationships that integrate fuel metabolism in mammals.

PROBLEMS

- Marathon runners preparing for a race engage in “carb loading” to maximize their carbohydrate reserves. This involves eating large quantities of starchy foods. Why is starch preferable to candy or sugar-rich foods?
- Supposing that an average human consumes energy at the rate of 1500 kcal/day at rest and that long-distance running consumes energy at 10 times that rate, how long would the glycogen reserves last during a marathon run? Recall that 1 kcal is equivalent to 4.183 kJ.
- What proportion of the total energy consumption supports brain function in an average resting human? What proportion in a human running in a marathon?
- Proteolysis increases during the early phases of fasting, but later it decreases as the body adapts to using alternative energy sources. Given that feedback control mechanisms have not been described for intracellular proteases, how might you explain these apparent changes in protease activity?
- Glucose has been found to react nonenzymatically with hemoglobin, through Schiff base formation between C-1 of glucose and the amino termini of the β chains. How might this finding be applied in monitoring diabetic patients?
- Ketone bodies are exported from liver for use by other tissues. Because many tissues can synthesize ketone bodies, what enzymatic property of liver might contribute to its special ability to export these compounds?
- Adipose tissue cannot resynthesize triacylglycerols from glycerol released during lipolysis (fat breakdown). Why not? Describe the metabolic route that is used to generate a glycerol compound for triacylglycerol synthesis.
- (a) Briefly describe the relationship between intracellular malonyl-CoA levels in the liver and the control of ketogenesis.
(b) Describe how the action of glucokinase helps the liver to buffer the level of blood glucose.
- The action of glucagon on liver cells leads to inhibition of pyruvate kinase. What is the most probable mechanism for this effect?

CHAPTER 19

Lipid Metabolism II: Membrane Lipids, Steroids, Isoprenoids, and Eicosanoids

Chapter 17 was concerned primarily with energetic aspects of lipid metabolism—synthesis and oxidation of fatty acids, interorgan transport of lipoproteins, and metabolism of triacylglycerols. In addition to their roles in energy storage, lipids function as membrane components and as biological regulators. Our attention now shifts to the roles played by these more complex lipids, as well as pathways for their synthesis and degradation. The cell biology of some of these processes is schematized in Figure 19.1.

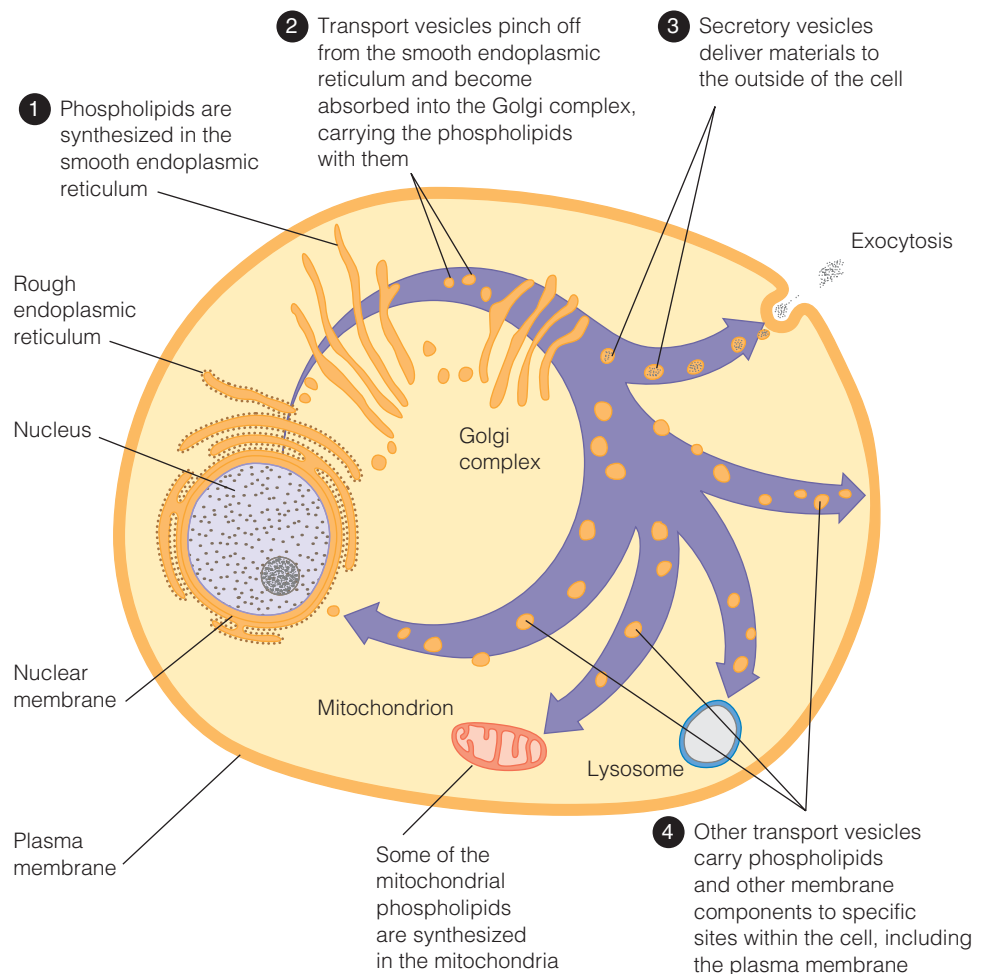

This chapter focuses on the following major classes: *glycerophospholipids* (also called *phosphoglycerides*), which are primarily membrane components but which also play some specialized regulatory roles; *sphingolipids*, which in animals are found abundantly in nervous tissue; *steroids* and other *isoprenoid* compounds, which function as hormones, vitamins, and membrane constituents; and the *eicosanoids*, a class of biological regulators synthesized from arachidonic acid. Two major topics involving lipids and regulation are discussed later in this book: the actions of steroid hormones (in Chapters 23 and 27) and the second-messenger regulatory role of inositol phospholipids (in Chapter 23).

Metabolism of Glycerophospholipids

The most abundant phospholipids are those derived from glycerol. These **glycerophospholipids** are found primarily as components of membranes. Membrane phospholipids are also metabolic precursors to various regulatory elements of signal transduction pathways. In animals, phospholipids also participate in the transport of triacylglycerols and cholesterol, as discussed in Chapter 17, by forming the surface of lipoproteins. In addition, phospholipids play specific roles in processes as diverse as blood clotting and lung functioning. Pathways of glycerophospholipid synthesis are outlined in Figure 19.2 and are presented in more detail in the following sections. The major membrane lipids other than glycerophospholipids are the sphingolipids.

FIGURE 19.1

Intracellular synthesis and transport of membrane phospholipids.

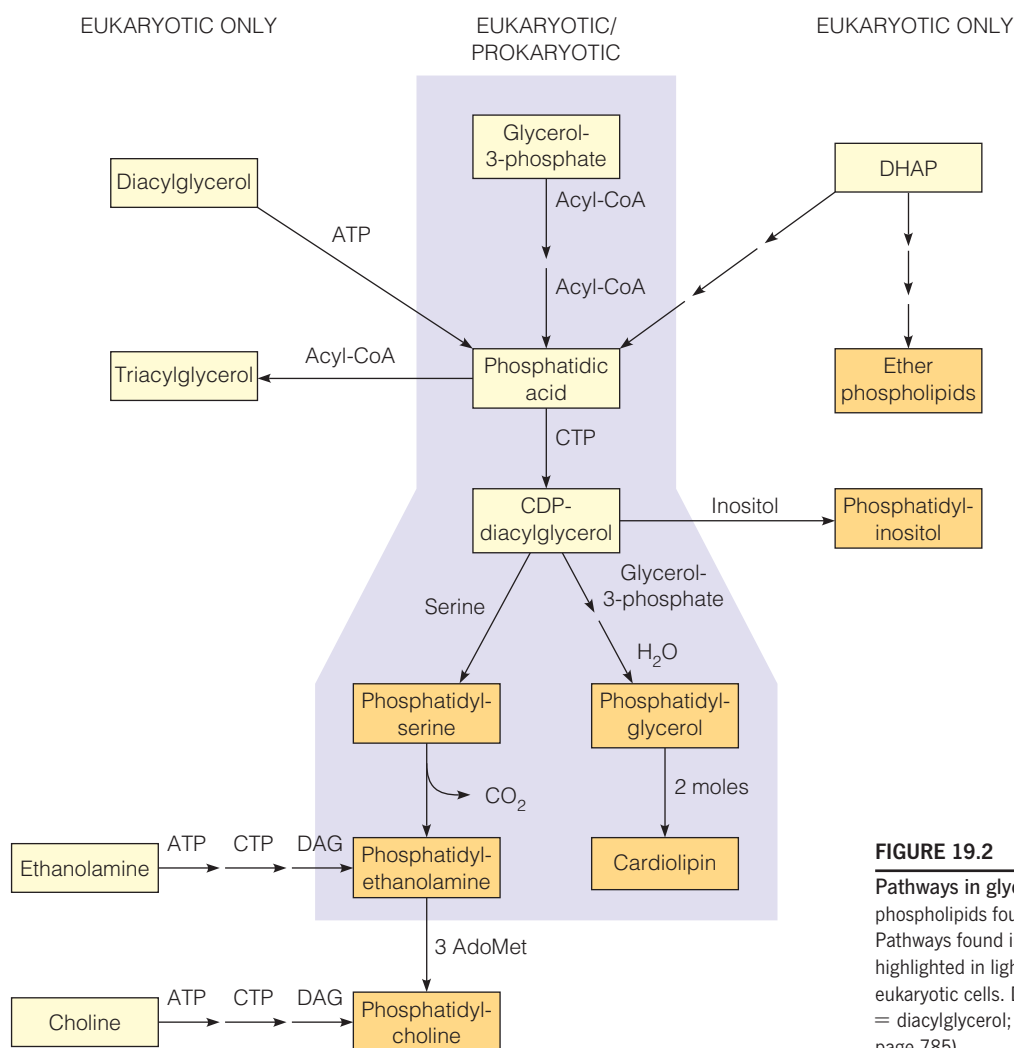

Biosynthesis of Glycerophospholipids in Bacteria

We begin our discussion of phospholipid metabolism in the prokaryotic kingdom, partly because of the relative simplicity of the biological systems involved. In bacteria, phospholipids may constitute 10% of the dry weight of the cell, yet their only known role is as components of membranes. The membranes of *E. coli* contain only three phospholipids in significant amounts. Phosphatidylethanolamine (PE) constitutes 70%–80% of the total phospholipid, with phosphatidylglycerol (PG) and cardiolipin (CL) making up the remaining 20%–30%. The relative amounts of PG and CL depend on growth conditions, with PG more abundant in logarithmically growing cells and CL more abundant in stationary phase cells. The fatty acid content of these lipids is also simple, with three dominating—palmitate (16:0), palmitoleate (16:1cΔ9), and *cis*-vaccenate (18:1cΔ11).

Because they are easy to grow in large quantities, bacteria provide abundant sources for large-scale isolation of the enzymes involved in lipid metabolism. Much of our earliest information on both phospholipid synthesis and fatty acid synthesis came from studies with *E. coli*. Whereas the fatty acid chains are synthesized by a soluble type II fatty acid synthase (Chapter 17), all of the enzymes involved in phospholipid synthesis are bound to the plasma (cytoplasmic) membrane. More recently, studies on bacterial mutants have offered insight into control of membrane lipid synthesis and, in particular, the mechanisms used for temperature regulation of the fatty acid content of these lipids. Recall from Chapter 10 that, when grown at low temperature, bacteria increase the unsaturation of their membrane fatty acids to maintain optimal fluidity. One of the most intriguing areas of contemporary lipid biochemistry involves genetic analysis of mechanisms that maintain the optimal pattern of unsaturation at a given temperature.

E. coli membranes contain just three different phospholipids, which contain predominantly three different fatty acids.

FIGURE 19.2

Pathways in glycerophospholipid biosynthesis. The major phospholipids found in membranes are shown in orange. Pathways found in both prokaryotic and eukaryotic cells are highlighted in light purple. Other reactions are confined to eukaryotic cells. DHAP = dihydroxyacetone phosphate; DAG = diacylglycerol; AdoMet = S-adenosylmethionine (see page 785).

Biosynthesis of Phosphatidic Acid and Polar Head Groups

In Chapter 17 we described the synthesis of phosphatidic acid (diacylglycerol-3-phosphate), starting from *L*-*sn*-glycerol-3-phosphate (refer to Chapter 10, page 365 for description of the stereospecific numbering system). As shown in Figure 19.2, phosphatidic acid represents a branch point between the syntheses of triacylglycerols and phospholipids. The energy cofactor for phospholipid biosynthesis is cytidine triphosphate (CTP), whose role is similar to that of UTP in polysaccharide synthesis (Chapter 9).

Recall that phosphatidic acid is synthesized by two successive acylations of glycerol-3-phosphate. In bacteria these 16- to 18-carbon fatty acyl groups are borne on acyl carrier protein (ACP) (Figure 19.3), the products of fatty acid synthase (Chapter 17). Two different glycerol phosphate acyltransferase enzymes are involved, as revealed in part by their differences in specificity for fatty acyl-ACPs: About 90% of the acyl groups esterified at position 1 are saturated, whereas 90% at position 2 are unsaturated. Phosphatidic acid next becomes metabolically activated by reaction with CTP. Mechanistically, this reaction is reminiscent of the activation of glucose-1-phosphate by UTP to yield UDP-glucose (Chapter 13, page 565). The phosphoryl oxygen of phosphatidic acid attacks the α phosphorus atom of CTP to form **CDP-diacylglycerol** and pyrophosphate. The ΔG° of this phosphoanhydride exchange is nearly zero. However, the reaction is pulled to completion by the highly exergonic hydrolysis of the PP_i .

CDP-diacylglycerol is now activated (CMP is a good leaving group) for nucleophilic attack by the various polar head groups. In one reaction sequence

Phosphatidic acid is a branch metabolite between triacylglycerol biosynthesis and phospholipid biosynthesis.

Metabolic activation of phospholipid precursors is carried out by reaction with CTP.

**FIGURE 19.3**

Synthesis of phosphatidic acid and CDP-diacylglycerol in bacteria. Two separate acyltransferases are involved in phosphatidic acid synthesis (reactions 1 and 2). The reaction of CTP with phosphatidic acid is catalyzed by CDP-diacylglycerol synthase (reaction 3). This reaction is drawn to the right by the enzymatic hydrolysis of pyrophosphate, catalyzed by the ubiquitous pyrophosphatase (reaction 4).

(Figure 19.4, left side), CMP is exchanged for serine, giving **phosphatidylserine**, which immediately undergoes decarboxylation to **phosphatidylethanolamine**. Consequently, phosphatidylserine does not accumulate in bacteria. In the other pathway (Figure 19.4, right side) the C1 hydroxyl of glycerol-3-phosphate attacks the highlighted phosphorus atom of CDP-diacylglycerol, eliminating CMP to form phosphatidylglycerol-3-phosphate, followed by a phosphatase reaction to give phosphatidylglycerol. Reaction with another mole of phosphatidylglycerol

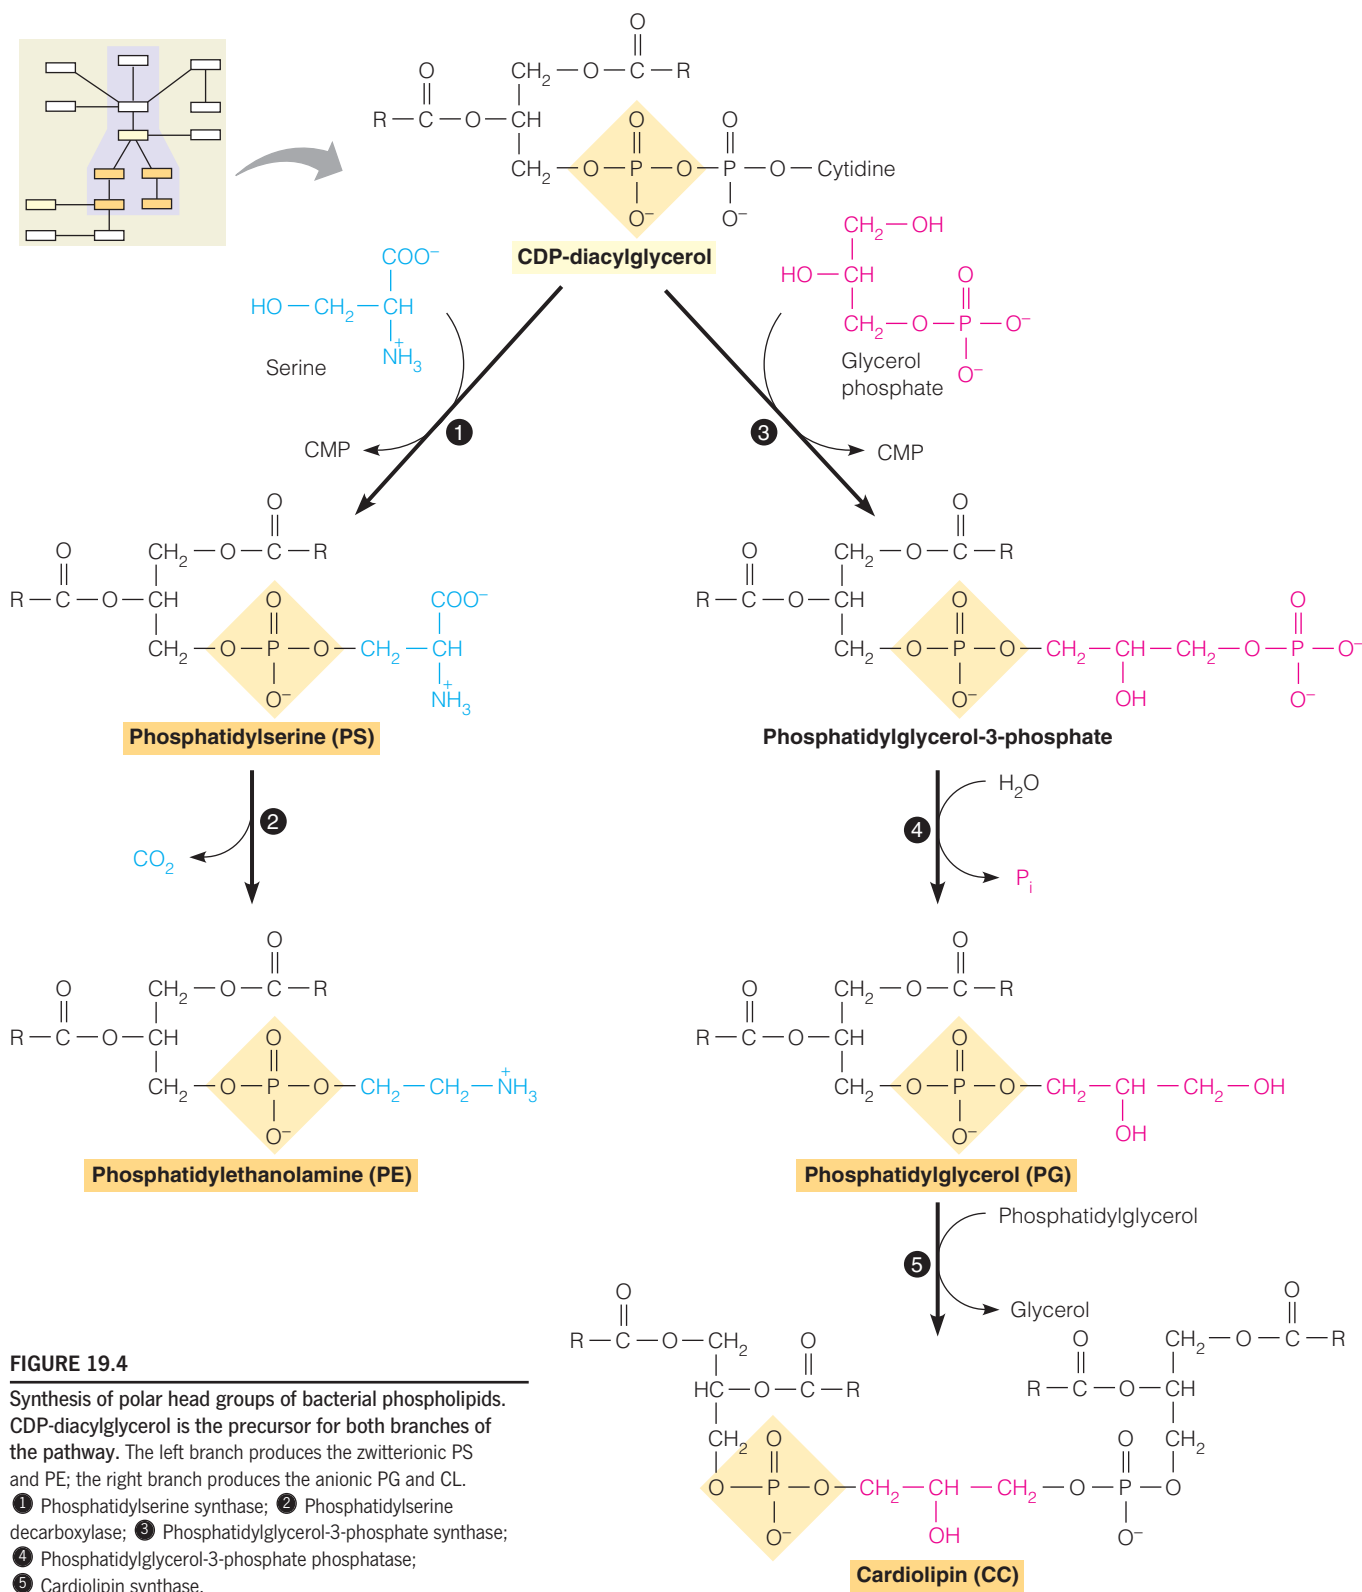

FIGURE 19.4

Synthesis of polar head groups of bacterial phospholipids. CDP-diacylglycerol is the precursor for both branches of the pathway. The left branch produces the zwitterionic PS and PE; the right branch produces the anionic PG and CL.

- ④ Phosphatidylglycerol-3-phosphate phosphatase;
- ⑤ Cardiolipin synthase.

gives **diphosphatidylglycerol**, or **cardiolipin**. In this reaction, the phosphoryl group of one of the phosphatidylglycerol molecules undergoes nucleophilic attack by the glycerol C1 OH group of the other, displacing a molecule of glycerol. Cardiolipin, which is particularly abundant in the membranes of spirochetes (motile chemoheterotrophic bacteria), is the principal antigenic component measured in the Wassermann test, formerly used for diagnosis of syphilis. In *E. coli*, phosphatidylglycerol and cardiolipin play specific roles in activating the protein product of the *dnaA* gene, involved in initiation of DNA replication at a membrane site (Chapter 25, page 1063).

Not shown in Figure 19.2 is the fact that phosphatidylethanolamine and phosphatidylglycerol both turn over relatively rapidly in bacterial membranes. The glycerol-1-P head group of phosphatidylglycerol is transferred to membrane-derived oligosaccharides, which function in the periplasmic space to regulate osmotic pressure. The other product is diacylglycerol, which can be converted to phosphatidic acid by diacylglycerol kinase. Phosphatidylethanolamine turns over by transfer of the fatty acid at its 1-position to membrane lipoproteins in the periplasm. The other product of this reaction is 2-acylglycerolphosphoethanolamine, which can be re-acylated to form phosphatidylethanolamine.

Control of Phospholipid Synthesis in Prokaryotes

The genetic analysis of *E. coli* phospholipid metabolism is fairly advanced, in the sense that the structural genes for most of the enzymes involved have been identified, mutant phenotypes have been analyzed in detail, and all of the genes have been cloned and sequenced. However, we still know rather little about how phospholipid synthesis is regulated. Current evidence suggests that the rate of phospholipid synthesis is controlled primarily at the level of fatty acid synthesis by the long-chain acyl-ACP end products. Acyl-ACPs inhibit both the production of malonyl-CoA by acetyl-CoA carboxylase and the elongation of fatty acyl-ACPs by fatty acid synthase. Because fatty acids in bacteria are used primarily for membrane synthesis, and not as energy substrates, it makes good metabolic sense to limit the synthesis of phospholipids at the earliest steps committed to membrane formation. Furthermore, because the biophysical properties of membranes are determined in large part by the composition of the fatty acids that are produced *de novo*, control at the level of fatty acid synthesis is important for maintaining membrane homeostasis. Recall that the two branches of phospholipid synthesis compete for a common pool of CDP-diacylglycerol (Figure 19.4). Control of the phospholipid polar head group composition is determined largely by the activity of phosphatidylserine synthase, catalyzing the first reaction of the left branch. This enzyme (PssA in Figure 19.5) is a peripheral membrane protein that binds to and is activated by the anionic phospholipids phosphatidylglycerol and cardiolipin, both products of the right branch. Activated phosphatidylserine synthase increases the synthesis of

FIGURE 19.5

phosphatidylserine, which is converted to phosphatidylethanolamine by phosphatidylserine decarboxylase (Psd in Figure 19.5). Once the proportion of phosphatidylethanolamine in the bilayer reaches a certain threshold, PssA dissociates from the membrane and its activity decreases, allowing the right branch of the pathway to catch up [catalyzed by phosphatidylglycerol-3-phosphate synthase (PgsA), phosphatidylglycerol-3-phosphate phosphatase (PgpP), and cardiolipin synthase].

Glycerophospholipid Metabolism in Eukaryotes

Most eukaryotic cells contain six classes of glycerophospholipids—the same PE, PG, and CL found in bacteria, plus phosphatidylserine (PS), phosphatidylcholine (PC), and phosphatidylinositol (PI). As outlined in Figure 19.2, phosphatidic acid serves as a major precursor to all six compounds, and the pathways to PE, PS, PG, and CL are virtually identical to those already presented for bacteria. However, eukaryotic cells possess additional pathways that start with the free base—choline and ethanolamine, respectively, leading to PC and PE. These pathways are also outlined in Figure 19.2 and elaborated upon in a following section.

Synthesis of Phosphatidic Acid

Eukaryotes display three biosynthetic routes to phosphatidic acid (Figure 19.6). The major pathway, starting with glycerol-3-phosphate, is similar to that used

FIGURE 19.6

Three routes to phosphatidic acid in eukaryotes. All eukaryotic cells possess the pathway starting from glycerol-3-phosphate (magenta pathway). Yeast and mammals can also synthesize phosphatidic acid starting from DHAP (blue pathway). In addition, eukaryotes can salvage diacylglycerol released from turnover of triacylglycerol or phospholipids (green pathway).

In eukaryotes, phosphatidic acid has three different origins: glycerol-3-phosphate, dihydroxyacetone phosphate, and diacylglycerol.

by bacteria (see Figure 19.3), except that the acyltransferases use acyl-CoAs as substrates instead of acyl-ACPs. These acyltransferases are located in the endoplasmic reticulum. Yeast and mammals also possess a second pathway that starts with dihydroxyacetone phosphate (DHAP), which accepts a fatty acyl moiety at position 1 from an acyl-CoA, followed by reduction to 1-acylglycerol-3-phosphate and a second acylation. The enzymes that catalyze this pathway are located in mitochondria and peroxisomes, as well as endoplasmic reticulum.

The third route simply involves phosphorylation by a specific kinase of diacylglycerol, which arises from metabolic turnover of phospholipids (see page 748).

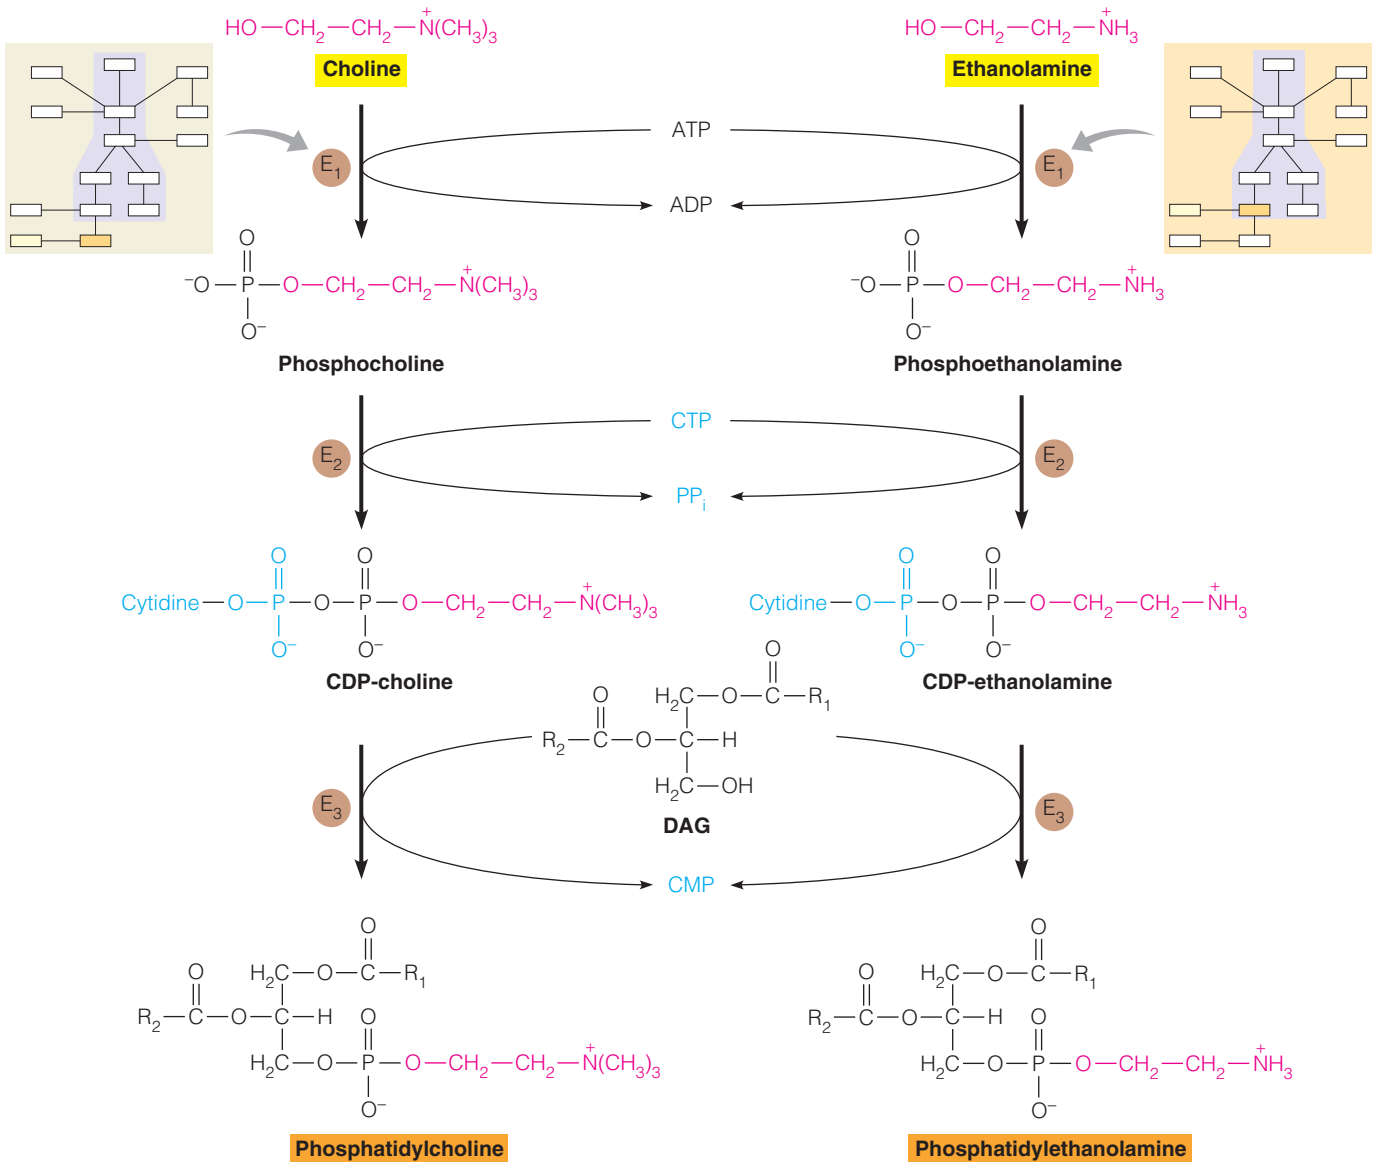

FIGURE 19.7

Synthesis of phosphatidylcholine and phosphatidylethanolamine in mammals. E_1 = choline kinase or ethanolamine kinase; E_2 = CTP:phosphocholine cytidyltransferase or CTP:phosphoethanolamine cytidyltransferase; E_3 = CDP-choline:1,2-diacylglycerol choline phosphotransferase or CDP-ethanolamine:1,2-diacylglycerol ethanolamine phosphotransferase.

Regardless of which route is used, phosphatidic acid is converted to CDP-diacylglycerol as previously described for bacteria. CDP-diacylglycerol in turn serves as precursor to PS, PE, PG, and CL. Another set of pathways starts from free bases, as described in the next section.

Pathways to Phosphatidylcholine and Phosphatidylethanolamine

The most abundant phospholipids in most eukaryotic cells are phosphatidylcholine and phosphatidylethanolamine. Both can be synthesized from phosphatidylserine or through alternative pathways that start with free choline or ethanolamine, respectively. Because choline and ethanolamine arise largely through the turnover of preexisting phospholipids, the latter pathways can be considered “salvage pathways” for reutilization of these breakdown products. The significance of reutilizing choline lies in the fact that the three methyl groups of choline are derived from the amino acid methionine. As we discuss in Chapter 20, methionine is nutritionally essential for many animals, also making essential the reuse of scarce metabolites such as choline. In fact, choline itself is an essential component of most animal diets.

The pathway for use of preformed choline or ethanolamine, which predominates in most animal cells, is summarized in Figure 19.7. The chemical strategy for forming the phosphodiester linkage between the polar head group and the diacylglycerol backbone is similar to that described for bacterial phospholipid synthesis (Figure 19.4), except that it is the head group that is activated rather than the diacylglycerol moiety. Choline or ethanolamine is phosphorylated, and the resultant **phosphocholine** or **phosphoethanolamine** is metabolically activated by reaction with CTP, to give the corresponding CDP derivatives (Figure 19.8). The phosphoryl group of the activated CDP-choline or CDP-ethanolamine then undergoes nucleophilic attack by the C3 OH group of diacylglycerol, displacing CMP to yield the corresponding phospholipid. The first enzyme in the pathway, **choline kinase** (E_1 in Figure 19.7) can phosphorylate both choline and ethanolamine. However, mammals also possess a specific **ethanolamine kinase**. The kinases are cytosolic enzymes, whereas the enzymes catalyzing the second step, **CTP:phosphocholine cytidyltransferase** and **CTP:phosphoethanolamine cytidyltransferase** (E_2), are distributed between cytosolic and endoplasmic reticulum fractions. These cytidyltransferases catalyze the rate-limiting step of this pathway. The last enzyme, **CDP-choline:1, 2-diacylglycerol choline phosphotransferase** or **CDP-ethanolamine:1, 2-diacylglycerol ethanolamine phosphotransferase** (E_3), is membrane-bound in the endoplasmic reticulum. Recent evidence suggests that only the membrane-bound form of the phosphocholine cytidyltransferase (E_2) is active and that the rate of phosphatidylcholine synthesis is controlled in part by translocation of this enzyme between cytosolic and membranous forms analogous to the regulation of phosphatidylserine synthase in bacteria (Figure 19.5). The enzyme has higher affinity for membranes with anionic head groups, which are thus depleted of phosphatidylcholine—membrane binding activates this rate-limiting enzyme to increase PC production. The physiological signals that regulate translocation of CTP:phosphocholine cytidyltransferase to cell membranes are not yet known. This enzyme is an example of an **amphitropic** protein, one that can exist in two alternative states: soluble and membrane-bound.

The second pathway to PE and PC begins with the conversion of phosphatidylserine (PS) to PE, which is catalyzed by either of two different enzymes. **Phosphatidylserine decarboxylase** is a mitochondrial enzyme that, like the corresponding bacterial enzyme, decarboxylates phosphatidylserine to phosphatidylethanolamine. The second enzyme is a calcium-activated transferase, **phosphatidylethanolamine serinetransferase**, which exchanges free ethanolamine

Salvage pathways to phospholipids, starting with choline or ethanolamine, are quantitatively important in eukaryotic cells.

FIGURE 19.8

Metabolic activation of phosphocholine. CTP:phosphocholine cytidyltransferase (E_2 in Figure 19.7) catalyzes nucleophilic attack at the α -phosphate of CTP by a phosphoryl oxygen of phosphocholine, displacing the β, γ -phosphates (pyrophosphate) of CTP, forming CDP-choline.

The Journal of Biological Chemistry 284:33535–33548, J. Lee, J. Johnson, Z. Ding, M. Paetzel, and R. B. Cornell, Crystal structure of a mammalian CTP: Phosphocholine cytidyltransferase catalytic domain reveals novel active site residues within a highly conserved nucleotidyltransferase fold. for the serine moiety of phosphatidylserine, yielding phosphatidylethanolamine and serine.

PE serinetransferase is found in endoplasmic reticulum and the Golgi complex. Mammals also possess a **phosphatidylcholine serinetransferase**, which exchanges free serine for the choline moiety of PC, yielding phosphatidylserine and choline. Both of these serinetransferases are readily reversible.

S-Adenosyl-L-methionine is the methyl group donor in synthesis of phosphatidylcholine and numerous other methylated metabolites.

However formed, phosphatidylethanolamine then undergoes three successive methylations, all catalyzed by phosphatidylethanolamine *N*-methyltransferase (PEMT), to give phosphatidylcholine. In animals this pathway occurs primarily in the liver. The methyl group donor for these reactions is an activated derivative of methionine, **S-adenosyl-L-methionine** (AdoMet). The product of methyl group transfer is **S-adenosyl-L-homocysteine** (AdoHcy). As we shall see throughout the remainder of this book, AdoMet is a “universal” methyl donor, involved in numerous methyl group transfer reactions in lipid, protein, amino acid, and nucleic acid metabolism. AdoMet has an unstable **sulfonium ion**, which has a high thermodynamic tendency to transfer its strongly electrophilic methyl group to nucleophiles and lose its charge. Note that the sulfonium ion is a chiral center—the sulfur has a pyramidal configuration, with the lone electron pair forming the absent 4th ligand. All known AdoMet-dependent methyltransferases are specific for the *S* isomer (shown below).

AdoMet is formed from methionine and ATP in an unusual reaction catalyzed by methionine adenosyltransferase, in which ATP is cleaved to yield inorganic triphosphate (PPP_i) plus an adenosyl moiety linked directly via the ribose C5 to the methionine sulfur. The triphosphate is hydrolyzed by the enzyme to pyrophosphate (PP_i) and orthophosphate (P_i), drawing the reaction to completion.

As might be expected from the critical role glycerophospholipids play in membrane synthesis and integrity, these biosynthetic pathways are essential in mammals. Disruption of the genes encoding these enzymes in mice is usually lethal during embryogenesis. The exceptions are for those enzymes that are encoded by multiple genes, or where alternative pathways exist. Thus, deficiency of PEMT can be compensated by the CDP-choline pathway (Figure 19.7). On the other hand, CTP:phosphoethanolamine cytidyltransferase (Figure 19.7, E₂) and phosphatidylserine decarboxylase (page 784) cannot substitute for one another, suggesting that the PE synthesized from these two pathways is compartmentalized differently. In fact, the serinetransferases, PS decarboxylase, and PEMT enzymes are all localized to a specialized domain of the endoplasmic reticulum that is closely associated with the outer mitochondrial membrane, providing a mechanism for the compartmentalization of this pathway from serine to phosphatidylcholine.

Redistribution of Phospholipid Fatty Acids: Lung Surfactant and Phospholipases

Having described the biosynthesis of polar head groups, let us now focus on the fatty acid constituents of phospholipids, after which we will return to one more important polar head group—the inositol of phosphoinositides. A variety of isotope labeling experiments show that phospholipids, even after insertion into membranes, are not metabolically inert. Specifically, the fatty acyl chains can change in response to varying environmental conditions or needs. Recall that saturated and monounsaturated fatty acids are usually found at the *sn*-1 position, whereas polyunsaturated acyl groups are usually esterified at the *sn*-2 position. This fatty acyl asymmetry is generated by rapid turnover of the *sn*-2-acyl moiety in a remodeling pathway originally described by William Lands in 1958. This process (termed the Lands' cycle) involves the concerted and coordinated actions of **phospholipase A₂** and a family of acyltransferases specific for **lysophospholipids**, phospholipids lacking an acyl chain at the *sn*-2 position. Lysophospholipids derive their name from the fact that they are powerful detergents, able to solubilize membranes and hence cause cells to lyse; erythrocytes are particularly susceptible to this action (hemolysis). Phospholipase A₂ is one of a class of four enzymes that hydrolyze specific bonds in phospholipids; the others are phospholipases A₁, C, and D (Figure 19.9). One form of phospholipase A₂ comes from snake venom, which has the ability to cause hemolysis. The release of one fatty acyl chain from phosphatidylcholine yields 1-acylglycerophosphorylcholine, more commonly known as **lysolecithin** (phosphatidylcholine itself is commonly called lecithin).

Fatty acid chains in phospholipids are remodeled through the concerted actions of phospholipase A₂ and specific lysophospholipid acyltransferases to meet the needs of the organism.

FIGURE 19.9
Specificities of phospholipases A₁, A₂, C, and D.

FIGURE 19.10

Structure of phospholipase A_2 , an enzyme that metabolizes membrane phospholipids. Catabolism of phospholipids at membrane–water interfaces is important both in modification of membrane structure and as a source of second messengers and other regulators. The crystal structure of the porcine pancreas phospholipase A_2 (PDB ID 2B01) reveals the catalytic triad (D99–H48–water) and the active site Ca^{2+} ion, liganded to a second water molecule (W2). Hydrogen bonds and Ca^{2+} liganding interactions are indicated by thin white lines.

Several remodeling acyltransferases are now known that are specific for either lysolecithin, lysophosphatidylethanolamine, lysophosphatidylcardiolipin, or lysophosphatidylglycerol. Each enzyme also has a unique selectivity for the acyl-CoA chain it transfers to the *sn*-2 position of the lysophospholipid. This remodeling process is particularly important during biosynthesis of the phospholipid component of **pulmonary surfactant**, a lipid- and protein-containing substance that is secreted by alveolar cells in the lung and, by maintaining high surface tension, prevents collapse of the alveoli when air is expelled. Pulmonary surfactant contains some 50% to 60% **dipalmitoylphosphatidylcholine**, an unusual form of phosphatidylcholine in which saturated palmitoyl chains occupy both positions *sn*-1 and *sn*-2. Infants afflicted with **respiratory distress syndrome** show defects in the metabolism of pulmonary surfactant—deficiencies in either synthesis or secretion of this substance. Phospholipase A_2 first hydrolyzes the original acyl group at the *sn*-2 position to give a lysophosphatidylcholine. Alveolar cells express a specific lysophosphatidylcholine acyltransferase that has a clear preference for saturated fatty acyl-CoAs, especially palmitoyl-CoA, as acyl donor for replacement of the *sn*-2 chain. Synthesis of dipalmitoylphosphatidylcholine in lung tissue is greatly increased after birth, partly as a result of translocation of CTP:phosphocholine cytidyltransferase (E_2 in Figure 19.7) to the endoplasmic reticulum and its consequent activation. Expression of the lysophosphatidylcholine acyltransferase is also increased during the perinatal period to provide the necessary remodeling activity. Because pulmonary surfactant production is not activated until babies reach full term, premature infants are often treated with a surfactant to prevent respiratory distress.

Phospholipases have been useful reagents in studies of both lipid and membrane structures. Structural studies on phospholipase A_2 have been of particular interest, partly because the enzyme is active at a membrane–water interface and serves as a probe of membrane structure, and partly because phospholipase actions lead to prostaglandins (page 813) and to second messengers (see Chapter 23). Phospholipase A_2 uses a catalytic triad similar to that in the serine proteases (Chapter 11), except that a water molecule replaces serine as the attacking nucleophile, and thus no acyl-enzyme intermediate forms in the reaction. As shown for the phospholipase A_2 from pig pancreas (Figure 19.10), the catalytic Asp99 and His 48 are located on adjacent α -helices, in a hydrogen bond network with a water molecule (W1). The active site also contains a catalytically important Ca^{2+} ion, which is liganded to a second water molecule (W2). The structure suggests that W2 is the catalytic water molecule, which is activated by both the Asp–His–W1 catalytic triad and the Ca^{2+} ion for nucleophilic attack on the ester linkage at the *sn*-2 position of the phospholipid. The Ca^{2+} ion is also proposed to stabilize the oxyanion of the tetrahedral reaction intermediate.

Another postulated role for phospholipase A_2 is in repair of damaged membrane phospholipids. As discussed in Chapter 15, fatty acids are susceptible to nonenzymatic attack by oxygen or reactive oxygen species such as superoxide to give fatty acid hydroperoxides. When a membrane phospholipid undergoes peroxidation of a fatty acyl chain, the structure of the membrane is distorted, and the function of the membrane can be affected. Current evidence suggests that phospholipase A_2 can remove these abnormal fatty acids from phospholipids still resident in a lipid bilayer, which leads to replacement of the damaged acyl chains by normal fatty acids.

The simplest possible lysophospholipid is **lysophosphatidic acid**, formed by action of phospholipase A_2 on phosphatidic acid. Lysophosphatidic acid has been identified as a biological signaling agent (see Chapter 23). Its release from activated cells such as platelets stimulates the growth of other cell types, through interaction with specific receptors, evidently as part of the wound-healing process.

Biosynthesis of Other Acylated Glycerophospholipids

The remaining major pathways outlined in Figure 19.2 are for synthesis of phosphatidylserine, phosphatidylglycerol, cardiolipin, and phosphatidylinositol. In yeast the CDP-diacylglycerol pathway to phosphatidylserine predominates. In

Phospholipases play roles in signal transduction and in membrane repair.

animals, phosphatidylserine is synthesized primarily by the calcium-activated exchange between phosphatidylethanolamine and serine (page 784). However, the ultimate source of ethanolamine for this process is not yet known. In animals the synthesis of phosphatidylglycerol, which is largely confined to mitochondria, is identical to the route used in bacteria. However, its conversion to cardiolipin involves CDP-diacylglycerol, rather than a second mole of phosphatidylglycerol, as the second substrate (Figure 19.11).

The biosynthesis of phosphatidylinositol, catalyzed by **phosphatidylinositol synthase**, involves CDP-diacylglycerol and *L*-*myo*-inositol (Figure 19.11). The latter is one of nine possible stereoisomers of hexahydrocyclohexane; it is synthesized

FIGURE 19.11

Biosynthesis of cardiolipin and phosphoinositides in eukaryotes.

Phosphatidylinositol and its phosphorylated derivatives play important roles as precursors of second messengers.

FIGURE 19.12

Biosynthetic route to alkyl ether phospholipids.

from D-glucose-6-phosphate. Phosphatidylinositol undergoes two successive phosphorylations to yield phosphatidylinositol-4-phosphate and phosphatidylinositol-4,5-bisphosphate (PIP₂), both of which are present in small but appreciable amounts. All three of these lipids, which are collectively termed **phosphoinositides**, are enriched in arachidonic acid at position 2. This enrichment evidently occurs via the deacylation–reacylation process we discussed earlier (see page 786).

It has long been known from ³²P labeling studies that the phosphoinositides are in a state of active metabolic flux. They are synthesized and degraded rapidly, particularly in nervous tissue in response to the binding of neurotransmitters. As described in Chapter 18, phosphatidylinositol 3,4,5-trisphosphate (PIP₃) plays an important role as a second messenger in **transmembrane signaling**, the transmission of an extracellular signal to some element of the intracellular metabolic apparatus. Our current understanding of these events is presented in Chapter 23. Another important metabolic role for phosphatidylinositol is its participation in the glycosylphosphatidylinositol (GPI) linkages used to anchor some glycoproteins to the extracellular face of the plasma membrane (Chapter 10).

Ether Phospholipids

Ether lipids contain an alkyl group, rather than an acyl group, linked by an ether bond to one of the oxygen atoms of glycerol. Alkyl and alkenyl phospholipids are widely distributed, but their abundance in tissues varies greatly. For example, consider the **plasmalogens**, or **vinyl ethers**, phospholipids that contain an alkenyl ether at position *sn*-1 of glycerol. These compounds are found in most mammalian membranes, but are particularly abundant in heart, brain, and spermatozoa, where they can account for more than 50% of the membrane phospholipids. Ethanolamine plasmalogens are much more abundant than choline plasmalogens, except in muscle. So far, little is known about the functional significance of this class of lipids. The acid-labile vinyl ether bond is quite susceptible to oxidative damage, and plasmalogens are important targets of reactive oxygen species (ROS; see Chapter 15, page 665). Thus, it has been proposed that plasmalogens protect against oxidative damage, such as lipid peroxidation, by “scavenging” ROS. Plasmalogens may also be important sources of arachidonic acid and docosahexaenoic acid (DHA), released from the *sn*-2 position by the action of phospholipase A₂. Arachidonic acid is the precursor to the eicosanoids (more about these later) and DHA is a polyunsaturated fatty acid (PUFA) with the ability to depress levels of both serum cholesterol and triacylglycerols (Chapter 17). A genetic deficiency of plasmalogen synthesis has serious consequences. Biosynthesis of ether lipids occurs in peroxisomes, organelles that also carry out both β - and α -oxidation pathways (see Chapter 17, page 732). In a rare autosomal recessive disorder called **Zellweger syndrome**, peroxisomes are absent, and plasmalogen synthesis is severely deficient. Individuals with this condition suffer damage to brain, liver, and kidney, before reaching an early death.

The biosynthesis of ether phospholipids (Figure 19.12) begins in the peroxisome with 1-acyldihydroxyacetone phosphate (see Figure 19.6). This undergoes exchange of an alkyl group for the acyl group; the saturated fatty alcohol used in this reaction is derived from NADPH-dependent reduction of the corresponding fatty acyl-CoA. Carbon 2 is then reduced from the keto to the hydroxyl level to give 1-alkylglycerol-3-phosphate. This intermediate moves from the peroxisome to the endoplasmic reticulum, where C2 is acylated. This gives the 1-alkyl analog of phosphatidic acid (last structure in the figure), which is converted to saturated ether phospholipids, or **glyceryl ethers**, by the pathways already presented in Figure 19.2 for phospholipid biosynthesis. The primary route leads to the glyceryl ether of phosphatidylethanolamine; the serine and choline analogs arise from the ethanolamine analog (as on page 784) by base

exchange and methylation, respectively. The synthesis of plasmalogens from glyceryl ethers then involves desaturation of the alkyl group at position *sn*-1 (Figure 19.13). The microsomal enzyme system involved, like that used for desaturation of stearoyl-CoA (see Figure 17.34, page 744), requires O₂, NADH, and cytochrome *b*₅.

An unusual ether lipid, called **platelet-activating factor**, has the structure **1-alkyl-2-acetylglycerophosphocholine**. Physiologically, this compound is perhaps the most potent compound known. At concentrations as low as 1 *picomolar* (10⁻¹² M), it has numerous effects, both in normal physiology and in inflammation reactions, including stimulation of blood platelet aggregation, reduction of blood pressure, activation of several white blood cell classes, decreased cardiac output, stimulation of glycogenolysis, and stimulation of uterine contraction. This lipid is synthesized via acetylation of the corresponding 1-alkylglycerophosphocholine by acetyl-CoA.

The discovery of a phospholipid with such a striking biological activity was without precedent, and it has opened a fascinating new realm of biochemistry. The factor acts through binding to a high-affinity receptor in the membrane of susceptible cells. The receptors interact with signal transduction systems through G proteins (see Chapter 23).

Ether-containing lipids are quite abundant in the membranes of halophilic (“salt-loving”) microorganisms. These bacteria and protozoans grow in media with NaCl concentrations as high as 4 M. Although we don’t know the relationship between ether lipids and the ability to grow in a high-salt environment, the greater stability of alkyl ethers against hydrolysis, as compared with acyl esters, may be a factor.

Intracellular Transport of Membrane Phospholipids

Of the six major classes of glycerophospholipids in eukaryotic membrane lipids, phosphatidylglycerol and cardiolipin are found primarily in mitochondrial membranes and are synthesized in mitochondria. The remaining four classes are synthesized simultaneously with their insertion into the cytosolic side of membranes of the endoplasmic reticulum. From there they undergo translocation to the luminal side of the membrane and ultimately are transported to other membranes—the nuclear envelope, mitochondrial membranes, and the plasma membrane. Just

FIGURE 19.13

how these events occur is the subject of one of the most active areas of contemporary cell biology. The three major questions are the following: (1) How do phospholipid molecules move from one side of a membrane to the other? (2) How do phospholipid molecules move from one site to another within the cell? (3) How does phospholipid transport directed to specific organelles account for the differences in phospholipid composition of membranes within a single cell?

Investigations of transmembrane movement of phospholipids (question 1) use specific lipid probes that allow detection of a lipid on only one side of a bilayer. As mentioned in Tools of Biochemistry 10A, one such approach involves the use of a **spin label**, a lipid analog that is detectable from its electron paramagnetic resonance spectrum. Such measurements show that transbilayer movement, or “flip-flop,” does occur spontaneously but is quite slow. Measurements *in vivo* show much faster transbilayer movement, catalyzed by flippases and floppases described in Chapter 10.

Transport of phospholipids within the cell (question 2) involves largely the transfer of fragments of membranes of the ER into the Golgi complex, as was shown in Figure 19.1. Membrane vesicles are constantly pinched off from the Golgi, and these vesicles, containing secretory products, fuse with the plasma membrane for secretion of their contents via **exocytosis** (transport out of the cell). It seems likely that this route is used not only for extracellular secretion but also for transport of membrane lipids to the plasma membrane. Probably comparable processes transport membrane lipids to mitochondria, plant chloroplasts, and nuclei, although these processes are not as well understood.

To explain the variability of membrane lipid composition within a given cell (question 3), we can postulate the existence in Golgi membranes of specific targeting proteins—proteins that preferentially associate with certain lipids and have an affinity for certain organelles. Another mechanism involves the action of **phospholipid exchange proteins**—cytosolic proteins that bind a phospholipid and can catalyze its exchange with a corresponding membrane lipid. The protein-bound lipid moves into the membrane, and the membrane lipid becomes bound to the cytosolic protein. This mechanism does not provide for net transfer of lipid to a membrane, but it does allow for modulation of the lipid composition of a particular membrane.

Membranes are assembled by membrane vesicles moving from synthesis sites in the endoplasmic reticulum and Golgi complex to existing membranes and fusing with them.

Metabolism of Sphingolipids

Interest in sphingolipids focuses largely on their important role in nervous tissue and, related to this role, a number of human genetic defects of sphingolipid metabolism. Sphingolipids are also widely distributed in the membranes of plant cells and in lower eukaryotes such as yeast.

Recall from Chapter 10 that sphingolipids are derivatives of the base *sphingosine*. Plant sphingolipids contain a slightly different form of this compound, called **phytosphingosine**. The sphingolipids include *ceramide* (*N*-acylsphingosine), *sphingomyelin* (*N*-acylsphingosine phosphorylcholine), and a family of carbohydrate-containing sphingolipids called neutral and acidic **glycosphingolipids**; the latter substances include *cerebrosides* and *gangliosides* (which also contain sialic acid). Ceramide serves as the precursor to both sphingomyelin and the glycosphingolipids.

In animals the pathway to ceramide starts with the synthesis of a sphingosine derivative, **sphinganine**, from palmitoyl-CoA and serine (Figure 19.14). After reduction of the palmitoyl keto group, the amino group of sphinganine is acylated to give a ceramide. After transport to the Golgi complex, the sphinganine unit of this compound is desaturated to give a ceramide with a sphingosine base. Transfer of a phosphocholine unit from phosphatidylcholine yields sphingomyelin plus diacylglycerol.

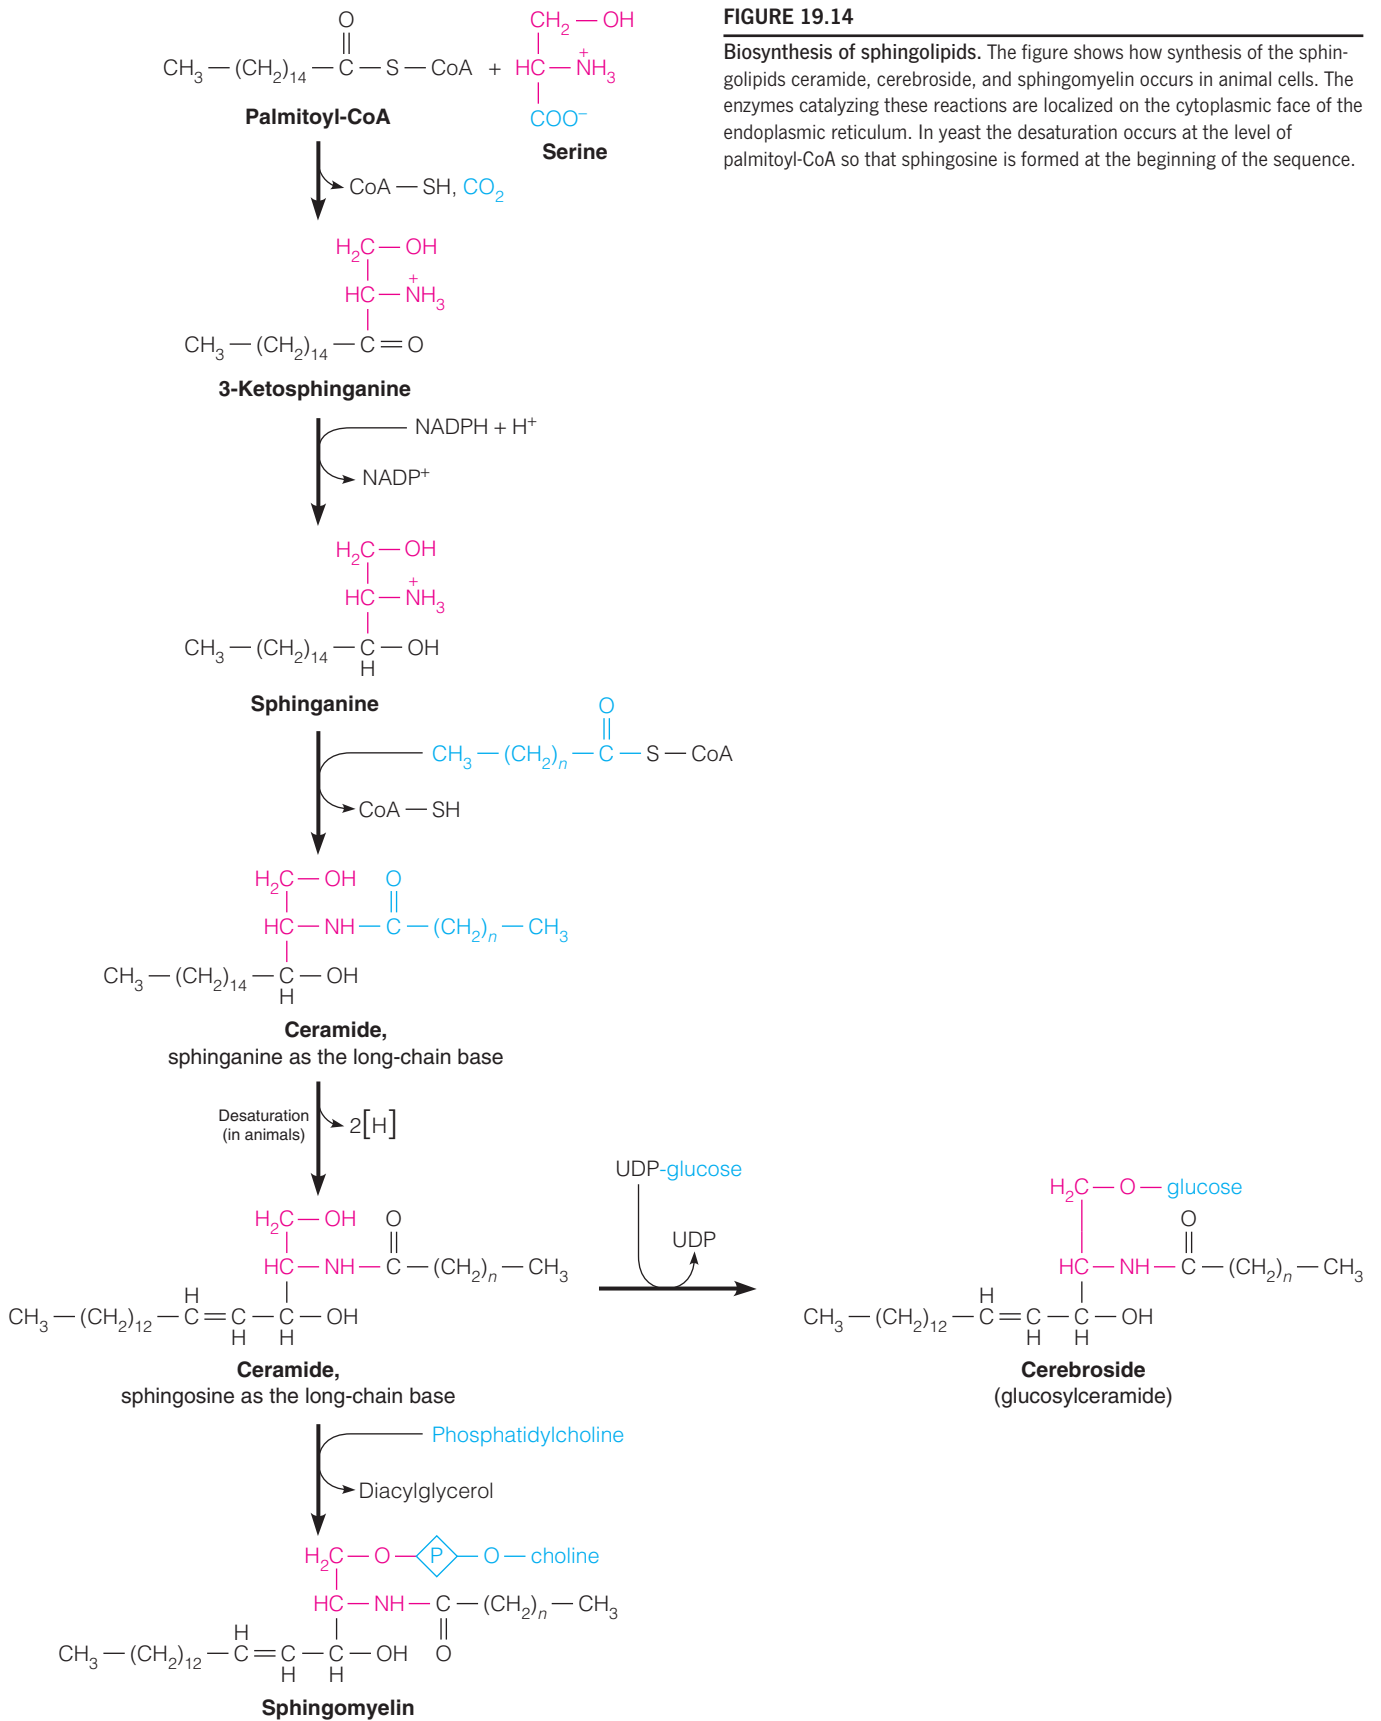

FIGURE 19.14
Biosynthesis of sphingolipids. The figure shows how synthesis of the sphingolipids ceramide, cerebroside, and sphingomyelin occurs in animal cells. The enzymes catalyzing these reactions are localized on the cytoplasmic face of the endoplasmic reticulum. In yeast the desaturation occurs at the level of palmitoyl-CoA so that sphingosine is formed at the beginning of the sequence.

Nucleotide-linked sugars and glycosyltransferases are involved in glycosphingolipid biosynthesis.

The pathways leading to glycosphingolipids are more numerous, but the metabolic strategies are comparable to those we have encountered before in synthesis of the oligosaccharide chains of glycoproteins (see Chapter 9). The pathways involve the stepwise addition of monosaccharide units, using nucleotide-linked sugars as the activated biosynthetic substrates and with ceramide as the initial monosaccharide acceptor (Figure 19.14). The sugar nucleotides involved in glycosphingolipid synthesis include UDP-glucose (UDP-Glc), UDP-galactose (UDP-Gal), UDP-*N*-acetylgalactosamine (UDP-GalNAc), and CMP-*N*-acetylneuraminic acid (CMP-Sia, or CMP-sialic acid). Figure 19.15 shows pathways leading to some of the most abundant glycosphingolipids.

Sphingolipids, especially sphingomyelin, are abundant components of the *myelin sheath*, a multilayered structure that protects and insulates cells of the central nervous system (Figure 19.16; see also Figure 10.45, page 397). In human myelin, sphingolipids constitute some 25% of the total lipid. Sphingolipids are in a continuous state of metabolic turnover, both synthesis and degradation. Degradation occurs in the lysosomes, by a family of hydrolytic enzymes. These

TABLE 19.1 Inherited diseases of sphingolipid catabolism

Disease	Defective Enzyme ^a	Accumulated Intermediate
GM ₁ gangliosidosis	① β-Galactosidase	GM ₁ ganglioside
Tay–Sachs disease	② β-N-Acetylhexosaminidase A	GM ₂ (Tay–Sachs) ganglioside
Fabry’s disease	③ α-Galactosidase A	Trihexosylceramide
Gaucher’s disease	④ β-Glucosidase	Glucosylceramide
Niemann–Pick disease (Types A and B)	⑤ Sphingomyelinase	Sphingomyelin
Farber’s lipogranulomatosis	⑥ Ceramidase	Ceramide
Globoid cell leukodystrophy (Krabbe’s disease)	⑦ β-Galactosidase	Galactosylceramide
Metachromatic leukodystrophy	⑧ Arylsulfatase A	3-Sulfogalactosylceramide
Sandhoff disease	⑨ N-Acetylhexosaminidases A and B	GM ₁ ganglioside and globoside

^aNumbers refer to enzymes shown in Figure 19.17.

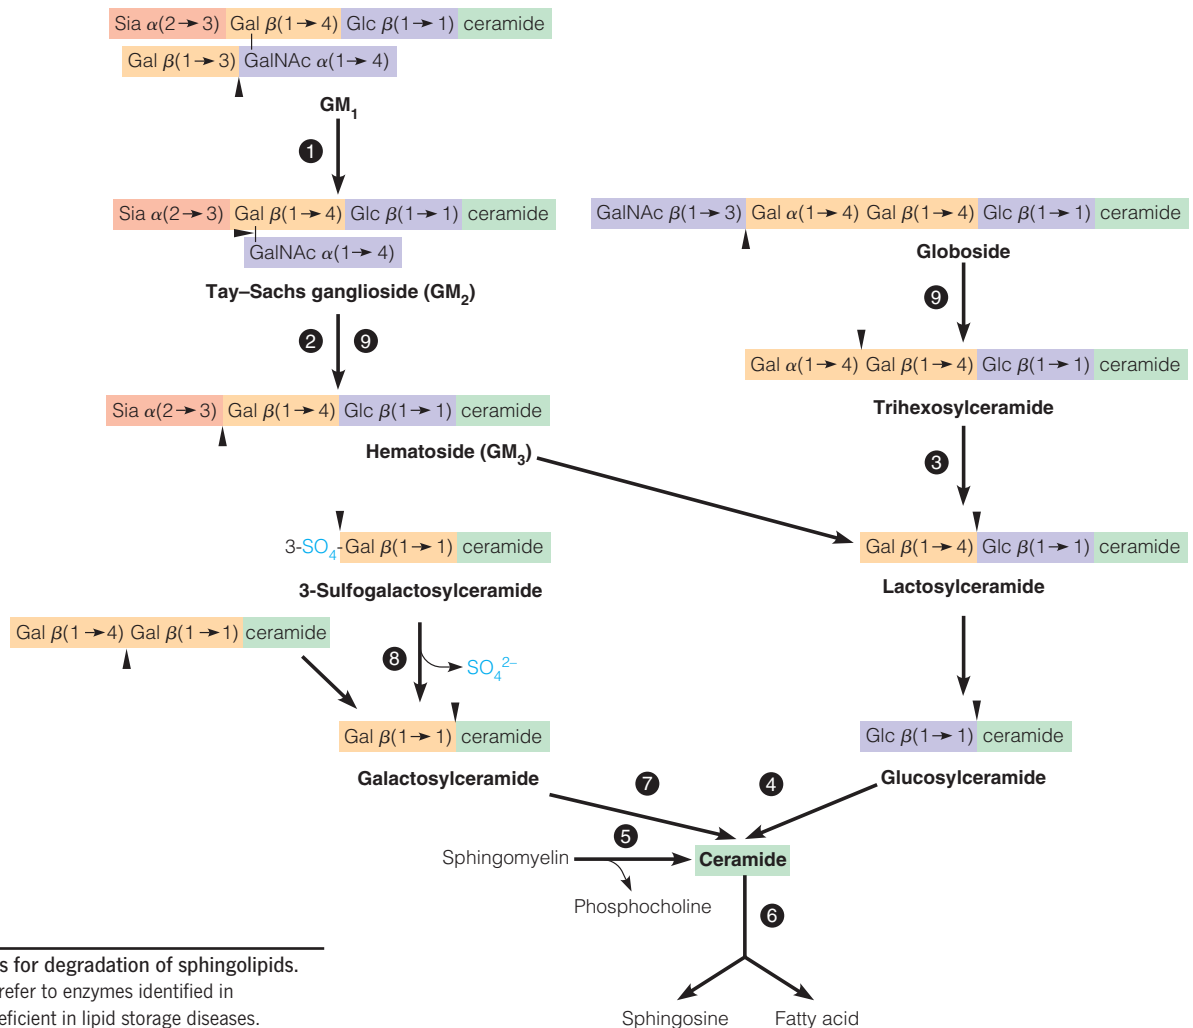

pathways are of great medical interest because of their relationship to a group of congenital diseases called **sphingolipidoses** (also known as **lipid storage diseases**). Each condition is characterized by deficiency of one of the degradative enzymes, with concomitant accumulation within the lysosome of the substrate for the deficient enzyme (Table 19.1). In fact, structural analysis of the abnormal metabolites that accumulate helped to establish the degradative pathways, which are depicted in Figure 19.17. Most of these diseases are autosomal recessive, which means that two defective alleles of the gene encoding a particular enzyme must be present in an individual for disease symptoms to be manifest. Because of the large amounts of sphingolipids in nervous tissue, it is perhaps not surprising that most of the sphingolipidoses involve severely impaired central nervous system function.

The best known of the sphingolipidoses is **Tay–Sachs disease**, originally described in 1881, which is a deficiency of the lysosomal **N-acetylhexosaminidase A**. The enzyme deficiency causes accumulation of the ganglioside called GM₂, particularly in the brain (see Figure 19.17; structure shown in Figure 10.8b, page 368). The disease is devastating, causing nervous system degeneration, mental retardation, blindness, and death, usually by the age of four.

Although Tay–Sachs disease is rare in the general population, the defective gene is relatively common among Ashkenazic Jews (those of middle and eastern European extraction). Among American Jews, about 1 in 30 individuals carries the defective gene. Thus, two Jewish parents carry an appreciable risk of bearing a Tay–Sachs child. Because there is no known cure for the disease, attention has focused on prenatal detection. In fact, this was one of the first genetic diseases to be successfully diagnosed in conjunction with amniocentesis. Two prospective parents both shown to be heterozygous for this condition can be counseled that they have a 25% chance of conceiving a child with Tay–Sachs.

Sphingolipids function not only as membrane components but also as signaling molecules. Among the sphingolipids, ceramide signaling has been implicated in the regulation of cell growth and migration, differentiation, senescence, and **apoptosis**, or programmed cell death. This process, which we present in more

Genetic defects in glycosphingolipid catabolism cause breakdown intermediates to accumulate in nervous tissue, with severe consequences.

**FIGURE 19.17**

Lysosomal pathways for degradation of sphingolipids. The circled numbers refer to enzymes identified in Table 19.1 that are deficient in lipid storage diseases.

detail in Chapter 28, involves the death of certain cells as part of normal development or after environmental damage to a cell so severe that the cell's survival would be harmful to the organism. Extracellular factors activate the enzymatic cleavage of sphingomyelin within membranes, and the ceramide that is released activates specific protein phosphatases and protein kinases. Many details of this signal transduction pathway remain to be discovered.

Gangliosides act as receptors for specific agents, such as cholera toxin, which binds to ganglioside GM₁, or influenza virus, which recognizes the sialic acid portion of certain gangliosides. Influenza virus encodes a neuraminidase, which cleaves these gangliosides as part of the viral entry process into cells. Inhibitors of this enzyme, such as oseltamivir (Tamiflu), have found wide use as antiviral drugs to treat influenza. Also of great interest is the observation that some gangliosides promote the growth of neural tissue in cell culture, suggesting that they might be used to promote regeneration of nerve tissue after spinal cord injury. In fact, New York Jets lineman Dennis Byrd was treated with GM₁ ganglioside, as well as with surgery, after breaking his neck in a 1992 football injury, and this may have been partially responsible for his remarkable recovery.

Steroid Metabolism

We turn now to an extraordinarily large and diverse group of lipids, the **isoprenoids**, or **terpenes**. These compounds are built up from one or more five-carbon activated derivatives of **isoprene**. The family includes steroids and bile acids; the lipid-soluble

vitamins; the dolichol and undecaprenol phosphates we encountered in glycoprotein synthesis; phytol, the long-chain alcohol in chlorophyll; **gibberellins**, a family of plant growth hormones; insect juvenile hormones; the major components of rubber; coenzyme Q; and many more compounds.

Much of our discussion of isoprenoids focuses on a single steroid compound, cholesterol. As discussed in Chapter 10, this lipid is a major component of animal cell membranes, where it participates in modulation of membrane fluidity. In animals it also serves as precursor to all of the steroid hormones, to vitamin D, and to the bile acids, which aid in fat digestion. And as we discussed in Chapter 17, there is intense medical interest in cholesterol because of the relationships among diet, blood cholesterol levels, atherosclerosis, and heart disease. These biological relationships, coupled with the complex stereochemistry of its structure and the elegance of its biosynthetic pathway from a single low-molecular-weight precursor, have focused attention on this compound ever since its first isolation from gallstones, in 1784. Michael Brown and Joseph Goldstein have proclaimed cholesterol “the most highly decorated small molecule in biology,” with 13 Nobel Prizes having been awarded to scientists, including themselves, who devoted major parts of their careers to cholesterol.

Some Structural Considerations

Steroids constitute a class of lipids that are derivatives of the saturated tetracyclic hydrocarbon **perhydrocyclopentanophenanthrene** (Figure 19.18). Note the letters used to denote the four rings—A, B, C, and D, with D being the five-membered ring—and the carbon numbering system. Cholesterol differs from the basic ring system in having an aliphatic chain at C-17, axial methyl groups at C-10 and C-13, a double bond in ring B, and a hydroxyl group in ring A. The alcoholic functional group and the carbon chain at C-17 make cholesterol a **sterol**, which is the generic term used to identify steroid alcohols.

The cyclohexane rings of the steroids adopt puckered conformations, of which the more stable chair form (see Figure 10.9, page 369) predominates over the boat. This gives cholesterol a rigid molecular structure, with only the hydroxyl group generating a little polarity at one end. Much of the cholesterol in lipoproteins and intracellular storage droplets is esterified at this position with a long-chain fatty acid, which makes the resultant cholesterol ester much more hydrophobic than cholesterol itself. The structure makes apparent how increasing concentrations of cholesterol in a membrane can alter the fluidity of that membrane, by reducing the proportion of total lipid that can undergo a phase transition and by reducing the lateral mobility of polar lipids within the membrane (see Figure 10.12b, page 371).

During most of our treatment of steroid metabolism, we shall use structural representations, as in Figure 19.18c, instead of three-dimensional configurational models. By convention, the methyl group at position 10 projects *above* the plane of the rings. This and all other substituents that project above the plane are denoted β and are drawn with a solid wedge. Substituents that project *below* the plane of the ring are called α and are denoted by a dashed wedge. These conventions are shown in Figure 19.18c for **cholestanol**, one of the two fully saturated derivatives of cholesterol.

Biosynthesis of Cholesterol

The pathway by which cholesterol is synthesized is worthy of study because of the diversity of metabolites synthesized by the pathway and the elegance of the pathway itself. Isotopic tracer studies have shown that all 27 carbons of cholesterol come from a two-carbon precursor—acetate. How could such a simple compound be built up to give a structure of the great complexity of cholesterol? That is what concerns us next.

FIGURE 19.18

Ring identification system (a) and carbon numbering system (b) used for steroids. (c) Structural conventions, with cholestanol as the example. α substituents project below the plane of the steroid ring system (blue dashed wedge), and β substituents project above that plane (magenta solid wedge). The hydrogens at positions 5, 9, and 14 have the α configuration, whereas the hydroxyl, the two methyl groups, the hydrogen at C-8, and the aliphatic side chain at C-17 are all β substituents.

Cholesterol, the precursor to all steroids, derives all of its carbon atoms from acetate.

Early Studies of Cholesterol Biosynthesis

Most of our early insights into cholesterol biosynthesis came out of Konrad Bloch's laboratory in the 1940s. Taking note that cholesterol biosynthesis in vertebrates is confined largely to the liver, Bloch fed rats with acetate having ^{14}C either in the methyl group position or in the carboxyl group. After each administration, cholesterol was isolated from the liver and subjected to chemical degradation, with radioactive counting of the fragments. This procedure established the pattern shown in the margin, in which each carbon of cholesterol was found to originate from either the methyl carbon (blue) or the carboxyl carbon (magenta) of acetate (actually, acetyl-CoA).

Other early insights came from the realization that the five carbons of isoprene could be derived metabolically from three molecules of acetate, and the prediction that cholesterol was a product of the cyclization of the linear C_{30} hydrocarbon **squalene**. Squalene contains six isoprene units (delineated by magenta marks on the structures below), and its configuration makes it a plausible steroid precursor.

Squalene

Postulated precyclization configuration of squalene

In 1956 another important development occurred, when Karl Folkers discovered that a C_6 organic acid, **mevalonic acid**, could permit the growth of certain acetate-requiring strains of *Lactobacillus*. Folkers showed that mevalonic acid was readily converted to an activated C_5 isoprenoid compound, **isopentenyl pyrophosphate**. Interestingly, *Lactobacillus* does not synthesize steroids, but it uses the first several steps of the pathway to synthesize other isoprenoid compounds. In animals, mevalonate is readily converted to squalene. Once this had been established, the stage was set for considering cholesterol biosynthesis as three distinct processes.

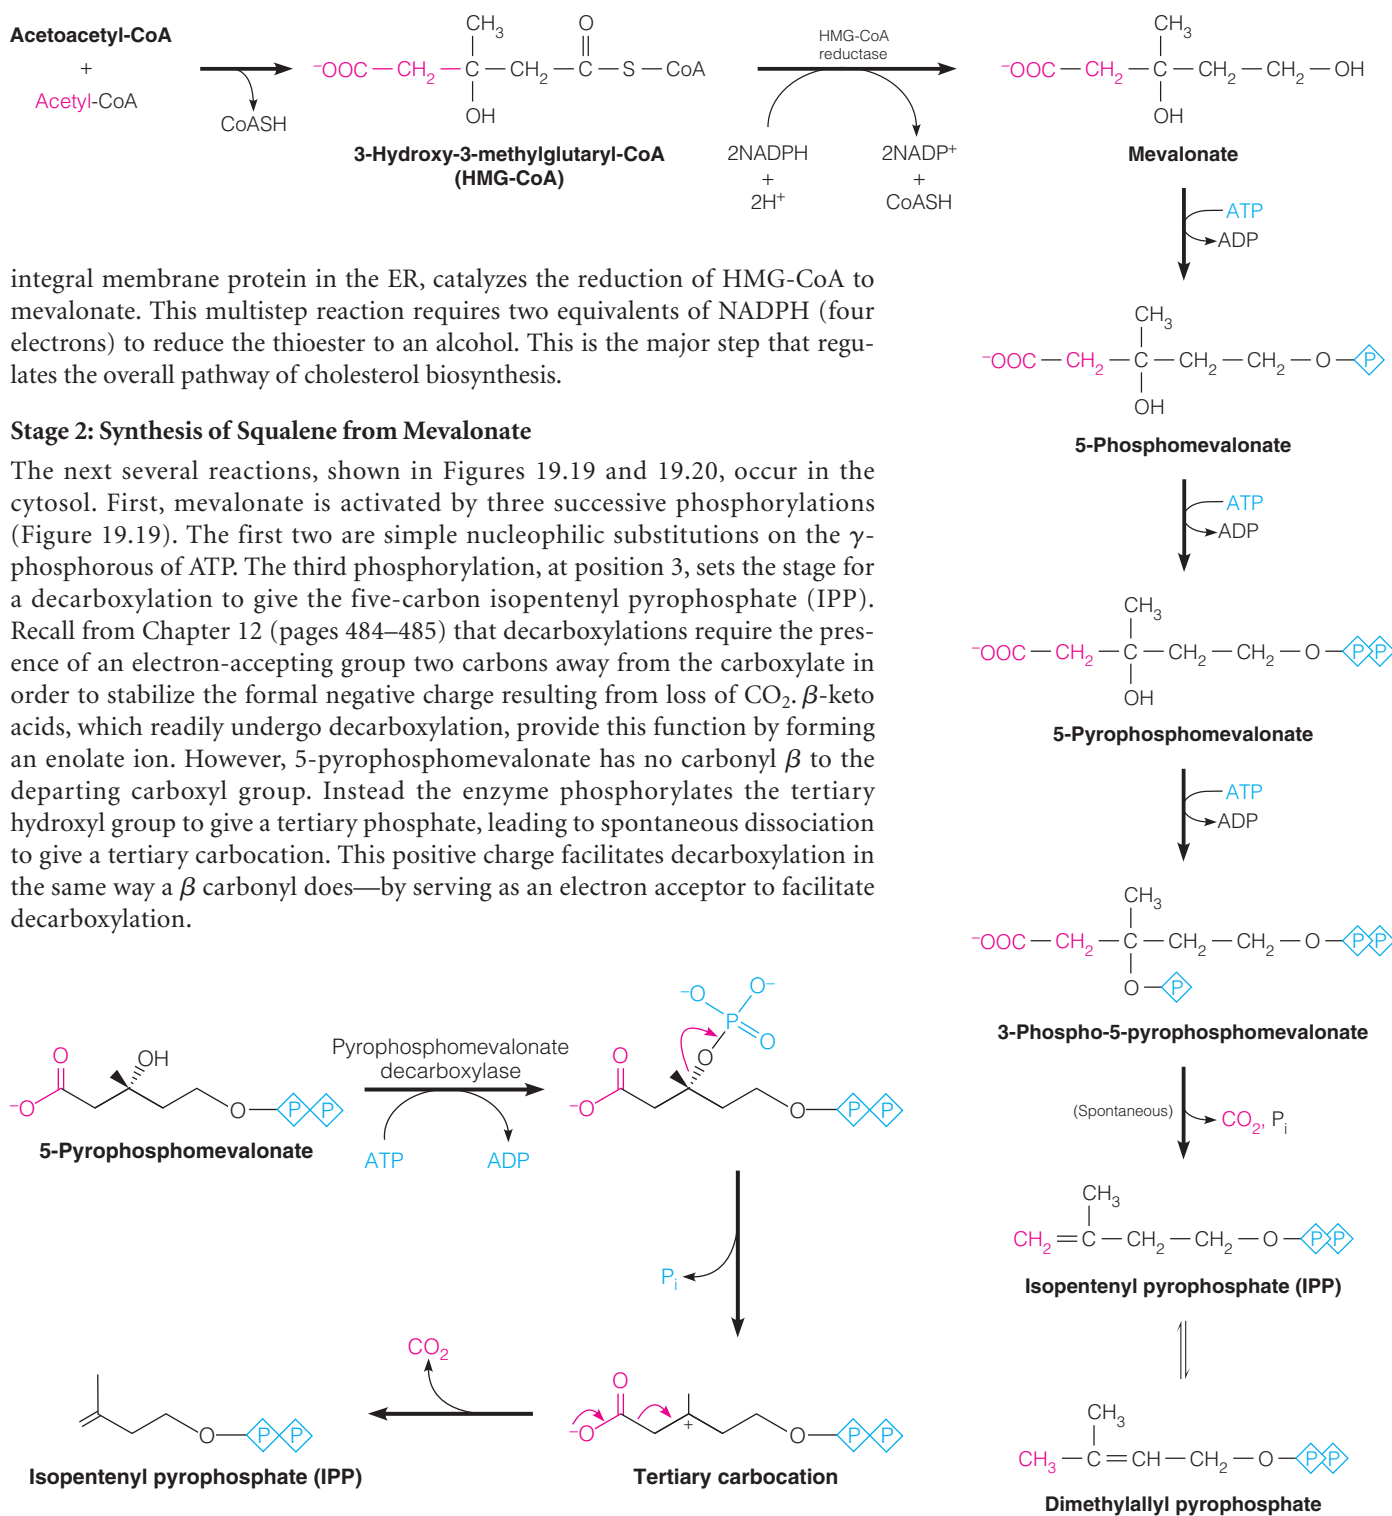

1. Conversion of C_2 fragments (acetate) to a C_6 isoprenoid precursor (mevalonate)
2. Conversion of six C_6 mevalonates, via activated C_5 intermediates, to the C_{30} squalene
3. Cyclization of squalene and its transformation to the C_{27} cholesterol

Now let us consider these three processes in detail.

Stage 1: Formation of Mevalonate

The first part of the pathway is identical to reactions used in ketogenesis (Chapter 17), although it occurs in a different cell compartment. Ketogenesis occurs in mitochondria, whereas cholesterol biosynthesis occurs in the cytosol and the endoplasmic reticulum (ER).

Stage 1 begins with condensation of two molecules of acetyl-CoA to give acetoacetyl-CoA. Figure 19.19 shows the rest of this stage. Acetoacetyl-CoA reacts with a third molecule of acetyl-CoA to give 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA). Recall from Figure 17.24 (page 735) that during ketogenesis, HMG-CoA cleaves to give acetoacetate plus acetyl-CoA in the mitochondrial matrix. However, the HMG-CoA lyase that accomplishes this cleavage is missing from the ER, where cholesterol biosynthesis begins. Instead, **HMG-CoA reductase**, an

integral membrane protein in the ER, catalyzes the reduction of HMG-CoA to mevalonate. This multistep reaction requires two equivalents of NADPH (four electrons) to reduce the thioester to an alcohol. This is the major step that regulates the overall pathway of cholesterol biosynthesis.

Stage 2: Synthesis of Squalene from Mevalonate

The next several reactions, shown in Figures 19.19 and 19.20, occur in the cytosol. First, mevalonate is activated by three successive phosphorylations (Figure 19.19). The first two are simple nucleophilic substitutions on the γ -phosphorous of ATP. The third phosphorylation, at position 3, sets the stage for a decarboxylation to give the five-carbon isopentenyl pyrophosphate (IPP). Recall from Chapter 12 (pages 484–485) that decarboxylations require the presence of an electron-accepting group two carbons away from the carboxylate in order to stabilize the formal negative charge resulting from loss of CO_2 . β -keto acids, which readily undergo decarboxylation, provide this function by forming an enolate ion. However, 5-pyrophosphomevalonate has no carbonyl β to the departing carboxyl group. Instead the enzyme phosphorylates the tertiary hydroxyl group to give a tertiary phosphate, leading to spontaneous dissociation to give a tertiary carbocation. This positive charge facilitates decarboxylation in the same way a β carbonyl does—by serving as an electron acceptor to facilitate decarboxylation.

FIGURE 19.19

Biosynthesis of mevalonate and conversion to isopentenyl pyrophosphate and dimethylallyl pyrophosphate. The two carbons of the third acetyl group are shown in magenta.

IPP isomerase catalyzes the isomerization of one molecule of the resulting isopentenyl pyrophosphate to the C_5 **dimethylallyl pyrophosphate**. The latter compound, as shown in Figure 19.20, reacts with a second molecule of isopentenyl pyrophosphate to give the C_{10} **geranyl pyrophosphate**, and still another molecule of isopentenyl pyrophosphate reacts with this product to give the C_{15} **farnesyl pyrophosphate**. Both of these reactions involve a tertiary carbocation intermediate in an $\text{S}_{\text{N}}1$ mechanism. Dissociation of PP_i from dimethylallyl pyrophosphate produces an allylic carbocation. The double bond of IPP behaves

FIGURE 19.20

Conversion of isopentenyl pyrophosphate and dimethylallyl pyrophosphate to farnesyl pyrophosphate. Both of these head-to-tail condensations are catalyzed by the same prenyltransferase (farnesyl pyrophosphate synthase).

Hydroxymethylglutaryl-CoA reductase, which catalyzes an early reaction in cholesterol biosynthesis, is the major control point for the overall process.

as a nucleophile, condensing with the carbocation to give a second carbocation, which eliminates a proton to form the product.

Figure 19.21 shows the final reactions of squalene synthesis, catalyzed by **squalene synthase**, which is bound to membranes of the endoplasmic reticulum. This enzyme uses carbocation intermediates to join two molecules of farnesyl pyrophosphate in head-to-head fashion to give **presqualene pyrophosphate**. This activated cyclopropane intermediate then undergoes pyrophosphate elimination and rearrangement to a cyclopropylcarbanyl cation intermediate, which is reduced by NADPH to yield the C₃₀ squalene.

A remarkable feature of this part of the pathway is its stereochemistry. In the 1960s two British scientists, George Popják and John Cornforth, identified 14 “stereochemical ambiguities”—that is, 14 steps in the overall process that could go in either of two ways. For example, the triphosphorylated mevalonate derivative shown in Figure 19.19 could undergo decarboxylation by either a *cis* or *trans* elimination of the carboxyl and phosphoryl groups. Thus, 2¹⁴, or 16,384, *different* stereochemical routes were possible for conversion of mevalonate to squalene. Remarkably, these scientists and their colleagues were able to identify the single stereochemical pathway that actually takes place among these 16,384 possibilities.

Stage 3: Cyclization of Squalene to Lanosterol and Its Conversion to Cholesterol

All subsequent reactions occur in the endoplasmic reticulum. The cyclization of squalene to lanosterol and the conversion of lanosterol to cholesterol are shown in Figure 19.22. The formation of lanosterol, which has the four-ring sterol nucleus, occurs in two steps. First, a mixed-function oxidase introduces an epoxide function at carbons 2 and 3. Protonation of this functional group initiates a series of *trans* 1,2 shifts of methyl groups and hydride ions, to produce lanosterol. A series of about 20 reactions follows, involving double-bond reductions and three demethylations; one methyl group is removed from C-14 and two from C-4. The penultimate product is 7-dehydrocholesterol, which undergoes a final reduction to yield cholesterol.

Cyclization of squalene, a C₃₀ hydrocarbon, creates the four-ring sterol nucleus.

FIGURE 19.21

Conversion of farnesyl pyrophosphate to squalene, catalyzed by squalene synthase. Dissociation of the pyrophosphate group on one of the molecules of farnesyl pyrophosphate (magenta) yields an allylic carbocation. The C2=C3 double bond nucleophilically attacks the carbocation, forming a tertiary cation at C3 of the first farnesyl pyrophosphate (black). Loss of a proton from C1 gives the activated cyclopropane intermediate, presqualene pyrophosphate. Dissociation of the second pyrophosphate leads to rearrangement and formation of another tertiary carbocation intermediate. Hydride transfer from NADPH completes the rearrangement, giving squalene.

Control of Cholesterol Biosynthesis

In Chapter 17, we learned that intracellular cholesterol levels are regulated by several mechanisms, including controlling de novo cholesterol biosynthesis, storing excess cholesterol in the form of cholesterol esters, and regulating the synthesis of the LDL receptor, which is responsible for endocytosis of cholesterol from the bloodstream. As noted earlier, HMG-CoA reductase, which catalyzes the committed reaction in

cholesterol biosynthesis, represents a major target for regulation of the overall pathway (see Figure 17.9, page 718). It has long been known from feeding studies that dietary cholesterol efficiently suppresses the endogenous synthesis of cholesterol. But this regulation is not a simple case of feedback inhibition of the rate-limiting enzyme. The cholesterol pathway presents two complications. First, the end-product—cholesterol—is located entirely within the membrane. How does the cell monitor the levels of a membrane component? Second, the pathway from mevalonate produces several other important products besides cholesterol, including geranyl and farnesyl pyrophosphate for prenylation of proteins and synthesis of ubiquinone and dolichol. How does the cell coordinate the synthesis of all of these products? Control of HMG-CoA reductase occurs at both transcriptional and posttranscriptional levels, in a process that employs a set of protein–protein interactions that take place within the ER membrane. The central players in this elegant regulatory mechanism are **Insig**s (**In**sulin-**in**duced growth response genes), **SREBPs** (sterol regulatory element

FIGURE 19.22

Conversion of squalene to cholesterol. Formation of squalene epoxide leads to a series of double-bond electron shifts that close the four rings, and a migration of a carbon atom from C-14 to C-13 yields the first steroid intermediate, lanosterol. Many subsequent reactions lead to 7-dehydrocholesterol, which undergoes reduction to cholesterol.

binding proteins), and **Scap** (SREBP cleavage-activating protein). All of these proteins are anchored in the ER membrane by multiple transmembrane segments. Insig was first identified as an mRNA whose abundance increased when cultured cells were treated with insulin, but the function of the protein was not known. We now understand that Insigs control cholesterol synthesis through sterol-induced protein–protein interactions within the ER membrane.

Mammalian HMG-CoA reductase is also anchored in the ER membrane, by a hydrophobic N-terminal domain composed of eight membrane-spanning segments. The catalytic C-terminal domain projects into the cytosol. In sterol-depleted cells, this protein is degraded quite slowly, with a half-life of more than 12 hours. However, when sterols accumulate in the ER membrane, HMG-CoA reductase is rapidly degraded ($t_{1/2} < 1$ hr) by the ubiquitin–proteasome pathway (Chapters 20 and 28). Membrane sterols bind to a sterol-sensing domain within the N-terminal membrane domain of the enzyme (Figure 19.23). Sterol binding causes HMG-CoA reductase to bind to a population of Insigs that are associated with a ubiquitination complex comprising gp78, Ubc7, and VCP. Gp78 is an E3 ubiquitin ligase, which transfers ubiquitin from the E2 ubiquitin-conjugating enzyme Ubc7 to specific lysine residues of HMG-CoA reductase. This protein–protein interaction, stimulated by sterol binding, thus leads to ubiquitination of HMG-CoA reductase. VCP is an ATPase that extracts ubiquitinated reductase from membranes and delivers it to proteasomes for degradation. A nonsterol isoprenoid derived from mevalonate, such as geranylgeraniol, is also required for the extraction and degradation of ubiquitinated HMG-CoA reductase.

Several details of this regulatory process remain to be worked out, including the exact identity of the sterols that mediate it. In permeabilized cells, the most potent compounds are oxysterols (cholesterol derivatives that contain hydroxyl groups at various positions in the aliphatic side chain) and methylated sterols such as lanosterol (Figure 19.22) and 24,25-dihydrolanosterol. Cholesterol itself does not appear to regulate the degradation of HMG-CoA reductase.

Cholesterol metabolism is also controlled at the transcriptional level, and this is where SREBPs and Scap come in. As implied by their name (sterol regulatory element binding proteins), SREBPs are transcription factors that bind to the promoters of genes required to produce cholesterol, including the HMG-CoA reductase gene. Conversion of acetyl-CoA to cholesterol requires at least 20 enzymes, all of whose genes are activated by SREBP binding. SREBP also activates transcription of the gene for the LDL receptor, which mediates uptake of dietary cholesterol. However, as shown in Figure 19.24, SREBPs are synthesized as integral membrane proteins in the ER. When cells are depleted of cholesterol, the SREBPs translocate to the Golgi, where they are proteolytically processed to yield active transcription factors that enter the nucleus. This process requires Scap, which serves as an escort protein, and two specific proteases in the Golgi (S1P and S2P). When sterols accumulate in ER membranes (either from cellular uptake, or from de novo biosynthesis), exit of Scap–SREBP complexes from the ER is inhibited, blocking the proteolytic activation of SREBPs. This causes a decrease in the transcription of SREBP target genes, leading to lower rates of cholesterol synthesis and uptake. Like degradation of HMG-CoA reductase, the SREBP pathway is also controlled by membrane sterols and Insigs. In this case, cholesterol itself binds to a sterol-sensing domain within Scap, causing a conformational change in Scap that promotes Insig binding. This interaction blocks the binding of Scap to COPII proteins, which mediate the translocation of cargo molecules from the ER to the Golgi (Chapter 28). Thus, in sterol-replete cells, Insig sequesters Scap so that proteolytic processing of SREBP is prevented. In sterol-depleted cells, however, Scap–SREBP complexes no longer bind Insig, which becomes ubiquitinated and degraded. The Scap–SREBP complexes are free to translocate to the Golgi, where the SREBPs are processed to active transcription factors that stimulate gene expression, eventually leading to restoration of cholesterol levels.

FIGURE 19.23

Regulation of HMG-CoA reductase by ubiquitin-mediated proteolysis. Sterol binding leads to rapid degradation of the enzyme. See text for details.

FIGURE 19.24

Insig-mediated regulation of SREBP activation. When cholesterol levels in the cell are low, Scap transports SREBP to the Golgi. Proteolytic processing by membrane-bound proteases S1P and S2P releases SREBP's transcription factor domain (bHLH), which enters the nucleus and binds to sterol regulatory elements (SRE) in the promoters of target genes, stimulating their transcription. High levels of cholesterol block this process by Insig-mediated retention of Scap-SREBP in the ER.

Modified from *Cell* (2006) 124:35–46, J. L. Goldstein, R. A. DeBose-Boyd, and M. S. Brown; and *Cell Research* (2008) 18:609–621, R. A. DeBose-Boyd.

Insig proteins integrate these transcriptional and posttranscriptional regulatory mechanisms. In both processes, sterol binding to a sterol-sensing domain (in HMG-CoA reductase or Scap) stimulates Insig binding. For HMG-CoA reductase, Insig binding means ubiquitination and destruction. For Scap, Insig binding turns off a transcriptional activation pathway. Together, these mechanisms ensure fine control over cellular cholesterol metabolism.

Finally, in some tissues, HMG-CoA reductase is subject to short-term regulation by reversible phosphorylation/dephosphorylation. Phosphorylation on a specific serine residue near the C-terminus of its catalytic domain inactivates the enzyme. This covalent modification is catalyzed by AMP-activated protein kinase (AMPK). Recall from Chapter 18 that the AMPK system acts as a sensor of cellular energy status—it is activated by increases in the cellular AMP:ATP ratio. Cholesterol biosynthesis is a particularly expensive pathway, requiring 36 moles of ATP and 16 moles of NADPH per mole of cholesterol. Thus, under conditions of low energy charge, activated AMPK switches off cholesterol synthesis by inhibiting HMG-CoA reductase. The enzyme is reactivated by dephosphorylation, catalyzed by a type 2A protein phosphatase.

In vertebrates cholesterol synthesis is controlled beautifully through the rate at which cholesterol enters cells from the bloodstream. As we discussed in Chapter 17, homeostasis is maintained by a mechanism that coordinates dietary intake of cholesterol, rate of endogenous cholesterol synthesis in the liver (and to a lesser extent

in the intestine), and rate of cholesterol use by cells. That mechanism involves the LDL receptor, the agent most responsible for transporting cholesterol in the bloodstream. However, when these regulatory mechanisms break down in disease, or are overwhelmed by excessive dietary cholesterol, hypercholesterolemia, and eventually atherosclerosis, can result. Once the rate-limiting role of HMG-CoA reductase in cholesterol biosynthesis was understood, specific inhibitors were sought as a therapeutic approach to lowering blood cholesterol levels. Beginning in the 1970s, teams led by Akira Endo in Japan, and Alfred Alberts and Roy Vagelos in the U.S., screened several thousand fungal cultures for compounds that inhibited HMG-CoA reductase. Several compounds were discovered, collectively called **statins**, that act by competitively inhibiting HMG-CoA reductase. Shown in the margin are the structures of several widely used statins, including the fungal polyketides lovastatin and simvastatin and the synthetic atorvastatin (Lipitor). Each statin carries a mevalonate-like moiety (blue), explaining the competitive nature of their activity. Inhibition of HMG-CoA reductase depresses *de novo* cholesterol biosynthesis and, hence, intracellular cholesterol levels. This in turn leads to increased production of LDL receptors, allowing more rapid clearance of extracellular cholesterol from the blood, thus lowering blood cholesterol levels. Statins have proven to be spectacularly effective in the treatment of hypercholesterolemia, and are among the most widely prescribed drugs in the United States, Canada, and other developed nations.

Intermediates in Cholesterol Synthesis in Protein Prenylation

Prenylation involves transfer of C_{15} (farnesyl) or C_{20} (geranylgeranyl) groups from intermediates in cholesterol synthesis (see Figure 19.20) to cysteine residues four positions from the C-terminus of the target protein (Figure 19.25). Subsequent modifications involve the removal of the three C-terminal amino acid residues by an endoprotease and AdoMet-dependent methylation of the terminal carboxyl group. This results in a prenylated and carboxymethylated C-terminal cysteine residue, which is very hydrophobic, thus anchoring the protein in the bilayer. Most prenylated proteins are members of the small G protein superfamily, with the *ras* oncogene protein (see page 985) being the most prominent example. The enzyme **farnesyltransferase**, which transfers a C_{15} unit from **farnesyl pyrophosphate** to a substrate protein (Figure 19.25), has been recognized as an attractive target for inhibition in cancer chemotherapy. Inhibitors of this enzyme interfere with the growth of cancer cells in culture. Although the precise mechanisms of growth inhibition are not known, this is a promising area for molecular pharmacology.

Bile Acids

Now let us turn to the use of cholesterol for synthesis of other important metabolites—bile acids and steroid hormones. As mentioned in Chapter 17, bile acids are steroid derivatives with detergent properties, which emulsify dietary lipids in the intestine and thereby promote fat digestion and absorption. They are secreted from the liver, stored in the gallbladder, and passed through the bile duct and into the intestine. Biosynthesis of bile acids represents the major metabolic fate of cholesterol, accounting for approximately 90% of cholesterol catabolism in the normal human adult. By contrast, steroid hormone synthesis accounts for only about 50 mg of cholesterol metabolized per day.

Although about 400 to 500 mg of bile acids are synthesized daily, much more than this is secreted into the intestine. Most of the bile acids secreted into the upper small intestine are absorbed in the lower small intestine and returned to the liver for reuse, through the portal blood. This process, which handles 20 to 30 g of bile acids per day, is called the **enterohepatic circulation**. Daily elimination of bile acids in the feces amounts to just 0.5 g/day or less, which is compensated for by synthesis in the liver.

The most abundant bile acids in humans are **cholic acid** and **chenodeoxycholic acid** (shown in Figure 19.26 as the respective bile salts, cholate and chenodeoxycholate). These are usually conjugated in amide linkage with the amino acids

Mevalonate

FIGURE 19.25

The protein prenylation pathway. aa = amino acid residue.

glycine or **taurine**, giving compounds called **bile salts**. The cholic acid conjugates with glycine and taurine are called **glycocholate** and **taurocholate**, respectively. Another bile acid, **deoxycholate**, is abundant in the bile of some other mammals. It is widely used as a laboratory reagent, to solubilize membrane proteins.

In the biosynthetic routes to cholate, glycocholate, and taurocholate outlined in Figure 19.26, a series of hydroxylations occurs, catalyzed by microsomal cytochrome P450 mixed-function oxidases. The first of these, catalyzed by cholesterol 7 α -hydroxylase (CYP7A1), is rate-determining and hence plays the major role in controlling the overall pathway. The activity of this enzyme is suppressed by dietary bile acids. Most of the enzymes in bile acid synthesis also participate in other pathways, including oxysterol synthesis, steroid synthesis, or metabolism of very long-chain fatty acids.

Steroid Hormones

Cholesterol is the biosynthetic source of all steroid hormones, the extracellular messengers secreted by the gonads and the adrenal cortex, plus the placenta in pregnant females. In this chapter we introduce the biosynthetic pathways to steroid hormones; their actions are discussed in Chapter 23. In general, steroid

The principal categories of steroid hormones in vertebrates are progestins, glucocorticoids, mineralocorticoids, androgens, and estrogens.

hormones control metabolism at the gene level. They interact with intracellular protein receptors, and the hormone–receptor complexes bind to specific sites on the genome and affect transcription of neighboring genes.

Five major classes of hormone will concern us: (1) the **progestins** (progesterone), which regulate events during pregnancy; (2) the **glucocorticoids** (cortisol and corticosterone), which promote gluconeogenesis and, in pharmacological doses, suppress inflammation reactions; (3) the **mineralocorticoids** (aldosterone), which regulate ion balance by promoting reabsorption of K^+ , Na^+ , Cl^- , and HCO_3^- in the kidney; (4) the **androgens** (androstenedione and testosterone), which promote male sexual development and maintain male sex characteristics; and (5) the **estrogens** (estrone and estradiol), or female sex hormones, which support female characteristics. Most of these hormones are

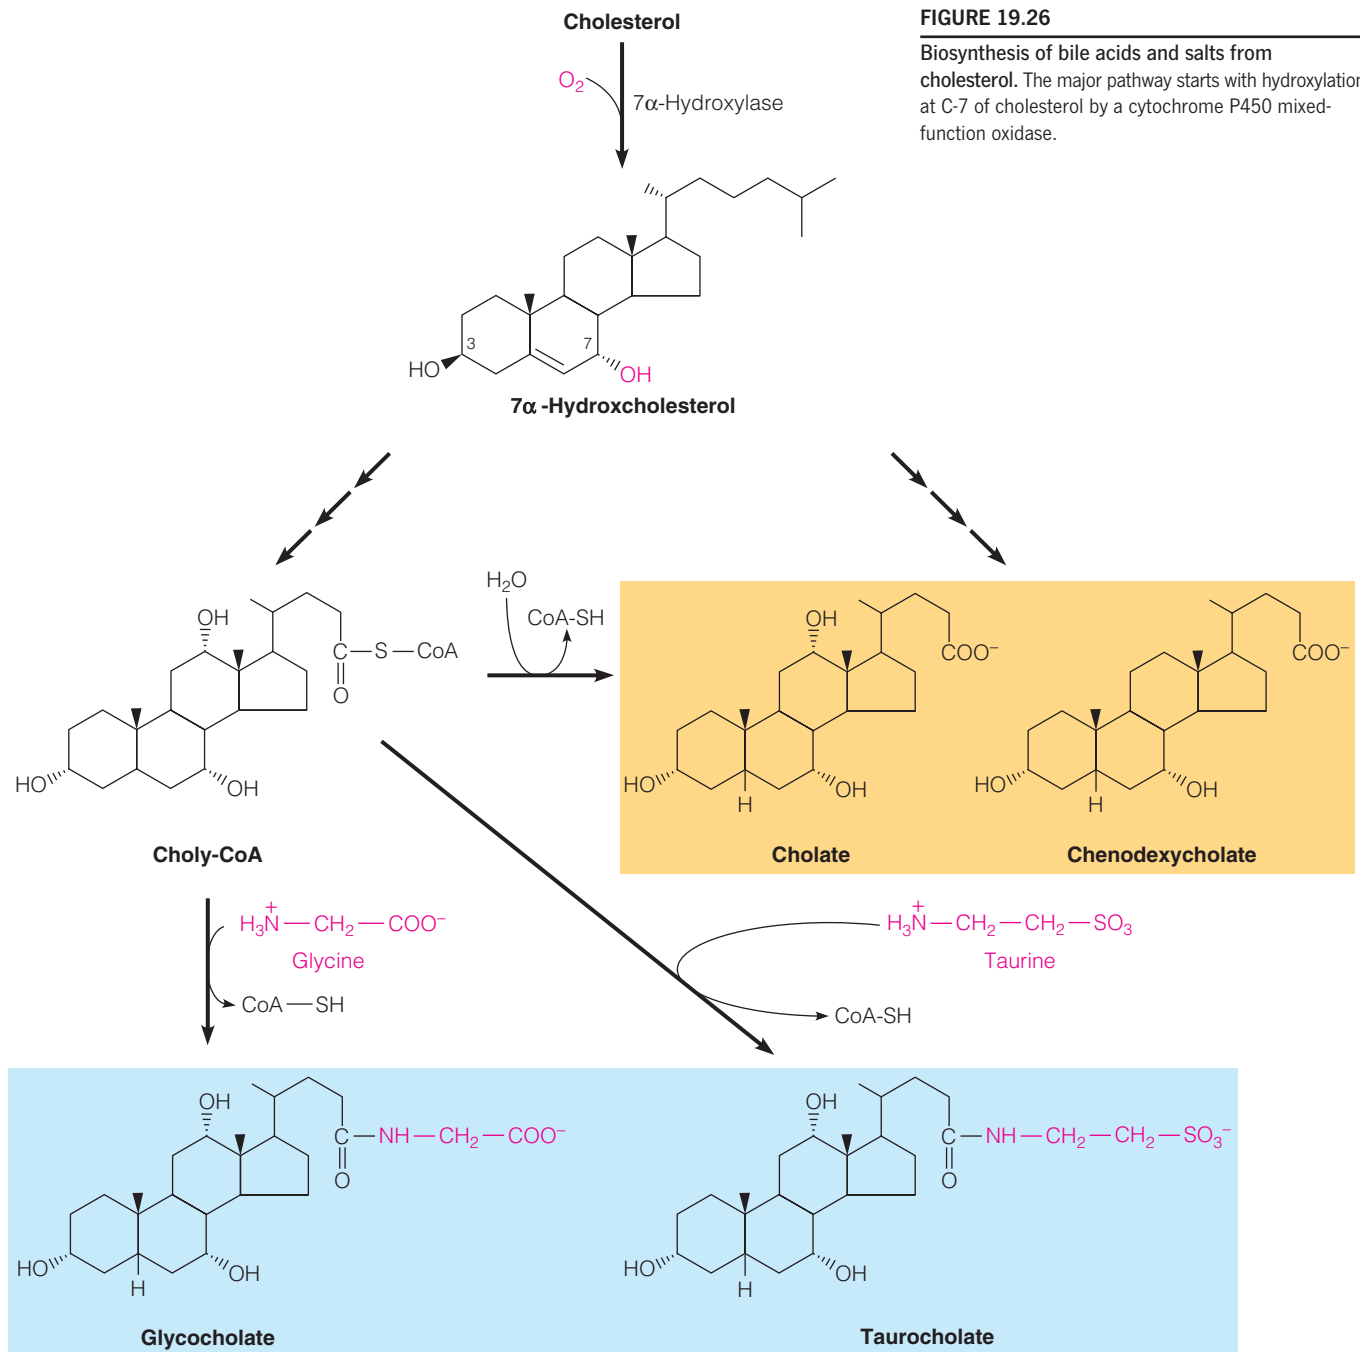

FIGURE 19.26

Biosynthesis of bile acids and salts from cholesterol. The major pathway starts with hydroxylation at C-7 of cholesterol by a cytochrome P450 mixed-function oxidase.

shown in Figure 19.27, which also summarizes their routes of synthesis (described below). In each case the side chain in cholesterol is either greatly shortened or nonexistent.

A general feature of steroid hormones is that they are not stored for release after synthesis. Therefore, the level of a circulating hormone is controlled primarily by its rate of synthesis, which is often controlled ultimately by signals from the brain. These signals usually act through intermediary hormones. For example, the peptide neurohormone **corticotropin releasing hormone (CRH)** is released from cells in the hypothalamus in response to central nervous system inputs (see Chapter 23). CRH stimulates release from the pituitary gland of **corticotropin**, or **adrenocorticotrophic hormone (ACTH)**, which in turn stimulates the synthesis of glucocorticoids in adrenal cortex.

Activation of steroid hormone synthesis involves stimulation of both hydrolysis of cholesterol esters and uptake of cholesterol from cellular stores (ER and plasma membrane) into mitochondria of cells in the target organ. Translocation of cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane (IMM) is the rate-limiting step in the production of all steroids, and requires at least two proteins: steroidogenic acute regulatory (STAR) protein and translocator protein (TSPO). Once in the IMM, an integral membrane cytochrome P450 called **cholesterol side chain cleavage enzyme** hydroxylates the side chain of cholesterol at C-20 and C-22 and cleaves it, to yield **pregnenolone**, the precursor to all other steroid hormones.

Pregnenolone is an intermediate en route from cholesterol to all other known steroid compounds.

Pregnenolone then moves to the ER, where its conversion to all of the other steroid hormones takes place, as shown in Figure 19.27. 3β -Hydroxysteroid dehydrogenase catalyzes oxidation of the C-3 hydroxyl to a ketone and isomerization of the double-bond. Hydroxylation at C-21 by an adrenal cortex enzyme, followed by two more hydroxylations and a dehydrogenation to form an aldehyde group, gives aldosterone, a mineralocorticoid. Hydroxylation of progesterone at C-17 gives 17α -hydroxyprogesterone, the precursor to all other steroids. Two hydroxylations of this intermediate give cortisol (a glucocorticoid), primarily in the adrenal gland. An enzyme in adrenal cortex and in gonads cleaves the side chain of 17 -hydroxyprogesterone at C-17, giving **androstenedione**, a precursor to androgens and estrogens (and one of the now-banned “performance enhancing drugs” that have tainted professional baseball). All of these hydroxylations are catalyzed by cytochrome P450 enzymes, typically obtaining the necessary reducing equivalents from NADPH via P450 oxidoreductase (see Figure 15.32, page 664). Testosterone undergoes reduction at C-5, giving 5α -dihydrotestosterone, a somewhat more potent androgen. Androgens are converted to estrogens by aromatization of the A ring. This conversion involves multiple hydroxylation and elimination reactions catalyzed by a single cytochrome P450 enzyme called **aromatase**. Note that the reactions catalyzed by this enzyme represent the only known route for synthesis of aromatic rings in animal cells.

Human enzyme deficiencies have been described for all of the above enzymes. A deficiency of the 21-hydroxylase inhibits synthesis of glucocorticoids and mineralocorticoids. Progesterone and 17 -hydroxyprogesterone accumulate due to the block, and are shunted through the androgen pathway, leading to overproduction of testosterone in the adrenal glands. At the same time, the underproduction of

FIGURE 19.27

Biosynthetic routes from pregnenolone to other steroid hormones.

cortisol interferes with a feedback loop of hormonal control involving corticotropin releasing factor (Chapter 23) and ACTH; increased ACTH secretion stimulates the adrenals to grow (hyperplasia) and synthesize steroids, exacerbating the testosterone overproduction. This causes virilization (masculinization) of females. A deficiency of the 11 β -hydroxylase also causes adrenal hyperplasia and is characterized by accumulation of the mineralocorticoid 11-deoxycorticosterone, causing

hypertension, and the glucocorticoid 11-deoxycortisol. A deficiency of the 5α -reductase decreases effective androgen levels and leads to feminization of males. Fortunately, these and other steroid abnormalities can be treated with hormone replacement therapy, if detected early enough in life.

Hundreds of synthetic compounds with steroid hormone-like activity have been tested and used for various purposes. Widely used synthetic steroids are anti-inflammatory glucocorticoids. **Diethylstilbestrol**, a synthetic estrogen, was widely used to promote growth of beef cattle, until it was found to be potentially carcinogenic at the levels found in meat from treated cattle. Oral contraceptives are formulated with compounds containing progesterone and estrogen activities. Two widely used synthetic estrogens are **norethynodrel** and **mestranol**.

FIGURE 19.28

Metabolism of vitamin A.

Mixtures of either drug with progesterone inhibit pituitary secretion of hormones that control the female reproductive cycle. This inhibition suppresses maturation of the ovarian follicle and ovulation.

Recent concern has focused upon environmental substances produced through human activity, such as certain pesticides, which happen to have estrogen-like activity. Some of these have been shown to interact with estrogen receptors and to stimulate similar biochemical responses. Solid evidence is accumulating that these “endocrine disrupters” may be responsible for declines in fertility of a number of animal species, possibly including humans, as well as increases in obesity and diabetes.

Mammalian cells lack the capacity for complete degradation of steroid compounds. Although a number of catabolic reactions do occur, most steroids and their metabolites become conjugated, through their hydroxyl groups, to glucuronate or sulfate. Either modification greatly increases solubility of the steroid and facilitates its elimination in the urine.

Other Isoprenoid Compounds

Lipid-Soluble Vitamins

The four lipid-soluble vitamins—A, D, E, and K—are all isoprenoid compounds. They are made up, like steroids, of activated five-carbon units. Thus, as a group they have a structural relatedness not seen among the water-soluble vitamins. On the other hand, the water-soluble vitamins have a *functional* uniformity in that all are designed to carry mobile metabolic groups, whereas the lipid-soluble vitamins are diverse in their functions.

Vitamin A

There are three active forms of vitamin A: **all-trans-retinol**, **-retinal**, and **-retinoic acid**. Collectively, these are referred to as **retinoids**. The vitamin can be either consumed in the diet as esterified retinol, or biosynthesized from **β -carotene**, a plant isoprenoid especially abundant in carrots. **β -carotene** is cleaved in the intestine by a monooxygenase to form two molecules of all-trans-retinal (retinaldehyde), which are then reduced to retinol (Figure 19.28). All-trans-retinol is the form which circulates in the blood and which has the highest biological activity.

Ingestion of this form will satisfy all the nutritional requirements for the vitamin. Oxidation of retinol (alcohol at C-15) to retinal (aldehyde at C-15) is reversible whereas its subsequent oxidation to retinoic acid is irreversible. These two reactions are catalyzed by specific dehydrogenases in peripheral tissues.

Vitamin A plays an important role in the visual process in rod cells of the retina, the cells primarily responsible for low-light vision, with relatively little color detection (Figure 19.29). The rod cell outer segments contain lamellar protein disks that are rich in the protein **opsin**. In the disks, all-*trans*-retinol undergoes isomerization followed by dehydrogenation to give **11-*cis*-retinal**. The chemical changes in photoreception are shown in Figure 19.30. 11-*cis*-Retinal forms a Schiff base with a lysine residue in opsin, giving **rhodopsin** (step 1). Rhodopsin has very strong light absorption in the 400- to 600-nm range (the visible wavelength of the spectrum). Absorption of a photon of light triggers a chain of events leading to neural excitation. The excited retinal in rhodopsin isomerizes to an all-*trans* form (step 2), followed by several conformational changes and release of all-*trans*-retinal (steps 3 and 4). After isomerization (step 5), the process can begin anew. Step 3 in Figure 19.30 is the key to the transduction of photon reception to a neural action potential. This process involves cyclic GMP and a G protein called **transducin**. Further details of this process are presented in Chapter 23.

Retinoids (mainly all-*trans*- and 9-*cis*-retinoic acid) also play important roles as developmental regulators, acting much like steroid hormones (see page 980). They interact with specific receptor proteins in the cell nucleus. The ligand-receptor complexes bind to specific DNA sequences, where they control the transcription of genes involved in embryonic development, reproduction, postnatal growth, differentiation of epithelia, and even immune responses. Indeed, the earliest effect of vitamin A deficiency is a keratinization of epithelial tissues of the respiratory and urogenital tracts, in which the columnar epithelia become replaced by squamous epithelium. Lesions in the eyes (e.g., night blindness) occur much later in vitamin A deficiency.

Vitamin D

The most abundant form of vitamin D is vitamin D₃, or **cholecalciferol**. This is not truly a vitamin because it is not required in the diet. Instead, it arises by synthesis from 7-dehydrocholesterol, an intermediate in cholesterol biosynthesis (see margin, page 811). It is more accurate to think of vitamin D₃ as a prohormone because it is converted to a metabolite that acts analogously to a steroid hormone. Its action involves the regulation of calcium and phosphorus metabolism, particularly with respect to synthesis of the inorganic matrix of bone, which consists largely of calcium phosphate.

In skin cells, 7-dehydrocholesterol undergoes ultraviolet photolysis to give cholecalciferol. Because the UV rays come from sunlight, insufficient sunlight exposure can cause a deficiency of vitamin D₃ and result in the bone malformation known as **rickets**. Mild deficiency can lead to **osteoporosis**, loss of calcium from the bones. Vitamin D₃ is often added to dairy products as a dietary supplement because sunlight exposure is limited in many regions for much of the year.

Cholecalciferol undergoes two successive hydroxylations, each catalyzed by a mixed-function oxidase. The first, at carbon 25, involves a microsomal enzyme system in liver. 25-Hydroxycholecalciferol is then transported to the kidney, where a mitochondrial enzyme hydroxylates it at carbon 1. This reaction is activated by **parathyroid hormone**, which is secreted from the parathyroid gland when calcium levels are low. When calcium levels are adequate, the second hydroxylation occurs at C-24, instead of C-1, to give an inactive metabolite.

1,25-Dihydroxycholecalciferol, or 1,25(OH)₂D₃, is the hormonally active form of vitamin D. This compound migrates to target cells in the intestine and in osteoblasts (bone cells), where it binds to protein receptors that migrate to the cell nucleus. In intestine the hormone-receptor complex stimulates transcription,

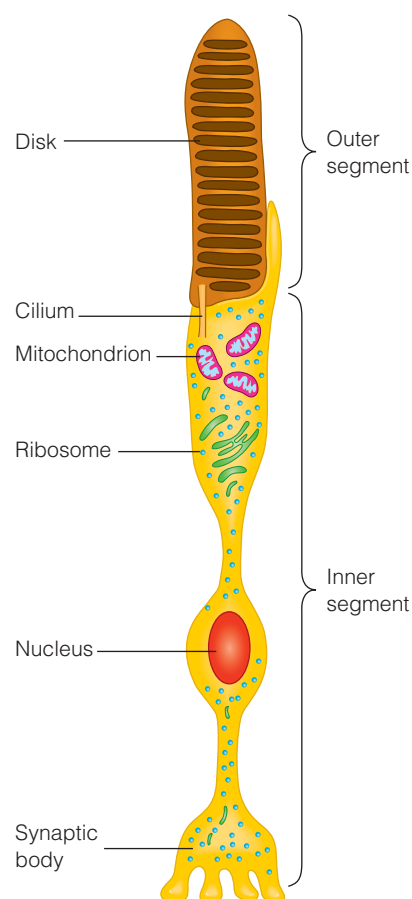

FIGURE 19.29

Schematic drawing of a rod cell. The outer segment is a stack of membranous disks, which contain the photoreceptive pigments. This segment is connected by a thin cilium to the inner segment, which contains the cell nucleus, cytosol, and synaptic body. The potential change produced in the outer segment travels to the synaptic body and is transmitted to one or more of the neurons of the retina.

Isomerization of a protein-bound form of vitamin A in the retina is the mechanism by which light energy is received in the eye.

1,25-Dihydroxycholecalciferol controls bone metabolism by regulating intestinal absorption of calcium.

**FIGURE 19.30****The chemical changes in photoreception.**

11-cis-Retinal and opsin in a rod cell combine to form rhodopsin. Absorption of a photon of light leads to the chemical changes shown in steps 2 and 3. Step 3 involves at least 3 distinct conformational changes that occur in ~1 ms. Metarhodopsin II is the species that activates transducin (not shown) to initiate the visual cascade described in Chapter 23. After about 1 second, metarhodopsin II dissociates into all-trans-retinal, which isomerizes as the cycle begins again.

resulting in synthesis of a protein that stimulates calcium absorption into the bloodstream. In osteoblasts, $1,25(\text{OH})\text{D}_3$ stimulates calcium uptake for deposition as calcium phosphate.

Vitamin E

Vitamin E, also called α -tocopherol, was originally recognized in nutritional studies as an agent that prevented sterility in rats. The vitamin appears to play an antioxidant role, particularly in preventing attack of peroxides on unsaturated fatty acids in membrane lipids (see also Chapter 15, page 666). α -Tocopherol does prevent fatty acid peroxidation in vitro. However, vitamin E deficiency results in additional symptoms such as erythrocyte hemolysis and neuromuscular dysfunction that are not relieved by other antioxidants. Therefore, additional biological roles seem likely for this vitamin.

Vitamin K

Vitamin K was originally discovered as a lipid-soluble substance involved in blood coagulation. Vitamin K_1 , or **phyloquinone**, is found in plants; the quinone portion of this molecule has a largely saturated side chain. Another form of the vitamin, vitamin K_2 , or **menaquinone**, is found largely in animals and bacteria. Menaquinone has a partly unsaturated side chain. In animals, vitamin K_2 is essential for the carboxylation of glutamate residues in certain proteins, to give γ -**carboxyglutamate**. This modification allows the protein to bind calcium, an

essential event in the blood clotting cascade (discussed in Chapter 11). Newborn children routinely receive vitamin K injections because most of our vitamin K comes from intestinal bacteria, which have not yet colonized the guts of newborns.

Carboxylation of glutamate residues occurs in other proteins that are active in the mobilization or transport of calcium. The carboxylating enzyme uses the reduced, hydroquinone, form of vitamin K. During the reaction, the hydroquinone becomes oxygenated to a quinone epoxide, and this reaction facilitates the attack of CO_2 on C-4 of a glutamate residue by deprotonating that carbon.

Other Terpenes

Terpene is a generic term for all compounds that are biosynthesized from isoprene precursors. Therefore, the compounds we have been discussing—cholesterol, bile acids, steroids, and lipid-soluble vitamins—are terpenes; they received special attention because of their importance in animal metabolism. Here we take a brief glimpse at the vast range of other terpene compounds. They include insect hormones and plant growth hormones, as well as the lipid-linked sugar carriers we encountered in Chapter 9.

Terpenes are biosynthesized ultimately from isopentenyl pyrophosphate (C_5) and dimethylallyl pyrophosphate (C_5). When these combine to yield geranyl pyrophosphate (C_{10}) (see Figure 19.20), any terpene formed thereby is called a **monoterpene**. When a compound is formed from 1 mole of farnesyl pyrophosphate (C_{15}), the product is called a **sesquiterpene**. **Triterpenes** (C_{30}) are formed from 2 moles of farnesyl pyrophosphate. Geranylgeranyl pyrophosphate (C_{20}) yields either **diterpenes** (C_{20}) or **tetraterpenes** (C_{40}). The dolichols and undecaprenol, introduced in Chapter 9, are examples of **polyprenols** (polyisoprenoid alcohols), which have more than 50 carbons. Structures of some common terpenes are given in Figure 19.31.

Eicosanoids: Prostaglandins, Thromboxanes, and Leukotrienes

We turn finally to a class of lipids that are distinguished by their potent physiological properties, low levels in tissues, rapid metabolic turnover, and common metabolic origin. The most important of these compounds are the **prostaglandins**; also included are the **thromboxanes** and **leukotrienes**. Collectively, these compounds are called **eicosanoids** because of their common origin from C_{20} polyunsaturated fatty acids, the eicosaenoic acids, particularly arachidonic acid, which is all-*cis*-5,8,11,14-eicosatetraenoic acid. Recall from Chapter 17 that arachidonic acid is synthesized from linolenic acid. Related C_{20} trienoic and pentaenoic acids serve as minor precursors to some prostaglandins and their relatives. In addition to the compounds discussed here, the eicosaenoic acids serve as precursors to another class of compounds, the hydroxyeicosaenoic acids and hydroperoxyeicosaenoic acids. The latter compounds are metabolic precursors to the leukotrienes. Related compounds are derived from polyunsaturated fatty acids shorter or longer than C_{20} , and the term **oxylipin** has been proposed as a generic term for this class of lipids, encompassing all chain lengths.

The prostaglandins and the closely related thromboxanes are derived from a common pathway; a different pathway leads from arachidonic acid to the leukotrienes. Like hormones, the eicosanoids exert specific physiological effects on target cells. However, they are distinct from most hormones in that they act locally, near their sites of synthesis, and they are catabolized extremely rapidly. Moreover, the actions of a given prostaglandin seem to vary in different tissues. The biological properties of the eicosanoids have led to great interest in their medical use and in uses of their analogs.

The biologically active eicosanoids, derived from arachidonic acid, include prostaglandins, thromboxanes, and leukotrienes. They are short-lived, locally acting signaling molecules.

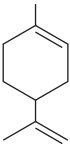

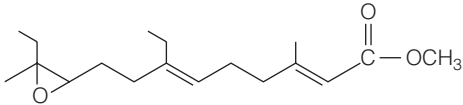

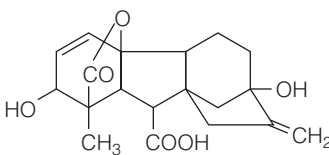

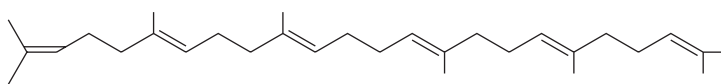

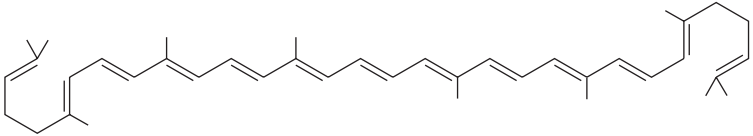

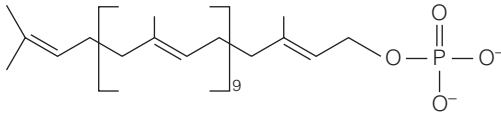

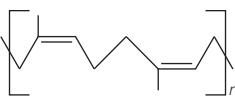

Class	Example	Function
Monoterpenes	 <p>Limonene</p>	Responsible for the characteristic odor of lemons
Sesquiterpenes	 <p>Juvenile hormone I</p>	Controls metamorphosis in insects
Diterpenes	 <p>Gibberellic acid</p>	Plant growth hormone
Triterpenes	 <p>Squalene</p>	Cholesterol precursor
Tetraterpenes	 <p>Lycopene</p>	Tomato pigment
Polyprenols	 <p>Undecaprenol phosphate</p>	Sugar carrier for oligosaccharide synthesis
	 <p>cis-Polyisoprene</p>	Natural rubber

FIGURE 19.31

Some terpene compounds. These examples are representative of an enormous class of natural products.

Some Historical Aspects

The most important early chapters in prostaglandin research were written in Sweden. In the mid-1930s Ulf von Euler discovered that lipid extracts of human semen contained active compounds that, on injection into animals, stimulated smooth muscle contraction or relaxation and affected the blood pressure. Because of their presumed origin in the prostate gland, he named these compounds *prostaglandins*. Later it was realized that these compounds are widely distributed in animal tissues. The first structural elucidations were reported in the late 1950s, under the direction of Sune Bergström and Bengt Samuelsson, and biosynthetic pathways were described in the mid-1960s, in Sweden and in the Netherlands.

The biological properties of the prostaglandins attracted intense interest in the pharmaceutical industry, but initial progress was limited by the low availabilities of these compounds. Interest reached a peak in 1971 with the discovery that aspirin inhibits one of the enzymes in prostaglandin biosynthesis. This inhibition is now known as the major site of action of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs). Later in the 1970s the thromboxanes and leukotrienes were discovered.

Structure

The first two prostaglandins to be isolated were called prostaglandins E and F, respectively, because of their preferential solubility in ether (E) or in phosphate buffer (F for *fosfat*, the Swedish word). We now denote these compounds by PGE and PGF, respectively; all other prostaglandins are denoted by a letter, for instance, PGA and PGH. Each prostaglandin has a cyclopentane ring and two side chains, with a carboxyl group in one side chain. A subscript numeral denotes the number of double bonds in the two chains. The most abundant prostaglandins, those synthesized from arachidonic acid, contain two double bonds; thus, PGE₂ would be the prostaglandin E derived from arachidonic acid. Finally, in the PGF series a subscript α indicates that the hydroxyl group at C-9 is *cis* to the 11-hydroxyl group, and β signifies a *trans* configuration. Structures of the most common prostaglandins are shown in Figure 19.32, along with that of thromboxane A₂ (TxA₂). TxA₂ was originally isolated from thrombocytes, or blood platelets, as a compound that stimulated platelet aggregation, an early step in blood clotting. Note its structural resemblance to PGE₂, except for the cyclic ether ring. Another thromboxane, TxB₂, is a hydrolysis product of TxA₂.

Biosynthesis and Catabolism

Here we discuss only the biosynthesis of the 2-series of prostaglandins. The 1- and 3-prostaglandins are synthesized identically, from related C₂₀ fatty acids. The biosynthetic pathways, which occur in endoplasmic reticulum, are shown in

FIGURE 19.32

Structures of the major prostaglandins and thromboxane A₂. The figure shows the most abundant prostaglandins, those of the 2-series. They are derived from arachidonic acid, as is thromboxane A₂. Numbering of carbons begins with the carboxyl group as shown for the structure of PGG₂.

FIGURE 19.33

Summary of biosynthetic routes to the major prostaglandins and thromboxane A_2 . PLA₂, phospholipase A₂; PLC, phospholipase C; DGL, diacylglycerol lipase; MGL, monoacylglycerol lipase.

Figure 19.33. We can consider these pathways as occurring in three distinct stages: (1) release of arachidonic acid from membrane phospholipids; (2) oxygenation of arachidonate to yield PGH₂, a prostaglandin endoperoxide that serves as precursor to other prostaglandins; and (3) depending on the enzymes present in a cell, the conversion of PGH to other prostaglandins or to TxA₂.

The release of arachidonic acid from membrane phospholipids in stage 1 occurs as a result of tissue-specific stimuli by hormones such as **bradykinin** or epinephrine or by proteases such as thrombin. Pathological release can occur if membranes are perturbed. For example, the inflammation caused by bee stings is probably due to arachidonate release stimulated by the venom protein **melittin**. Arachidonic acid is commonly esterified at the glycerol C2 position in phosphatidylinositol and other membrane phospholipids and can be released by different enzymatic processes. One pathway involves the action of a cytosolic phospholipase A₂ on phosphatidylcholine or phosphatidylethanolamine, yielding arachidonate. A second route, prominent in brain, involves the action of phospholipase C on phosphatidylinositol, yielding diacylglycerol, which in turn undergoes cleavage by diacylglycerol lipase and then monoacylglycerol lipase (MGL; see page 722 in Chapter 17) to give free arachidonate.

Free arachidonate is acted on, in stage 2, by **PGH synthase**, a bifunctional endoplasmic reticulum membrane enzyme with two activities in a single heme-containing polypeptide chain. The first, a **cyclooxygenase**, introduces two molecules of O₂, one to form the ring and one to form a hydroperoxy group at C-15, giving PGG₂ (Figure 19.32). This complex reaction involves a tyrosyl radical, generated by the heme cofactor. The second activity, a **peroxidase**, involves a two-electron reduction of the peroxide to give PGH₂, with a hydroxyl group at C-15 (Figure 19.32). Mammalian cells contain two distinct forms of PGH synthase, called PGHS-1 and PGHS-2 (or COX-1 and COX-2, where COX stands for

The cyclooxygenase reaction, one of the first steps in eicosanoid synthesis, is the target site for aspirin action.

cyclooxygenase). COX-1 is constitutively expressed in most tissues, and is responsible for the physiological production of prostaglandins. COX-2 is induced by cytokines, mitogens, and endotoxins in inflammatory cells and is responsible for the elevated production of prostaglandins during inflammation. Both isoforms are covalently modified, and hence inactivated, by reaction with aspirin (acetylsalicylic acid). As shown, aspirin acetylates a specific serine residue, which in turn blocks access of the fatty acid substrate to the cyclooxygenase active site.

The anti-inflammatory and analgesic properties of aspirin derive from the inhibition of COX-2. However, the inhibition of COX-1 has undesirable side effects on the gastrointestinal system, including ulceration. Another widely used NSAID, ibuprofen (Figure 19.34), acts somewhat more specifically upon COX-2 but is a less effective inhibitor than aspirin. Using structural data on the two COX isoforms, molecular pharmacologists designed aspirin analogs that selectively acylate COX-2, and these have the desirable properties of aspirin without the gastrointestinal side effects. Highly selective COX-2 inhibitors such as Vioxx and Celebrex (Figure 19.34), introduced in the late 1990s for relief of arthritis pain, bind much more tightly to COX-2 than to COX-1. Their selectivity for COX-2 is due the phenylsulfonamide moiety, which binds in a side pocket that is larger in COX-2 than in COX-1. As shown in Figure 19.35, COX-1 has the bulkier isoleucine in place of valine at position 523, essentially blocking the binding of drugs that would occupy this side pocket. Aspirin and other nonselective NSAIDs can still bind to COX-1 because they lack a phenylsulfonamide moiety that would occupy this side pocket. Despite the effectiveness of selective COX-2 inhibitors in the treatment of arthritis, more recent studies have revealed that long-term, high-dosage use of these drugs is associated with increased risk of heart attack and stroke (Vioxx was withdrawn from the market in 2004).

In stage 3 of Figure 19.33, a series of specific enzymes converts PGH_2 to other prostaglandins and to thromboxane A_2 . Another pathway leads from arachidonate to the leukotrienes. Leukotriene C was originally discovered in the class of white blood cells called polymorphonuclear leukocytes and was named after the source (*leukocytes*) and the *triene* structure (three double bonds). It is a potent muscle contractant that is involved in the pathogenesis of asthma, through constriction of the small airways in the lung. As shown in Figure 19.36, leukotrienes are formed from the initial attack on arachidonate of a **lipoxygenase**, which adds O_2 to C-5, giving 5-hydroperoxyeicosatetraenoic acid (5-HPETE). A dehydration to give the epoxide coupled with isomerization of double bonds gives leukotriene A_4 . Hydrolysis of the epoxide ring yields leukotriene B_4 . Transfer of the thiol group of glutathione yields leukotriene C_4 . Subsequent modifications of the peptide chain (not shown) yield related compounds, leukotrienes D and E.

All of the eicosanoids are metabolized extremely rapidly, with most failing to survive a single pass through the circulatory system. The lung is a major site of prostaglandin catabolism. The many catabolic pathways all seem to start with conversion to 15-keto-13,14-dihydro derivatives.

Biological Actions

As noted earlier, prostaglandins and their relatives can be considered as locally acting hormones. Evidently they act through binding to specific cellular receptors.

Ibuprofen (Advil)

Naproxen (Aleve)

Rofecoxib (Vioxx)

Celecoxib (Celebrex)

FIGURE 19.34

Nonsteroidal anti-inflammatory drugs (NSAIDs). Ibuprofen and naproxen are examples of nonselective COX inhibitors. Rofecoxib (Vioxx) and celecoxib (Celebrex) are selective COX-2 inhibitors. The phenylsulfonamide moieties, which contribute to their selectivity, are highlighted in magenta.

FIGURE 19.36

Biosynthesis of leukotrienes.

FIGURE 19.35

Structural basis for selective inhibition of COX-2. (a) Ovine COX-1 with the nonselective NSAID flurbiprofen (blue) bound in the COX active site (PDB ID 1EQH). Residues Ile 434, His 513, Phe 518, Ile 523, and the inhibitor are shown in space-filling representations. Arg-120 (green), which is important in binding the normal substrate arachidonic acid, extends behind flurbiprofen to interact with its carboxylate. The heme cofactor is shown in red, and the tyrosine (pink) that forms the active site radical is indicated by an asterisk (*). (b) Mouse COX-2 with the selective inhibitor SC-588 (blue) bound in the COX active site (PDB ID 1CX2). Residues Val 434, Arg 513, Phe 518, Val 523, and the inhibitor are shown in space-filling representations. The phenylsulfonamide group of SC-588 extends into the side pocket made accessible by Val 523 (gray, barely visible behind the drug). The bulkier isoleucine at this position would prevent binding of SC-588 to COX-1. The chemical structures of the bound inhibitors are shown below.

Modified from *Annual Review of Biochemistry* 69:145–182, W. L. Smith, D. L. DeWitt, and R. M. Garavito, Cyclooxygenases: Structural, cellular, and molecular biology. © 2000 Annual Reviews.

We know relatively little about their subsequent effects at the molecular level, though there clearly are interactions with cyclic nucleotide metabolism. PGE stimulates adenylate cyclase in some cells, and PGF_2 has been reported to elevate levels of cyclic GMP in target cells. Although receptors for these compounds have not yet been characterized in detail, several compounds now under clinical study as anti-inflammatory agents apparently act by binding to receptors for leukotriene B₄. A number of the eicosanoids play roles in the inflammation process, as evidenced by the fact that the anti-inflammatory effects of aspirin derive, at least in part, from the inhibition of cyclooxygenase.

Other biological effects include inhibition of platelet aggregation and relaxation of coronary arteries by PGI_2 , effects that are counteracted by TxA_2 . It seems likely that the action of PGI_2 could prevent platelet binding to arterial walls. In damaged areas the inhibition of PGI_2 synthesis could allow TxA_2 to bind and cause platelet aggregation, thereby promoting the formation of a clot.

Although little is known so far about molecular actions of the eicosanoids, knowledge of their physiology is being applied in useful ways. Recent studies indicate that long-term aspirin administration reduces the risk of heart attacks. Presumably this effect is related to the reduced synthesis of eicosanoids (particularly TxA_2) that induce platelet aggregation, an early step in the clot formation that participates in myocardial infarction. Because prostaglandin release is involved in the uterine muscle contraction that occurs in labor, $\text{PGF}_{2\alpha}$ is used when it is necessary to induce labor in mothers at term. Related to this effect is that $\text{PGF}_{2\alpha}$ inhibits progesterone secretion and regression of the corpus luteum. $\text{PGF}_{2\alpha}$ and PGE_2 are used as well to induce abortion in the second trimester or to induce delivery in case of the death of a fetus. Prostaglandin derivatives are used in animal husbandry, to bring a group of female animals into heat simultaneously. PGI_2 is used to reduce the risk of blood clotting during cardiopulmonary bypass operations. PGE_1 , a vasodilator, is being tested against various circulatory disorders, and forms of PGE, which also inhibit gastric secretion, are being used in the experimental treatment of stomach ulcers. Efforts in the pharmaceutical industry are devoted to developing longer-lived prostaglandin analogs.

SUMMARY

Glycerophospholipids, the predominant membrane lipids, are synthesized by routes that start from phosphatidic acid and intermediates activated by reaction with cytidine triphosphate. Retailoring of fatty acid side chains in phospholipids, exchange of polar head groups, and the actions of phospholipid exchange proteins, which insert phospholipids into membranes, all play roles in shaping the lipid composition of specific membranes. *S*-Adenosylmethionine is the methyl group donor for phosphatidylcholine synthesis.

Glycosphingolipids are assembled from ceramide and successive sugar additions involving glycosyltransferases and nucleotide-linked sugars. The pathway for turnover of these compounds in nervous tissue was elucidated from analysis of products that accumulated in cells of individuals with enzymatic defects in the pathway.

All steroid compounds—and indeed all isoprenoid compounds—are synthesized from acetate, by a pathway that proceeds through the six-carbon mevalonic acid and involves C_5 , C_{10} , and C_{15} intermediates. Cyclization of the C_{30} hydrocarbon squalene leads to cholesterol, the precursor for all bile acids and steroid hormones. Synthesis of steroid hormones occurs in endocrine glands and involves cytochrome P450-dependent hydroxylations, oxidoreduction reactions, and side chain cleavage reactions. All steroid hormone synthesis proceeds from cholesterol through pregnenolone.

Arachidonic acid and other C_{20} unsaturated fatty acids are precursors to physiologically potent, locally acting hormones that include prostaglandins, thromboxanes, and leukotrienes. Although actions of these biological regulators are not yet understood at the molecular level, metabolism of these eicosanoids presents therapeutic targets for drugs used to control inflammation, blood clotting, and gastric secretion and to manipulate reproductive processes in various ways.

PROBLEMS

1. Would you expect the reaction catalyzed by cardiolipin synthase to be strongly exergonic or strongly endergonic? Explain your reasoning.
- *2. Phosphatidylserine (PS) is considered to be an intermediate in the biosynthesis of phosphatidylethanolamine (PE) in *E. coli*, yet PS is not found in appreciable amounts among *E. coli* membrane phospholipids. Because PS must be present in the membrane to serve as an intermediate, how might you explain its failure to accumulate to a significant extent? What kinds of experiments could test your proposed explanation?
3. Melittin is a protein in bee venom that activates phospholipase A₂. How might this effect contribute to the local inflammation that is caused by bee stings?
4. What would you expect to happen to levels of mevalonate in human plasma if an individual were to go from a meat-containing diet to a vegetarian diet?
5. Write a balanced equation for the synthesis of *sn*-1-stearoyl-2-oleylglycerophosphorylserine, starting with glycerol, the fatty acids involved, and serine.
6. If mevalonate labeled with ¹⁴C in the carboxyl carbon were administered to rats, which carbons of cholesterol would become labeled?
7. Which step in lipid metabolism would you expect to be affected by 3,4-dihydroxybutyl-1-phosphonic acid (shown here)? Explain your answer.
- *8. Methyl-labeled [¹⁴C]methionine at a specific activity of 2.0 millicuries per millimole was injected into rats. Six hours later the rats were killed. Phosphatidylcholine was isolated from the liver and found to have a specific activity of 1.5 millicuries per millimole. Calculate the proportions of phosphatidylcholine synthesized by the phosphatidylserine pathway and by the pathway starting from free choline. What further information would you need for your calculated values to reflect the true rates of these processes?
9. Identify a pathway for utilization of the four carbons of acetoacetate in cholesterol biosynthesis. Carry your pathway as far as the rate-determining reaction in cholesterol biosynthesis.
10. Explain why a deficiency of steroid 21-hydroxylase leads to excessive production of sex steroids (androgens and estrogens).
11. *cis*-Vaccenate is an 18-carbon unsaturated fatty acid abundant in *E. coli* membrane lipids. Propose a metabolic route for synthesis of this fatty acid, in light of the fact that stearic acid, the C₁₈ saturated analogous fatty acid, is virtually absent from *E. coli* lipids.
12. The synthesis of phosphatidylcholine from phosphatidylethanolamine proceeds via three successive AdoMet-dependent methylation reactions. How might you determine experimentally whether these three reactions are catalyzed by the same enzyme or by three separate enzymes?
13. Briefly describe how cyclic AMP controls phospholipid synthesis.
- *14. Assuming that all terpene compounds are synthesized by the HMG-CoA/mevalonate pathway, select a simple terpene (limonene, retinol, phylloquinone, or the like) and propose a route for its synthesis from isopentenyl pyrophosphate and dimethylallyl pyrophosphate.

CHAPTER 20

Metabolism of Nitrogenous Compounds I: Principles of Biosynthesis, Utilization, and Turnover

Thus far our study of metabolism has concerned itself primarily with compounds that can be degraded completely to carbon dioxide and water—in other words, compounds containing only carbon, hydrogen, and oxygen. We turn now to nitrogen-containing compounds—amino acids and their derivatives, nucleotides, and the polymeric nucleic acids and proteins. This chapter and the next two describe the metabolism of low-molecular-weight nitrogenous compounds (Figure 20.1). The metabolism of specific amino acids is presented in Chapter 21, and nucleotide metabolism is covered in Chapter 22. This chapter focuses on how cells assimilate nitrogen and how they dispose of excess nitrogen. Because the biological availability of nitrogen is limited, and because the breakdown of nitrogenous compounds often yields toxic products, we will encounter some new metabolic principles.

The existence of 20 different amino acids in proteins implies the existence of 20 biosynthetic pathways and 20 degradative pathways. Although this might seem intimidating at first glance, the common features of pathways involving various amino acids should ease the task of learning. More important than many of the details of biosynthesis and degradation, however, are the numerous roles of amino acids other than as protein constituents, including their functions as precursors to hormones, vitamins, coenzymes, porphyrins, pigments, and neurotransmitters.

Chapters 20–22 also indicate how much we have learned from naturally occurring human mutations, as well as from mutations generated in the laboratory, in cultured cells, or in bacteria. Whereas a mutation that inactivates an enzyme in one of the central energy-generating or energy-storing pathways is likely to be lethal and, hence, not observed in living individuals, mutations that affect amino acid

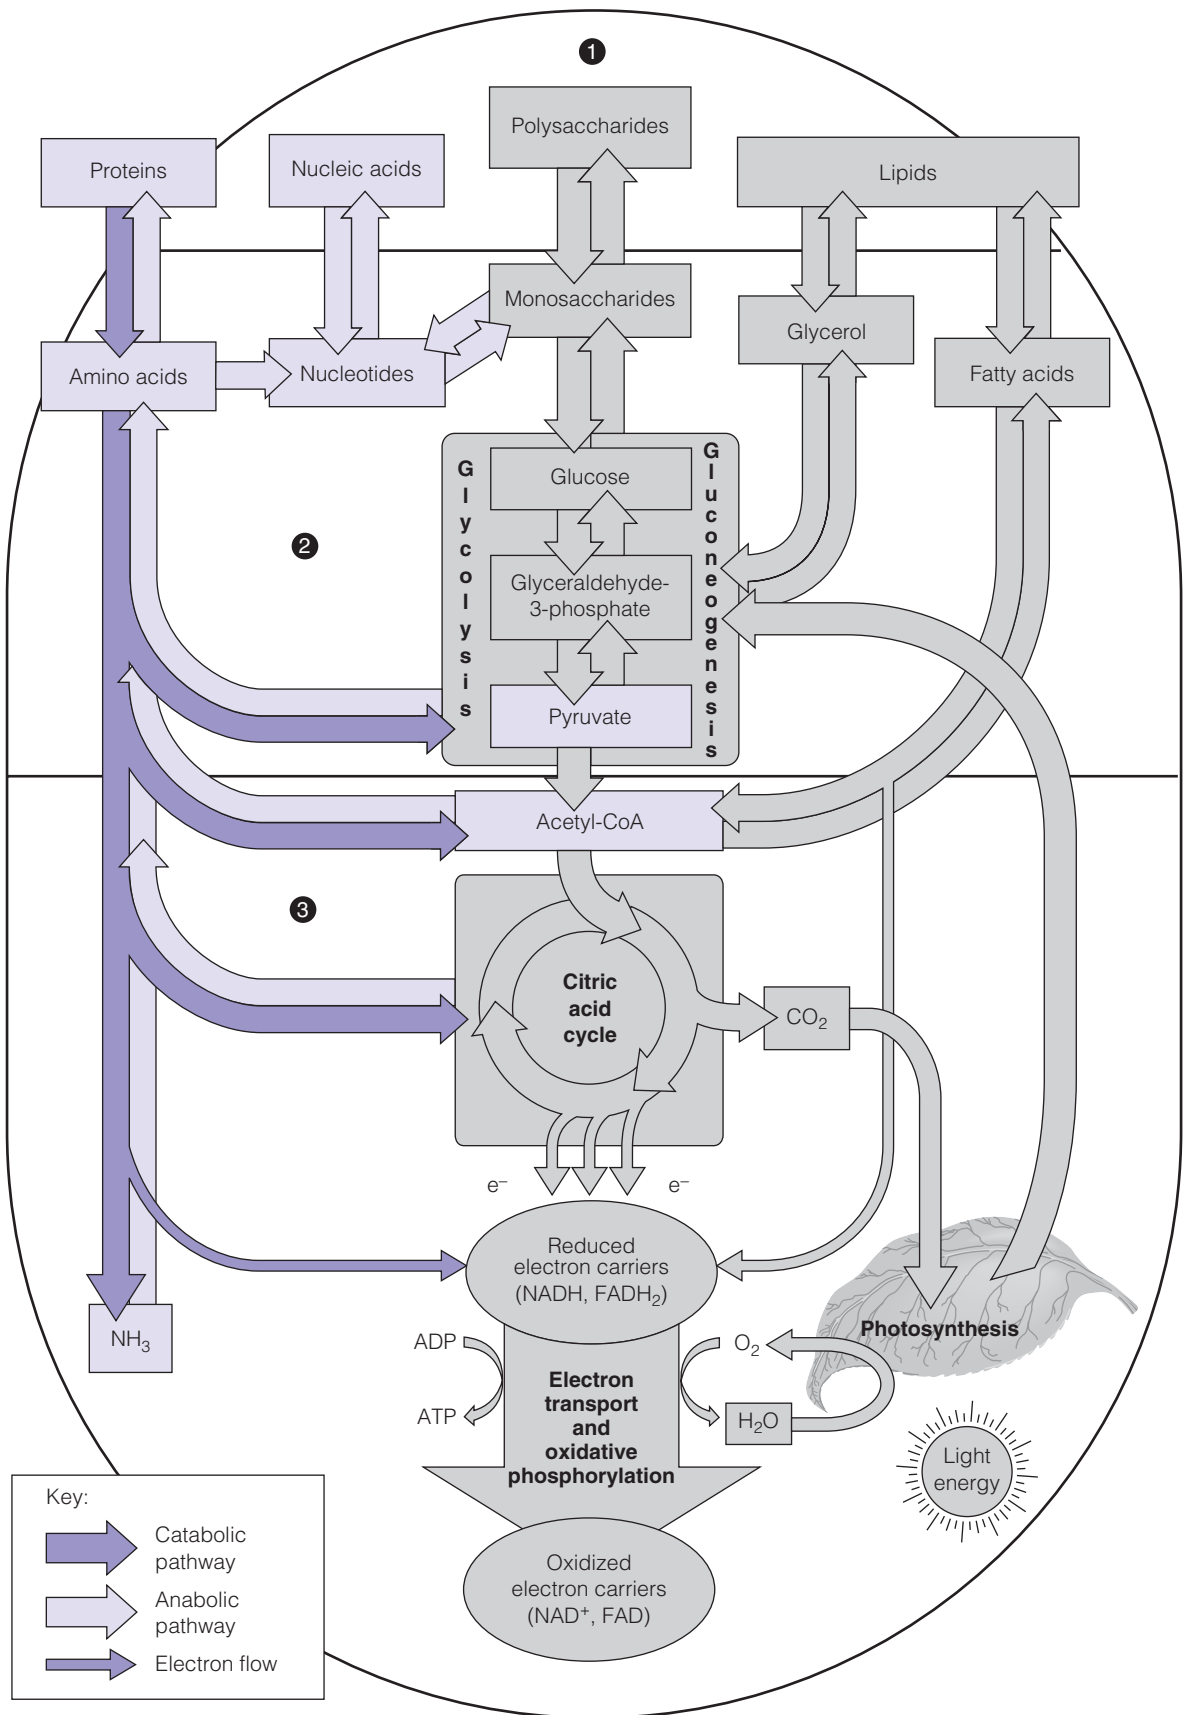

FIGURE 20.1

Pathways of nitrogen metabolism (purple) in the general pattern of intermediary metabolism.

metabolism are often not lethal and *are* found in living humans. The clinical consequences of these mutations are often tragic, but these inherited metabolic diseases have greatly enhanced our understanding of human biochemistry.

Utilization of Inorganic Nitrogen: The Nitrogen Cycle

Few organisms can use the N_2 in air and many soils are poor in nitrate. Thus, nitrogen bioavailability limits growth for most organisms.

For many organisms, growth and reproduction are limited by the availability of utilizable nitrogen, which in turn is limited by the abilities of organisms to utilize different inorganic forms of nitrogen. All organisms can convert ammonia (NH_3) to organic nitrogen compounds—that is, substances containing C—N bonds. However, not all organisms can synthesize ammonia from the far more abundant forms of inorganic nitrogen—dinitrogen gas (N_2), the most abundant component of the earth's atmosphere, and nitrate ion (NO_3^-), a soil constituent essential for the growth of most plants. The reduction of N_2 to NH_3 , termed **biological nitrogen fixation**, is carried out only by certain microorganisms called **diazotrophs**. The reduction of NO_3^- to NH_3 , by contrast, is widespread among both plants and microorganisms.

As in the consideration of any limited resource, it is useful to think about nitrogen metabolism in terms of an economy—a **nitrogen economy**—that focuses on questions of supply, demand, turnover, reuse, growth, and maintenance of a steady state. Within the biosphere, a balance is maintained between total inorganic and total organic forms of nitrogen. The conversion of inorganic to organic nitrogen, which starts with nitrogen fixation or nitrate reduction, is counterbalanced by catabolism, **denitrification**, and decay (Figure 20.2). Catabolism yields ammonia and various organic nitrogenous end products, which can in turn be metabolized by various bacteria: *Nitrosomonas* species oxidize ammonia to nitrite (NO_2^-), and *Nitrobacter* species oxidize nitrite to nitrate. These oxidations generate biological energy, just as other organisms derive energy from oxidation of carbohydrate or fat to CO_2 . Other bacteria, the **denitrifying bacteria**, catabolize ammonia to N_2 . Because of the toxicity of ammonia, there is much interest in using denitrifying bacteria and their enzymes in **bioremediation**, the use of living organisms to purify and detoxify environmental residues of human activity, such as manufacturing, or in waste disposal. Our concern here is with the use of nitrogen for amino acid and nucleotide biosynthesis, so our focus in the rest of this section will be on synthesis of ammonia from N_2 or from nitrate ion.

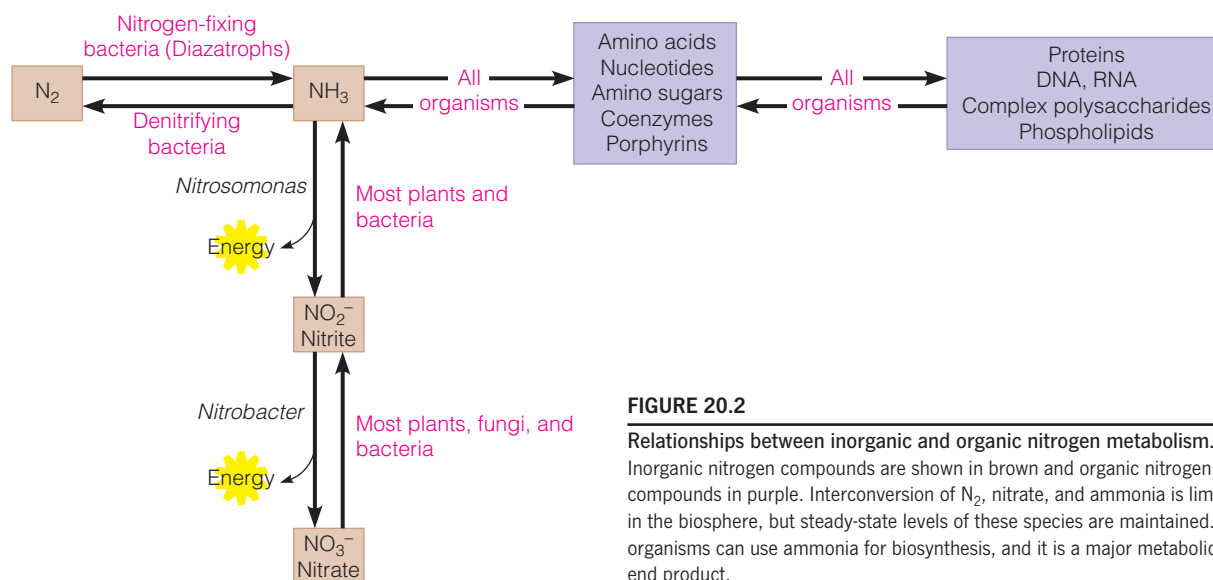

FIGURE 20.2

Relationships between inorganic and organic nitrogen metabolism.

Inorganic nitrogen compounds are shown in brown and organic nitrogen compounds in purple. Interconversion of N_2 , nitrate, and ammonia is limited in the biosphere, but steady-state levels of these species are maintained. All organisms can use ammonia for biosynthesis, and it is a major metabolic end product.

Biological Nitrogen Fixation

Although nitrogen gas makes up about 80% of the earth's atmosphere, its reduction to ammonia occurs in relatively few living systems—some free-living soil bacteria, such as *Klebsiella* and *Azotobacter*; photosynthetic cyanobacteria (blue-green algae); some archaea; and symbiotic nodules on the roots of leguminous plants, such as beans or alfalfa, that have been infected with certain bacteria, notably of the genus *Rhizobium* (Figure 20.3). The infecting bacterium assumes a modified form, called a **bacteroid**, inside the cells of infected plants. This symbiosis allows the host plant to grow without an exogenous nitrogen source. Some trees, such as alder, also form nitrogen-fixing nodules and thus have the capacity to fix nitrogen. Recent discoveries have revealed an impressive diversity of diazotrophs, including hyperthermophilic methane-producing archaea from hydrothermal vents and anaerobic methane-oxidizing archaea from deep-sea cold seeps.

Because nitrogen availability is the factor limiting the fertility of most soils, an understanding of biological nitrogen fixation is directly related to increasing the world's food supply. The triply bonded N_2 molecule, $N\equiv N$, with a bond energy of about 940 kJ/mol, is extraordinarily difficult to reduce. Industrially, the reduction is done by the Haber–Bosch process, a low-yield catalytic hydrogenation carried out at high temperature and pressure. This process is used in the manufacture of ammonia-based fertilizers. Interest in the molecular details of biological nitrogen fixation has derived partly from hopes of supplanting this energy-intensive process with a means of ammonia production that can take place under milder conditions.

Formally, nitrogen fixation can be compared with photosynthesis. Both N_2 and CO_2 are stable inorganic compounds whose reduction requires both energy and low-potential electrons—in the form of reduced electron carriers of very low E_0 . As we saw in Chapter 16, photosynthesis uses light to generate both energy (through photophosphorylation) and low-potential electrons (as in reduced ferredoxin). Comparable mechanisms used in nitrogen fixation are still not completely understood, partly because the enzymes involved are extremely sensitive to oxygen and can be studied only under anaerobic conditions. The major reason nitrogen can be fixed in root nodules of plants infected with *Rhizobium* is that the nodules contain an abundant protein called **leghemoglobin**, which maintains an anaerobic environment by binding any O_2 that finds its way into the nodule and presenting it to respiratory enzymes—in a manner somewhat akin to the behavior of myoglobin in animals.

Biological N_2 reduction is catalyzed by the enzyme **nitrogenase**, of which four types are known. The most abundant and widely studied nitrogenase is the molybdenum (Mo)-dependent enzyme, such as that found in *Azotobacter vinelandii*. The stoichiometry of the overall reaction is as follows:

Nitrogen fixation is a very expensive process, requiring hydrolysis of two ATPs per electron transferred. The ATP is generated through energy-yielding pathways of the organism, primarily carbohydrate catabolism. Although eight total electrons are required, reduction of N_2 to $2NH_3$ is a six-electron process. The other two electrons are “wasted” in the formation of H_2 . Electrons for N_2 reduction are derived from low-potential carriers, either reduced ferredoxin or flavodoxin, a low-potential flavoprotein. H_2 is a by-product of nitrogen reduction. Some nitrogen-fixing species have the ability to “recycle” this hydrogen, to generate low-potential electron carriers for additional cycles of N_2 reduction.

The Mo-dependent nitrogenase consists of two separate metalloproteins. As outlined in Figure 20.4, one protein—called **molybdenum–iron (MoFe) protein, dinitrogenase, or component I**—catalyzes the reduction of N_2 . The other—called **iron (Fe) protein, dinitrogenase reductase, or component II**—transfers electrons and protons, one at a time, to the MoFe protein, in a process coupled to the hydrolysis of two MgATPs. Both proteins contain iron–sulfur clusters, and MoFe protein also

The Haber–Bosch process

FIGURE 20.4

Mechanism of the two-component molybdenum-dependent nitrogenase reaction. MoFe protein (green) is molybdenum–iron protein, or dinitrogenase. Fe protein (pink) is iron protein, or dinitrogenase reductase. (These colors correspond to the protein structures in Figure 20.5.) MoFe protein catalyzes the reduction of N_2 and is reduced in turn by Fe protein. The Fe protein is believed to undergo a three-state cycle, and the MoFe protein a nine-state cycle. Binding of ATP to reduced Fe protein ($FeP^{Red}-ATP$) is thought to generate an altered conformation of Fe protein, with a very low reduction potential. Transfer of the electron from reduced Fe protein to MoFe protein is accompanied by hydrolysis of bound ATP to $ADP + P_i$. Oxidized Fe protein ($FeP^{Ox}-ADP + P_i$) then dissociates from the MoFe protein (this is the rate-limiting step for N_2 reduction) and is regenerated by exchange with ATP and reduction back to the +1 oxidation state. In the MoFe protein cycle, the transfer of an H^+ and an electron from Fe protein to MoFe protein occurs eight times during the reduction of one N_2 molecule. Sequential reduced states are represented by E_n , where n is the total number of electrons donated by the Fe protein. At least three e^-/H^+ must accumulate within the MoFe protein before N_2 binds, and binding of N_2 to MoFe protein occurs concomitantly with release of two bound hydrogens as H_2 . Cleavage of the $N-N$ bond occurs after $5e^-/H^+$ have been added.

Iron–molybdenum cofactor (FeMo-co)

*R*-homocitrate

contains molybdenum, in the form of a tightly bound **iron–molybdenum cofactor** (FeMo-co). N_2 binds to this cofactor during its reduction, although the precise mode of binding is not yet known. The ultimate electron donor for the Fe protein depends on the organism, with reduced ferredoxin or flavodoxin being the most common donor.

Several crystal structures have been described for the individual Fe protein and MoFe protein components from *Azotobacter vinelandii* and, in 1997, a structure for the entire complex was reported. As shown in Figure 20.5, the Fe protein is a homodimer of ~32 kilodalton subunits with a single Fe_4S_4 cluster bridging the two subunits. Each subunit has one nucleotide binding site (bound by MgADP in Figure 20.5). Binding of ATP evidently forces a conformational change in the Fe protein, which drives its docking to the MoFe protein. The MoFe protein is an $\alpha_2\beta_2$ -heterotetramer ($M_r \approx 250,000$) that contains two novel iron–sulfur complexes—the P cluster, which contains seven sulfurs and eight irons, and the iron–molybdenum cofactor (FeMo-co), which, as shown, contains nine sulfurs, seven irons, and one molybdenum atom coordinated to a molecule of **R-homocitrate** through its 2-hydroxy and 2-carboxyl groups (see margin). FeMo-co also contains an unidentified atom (X) (colored blue in the structures). As shown in Figure 20.5, electrons flow from ferredoxin or flavodoxin to the Fe_4-S_4 complex in

FIGURE 20.5

Structure of molybdenum-dependent nitrogenase from *Azotobacter vinelandii*.

Left: The two subunits of the homodimeric Fe protein (PDB ID 1FP6) are shown in shades of pink, each containing a bound MgADP and the bridging Fe₄-S₄ cluster. The α and β subunits of the α₂β₂ tetramer of MoFe protein (PDB ID 1M1N) are shown in dark green and light green, respectively. (These colors correspond to those in Figure 20.4.) Each αβ unit binds one P iron-sulfur cluster and one FeMo-co iron-sulfur cluster.

Right: The relative positions and structures of the Fe₄-S₄ cluster of the Fe protein, and the P cluster and the FeMo cofactor (FeMo-co) of the MoFe protein are shown. Sulfur atoms are yellow, iron atoms are orange, and the molybdenum atom is purple. The flow of electrons from reduced ferredoxin or flavodoxin (Fd) through the iron-sulfur clusters to N₂ is indicated. Hydrolysis of bound ATP is thought both to drive the reduction of P cluster by Fe protein and to trigger a conformational change in Fe protein that causes it to dissociate transiently from MoFe protein, assuring unidirectional electron flow.

Modified from *Annual Review of Biochemistry* 78:701–722, L. C. Seefeldt, B. M. Hoffman, and D. R. Dean, Mechanism of Mo-dependent nitrogenase. © 2009 Annual Reviews.

the Fe protein, and the hydrolysis of bound ATP somehow drives the electrons to the P cluster in the MoFe protein and then to FeMo-co. These three clusters are sufficiently close together in the complex to allow facile electron transfer.

Some bacteria have been found to contain more than one nitrogenase complex. *Azotobacter* contains three such systems, one of which uses vanadium instead of molybdenum, and one that has iron as the sole bound metal.

The genetics of nitrogen fixation is under intense study because of the desirability of transferring nitrogen-fixing capabilities to higher plants, thereby reducing the use of nitrogenous fertilizers. In *Klebsiella*, 13 genes known to be essential to the process are linked within one region of DNA some 24,000 base pairs in length, the *nif* gene cluster. Seven interspersed genes participate but are not essential for nitrogen fixation. Products of the essential genes include the two polypeptide subunits of MoFe protein, the one subunit of Fe protein, flavodoxin, and enzymes that synthesize FeMo-co.

A twist on the nitrogen-fixing symbiosis in leguminous plants was recently discovered. Although homocitrate is an essential component of the iron-molybdenum cofactor, the *nifV* gene that encodes homocitrate synthase is not present in most *Rhizobium* species that infect the host plant. Instead, the homocitrate synthase expressed in the root nodules is encoded by the host plant. Thus, functional nitrogenase requires homocitrate produced by the host plant cells, providing a molecular basis for the interdependent partnership between legumes and rhizobia in symbiotic nitrogen fixation.

Nitrate Utilization

The ability to reduce nitrate to ammonia is common to virtually all plants, fungi, and bacteria. The first step, reduction of nitrate (+5 oxidation state) to nitrite (+3 oxidation state) is catalyzed by **nitrate reductase**. The eukaryotic enzyme contains bound FAD, molybdenum, and a cytochrome *b*₅. The enzyme carries out the overall reaction:

Modified from *Annual Review of Plant Biology* 57: 623–647, G. Schwarz and R. R. Mendel, Molybdenum cofactor biosynthesis and molybdenum enzymes. © 2006 Annual Reviews.

NADH-specific enzymes are found most commonly in plants and algae; NADPH-specific enzymes are found only in fungi; and bispecific NAD(P)H forms are found in all three groups but most commonly in fungi. The electrons are transferred from NAD(P)H to enzyme-bound FAD, then to cytochrome b_5 , then to molybdenum, and finally to the substrate. The molybdenum is bound to a cofactor containing a *pteridine* ring (see page 825), which is quite distinct from the structure of FeMo-co. In fact, all known molybdenum-requiring enzymes except nitrogenase contain a structure similar to that of this **molybdopterin**, in which the Mo center shows a pyramidal geometry.

Reduction of nitrite to ammonia is carried out in three steps

by one enzyme, **nitrite reductase**. Higher plants, algae, and cyanobacteria use ferredoxin as the electron donor in this six-electron reaction. This enzyme contains one Fe_4S_4 center and one molecule of **siroheme**, a partially reduced iron porphyrin.

Utilization of Ammonia: Biogenesis of Organic Nitrogen

Several ubiquitous enzymes use ammonia as a substrate for synthesis of glutamate, glutamine, asparagine, or carbamoyl phosphate.

Carbamoyl phosphate

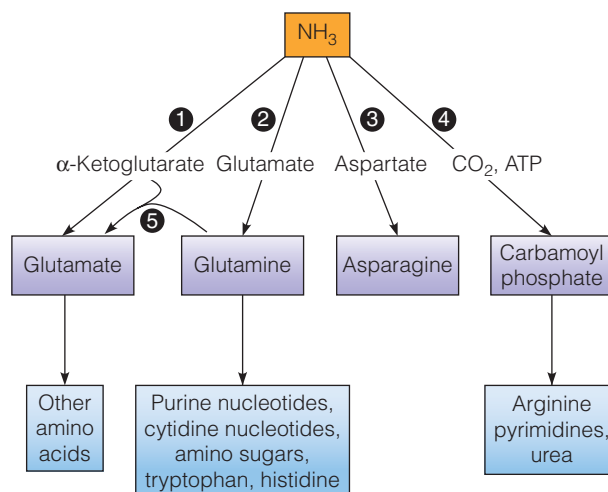

Although plants, animals, and bacteria derive their nitrogen from different sources, virtually all organisms share a few common routes for utilization of inorganic nitrogen in the form of ammonia. Ammonia in high concentrations is quite toxic, but at lower levels it is a central metabolite, serving as substrate for four enzymes that convert it to various organic nitrogen compounds. At physiological pH the dominant ionic species is ammonium ion, NH_4^+ ($\text{p}K_a = 9.2$). However, the four reactions involve the unshared electron pair of NH_3 , which is therefore the reactive species.

All organisms assimilate ammonia via reactions leading to glutamate, glutamine, asparagine, and **carbamoyl phosphate** (Figure 20.6). Because carbamoyl phosphate is used only in the biosynthesis of arginine, urea, and the pyrimidine nucleotides, most of the nitrogen that finds its way from ammonia to amino acids and other nitrogenous compounds does so via the two amino acids glutamate and glutamine. The α -amino nitrogen of glutamate and the side chain *amide* nitrogen of glutamine are both primary sources of N in biosynthetic pathways.

FIGURE 20.6

Reactions in assimilation of ammonia and major fates of the fixed nitrogen.

① Glutamate dehydrogenase; ② Glutamine synthetase; ③ Asparagine synthetase; ④ Carbamoyl phosphate synthetase; ⑤ Glutamate synthase. In animals, glutamine, rather than NH_3 , is the chief nitrogen source for pyrimidines.

Glutamate Dehydrogenase: Reductive Amination of α -Ketoglutarate

Glutamate dehydrogenase catalyzes the reductive amination of α -ketoglutarate:

The reaction is reversible, but the enzyme has a high K_M for ammonia (~ 1 mM). Most bacteria and many plants contain an NADPH-specific form of the enzyme, which acts primarily in the direction of glutamate formation. Consistent with these characteristics is that bacteria growing with ammonia as their sole nitrogen source use this reaction as the primary route for nitrogen assimilation. In animal cells, the reaction occurs in both directions, although the catabolic direction, supplying α -ketoglutarate for the citric acid cycle, probably predominates because intracellular ammonia concentrations are normally very low. The animal enzyme uses NAD^+ as its principal cofactor, but it can also use NADP^+ . In animals, glutamate dehydrogenase, a hexamer of identical subunits, is located in the inner mitochondrial membrane, consistent with a primary role in energy generation. Moreover, the animal enzyme is allosterically controlled; α -ketoglutarate synthesis is inhibited by GTP and ATP and stimulated by ADP. Thus, the enzyme is activated under conditions of low energy charge. Yeasts and fungi contain both types of glutamate dehydrogenase—each appropriately regulated, with one tailored for nitrogen assimilation and one functioning primarily in catabolism.

A related enzyme that occurs only in microorganisms, plants, and lower eukaryotes, **glutamate synthase**, catalyzes a reaction comparable to that catalyzed by glutamate dehydrogenase but functions primarily in glutamate biosynthesis:

In this reductive amination reaction, the amide N of glutamine replaces NH_3 as the N donor. Because glutamate dehydrogenase has a relatively high K_M for ammonia, glutamate synthase plays a larger role in glutamate synthesis in most cells where ammonia levels are lower (together with glutamine synthetase; see the next section). Glutamate synthase as isolated from several bacteria contains two types of subunits (α and β) in an 800-kilodalton holoenzyme; the $\alpha\beta$ protomer contains FAD, FMN, and several iron–sulfur centers. The enzyme from plants uses either NADPH, NADH, or ferredoxin, whereas glutamate synthase from other organisms uses NADH exclusively.

Glutamine Synthetase: Generation of Biologically Active Amide Nitrogen

Whether formed by action of glutamate dehydrogenase or glutamate synthase, or by transamination (see page 619, Chapter 14), glutamate can accept a second ammonia moiety to form glutamine in the reaction catalyzed by **glutamine synthetase**. Mn^{2+} is required.

This enzyme is named a *synthetase*, rather than a *synthase* because the reaction couples bond formation with the energy released from ATP hydrolysis. Both enzymes are classified as ligases (see page 449), but a synthase does not require ATP.

The glutamine synthetase reaction occurs via an acyl phosphate intermediate. ATP phosphorylates the δ -carboxylate of glutamate to give a carboxylic-phosphoric acid anhydride (γ -glutamyl phosphate), which undergoes nucleophilic attack by the nitrogen of ammonia to give the amide product, glutamine.

As revealed originally by electron microscopy and more recently by X-ray crystallography, bacterial glutamine synthetase is a dodecamer, with 12 identical subunits forming two facing hexagonal arrays (Figure 20.7). The holoenzyme has a molecular weight of about 620,000. Each of the 12 catalytic sites is formed at an interface between subunits within a hexamer, and the reaction requires residues from two adjacent subunits.

Regulation of Glutamine Synthetase

Glutamine occupies a central role in nitrogen metabolism (see Figure 20.6). The amide nitrogen is used in biosynthesis of several amino acids (including glutamate, tryptophan, and histidine), purine and pyrimidine nucleotides, and amino sugars. In animals, glutamine synthetase is a key participant in detoxifying ammonia formed from amino acid catabolism, particularly in brain. In fact, glutamate and glutamine are two of the most abundant free amino acids in brain cells; accumulation of these amino acids can deplete α -ketoglutarate, their principal precursor, thereby interfering with the citric acid cycle and energy generation. In addition, glutamine participates in ammonia excretion in the kidney, and it is a major fuel for cells in the immune system. It is not surprising, therefore, that the glutamine synthetase reaction is tightly regulated.

FIGURE 20.7

Structure of *Salmonella typhimurium* glutamine synthetase. (a) Top view of the enzyme, as revealed from the crystal structure (PDB ID 1FPY). Only six subunits can be seen from this viewpoint. The adenylylation site (Tyr 397) is shown in yellow and the two Mn^{2+} ions at each catalytic site are shown in red.

(b) Side view of the dodecamer.

As revealed primarily in *E. coli*, several remarkable control mechanisms for this reaction interact with one another in complex ways. The activity of glutamine synthetase is controlled by two distinct but interlocking mechanisms: (1) allosteric regulation by **cumulative feedback inhibition** and (2) covalent modification of the enzyme brought about by a regulatory cascade.

Cumulative feedback inhibition involves the action of eight specific feedback inhibitors. Those eight inhibitors are either metabolic end products of glutamine (tryptophan, histidine, glucosamine-6-phosphate, carbamoyl phosphate, CTP, and AMP; see Figure 20.6) or indicators in some other way of the general status of amino acid metabolism (alanine, glycine). Remarkably, each ~50,000-dalton subunit of glutamine synthetase must contain binding sites for each of the eight inhibitors, as well as for substrates and products. Each of the eight compounds alone gives only partial inhibition, but in combination the degree of inhibition is increased until a mixture of all eight gives virtually complete blockage. This makes good metabolic sense because it ensures that an accumulation of the end product of one pathway does not shut off the supply of a substrate (glutamine) needed for other pathways.

Superimposed on the cumulative feedback inhibition is a mode of regulation involving covalent modification of the enzyme. Glutamine synthetase is regulated by **adenylylation**: A specific tyrosine residue in the enzyme (Tyr 397) reacts with ATP to form an ester between the phenolic hydroxyl group and the phosphate of the resultant AMP. That tyrosine residue lies very close to a catalytic site (Figure 20.7). Adenylylation inactivates the adjacent catalytic site. An enzyme molecule with all 12 sites adenylylated is completely inactive, whereas partial adenylylation yields partial inactivation.

Adenylylation and deadenylylation of glutamine synthetase involve a complex series of regulatory cascades (Figure 20.8). Both reactions are catalyzed by the same enzyme: a complex of **adenylyltransferase (AT)** and a small regulatory protein, **P_{II}**. The molecular form of P_{II}—uridylylated or deuridylylated—determines whether the complex catalyzes adenylylation or deadenylylation. Reversible uridylylation of P_{II} is catalyzed by yet another enzyme, a bifunctional **uridylyltransferase (UT)/uridylyl-removing enzyme (UR)**, in response to the intracellular glutamine concentration. The uridylyltransferase activity transfers a UMP residue to a specific tyrosine on the P_{II} molecule. The product, **P_{II}-UMP**, binds to adenylyltransferase to stimulate its *de*adenylylation of glutamine synthetase. P_{II}-UMP is deuridylylated by hydrolysis of the UMP residue, catalyzed by the uridylyl-removing activity of the bifunctional UT/UR. The non-UMP-containing form of P_{II} converts adenylyltransferase to an adenylylating enzyme. Activity of the uridylyltransferase is inhibited by glutamine; activity of the uridylyl-removing enzyme is stimulated by glutamine. α -Ketoglutarate concentration is sensed by the unmodified form of P_{II}—its ability to activate adenylyltransferase is antagonized by high concentrations of α -ketoglutarate.

These regulatory cascades provide a responsive mechanism ensuring that, when the supply of activated nitrogen (glutamine) is high, its further biosynthesis is shut down; the UMP-free form of P_{II} accumulates and activates the adenylylation activity of adenylyltransferase. This causes the AMP-containing, or less active, form of glutamine synthetase to accumulate. Conversely, when activated nitrogen supplies are low, α -ketoglutarate accumulates, stimulating the activity of glutamine synthetase by the opposite mechanism.

The modification state of P_{II} also controls the transcription of several nitrogen-regulated genes (Ntr), including the *glnA* gene encoding glutamine synthetase. This regulatory system involves interactions with a specific protein kinase and its transcription factor target. Thus, under conditions of nitrogen starvation (low glutamine), P_{II} is mostly in the P_{II}-UMP state, and *glnA* transcription is stimulated.

In contrast to the 12-subunit bacterial enzymes, mammalian glutamine synthetase is a homodecamer, composed of two pentameric rings stacked face-to-face.

Prokaryotic glutamine synthetase is controlled by cumulative feedback inhibition and covalent modification.

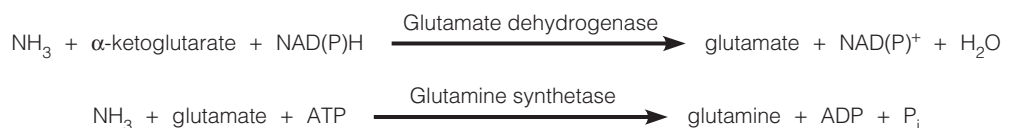

FIGURE 20.8

Regulation of the activity of bacterial glutamine synthetase. The complex of AT (adenylyltransferase) and P_{II} (a regulatory protein) catalyzes both the adenylation and deadenylation of glutamine synthetase (GS), depending on whether P_{II} is deuridylylated (left) or uridylylated (right). Uridylylation of P_{II} is catalyzed by uridylyltransferase (UT), and deuridylylation is catalyzed by uridylyl-removing enzyme (UR), both activities part of a bifunctional enzyme. Components shown in blue tend to promote activity of glutamine synthetase, whereas those shown in orange are associated with enzyme inactivation.

Despite sharing less than 20% amino acid sequence identity with the bacterial enzymes, the subunit folds and active site architectures are strikingly similar. Less is known about how glutamine synthetase is regulated in animal cells. In the liver, glutamine synthetase is feedback inhibited by carbamoyl phosphate, glutamine, and several other amino acids, whereas in the brain, the enzyme is inhibited only by carbamoyl phosphate. Mammalian glutamine synthetase does not appear to be regulated by covalent modification and, in fact, lacks the adenylation loop of the bacterial enzymes.

To assimilate NH_4^+ in bacteria, glutamine synthetase functions together with glutamate dehydrogenase or glutamate synthase, depending on ammonia levels. If NH_4^+ levels are high, the glutamate dehydrogenase/glutamine synthetase pathway operates:

When NH_4^+ levels are low, the glutamate synthase/glutamine synthetase pathway predominates:

In this pathway, only glutamine synthetase fixes ammonia—the role of glutamate synthase is to regenerate glutamate for the glutamine synthetase reaction.

Asparagine Synthetase: A Similar Amidation Reaction

Asparagine synthetase catalyzes a reaction comparable to that of glutamine synthetase. Although widespread, asparagine synthetase accounts for much less ammonia assimilation. This enzyme uses ammonia or glutamine in catalyzing the conversion of aspartate to asparagine.

Note that asparagine synthetase cleaves ATP to yield AMP and PP_i , whereas glutamine synthetase yields ADP and P_i . Asparagine synthetase also differs in that glutamine is strongly preferred as a substrate over ammonia. The reactive species in bond formation is ammonia, which is generated at the active site by hydrolysis of the substrate glutamine.

Carbamoyl Phosphate Synthetase: Generation of an Intermediate for Arginine and Pyrimidine Synthesis

Recall from Figure 20.6 that the final route for assimilating ammonia first forms carbamoyl phosphate. The enzyme responsible is **carbamoyl phosphate synthetase**. Either ammonia or glutamine can serve as the nitrogen donor:

The bacterial enzyme can catalyze both reactions, although glutamine is the preferred substrate. Eukaryotic cells contain two forms of the enzyme. Form I, localized in mitochondria, has a preference for ammonia as substrate and is used in the arginine biosynthetic pathway and the urea cycle (see pages 841–842). Form II, present in the cytosol, has a strong preference for glutamine. It is inhibited by uridine triphosphate, consistent with its demonstrated involvement in pyrimidine nucleotide biosynthesis. As we will see in Chapter 22, the form II enzyme is part of a large multifunctional protein with three distinct catalytic sites, which catalyze the first three reactions of pyrimidine nucleotide synthesis.

Carbamoyl phosphate

The Nitrogen Economy: Aspects of Amino Acid Synthesis and Degradation

Metabolic Consequences of the Absence of Nitrogen Storage Compounds

Early biochemists and physiologists believed that the proteins of an adult animal were quite stable, while proteins in the diet were immediately metabolized to provide energy and the end products excreted. This dogma was challenged in the 1930s by Rudolf Schoenheimer. Schoenheimer had escaped Hitler's Germany and joined the Department of Biochemistry at Columbia University, where Harold Urey had discovered deuterium a few years earlier. This environment inspired Schoenheimer to explore the use of isotopic tracers to study metabolism in whole animals (see Tools of Biochemistry 12A). Urey succeeded in enriching nitrogen with ^{15}N , which Schoenheimer's group used to synthesize ^{15}N -labeled tyrosine. They discovered that following administration of ^{15}N -labeled tyrosine to a rat, only about 50% was recovered in the urine. Most of the remainder was incorporated into tissue proteins. Importantly, only a small amount of the ^{15}N found in the tissue proteins was attached to the original tyrosine carbon skeleton—most had been incorporated into other amino acids. Finally, they observed that an equivalent amount of unlabeled protein nitrogen was excreted, keeping the rat in **nitrogen equilibrium**.

Most organisms lack nitrogen storage depots.

Protein and nucleic acid metabolism differs significantly from the metabolism of carbohydrates and lipids. Whereas carbohydrates and lipids can be stored for mobilization as needed by an organism for energy generation or for biosynthesis, most organisms past the embryonic state have no polymeric nitrogen compounds whose function is to be stored and released on demand. Although plants store some nitrogenous compounds, such as asparagine in asparagus, and some insects have storage proteins in their blood, such compounds do not represent widely used nitrogen storage depots. The lack of such depots imposes special requirements on organisms, particularly because of the limited availability of utilizable nitrogen. Animals must continually replenish nitrogen supplies through the diet to replace nitrogen lost through catabolism. In much of the world, protein-rich foods cannot be produced in sufficient quantity to meet the nutritional needs of humans and domestic animals. When dietary protein is insufficient, proteins synthesized for other purposes, mostly muscle proteins, are broken down and not replaced. Such consequences occur even when the diet contains an adequate caloric content of protein, if that protein does not contain the needed amino acids (essential amino acids, see next section).

Just as we can think of a nitrogen economy for the biosphere, we can see it also in relation to individual organisms. Under optimal conditions, animals maintain nitrogen intake and excretion at equivalent rates. A well-nourished adult is said to be in nitrogen equilibrium or **normal nitrogen balance** if the daily intake of nitrogen through the diet is equal to that lost through urinary excretion and other processes, such as ammonia loss in sweat. Positive nitrogen balance, in which normal nitrogen intake exceeds nitrogen loss, is seen during pregnancy, growth of a juvenile, or recovery from starvation. In negative nitrogen balance, more nitrogen is lost than is taken in, a situation found in senescence, starvation, and certain disease states. Plants and microorganisms commonly excrete very little nitrogen. Microorganisms often grow so rapidly that nitrogen released by catabolism is reassimilated, and in plants nitrogen is often available in such severely limited amounts that this factor itself limits cellular growth rates.

Biosynthetic Capacities of Organisms

Organisms vary widely in their ability to synthesize amino acids. Many bacteria and most plants can synthesize all of their nitrogenous metabolites starting from a single nitrogen source, such as ammonia or nitrate. However, many microorganisms will

use a preformed amino acid, when available, in preference to synthesizing that amino acid. Sometimes preformed amino acids are required. For example, over the course of evolution, the genus *Lactobacillus* has lost many biosynthetic capacities because they grow in milk, a very nutrient-rich environment. Some *Lactobacillus* species must therefore be provided with most of the 20 amino acids to be grown in the laboratory. Mammals are intermediate, being able to biosynthesize about half of the amino acids in quantities needed for growth and for maintenance of normal nitrogen balance.

The amino acids that must be provided in the diet to meet an animal's metabolic needs are called **essential amino acids** (Table 20.1). Those that need not be provided because they can be biosynthesized in adequate amounts are called **nonessential amino acids**. In general, the essential amino acids include those with complex structures, including aromatic rings and hydrocarbon side chains. The nonessential amino acids include those that are readily synthesized from abundant metabolites, such as intermediates in glycolysis or the citric acid cycle.

Although dietitians recommend a protein intake of 50 to 100 grams per day or more, a human can do quite well on a diet containing as little as 20 grams per day, if that protein is of high nutritional quality—that is, if it contains adequate proportions of essential amino acids. In general, the more closely the amino acid composition of ingested protein resembles the amino acid composition of the animal eating the protein, the higher the nutritional quality of that protein. For humans, mammalian protein is of the highest nutritional quality, followed by fish and poultry, and then by fruits and vegetables. (In this context, nutritional quality refers only to the single criterion of essential amino acid content.) Plant proteins in particular are often deficient in lysine, methionine, or tryptophan. However, a vegetarian diet provides adequate protein if it contains a variety of protein sources, with a deficiency in one source being compensated for by excess in another source.

Transamination

In Chapter 14 we introduced transamination, a process whereby amino acids can replenish citric acid cycle intermediates. Transamination plays a somewhat broader role in amino acid metabolism, in that it provides a route for redistribution of amino acid nitrogen. Because of the key role of glutamate in ammonia assimilation, it is a star player in transamination. In other words, glutamate is an abundant product of ammonia assimilation, and transamination uses glutamate nitrogen to synthesize other amino acids.

Transamination reactions are catalyzed by enzymes called **transaminases** or, more properly, **aminotransferases**. As shown below, transamination involves transfer of the α -amino group, usually of glutamate, to an α -keto acid, with formation of the corresponding amino acid plus the α -keto derivative of glutamate, which is α -ketoglutarate.

Specific aminotransferases exist in animal cells for the synthesis of all of the amino acids found in proteins except threonine and lysine, so long as the corresponding α -keto acids are available. Thus, the inability of animal cells to synthesize most of the essential amino acids results from an inability to synthesize the carbon skeletons in the form of α -keto acids.

Essential amino acids cannot be biosynthesized in adequate amounts and must be provided in the diet.

TABLE 20.1 Nutritional requirements for amino acids in mammals

Essential

Arginine*, histidine, isoleucine, leucine, lysine, methionine*, phenylalanine, threonine, tryptophan, valine

Nonessential

Alanine, asparagine, aspartate, cysteine, glutamate, glutamine, glycine, proline, serine, tyrosine

*Although mammals can synthesize arginine and methionine, the use of these amino acids for the production of urea and methyl groups, respectively, is greater than the capacity of their biosynthetic pathways.

Transamination is the reversible transfer of an amino group from an α -amino acid to an α -keto acid, with pyridoxal phosphate as a coenzyme.

Pyridoxal phosphate

Schiff base between amino acid and pyridoxal phosphate

Aminotransferases utilize a coenzyme, **pyridoxal phosphate**, that is derived from vitamin B₆. The functional part of the cofactor is an aldehyde functional group, —CHO, attached to a pyridine ring. The catalytic cycle begins with condensation of this aldehyde with the α -amino group of an amino acid, to give a Schiff base, or aldimine, intermediate. Because pyridoxal phosphate participates in a diversity of reactions involving amino acids, we discuss catalytic mechanisms in a separate section, beginning on page 845.

Transamination reactions have equilibrium constants close to unity. Therefore, the direction in which a particular transamination proceeds is controlled in large part by the intracellular concentrations of substrates and products. This means that transamination can be used not only for amino acid synthesis but also for degradation of amino acids that accumulate in excess of need. In degradation the transaminase works in concert with glutamate dehydrogenase, as exemplified by the degradation of alanine:

Thus, we see transamination as a mechanism for amino acid synthesis *or* degradation. Because the amino acids within a cell are rarely present in the proportions needed to synthesize the specific proteins of that cell, transamination plays an important role in bringing the amino acid composition into line with the organism's needs. It also participates in funneling excess amino acids toward catabolism and energy generation.

Most aminotransferases use glutamate/ α -ketoglutarate as one of the two α -amino/ α -keto acid pairs involved. Two such enzymes are important in the clinical diagnosis of human disease—serum glutamate-oxaloacetate transaminase (SGOT) and serum glutamate-pyruvate transaminase (SGPT):

These enzymes, abundant in heart and in liver, are released from cells as part of the cell injury that occurs in myocardial infarction, infectious hepatitis, or other damage to either organ. Assays of these enzyme activities in blood serum can be used both in diagnosis and in monitoring the progress of a patient during treatment. Note the convention used in naming transaminases; the amino donor and the α -keto acid acceptor are named.

Protein Turnover

Proteins are subject to continuous biosynthesis and degradation, a process called **protein turnover**. For an intracellular protein whose total concentration does not change with time, the steady state level is maintained by synthesis of the protein at a rate just sufficient to replenish protein lost by degradation. Many of the amino acids released during protein turnover are reutilized in the synthesis of new proteins.

Quantitative Features of Protein Turnover

The macroscopic dimensions of protein turnover can be appreciated by considering a day in the life of a 70-kilogram person. That individual typically will consume 100 grams of protein during the day and, because he or she is in normal

nitrogen balance, will excrete an equivalent amount of nitrogenous end products. Yet isotope labeling studies show that about 400 grams of protein are synthesized per day, and 400 grams broken down. About three-quarters of the released amino acids are reused in protein synthesis, with the remainder being degraded and the nitrogen excreted. Thus, the total amino acid pool consists of 500 g/day—100 ingested and 400 released via protein degradation. From this pool, 400 grams are used in protein synthesis and 100 grams are catabolized and excreted.

Individual proteins exhibit tremendous variability in their metabolic lifetimes, from a few minutes to many months. You should realize, however, that all of the proteins in the body are represented among the 400 grams broken down in a typical day. Extensive pulse-chase experiments in laboratory animals (see Tools of Biochemistry 12A) show that protein degradation follows first-order kinetics. For a particular protein, individual molecules are degraded at random, such that a semilogarithmic plot of isotope remaining in a protein versus time is linear. Thus, we can determine the metabolic half-life of a particular protein. In the rat the average protein has a half-life of 1 or 2 days. Table 20.2 gives information about the half-lives of some specific proteins.

As you might expect, proteins that are secreted into an extracellular environment, such as digestive enzymes, polypeptide hormones, and antibodies, turn over quite rapidly, whereas proteins that play a predominantly structural role, such as collagen of connective tissue, are much more stable metabolically. Enzymes catalyzing rate-determining steps in metabolic pathways are also short-lived. Indeed, for many enzymes the rate of breakdown is an important regulatory factor in controlling intracellular enzyme levels. By contrast, proteins that do not represent metabolic control points turn over relatively slowly. In the rat, cytochrome *c* has a half-life of nearly a week; in the human, hemoglobin is as long-lived as the erythrocyte in which it resides (about 120 days). But why should such proteins turn over at all, if their degradation does not represent a metabolic control mechanism? Isn't such turnover wasteful of energy? Let us consider that point.

Biological Importance of Protein Turnover

Like all other intracellular constituents, proteins are subjected to a barrage of environmental influences, primarily reactive oxygen species (see Chapter 15), which can affect their structure, conformation, and biological activity. The capacity of proteins to repair the resulting damage is limited. Protein turnover could be seen

TABLE 20.2 Half-lives and intracellular sites of degradation in protein turnover

Half-Life (hours)	Intracellular Location			
	Nucleus	Cytosol	Mitochondria	Endoplasmic Reticulum and Plasma Membrane
<2	Oncogene products	Ornithine decarboxylase, tyrosine aminotransferase, protein kinase C	δ -Aminolevulinic acid synthetase	HMG-CoA reductase
2–8	—	Tryptophan oxygenase, cAMP-dependent protein kinase	—	γ -Glutamyl transferase
9–40	Ubiquitin	Calmodulin, glucokinase	Acetyl-CoA carboxylase, alanine aminotransferase	LDL receptor, cytochrome P450
41–200	Histone H1	Lactate dehydrogenase, aldolase, dihydrofolate reductase, phytochrome P670	Cytochrome oxidase, pyruvate carboxylase, cytochrome <i>c</i>	Cytochrome <i>b</i> ₅ , <i>cyt b</i> ₅ reductase
>200	Histones H2A, H2B, H3, H4	Hemoglobin, glycogen phosphorylase	—	Acetylcholine receptor

as an inefficient quality control system in which both normal and modified proteins are randomly degraded and replaced. However, it was discovered that proteolysis requires an input of energy, a surprising finding given that amide bond hydrolysis is exergonic. This energy requirement suggested that the process might be nonrandom and regulated. Indeed, protein molecules that have become chemically altered are preferentially degraded. A certain chemical change may mark a protein molecule, targeting it for degradation by a proteolytic enzyme that specifically recognizes the marker.

We know that in bacteria, mutant proteins are degraded much more rapidly than their wild-type counterparts. Evidently evolution has generated proteins whose conformation renders maximum stability in the intracellular environment, and most structural changes decrease this stability.

Protein turnover also represents a route for cellular adaptation to altered environmental conditions. For example, in many bacteria, extensive proteolysis is one of the metabolic events interlinked with **sporulation**, or spore formation. Spores represent a heat-stable form of the microorganism; they metabolize at negligible rates and can remain dormant for months or years. When metabolic conditions induce a growing cell to sporulate, extensive protein turnover occurs, with the amino acids released being used to synthesize proteins of the spore. This quasi-dormant state can be maintained indefinitely, with germination to vegetative cells occurring after improvement in the environmental conditions.

Except for specialized functions such as sporulation, it was thought until the early 1970s that protein turnover, meaning its complete degradation to amino acids, served just two major functions: (1) protein digestion, providing amino acids for synthesis of proteins and other metabolites derived from amino acids, and (2) ridding cells of defective proteins, including those that were mutationally or environmentally damaged. Accordingly, most intracellular proteases were thought to participate in protein turnover. Of course, it has long been recognized that specific endopeptidase protein cleavage reactions are involved in enzyme activation; an example is the blood clotting cascade, which we discussed in Chapter 11. Over the past three decades, it has become clear that this process of limited proteolysis—cleavage of a few specific peptide bonds in a protein—has a host of additional functions, including regulation of gene expression, response to environmental stress, and participation in cell signaling pathways. Of great current interest is the involvement of selective proteolytic reactions in signaling pathways leading to *apoptosis*, a process in normal development in which certain cells, having fulfilled their function in differentiation, undergo a programmed death. These functions are presented in detail in Chapter 29. Here we concern ourselves with those aspects of protein turnover that relate specifically to amino acid metabolism, to identifying major classes of intracellular proteases, and to describing some of the structural features that predispose certain proteins to degradation.

Intracellular Proteases and Sites of Turnover

Because most proteins are used intracellularly, most turn over within the cell. The earliest intracellular proteases to be characterized were in lysosomes. Although the lysosomal system is inside the cell, it functions primarily in the proteolysis of extracytoplasmic proteins, which enter the cell via endocytosis and are degraded within the vacuolar lumen. Lysosomes, which form by budding from the Golgi complex, are bags of digestive enzymes, containing proteases, nucleases, lipases, and carbohydrate-cleaving enzymes. As discussed further in Chapter 28, lysosomes play various cellular roles: secretion of digestive enzymes, digestion of organelles destined for destruction, digestion of food particles or bacteria engulfed by phagocytosis, and the nonselective engulfment and degradation of bulk cellular constituents (**autophagy**).

In eukaryotic cells two distinct classes of proteases have been found in the cytosol—a family of Ca^{2+} -activated neutral cysteine proteases called **calpains**,

All proteins are in a constant state of turnover and replacement, for repair of damage and for biological regulation.

and a large (2.5 megadalton) multisubunit ATP-dependent protease called the **proteasome** (Figure 20.9). Mammals have at least 14 different calpain proteases, which play important roles in necrotic cell death (**oncosis**). These enzymes are distinct from the lysosomal proteases, called **cathepsins**, which are designed to function in an acidic milieu. The proteasome, as we shall see, degrades proteins that have been modified by the attachment of the small protein ubiquitin.

In contrast to lysosomal enzymes, which are usually safely sequestered in their vesicles, any protease activity free in normal cytosol must be under strict control, so as to attack only those proteins whose destruction is needed—damaged, mutant, or otherwise dispensable proteins. The identification, or marking, of those proteins whose degradation suits the interests of the cell involves various tagging schemes described in the next section.

Chemical Signals for Turnover

The turnover rates for different proteins vary by as much as 1000-fold, whereas differences in protein stability, as measured by denaturation *in vitro*, may be much less. Four structural features are currently thought to be interrelated determinants of turnover rate: (1) **ubiquitination**, (2) metal-catalyzed oxidation of particular residues, (3) **PEST sequences**, and (4) particular N-terminal residues.

Ubiquitination

Ubiquitin is a small (76-residue) protein expressed in all eukaryotic cells—it derives its name from its widespread (ubiquitous) distribution. Ubiquitin is covalently conjugated to specific cellular proteins in an ATP-dependent reaction, which condenses the terminal carboxyl group of ubiquitin with lysine amino groups on target proteins, as shown in Figure 20.10. In the first reaction, catalyzed by the ubiquitin-activating enzyme E1, a thioester is formed between the C-terminal Gly residue of ubiquitin and an internal Cys residue of E1 in a two-step process. Formation of this high-energy covalent linkage is driven by ATP hydrolysis, via a ubiquitin-adenylate intermediate. AMP is released upon nucleophilic attack by the Cys-SH of E1. The activated ubiquitin is next transferred to a Cys-SH of one of several E2 enzymes (ubiquitin-conjugating enzymes) in a trans-thiolation reaction. A ubiquitin-protein ligase, E3, is required for step 3—covalent attachment of ubiquitin to the ϵ -NH₃⁺ group of one or more lysine residues on the target protein via an *isopeptide* bond. The use of high-energy thioester bonds to activate ubiquitin makes formation of the isopeptide bond thermodynamically favorable. Expenditure of the equivalent of two ATPs per ubiquitin added ensures that the reaction is both irreversible and specific. We will see an even more dramatic example of the cost of specificity when we discuss protein synthesis in Chapter 28 (see page 1211).

E3 can catalyze the successive addition of a ubiquitin moiety to a previously conjugated ubiquitin, forming a polyubiquitin chain in which a Lys of ubiquitin forms an isopeptide bond with the C-terminal Gly carboxyl group of the succeeding ubiquitin. Ubiquitin contains seven lysine residues, and polyubiquitin chains can involve one or more of these residues, although the functions of chains linked through Lys29, Lys48, and Lys63 are the best characterized. There appear to be just two E1 enzymes in mammals, which activate and transfer ubiquitin to all E2 enzymes. About 28 E2 enzymes are known in humans, each of which can transfer ubiquitin to several E3 proteins. Target protein selectivity resides with the E3 components, and based on commonly shared structural motifs, the human genome may contain as many as 1000 E3s. Two major families of E3 ubiquitin–protein ligases have been described: the HECT domain-containing E3s and the RING-finger domain-containing E3s. These two E3 families differ in structure and in mechanism (Figure 20.10). Because of the central role of E3 in

FIGURE 20.9

Structure of the proteasome. (a) This image was generated by averaging multiple electron micrographs of the 26S proteasome of the toad *Xenopus laevis*. The proteasome contains two major assemblies, a 28-subunit core particle (also known as the 20S particle) and a 19-subunit regulatory particle (also known as the 19S particle), which forms the base and lid assemblies. (b) and (c) The proteolytic active sites are located within the large internal space ($\sim 100 \times 60 \text{ \AA}$) of the 20S core particle. The lid and base assemblies of the 19S regulatory particle control substrate entry into the 20S core particle. Proteins tagged with the protein ubiquitin pass through the tube in an ATP-dependent fashion.

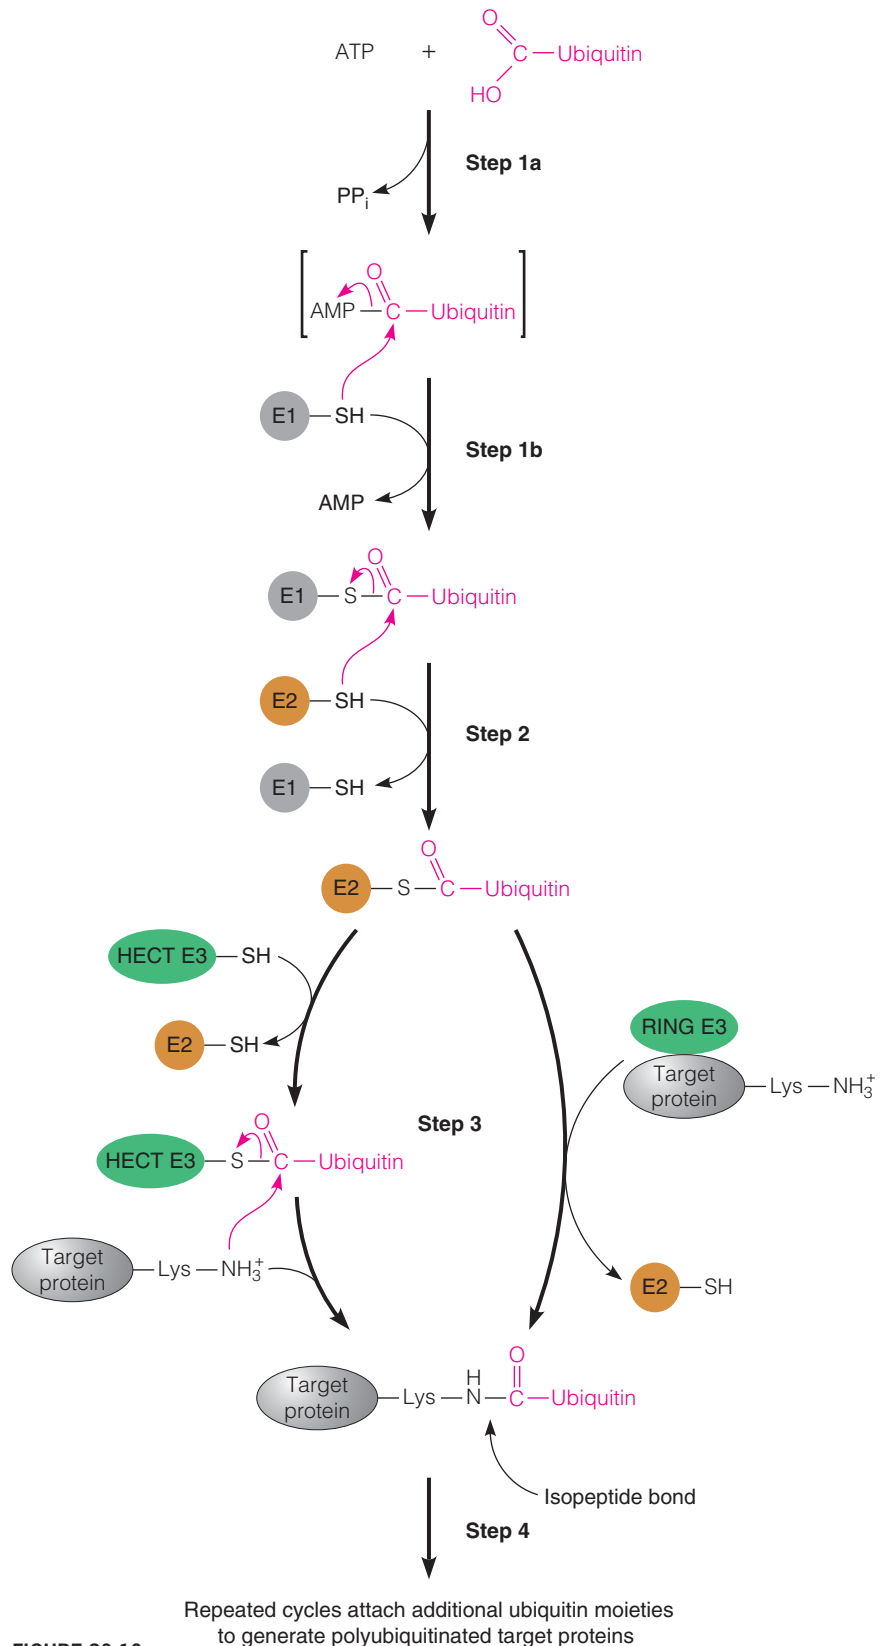

FIGURE 20.10

Enzymatic pathway for attachment of ubiquitin to target proteins. E1, E2, and E3 are proteins involved in the ubiquitin transfer to lysine residues on target proteins. **Steps 1a and 1b:** ATP-dependent formation of a thioester bond between the ubiquitin C-terminus and a cysteine thiol on E1. **Step 2:** Transfer of ubiquitin from E1 to E2. **Step 3:** Transfer of ubiquitin to lysine residue on the target protein. HECT domain-containing E3s (left pathway) catalyze formation of an E3-ubiquitin thioester intermediate before transferring ubiquitin to the substrate. RING-finger domain-containing E3s (right pathway) function as docking proteins, with E2 catalyzing nucleophilic attack of the substrate protein lysine amino group on the E2-ubiquitin thioester. **Step 4:** Formation of polyubiquitin chain on target protein.

determining the specificity and selectivity of the proteasome system, these proteins are implicated in a number of disease states, including neurodegenerative disorders, inflammatory diseases, muscle wasting disorders, and cancer.

Lys29- and Lys48-linked polyubiquitin chains serve as recognition markers for the 26S proteasome, and such tagged proteins dock at the proteasome via specific ubiquitin receptors. The target proteins are subsequently degraded to short peptides in an ATP-dependent process. The polyubiquitin chains are not degraded, but instead are released and disassembled by deubiquitinating enzymes in the lid of the proteasome. The free ubiquitin monomers can then be reused.

Until recently, the role of the ubiquitin system was thought to be limited to regulated proteolysis. It is now clear, however, that Lys63-linked polyubiquitin chains (and probably others as well) have nonproteasomal functions involved in the regulation of many critical processes, including cell cycle progression (Chapter 24), cholesterol synthesis (Chapter 19), inflammation, response to hypoxia (Chapter 18), and apoptosis (Chapter 28). As we have seen for other regulatory systems, ubiquitination is reversible. Ubiquitin removal is catalyzed by a family of **deubiquitinating enzymes** (Dubs)—the human genome encodes ~95 distinct Dubs. We also know of several other ubiquitin-like proteins, such as SUMO (small ubiquitin-like modifier) and ISG15 (interferon-stimulated gene 15kD), which use similar modification/deconjugation machinery and are involved in the regulation of numerous biological processes, including transcription, DNA repair, stress response, and innate immunity.

Although bacteria lack the 26S proteasome, they do possess functionally similar ATP-dependent proteolytic assemblies known as the **Lon** and **Clp proteases**. Both of these proteins are barrel-shaped, with the protease active sites located in a central cavity, like the 26S proteasome of eukaryotes. Homologs of Lon are found in archaea and in mitochondria of eukaryotes.

PEST Sequences

Examination of the amino acid sequences of short-lived proteins ($t_{1/2} < 2$ hours) shows that virtually all of these proteins contain one or more regions rich in proline, glutamate, serine, and threonine. From the one-letter designations for these amino acids (P, E, S, and T, respectively), these regions, some 12 to 60 residues long, have been called PEST sequences. Very few longer-lived proteins contain these regions. Moreover, creation of PEST sequences in long-lived proteins by site-directed mutagenesis increases their metabolic lability. PEST-containing proteins are degraded primarily by the ubiquitin–proteasome system. Current evidence indicates that phosphorylation of serine or threonine residues in the PEST sequence triggers ubiquitination and subsequent degradation of the protein. Thus, the PEST sequence represents another recognition scheme for targeting short-lived proteins to degradation by the 26S proteasome.

N-Terminal Amino Acid Residue

Experiments with bacteria carried out by Alexander Varshavsky revealed that the intracellular half-life of a particular protein varies depending on the identity of its N-terminal amino acid residue. An N-terminal residue of Phe, Leu, Tyr, Trp, Lys, or Arg is correlated with short metabolic lifetimes, whereas proteins with other amino termini are far longer-lived. These findings, originally made with natural proteins, are supported by experiments in which amino termini of proteins were altered by site-directed mutagenesis, with corresponding changes in metabolic half-lives of the mutant proteins. The same “N-end rule” has also been shown to apply to animal and plant cells, and represents yet another ubiquitin-dependent proteolytic system. The N-terminal residues of short-lived proteins function as degradation signals called **N-degrons**, which are recognized by specific E3 ligases called **N-recognins**. In prokaryotes, which lack the ubiquitin system, the N-degron is recognized and processed by the Clp protease system.

These and other observations indicate that specific structural features on proteins convey information about the metabolic stability of the proteins. The molecular nature of that information processing and the identities of the enzymes involved remain to be determined, and, as discussed further in Chapter 29, proteolysis is becoming recognized as comparable to phosphorylation in its importance as a metabolic regulatory mechanism.

Amino Acid Degradation and Metabolism of Nitrogenous End Products

Common Features of Amino Acid Degradation Pathways

In animals whose dietary protein intake exceeds the need for protein synthesis and other biosyntheses, the excess nitrogen is mostly degraded, with the carbon skeletons being metabolized in the citric acid cycle. Protein can thus be a significant contributor toward an animal's energetic requirements. In contrast, plants and bacteria generally can synthesize most of their own amino acids, and they regulate the anabolic pathways so that excesses rarely develop. Generally, microorganisms use preformed amino acids in preference to synthesizing their own, even though many bacteria can satisfy all of their requirements for nitrogen *and* carbon from a single amino acid. The degradative pathways active here are in general similar to those described in animals.

Amino acid degradation usually begins with conversion to the corresponding α -keto acid by transamination or oxidative deamination.

With a few exceptions, the first step in amino acid degradation involves removal of the α -amino group to give the corresponding α -keto acid. This modification is usually effected by transamination, with the concomitant synthesis of glutamate from α -ketoglutarate. This is followed by the glutamate dehydrogenase reaction, as was shown on page 834. Thus, the net process is the deamination of the α -amino acid to the corresponding α -keto acid plus ammonia. The same net conversion can also be catalyzed by **L-amino acid oxidase**, a flavoprotein enzyme found in liver and kidney.

The peroxide formed is decomposed by catalase. Kidney and liver are also rich in FAD-containing **D-amino acid oxidase**. The function of this enzyme in animals is unknown because the D isomers of amino acids are quite rare. However, bacterial cell walls contain D-amino acids, and a number of bacterial cells contain D-amino acid oxidases.

Once the nitrogen has been removed, the carbon skeleton can, depending on the physiological state of the organism, either proceed toward oxidation in the citric acid cycle or be used for biosynthesis of carbohydrate. Figure 20.11 shows the entry points into the citric acid cycle for the breakdown products of each of the amino acids. The individual pathways are presented in Chapter 21.

Amino acids whose skeletons generate pyruvate or oxaloacetate (examples are alanine and aspartate) are efficiently converted to carbohydrates via gluconeogenesis. Amino acids leading to acetyl-CoA or acetoacetyl-CoA, such as leucine, contribute heavily toward ketogenesis. The terms **glucogenic** and **ketogenic** have been used to classify amino acids as generators primarily of carbohydrate or ketone bodies, respectively.

Detoxification and Excretion of Ammonia

Although ammonia is a universal participant in amino acid synthesis and degradation, its accumulation in abnormal concentrations has toxic consequences.

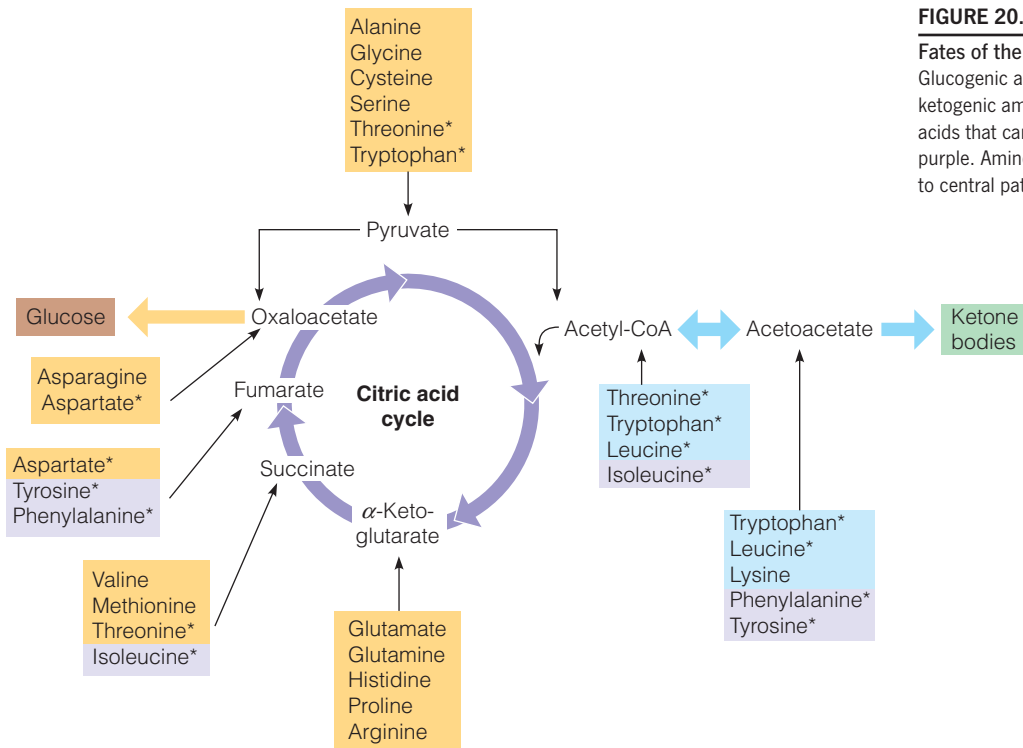

FIGURE 20.11

Fates of the amino acid carbon skeletons. Glucogenic amino acids are shown in orange, ketogenic amino acids in blue, and the few amino acids that can be both glucogenic and ketogenic in purple. Amino acids with more than one route of entry to central pathways are marked by an asterisk.

Therefore, cells undergoing active amino acid catabolism must be able to detoxify and/or excrete ammonia as fast as it is generated. For most aquatic animals, which can take in and pass out unlimited quantities of water, ammonia simply dissolves in the water and diffuses away. Because terrestrial animals must conserve water, they convert ammonia to a form that can be excreted without large water losses. Birds, terrestrial reptiles, and insects convert most of their excess ammonia to **uric acid**, an oxidized purine. Because uric acid is quite insoluble, it precipitates and can be excreted without a large water loss and without building up osmotic pressure. This is particularly important during the part of each animal's lifetime that is spent in the egg. The biosynthesis of uric acid occurs by the route used to synthesize purine nucleotides, a pathway presented in Chapter 22. Most mammals excrete the bulk of their nitrogen in the form of **urea** (an interesting exception is the Dalmatian dog, which excretes most nitrogen as uric acid). Urea is highly soluble and, lacking ionizable groups, does not affect the pH when it accumulates, as does ammonia.

Animals have evolved pathways, adapted to their lifestyles, for excretion of ammonia, uric acid, or urea as the major nitrogenous end product.

Uric acid

Urea

The Krebs–Henseleit Urea Cycle

Urea is synthesized almost exclusively in the liver and then transported to the kidneys for excretion. The synthetic pathway, which is cyclic, was discovered by Hans Krebs and Kurt Henseleit in 1932, five years before the other cycle for which Krebs is famous. Krebs and Henseleit were investigating the pathway by adding possible precursors to liver slices and then measuring the amount of urea produced. When arginine was added, urea was produced in 30-fold molar excess over the amount of arginine administered. Similar results were seen if either of two structurally related amino acids, **ornithine** or **citrulline**, was substituted for arginine. Because these three amino acids seemed to function catalytically to promote urea synthesis, Krebs and Henseleit proposed the existence of a cyclic pathway (see margin).

That proposal was correct, as was subsequently confirmed by isolation of the enzymes involved and identification of the biosynthetic route to ornithine, which begins the pathway. These details are shown in Figure 20.12. Ornithine serves as a “carrier,” upon which are assembled the carbon and nitrogen atoms that will

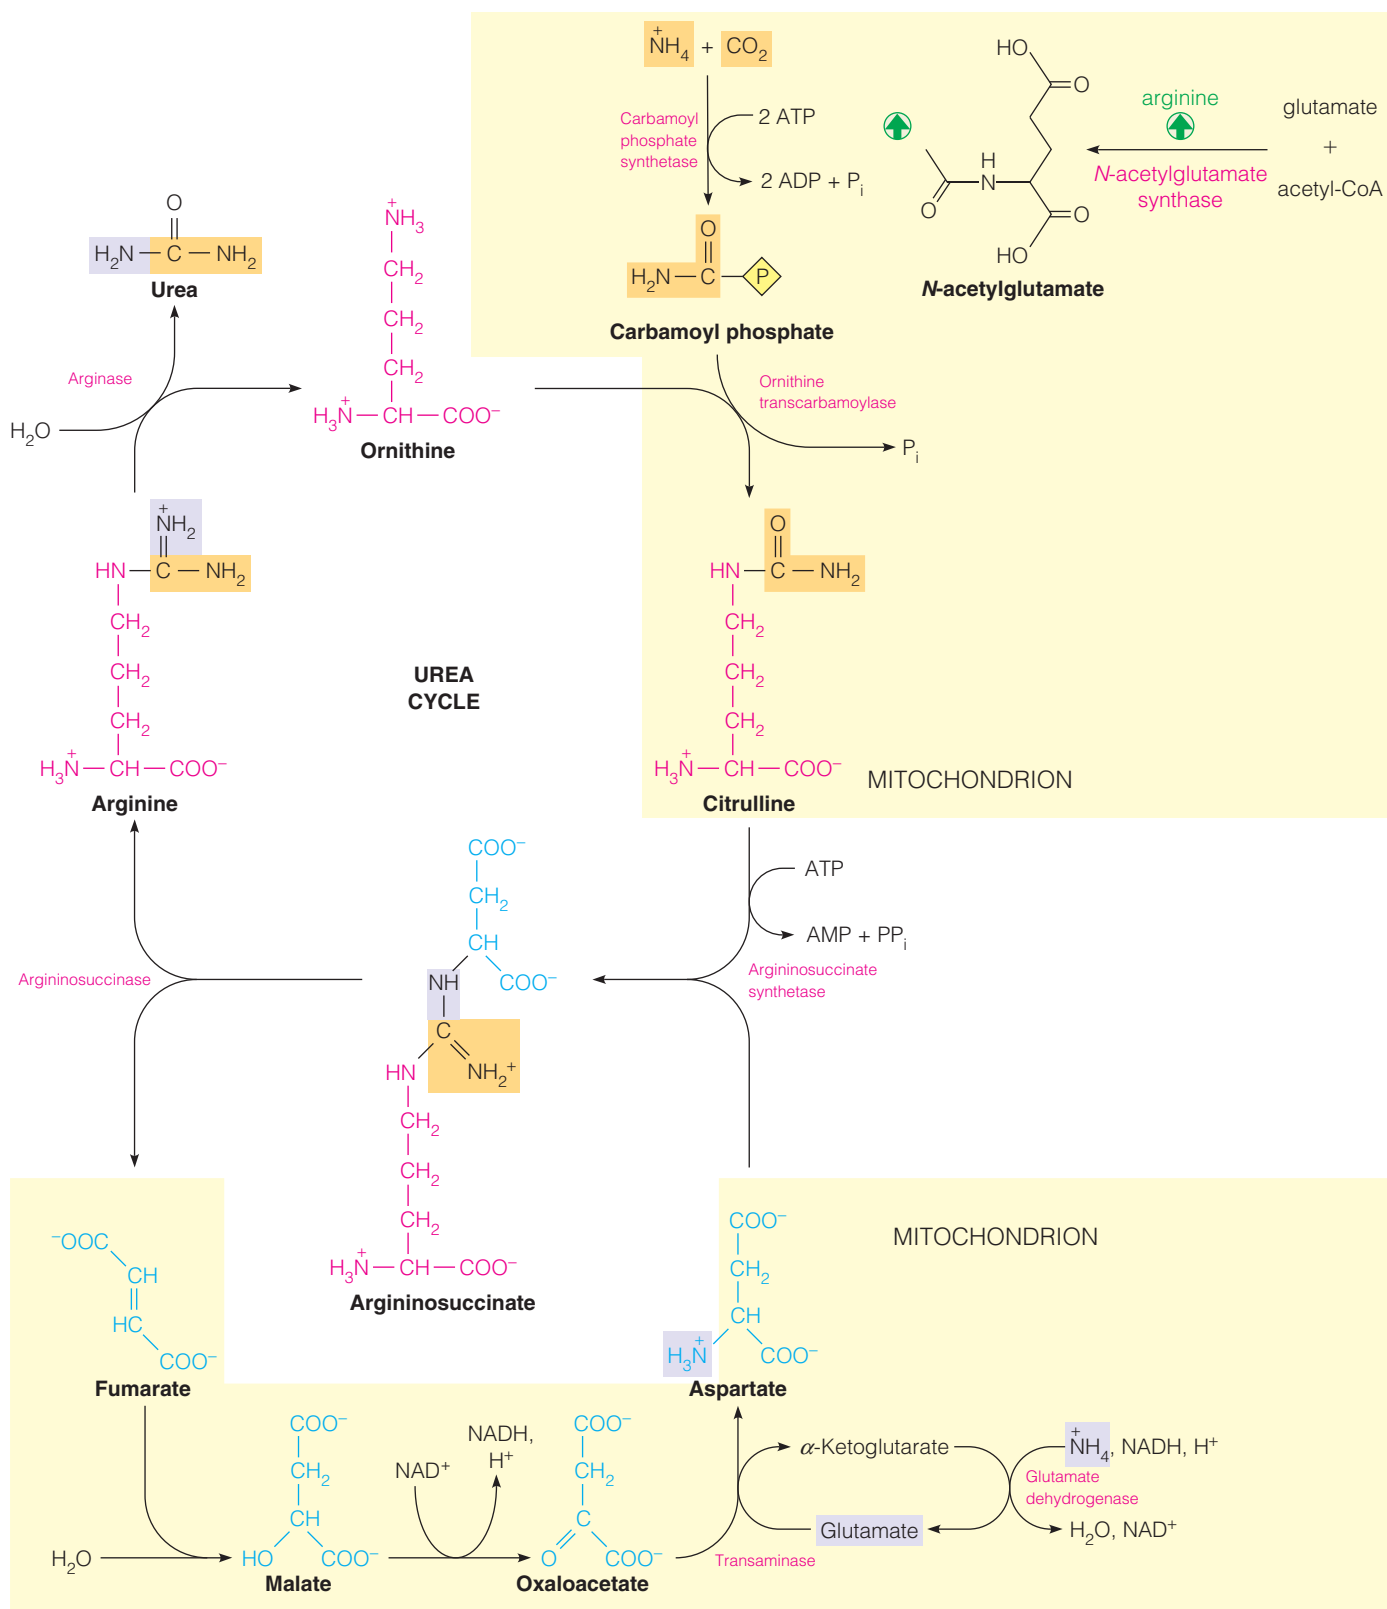

FIGURE 20.12

The Krebs-Henseleit urea cycle. Urea (upper left) contains a carbon and a nitrogen (orange) derived from carbamoyl phosphate and a nitrogen (purple) derived from aspartate. CO_2 and NH_4^+ , the ultimate sources of these atoms, were incorporated in turn through the actions of carbamoyl phosphate synthetase (upper right) and glutamate dehydrogenase (lower right). Glutamate can serve directly as the source of some urea nitrogen. Yellow shading identifies reactions occurring in mitochondria. The rest of the pathway takes place in cytosol.

eventually constitute urea. Ornithine itself is synthesized from glutamate, by a pathway described in Chapter 21 (see Figure 21.31, page 904). The source of the carbon and one nitrogen atom in urea is carbamoyl phosphate, synthesized from NH_4^+ and CO_2 by carbamoyl phosphate synthetase I (CPS I; page 831). Carbamoyl phosphate reacts with ornithine, via the enzyme **ornithine transcarbamoylase**, to give citrulline. The second nitrogen comes from aspartate, which reacts with citrulline to form **argininosuccinate**, through the action of **argininosuccinate synthetase**. Next, **argininosuccinase** cleaves argininosuccinate in a nonhydrolytic, nonoxidative reaction to give arginine and fumarate. Arginine is cleaved hydrolytically by **arginase**, to regenerate ornithine and yield one molecule of urea.

The reactions of the urea cycle are compartmentalized in mitochondria and cytosol of liver cells. Glutamate dehydrogenase, the citric acid cycle enzymes, carbamoyl phosphate synthetase I, and ornithine carbamoyltransferase are localized in the mitochondrion, and the rest of the cycle occurs in the cytosol. This means that ornithine must be transported into mitochondria, and citrulline exported to the cytosol, in order for the cycle to proceed.

The enzyme arginase is responsible for the cyclic nature of the urea biosynthetic pathway. Virtually all organisms synthesize arginine from ornithine by the reactions shown in Figure 20.12. However, only **ureotelic** organisms (those excreting most of their nitrogen as urea) contain arginase and, hence, only those organisms carry out the cyclic pathway. Interestingly, the capacity to synthesize arginase develops in frogs at the same time that they undergo metamorphosis from the tadpole stage to the adult animal. Because the tadpole lives in water, it can excrete ammonia. The adult frog, being adapted to a terrestrial lifestyle, develops the ability to synthesize urea.

As noted already, one nitrogen atom in urea comes from aspartate. This atom is derived from ammonia, which is transferred to glutamate via the glutamate dehydrogenase reaction, then to aspartate by transamination. Note from the bottom of Figure 20.12 that a second cycle is used to maintain carbon balance by conversion of the fumarate produced from argininosuccinate cleavage to oxaloacetate in the citric acid cycle and then back to aspartate by transamination.

The use of aspartate as a nitrogen donor is a two-step process that deserves further comment. In the first step, catalyzed by argininosuccinate synthetase, the amide group of citrulline is condensed with the α -amino group of aspartate. The role of ATP in this reaction is to activate the amide for a nucleophilic acyl substitution by aspartate. The amide carbonyl of citrulline attacks the α -phosphate of ATP, displacing PP_i and producing an AMP-citrulline intermediate. This reaction is reversible, but is driven forward by hydrolysis of PP_i to 2P_i . The nucleophilic amino group of aspartate then adds to the $\text{C}=\text{N}^+$ double bond to give a tetrahedral intermediate, which expels AMP to yield argininosuccinate. In the second step, catalyzed by argininosuccinase, the aspartate carbon skeleton is eliminated as fumarate. The net result of these two reactions is transfer of the amino group of aspartate to citrulline, producing arginine. We will see this same strategy used again in de novo purine biosynthesis (Chapter 22).

The net reaction for one turn of the urea cycle is as follows:

Two molecules of ATP are required to reconvert AMP to ATP, so really four (not three) high-energy phosphates are consumed in each turn of the cycle. Thus, the synthesis of this excretion product is energetically expensive. Excess ammonia is also produced when the animal is forced to catabolize amino acids in muscle as energy sources, for example during fasting. Animals have evolved both long-term and short-term mechanisms to regulate flux through the urea cycle. The levels of the four urea cycle enzymes and CPS I are increased in animals on high-protein diets and are decreased in animals fed protein-free diets. This long-term mechanism allows the animal to adjust its urea cycle capacity to changes in its diet.

Argininosuccinate synthetase mechanism

© 2005 Roberts and Company Publishers. Modified from *The Organic Chemistry of Biological Pathways*, John McMurry and Tadhg Begley.

Urea is synthesized by an energy-requiring cyclic pathway that begins and ends with ornithine.

Allosteric activation of CPS I by ***N*-acetylglutamate** provides short-term regulation of flux through the urea cycle. *N*-acetylglutamate is synthesized from acetyl-CoA and glutamate in a reaction catalyzed by ***N*-acetylglutamate synthase** (Figure 20.12, upper right). Mitochondrial levels of *N*-acetylglutamate are determined by the levels of glutamate, which rise with increased amino acid breakdown through transamination reactions. Thus, flux through the urea cycle is tied to the rate of amino acid degradation.

CPS I is also regulated by covalent modification—acetylation of specific lysine residues inactivates the enzyme. The enzyme responsible for acetylation is not known, but a specific mitochondrial sirtuin (SIRT5) catalyzes the deacetylation of CPS I. Recall from Chapter 18 (page 763) that sirtuins catalyze NAD⁺-dependent deacetylation of proteins. Sirtuins are activated by intracellular NAD⁺ levels, and mitochondrial NAD⁺ levels rise during fasting. This rise activates SIRT5, which deacetylates CPS I to its active state, leading to increased carbamoyl phosphate synthesis and thus increased urea cycle flux. This sirtuin-mediated reversible acetylation of CPS I provides a mechanism to increase the capacity for ammonia disposal (via increased urea synthesis) under fasting conditions, when amino acids are being used as energy sources.

Several inherited disorders are known in humans, each caused by a defect in one of the five enzymes in the urea cycle. Although clinical symptoms vary, **hyperammonemia** (high blood NH₄⁺ levels) is common to all of these diseases. Symptoms usually present in infants, and include lethargy, vomiting, irreversible brain damage, and even death. The ammonia toxicity is thought to be due to its effects on amino acid and energy metabolism—ammonia depletes citric acid cycle intermediates and NADH by overloading the glutamate dehydrogenase reaction, leading to an ATP deficiency. The brain is especially susceptible to ammonia toxicity.

Following its synthesis, urea is transported in the bloodstream to the kidneys, which filter it for excretion. Measurements of blood urea nitrogen (BUN) levels provide a sensitive clinical test of kidney function because filtration and removal of urea are impaired in cases of kidney malfunction. Analogously, blood ammonia measurements are a sensitive test of liver function. Liver damage, whether acute (hepatitis, poisoning) or chronic (alcoholic cirrhosis), reduces activity of the urea cycle. The accumulation of ammonia is toxic to the brain and thus is related to the comatose condition seen in advanced cases of chronic alcoholism.

Transport of Ammonia to the Liver

All animal organs degrade amino acids and produce ammonia. Two mechanisms are involved in transporting this ammonia from other tissues to liver for its eventual conversion to urea (Figure 20.13). Most tissues use glutamine synthetase to convert ammonia to the nontoxic, and electrically neutral, glutamine. The glutamine is transported in the blood to the liver, where, as noted also in Chapter 13, it is cleaved hydrolytically by glutaminase.

Muscle, which derives most of its energy from glycolysis, uses a different route, the **glucose–alanine cycle**. Glycolysis generates pyruvate, which undergoes transamination with glutamate to give alanine and α -ketoglutarate. The glutamate in turn has acquired its nitrogen from ammonia, via glutamate dehydrogenase. The resultant alanine is transported to the liver, where it loses its nitrogen by a reversal of the previous processes. This reversal yields ammonia for urea synthesis, plus pyruvate. The pyruvate undergoes gluconeogenesis to give glucose, which is released to the blood for transport back to the muscle or for nourishment of the brain. This cyclic process helps muscle get rid of ammonia, with the carbon from the pyruvate being returned to the liver for gluconeogenesis.

At least five different diseases in humans result from inherited defects in urea cycle enzymes.

The glucose–alanine cycle removes toxic ammonia from muscle. Glutamine synthetase and glutaminase do the same for most other tissues.

**FIGURE 20.13**

Transport of ammonia to the liver for urea synthesis. The carrier is glutamine in most tissues but is alanine in muscle.

Coenzymes Involved in Nitrogen Metabolism

Before presenting in detail the metabolism of amino acids and nucleotides, as we do in the next two chapters, we should consider three families of coenzymes that play major roles in amino acid and/or nucleotide metabolism. Although all have been mentioned before, we shall consider their actions in detail here. These cofactors include (1) pyridoxal phosphate, the cofactor for transamination and many other reactions of amino acid metabolism; (2) the folic acid coenzymes, which transfer single-carbon functional groups in synthesizing nucleotides and certain amino acids; and (3) the B₁₂, or cobalamin, coenzymes, which participate in the synthesis of methionine and, as noted in Chapter 17, the catabolism of methylmalonyl-CoA.

Pyridoxal Phosphate

Vitamin B₆ was discovered in the 1930s as the result of nutritional studies with rats fed vitamin-free diets. The vitamin as originally isolated is **pyridoxine**, named from its structural similarity to pyridine. Pyridoxine contains a hydroxymethyl group at position 4 of the pyridine ring. However, in the active coenzyme this group has been oxidized to an aldehyde and the hydroxymethyl group at position 5 is phosphorylated. Pyridoxal phosphate (which we shall abbreviate PLP) is the predominant coenzyme form, with pyridoxamine phosphate (PMP) being an intermediate in transamination reactions.

Marginal vitamin B₆ deficiency occurs frequently in humans and is associated with coronary artery disease, stroke, and an elevated risk of Alzheimer's disease. In addition, many drugs and poisons *induce* deficiency states, usually by reacting with the aldehyde group and thereby sequestering the coenzyme. A well-understood case is the induced B₆ deficiency arising during treatment of the mycobacterial infection known as tuberculosis. The antimycobacterial agent **isoniazid** (isonicotinic acid hydrazide) reacts covalently with pyridoxal

**Pyridoxine****Pyridoxal****Pyridoxal phosphate (PLP)****Pyridoxamine phosphate (PMP)**

All pyridoxal phosphate reactions involve initial Schiff base formation, followed by bond labilization caused by electron withdrawal to the coenzyme's pyridine ring.

to make it unavailable for phosphorylation by pyridoxal kinase. Because the mycobacterium contains low levels of the kinase, its growth is effectively blocked by the agent. Prolonged treatment with this drug can generate a B_6 deficiency in the patient by the same mechanism, unless the diet is supplemented with the vitamin.

Pyridoxal phosphate is a remarkably versatile coenzyme. In addition to its involvement in transamination reactions, PLP serves as coenzyme for the majority of enzymes that catalyze some chemical change at the α -, β -, or γ -carbons of the common amino acids, including decarboxylations, eliminations, racemizations, and retro-aldol reactions. A key clue to the mechanism by which this coenzyme functions was the finding in Esmond Snell's laboratory in the 1940s that all of the known PLP-requiring enzyme reactions can be catalyzed, in the absence of any enzyme, by pyridoxal itself. Certain metal ions are required as well, such as Al^{3+} or Cu^{2+} . Although the reaction rates were much lower than those achieved by enzyme catalysis, the model studies permitted a detailed analysis that led to formulation of a unified mechanism for the action of PLP-requiring enzymes. The metal ion was postulated to stabilize a Schiff base or aldimine, formed between pyridoxal and the amino acid substrate, shown in the margin. Normally this role would be played by an amino acid residue in the active site of the enzyme. This is the same chemical strategy used in the fructose-1,6-bisphosphate aldolase reaction (Figure 13.5, page 528), in which a cationic imine (the Schiff base) lowers the energy barrier to the reaction. The ability of PLP to form a stable Schiff base is the key to its versatility in enzyme-catalyzed reactions.

Although pyridoxal phosphate is the coenzyme for all of these reactions, the reactive species is not the aldehyde group but rather an aldimine, formed between the coenzyme and an ϵ -amino group of a lysine residue in the active site. This bond can be reduced by sodium borohydride, to give irreversible bonding of the coenzyme to the active lysine residue. This finding allowed identification of the catalytic site on the enzyme and the specific lysine residue involved in coenzyme binding.

We now know that all pyridoxal phosphate-requiring enzymes act via the formation of a Schiff base between the amino acid and coenzyme (Figure 20.14). A cation, whether a metal (as in the nonenzymatic model system) or a proton (as in the enzymatic reaction), is essential to bridge the phenolate ion of the coenzyme and the imino nitrogen of the amino acid. This bridging maintains planarity of the structure allowing a large conjugated π molecular orbital system, which is essential for catalysis. The most important catalytic feature of the coenzyme is the electrophilic nitrogen of the pyridine ring, which acts as an *electron sink*, drawing electrons away from the amino acid and labilizing one of the three σ bonds on the α -carbon. The second important function is stabilizing the carbanion intermediate that results from bond cleavage. When an amino acid forms an imine with PLP, and the pyridinium N is protonated, all three σ bonds on the α -carbon become electron-deficient, and are susceptible to heterolytic cleavage. The σ bond that is aligned perpendicular to the plane of the π molecular orbital system is the one cleaved, and this is determined by the angle of rotation of the $C_\alpha-N$ bond, specified by interactions with the enzyme active site (see margin). *All of the known reactions of PLP enzymes can be described mechanistically in the same way:* formation of a planar Schiff base or aldimine intermediate, followed by bond cleavage and formation of a resonance-stabilized carbanion with a quinonoid structure, as shown in Figure 20.14. Depending on the bond labilized, formation of the aldimine can lead to transamination (as detailed in Figure 20.14), to decarboxylation, to racemization, or to retro-aldol cleavage (Figure 20.15).

For many years it was thought that PLP was the cofactor for all amino acid decarboxylases. However, a class of enzymes that uses *pyruvic acid* as a cofactor

FIGURE 20.14

Involvement of pyridoxal phosphate in transamination. The figure shows the action of the positively charged pyridinium ion as an electron sink.

1 Amino acid- R_1 reacts with the enzyme-bound PLP, displacing the lysine amino group. 2 Base-catalyzed deprotonation (cleavage of the labile C—H σ bond that is perpendicular to the plane of the π molecular orbital system of the Schiff base intermediate) leads to formation of a carbanion, which is resonance stabilized by interconversion with a quinonoid intermediate. 3 Reformation on the PLP carbon results in tautomerization of the imine C—N bond. 4 Hydrolysis via a carbinolamine intermediate yields an α -keto acid product (R_1) and pyridoxamine phosphate. 5 The transamination is completed by reaction of pyridoxamine phosphate with a second α -keto acid (R_2) and conversion, by reversal of steps 1–4, to enzyme-bound PLP and amino acid R_2 .

FIGURE 20.15

Versatility of the pyridoxal phosphate Schiff base (aldimine) in amino acid reactions. All three substituents at the α -carbon of the amino acid moiety can be labilized. Labilization of the R group ① leads to retro-aldol cleavage. Labilization of the carboxyl group ② leads to decarboxylation. Labilization of the hydrogen ③ leads to racemization or transamination (as shown in Figure 20.14).

is now known. Although structurally dissimilar to PLP, pyruvate serves a mechanistically similar role. The pyruvyl group is formed from an internal serine residue in the proenzyme by a nonhydrolytic cleavage reaction and remains covalently bound to the new N-terminal residue via an amide linkage. During catalysis, the keto oxygen of pyruvate plays a role comparable to that of the PLP ring nitrogen, withdrawing electrons and resonance stabilizing the carbanion intermediate, as shown for the enzyme **histidine decarboxylase** of *Lactobacillus*.

Tetrahydrofolate Coenzymes and One-Carbon Metabolism

Discovery and Chemistry of Folic Acid

Coenzymes derived from the vitamin **folic acid** participate in the generation and utilization of single-carbon functional groups—methyl, methylene, and formyl. The vitamin was discovered by the British physician Lucy Wills in the 1930s, when she found that people with a certain type of **megaloblastic anemia** could be cured by treatment with yeast or liver extracts. The condition is characterized, like all anemias, by reduced levels of erythrocytes. The cells that remain are characteristically large and immature, suggesting a role for the vitamin in cell proliferation and/or maturation. The active component in the extracts was also shown to be essential for the growth of chicks and to be required in the growth media for certain bacteria, notably *Lactobacillus casei* and *Streptococcus faecium*. The latter findings allowed Esmond Snell to develop a rapid bioassay based on the growth of these bacteria, and isolation and structural identification soon followed. Snell and Herschel Mitchell, working with Roger Williams at the University of Texas, had to process *four tons* of spinach to obtain a few hundred micrograms of the active component. Because the vitamin was relatively abundant in leafy green vegetables such as spinach, it was named folic acid, from the Latin *folium* for leaf.

Chemically, folic acid is formed from three distinct moieties: (1) a bicyclic, heterocyclic **pteridine** ring, 6-methylpterin; (2) ***p*-aminobenzoic acid (PABA)**, which is itself required for the growth of many bacteria; and (3) glutamic acid. These three moieties are shown in the overall structure:

The pteridine ring was already known in nature, having been discovered in a large class of biological pigments. Insect wings and eyes contain pteridine pigments, as does the skin of amphibians and fish. Butterfly wings are particularly abundant in pteridines and were the first source from which any such compounds were identified structurally. These compounds are named after the Greek *pteron* (“wing”). Folic acid and its many derivatives are referred to as **folates**.

Conversion of Folic Acid to Tetrahydrofolate

Once inside a cell, folic acid is converted to active forms by two successive reductions of the pyrazine part of the pteridine ring. Both reactions are catalyzed by the NADPH-specific enzyme **dihydrofolate reductase**. The mechanism of this enzyme was described in Chapter 11 (page 430). The first reduction yields **7,8-dihydrofolate**, and the second reduction yields **5,6,7,8-tetrahydrofolate**.

Folate coenzymes contain multiple glutamate residues, which help them be retained within cells and bind more tightly to enzymes.

For reasons that will become clear later, dihydrofolate is the preferred substrate, and hence its name is given to the enzyme. Note that reduction of the 5–6 double bond generates a new chiral center at C-6; the 6*S*-isomer of tetrahydrofolate is the naturally occurring form used by enzymes.

Aminopterin (4-aminofolate)

Methotrexate (4-amino-10-methylfolate)

Trimethoprim

Pyrimethamine

Dihydrofolate reductase is the target for a number of useful anticancer, antibacterial, and antiparasitic drugs.

This structure illustrates two critical features of tetrahydrofolate. First, the N-5 and N-10 positions can carry single carbon units, designated as R_1 and R_2 , for donation in biosynthetic processes (more about this below). Second, the naturally occurring intracellular folates contain a “tail” of glutamate residues, ranging from three to eight or more residues. These residues are linked to one another, not by the familiar peptide bond but rather by an amide bond between the γ -carboxyl group of the first glutamate and the α -amino group of the next. The glutamates are added, one at a time, in an ATP-dependent reaction catalyzed by **folypoly- γ -glutamate synthetase**.

Most enzymes that use folate coenzymes bind more tightly to, and are more active with, polyglutamated forms than the monoglutamates. The additional glutamate residues are also important for intracellular retention of folates. Animal cells take up folates by active transport, but only the monoglutamated form is taken up efficiently. However, the monoglutamate forms can also be transported out of cells, so conjugation with additional glutamate residues converts the folate to a highly anionic form that cannot exit the cell.

Dihydrofolate reductase has been thoroughly studied because it is the target for action of a number of clinically useful **antimetabolites**. An antimetabolite is a synthetic compound, usually a structural analog of a normal metabolite, that interferes with the utilization of the metabolite to which it is related structurally. As early as 1948, two analogs of folate—**aminopterin** and **methotrexate**—had been synthesized and found to induce remissions in acute leukemias.

A decade later it was found that these compounds inhibit dihydrofolate reductase, binding to the enzyme at least 1000-fold more tightly than the normal substrates do. Thus, these analogs block the utilization of folate and dihydrofolate. We now know that their effectiveness derives from the involvement of dihydrofolate reductase in the biosynthesis of thymine nucleotides and, hence, of DNA. Inhibiting DNA synthesis blocks the proliferation of cancer cells, as discussed further in Chapter 22. Nearly two more decades passed before a detailed understanding of the mechanism of dihydrofolate reductase inhibition became available, through crystallization of enzyme–inhibitor complexes and determination of their three-dimensional structure (Figure 20.16).

Folate analogs such as methotrexate have been used in treating many different cancers in addition to leukemia. Other clinically useful dihydrofolate reductase inhibitors show selectivity among species-specific forms of the enzyme. **Trimethoprim** specifically inhibits bacterial dihydrofolate reductases and is widely used to treat bacterial infections, and **pyrimethamine** shows similar specificity against the enzyme of protozoal origin.

The entire concept of antimetabolites as drugs arose from early work on folate metabolism. Before World War II, one of the few effective antibacterial drugs available was **sulfanilamide**, one of the class of sulfonamide drugs (“sulfa drugs”). A British biochemist, D. D. Woods, noted a structural similarity between sulfanilamide and *p*-aminobenzoate, which was known to be essential for bacterial growth. Before anything was known about the relation between PABA and folic acid, Woods proposed that sulfanilamide acts by blocking the normal utilization of PABA, and he coined the term *antimetabolite*. PABA is not required for growth of animal cells, so the drug is not toxic to human cells. Years later, when the pathway of folate biosynthesis had been established, it was learned that Woods was right; the enzyme incorporating PABA is inhibited by sulfonamides. Because animal cells do

FIGURE 20.16

Human dihydrofolate reductase complexed with ligands. This figure shows the X-ray crystal structure of the human enzyme with bound NADPH (yellow) and methotrexate (red) (PDB ID 1U72). The additional amino group on methotrexate allows formation of an additional hydrogen bond to the enzyme, which increases its binding affinity to the folate binding site. These two ligands bind such that the pyridine ring of NADPH is in close proximity to the pteridine ring of the folate ligand, as required for the hydride transfer catalyzed by this enzyme. Notice that the folate binds in a bent, rather than linear, form.

not carry out the synthetic pathway but instead take up fully formed folate from the diet, they are not harmed by the drug. The concept elucidated by Woods, of seeking a metabolic difference between normal cells and pathological cells—infected parasites, virus-infected cells, or cancer cells—and of exploiting that difference chemically, has had an enormous impact on the field of pharmacology.

Tetrahydrofolate in the Metabolism of One-Carbon Units

The coenzymatic function of tetrahydrofolate (THF) is the mobilization and utilization of single-carbon functional groups (one-carbon units). These reactions are involved in the metabolism of serine, glycine, methionine, and histidine, among the amino acids, and in the biosynthesis of purine nucleotides and the methyl group of thymine.

Tetrahydrofolate carries one-carbon units at the methyl, methylene, and formyl oxidation levels, equivalent in oxidation level to methanol, formaldehyde, and formic acid, respectively (Figure 20.17). One-carbon groups on THF can be carried on N-5 or N-10, or bridged between N-5 and N-10. The THF derivatives are named according to the oxidation state of the one-carbon unit and the nitrogen positions to which it is attached. Thus, **5,10-methylenetetrahydrofolate** (5,10-methylene-THF) carries a methylene group ($-\text{CH}_2-$) attached to N-5 and N-10:

5,10-methylenetetrahydrofolate

One-carbon units attached to tetrahydrofolate are activated for the formation of new carbon bonds ($\text{C}-\text{S}$, $\text{C}-\text{N}$, or $\text{C}-\text{C}$) in various biosynthetic reactions. The most reduced form, **5-methyltetrahydrofolate** (5-methyl-THF), donates its one-carbon unit to just one acceptor—homocysteine, forming the terminal $\text{C}-\text{S}$ bond of methionine (reaction 1 in Figure 20.17). The one-carbon unit carried by 5,10-methylenetetrahydrofolate is used to form new $\text{C}-\text{C}$ bonds, as in reactions 3, 4, and 5. The most oxidized form, **10-formyltetrahydrofolate** (10-formyl-THF), forms new $\text{C}-\text{N}$ bonds. Because the formyl group is being transferred from the N-10 of tetrahydrofolate to an N atom on the acceptor molecule, enzymes that use 10-formyltetrahydrofolate as a one-carbon donor are called **transformylases** or **formyltransferases**.

Tetrahydrofolate can acquire one-carbon units from diverse sources. For example, many cells carry out the ATP-dependent activation of formate to 10-formyltetrahydrofolate (reaction 8 in Figure 20.17). The degradation of histidine, in both bacterial and animal cells, provides one-carbon units at the level of methylenetetrahydrofolate via 5-formiminotetrahydrofolate (reactions 9 and 10). The bacterial fermentation of purines also produces 5-formiminotetrahydrofolate. However, most organisms derive the majority of their activated one-carbon units from the β -carbon of serine and the subsequent oxidation of glycine (reactions 3 and 4 in Figure 20.17). The first of these reactions is catalyzed by **serine hydroxymethyltransferase**:

This is a reversible reaction that, in the direction shown, yields glycine and 5,10-methylenetetrahydrofolate, but it can also be used for serine biosynthesis as needed. The enzyme also requires pyridoxal phosphate, so the actual substrate is the Schiff base formed from serine and PLP.

p-Aminobenzoic acid (PABA)

Tetrahydrofolate coenzymes transfer and interconvert one-carbon units at the methyl, methylene, and formyl oxidation levels.

FIGURE 20.17

Metabolic reactions involving synthesis, interconversion, and utilization of one-carbon adducts of tetrahydrofolate. Major end products of one-carbon metabolism are highlighted in pink, and major sources of one-carbon units are highlighted in orange. The enzymes involved are 1) homocysteine methyltransferase (also called methionine synthase), 2) methylenetetrahydrofolate reductase, 3) serine hydroxymethyltransferase, 4) glycine cleavage system, 5) thymidylate synthase, 6) methylenetetrahydrofolate dehydrogenase, 7) methenyltetrahydrofolate cyclohydrolase, 8) 10-formyltetrahydrofolate synthetase, 9) glutamate formiminotransferase, 10) 5-formiminotetrahydrofolate cyclodeaminase, and 11) 5-formyltetrahydrofolate cycloligase (also called methenyltetrahydrofolate synthetase). THF = tetrahydrofolate, DHF = dihydrofolate, R = PABA-glutamate.

Glycine can yield an additional molecule of 5,10-methylenetetrahydrofolate through action of the **glycine cleavage system**, a multienzyme complex located in mitochondria:

This reaction represents the chief catabolic route for glycine in most organisms. The overall reaction is as shown, and the pathway is mechanistically similar to that catalyzed by the pyruvate dehydrogenase complex (see Chapter 14). Four subunits are involved: P-protein, which catalyzes the PLP-dependent decarboxylation of glycine; T-protein, which catalyzes a THF-dependent aminomethyl transfer; L-protein, an FAD-dependent lipoamide dehydrogenase; and H-protein, a hydrogen carrier protein containing lipoic acid. The P-, T-, and H-protein subunits are unique to the glycine cleavage system, whereas the L-protein is shared with other mitochondrial α -ketoacid dehydrogenases, including the pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes. The serine hydroxymethyltransferase and glycine cleavage reactions also compose that part of the photorespiration pathway that occurs in plant mitochondria (Chapter 16, page 701).

Once a one-carbon unit has been activated via its attachment to tetrahydrofolate, it can undergo interconversions, such as a change in oxidation state, or it can be used directly in a biosynthetic reaction. Figure 20.17 shows most of the known reactions involving tetrahydrofolate coenzymes. Note the reactions that involve a change in the oxidation level of the bound one-carbon unit: the reversible oxidation of 5,10-methylene-THF to 5,10-methenyl-THF, catalyzed by **5,10-methylenetetrahydrofolate dehydrogenase** (reaction 6), and the irreversible reduction of 5,10-methylene-THF to the 5-methyl derivative, brought about by a flavin-dependent **5,10-methylenetetrahydrofolate reductase** (reaction 2). Many organisms contain multifunctional enzymes or complexes that help channel these scarce and/or unstable intermediates. For example, reactions 6, 7, and 8 are combined into a single trifunctional protein called C₁-THF synthase in eukaryotes, and reactions 9 and 10 are found as a bifunctional enzyme in mammals. In addition, several of these reactions occur in both the cytoplasm and mitochondria.

As shown in Figure 20.17, one-carbon units derived from THF coenzymes are used in synthesis of purine nucleotides, thymine nucleotides (dTMP), and methionine, in addition to the reactions we have discussed. Furthermore, in prokaryotes and in eukaryotic mitochondria, 10-formyl-THF participates in synthesis of **N-formylmethionyl-tRNA**, which is involved in initiation of protein synthesis (discussed further in Chapter 28). In the synthesis of thymine nucleotides, catalyzed by **thymidylate synthase** (reaction 5), the THF coenzyme serves both as a one-carbon donor and as a source of reducing power. Because this enzyme generates the methyl group of thymine from 5,10-methylene-THF, it catalyzes both a one-carbon transfer and a reduction. The electrons come from the reduced pteridine ring, to give dihydrofolate as a product. Although dihydrofolate reductase can act on either folate or dihydrofolate, the reduction of dihydrofolate is more significant *in vivo* than that of folate because of the need for constant regeneration of tetrahydrofolate from dihydrofolate produced in the thymidylate synthase reaction. We will discuss the chemistry of the thymidylate synthase reaction in more detail in Chapter 22.

B₁₂ Coenzymes

Vitamin B₁₂ was discovered through studies of a formerly incurable disease, pernicious anemia. This condition begins with a megaloblastic anemia, which is virtually identical to that seen in folate deficiency but which leads to an irreversible degeneration of the nervous system if untreated. In 1926 two Harvard physicians, George Minot and William Murphy, found that symptoms of the disease could be alleviated by feeding patients large amounts of raw liver. The active material in the

FIGURE 20.18

Structure of vitamin B₁₂. The molecule shown here is the cyanide-containing form originally isolated (cyanocobalamin). In cells, a water molecule or hydroxyl group takes the place of CN, forming the precursor to the coenzyme forms of B₁₂. The corrin ring is shown in magenta. 5,6-Dimethylbenzimidazole (DMB), which is linked to the cobalt, is shown in blue.

liver, which was named vitamin B₁₂, was present in exceedingly small amounts, so many years passed until sufficient material had been isolated for characterization. In England in 1956, Dorothy Hodgkin and her colleagues used X-ray crystallography to complete the structure determination for this active substance. Hodgkin was awarded the Nobel Prize for this work.

The structure of vitamin B₁₂ is shown in Figure 20.18. The metal cobalt is coordinated with a tetrapyrrole ring system, called a **corrin** ring, which is similar to the porphyrin ring of heme compounds. The cobalt is also linked to a heterocyclic base, 5,6-dimethylbenzimidazole (DMB). In the vitamin as isolated, the sixth coordination position of the cobalt is occupied by cyanide ion, but this ion is introduced during isolation. The vitamin as it exists in tissues contains either water or a hydroxyl moiety at this site. Because of the presence of cobalt and many amide nitrogens, B₁₂ compounds are called **cobamides** or, more commonly but less accurately, **cobalamins**. B₁₂ derivatives are also named in terms of the group occupying the sixth coordination position. Thus, the vitamin as isolated is **cyanocobalamin**, and the intracellular forms are **aquocobalamin** or **hydroxocobalamin**.

B₁₂ coenzymes have either a methyl group or a 5'-deoxyadenosyl moiety linked to cobalt, making them the first known organometallics in metabolism.

Coenzyme Forms of B₁₂

Two coenzymatically active forms of B₁₂ are known to exist, in which the upper axial cobalt ligand is either a 5'-deoxyadenosyl or a methyl group (Figure 20.19). The first, **5'-deoxyadenosylcobalamin**, was discovered in 1958 by H. A. Barker. The bacterium *Clostridium cylindrosporium* ferments glutamate by first isomerizing it to β -methylaspartate. Barker and his colleagues showed that 5'-deoxyadenosylcobalamin is essential for this reaction to occur. Shortly afterward, studies of the enzymatic synthesis of methionine from **homocysteine** revealed the existence of a second coenzymatically active form, **methylcobalamin**, or methyl-B₁₂. Both 5'-deoxyadenosylcobalamin and methylcobalamin contain a covalent carbon-cobalt bond, making them true organometallics. In methionine synthesis the coenzyme transfers its methyl group and the cobalt cycles between the +3 (Co^{III}) and +1 (Co^I) oxidation states. Note that the methyl group is derived ultimately from 5-methyltetrahydrofolate (reaction 1, Figure 20.17).

Three classes of B_{12} -dependent enzymes are now known—isomerases, methyl-transferases, and reductive dehalogenases. Most of these occur in only a few bacterial species that carry out specialized fermentations. Also of interest is the involvement of methyl- B_{12} in methane synthesis by methanogenic bacteria. Only two B_{12} -dependent reactions occur to a significant extent in mammalian metabolism: the synthesis of methionine from homocysteine, which we have shown here, and the isomerization of methylmalonyl-CoA to succinyl-CoA, which we introduced in Chapter 17 (page 732) as a key step in the oxidation of odd-chain fatty acids. As we saw with the methionine synthase reaction, B_{12} -dependent methyl-transferases use methylcobalamin as the cofactor. The role of the B_{12} coenzyme in the reductive dehalogenases is poorly understood. The isomerases catalyze 5'-deoxyadenosylcobalamin-dependent rearrangements involving exchange of a carbon-bound hydrogen with another carbon-bound functional group, as shown here; methylmalonyl-CoA mutase catalyzes a reaction of this type.

The migrating group (X) can be carbon, $-\text{NH}_2$, or $-\text{OH}$.

Action of Adenosylcobalamin

Carbon–carbon bonds are generally difficult to break and to form. B_{12} -dependent enzymes readily catalyze such reactions, and this activity, plus the novel cobalt–carbon bond, has focused attention on mechanisms of action of 5'-deoxyadenosylcobalamin. The carbon–cobalt bond is relatively weak, with a bond dissociation energy on the order of 140 kJ/mol (compared with 348 kJ/mol for a typical C–C bond). In fact, exposure to light easily breaks this Co–C bond, explaining the extreme light sensitivity of the B_{12} coenzymes. 5'-deoxyadenosylcobalamin-dependent isomerases exploit the lability of the Co–C bond by generating free radical intermediates during catalysis. From studies on methylmalonyl-CoA mutase and other enzymes, the following facts have emerged: (1) Hydrogen transfer is stereospecific; some of the reactions proceed with inversion of configuration, and others do not. (2) Hydrogen that is transferred does not exchange with the protons of water; isotopic hydrogen present in a

FIGURE 20.19

Coenzymes derived from vitamin B_{12} . The corrin ring, identical in all known forms of B_{12} , is indicated here schematically. The Co bears a positive charge ($n = 1, 2, \text{ or } 3$), while each molecule is uncharged overall.

FIGURE 20.20

The intramolecular isomerization catalyzed by methylmalonyl-CoA mutase.

This proposed mechanism is consistent with experimental observations and is representative of the general mechanism for other B_{12} -dependent 1,2-isomerizations. **Step 1:** Homolytic cleavage of carbon–cobalt bond and formation of 5'-deoxyadenosyl radical.

Step 2: Hydrogen abstraction and formation of substrate radical. **Steps 3 and 4:** 1,2 rearrangement involving a cyclopropyloxy radical. **Step 5:** Hydrogen abstraction from 5'-deoxyadenosine to give succinyl-CoA and 5'-deoxyadenosyl radical. **Step 6:** Reformation of carbon–cobalt bond.

substrate is conserved in the product. (3) The transferred hydrogen is transiently carried on the 5' carbon of the deoxyadenosyl moiety; labeling of this position with tritium leads to incorporation of that label into product. (4) Spectral studies indicate that the cobalt changes its oxidation state during catalysis.

All of these observations imply that the covalent carbon–cobalt bond on the 5'-deoxyadenosylcobalamin undergoes transient **homolytic** cleavage during catalysis. That is, the cobalt and the carbon each acquire one electron from the pair that formed the bond, creating a free radical at the deoxyadenosine C-5. Interaction with the substrate then creates a substrate radical, as shown for methylmalonyl-CoA mutase in Figure 20.20, leading to rearrangement of the substrate.

X-ray crystal structures of several B_{12} -dependent enzymes have revealed two different modes of coenzyme binding. In some enzymes, such as methylcobalamin-dependent methionine synthase and 5'-deoxyadenosylcobalamin-dependent methylmalonyl-CoA mutase, the coenzyme undergoes a major conformational change upon binding to the enzyme. As shown in Figure 20.21a, the DMB-containing “tail” is no longer coordinated to the cobalt. Instead, the tail has moved into a deep pocket, which helps bind the coenzyme tightly. Replacing the DMB in coordination with cobalt is a histidine residue on the enzyme, indicating a role for the enzyme in stabilizing reaction intermediates. In other B_{12} -dependent enzymes, such as diol dehydratase (Figure 20.21b) and ribonucleotide reductase, the DMB moiety remains coordinated to the cobalt in the lower axial position, as observed for the free coenzyme (Figure 20.18).

FIGURE 20.21

Two modes of coenzyme B_{12} binding. The cobalamin coenzyme is in red, with its corrin ring viewed from the edge. **(a)** The crystal structure of methylmalonyl-CoA mutase from *Propionibacterium shermanii* and bound coenzyme (PDB ID 4REQ), showing the DMB buried in a deep crevice. A histidine residue on the enzyme (yellow) contacts the upper face of the corrin ring, in place of DMB. **(b)** The crystal structure of diol dehydratase from *Klebsiella oxytoca* and bound coenzyme (PDB ID 1DIO), with DMB coordinated to the cobalt.

B₁₂ Coenzymes and Pernicious Anemia

Now let us return to the role of B₁₂ coenzymes in mammalian metabolism. Recall that vitamin B₁₂ was isolated as a factor that could cure pernicious anemia, which suggested that the disease is caused by B₁₂ deficiency. In fact, pernicious anemia is a disease of the stomach. Gastric tissue secretes a glycoprotein called **intrinsic factor**, which complexes with ingested B₁₂ in the digestive tract and promotes its efficient absorption through the terminal portion of the small intestine into the bloodstream. Pernicious anemia results from insufficient secretion of intrinsic factor. This is usually caused by an autoimmune process in which the body destroys the gastric lining cells that produce intrinsic factor. Indeed, patients who undergo surgical removal of the stomach for cancer or other problems can also develop the symptoms of pernicious anemia. The uncomplexed vitamin can be absorbed, but so poorly that massive doses must be administered to cure or prevent the disease.

But what is the relationship between failure to absorb B₁₂ and the defect in red blood cell formation that defines anemias? Given the hematologic similarity between anemias of folate deficiency and pernicious anemia, a relationship between folate and B₁₂ metabolism has long been suspected. In fact, the megaloblastic anemia seen in early stages of pernicious anemia is improved if folic acid is administered. However, this treatment only hastens the onset of the far more severe neurological symptoms of B₁₂ deficiency. Given that these neurological problems are never seen in simple folate deficiency, what is the metabolic relationship between these two vitamins?

Figure 20.22 outlines our current understanding: (1) When B₁₂ levels are low, flux through the methionine synthase reaction (reaction 1, Figure 20.17) decreases, but because adequate dietary methionine is usually available, there is no immediate disturbance of protein metabolism. (2) Reduction of 5,10-methylene-THF to 5-methyl-THF (reaction 2, Figure 20.17) continues because this reaction is virtually irreversible. (3) Because methionine synthase is the only mammalian enzyme known to use 5-methyl-THF, the decreased intracellular activity of this enzyme causes 5-methyl-THF to accumulate, at the expense of depleted pools of the other tetrahydrofolate coenzymes. In essence, the intracellular THF pool becomes “trapped” as 5-methyl-THF. Thus, even though total folate levels may seem ample, there is a *functional* folate deficiency, with insufficient levels of the formyl-THF and methylene-THF coenzymes needed for synthesis of nucleic acid precursors.

The methyl-trap hypothesis does not explain why untreated pernicious anemia progresses to a neurological disease because simple folate deficiency anemias show no such complications. Early observations suggested that abnormal fatty acid metabolism caused by inhibition of methylmalonyl-CoA mutase was responsible. The problem is extraordinarily difficult because dietary B₁₂ requirements are so low that generating animal models for B₁₂ deficiency is almost impossible. Some insight has been gained through the observation that the

Pernicious anemia is caused by deficiency of a glycoprotein needed for intestinal absorption of vitamin B₁₂, leading to intracellular deficiencies of B₁₂ coenzymes.

B₁₂ deficiency causes 5-methyltetrahydrofolate to accumulate, with concomitant depletion of other folate coenzymes.

FIGURE 20.22

A relationship between folate and B₁₂ metabolism. This scheme is based on the apparent folate deficiency seen in early stages of B₁₂ deficiency as a result of decreased flux through the methionine synthase reaction. The diagram identifies intermediates that either accumulate (blue) or are depleted (gold).

commonly used anaesthetic nitrous oxide (N_2O), or laughing gas, induces a pernicious anemia-like state by inactivating methionine synthase. N_2O oxidizes the cobalt in B_{12} from the +1 (Co^{I}) to the +2 (Co^{II}) state and is converted to a potent oxidant that irreversibly damages the enzyme. Because methylmalonyl-CoA mutase does not use the Co^{I} oxidation state of cobalamin, it is resistant to N_2O treatment. These studies might argue that inhibition of methionine synthesis is responsible for the neurological dysfunction in pernicious anemia, but the biochemical mechanisms involved are not yet understood.

Folic Acid in the Prevention of Heart Disease and Birth Defects

In the mid-1990s, a series of clinical reports described correlations between folate deficiencies and increased risk of myocardial infarction. The same studies revealed that individuals at risk for heart attack also showed abnormally high levels of serum homocysteine. The simplest interpretation is that in folate-deficient individuals, decreased levels of tetrahydrofolate cofactors limit metabolic flux through the methionine synthase reaction (reaction 1, Figure 20.17), with consequent accumulation of homocysteine, the substrate for this enzyme. Elevated plasma homocysteine (homocysteinemia) is now considered to be a major independent risk factor for many types of cardiovascular disease, including coronary artery disease, stroke, and peripheral vascular occlusive disease. Homocysteine is presumed to be the toxic metabolite responsible for damage to the heart, although the mechanisms are not known, and, indeed, some studies have failed to show a correlation between folate status and heart disease. However, folate deficiencies have other recently recognized biological consequences, including abnormally high levels of uracil in DNA. As we discuss in Chapter 22, this phenomenon, which can lead to chromosome breakage, is a consequence of limitation of the biosynthesis of thymine nucleotides. Folate deficiency during embryogenesis causes a significant proportion of birth defects, including those affecting the craniofacies (e.g., cleft palate), the neural tube (e.g., anencephaly and spina bifida), and the heart. The normal development of all three of these regions depends on the proper growth, differentiation, and migration of a set of multipotent neural crest cells. These cells apparently have a high demand for folate. Consequently, women are urged to take folic acid supplements throughout their pregnancies, but especially in the early stages, when the fetus's nervous system develops most rapidly. For example, neural tube development and closure is usually complete by 28 days post-conception. Neural tube defects (NTDs) occur with a prevalence of about 1 in 1,000 births, but periconceptional folic acid supplementation prevents 50%–75% of NTDs. Because the window during which folic acid supplementation is effective generally occurs before a woman discovers she is pregnant, the United States began fortifying enriched flour and other cereal grain products with folic acid to ensure that women of childbearing age have adequate folate levels. The prevalence of NTDs has indeed declined in the United States since 1998, when fortification became mandatory.

Folic acid deficiency increases the risk of cardiovascular disease and birth defects in humans.

SUMMARY

Although inorganic nitrogen is abundant, metabolism of most organisms is limited by nitrogen bioavailability. Reduction of N_2 in biological nitrogen fixation and reduction of nitrate in plant and bacterial metabolism generate ammonia, which all organisms can utilize. The capacity for amino acid synthesis varies greatly among organisms, with mammals requiring about half of the 20 common amino acids in the diet. Proteins are in a continual state of turnover and replacement, partly for replacement of damaged proteins and partly as the result

of normal cellular regulatory mechanisms. Most amino acids released by protein turnover are reutilized for protein synthesis. When amino acids are degraded, either for catabolism of an oversupply or when needed for energy generation, the first step is usually removal of the α -amino group, either through transamination or oxidative deamination. The resultant ammonia is excreted directly (in fish), converted to uric acid (in most reptiles, insects, and birds), or converted to urea (in mammals). Urea synthesis is a cyclic pathway involving ornithine and arginine as intermediates. Transamination and numerous additional reactions undergone by amino acids use pyridoxal phosphate as a coenzyme. After condensation of the amino group of the amino acid with the aldehyde of the coenzyme to give a Schiff base, the pyridine ring of the coenzyme withdraws electrons transiently and destabilizes bonds that are broken in the reaction. Tetrahydrofolate binds one-carbon units at three different oxidation states, interconverts them, and transfers them in the synthesis of purine nucleotides, thymidine nucleotides, and several amino acids. B₁₂ coenzymes include methylcobalamin, which participates in methionine biosynthesis, and 5'-deoxyadenosylcobalamin, the coenzyme for methylmalonyl-CoA mutase. Folate metabolism presents various chemotherapeutic targets, and folate and B₁₂ deficiencies both have important clinical consequences.

PROBLEMS

1. Identify the most likely additional substrates, products, and coenzymes for each reaction in the following imaginary pathway.

2. The following diagram shows the biosynthesis of B₁₂ coenzymes, starting with the vitamin. DMB is dimethylbenzimidazole.
- (a) What one additional substrate or cofactor is required by enzyme B?
- (b) Genetic deficiency in animals of enzyme C would result in excessive urinary excretion of what compound?

- (c) Some forms of the condition described in (b) can be successfully treated by injection of rather massive doses of vitamin B₁₂. What kind of genetic alteration in the enzyme would be consistent with this result?
- (d) Genetic deficiency in animals of enzyme B will result in excessive urinary excretion of what amino acid?
- *3. Using the principles described in the text regarding pyridoxal phosphate mechanisms, propose a mechanism for the reaction catalyzed by serine hydroxymethyltransferase.
4. Use numbers 1 to 5 to identify each carbon atom in the product of this reaction. What coenzyme is involved?

- *5. Based on the mechanism for methylmalonyl-CoA mutase shown in Figure 20.20, propose a mechanism for the diol dehydrase reaction:

6. The precise mechanism of ammonia toxicity to the brain is not known. Speculate on a possible mechanism, based on possible effects of ammonia on levels of key intermediates in energy generation.
- *7. Mutants of *Neurospora crassa* that lack carbamoyl phosphate synthetase I (CPS I) require arginine in the medium in order to grow, whereas mutants that lack carbamoyl-phosphate synthetase II (CPS II) require a pyrimidine, such as uracil. A priori, one would expect the active CPS II in the arginine mutants to provide sufficient carbamoyl phosphate for arginine synthesis, and the active CPS I in the pyrimidine mutants to “feed” the pyrimidine pathway. Explain these observations.
8. In some forms of leukemia the proliferating white blood cells contain very low levels of asparagine synthetase. Some years ago there was interest in treating these leukemias by purifying the enzyme asparaginase from *E. coli* and injecting it into the bloodstream of leukemic patients. Asparaginase catalyzes the hydrolysis of asparagine to aspartate plus ammonia. What is the rationale behind this mode of therapy, and why might you expect it not to work?
9. Indicate whether each of the following statements is true or false, and briefly explain your answer.
- In general, the metabolic oxidation of protein in mammals is less efficient, in terms of energy conserved, than the metabolic oxidation of carbohydrate or fat.
 - Given that the nitrogen of glutamate can be redistributed by transamination, glutamate should be a good supplement for nutritionally poor proteins.
 - Arginine is a nonessential amino acid for mammals because the enzymes of arginine synthesis are abundant in liver.
 - Alanine is an essential amino acid because it is a constituent of every protein.
10. Write a series of balanced equations and a summary equation for the reactions of the glucose–alanine cycle.
11. Consider the following questions about glutamate dehydrogenase.
- The reaction as shown on page 827 has NH_3 as a reactant, instead of NH_4^+ , which is far more abundant at physiological pH. Why is NH_3 preferred?
 - Glutamate dehydrogenase has a K_M for ammonia (NH_3) of ~ 1 mM. However, at physiological pH the dominant ionic species is ammonium ion, NH_4^+ ($\text{p}K_a = 9.2$). Calculate the velocity (as a fraction of V_{max}) that would be achieved by glutamate dehydrogenase if the total intracellular ammonia concentration ($\text{NH}_3 + \text{NH}_4^+$) is $100 \mu\text{M}$ (approximate physiological concentration). Assume a mitochondrial matrix pH of 8.0.
 - The thermodynamic equilibrium for the reaction greatly favors α -ketoglutarate reduction, yet in mitochondria the enzyme acts primarily to oxidize glutamate to α -ketoglutarate. Explain.
 - Propose a reasonable mechanism for this reaction.
12. Explain the basis for the following statement: As a coenzyme, pyridoxal phosphate is covalently bound to enzymes with which it functions, yet during catalysis the coenzyme is not covalently bound.
13. Consider the regulation of *E. coli* glutamine synthetase, and explain the metabolic rationale for each of the following effects:
- Inhibition of glutamine synthetase by carbamoyl phosphate
 - Activation of the deuridylylation of P_{II} -UMP by α -ketoglutarate
 - Activation of the uridylylation of P_{II} by ATP
14. Suppose that you wanted to determine the metabolic half-life of glutamine synthetase in HeLa cells (a line of human tumor cells) growing in tissue culture. Describe how this could be done experimentally.

- *15. Folic acid is synthesized in bacteria as dihydrofolate, in a pathway starting from guanosine triphosphate. In this pathway, C-8 is lost as formate. From the structural similarities between guanine and pterin, predict which carbon and nitrogen atoms of GTP are the precursors to N-1, C-2, C-4, N-5, C-7, N-8, and C-9 of dihydrofolate.

Dihydrofolate

GTP

16. Which folate structure (from the list below)
- Is the substrate for the enzyme that is inhibited by methotrexate and trimethoprim?
 - Has the most highly oxidized one-carbon substituent?
 - Is used in the conversion of serine to glycine?
 - Transfers its one-carbon substituent to a B_{12} coenzyme? What amino acid is synthesized as the end result of this reaction?
 - Is the coenzyme for the thymidylate synthase reaction?
 - Is not known to exist in nature?
 - Is used in purine nucleotide synthesis?

17. Glutamine affects the regulatory system for *E. coli* glutamine synthetase so as to promote the adenylation of glutamine synthetase and inhibit the deadenylation. Why do these effects make good metabolic sense?
18. Briefly discuss how a yeast cell might contain two glutamate dehydrogenases, one specialized for nitrogen assimilation and one for amino acid catabolism, and not dissipate energy in the futile cycle $\text{glutamate} \rightleftharpoons \alpha\text{-ketoglutarate}$.

CHAPTER 21

Metabolism of Nitrogenous Compounds II: Amino Acids, Porphyrins, and Neurotransmitters

In Chapter 20 we presented unifying principles of amino acid metabolism—general features of synthetic and degradative pathways, common routes for utilizing and excreting ammonia, and coenzymes used in nitrogen metabolism. Here we consider the metabolism of the 20 standard amino acids, focusing on the fates and sources of their carbon skeletons. Our approach is to organize these amino acids into families that are metabolically related. We will begin with the degradation pathways and the major roles of each amino acid as an intermediate en route to metabolites other than protein. Some of the biological roles of amino acids—as neurotransmitters and neurotransmitter precursors and as porphyrin precursors—are so important that they are presented as separate major divisions within this chapter. Finally, we will discuss amino acid biosynthesis, focusing on the most common pathways leading to the nonessential amino acids. Biosynthesis of the essential amino acids, which is restricted to microorganisms and plants, will be touched on only briefly to illustrate important metabolic and mechanistic principles.

Pathways of Amino Acid Degradation

We learned in the preceding chapters that animals generate most of their metabolic energy from oxidation of carbohydrates and fats. Nevertheless, animals obtain 10%–15% of their energy from the oxidative degradation of amino acids. Chapter 20 described the processes by which amino acids are deaminated and the amino groups converted either to ammonia or to the amino group of aspartate for the production of urea. We now turn to the fates of the carbon skeletons. Because each of the 20 amino acids has a unique carbon skeleton, each amino acid requires its own degradation pathway. However, these 20 pathways all converge on just seven common metabolic intermediates: pyruvate, α -ketoglutarate, succinyl-CoA, fumarate, oxaloacetate, acetyl-CoA, and acetoacetate. We have already seen that several of these intermediates (pyruvate, α -ketoglutarate, succinyl-CoA, fumarate,

oxaloacetate) are precursors for glucose synthesis (Chapters 13 and 14). Thus, amino acids whose carbon skeletons are degraded to one of these five intermediates are referred to as **glucogenic amino acids** (Figure 21.1). Acetyl-CoA and acetoacetate can be converted to ketone bodies (Chapter 17); amino acids whose carbon skeletons are degraded to either of these are referred to as **ketogenic amino acids**. Some amino acids are both glucogenic and ketogenic. Our discussion of these catabolic pathways will be organized around the seven common metabolic intermediates mentioned above.

Pyruvate Family of Glucogenic Amino Acids

Alanine, serine, and cysteine, each with three-carbon skeletons, are converted in one or two steps to the three-carbon metabolite pyruvate (Figure 21.2). Alanine is transaminated to pyruvate using the pyridoxal phosphate (PLP)-dependent chemistry we described in Chapter 20. Serine is dehydrated and deaminated to pyruvate by another PLP-dependent enzyme, **serine-threonine dehydratase**. Like all PLP-dependent enzymes, serine dehydratase catalyzes the formation of a planar Schiff base between PLP and the amino acid, but in this reaction, the substrate undergoes elimination of its C_{α} -hydrogen and C_{β} -OH (α,β elimination of H_2O) (see margin). The resulting enamine tautomerizes to an imine, which spontaneously hydrolyzes to form pyruvate and ammonia.

Cysteine is first transaminated by the same enzyme that transaminates aspartate. The resulting β -mercaptopyruvate can then undergo desulfuration by **mercaptopyruvate sulfurtransferase** to give pyruvate and H_2S , thiocyanate (SCN^-), sulfite (SO_3^{2-}), or thiosulfate ($S_2O_3^{2-}$). This reaction is one source of the gas H_2S in animals. Like another **gasotransmitter** molecule, nitric oxide (NO, see Chapter 23), H_2S is involved in the regulation of vascular blood flow and blood pressure. Indeed, the cardioprotective and antihypertensive effects of dietary garlic are mediated in large part by the production of H_2S from organic polysulfides that

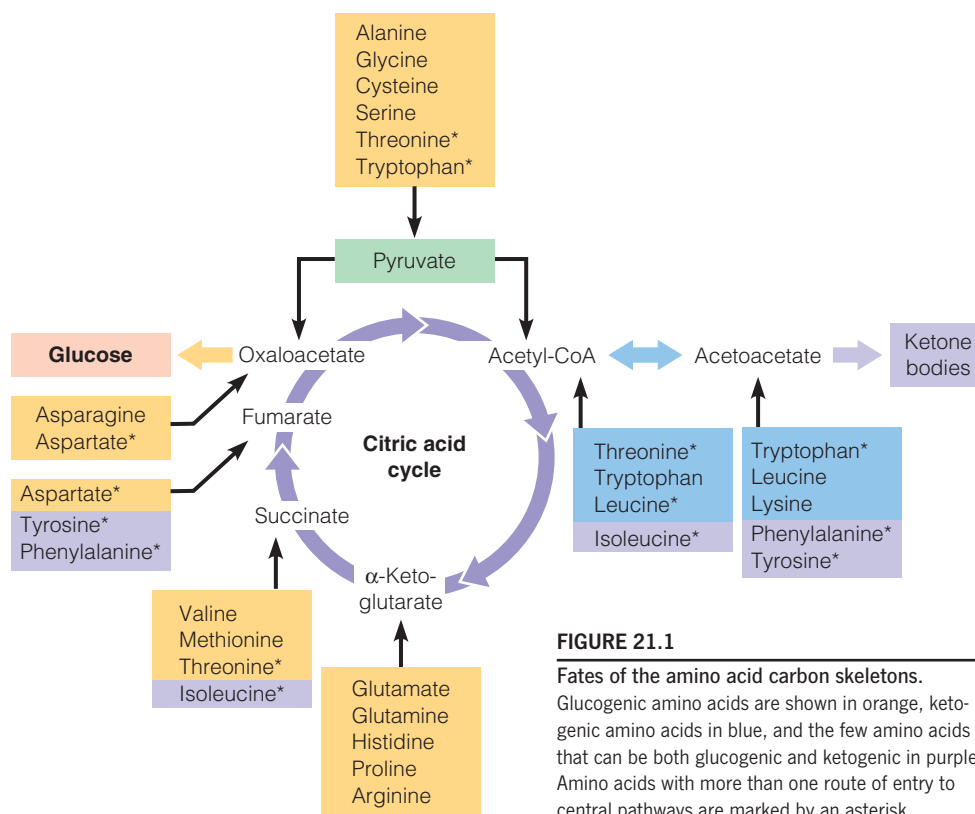

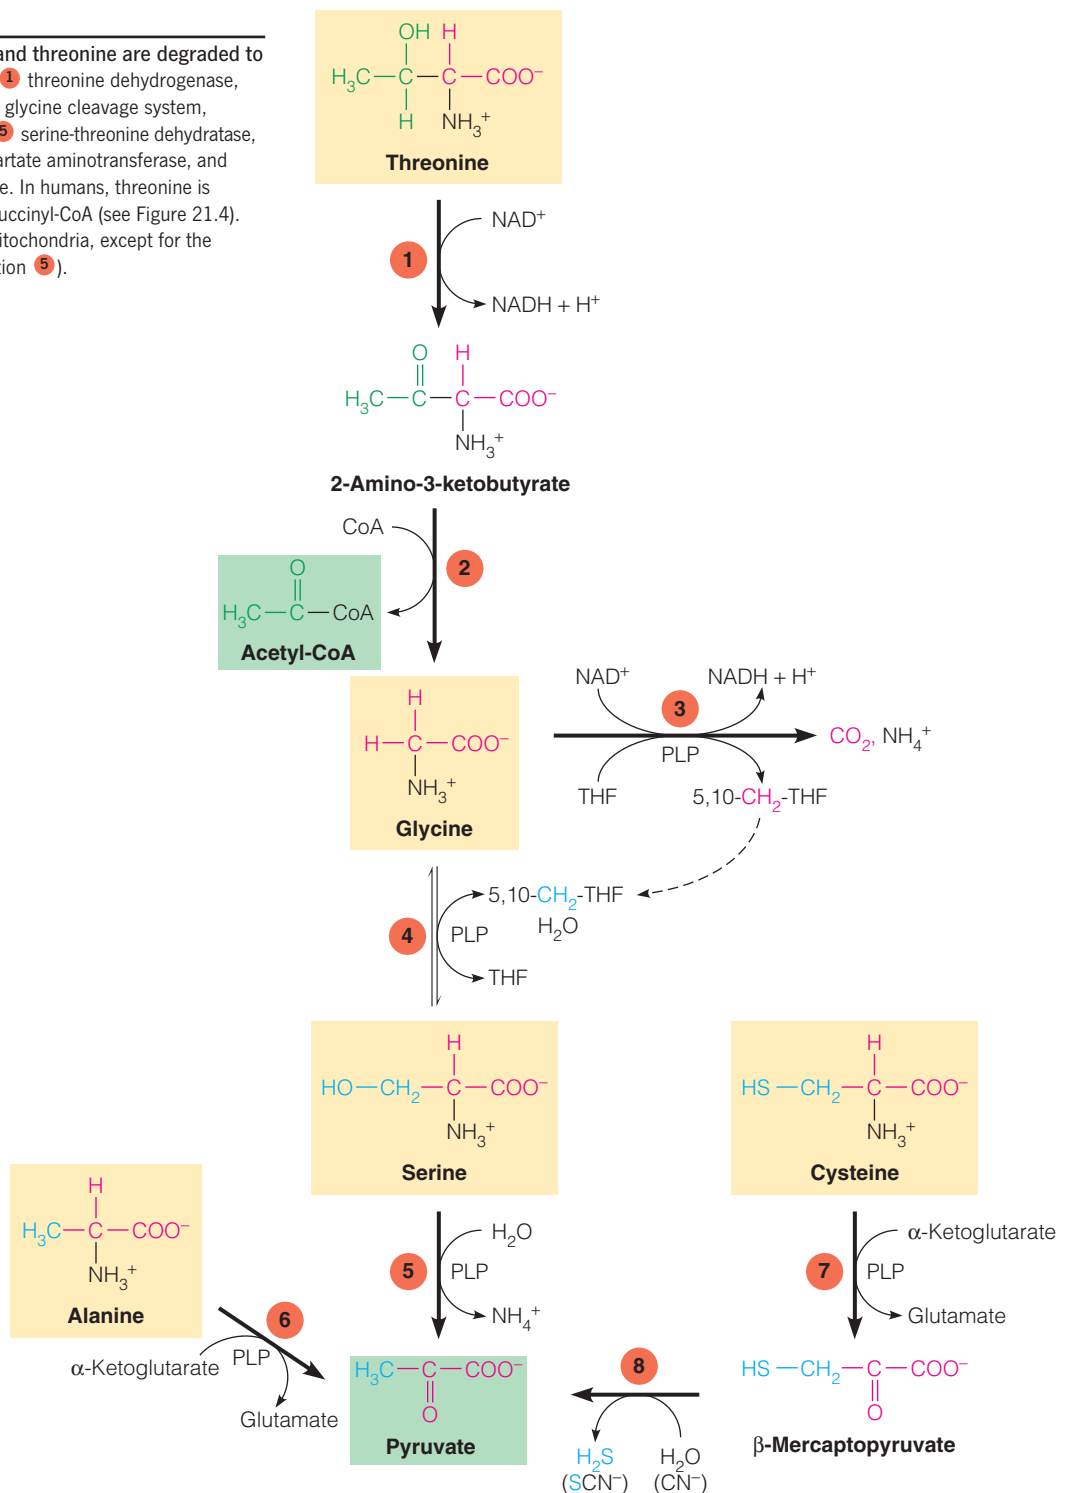

FIGURE 21.1

Fates of the amino acid carbon skeletons. Glucogenic amino acids are shown in orange, ketogenic amino acids in blue, and the few amino acids that can be both glucogenic and ketogenic in purple. Amino acids with more than one route of entry to central pathways are marked by an asterisk.

FIGURE 21.2

Alanine, cysteine, glycine, serine, and threonine are degraded to pyruvate. The enzymes involved are ① threonine dehydrogenase, ② 2-amino-3-ketobutyrate ligase, ③ glycine cleavage system, ④ serine hydroxymethyltransferase, ⑤ serine-threonine dehydratase, ⑥ alanine aminotransferase, ⑦ aspartate aminotransferase, and ⑧ mercaptopyruvate sulfurtransferase. In humans, threonine is degraded by a different pathway, to succinyl-CoA (see Figure 21.4). All of these enzymes are located in mitochondria, except for the cytoplasmic serine dehydratase (reaction ⑤).

are abundant in garlic. Mercaptopyruvate sulfurtransferase can also transfer the sulfur to CN⁻ to give thiocyanate, an important mechanism for detoxifying cyanide.

In most organisms, threonine degradation begins with oxidation of its 2° alcohol, converting carbons 3 and 4 into an acetyl group. 2-Amino-3-ketobutyrate then undergoes a thiolytic cleavage analogous to that found in the β-oxidation of fatty acids (Chapter 17, page 728), releasing carbons 3 and 4 as acetyl-CoA, and carbons 1 and 2 as glycine. Glycine can be degraded to CO₂, NH₄⁺, and 5,10-methylene-tetrahydrofolate by the PLP- and THF-dependent **glycine cleavage system**

Hydrogen sulfide (H₂S), derived from cysteine, is a powerful gaseous signaling molecule involved in the regulation of vascular blood flow and blood pressure.

described in Chapter 20 (page 853). Alternatively, glycine can be converted to serine by the other PLP- and THF-dependent enzyme described in Chapter 20, **serine hydroxymethyltransferase**. The hydroxymethyl group of serine (C3) comes from 5,10-methylene-THF, which might derive from glycine cleavage (reaction 3) or some other one-carbon donor (see Figure 20.17, page 852). The importance of this pathway for glycine degradation is revealed by the inherited disease **nonketotic hyperglycinemia**. This is an autosomal recessive disease caused by defects in subunits of the glycine cleavage system, resulting in elevated glycine levels in cerebrospinal fluid, plasma, and urine. The disease typically occurs as a severe neonatal disorder with severe neurological symptoms, including mental retardation.

Threonine has a different fate in humans because we lack a functional threonine dehydrogenase (Figure 21.2, reaction 1). Instead, threonine is first dehydrated and deaminated by serine-threonine dehydratase to give a carbon skeleton that is eventually converted to succinyl-CoA (see Figure 21.4).

As was pointed out in Chapter 20, pyridoxal phosphate is a remarkably versatile coenzyme—the five PLP-dependent reactions in Figure 21.2 nicely illustrate this versatility.

Oxaloacetate Family of Glucogenic Amino Acids

The four-carbon skeletons of asparagine and aspartate are converted to oxaloacetate in a simple pathway (see margin). **Asparaginase** catalyzes hydrolytic cleavage of the asparagine amide to aspartate and ammonium. Aspartate is then transaminated directly to oxaloacetate by **aspartate transaminase**, the same enzyme that transaminates cysteine (Figure 21.2, reaction 7). Asparaginase is an interesting example of enzyme-based chemotherapy. The *E. coli* enzyme is widely used in the treatment of childhood acute lymphoblastic leukemia. Normal and malignant lymphocytes depend on the uptake of asparagine from the blood for growth—asparaginase depletes circulating asparagine, and this leads to complete remission in many cases.

α -Ketoglutarate Family of Glucogenic Amino Acids

The carbon skeletons of arginine, glutamine, histidine, and proline are all degraded to α -ketoglutarate via glutamate. Figure 21.3 presents the major catabolic routes for these five amino acids. Both proline and arginine are converted to glutamate through the intermediate **glutamate γ -semialdehyde**, which is then oxidized to glutamate. Histidine degradation begins with a nonoxidative deamination, followed by hydration and ring opening to yield **N-formiminoglutamic acid**, which is of interest because it serves as a donor of active one-carbon fragments (see Figure 20.17, page 852). The formimino group, derived from C2 and N3 of the imidazole ring, is transferred to tetrahydrofolate, yielding 5-formiminotetrahydrofolate and glutamate. Glutamine is hydrolyzed to glutamate by **glutaminase**, which in animals participates in transporting ammonia to the liver (see Figure 20.13, page 845). Finally, glutamate is oxidatively deaminated to α -ketoglutarate by glutamate dehydrogenase, which was discussed in depth in Chapter 20.

Histidine also undergoes decarboxylation to generate **histamine**, a substance with multiple biological actions. When secreted in the stomach, histamine promotes the secretion of hydrochloric acid and pepsin, both of which aid digestion. It is a potent vasodilator, released locally in sites of trauma, inflammation, or allergic reaction. The local enlargement of blood capillaries is the basis for the reddening that occurs in inflamed tissues. Release of histamine in trauma contributes to the dangerous lowering of blood pressure that can lead to shock. A large number of **antihistamines**, such as the two shown in the box, are in use to treat allergies and other inflammations. Typically, these drugs prevent the binding of histamine to its receptors.

FIGURE 21.3

Arginine, glutamate, glutamine, histidine, and proline are degraded to α -ketoglutarate. The enzymes involved are 1 proline oxidase, 2 arginase, 3 ornithine δ -aminotransferase, 4 glutamate γ -semialdehyde dehydrogenase (also called Δ^1 -pyrroline-5-carboxylate dehydrogenase), 5 glutamate formiminotransferase, 6 glutaminase, 7 glutamate dehydrogenase.

Succinyl-CoA Family of Glucogenic Amino Acids

Isoleucine, valine, threonine, and methionine are degraded to the citric acid cycle intermediate, succinyl-CoA, by way of propionyl-CoA (Figure 21.4). The catabolism of methionine begins after it has donated its methyl group, via S-adenosylmethionine, in the methyl cycle (see Figure 21.9). The demethylated

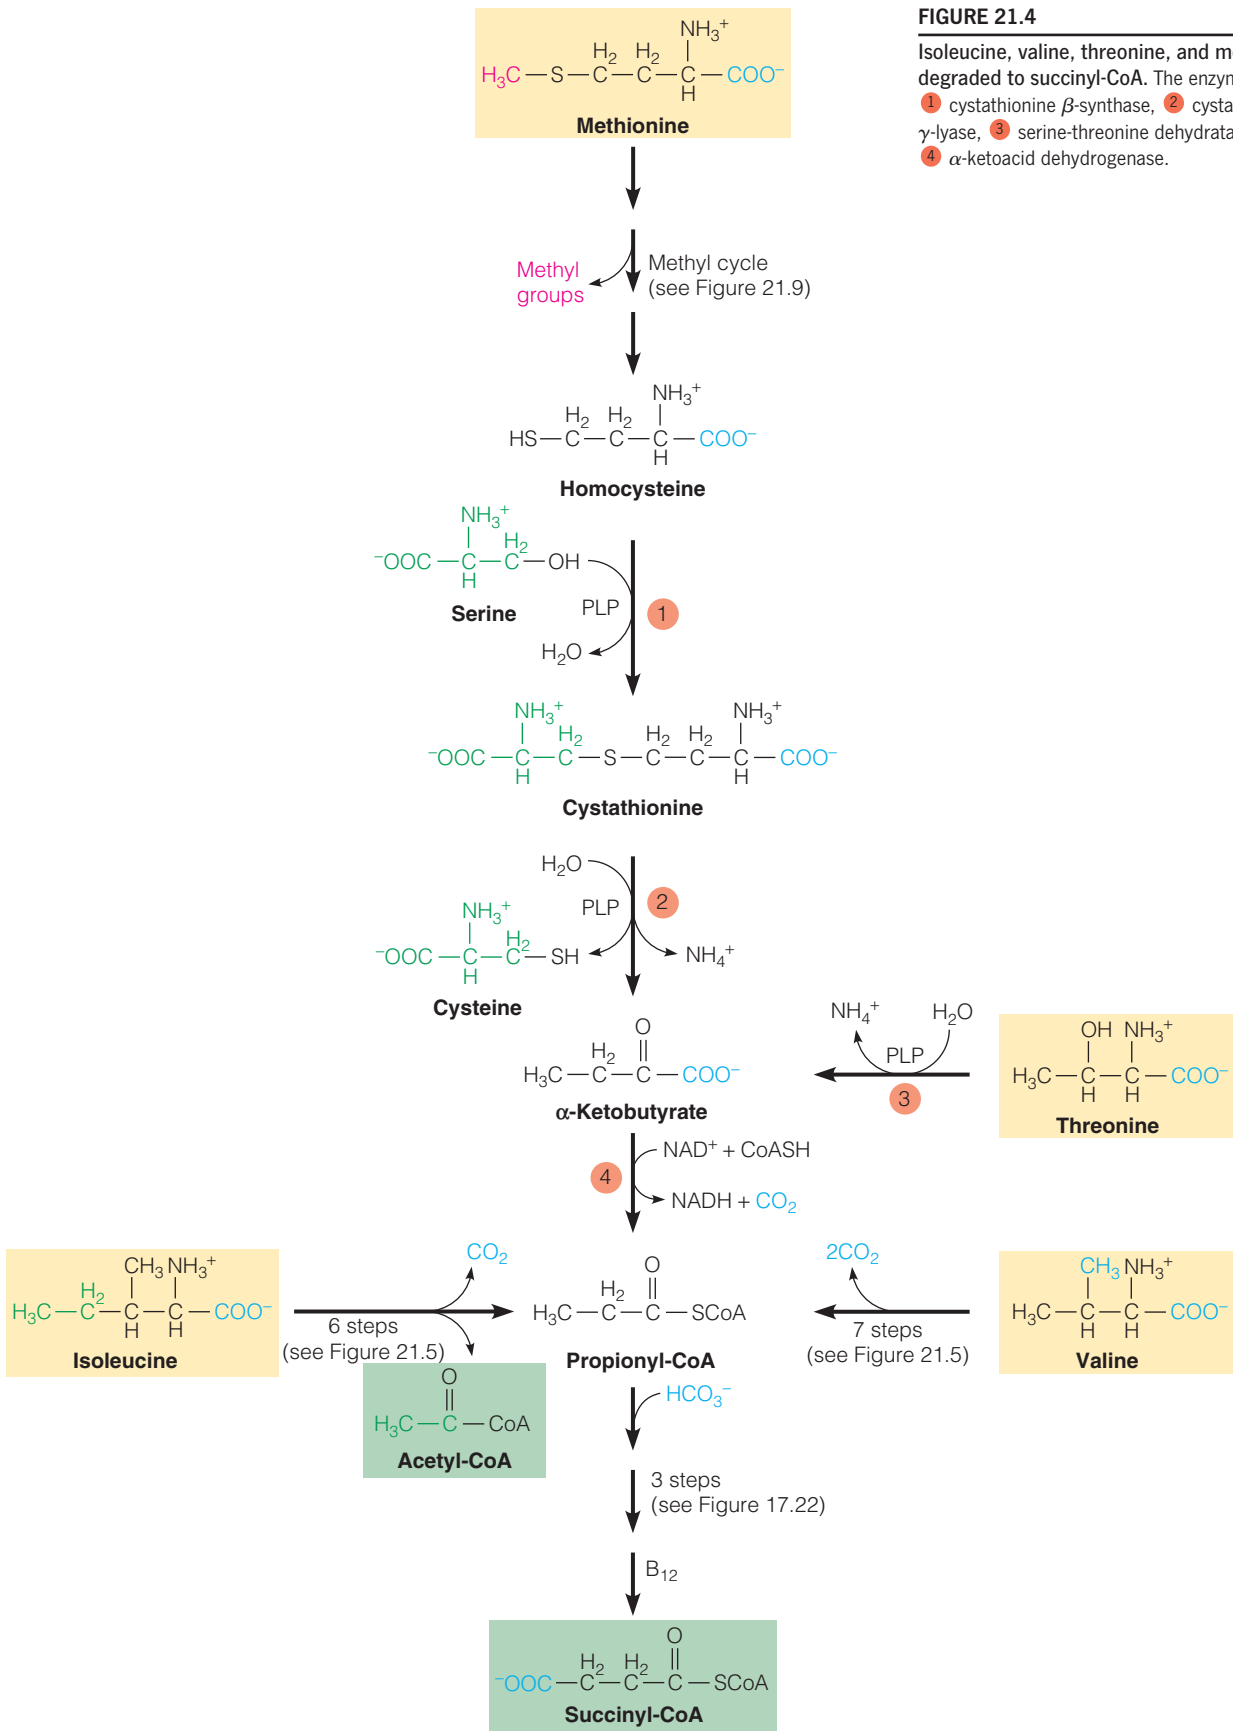

FIGURE 21.4

Isoleucine, valine, threonine, and methionine are degraded to succinyl-CoA. The enzymes involved are 1 cystathionine β-synthase, 2 cystathionine γ-lyase, 3 serine-threonine dehydratase, and 4 α-ketoacid dehydrogenase.

carbon skeleton, **homocysteine**, is converted to α -ketobutyrate and the —SH group replaces the —OH of serine to form cysteine. This is, in fact, the route by which animals synthesize cysteine (see Figure 21.29). In the first step of this two-step **transsulfuration** process, catalyzed by cystathionine β -synthase, homocysteine and serine condense to form the thioether **cystathionine** (Figure 21.4, reaction 1). In the second step, cystathionine γ -lyase catalyzes a γ -elimination to give cysteine, α -ketobutyrate, and ammonia (reaction 2). Thus, cleavage occurs on the other side of the S atom, resulting in transfer of the —SH group from the four-carbon backbone (homocysteine) to the three-carbon backbone (cysteine). Both transsulfuration β -synthases are PLP-dependent; cystathionine β -synthase also requires a b-type heme cofactor. α -Ketobutyrate is oxidatively decarboxylated to propionyl-CoA (reaction 4), which is then converted to succinyl-CoA by the same B₁₂-requiring pathway we introduced in Chapter 17 as a key step in the oxidation of odd-chain fatty acids (page 732).

α -Ketobutyrate is also an entry point for carbon from threonine (Figure 21.4, reaction 3). Both threonine and serine are dehydrated and deaminated by the same dehydratase. This is the major pathway for threonine degradation in humans.

Isoleucine and valine are also degraded to the three-carbon propionyl-CoA. However, two of isoleucine's carbons are released as acetyl-CoA and one as CO₂; valine loses two carbons as CO₂. Oxidation of the branched-chain amino acids, including leucine, starts with a PLP-dependent transamination to the corresponding α -keto acid and then follows a common chemical strategy (Figure 21.5): (1) oxidative decarboxylation to give an acyl-CoA derivative; (2) FAD-dependent acyl-CoA dehydrogenation to introduce a double bond; (3) hydration of the double bond to introduce a hydroxyl group; and (4) NAD⁺-dependent dehydrogenation to the corresponding keto derivative. All three branched-chain amino acids follow this same strategy, with only minor deviations. The final step in isoleucine degradation is a thiolytic cleavage that produces acetyl-CoA and propionyl-CoA. In the valine pathway, CoA is hydrolyzed off the carbon skeleton before the second dehydrogenation; a final decarboxylation gives propionyl-CoA. In the leucine pathway, the hydration step gives **3-hydroxy-3-methylglutaryl-CoA (HMG-CoA)**, an intermediate also involved in ketogenesis (Figure 17.24, page 735) and cholesterol biosynthesis (Figure 19.19, page 797). HMG-CoA is cleaved to acetoacetate plus acetyl-CoA by the same mitochondrial **HMG-CoA lyase** used in ketogenesis.

The chemical strategy used to oxidize the branched-chain amino acids should look familiar to you because you have seen it twice before. This same strategy forms the core of both the β -oxidation of fatty acids (Chapter 17) and the citric acid cycle (Chapter 14). These two pathways are shown alongside the branched-chain amino acid oxidation pathways in Figure 21.5. Once the amino acids are transaminated to the corresponding α -keto acids, they follow the same sequence we first learned in the citric acid cycle. β -oxidation adds a thiolytic cleavage at the end of this core pathway. This commonality illustrates a couple of important points about metabolic pathways. First, as we discussed in Chapter 12, metabolic pathways are the products of evolution, being built from enzymes and pathways that may have had other functions initially. It is thus likely that the branched-chain amino acid oxidation pathways arose from the evolutionarily ancient citric acid cycle pathway. Second, a cell can “economize” by using the same enzyme to metabolize several related substrates. Indeed, the first two steps of branched-chain amino acid degradation in Figure 21.5 are each catalyzed by a single enzyme that acts on all three carbon skeletons. **Branched-chain amino acid aminotransferase** uses α -ketoglutarate as the amino acceptor from all three amino acids and exists in two isozymes—cytoplasmic and mitochondrial—in mammals. This enzyme is at low levels in human liver but abundant in muscle, adipose, kidney, and brain, where branched-chain amino acids are important

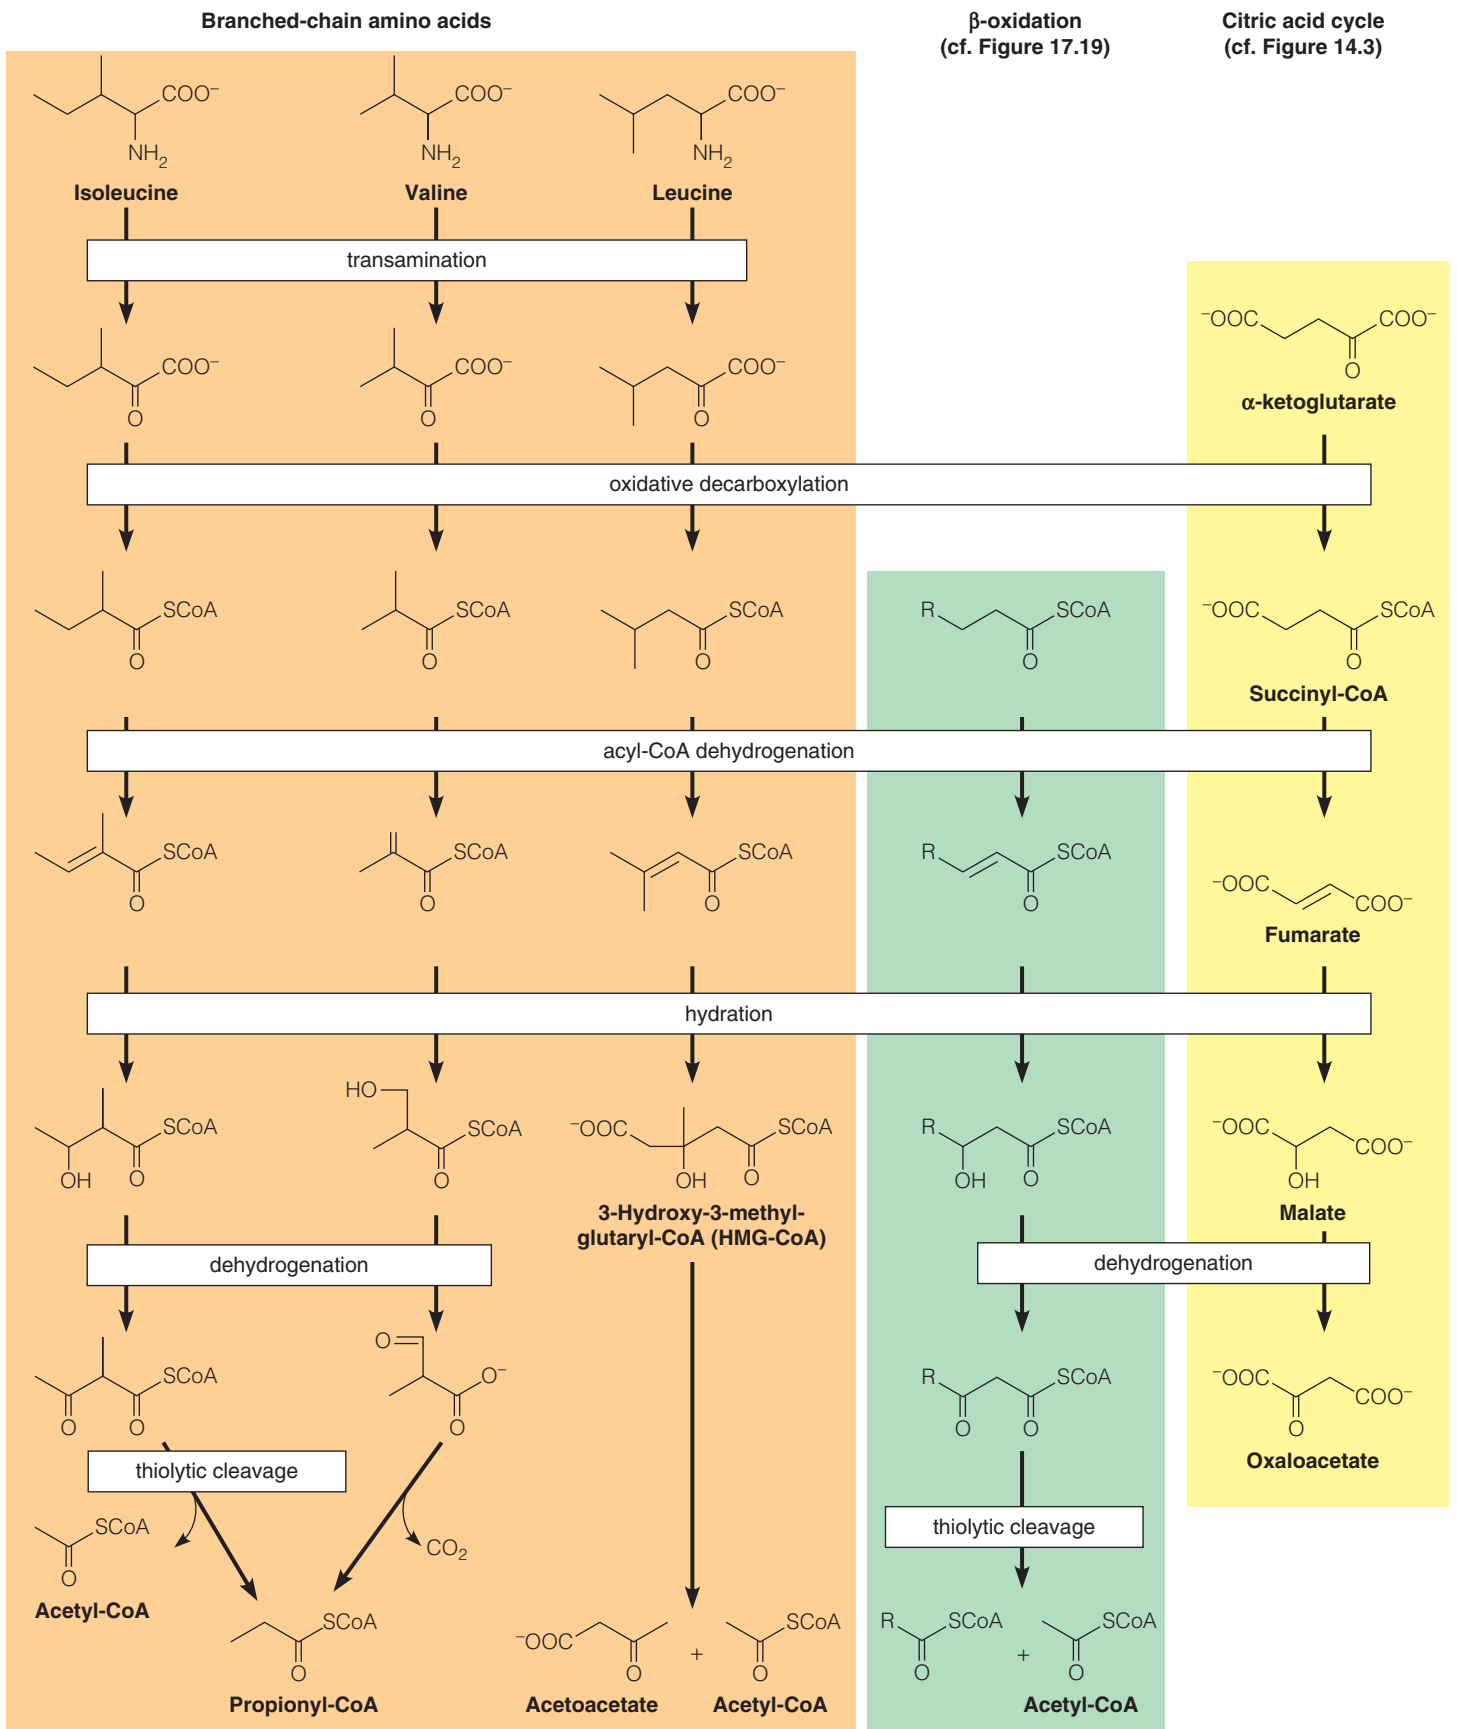

FIGURE 21.5

Branched-chain amino acid oxidation, fatty acid β -oxidation, and the citric acid cycle share a common chemical strategy.

A deficiency of branched-chain α -keto acid dehydrogenase complex, which metabolizes valine, leucine, and isoleucine in humans, leads to a severe mental developmental defect called maple syrup urine disease.

fuel sources during fasting. The subsequent oxidative decarboxylation of all three α -keto acid derivatives is carried out by the mitochondrial **branched-chain α -keto acid dehydrogenase complex**, which has the same E_1 - E_2 - E_3 multienzyme structure and mechanism of the pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes (Chapter 14). Indeed, the E_3 subunits are identical in all three complexes from a given species. In a rare human disorder called **maple syrup urine disease**, or branched-chain ketoaciduria, this complex is defective. All three amino acids and their α -keto acid derivatives accumulate in the urine, and their characteristic odor gives the condition its name. The condition involves severe mental retardation.

Acetoacetate/Acetyl-CoA Family of Ketogenic Amino Acids

Lysine Degradation

We have already discussed the path by which leucine is degraded to acetoacetate and acetyl-CoA (Figure 21.5). Based on our experience with the branched-chain amino acids, we might predict that lysine degradation follows a similar strategy, once its two amino groups are removed. We know how to remove the α -amino group—by transamination—but what about lysine's ϵ -amino group? Although lysine is degraded by several pathways, the major route in mammals, the **saccharopine** pathway, does indeed follow this predicted strategy. Saccharopine is the intermediate in the two-step process that removes the ϵ -amino group from lysine:

These two reactions are catalyzed by a bifunctional enzyme named **α -aminoadipic semialdehyde synthase**. The mammalian enzyme is a single protein composed of separate domains for the two catalytic activities. Although this process uses α -ketoglutarate as the amino acceptor, and produces glutamate, it is more similar to the argininosuccinate synthetase–argininosuccinase reactions of the urea cycle (Figure 20.12, page 842) than to a transamination:

The rest of the pathway involves oxidation of the semialdehyde to the acid and transamination to remove the α -amino group, followed by the now familiar oxidative decarboxylation to give an acyl-CoA derivative; FAD-dependent acyl-CoA dehydrogenation to introduce a double bond; hydration of the double bond to introduce a hydroxyl group; and NAD^+ -dependent dehydrogenation to the corresponding keto derivative. The only variation on this theme required by lysine is an extra decarboxylation after the acyl-CoA dehydrogenation step to remove the terminal carbon (the aldehyde of α -amino adipic semialdehyde). The final degradation product is acetoacetate.

Tryptophan Degradation

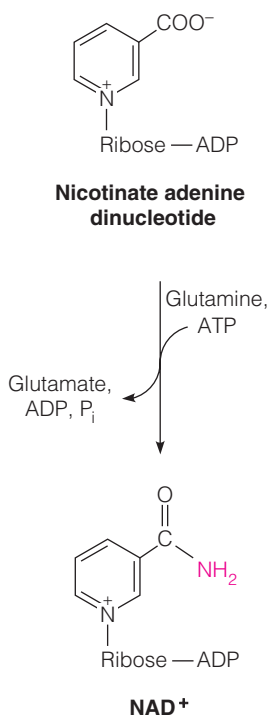

Tryptophan is transformed by many pathways, but the major catabolic route proceeds via **kynurenine** to α -ketoacidipate (Figure 21.6). The first reaction in the degradation of tryptophan is catalyzed by **tryptophan 2,3-dioxygenase**, a heme protein that incorporates both atoms of O_2 into the substrate. The fourth step, catalyzed by **kynureninase**, is a PLP-dependent cleavage of the $\text{C}_\beta\text{—C}_\gamma$ bond, releasing the α and β carbons of the original tryptophan skeleton as alanine, which is readily transaminated to pyruvate. The other product of the cleavage reaction, 3-hydroxyanthranilic acid, is eventually converted to α -ketoacidipate, an intermediate in the saccharopine pathway of lysine degradation. Indeed, the last seven steps of tryptophan and lysine degradation are identical, ending with acetoacetate.

FIGURE 21.6

Metabolic fates of tryptophan. The figure shows two major pathways—the major catabolic pathway that degrades most of the tryptophan molecule to acetoacetate and alanine, and the synthetic pathway to the nicotinamide nucleotides.

The amide nitrogen of glutamine is used in many amidotransferase reactions leading to purine and pyrimidine nucleotides, amino sugars, and nicotinamide nucleotides.

Tryptophan is also an important precursor for the synthesis of nicotinamide nucleotides, accounting for as much as 50% of an animal's NAD⁺. The rest comes from the vitamin niacin (see Table 11.8 on page 446). For both pathways the last reaction is catalyzed by a **glutamine-dependent amidotransferase** (see margin), in which glutamine donates its amide N and ATP hydrolysis provides the driving force for the reaction. Glutamine-dependent amidotransferases are widespread in metabolism, including reactions leading to other amino acids, to nucleotides, and to amino sugars and glycoproteins. We will look more closely at the mechanism of these enzymes in Chapter 22.

The role of tryptophan in NAD⁺ biosynthesis can be inferred from studies of the nicotinamide deficiency disease **pellagra**. Pellagra was formerly endemic in regions where corn is a dietary staple such as the southern United States. Because corn proteins contain little tryptophan, deficiencies of this amino acid were common. The symptoms of tryptophan deficiency are identical to those of nicotinamide deficiency, as expected if a major role of tryptophan is as a nicotinamide substitute.

Phenylalanine and Tyrosine Degradation

The final two amino acids are degraded by a single pathway that begins with the hydroxylation of phenylalanine to tyrosine, catalyzed by **phenylalanine hydroxylase**. This interesting enzyme belongs to the **aromatic amino acid hydroxylase** family, along with tyrosine hydroxylase and tryptophan hydroxylase. In animals and microbes, all three enzymes are nonheme iron-containing monooxygenases that use an Fe(IV)O intermediate to hydroxylate their amino acid substrates. All three hydroxylases also require a pterin cofactor, **tetrahydrobiopterin** (BH₄). Although structurally similar to tetrahydrofolate, BH₄ is not derived from folic acid, but is instead synthesized from GTP in most mammalian cells and tissues. In the **phenylalanine hydroxylase** reaction, one O atom becomes the hydroxyl of tyrosine and the other hydroxylates BH₄ to a carbinolamine, which is converted to the quinonoid form of 7,8-dihydrobiopterin by **pterin-4a-carbinolamine dehydratase**, as shown in Figure 21.7. The pterin coenzyme is regenerated through the action of the **dihydropteridine reductase** (analogous, but not identical, to dihydrofolate reductase). Although dihydropteridine reductase can use either NADH

FIGURE 21.7

The phenylalanine hydroxylation system. Conversion of phenylalanine to tyrosine is catalyzed by phenylalanine hydroxylase, accompanied by hydroxylation of the cofactor, tetrahydrobiopterin, to pterin-4a-carbinolamine. Tetrahydrobiopterin is regenerated by dehydration of the carbinolamine to dihydrobiopterin, followed by reduction catalyzed by the enzyme dihydrobiopterin reductase.

or NADPH as an electron donor, it has a much lower K_M for NADH. This three-enzyme phenylalanine hydroxylation system occurs primarily in liver and, to a lesser extent, in kidney. The aromatic amino acid hydroxylases in plants use a tetrahydrofolate cofactor rather than tetrahydrobiopterin.

A hereditary deficiency of phenylalanine hydroxylase is responsible for **phenylketonuria (PKU)**, a condition that afflicts about 1 in 10,000 newborn infants in western Europe and the United States. PKU is an autosomal recessive trait, meaning that two parents heterozygous for the trait have 1 chance in 4 of having a phenylketonuric child. From the incidence of the disease, we can estimate that about 2% of the population are carriers. In phenylketonuria, phenylalanine accumulates to very high levels (**hyperphenylalaninemia**) because of the block in conversion to tyrosine, and much of this phenylalanine is metabolized via pathways that are normally little used—particularly transamination to phenylpyruvate (a phenylketone), and also subsequent conversion of phenylpyruvate to phenyllactate and phenylacetate. These compounds are excreted in urine in enormous quantities (1 to 2 grams per day).

If undetected and untreated, PKU leads to profound mental retardation; the precise biochemical causation is not known, but evidence is accumulating that phenylalanine itself is the neurotoxic molecule. Fortunately, PKU can readily be detected at birth, and many hospitals carry out routine screening of newborns. If the condition is detected early, the onset of retardation can be prevented by feeding for several years a synthetic diet low in phenylalanine and rich in tyrosine, to allow normal development of the nervous system. Because the use of this synthetic diet is quite expensive, there has been much interest in prenatal diagnosis of PKU and in identification of heterozygous carriers. More than 500 distinct pathogenic mutations have been mapped on the human gene for phenylalanine hydroxylase. Most of these are missense mutations that lead to amino acid substitutions in the 452-amino acid protein. The structure of human phenylalanine hydroxylase has been determined by X-ray crystallography, and it is now possible to provide a molecular explanation for many of the PKU mutations.

PKU is by far the most common, but not the only, form of hyperphenylalaninemia. Hereditary deficiency of dihydropteridine reductase, pterin-4 α -carbinolamine dehydratase, or any of the enzymes required for the biosynthesis of BH_4 lead to non-PKU hyperphenylalaninemia. Because tetrahydrobiopterin is involved in other hydroxylations, including those of tyrosine and tryptophan, defects in its synthesis or recycling cause more severe symptoms.

Degradation of tyrosine to fumarate and acetoacetate begins with its transamination by **tyrosine aminotransferase**, the rate-determining enzyme in this catabolic pathway (Figure 21.8). The product, *p*-hydroxyphenylpyruvate, is acted on by ***p*-hydroxyphenylpyruvate dioxygenase**, an unusual iron-containing enzyme, which catalyzes a ring hydroxylation, decarboxylation, and side chain migration, using ascorbate as a cofactor. Procollagen prolyl hydroxylase catalyzes the same chemistry (see page 906). This reaction involves a mechanism called the **NIH shift**, after scientists at the National Institutes of Health, who described a ring

FIGURE 21.8

Catabolism of phenylalanine and tyrosine to fumarate and acetoacetate.

hydroxylation that proceeds via formation of an epoxide intermediate and migration of the alkyl side chain.

Phenylketonuria, if left untreated, leads to a severe mental deficiency arising from genetic insufficiency of phenylalanine hydroxylase.

The phenylalanine hydroxylase reaction also involves an NIH shift, with migration of the hydrogen at C-4 of phenylalanine to C-3 of tyrosine, without mixing with solvent.

The product of *p*-hydroxyphenylpyruvate oxidation, **homogentisic acid**, is oxidized by an iron-containing enzyme, **homogentisate dioxygenase**, that cleaves the ring to yield a straight-chain eight-carbon compound that isomerizes to **fumarylacetoacetate**. The latter ultimately cleaves to yield fumarate and acetoacetate, both of which are catabolized by standard energy-yielding pathways. In plants, homogentisate is the precursor to the plastoquinones used in photosynthesis (Chapter 16) and to the aromatic ring portion of vitamin E (see page 811).

A hereditary deficiency of the enzyme homogentisate dioxygenase in humans causes a condition that was known for centuries as the “dark urine disease” but is now called **alkaptonuria**. Homogentisate accumulates and is excreted in large amounts in the urine; its oxidation on standing causes the urine to become dark. Although the clinical symptoms of the disease are not severe, it is of considerable historical interest. Early in the twentieth century Sir Archibald Garrod examined pedigrees of the families of afflicted individuals, and in 1909 he wrote, “We may further conceive that the splitting of the benzene ring in normal metabolism is the work of a special enzyme, that in congenital alcaptonuria this enzyme is wanting, whilst in disease its working may be partially or even completely inhibited.” In other words, Garrod proposed that one gene encodes one enzyme, long before the chemical nature of either genes or enzymes was known, and developed the concept of inheritable metabolic diseases.

Amino Acids as Biosynthetic Precursors

Beyond their incorporation into proteins, amino acids serve as precursors for a tremendous variety of other important metabolites, such as polyamines, glutathione, methyl groups, heme, neurotransmitters and other signaling molecules, and nucleotides (Chapter 22). In the following section, we highlight some of the most important pathways and products of amino acid metabolism.

S-Adenosylmethionine and Biological Methylation

In Chapter 19 we introduced S-adenosylmethionine (AdoMet) as a metabolically activated form of methionine, when we described the biosynthesis of phosphatidylcholine from phosphatidylethanolamine. Recall that the synthesis of AdoMet from methionine and ATP generates a sulfonium compound with a high group transfer potential. Most, though not all, of the group transfer reactions involving AdoMet are **transmethylations**, in which the methyl group is transferred to an acceptor, with the other product being S-adenosylhomocysteine (AdoHcy). The syntheses of creatine (see Figure 21.16) and of phosphatidylcholine (see page 784) are good examples of transmethylations.

Table 21.1 lists a number of biologically important AdoMet-dependent transmethylations. Note that the substrates can be polymeric proteins or nucleic acids. We

discuss the functions of DNA and RNA methylation in later chapters. However, a brief discussion of protein methylation is in order here. Methylatable residues include—in different proteins—lysine, arginine, and residues containing free carboxyl groups. Histones are extensively methylated, with specific arginine and lysine residues being modified at particular times in the cell cycle. Lysine can be mono-, di-, or trimethylated; arginine can be dimethylated, in either a symmetric or asymmetric configuration. These post-translational modifications of histones play a central role in regulating transcription and maintaining genomic integrity, and they also contribute to the **epigenome** (inheritable, non-DNA chemical tags that influence gene expression; more about this in Chapter 29). We also know that ϵ -*N*-trimethyllysine, derived specifically from the enzymatic hydrolysis of methylated protein, serves as the precursor to carnitine, whose role in fatty acyl group transfer across membranes was presented in Chapter 17. Furthermore, in bacteria, protein methylation plays an important role in **chemotaxis**, the process whereby bacteria sense a concentration gradient of a chemical substance in the medium and move either toward or away from it. Chemotaxis is being studied as a rudimentary model for sensory transduction; it involves the cyclic methylation and demethylation of a group of proteins called **MCPs**, or methylatable chemotactic proteins. Finally, there are indications that protein methylation protects proteins, in at least two ways: (1) By blocking sites of ubiquitination (see Chapter 20), methylation evidently helps protect proteins from turnover. (2) Spontaneous damage of protein molecules during aging causes deamidation, isomerization, and racemization of their asparagine and aspartate residues. A methylation reaction can initiate the repair of these damaged residues.

The central metabolic role of AdoMet can be appreciated if you keep in mind that, except for a few reactions in bacterial metabolism, *the only known methyl group transfer that does not involve AdoMet is the synthesis of methionine itself*. As noted in Chapter 20, a methyl group is generated *de novo* through the reduction of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate (5-methyl-THF), catalyzed by a flavin-dependent methylenetetrahydrofolate reductase (MTHFR). The MTHFR reaction in mammalian liver uses NADPH as electron donor, and is consequently physiologically irreversible due to the high cytosolic NADPH/NADP⁺ ratio and the large standard free energy change for the reduction of 5,10-methylene-THF. The methyl group is then transferred to homocysteine to yield methionine via methyl-B₁₂ and the action of methionine synthase (Figure 21.9). This methyl group is then activated for methyl transfers by the ATP-dependent conversion of methionine to AdoMet. *S*-adenosylhomocysteine, formed from AdoMet-dependent transmethylation, is hydrolyzed to yield adenosine and homocysteine by *S*-adenosylhomocysteine hydrolase. Homocysteine is remethylated to methionine, completing the *methyl cycle*. Homocysteine can be removed from the methyl cycle by conversion to cysteine, via the transsulfuration pathway we first described in Figure 21.4. Remethylation and transsulfuration each normally account for ~50% of homocysteine metabolism.

As shown in Figure 21.9, the methyl cycle is tightly connected to a *one-carbon cycle*—indeed, the ultimate source of all the methyl groups donated by AdoMet is the tetrahydrofolate one-carbon pool. Serine is the major donor of one-carbon

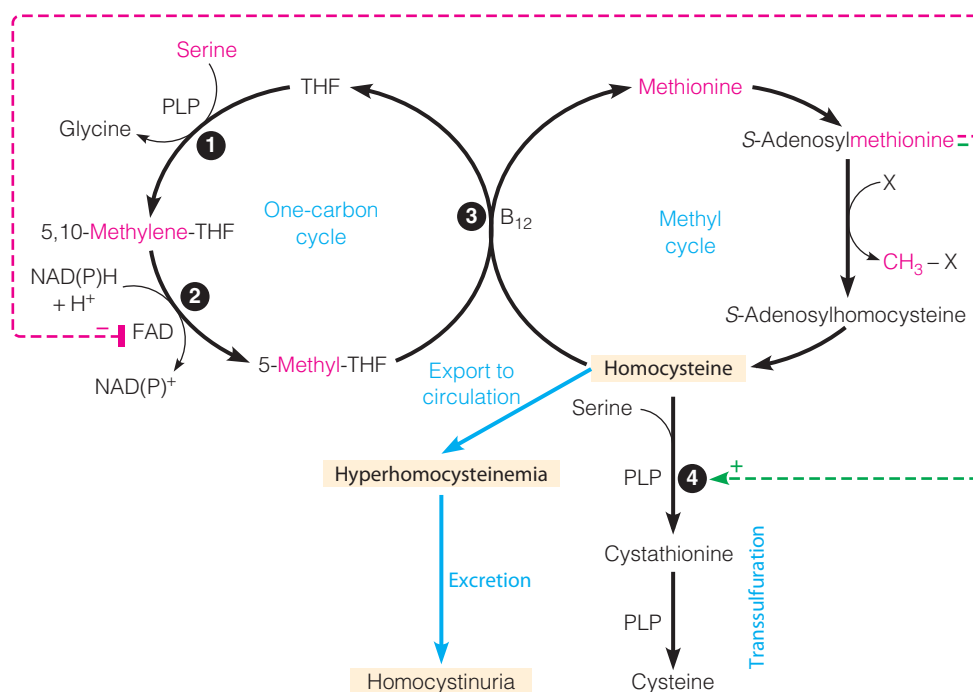

FIGURE 21.9

Methyl group metabolism and homocystinuria. Serine hydroxymethyltransferase ① catalyzes the entry of one-carbon units into the tetrahydrofolate (THF) pool. A deficiency of methylenetetrahydrofolate reductase (MTHFR) ② or methionine synthase ③ blocks the conversion of homocysteine to methionine. X represents any methyl acceptor in an S-adenosylmethionine (AdoMet)-dependent methyltransferase reaction. A defect in cystathionine β -synthase ④ causes homocysteine to accumulate because conversion to cystathionine is impaired. In any of these cases, excess homocysteine accumulates in the circulation (hyperhomocysteinemia) and urine (homocystinuria). Dashed lines indicate allosteric inhibition (magenta) or activation (green) of regulatory enzymes.

5-Methyltetrahydrofolate transfers a methyl group in methionine synthesis, but all other biological methyl transfers involve S-adenosylmethionine.

units, via the PLP-dependent serine hydroxymethyltransferase described in Chapter 20. Reduction of 5,10-methylene-THF to 5-methyl-THF commits this one-carbon unit to methyl group biogenesis because methionine synthase is the only enzyme known to utilize 5-methyl-THF in eukaryotes. Thus, if the methionine synthase reaction is blocked for some reason (e.g., a vitamin B₁₂ deficiency), 5-methyl-THF accumulates, at the expense of depleted pools of the other THF coenzymes. This is the basis of the methyl trap we described in Chapter 20 (page 857).

As you might expect, regulatory mechanisms have evolved to maintain balance between the supply of one-carbon units and the production of methyl groups in the form of AdoMet. Because the MTHFR reaction catalyzes the committed step in methyl group biogenesis, the regulation of MTHFR is crucial for one-carbon metabolism in all organisms. Eukaryotic MTHFRs are feedback inhibited by AdoMet, a key regulatory feature that prevents CH₂-THF depletion when AdoMet levels are adequate (Figure 21.9). Most eukaryotic MTHFRs are composed of an N-terminal domain that contains the catalytic site and a C-terminal regulatory domain that contains an AdoMet allosteric binding site. Plant and bacterial MTHFRs are not inhibited by AdoMet, but those enzymes use NADH rather than NADPH. Due to the high cytosolic NAD⁺/NADH ratio, the MTHFR reaction in these organisms is likely to be reversible, obviating a need for feedback regulation by AdoMet. The other important regulatory site is the first step of the transsulfuration pathway, where AdoMet is a positive allosteric effector of cystathionine β -synthase (Figure 21.9). Thus, under conditions of adequate methionine and methyl groups, AdoMet simultaneously turns off entry of one-carbon units into the methyl cycle, and diverts excess homocysteine into the transsulfuration pathway.

In humans, a genetic deficiency of cystathionine β -synthase leads to a condition called **homocystinuria**, in which homocysteine accumulates, as evidenced by excessive urinary excretion of homocysteine (the oxidized disulfide derivative of homocysteine). Homocystinuria results in severe mental retardation, damage to blood vessels, and dislocation of the lens of the eye. In some patients, homocystinuria can be treated with vitamin B₆ (pyridoxine). Recall that cystathionine β -synthase is a PLP-dependent enzyme (Figure 21.4). The cystathionine β -synthase mutations in B₆-responsive patients typically produce enzymes with two- to five-fold lower affinity for PLP. These “K_M mutants” can often be rescued in vivo by administration of high doses of vitamin B₆.

After cystathionine β -synthase deficiency was described, it was found that similar symptoms resulted from deficiencies of either of two related enzymes—methionine synthase or 5,10-methylenetetrahydrofolate reductase. Deficiency of methionine synthase causes megaloblastic anemia and homocysteinemia, but is very rare in humans. MTHFR deficiency, however, is the most common inborn error of folate metabolism. Although a few cases of severe MTHFR deficiency are known, causing homocystinuria, much more common are patients that exhibit only moderate deficiency of MTHFR enzyme activity. In 1995, Rima Rozen and colleagues at McGill University in Montreal identified a C \rightarrow T substitution in exon 4 of the human MTHFR gene, producing an Ala \rightarrow Val substitution at position 222 in the catalytic domain of the enzyme (Figure 21.10). This missense, or nonsynonymous, codon change is quite common in North America, with up to 45% of the Caucasian population being heterozygous (carrying one T allele and one C allele), and 10%–15% being homozygous for the T allele. When a particular mutation occurs relatively frequently ($>1\%$ of the alleles in a population), it is called a *polymorphism*. Because this genetic change involves only a single nucleotide, it is called a single nucleotide polymorphism, or SNP. Patients who are homozygous for this C \rightarrow T polymorphism in MTHFR exhibit mild homocysteinemia, but only if they also have low folate and riboflavin nutritional status. Heterozygotes generally have normal plasma homocysteine levels.

Biochemical analysis of the valine variant of the enzyme (product of the T allele) has provided a molecular explanation for the clinical findings. Compared to the normal alanine-containing enzyme (product of the C allele), the valine variant is *thermolabile*—it is completely inactivated at 46 $^{\circ}\text{C}$, and is less stable than the Ala enzyme even at 37 $^{\circ}\text{C}$. Lymphocytes taken from TT homozygotes have only $\sim 50\%$ of the MTHFR enzymatic activity of CC homozygotes in in vitro assays. How does this single amino acid substitution cause this thermolability? There is no crystal structure of a mammalian MTHFR yet, but structural studies of the *E. coli* homolog have shed much light on the problem. As mentioned above, bacterial MTHFRs lack the regulatory domain of the eukaryotic enzymes, but they are homologous to the catalytic domains. The *E. coli* enzyme is a homotetramer of 296 amino acid subunits. Each subunit is a classic $\beta_8\alpha_8$ barrel structure with the flavin cofactor (FAD) bound at the C-termini of the β -strands (Figure 21.11). Like the eukaryotic valine variant, the corresponding *E. coli* valine variant exhibits thermolability (Figure 21.12a). Kinetic studies of the Ala and Val versions of the *E. coli*

FIGURE 21.10

DNA sequencing reveals a common polymorphism in human methylenetetrahydrofolate reductase (MTHFR). The DNA sequence was obtained from the anti-sense strands of the MTHFR gene from two individuals, one carrying the C allele (left) and the other the T allele (right). The corresponding sense strands would encode a GCC codon (Ala) or GTC codon (Val), respectively.

FIGURE 21.11

E. coli MTHFR complexed with ligands. This figure shows the X-ray crystal structure of the bacterial enzyme with bound FAD (green) (PDB ID 1B5T). The left panel shows a view down the axis of the $\beta_8\alpha_8$ barrel looking toward the C-terminal ends of the β strands (yellow). The right panel is a view perpendicular to the barrel axis. Alanine-177, shown in space-filling mode (red), is located at the N-terminal ends of the barrel. Substitution of this residue with a bulky valine perturbs packing of the adjacent α helix (cyan) that projects toward the FAD binding site.

FIGURE 21.12

Biochemical analysis of Ala177Val mutant of *E. coli* MTHFR. (a) Differential-scanning calorimetry (see Tools of Biochemistry 6C) reveals the thermolability of the valine variant (A177V) as compared to the wild-type (wt) Ala177 enzyme. The melting temperatures (T_m) decrease for both enzymes as the protein concentrations decrease. (b) FAD dissociation was followed by observing the increase in flavin fluorescence (inset) over time after concentrated enzyme was diluted to the concentrations indicated on the x-axis. The Val177 enzyme loses FAD ~10 times faster than the Ala177 enzyme. (c) Folate cofactor (5-methyl-THF) protects both wild-type and mutant enzymes against FAD loss in a concentration-dependent fashion.

Courtesy of Rowena Matthews, University of Michigan.

Homocysteinemia can result from genetic defects in cystathionine β -synthase, methionine synthase, or 5,10-methylenetetrahydrofolate reductase, as well as from dietary deficiency of folic acid, vitamin B₆, or vitamin B₁₂.

enzyme revealed that the valine substitution did not affect K_M or k_{cat} values. Rather, the valine substitution greatly increases the propensity of the enzyme to lose its FAD cofactor (Figure 21.12b). Dissociation of the flavin cofactor decreases the thermal stability of the enzyme. Importantly, the folate substrate protects the enzyme against flavin loss (Figure 21.12c) and against thermal inactivation. In the *E. coli* enzyme, Ala177 (equivalent to Ala222 of human enzyme) is located at bottom of the β barrel, ~15 Å away from the catalytic site (Figure 21.11). Despite this distance, substitution of the larger valine residue disrupts the packing of an α helix that contributes to the FAD binding site. Propagation of this structural change through the protein decreases the binding affinity of the FAD cofactor compared to the normal alanine enzyme. Bound folate cofactor slows the loss of FAD. Thus, the biochemical properties of the enzyme predict the clinical phenotype: As long as cellular folate levels are adequate, TT homozygotes expressing the Val variant retain sufficient MTHFR activity. If their folate intake falls below a certain threshold level, however, MTHFR is no longer saturated with folate cofactor. FAD dissociation accelerates, leading to thermolability, decreased MTHFR activity, and decreased production of the 5-methyl-THF needed to remethylate homocysteine. This is a beautiful example of how structural and biochemical studies can lead to a better understanding of the molecular bases of inherited metabolic diseases.

From Figure 21.9, you can see how a deficiency in either cystathionine β -synthase, methionine synthase, or 5,10-methylenetetrahydrofolate reductase would cause homocysteine accumulation. In addition to these genetic causes, dietary deficiency of folic acid, vitamin B₆, or vitamin B₁₂ can also lead to homocysteinemia.

Whereas the one-carbon and methyl cycles shown in Figure 21.9 are found in virtually all cells, liver and kidney possess an additional route for methionine synthesis that involves a different kind of transmethylation. Homocysteine can be remethylated using **betaine** as the methyl donor in a reaction catalyzed by the cytosolic betaine-homocysteine methyltransferase. Betaine, also known as trimethylglycine, is formed from the mitochondrial oxidation of choline.

The betaine, which is a quaternary amine derivative of an amino acid, has a positive charge and a high group transfer potential, as does AdoMet itself. Because the methyl groups on betaine came originally from AdoMet during phosphatidyl choline synthesis (Chapter 19, page 784), the existence of this transmethylation process is consistent with the statement that all methyl groups come from methionine except those used in the synthesis of methionine.

Betaine synthesis is especially important in plants, where it accumulates to protect against the osmotic stresses of drought or high salinity. Betaine is one of several plant **osmoprotectants**, small, electrically neutral, nontoxic molecules that can stabilize proteins and membranes against denaturation by high salts and other solutes. The demand for methyl groups for betaine synthesis (via choline) often dwarfs that for all other methyl transfers in a stressed plant.

Methionine is also the source of dimethylsulfoniopropionate (DMSP), an osmoprotectant produced by many marine algae, coral-associated bacteria, and other phytoplankton. As shown in Figure 21.13, methionine is first transaminated and reduced. A second methyl group is donated by AdoMet, followed by an oxidative decarboxylation to give DMSP. This compound is catabolized by two

**FIGURE 21.13****Environmental significance of dimethyl sulfide metabolism.**

competing pathways in marine bacteria. One pathway leads to methanethiol (CH_3SH) and acetic acid. In the pathway shown in Figure 21.13, DMSP is hydrolyzed to dimethyl sulfide (DMS) and acrylic acid. DMS is the principal volatile form of sulfur in the oceans, contributing approximately 1.5×10^{13} g of S to the atmosphere annually. The release of DMS to the atmosphere is probably responsible for the distinctive, and misnamed, “salt-air fragrance” that we associate with the sea. This smell attracts sea birds, who recognize it as an indicator of biological productivity in the ocean. Also, DMS in the atmosphere undergoes photooxidation to methyl sulfate (MSA), which serves as nucleation sites for the formation of clouds. DMS is also easily oxidized to dimethylsulfoxide (DMSO),

but marine organisms possess an enzyme, **dimethylsulfoxide reductase**, that catalyzes the regeneration of DMS. DMSO reductase uses the same molybdopterin cofactor described in Chapter 20 (page 825). Thus, DMSO and DMS play an important role in controlling climate, contributing toward modulating the earth's temperature. A variation on this pathway is also used to produce sulfur-containing compounds in the fruiting bodies of some fungi. These volatile compounds, including DMS and H₂S, are important components of the aroma of truffles.

S-Adenosylmethionine plays an additional role in plant metabolism, as the precursor to the hydrocarbon hormone **ethylene**. Ethylene promotes plant growth and development and induces the ripening of fruit. Although mechanistic details are not yet clear, we know that the main carbon skeleton of methionine, rather than the methyl group, is split off in this process, to yield **1-aminocyclopropane-1-carboxylic acid**. This unusual reaction is based on the same chemistry that makes AdoMet such a good methyl donor: the positively charged sulfonium makes all three adjacent carbon centers strongly electrophilic and easily transferred, including the methythioadenosine moiety, as in this case. The cyclopropane, representing carbons 1–4 of methionine, is fragmented as shown, to yield ethylene, CO₂, and cyanide.

Isotope labeling studies with methionine fed to plants have revealed the source of each carbon atom.

AdoMet is also used in the biosynthesis of cyclopropane fatty acids, such as lactobacillic acid, that occur in the phospholipids of many bacteria. These unusual fatty acids are formed by the addition of a methylene group, derived from the methyl group of AdoMet, across the carbon–carbon double bond of unsaturated fatty acids.

S-Adenosylmethionine and Polyamines

The synthesis of ethylene involves transfer, not of the methyl group but of the four-carbon moiety of AdoMet-bound methionine. A comparable process occurs during synthesis of the widely distributed polyamines **spermine** and **spermidine** (Figure 21.14). The names of these substances suggest the source of their original detection—human semen. These polyamines are widely distributed cationic cell components, being especially abundant in rapidly proliferating cells. Ornithine undergoes decarboxylation to give 1,4-diaminobutane, which has the trivial name **putrescine** because of its original isolation from rotting meat. Although putrescine and its homolog **cadaverine** are classified among the polyamines, they are in fact diamines; they are synthesized by decarboxylation of ornithine and lysine, respectively. Ornithine, in turn, is synthesized from glutamate in the same pathway that leads eventually to arginine and proline (see Figure 21.31). **Ornithine decarboxylase** is a highly regulated enzyme whose activity responds to many hormonal stimuli. It has an extremely short metabolic half-life (approximately 10 minutes), and its intracellular activity is controlled largely at the level of protein degradation.

As polycations, the polyamines play multiple roles in stabilizing conformations of negatively charged nucleic acids. A polyamine molecule can bind to phosphates on both strands of a duplex, thereby stabilizing double-stranded DNA or a duplex region of RNA. In bacteriophage T4, for instance, about 40% of the negative charge on the viral DNA is neutralized by polyamines. Transfer RNA from some sources

Polyamines are required for cell proliferation because of their roles in stabilizing duplex DNA structures.

FIGURE 21.14

Biosynthesis of putrescine, spermidine, and spermine.

contains two molecules of tightly bound spermine or spermidine per molecule of transfer RNA. Some proteins contain covalently bound polyamines, with the nitrogens linked to glutamate γ -carboxyl groups. In bacterial cells, polyamines also participate in regulating internal osmotic strength and they help to stabilize membranes. In animal cells, polyamines are involved in control of the electrical properties of excitable membranes. Also, polyamine biosynthesis is closely related to the proliferative state of the cell; when nucleic acid synthesis is activated, so is polyamine synthesis. Consequently, investigators are asking whether activation of polyamine synthesis early in tumorigenesis could be a marker for early cancer diagnosis or a target for cancer treatment. Consistent with the latter, the antiparasitic drug **difluoromethylornithine (DFMO)** arrests progression through the cell division cycle (see Chapter 28) by inhibiting ornithine decarboxylase, suggesting a role for polyamines in cell cycle regulation.

Putrescine serves as the precursor to spermidine, then to spermine, through the AdoMet-mediated transfer of active propylamino groups (Figure 21.14). First, AdoMet is decarboxylated by **AdoMet decarboxylase**. This enzyme is an example of a decarboxylase that contains as its cofactor not pyridoxal phosphate but covalently bound pyruvate (see page 848). The resulting propylamino group is then transferred to putrescine to give spermidine, and a second group is transferred to spermidine, catalyzed by spermine synthase, to give spermine. The other product of these reactions is 5'-methylthioadenosine, which undergoes phosphorolytic

Difluoromethylornithine

Glutamate

 γ -Aminobutyric acid

cleavage to adenine and **5-methylthioribose-1-phosphate**. The latter compound is used for resynthesis of methionine by another pathway, not shown here.

Spermine is clearly required for normal development in mammals. In humans, the rare X-linked Snyder-Robinson syndrome is caused by mutation of the gene encoding spermine synthase. This syndrome is characterized by mental retardation, skeletal defects, osteoporosis, and facial asymmetry.

Other Precursor Functions of Glutamate

γ -Aminobutyric Acid

In addition to serving as a precursor for ornithine and the polyamines, glutamate is one of several amino acids serving as precursors to compounds that function in transmission of nerve impulses. Decarboxylation of glutamate yields **γ -aminobutyric acid**, or **GABA**. In addition, glutamate itself is a neurotransmitter. Functions of both glutamate and GABA in neurotransmission will be discussed later in this chapter.

Glutathione

Another major and ubiquitous metabolic fate of glutamate is the synthesis of **glutathione (GSH)**, or γ -glutamylcysteinylglycine. This tripeptide is synthesized by linking glutamate, cysteine, and glycine through amide bonds, but glutamate is linked via its γ -carboxyl rather than its α -carboxyl. GSH synthesis occurs as part of the **γ -glutamyl cycle**, which functions to transport amino acids into the cell (Figure 21.15). Amide bond formation is driven by ATP hydrolysis; each carboxyl group is activated for nucleophilic substitution by formation of an acyl phosphate intermediate (see margin, page 883). After its synthesis inside the cell, GSH is transported across the plasma membrane where it is hydrolyzed and its γ -glutamyl moiety is transferred to an extracellular amino acid (usually cysteine or methionine), forming a γ -glutamyl-amino acid conjugate. This reaction is catalyzed by **γ -glutamyl transpeptidase**, a plasma membrane protein whose active site faces the extracellular space. ATP is not required to drive this reaction because it involves the exchange of one amide bond for another. The γ -glutamyl-amino

Glutathione and the γ -glutamyl cycle. The enzymes involved are ① γ -glutamylcysteine synthase, ② glutathione synthase, ③ γ -glutamyl transpeptidase, ④ γ -glutamyl cyclotransferase, ⑤ 5-oxoprolinase, ⑥ dipeptidase.

FIGURE 21.16

Biosynthesis of nitric oxide and creatine phosphate from arginine. In NO synthesis, the N^{ω} -hydroxy-L-arginine intermediate remains tightly bound to NO synthase (NOS).

NO synthase (NOS), which catalyzes a two-step NADPH-dependent oxidation of arginine by O_2 , contains bound FMN, FAD, heme iron, and tetrahydrobiopterin, the same cofactor involved in the synthesis of tyrosine from phenylalanine (Figure 21.7). The physiological role and mechanism of action of this gaseous signaling molecule is described in Chapters 7 and 23.

Arginine is also the precursor to the energy storage compound creatine phosphate (see Chapter 3, page 76). The guanidino group is transferred to glycine, releasing the rest of the arginine molecule as ornithine (Figure 21.16). Arginine can be regenerated from ornithine via the urea cycle (see Figure 20.12, page 842). The other product of the amidinotransferase reaction, **guanidinoacetic acid**, is methylated by *S*-adenosylmethionine to give creatine, followed by phosphorylation of the latter to creatine phosphate, catalyzed by creatine kinase. The amidinotransferase reaction is the rate-limiting step for creatine synthesis; its expression is repressed by creatine. Based on the tissue distribution of the enzymes involved, creatine biosynthesis appears to be an interorgan process in mammals. Guanidinoacetate is produced by the kidney and transported to the liver for methylation to creatine. Because creatine kinase is very low in liver, creatine is released into the bloodstream. Tissues with high energy demand, such as muscle and brain, take up creatine from blood and phosphorylate it to creatine phosphate.

Both creatine and creatine phosphate spontaneously cyclize to creatinine (Figure 21.16), which is excreted in the urine (1–2 gm per day in a normal adult). A typical western diet can supply about half of this lost creatine; the other half is from endogenous biosynthesis, and it has been estimated that adult humans synthesize ~4–8 mmol creatine per day. Indeed, the methylation of guanidinoacetic acid to creatine consumes more AdoMet than all other methylation reactions combined.

Tyrosine Utilization in Animals

Tyrosine plays several important roles in animal metabolism—as precursor to thyroid hormones, the biological pigments called **melanins**, and the *catecholamines*, which serve both as hormones and as neurotransmitters (discussed later in this chapter).

Thyroid Hormones

Thyroid hormones stimulate a number of metabolic processes, through activation of the transcription of particular genes (see Chapter 23). The synthesis of thyroid hormones, principally **thyroxine** (T_4) and **triiodothyronine** (T_3), occurs by an unusual pathway, at the level of tyrosine residues in a specific protein, **thyroglobulin**. This process occurs in the thyroid gland, which concentrates iodide ion from the blood serum for this purpose. Thyroglobulin is a large (2750 amino acids per monomer in humans) homodimeric glycoprotein synthesized by follicle cells of the thyroid gland and secreted into the follicular lumen. As many as 20% of the 140 tyrosine residues in thyroglobulin are iodinated in a reaction catalyzed by thyroperoxidase. In this H_2O_2 -requiring reaction, iodide (I^-) is oxidized and covalently bound to tyrosyl side chains of thyroglobulin, forming mono- and di-iodotyrosyl residues. As shown in Figure 21.17, two iodinated tyrosine residues on the same polypeptide chain are oxidatively coupled (also catalyzed by thyroperoxidase) to give a residue of T_3 or T_4 . Iodinated thyroglobulin is pinocytosed back into the follicle cell, where upon hormonal stimulation, it undergoes degradation to yield the free hormones, which are transported to their sites of action through the bloodstream. One result of iodine deficiency is **goiter**, a condition in which the thyroid gland grows abnormally large as it attempts to scavenge all available iodine. Before iodized salt came into widespread use, goiter was endemic in regions whose soil was deficient in iodine.

Melanins

The synthesis of melanins (Figure 21.18) occurs in pigment-producing cells, the **melanocytes**. Melanocytes in mammals and birds produce two chemically distinct types of melanin, **eumelanin** and **pheomelanin**. The biochemical machinery for melanin synthesis is contained within membrane-bound organelles

FIGURE 21.17

Biosynthesis of thyroid hormones as residues in the protein thyroglobulin. The iodinated forms of tyrosine—triiodothyronine (T_3) and thyroxine (T_4)—are released from these proteins by proteolytic degradation.

FIGURE 21.18

Biosynthetic pathways from tyrosine to melanins. Only a few steps are enzyme-catalyzed; most are spontaneous. Several steps involve a dopaquinone-dependent redox exchange; the dopa formed can be recycled to dopaquinone (DQ) via tyrosinase. The structures of eumelanin and pheomelanin are general ones; the arrows indicate sites for attachment to other units.

Photochemistry and Photobiology 84:582–592, S. Ito and K. Wakamatsu, Chemistry of mixed melanogenesis—pivotal roles of dopaquinone. © 2008 John Wiley & Sons, Inc. Modified with permission from John Wiley & Sons, Inc.

called melanosomes, to protect the cell against potentially toxic intermediates. Three major pigment enzymes are bound to the inner face of melanosome membranes: tyrosinase, tyrosinase-related protein-1 (TRP-1), and dopachrome tautomerase, also known as tyrosinase related protein-2 (TRP-2). The rate-limiting step is the first one, catalyzed by tyrosinase, a copper-containing oxygenase. It had been initially believed that **3,4-dihydroxyphenylalanine** (usually called **Dopa**) is formed first on the way to dopaquinone. Later work showed that dopaquinone is formed directly in the tyrosinase reaction. Dopaquinone (DQ) is highly reactive, and some of the subsequent reactions occur spontaneously. In the absence of sulfhydryl compounds, dopaquinone undergoes intramolecular addition of the amino group to produce cyclodopa. A nonenzymatic redox exchange between cyclodopa and dopaquinone then gives rise to dopachrome and dopa. Dopachrome then gradually rearranges to dihydroxyindoles, which are further oxidized and polymerized to produce the blackish-brown eumelanins.

In another branch of the pathway, dopaquinone reacts with cysteine en route to a related series of polymers, the yellowish- or reddish-brown pheomelanins. An individual's pigmentation is determined by the relative amounts of red and black melanins in the skin. These in turn result from the distribution and density of melanocytes in the basal layers of the skin, as well as the activities of the pathways leading to the different melanins. A genetic deficiency of tyrosinase causes an individual to lack pigmentation, a condition called **albinism**. The albino (white) mice and rats commonly used in research have an inherited defect in tyrosinase.

Humans exhibit a tremendous degree of variation in skin and hair color. Variations in skin color are adaptive, and are related to the amount of ultraviolet (UV) radiation that penetrates the skin. For the earliest *Homo sapiens* living in the equatorial tropics, dark skin provided protection against skin cancer. However, as early humans migrated out of Africa into more northern latitudes, skin pigmentation interfered with their ability to synthesize adequate levels of vitamin D, leading to rickets (Chapter 19). Lighter skinned variants would have had better reproductive success, and thus light skin became the predominant phenotype in these more northern populations. In addition to tyrosinase, polymorphisms in more than a dozen genes are now known to impact skin, hair, or eye color. One of the most prominent of these is the SLC24A5 gene, which encodes a potassium-dependent sodium–calcium ion exchanger. This protein is fully functional in African humans and most other vertebrates. However, virtually all lighter-skinned humans of European ancestry possess a nonsynonymous single nucleotide polymorphism (SNP) in the SLC24A5 gene that results in replacement of Ala with Thr at position 111 in the protein. Although the biochemical mechanism is not yet understood, this polymorphism impairs the sodium–calcium ion exchange activity of the protein, causing a significant reduction in melanin pigment production, and hence, lighter skin color.

Aromatic Amino Acid Utilization in Plants

Phenylalanine and tyrosine serve as precursors to an enormous number of plant substances, ranging from the polymeric lignin to tannins, pigments, and many of the flavor components of spices. In fact, the role of these amino acids as precursors to such substances in cinnamon oil, wintergreen oil, bitter almond, nutmeg, cayenne pepper, vanilla bean, clove, and ginger is related to their designation as *aromatic* amino acids. These are derived from coniferyl alcohol, which is also the central intermediate in lignin synthesis. *L*-Tyrosine is the starting point for the synthesis of opiates such as codeine and morphine in the poppy plant.

Coniferyl alcohol

Codeine

Morphine

A flavonoid

Phenylalanine serves as the precursor to a large number of plant pigments and related polyphenolic compounds called **flavonoids**. These include many flower colorants, which serve in part as ultraviolet protectants, and also the respiratory inhibitor rotenone (see page 634). In the generic structure shown in the margin, the aromatic ring on the right comes from phenylalanine via the scheme shown below, and the ring to the left comes from malonyl-CoA, in a process akin to fatty acid and polyketide synthesis (Chapter 17). The substituent groups (R) are combinations of —H, —OH, and —OCH₃.

The same biosynthetic scheme also leads to a class of flavonoids called **anthocyanins**, which are common flower pigments. Substituents on the rings determine specific color, as shown. An offshoot from this pathway leads to synthesis of cocaine.

If R and R' are both H, color is orange-red
 If R is H and R' is OH, color is crimson-purple
 If R and R' are both OH, color is blue

Coniferyl alcohol is the precursor to the complex and nearly inert **lignins**, a major constituent of woody tissue. Much of the effort in creating paper and textiles from wood involves degrading lignin to gain access to the cellulose fibers contained in woody tissues. An intriguing use of biotechnology involves the substitution of living organisms for the chemical pulping processes used to break down lignin, which release large quantities of sulfites to the environment. In these “biopulping” applications, fungi that produce lignin-degrading enzymes are being developed for production of cellulose without the accumulation of chemical pollutants.

Tryptophan is utilized for synthesis of a plant growth hormone. As shown here, the transamination product of tryptophan is decarboxylated to yield **indole-3-acetic acid**, or **auxin**.

Porphyrin and Heme Metabolism

Biosynthesis of Tetrapyrroles: The Succinate–Glycine Pathway

A major metabolic fate of glycine is its utilization for tetrapyrrole biosynthesis. *Tetrapyrrole* is a generic term for compounds containing four linked pyrrole rings. Four such classes of compounds are widespread in biology: the widely distributed iron *porphyrin* heme; the *chlorophylls* of plants and photosynthetic bacteria; the **phycobilins**, photosynthetic pigments of algae (Chapter 16); and the *cobalamins*, notably vitamin B₁₂ and its derivatives (Chapter 20). Structures of most of these compounds have been shown previously. All tetrapyrroles are synthesized from a common precursor, **δ-aminolevulinic acid (ALA)** (also called 5-aminolevulinic acid). Figure 21.19 illustrates the relationships among the various synthetic pathways.

We shall concentrate here on the well-understood porphyrin synthetic pathway, which leads to heme. This pathway is widespread in animal tissues and, so far as is known, is similar in all organisms containing heme proteins, such as cytochromes. Eight reactions are involved, and they occur in two different cell compartments (Figure 21.20). The first reaction occurs in mitochondria, followed by four reactions in the cytosol, and finally, three more mitochondrial reactions. As we shall see, this compartmentation provides the opportunity for a novel control mechanism for the pathway.

Early labeling studies in animals revealed that *all of the nitrogen of heme is derived from glycine, and all of the carbon is derived from succinate and glycine*. Hence, this synthesis is often called the **succinate–glycine pathway**. The first reaction is catalyzed by a pyridoxal phosphate–dependent enzyme, **δ-aminolevulinic acid synthase**, or ALA synthase. As shown in Figure 21.21, the binding of glycine to PLP (steps 1, 2) activates the α-carbon of glycine for an attack on the thioester carbon of succinyl-CoA (step 3). Elimination of CoASH (step 4) and decarboxylation (step 5) follow, to give the product ALA.

In most bacteria, archaea, and plants, ALA is formed by a completely different pathway, a three-step sequence beginning with glutamate (Figure 21.22). The first

δ-Aminolevulinic acid synthase brings together succinyl-CoA and glycine, which furnish all of the carbon and nitrogen in porphyrins, cobalamins, phycobilins, and chlorophylls.

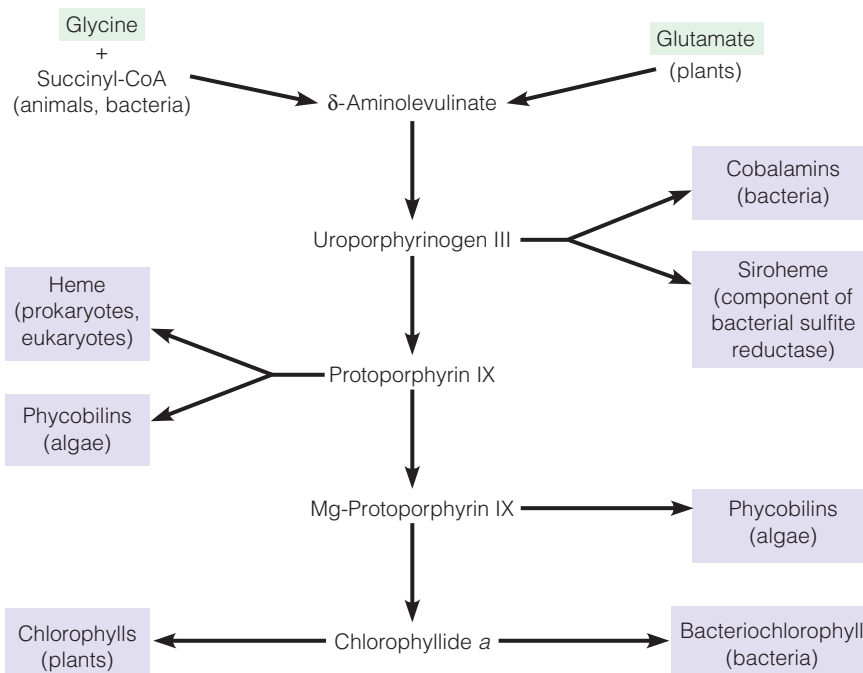

FIGURE 21.19

Biosynthetic pathways to tetrapyrroles. Tetrapyrroles include heme, chlorophylls, phycobilins, and cobalamins. All are synthesized from δ-aminolevulinic acid, which is formed differently in plants from the way it is formed in bacterial and animal cells.

FIGURE 21.21

The δ -aminolevulinic acid synthase reaction. The enzyme-bound pyridoxal phosphate (PLP) cofactor is shown in black. Like other PLP-requiring enzymes, the mechanism involves formation of a Schiff base between the amino acid and PLP, and a stabilized carbanion intermediate (compare with Figure 20.14, page 847).

FIGURE 21.22
Synthesis of δ -aminolevulinic acid in most bacteria, archaea, and plants.

Pyridoxamine phosphate (PMP)

reaction of this novel pathway links glutamate, through its carboxyl group, to a specific transfer RNA, just as occurs in protein synthesis. The carboxyl group thus activated is then reduced by NADPH, giving glutamate 1-semialdehyde, which finally undergoes rearrangement to give ALA. The last enzyme, glutamate 1-semialdehyde aminomutase, catalyzes a PLP-dependent *internal* transamination. The proposed mechanism requires the PLP cofactor to be already aminated, as pyridoxamine 5'-phosphate (PMP). This amino group is transferred to the carbonyl carbon of glutamate 1-semialdehyde to give the intermediate 4,5-diaminovalerate and PLP. The C4 amino group is then transferred to PLP to yield ALA and regenerate PMP on the enzyme.

Despite using different substrates, glutamate 1-semialdehyde aminomutase is mechanistically and structurally related to the animal ALA synthase.

Because the major end product of the pathway in plants is chlorophyll, the synthesis of ALA is regulated by light. The identity of the specific light-regulated steps is now under active investigation.

Whether in plants, animals, or microorganisms, the remainder of the porphyrin synthetic pathway (Figure 21.20) involves three distinct processes: (1) synthesis of a substituted pyrrole compound, **porphobilinogen** from ALA; (2) condensation of four porphobilinogen molecules to yield a partly reduced precursor called a **porphyrinogen**; and (3) modification of the side chains, dehydrogenation of the ring system, and introduction of iron, to give the porphyrin product, heme. In the first stage, two molecules of ALA condense in the cytosol to form one molecule of porphobilinogen. The reaction is catalyzed by **ALA dehydratase**:

Next, a PLP-requiring deaminase catalyzes the stepwise condensation of four molecules of porphobilinogen to give a linear tetrapyrrole, hydroxymethylbilane. **Uroporphyrinogen III synthase** then catalyzes an intramolecular rearrangement and ring closure to form the asymmetric **uroporphyrinogen III** (Figure 21.20; asymmetry refers to the arrangement of the acetate and propionate side chain substituents). In the absence of uroporphyrinogen III synthase, hydroxymethylbilane rapidly cyclizes nonenzymatically to the symmetrical **uroporphyrinogen I**. The symmetric compound and some metabolites derived from it are produced as nonfunctional side products, in low amounts.

Uroporphyrinogen III undergoes decarboxylation of its acetic acid side chains. The product then reenters the mitochondrion for further modifications: first, side chain modifications, then ring oxidation to yield a fully conjugated system, and finally the insertion of iron. The last reaction can proceed spontaneously,

Porphyrin biosynthesis involves (1) formation of a pyrrole ring; (2) condensation of four pyrrole moieties, giving a cyclic tetrapyrrole; and (3) side chain modifications and ring oxidations.

but it is catalyzed by **ferrochelatase**, an enzyme on the inner mitochondrial membrane that also requires a reducing agent. At this stage the completed heme is transported out of the mitochondrion for insertion into polypeptides to give completed heme proteins, including myoglobin and hemoglobin in vertebrates, and cytochromes and other heme proteins in all aerobic organisms.

In a rare hereditary condition called **congenital erythropoietic porphyria**, uroporphyrinogen III synthase is defective, and the symmetrical (and metabolically useless) type I porphyrins accumulate beyond the capacity of the body to excrete them. Their accumulation causes the urine to turn red, the skin to become acutely photosensitive, and the teeth to become fluorescent, all because of the deposition of the strongly light-absorbing porphyrins. In addition, erythrocytes are destroyed prematurely and insufficient heme is synthesized, making afflicted individuals quite anemic. It has been speculated that people labeled as vampires in medieval folktales suffered from this condition, which would explain their preference for the dark, their bizarre appearance, and their propensity for drinking blood. In fact, individuals with congenital erythropoietic porphyria can be treated by injections of heme.

Quite distinct from the above condition is **acute intermittent porphyria**, which results from deficiency in porphobilinogen deaminase. This deficiency causes ALA and porphobilinogen to accumulate in the liver. The condition is accompanied by episodes of acute abdominal pain and neurological disorders. It has been suggested that King George III of England suffered from this condition; evidence for this was put before the general public in the successful stage play and film *The Madness of King George*. Symptoms of porphyrias can also be acquired, most notably in lead poisoning. The crystal structure of ALA dehydratase shows that lead can displace zinc, the natural metal cofactor, and inhibit the enzyme, causing great accumulation of ALA.

Being the first committed step in heme synthesis, the ALA synthetase reaction (Figure 21.20) is the major control point. Heme and related compounds feedback-inhibit the enzyme. Heme also has two other important effects. At low concentrations, heme inhibits the *synthesis* of ALA synthetase at both transcriptional and translational levels. At higher levels, heme somehow blocks the *translocation* of ALA synthetase from the cytosol, where it is synthesized on ribosomes, into the mitochondrion, where it acts. Heme also inhibits the ferrochelatase reaction (Figure 21.20). A number of drugs and poisons cause excessive heme synthesis. In some cases, this effect results from stimulation of the synthesis of several cytochromes P450, which increases the demand for heme and hence activates ALA synthetase.

Tetrapyrrole biosynthesis is being exploited as a target for the action of weedkillers. The idea is to spray weeds in the dark with ALA. The pathway to chlorophyll begins, and when it becomes light, the pathway is completed, and chlorophyll is produced in such massive amounts that the plant weakens and dies.

Degradation of Heme in Animals

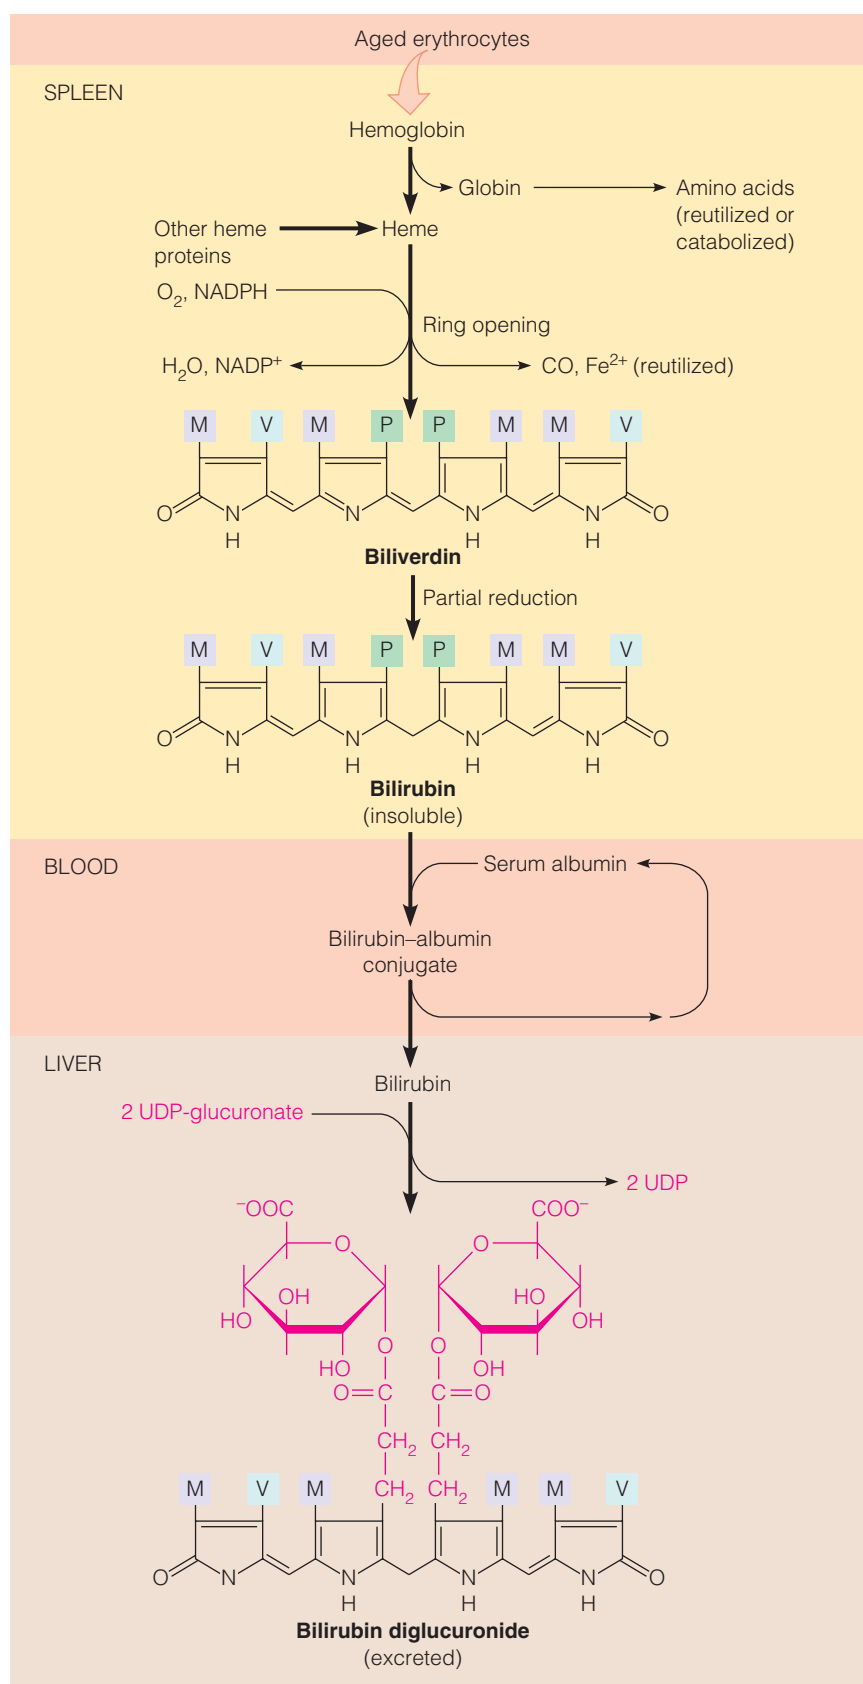

By far the most abundant porphyrin compound in vertebrates is the heme of hemoglobin. Therefore, the story of porphyrin degradation is largely the story of hemoglobin and heme degradation. Lacking nuclei, mammalian erythrocytes are incapable of renewal and self-destruct after characteristic intervals. In humans, the average erythrocyte life span is 120 days. Aged or damaged erythrocytes are destroyed upon passage through the spleen or liver (Figure 21.23).

Amino acids released from the globin portion of the hemoglobin molecule are catabolized or reused for protein synthesis. The heme portion undergoes degradation, starting with a mixed-function oxidase reaction that opens the ring and converts one of the methene bridge carbons to carbon monoxide. Iron is released from the resulting linear tetrapyrrole, called **biliverdin**, and is transported to storage pools in bone marrow for reuse in erythrocyte production. The tetrapyrrole is next reduced to **bilirubin**, which is excreted. Bilirubin is quite insoluble, and its

Porphyrias involve abnormal accumulations of heme precursors, either from overproduction of the unnatural type I porphyrins or from abnormally high flux through δ -ALA synthetase.

FIGURE 21.23

Catabolism of heme. Most of the heme comes from breakdown of aged erythrocytes, but some comes from cytochromes and other heme proteins. Letter abbreviations indicate side chains: P (propionic acid), $-\text{CH}_2-\text{CH}_2-\text{COO}^-$; A (acetic acid), $-\text{CH}_2-\text{COO}^-$; V (vinyl), $-\text{CH}=\text{CH}_2$; M (methyl), $-\text{CH}_3$.

removal involves several organ systems. First, it complexes with serum albumin for transport to the liver. There, bilirubin is solubilized by conjugation with two molecules of **glucuronic acid**. The reaction is comparable to other glycosyltransferase reactions we have encountered (see Chapter 9), with the substrate being **UDP-glucuronate**. This solubilized compound, **bilirubin diglucuronide**, is secreted into the bile and ultimately excreted via the intestine.

Because several organ systems participate in the degradation of heme, there are numerous ways for things to go wrong. When heme catabolism is defective, bilirubin accumulates in the blood. This defect is first recognized because the distinctive color of bilirubin gives a yellow cast to the skin and the whites of the eyes. This condition, known as **jaundice**, is seen, for example, in acute or chronic liver disease, in which the glucuronate conjugating system is impaired and albumin synthesis might be defective; in bile duct obstruction (e.g., gallstone), when bilirubin diglucuronide cannot be secreted into the intestine; in Rh incompatibility reactions of infants, in which erythrocytes are destroyed by the immune system faster than the heme can be catabolized; or in premature infants, when the bilirubin conjugating system is not fully developed. Jaundiced infants are often placed under intense fluorescent light, which rearranges the structure of circulating bilirubin to more soluble products.

Heme protein degradation in animals releases amino acids and iron, which are reused, and bilirubin, which must be solubilized for excretion.

Amino Acids and Their Metabolites as Neurotransmitters and Biological Regulators

Many amino acids and their metabolites participate in signal transduction processes—in hormonal control and in synaptic transmission of nervous impulses. As introduced in Chapter 10 and discussed further in Chapter 23, these two roles are comparable in that a low-molecular-weight substance released from one cell migrates to a target cell, where it interacts with specific receptors in the target cell membrane. The difference is that neurotransmission involves movement across a synapse, between two adjacent cells, whereas hormonal transmission occurs over a distance, with the hormonal messenger being transported through the bloodstream to the effector cell. The similarity of these two signal transduction processes is highlighted by the participation of compounds like epinephrine and histamine in both processes.

Among canonical amino acids that serve directly as neurotransmitters are glycine and glutamate. As noted earlier, GABA, the decarboxylation product of glutamate, is also a neurotransmitter. Several aromatic amino acid metabolites also function in neurotransmission. They include histamine, derived from histidine; **serotonin** (5-hydroxytryptamine), derived from tryptophan; and the **catecholamines**—epinephrine, **dopamine**, and **norepinephrine**—derived from tyrosine. We will describe the biosynthetic routes to these compounds here, and then we'll discuss their involvement in neurotransmission in Chapter 23.

Glutamate, tyrosine, glycine, and tryptophan serve as neurotransmitters or precursors to neurotransmitters.

Biosynthesis of Serotonin and Catecholamines

The pathway to serotonin begins with hydroxylation of tryptophan by a tetrahydrobiopterin-dependent aromatic amino acid hydroxylase, similar to phenylalanine hydroxylase (see Figure 21.7). This reaction is followed by a PLP-dependent decarboxylation to yield serotonin.

Tryptophan hydroxylase and tyrosine hydroxylase are both tetrahydrobiopterin-dependent monooxygenases and are mechanistically and structurally related to phenylalanine hydroxylase. The mechanism of all three members of the aromatic amino acid hydroxylase family involves an NIH shift, with migration of a hydride accompanying the hydroxylation.

Tyrosine is hydroxylated to L-dopa by two distinct mechanisms in the synthesis of catecholamines and melanins.

Decarboxylation reactions of tryptophan, L-dopa, and histidine lead to a series of potent biological regulators.

Serotonin plays multiple regulatory roles in the nervous system, including neurotransmission. It is produced in the pineal gland, where it serves as precursor to **melatonin** (*O*-methyl-*N*-acetylserotonin). The pineal is known to regulate light–dark cycles in animals, and the levels of serotonin and melatonin undergo cyclic variations in phase with these cycles. Thus, although the cycle-related actions of these compounds are not yet known, they point to serotonin and melatonin as regulators of sleep and wakefulness. Many long-distance airline passengers take melatonin pills to escape jet lag by resetting their biological clocks. Serotonin is also secreted by cells in the small intestine, where it regulates intestinal peristalsis. Finally, serotonin is a potent vasoconstrictor, which helps regulate blood pressure. Several antiobesity treatments act by increasing serotonin levels, thereby creating a sense of satiety, or well-being with regard to food.

As shown in Figure 21.24, the pathway to catecholamines is similar, starting with another tetrahydrobiopterin-dependent hydroxylation (of tyrosine) followed by a decarboxylation. Tyrosine hydroxylase catalyzes the rate-limiting step of catecholamine synthesis, and it is feedback inhibited by the end products of the pathway—dopamine, norepinephrine, and epinephrine. The tyrosine hydroxylation product is L-dopa, which is formed by a quite different mechanism in melanin synthesis (see Figure 21.18, page 886). However, the latter pathway is localized to melanocytes, whereas most catecholamine synthesis occurs in the adrenal medulla and in the central nervous system.

Once formed, L-dopa undergoes a PLP-dependent decarboxylation (by the same enzyme that decarboxylates 5-hydroxytryptophan) to give dopamine. Dopamine serves in turn as substrate for a copper-containing monooxygenase, **dopamine β -hydroxylase**, giving norepinephrine (noradrenaline), which in turn is methylated by *S*-adenosylmethionine to give epinephrine (adrenaline). Although dopamine and norepinephrine are intermediates in epinephrine synthesis, each is a neurotransmitter in its own right, as discussed in Chapter 23.

FIGURE 21.24

Biosynthesis of the catecholamines—dopamine, norepinephrine, and epinephrine—from tyrosine.

Amino Acid Biosynthesis

All amino acids can be synthesized from intermediates in glycolysis, the pentose phosphate pathway, or the citric acid cycle (Figure 21.25). About half are biosynthesized more or less directly from intermediates in the citric acid cycle or from pyruvate. We include in this family glutamate, aspartate, and alanine, which can be formed directly by transamination from α -ketoglutarate, oxaloacetate, and pyruvate, respectively. The family also includes glutamine and asparagine, which are formed directly from glutamate and aspartate, respectively; and proline and arginine, which are formed in short pathways from glutamate. Aspartate is also the starting point for threonine, methionine, and lysine. The carbon skeletons of serine, glycine, cysteine, and histidine, as well as the branched chain amino acids and the aromatic amino acids, are all derived from glycolytic intermediates.

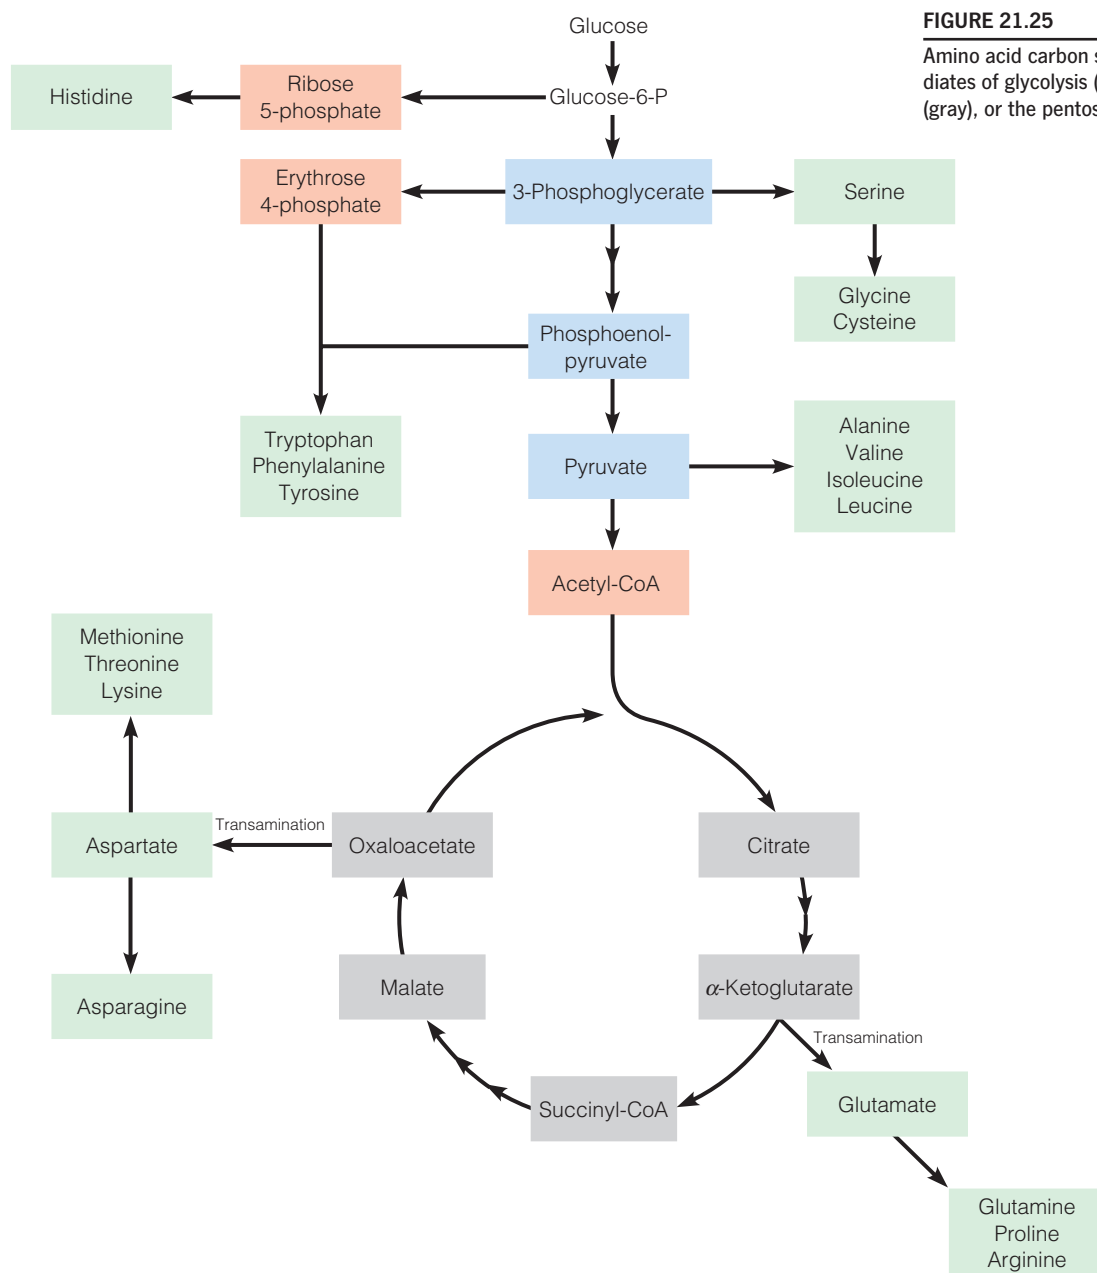

FIGURE 21.26

Synthesis of alanine, aspartate, glutamate, asparagine, and glutamine. ① asparagine synthetase, ② glutamine synthetase.

We will not cover all of the amino acid biosynthetic pathways in this final section of the chapter, but we will highlight the common pathways and those with particularly interesting chemistry.

Synthesis of Glutamate, Aspartate, Alanine, Glutamine, and Asparagine

PLP-dependent transamination provides the major route for the synthesis of glutamate, aspartate, and alanine, from α -ketoglutarate, oxaloacetate, and pyruvate, respectively (Figure 21.26). Reactions catalyzed by glutamate dehydrogenase and glutamate synthase, introduced in Chapter 20, present additional routes for glutamate synthesis from α -ketoglutarate. Asparagine is synthesized from aspartate in a reaction catalyzed by asparagine synthetase, a glutamine-dependent amidotransferase. Glutamine is synthesized from glutamate by a similar amidation reaction, except that ammonia provides the amide N. The γ -glutamyl phosphate intermediate in this glutamine synthetase reaction was described in Chapter 20 (page 828).

In animals, a major metabolic function of alanine is its role in the glucose-alanine cycle as a carrier of carbon for gluconeogenesis from muscle to liver (see Figure 20.13, page 845).

Synthesis of Methionine, Threonine, and Lysine from Aspartate

The nitrogen of aspartate is used in the biosynthesis of arginine and urea, as noted in Chapter 20. Similar reactions are involved in purine nucleotide synthesis, and the entire aspartate molecule is used in pyrimidine nucleotide biosynthesis; both of these processes are discussed in Chapter 22. However, in plants and bacteria, aspartate is a precursor to three other amino acids via its conversion to **aspartate β -semialdehyde** and **homoserine**, as shown here. Separate pathways

Aspartate leads via homoserine to threonine, lysine, and methionine.

then lead from aspartate β -semialdehyde to lysine and from homoserine to methionine and threonine.

The first enzyme in this pathway, **aspartokinase**, is a major site for regulation of each biosynthetic pathway. Bacteria contain three distinct forms of aspartokinase, each with its own mode of allosteric regulation. Two of the isoenzymes are bifunctional enzymes, containing distinct domains that catalyze the first step (aspartokinase) and the third step (**homoserine dehydrogenase**). In one of the bifunctional isozymes, both catalytic activities are subject to allosteric inhibition by threonine, which can be thought of as an end product of the pathway. The third isoenzyme, a monofunctional aspartokinase, is subject to feedback inhibition by lysine. These observations suggest that the different isozymes are specialized to serve just one of the three end products. Bacteria contain a separate monofunctional enzyme, **aspartate- β -semialdehyde dehydrogenase**, that catalyzes the intervening reductive dephosphorylation of aspartyl- β -phosphate.

Lysine biosynthesis is distinguished by the fact that there are two distinct pathways. The most widespread pathway, found in bacteria, some lower fungi, algae, and higher plants, begins with aspartate β -semialdehyde. This pathway is named after its principal intermediate, **diaminopimelate**, which also serves an important function as a constituent of bacterial cell walls. The less common pathway, found in certain fungi and yeast, and in the protist *Euglena*, begins with α -ketoglutarate and involves **α -aminoadipic acid** and **saccharopine** (see page 870) as intermediates.

Homoserine has an interesting role in microbial metabolism unrelated to its function in amino acid synthesis. Bacterial cultures carry out certain processes only after reaching a particular cell density. This cell-cell communication phenomenon is called **quorum-sensing**, in which bacteria produce and detect extracellular chemicals to monitor when a certain population-density threshold has been crossed. Quorum sensing allows the bacteria to synchronously control gene expression in response to changes in cell density, triggering physiological responses as diverse as bioluminescence, biofilm production, antibiotic synthesis, virulence factor secretion, and conjugal gene transfer. For many bacteria the signaling molecule, called an autoinducer, is one of several long-chain *N*-acyl derivatives of homoserine (see margin). *N*-Acylhomoserine lactone is synthesized and secreted at a low, constant rate, and it diffuses back into cells. At a sufficiently high cell density, the extracellular and, hence, the intracellular concentrations of the lactone have risen high enough for it to bind to genetic regulatory proteins, which in turn stimulate transcription of genes required to activate the particular process.

***N*-Acylhomoserine lactone**

Methionine and Threonine Biosynthesis

In plants and bacteria, homoserine provides the carbon skeleton for methionine synthesis, with the sulfur coming from cysteine (Figure 21.27). Homoserine first reacts with succinyl-CoA to form ***O*-succinylhomoserine**. This reaction evidently is a control point because the enzyme catalyzing this reaction is feedback inhibited by methionine. *O*-Succinylhomoserine reacts with cysteine to give **cystathionine**,

FIGURE 21.27

Biosynthesis of methionine and threonine from homoserine, as it occurs in plants and bacteria.

the same thioether compound we first saw in the methionine degradation pathway (Figure 21.4). Cleavage of cystathionine then occurs, with the sulfur becoming linked to the four-carbon side chain that started as homoserine. This is essentially the transsulfuration pathway running in the opposite direction from that in Figure 21.4. In this direction, the three-carbon pyruvate, rather than the four-carbon α -ketobutyrate, is the other product in this direction because a three-carbon donor (cysteine) was used to form cystathionine. The resulting sulfur-containing carbon skeleton, homocysteine, is the substrate for methionine synthase, which, as presented in Chapter 20, uses B₁₂ to transfer a methyl group from 5-methyltetrahydrofolate, yielding methionine (see Figure 21.9).

Threonine is an essential amino acid for animals because its biosynthesis is limited to plants and prokaryotes. Threonine synthesis also begins with homoserine, which undergoes a phosphorylation, followed by a pyridoxal phosphate–dependent reaction that eliminates phosphate and rehydrates the resultant double bond with hydroxyl group migration to the β -carbon (Figure 21.27).

Metabolism of Sulfur-Containing Amino Acids

Reduction of Inorganic Sulfur

As shown in Figure 21.27, the S of methionine is derived from cysteine. How does cysteine obtain its sulfur atom? Like carbon and nitrogen, sulfur is made available to organisms largely in the form of inorganic compounds—principally sulfate, although some bacteria can synthesize organic compounds from elemental sulfur or from sulfite. Just as CO₂ and N₂ must undergo fixation to be utilized, the utilization of sulfate requires metabolic activation to a form that can readily undergo reduction. The process for sulfate is largely confined to plants and bacteria. The end product of this eight-electron reduction is S²⁻ (sulfide), and this is used for cysteine and methionine synthesis. The activated sulfate compound is **3-phosphoadenosine-5-phosphosulfate (PAPS)**. This nucleotide is formed in two steps from ATP and sulfate ion.

PAPS is then reduced to sulfite and then sulfide by two NADPH-dependent reductases.

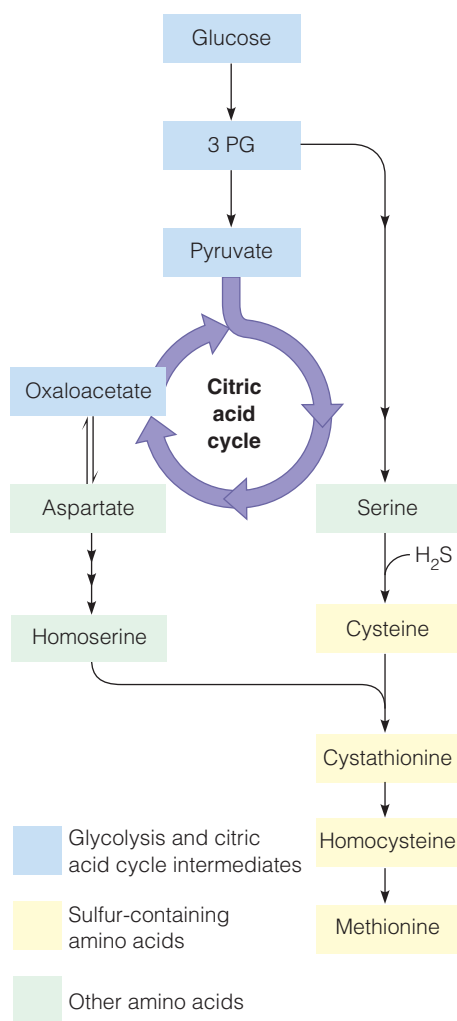

In all organisms, PAPS serves as an active agent for sulfate esterification, as in the synthesis of sulfated polysaccharides such as chondroitin sulfate (Chapter 9) and sulfated glycosphingolipids such as sulfogalactosylceramide (Chapter 19).

In bacteria, PAPS also serves as the substrate for sulfate reduction. Reduction of the sulfate in PAPS to sulfite (SO₃²⁻) involves **thioredoxin**, a small protein (M_r ≈ 12,000) that contains two reversibly oxidizable cysteine thiol groups. Thioredoxin is involved in several other intracellular redox reactions, as described in Chapters 16 and 22. The sulfite is subsequently reduced by **sulfite reductase**, a large and complex enzyme that catalyzes a six-electron transfer. The electrons are shuttled along a pathway involving NADPH, FAD, FMN, an iron–sulfur center, and the porphyrin siroheme (see page 826). No intermediates accumulate, just the product H₂S. In plants, adenosine 5-phosphosulfate, rather than PAPS, is the substrate for reduction.

Phosphoadenosine phosphosulfate (PAPS) is an activated form of sulfate used both for sulfation reactions and as a substrate for sulfate reduction.

**FIGURE 21.28**

Outline of pathways for cysteine and methionine synthesis in plants and bacteria.

Plants and bacteria synthesize cysteine from inorganic sulfur and synthesize methionine from cysteine. Animals synthesize cysteine from dietary methionine.

Synthesis of Cysteine in Plants and Bacteria

Bacteria and plants can synthesize cysteine by incorporation of H_2S , with serine providing the carbon skeleton (Figure 21.28). Animals, on the other hand, cannot directly incorporate sulfide, and so they derive cysteine either from the diet or from dietary methionine. Some bacteria can condense H_2S with serine directly, via a pyridoxal phosphate–dependent enzyme.

However, plants and most microorganisms use *O*-acetylserine as the substrate reacting with H_2S .

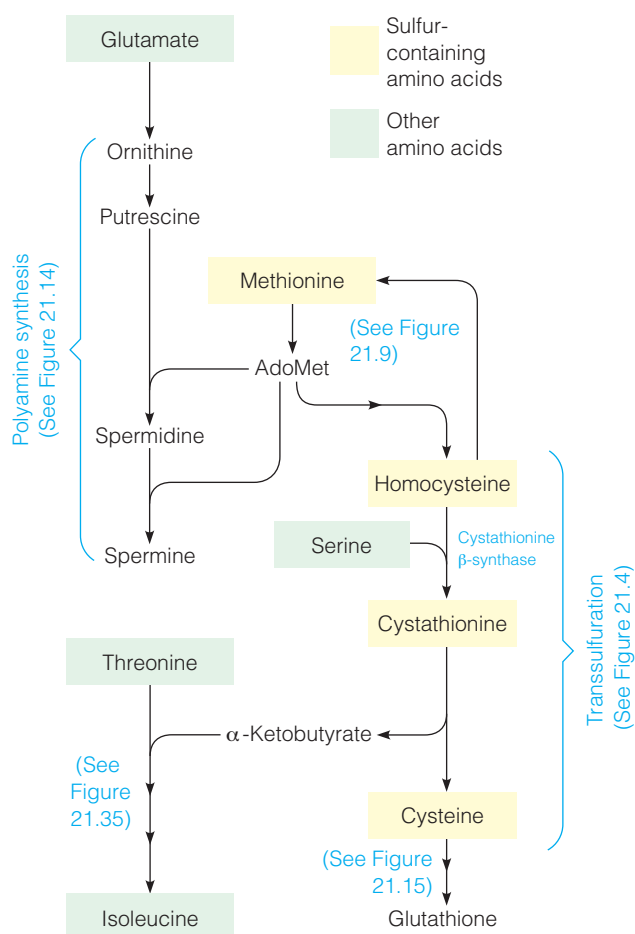

Methionine as the Source of Cysteine Sulfur in Animals

Methionine is classified as an essential amino acid for mammals, and cysteine is considered nonessential. Actually, the biosynthetic route in animals proceeds from methionine to cysteine, as summarized in Figure 21.29, so cysteine is nonessential only as long as the diet contains adequate methionine.

The synthesis of cysteine in animals resembles the reverse of the methionine biosynthetic pathway we just discussed, and which was described previously in the context of the pathway used to degrade methionine (refer to Figure 21.4). After methionine has donated its methyl group via *S*-adenosylmethionine (see Figure 21.9), the resulting homocysteine condenses with serine in the transsulfuration process to give cysteine. This two-step process results in the transfer of S from a four-carbon donor (homocysteine) to a three-carbon acceptor (serine), with the seven-carbon cystathionine as intermediate. The four-carbon skeleton of homocysteine is deaminated, forming α -ketobutyrate and ammonia. Plants and prokaryotes carry out the same pathway, with α -ketobutyrate used also for isoleucine biosynthesis.

Recall that homocysteine has two possible fates: remethylation or transsulfuration (Figure 21.9). As discussed previously (page 876), *S*-adenosylmethionine regulates these two fates by inhibiting remethylation at the methylenetetrahydrofolate reductase step and activating transsulfuration at the cystathionine β -synthase step. If the cell's methylation demands are being met, AdoMet levels will be high, and homocysteine will be directed down the transsulfuration pathway to cysteine (and glutathione) biosynthesis. Transsulfuration is also controlled by the cellular redox state: Oxidizing conditions increase flux from homocysteine to glutathione as a mechanism to protect the cell against oxidative stress. Cystathionine β -synthase is believed to sense the cellular redox state through its heme cofactor.

Note that cystathionine plays a central role both in the biosynthesis of methionine in plants and bacteria and in the biosynthesis of cysteine in animals. In methionine synthesis from cysteine (Figure 21.27), cystathionine cleavage accompanies the transfer of sulfur from a three-carbon to a four-carbon side chain. The converse occurs during the synthesis of cysteine from methionine (Figure 21.4).

Cysteine is also the precursor for a nonprotein amino acid, **taurine**, the most abundant free amino acid in animal tissues. The sulfhydryl of cysteine is oxidized to a sulfinate ($-\text{SO}_2^-$) and finally to a sulfonate ($-\text{SO}_3^-$) in taurine (Figure 21.30). This is an important pathway in liver, kidney, muscle, and brain, where taurine can reach an intracellular concentration of 25 mM. We do not know all the functions of taurine, but the main biological roles include the synthesis of the bile acid taurocholate (see Chapter 19), regulation of blood pressure, as an intracellular osmolyte, and as a potent antioxidant and anti-inflammatory agent. Interestingly, taurine is a major ingredient in Red Bull® energy drink—an 8 oz. can of the drink contains 1000 mg of taurine (compared with only 80 mg of caffeine). The health effects of such high intakes of taurine have not been carefully studied.

Synthesis of Proline, Ornithine, and Arginine from Glutamate

As we have seen, glutamate is perhaps the most active of all the amino acids in terms of its number of metabolic roles. Another important reaction of glutamate is the energy-requiring reduction of the γ -carboxyl group, to give **glutamate γ -semialdehyde** (Figure 21.31). Phosphorylation of the γ -carboxyl group to the unstable intermediate, γ -glutamyl phosphate, facilitates the endergonic reduction. This process, which leads toward both ornithine and proline, is comparable to the reduction of aspartate to aspartic semialdehyde (page 899). In plants and animals, this two-step reaction is catalyzed by a bifunctional enzyme composed of two domains—one catalyzes the ATP-dependent γ -carboxyl phosphorylation, the other catalyzes the NADPH-dependent reduction. The product, glutamate γ -semialdehyde, is in a nonenzymatic equilibrium with a cyclized tautomer, Δ^1 -**pyrroline-5-carboxylic acid (P5C)**. This equilibrium is strongly pH-dependent,

FIGURE 21.29

Outline of methionine metabolism. Except for the synthesis of isoleucine from threonine (see page 907), which is limited to plants and bacteria, these pathways occur in virtually all organisms.

FIGURE 21.30

Taurine biosynthesis. ① cysteine dioxygenase, ② cysteinesulfinate decarboxylase.

FIGURE 21.31

Proline and arginine are derived from glutamate. The enzymes involved are ① Δ^1 -pyrroline-5-carboxylate (P5C) synthase, a bifunctional enzyme comprising glutamate kinase 1a and γ -glutamyl phosphate reductase 1b activities; ② Δ^1 -pyrroline-5-carboxylate reductase; ③ ornithine δ -aminotransferase; ④ glutamate γ -semialdehyde dehydrogenase (also called Δ^1 -pyrroline-5-carboxylate dehydrogenase); ⑤ proline oxidase.

Glutamate, one of the most metabolically active amino acids, is a precursor to glutamine, arginine, creatine phosphate, proline, hydroxyproline, polyamines, glutathione, and α -aminobutyric acid.

Proline and arginine are synthesized and degraded by opposing pathways that utilize different enzymes and different cofactors, and occur in multiple compartments.

with P5C favored at pH above ~ 6.5 . Thus, P5C is the physiological product, and the bifunctional enzyme is named Δ^1 -pyrroline-5-carboxylic acid synthase, accordingly. Bacteria and lower eukaryotes use two separate enzymes encoded by two separate genes to carry out the glutamate kinase and γ -glutamyl phosphate reductase reactions. Sequence and structural analyses suggest that the bifunctional P5C synthase evolved from the two monofunctional enzymes, which are encoded by a single operon in bacteria. Finally, an NADPH-dependent reduction of Δ^1 -pyrroline-5-carboxylic acid follows, to give proline.

Glutamate γ -semialdehyde leads not only to proline but also to ornithine and hence arginine. Ornithine is formed directly from glutamate γ -semialdehyde by transamination at the aldehyde group in a reaction catalyzed by **ornithine δ -aminotransferase**. Arginine is then synthesized from ornithine through the urea cycle, as we saw in Chapter 20.

The pathways of proline and arginine biosynthesis from glutamate are essentially the reverse of their degradation pathways (compare Figure 21.31 with

Figure 21.3), so how does the cell prevent these opposing pathways from operating at the same time? Several of the principles of bioenergetics and metabolic organization that we first outlined in Chapter 12 come into play here. As expected, different enzymes and coenzymes are used in the anabolic and catabolic directions. In particular, the biosynthetic directions have different ATP coupling coefficients from the catabolic directions (e.g., -1 vs. 0 for the proline pathways). Proline synthesis from glutamate, a four-electron reduction, uses NADPH, whereas proline oxidation to glutamate involves a flavin dehydrogenase and NAD^+ . The only reversible enzymatic reaction is the transamination reaction catalyzed by ornithine δ -aminotransferase in the arginine pathway. Another factor that allows independent but coordinate control of the synthesis vs. degradation pathways is the intricate compartmentation of the enzymes in these pathways (Figure 21.31). Thus, P5C reductase, which catalyzes the reduction of P5C to proline, is cytoplasmic whereas proline oxidase, which catalyzes the oxidation of proline back to P5C, is mitochondrial. Both P5C synthase and proline oxidase are tightly bound to the matrix side of the inner membrane; ornithine δ -aminotransferase is a soluble matrix enzyme. Arginine metabolism, via the urea cycle, involves one mitochondrial reaction and two cytoplasmic reactions. Transport of P5C, proline, citrulline, and ornithine between the mitochondrial and cytosolic compartments is mediated by specific carriers in the mitochondrial inner membrane.

In bacteria, glutamate is acetylated to *N*-acetylglutamate before reduction, with the acetyl group being removed a couple of steps later (Figure 21.32). Acetylation prevents cyclization of the molecule after reduction, by condensation between the resulting aldehyde and the α -amino group as occurs nonenzymatically in proline synthesis. Ornithine is then converted to arginine by the same reactions found in the animal pathway (Figure 21.31).

In plants, glutamate γ -semialdehyde can also be synthesized from *N*-acetylglutamate γ -semialdehyde by transfer of the acetyl group on the latter to glutamate.

Hydroxyproline and Collagen

An important role of proline is its incorporation into polypeptide precursors to collagen and other connective tissue proteins, where it serves as a precursor to **hydroxyproline**. As mentioned in Chapter 5 (see page 144), hydroxyproline residues are generated by post-translational modification, following completion of the polypeptide chain. The nonhydroxylated collagen precursor is called **procollagen** (see Chapter 6). In this polypeptide, a proline residue two positions to the carboxyl side of a glycine residue is the preferred substrate for the action of **procollagen prolyl hydroxylase** (Figure 21.33). This enzyme belongs to the family of Fe(II)/ α -ketoglutarate-dependent dioxygenases, which require L-ascorbic acid and molecular oxygen in addition to α -ketoglutarate and nonheme ferrous iron. α -Ketoglutarate is stoichiometrically decarboxylated during hydroxylation, with one atom of the O_2 molecule being incorporated into succinate and the other into the hydroxy group on the proline residue. Ascorbate is not needed for this reaction, and the enzyme can catalyze a number of reaction cycles in its absence. However, prolyl hydroxylases sometimes catalyze decarboxylation of α -ketoglutarate that is not coupled to hydroxylation of a proline residue. During this uncoupled turnover of α -ketoglutarate to succinate, Fe(II) becomes oxidized and the enzyme is inactivated. Although its precise role is not yet known, ascorbate is proposed to reduce the oxidized iron back to the Fe(II) state, reactivating the enzyme. In this role, ascorbate is required stoichiometrically and is oxidized to dehydroascorbate. This reaction is of particular interest because it represents one of the few well-defined roles for ascorbic acid, or vitamin C. As mentioned in Chapter 6, vitamin C deficiency, or scurvy, involves degeneration of connective tissue, and these problems derive from defective synthesis or maturation of collagen in connective tissue. The earliest recorded

FIGURE 21.32

Biosynthesis of ornithine from glutamate in bacteria. The reduction of *N*-acetylglutamate (step 2) begins with phosphorylation of the carboxyl group by ATP, followed by NADPH-dependent reduction of the activated carboxyl group.

FIGURE 21.33

Enzymatic hydroxylation of procollagen proline residues in the synthesis of collagen. The fates of the two atoms of O_2 are indicated in magenta. X is any amino acid residue.

references to this deficiency disease go back at least 3500 years, but scurvy became a serious problem during the extended sailing voyages of exploration beginning in the 1500s. A breakthrough came when James Lind, a surgeon in the Royal Navy, was confronted with an outbreak of scurvy during a 1747 voyage. In what was the first controlled clinical trial in recorded history, Lind divided 12 scorbutic sailors into six pairs and treated each pair with a different “acidic” dietary supplement. The daily supplements he tested were a quart of cider; 25 drops of elixir of vitriol (sulfuric acid); 6 spoonfuls of vinegar (acetic acid); half a pint of seawater; two oranges plus one lemon; and a spicy paste plus a drink of barley water. The treatment of the citrus group stopped after six days when they ran out of fruit, but by that time both sailors showed significant improvement. The other groups continued to deteriorate. A longer trial of citrus fruit was conducted in 1794, and in 1795 the Royal Navy finally mandated lime or lemon juice for all British sailors on voyages of one month or longer (hence the nickname “limeys”).

Synthesis of Serine and Glycine from 3-Phosphoglycerate

Serine and glycine are closely interconnected via the serine hydroxymethyltransferase reaction (see Figure 21.2). Although serine can be synthesized from glycine via this reaction, it proceeds more often in the reverse direction, as the principal biosynthetic route to glycine and to 5,10-methylenetetrahydrofolate. Most de novo serine biosynthesis occurs in a three-step sequence from the glycolytic intermediate 3-phosphoglycerate: oxidation of the alcohol to a ketone, transamination of the ketone to introduce the α -amino group, and finally dephosphorylation to give serine.

In bacteria and plants, the first committed step to serine synthesis, the NAD-dependent oxidation of 3-phosphoglycerate, is feedback inhibited by L-serine. Phosphoglycerate dehydrogenase is also an important control point in mammalian tissues with low serine concentrations. On the other hand, in tissues where serine levels are high, such as liver, it is the final enzyme, phosphoserine phosphatase, that is sensitive to feedback inhibition by L-serine. This is an interesting exception to the general concept that key regulatory enzymes are located at the beginning of a pathway.

Serine is quite active metabolically; we have already considered its roles in biosynthesis of phospholipids (Chapter 19) and cysteine (page 902), as well as

Serine is involved in glycine, phospholipid, and cysteine synthesis. Glycine is active in biosynthesis of purine nucleotides and porphyrins.

FIGURE 21.34

Metabolic interconversions and fates of serine and glycine.

its contribution of activated one-carbon units to the pool of tetrahydrofolate coenzymes (Chapter 20). Glycine also plays multiple roles, including contributions to the one-carbon pool and as a precursor to glutathione (Figure 21.15), to purine nucleotides (see Chapter 22), and to porphyrins (Figure 21.19). Figure 21.34 summarizes the metabolic fates of glycine and serine.

Synthesis of Valine, Leucine, and Isoleucine from Pyruvate

The branched chain amino acids valine, leucine, and isoleucine are essential for mammals, and they are synthesized primarily in plant and bacterial cells. Furthermore, none of these amino acids is known to play significant metabolic roles other than as protein constituents and as substrates for their own degradation. The pathways involved are complex, and they are shown here only in outline.

Valine, leucine, and isoleucine are structurally related, and they share certain reactions and enzymes in their biosynthetic pathways (Figure 21.35). The last four reactions in valine and isoleucine biosynthesis are catalyzed by the same four enzymes. Valine biosynthesis begins with transfer of a two-carbon fragment from hydroxyethyl thiamine pyrophosphate to pyruvate. The two-carbon fragment derives from a second molecule of pyruvate in a TPP-dependent reaction similar to that catalyzed by pyruvate decarboxylase (Chapter 13). A similar TPP-dependent transfer of a two-carbon unit to α -ketobutyrate begins the pathway to isoleucine. The keto acid analog of valine is the input for a four-step pathway to leucine. In bacteria, each of these three amino acids controls its own synthesis by feedback inhibition of a different enzyme. In fact, the concept of allosteric control was developed largely in studies on the inhibition of threonine dehydratase by isoleucine.

FIGURE 21.35

Biosynthesis of valine and isoleucine. After the serine–threonine dehydratase reaction (see Figure 21.4), one set of enzymes catalyzes the comparable reactions in valine and isoleucine synthesis. In bacteria, each end product regulates its own synthesis by inhibiting a specific enzyme.

Serine and glycine are both major contributors to the pool of activated one-carbon groups, in the form of 5,10-methylenetetrahydrofolate.

**FIGURE 21.36**

Overview of the biosynthesis of aromatic amino acids. The central pathways leading to the three amino acids are essentially the same in plants and bacteria. Details of the shikimic acid pathway are presented in Figures 21.37 and 21.38.

The shikimic acid pathway leads to synthesis of nearly all aromatic compounds, including lignin, and is thus one of the most productive pathways in biology.

Synthesis of the Aromatic Amino Acids from Glycolytic Intermediates: The Shikimic Acid Pathway

Synthesis of these aromatic rings from noncyclic precursors involves complex chemistry. As with other lengthy biosynthetic pathways, such as the synthesis of vitamins, most of the aromatic biosynthetic capabilities have been lost during animal evolution. The synthetic pathways we shall discuss are limited to plants and bacteria—with one exception. That exception is the hydroxylation of phenylalanine to tyrosine, which we discussed in the context of phenylalanine degradation (Figure 21.7).

A single branched pathway in microorganisms and plants leads to synthesis of phenylalanine, tyrosine, tryptophan, and virtually all other aromatic compounds (Figure 21.36). Individual reactions of the pathway were established in bacteria. A large number of auxotrophic mutants could be isolated and characterized genetically (mapping), physiologically (identification of compounds that could satisfy growth requirements), and biochemically (identification of intermediates accumulating when a given step is blocked). So far as is known, the processes are quite similar in plants.

Several key findings were made. First, all of the carbon in phenylalanine and tyrosine was derived from erythrose-4-phosphate and the glycolytic intermediate phosphoenolpyruvate (PEP). Recall that erythrose-4-phosphate is also derived from glycolytic intermediates, via the pentose phosphate pathway (Chapter 13). Second, a class of mutants requiring phenylalanine, tyrosine, tryptophan, *p*-aminobenzoic acid, and *p*-hydroxybenzoic acid for growth could have all five requirements met by a single compound—**shikimic acid**. We now know that these mutants are blocked in the formation of shikimate (the fourth reaction in the part of the pathway shown in Figure 21.37) and that, when it is provided, all of the subsequent steps in the pathway can occur. Note that an unbranched pathway leads through shikimic acid to **chorismic acid**. From chorismic acid one pathway leads to **prephenic acid**, with subsequent branches leading to phenylalanine and tyrosine (Figure 21.38). Another pathway leads through **anthranilic acid** to tryptophan, still another pathway leads to *p*-aminobenzoic acid, and a final pathway leads, via *p*-hydroxybenzoic acid, to coenzyme Q. Thus, the shikimic acid pathway is responsible for biosynthesis of virtually all aromatic compounds because the products we have just mentioned serve in turn as precursors to other aromatic compounds.

Great attention has focused in recent years on the sixth reaction of the shikimic acid pathway, catalyzed by **5-enolpyruvylshikimate-3-phosphate synthase (EPSP synthase)**, in higher plants. This enzyme is specifically inhibited by a compound called **glyphosate**, or glycine phosphonate (a *phosphonate* is a compound with a covalent bond linking carbon to phosphorus). The growth of most crop and weed plants is inhibited by glyphosate, which is an effective broad-spectrum herbicide sold as Roundup®. A recent achievement of biotechnology is the transfer of genes conferring resistance to glyphosate into crop plants. For example, “Roundup Ready” cotton seed was sold to farmers in the mid-1990s, and other crop plants, similarly modified, are now on the market. This modification allows simplified and effective weed control. Spraying a field should eliminate all plants except the genetically engineered species.

Interesting control mechanisms are involved in regulating these pathways. Studies on the genetic control of tryptophan biosynthesis, described in Chapter 29, have provided some of our most important insights into transcriptional regulation. More recent studies on the reactions leading to chorismic acid have revealed the existence of several multifunctional enzymes—single polypeptide chains containing two or more active sites for catalysis of sequential reactions—obviously, an efficient way to control several reactions jointly.

Glyphosate

FIGURE 21.37

Details of the shikimic acid pathway, I. This figure depicts the initial unbranched pathway from erythrose-4-phosphate and phosphoenolpyruvate to chorismic acid. The first reaction is driven by loss of phosphate from phosphoenolpyruvate. In the second reaction an unusual cobalt-requiring enzyme effects ring closure with dehydration and loss of the second phosphate. Dehydration in the third step yields dehydroshikimate, which is then reduced by NADPH to shikimate. A three-carbon side chain is then attached via phosphorylation of shikimate and reaction with a second molecule of phosphoenolpyruvate. Dephosphorylation of this intermediate gives chorismate, the branch point of the pathway.

The first reaction in the pathway from anthranilic acid to tryptophan (Figure 21.38) involves an activated sugar derivative, **5-phosphoribosyl-1-pyrophosphate (PRPP)**, which plays its most widespread roles in nucleotide synthesis (see Chapter 22). In bacteria the genes encoding these enzymes are linked in a linear array, the **tryptophan operon**. As discussed in Chapter 27, an

FIGURE 21.38

Details of the shikimic acid pathway, II. This figure depicts the branched portion of the pathway shown in Figure 21.36, from chorismate to various aromatic products. Chorismate isomerizes to prephenate (shown below chorismate), a branch point en route to phenylalanine and tyrosine. Decarboxylation and dehydration of prephenate yield phenylpyruvate, which leads directly to phenylalanine by transamination. Alternatively, oxidative decarboxylation gives *p*-hydroxyphenylpyruvate, the immediate precursor of tyrosine. The pathway shown to the right of chorismate involves exchange of the amide nitrogen of glutamine for the side chain of chorismate. The enzyme, anthranilate synthetase, catalyzes the first committed step en route to tryptophan. In the next step, carbon 1 of 5-phosphoribosyl-1-pyrophosphate (PRPP) is linked to the nitrogen of anthranilate, driven by loss of pyrophosphate from carbon 1. Opening of the sugar ring is followed by decarboxylation and ring closure to give indole-3-glycerol phosphate. In the final step, the three-carbon side chain of the indole compound is exchanged for that of serine, yielding tryptophan.

operon is a linked set of genes whose expression is regulated jointly at the level of transcription. In bacteria, yeasts, molds, and plants the final enzyme in the pathway, **tryptophan synthase**, is an $\alpha_2\beta_2$ dimer. Isolated α and β subunits catalyze the following partial reactions, with the holoenzyme catalyzing a concerted reaction in which indole does not dissociate from the enzyme surface but immediately reacts with serine to give tryptophan.

Remarkably, X-ray crystallography shows that the intermediate, indole, is *channeled* from the α subunit active site to the β active site, a distance of 25 Å, through a tunnel in the interior of the protein molecule (Figure 21.39). Channeling refers to the direct transfer of a metabolite between sequential enzymes in a metabolic cycle. We will see another example of this in Chapter 22. Kinetic analysis, complementing more detailed structural analysis, suggests that each active site is covered intermittently by a “lid” (Figure 21.40), which acts to keep indole within the channel.

Synthesis of Histidine from Glycolytic Intermediates

The biosynthesis of histidine presents several parallels with the shikimic acid pathway, regarding methods used for its elucidation, complexity of the reactions involved, elegance of genetic pathway regulation, and practical applications of knowledge of the pathway. However, the histidine pathway is distinctive in being unbranched. As established largely in the laboratories of Bruce Ames and Philip

FIGURE 21.41

The pathway for histidine biosynthesis. After activation of a purine ring by reaction with 5-phosphoribosyl-1-pyrophosphate (PRPP, step 1), the ring opens to give the third intermediate (steps 2 and 3). The ribose ring derived from PRPP then opens (step 4). The transfer of amide nitrogen from glutamine (step 5) is accompanied by cleavage and ring closure, giving the first imidazole compound, imidazole glycerol phosphate. The other product is an intermediate in the synthesis of purine nucleotides. Imidazole glycerol phosphate is transformed to histidine by a straightforward sequence involving dehydration (step 6), transamination (step 7), dephosphorylation (step 8), and dehydrogenation (steps 9 and 10).

Hartman, the pathway is shown in Figure 21.41. Five of histidine's six carbons come from phosphoribosyl-1-pyrophosphate (PRPP), which is in turn derived from glucose-6-phosphate via the pentose phosphate pathway (Chapter 13). The sixth carbon and one of the imidazole nitrogen atoms come from ATP. The other imidazole nitrogen atom is introduced by a glutamine amidotransferase reaction, and the α -amino group comes from glutamate in a standard PLP-dependent aminotransferase reaction. Ten individual reactions are involved, starting with an unusual reaction that joins ATP and PRPP. One of the products of step 5, 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR), is an intermediate in purine biosynthesis (Chapter 22), linking these two pathways together.

The 10 structural genes for the enzymes of histidine synthesis in enteric bacteria are linked to one another in the same order as the order of the reactions of the pathway. This set of genes, the **histidine operon**, is coordinately regulated at the transcriptional level, and all 10 genes are transcribed to give one large messenger

RNA, which is translated to give the 10 enzymes. This highly organized gene arrangement may facilitate regulation of the pathway.

Once the genes and gene products had been identified, Bruce Ames used the mutant bacteria that had been generated for these investigations in a novel way—to search for mutagens in the environment. Using the **Ames test**, researchers can count mutations simply by measuring the rate at which mutants that cannot synthesize histidine (histidine **auxotrophs**) mutate to a form that can synthesize the amino acid (**prototrophs**). The researcher treats a culture of auxotrophs with a suspected mutagen, plates the bacteria on medium containing no histidine, and counts the colonies that appear as the result of reversion mutations. Using this system, Ames and colleagues reported a very high correlation between compounds known to be carcinogenic in animals and those found to be mutagens in this test. Thus, the Ames test provides a quick and inexpensive way to search for suspected carcinogens in the environment. Moreover, these findings provided support for the idea that cancer arises as the result of a series of somatic cell mutations, an idea we discuss further in Chapter 23.

SUMMARY

Amino acids play numerous roles as intermediates in the biosynthesis of other metabolites, including purine nucleotides (glutamine, glycine, serine), pyrimidine nucleotides (aspartate, glutamine), polyamines and methyl groups (methionine), glutathione (glutamate, cysteine, glycine), creatine phosphate (arginine), neurotransmitters (tyrosine, tryptophan, glutamate, arginine), lignin, aromatic compounds and pigments (phenylalanine), hormones (tyrosine, histidine), porphyrins (glycine and glutamate in plants), and other amino acids. The roles of amino acids as neurotransmitters and neurotransmitter precursors are particularly important, as are their roles in porphyrin synthesis. In porphyrin synthesis, glycine condenses with succinate to give a heterocyclic ring compound, porphobilinogen, which is the precursor to all four pyrrole rings in heme and other porphyrins. Degradation of porphyrins in animals yields iron, which is reutilized, and bilirubin, an insoluble tetrapyrrole that is excreted. Amino acids are synthesized from intermediates in the citric acid cycle, glycolysis, and the pentose phosphate pathway.

PROBLEMS

1. A clinical test sometimes used to diagnose folate deficiency or B₁₂ deficiency is a histidine tolerance test, where one injects a large dose of histidine into the bloodstream and then carries out a series of biochemical determinations. What histidine metabolite would you expect to accumulate in a folate- or B₁₂-deficient patient, and why?
2. In bacteria much of the putrescine is synthesized, not from ornithine but from arginine, which decarboxylates to yield *agmatine*. Formulate a plausible pathway from arginine to putrescine, using this intermediate.

Agmatine

3. The mitochondrial form of carbamoyl phosphate synthetase is allosterically activated by *N*-acetylglutamate. Briefly describe a rationale for this effect.
4. *Psilocybin* is a hallucinogenic compound found in some mushrooms. Present a straightforward pathway for its biosynthesis from one of the aromatic amino acids.

Psilocybin

- *5. One can identify phenylketonurics and PKU carriers (heterozygotes) by means of a phenylalanine tolerance test. One injects a large dose of phenylalanine into the bloodstream and measures its clearance from the blood by measuring serum phenylalanine levels at regular intervals. Sketch curves showing relative blood phenylalanine concentration versus time that you would expect to be displayed by (a) a PKU patient, (b) a heterozygote, and (c) a normal individual. What kind of tolerance test could you devise to distinguish between PKU resulting from either phenylalanine hydroxylase deficiency or dihydropteridine reductase deficiency?
6. (a) Formaldehyde reacts nonenzymatically with tetrahydrofolate to generate 5,10-methylenetetrahydrofolate. [¹⁴C]Formaldehyde can be used to prepare serine labeled in the β -carbon. What else would be needed?

Neurotransmitters

- (b) [¹⁴C]Serine, prepared as described above, is useful for many things, but you would probably not want to use it for studies on protein synthesis because it would label nucleic acids, carbohydrates, and lipids, as well as proteins. Indicate how each of these classes of compounds could become labeled by this precursor.
7. If oxidation of acetyl-CoA yields 10 ATPs per mole through the citric acid cycle, how many ATPs will be derived from the complete metabolic oxidation of 1 mole of alanine in a mammal? Would the corresponding energy yield in a fish be higher or lower? Why? How much energy would be derived from the metabolic oxidation of 1 mole of isoleucine to CO₂, H₂O, and NH₃? Of tyrosine?
8. Some bacteria contain three different forms of aspartokinase, each with its own mode of regulation. Based on the roles of aspartokinase, as discussed in the text, propose a regulatory scheme applicable to each form of aspartokinase.
9. Proline betaine is a putative osmoprotectant in plants and bacteria, helping to prevent dehydration of cells.

Propose a plausible pathway for biosynthesis of this compound.

10. Most bacterial mutants that require isoleucine for growth also require valine. Why? Which enzyme or reaction would be defective in a mutant requiring only isoleucine (not valine) for growth?
11. Describe a series of allosteric interactions that could adequately control the biosynthesis of valine, leucine, and isoleucine.
12. The structure shown below is an intermediate in the synthesis of which biogenic amine? Use arrows to show how the next intermediate in this reaction is formed, and draw the structure of that intermediate.

CHAPTER 22

Nucleotide Metabolism

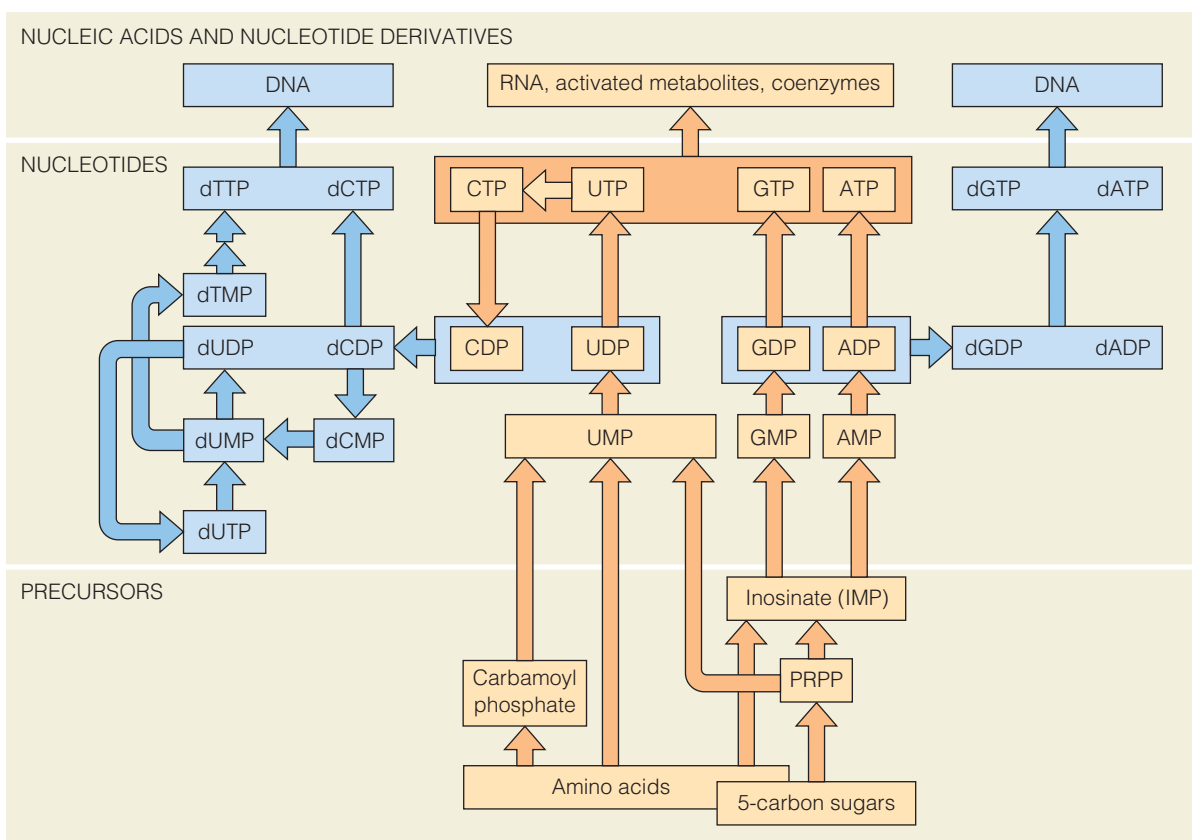

We have encountered nucleotides repeatedly during our exploration of biochemistry. They serve as precursors to nucleic acids, as critical elements in energy metabolism, as carriers of activated metabolites for biosynthesis (such as nucleoside diphosphate sugars), as structural moieties of coenzymes, and, finally, as metabolic regulators and signal molecules (notably, cyclic AMP). In this chapter we discuss pathways of biosynthesis and degradation of purine and pyrimidine nucleotides, and we explore regulation of these processes—particularly critical in pathways leading to DNA replication. We discuss nucleotide biosynthetic enzymes as targets for the action of antimicrobial and anticancer drugs, and we describe the metabolic consequences of certain heritable alterations of nucleotide metabolism. The roles of nucleotides in metabolic or genetic regulation are discussed elsewhere in this book, in connection with the specific processes regulated.

Before starting this chapter, you may find it useful to review the information on nucleotide structure in Chapter 4. You should be aware also of the distinction between nucleosides and nucleotides. On complete hydrolysis, a mole of *nucleoside* yields at least 1 mole each of a sugar and a heterocyclic base, whereas a mole of *nucleotide* yields at least 1 mole each of a sugar, a base, and inorganic phosphate. A mole of *mononucleotide* contains only 1 mole each of base and sugar, but it may contain more than one phosphate. If it contains, for example, three phosphates, it is called a *nucleoside triphosphate*. The *deoxyribonucleotides*, which are used in DNA synthesis, are formed from *ribonucleotides* (RNA constituents) by pathways discussed later in this chapter.

Outlines of Pathways in Nucleotide Metabolism

Biosynthetic Routes: De Novo and Salvage Pathways

Unlike the other classes of metabolites we have encountered, neither nucleotides nor the bases and sugars from which they are formed are required to meet nutritional requirements, with the exception of some protozoan parasites.

**FIGURE 22.1**

Overview of nucleotide metabolism. De novo pathways for synthesis and utilization of ribonucleotides (orange) and deoxyribonucleotides (blue).

Nucleotides arise through de novo synthesis from low-molecular-weight precursors or through salvage of nucleosides or bases.

Most organisms can synthesize purine and pyrimidine nucleotides from low-molecular-weight precursors in amounts sufficient for their needs. These so-called **de novo pathways** are essentially identical throughout the biological world (Figure 22.1). Most organisms can also synthesize nucleotides from nucleosides or bases that become available either in the diet or through enzymatic breakdown of nucleic acids. These processes are called **salvage pathways** because they involve the utilization of preformed purine and pyrimidine compounds that would otherwise be lost to biodegradation. As we shall see, salvage pathways represent important targets for treatment of microbial or parasitic diseases, sites for manipulation of biological systems (for example, in studies of mutagenesis or in preparation of monoclonal antibodies), and biological processes in which genetic alterations have severe and far-reaching consequences.

Nucleic Acid Degradation and the Importance of Nucleotide Salvage

Because salvage, or reuse, of purine and pyrimidine bases involves molecules released by nucleic acid degradation, let us begin by briefly considering these processes (Figure 22.2). Degradation can occur intracellularly (through the turnover of unstable messenger RNA species or through DNA repair pathways), as a result of cell death, or, in animals, through digestion of nucleic acids ingested in the diet.

In animals the extracellular hydrolysis of ingested nucleic acids represents the major route by which bases and nucleosides become available. The breakdown processes are comparable to those involved in protein digestion. Cleavage processes begin at internal linkages—in this case, phosphodiester bonds. Catalysis occurs via **endonucleases**, such as pancreatic ribonuclease or deoxyribonuclease, which function to digest nucleic acids in the small intestine. Endonucleolytic

FIGURE 22.2

Reutilization of purine and pyrimidine bases. The figure shows relationships between nucleic acid catabolism (blue) and resynthesis of nucleotides by salvage pathways (magenta).

cleavages yield oligonucleotides, which are then cleaved **exonucleolytically** (at linkages near the ends of molecules) by nonspecific enzymes called **phosphodiesterases**. The products are mononucleotides—nucleoside 5'- or 3'-monophosphates, depending on the specificities of the enzymes involved. Nucleotides can then be cleaved hydrolytically, by a group of phosphomonoesterases called **nucleotidases**, to yield orthophosphate plus the corresponding nucleoside. Although hydrolytic cleavage of the resultant nucleoside does occur, the most common route for cleavage to the free base (nucleobase) involves the action of a **nucleoside phosphorylase**. Like glycogen phosphorylase, nucleoside phosphorylases cleave a glycosidic bond by adding across it the elements of inorganic phosphate, to yield the corresponding base plus ribose-1-phosphate (or deoxyribose-1-phosphate if the substrate is a deoxyribonucleoside):

These reactions are readily reversible, such that a nucleoside phosphorylase can also catalyze the first step in salvage synthesis of nucleotides from free nucleobases. When that occurs, the product nucleoside can be phosphorylated by ATP, through the action of a **nucleoside kinase** (Figure 22.2). Such enzymes are not universal. For example, animal cells contain neither a guanosine kinase nor a uridine phosphorylase, although these enzymes are found in other organisms.

If bases or nucleosides are not reused for nucleic acid synthesis via salvage pathways, the purine and pyrimidine bases are further degraded, to uric acid or β -ureidopropionate, respectively, as indicated in Figure 22.2. We consider these pathways later in this chapter.

PRPP: A Central Metabolite in De Novo and Salvage Pathways

PRPP is an activated ribose-5-phosphate derivative used in both salvage and de novo pathways.

An alternative salvage pathway, also shown in Figure 22.2, synthesizes nucleoside 5-phosphates directly from free bases. This route involves a class of enzymes called **phosphoribosyltransferases** and an activated sugar phosphate, **5-phospho- α -D-ribose-1-pyrophosphate (PRPP)**. Identified in Chapter 21 as an intermediate in histidine and tryptophan biosynthesis, PRPP is a key intermediate in the de novo synthesis of both purine and pyrimidine nucleotides. It is formed through the action of **PRPP synthetase**, which activates carbon 1 of ribose-5-phosphate by transferring to it the pyrophosphate moiety of ATP:

A phosphoribosyltransferase reaction catalyzes the reversible transfer of a free base to the ribose of PRPP, displacing pyrophosphate and producing a nucleoside monophosphate. Because the deoxyribose analog of PRPP is absent from most cells, these enzymes are not involved directly in deoxyribonucleotide metabolism.

In principle, such a reaction could participate in nucleotide breakdown. However, in vivo, pyrophosphate is rapidly cleaved by pyrophosphatase to give inorganic phosphate. This dictates that phosphoribosyltransferases most commonly act in the direction of nucleotide biosynthesis, as a way to salvage free nucleobases.

De Novo Biosynthesis of Purine Nucleotides

Early Studies on De Novo Purine Synthesis

The reactions of de novo purine nucleotide biosynthesis were identified in the 1950s, in the laboratories of John Buchanan and Robert Greenberg. Elucidation of the pathway began with the realization that birds excrete most of their excess nitrogen compounds in the form of *uric acid*, an oxidized purine (see Chapter 20). Thus, researchers were able to identify low-molecular-weight precursors to purines by administering isotopically labeled compounds to pigeons, crystallizing uric acid from the droppings, and, by selective chemical degradation, determining which positions were labeled by which precursors. This procedure yielded the pattern shown in Figure 22.3. At that time, 10-formyltetrahydrofolate was not known, but compounds such as formate, or serine labeled in the hydroxymethyl carbon, readily labeled C-2 and C-8 of uric acid.

Next, two related antibiotics, **azaserine** and **6-diazo-5-oxonorleucine (DON)**, were identified as potent inhibitors of purine nucleotide synthesis. Recognition that these compounds are structural analogs of glutamine led to the eventual realization

FIGURE 22.3

Low-molecular-weight precursors to the purine ring. The source of each atom in the ring, as established with isotopic tracer studies of uric acid synthesis.

that azaserine and 6-diazo-5-oxonorleucine are irreversible inhibitors of a class of enzymes called the **glutamine amidotransferases**, which catalyze the ATP-dependent transfer of the amido nitrogen of glutamine to an acceptor. Three such reactions occur in purine nucleotide synthesis (and two in pyrimidine nucleotide synthesis)—we will look more closely at the mechanism of these enzymes later in the chapter.

In later experiments, bacteria treated with sulfonamide drugs, such as sulfanilamide, excreted large quantities of a red compound. This compound was identified as an oxidation product of **5-aminoimidazole-4-carboxamide ribonucleotide (AICAR)**, which resembles an incomplete purine nucleotide. This finding suggested that AICAR is a biosynthetic intermediate whose use was somehow blocked by the drug. Because sulfonamides block the synthesis of folate coenzymes (see page 851), the accumulation of AICAR suggested that a folate coenzyme participates in the next reaction. Moreover, these observations suggested that the pathway proceeds at the nucleotide level—in other words, that the purine ring is assembled while already attached to the ribose-5-phosphate moiety.

Purine Synthesis from PRPP to Inosinic Acid

Figure 22.4 summarizes the pathway leading from PRPP, the first intermediate, to the first fully formed purine nucleotide, **inosine 5'-monophosphate (IMP)**, also called **inosinic acid**. This compound is the 5'-ribonucleotide of the purine base **hypoxanthine**. Note that there are two glutamine amidotransferase reactions in this pathway, reactions 1 and 4. They differ mechanistically in that PRPP amidotransferase (reaction 1) does not require ATP because the substrate has been activated by ATP in the previous step. An inversion of configuration occurs in reaction 1, as the amido nitrogen displaces the pyrophosphate moiety. The latter is an excellent leaving group, giving a simple nucleotide (5-phosphoribosylamine), which carries the β -configuration at carbon 1 of the sugar, as do all the common nucleotides. This nitrogen will become N9 of the purine ring.

In reaction 2, the carboxyl group of glycine forms an amide with the amino group of phosphoribosylamine (PRA), giving glycinamide ribonucleotide (GAR). The role of ATP is to phosphorylate glycine's carboxyl group, activating it for nucleophilic attack by PRA's amino group. This is followed by a **transformylase** reaction, in which a formyl group is transferred from an N atom of 10-formyltetrahydrofolate (10-formyl-THF) to an N atom of the glycinamide—this carbon will become C8 of the purine ring. As we have noted, reaction 4 is catalyzed by an ATP-dependent amidotransferase, with glutamine providing N3 of the purine ring. Reaction 5 is an ATP-dependent ring closure, in which the formyl oxygen is activated by the γ -phosphate of ATP for nucleophilic attack by N1 of FGAR, giving the imidazole portion of the purine ring. Step 6, the carboxylation of aminoimidazole ribonucleotide (AIR) to form 4-carboxy-5-aminoimidazole ribonucleotide (CAIR), can occur by two distinct mechanisms. In higher organisms, AIR is reversibly carboxylated directly to CAIR by AIR carboxylase, as illustrated in Figure 22.4. In most bacteria, fungi, and plants, however, AIR is first converted to an unstable intermediate, N^5 -CAIR. This ATP-dependent reaction, catalyzed by N^5 -CAIR synthetase, is thought to occur via a carboxyphosphate intermediate, which is thereby activated for nucleophilic attack by the N^5 -amino group of AIR. A mutase then catalyzes the reversible transfer of the CO_2 group from the carbamate of N^5 -CAIR to C4, yielding CAIR.

These carboxylation reactions are unusual in that neither AIR carboxylase nor the two-step process requires biotin. It has been proposed that the unstable

Purines are synthesized at the nucleotide level, starting with PRPP conversion to phosphoribosylamine and purine ring assembly on the amino group.

FIGURE 22.4

De novo biosynthesis of the purine ring. In this and subsequent figures ribose — P refers to a ribose-5-phosphate moiety in a nucleotide. The enzymes involved are ① PRPP amidotransferase, ② GAR synthetase, ③ GAR transformylase, ④ FGAR amidotransferase, ⑤ AIR synthetase, ⑥ AIR carboxylase, ⑦ SAICAR synthetase, ⑧ adenylosuccinate lyase, ⑨ AICAR transformylase, and ⑩ IMP cyclohydrolase.

N^5 -CAIR intermediate functions as a CO_2 carrier like carboxybiotin (see Figure 14.20, page 619). The major function of the mutase then is to sequester the CO_2 released from N^5 -CAIR decarboxylation for CAIR formation. In fact, N^5 -CAIR mutase can catalyze the direct carboxylation of AIR, but its K_M for CO_2 is 110 mM. However, sequential action of N^5 -CAIR synthetase and N^5 -CAIR mutase produces CAIR with a K_M for CO_2 of less than 100 μM . In bacteria, these two enzymes are separate proteins, but in plants and yeast, the two activities are fused together in a single bifunctional enzyme, and it is likely that the unstable N^5 -CAIR intermediate is channeled between the two domains. The mechanism of the AIR carboxylase reaction is not yet understood. CO_2 , rather than bicarbonate, is the one-carbon donor, and ATP is not required to activate the CO_2 . However the CO_2 is introduced, it becomes C6 of the purine ring.

Reactions 7 and 8 result in the transfer of a nitrogen from aspartate, by a mechanism identical to that used to convert citrulline to arginine in the urea cycle (Figure 20.12, page 842) and to that used to remove the ϵ -amino group of lysine (Chapter 21, page 870). First, the entire aspartate molecule is transferred to the carboxyl group of 4-carboxy-5-aminoimidazole ribonucleotide (reaction 7). An α,β -elimination reaction follows (reaction 8), yielding AICAR, the intermediate shown to accumulate in sulfonamide-treated bacteria. The enzyme catalyzing reaction 8, adenylosuccinate lyase, actually has dual substrate specificity—it also catalyzes the second step in the conversion of IMP to AMP (see Figure 22.6). Reaction 9 is another transformylase reaction, with a one-carbon group transferred from 10-formyl-THF, becoming C2 of the purine ring. As in the transformylation in reaction 3, the formyl group is transferred from N10 of 10-formyl-THF to an N atom of the acceptor (FAICAR). Finally, an internal condensation reaction (reaction 10) yields the first purine compound, inosinic acid (IMP).

Evolution has also produced divergent chemistry for the two formylation reactions (3 and 9). Some bacteria and archaea use formate rather than 10-formyl-THF as the formyl donor in ATP-dependent ligase reactions. In each case, the γ -phosphate of ATP is transferred to formate to give a formyl-phosphate intermediate, followed by nucleophilic attack at the activated formyl carbon by the GAR or AICAR amino group.

Vertebrate cells contain several of these activities in the form of multifunctional enzymes. This fact came to light when cloned genes for these enzymes were transferred into *E. coli*, and single cloned genes were found to complement (that is, to replace the function of) two or three different bacterial genes. For example, a single cloned cDNA (see Tools of Biochemistry 4B) allowed growth of bacterial purine auxotrophs defective in E2, E3, or E5. Subsequent analysis showed that the cloned vertebrate DNA encoded a single polypeptide that catalyzed these three reactions. Similar observations confirmed that reactions 6 and 7, and reactions 9 and 10, are catalyzed by bifunctional enzymes. Thus, the 10 activities of de novo purine biosynthesis are contained on only six proteins in vertebrates. Moreover, there is evidence that these six proteins associate together in the cytoplasm in a multiprotein complex called the **purinosome** (Figure 22.5). This evidence comes from cross-linking (see Tools of Biochemistry 13A), affinity chromatography (see Tools of Biochemistry 5A), colocalization (see Tools of Biochemistry 7A), and genetic studies. Additional enzymes may also be part of the purinosome, including serine hydroxymethyltransferase (SHMT) and the trifunctional enzyme, C_1 -tetrahydrofolate (THF) synthase (see Figure 20.17, page 852). The combined activities of these two folate enzymes produce 10-formyl-THF, the formyl donor used by the two transformylases (reactions 3 and 9), from the one-carbon donor serine. The THF released from each transformylase reaction is recycled with another one-carbon unit from serine by SHMT (Figure 22.5).

Whether activities are carried on a multifunctional enzyme or a multienzyme complex such as the purinosome, several advantages of juxtaposing catalytic sites are readily apparent. Labile tetrahydrofolate coenzymes and purine intermediates can be protected. Intermediates whose concentrations are low can be “channeled” (that is, directly transferred from one catalytic site to the next). Finally, sequential enzyme activities can be jointly regulated under

FIGURE 22.5

Model of the purinosome. The figure shows a hypothetical model for a multienzyme complex in animal cells that transforms PRPP to IMP. E1–E10 correspond to the enzymes catalyzing reactions 1–10 in Figure 22.4.

Enzymes with the same coloring are contained on multifunctional enzymes. Serine hydroxymethyltransferase (SHMT) and the trifunctional enzyme C_1 -tetrahydrofolate (THF) synthase, also proposed to be part of the complex, channel one-carbon units from serine into 10-formyl-THF for the transformylase reactions.

changing environmental and nutritional conditions. Recent evidence suggests that assembly of the purinosome is regulated by reversible phosphorylation-dephosphorylation of one or more of its component enzymes.

We noted at the beginning of this section that birds use the *de novo* purine synthesis pathway to excrete excess nitrogen. Some tropical legumes, such as soybean and cowpea, use this pathway to assimilate nitrogen. As described in Chapter 20, these plants possess symbiotic root nodules infected with *Rhizobium*. Inorganic nitrogen, fixed by bacterial nitrogenase activity, is secreted into the cytoplasm of the plant cell principally as NH_3 or NH_4^+ , which is assimilated into the amide group of glutamine via glutamine synthetase and glutamate synthase (see page 831). The glutamine amide N is incorporated into the purine ring by enzymes located in cytoplasmic organelles, called plastids. The purines are oxidized to allantoin and allantoic acid (see Figure 22.9), and then exported from the nodule in xylem to provide the majority of the nitrogen for the plant's nutrition.

IMP, the first fully formed purine nucleotide, is a branch point between adenine and guanine nucleotide biosynthesis.

Xanthine

Synthesis of ATP and GTP from Inosinic Acid

Inosinic acid represents a branch point in purine nucleotide synthesis. IMP does not accumulate but is converted both to adenosine 5-monophosphate and to guanosine 5-monophosphate (Figure 22.6). The pathway to guanine nucleotides begins with an NAD^+ -dependent oxidation of the hypoxanthine ring, yielding the nucleotide **xanthosine monophosphate (XMP)**; XMP contains the base xanthine. A glutamine-dependent amidotransferase reaction follows, yielding GMP. The route to AMP involves the transfer of nitrogen from aspartate to IMP, by a mechanism similar to that of reactions 7 and 8 in the *de novo* synthesis of the purine ring. First, a succinyl nucleotide intermediate is formed, and then an α,β -elimination

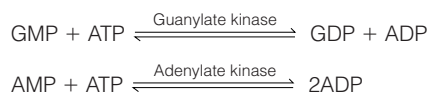

FIGURE 22.6

Pathways from inosinic acid (IMP) to GMP and AMP. Enzymes are as follows: G-1 = IMP dehydrogenase, G-2 = GMP synthetase, A-1 = adenylosuccinate synthetase, and A-2 = adenylosuccinate lyase.

reaction yields AMP plus fumarate. Indeed, the same enzyme (adenylosuccinate lyase) catalyzes both elimination reactions. Note from Figure 22.6 that the energy to drive the aspartate transfer reaction comes not from ATP but from GTP. This may represent a way to control the proportions of IMP that go to adenine and guanine nucleotide synthesis. GTP accumulation would tend to promote the pathway toward adenine nucleotides. Also, because the conversion of XMP to GMP is ATP-dependent, accumulation of ATP could promote guanine nucleotide synthesis.

Nucleotides are active in metabolism primarily as the nucleoside triphosphates. GMP and AMP are converted to their corresponding triphosphates through two successive phosphorylation reactions. Conversion to the diphosphates involves specific ATP-dependent kinases.

Phosphorylation of ADP to ATP occurs through energy metabolism—oxidative phosphorylation or substrate-level phosphorylations or (in plants) photophosphorylation. ATP can also be formed from ADP through the action of adenylate kinase, acting in the reverse of the direction shown here.

ATP is the phosphate donor for conversion of GDP (and other nucleoside diphosphates) to the triphosphate level through the action of **nucleoside diphosphate kinase**. This enzyme is highly active and has broad specificity, with regard to both phosphoryl group donor and acceptor.

Because ATP is by far the most abundant nucleoside triphosphate in most cells, equilibrium and mass action considerations dictate that it is used most readily as the donor of the γ (outer) phosphate in synthesis of other nucleoside triphosphates.

In most organisms the biosynthesis of deoxyribonucleotides for DNA synthesis begins at the ribonucleoside diphosphate level, with reduction of the ribose moiety to 2' deoxyribose. This process is presented in detail later. In purine metabolism, subsequent phosphorylation by nucleoside diphosphate kinase yields the deoxyribonucleoside triphosphates, dATP and dGTP.

Regulation of De Novo Purine Biosynthesis

Figure 22.7 summarizes the points of feedback regulation in de novo purine biosynthesis. Control over the biosynthesis of IMP is provided through feedback regulation of the early steps in purine nucleotide synthesis. PRPP synthetase (page 920) is inhibited by various purine nucleotides—particularly AMP, ADP, and GDP—and PRPP amidotransferase (reaction 1 of Figure 22.4) is inhibited allosterically by AMP, ADP, GMP, and GDP. This amidotransferase is also allosterically activated by PRPP, one of its substrates. Beyond the IMP branch point, GMP controls its own biosynthesis by inhibiting the conversion of IMP to XMP, and AMP controls its own formation by inhibiting the synthesis of adenylosuccinate (Figure 22.6). Additional control is exerted at the level of deoxyribonucleotide biosynthesis, as we discuss later. In bacteria, the expression of genes encoding these enzymes is controlled by a repressor protein (see Chapter 26), the product of the *purR* gene. This protein binds either hypoxanthine or guanine, and the resultant protein–purine base complex binds to DNA sites upstream of several genes of purine (and pyrimidine) synthesis, thereby inhibiting their transcription.

Utilization of Adenine Nucleotides in Coenzyme Biosynthesis

An important metabolic role of purine nucleotides is the synthesis of coenzymes, primarily those containing an adenylate moiety. These include the flavin

Nucleoside diphosphate kinase, an equilibrium-driven enzyme, transfers a phosphoryl group from ATP in the synthesis of all other nucleoside triphosphates.

FIGURE 22.7

Regulation of de novo purine biosynthesis.

nucleotides, the nicotinamide nucleotides, and coenzyme A, as shown in the following summary:

Purine Degradation and Clinical Disorders of Purine Metabolism

Formation of Uric Acid

All purine degradation leads to uric acid. In some animals, additional degradation occurs.

Purine nucleotide catabolism yields uric acid, by routes shown in Figure 22.8. The specific pathways vary among organisms and among tissues of the same organisms, but the general strategy is conversion of the nucleotides to nucleosides, cat-

FIGURE 22.8

Catabolism of purine nucleotides to uric acid.

alyzed by **nucleotidases**, removal of the ribose-1-phosphate moiety, catalyzed by **purine nucleoside phosphorylase (PNP)**, and finally oxidation of the free bases to uric acid. Mammalian purine nucleoside phosphorylase cannot act on adenosine or deoxyadenosine, so adenosine must be first deaminated by **adenosine deaminase (ADA)** to give inosine. Alternatively, AMP is deaminated to inosinic acid (IMP). Inosine, xanthosine, and guanosine can be formed by hydrolysis of the respective nucleoside monophosphates, which are acted on by PNP to give hypoxanthine, xanthine, and guanine, respectively. Guanine is deaminated to xanthine by **guanine deaminase**, an enzyme abundant in mammalian brain and liver. Hypoxanthine is oxidized to xanthine, and xanthine to uric acid, by **xanthine oxidoreductase**. This enzyme, which oxidizes several other heterocyclic nitrogen compounds, contains bound FAD, two Fe_2S_2 clusters, and a molybdopterin complex. Two forms of the enzyme are found in mammals, referred to as xanthine dehydrogenase (XDH) and xanthine oxidase (XO), respectively. XDH predominates in healthy tissues, but under pathological conditions the protein is readily converted to XO through the reversible formation of a cysteine disulfide bond or by the irreversible proteolytic cleavage of XDH into three fragments. In both forms of the enzyme, oxidation of xanthine takes place at the molybdopterin center, and the electrons are rapidly transferred to FAD via the Fe_2S_2 clusters. The two forms differ, however, in the electron acceptor used to reoxidize the enzyme. XDH uses NAD^+ to reoxidize the reduced flavin on the enzyme, whereas XO uses molecular oxygen. Thus, the XO form of the enzyme ultimately reduces oxygen to H_2O_2 , which is acted upon by catalase (see page 667).

In either mechanism, the keto oxygen atoms at C8 (and C2) derive from H_2O ; the initial product of xanthine oxidation is the enol form of uric acid ($\text{pK} = 5.4$) that tautomerizes to the more stable keto form.

Purine catabolism in humans and the great apes, birds, reptiles, and insects ends with uric acid, which is excreted. However, most animals possess additional enzymes to further oxidize the purine ring to **allantoin** (excreted by other mammals) and then to **allantoic acid**, which is either excreted (in teleost fishes) or further catabolized to urea (in cartilaginous fishes, some molluscs, and amphibians) or ammonia (in most marine invertebrates). Figure 22.9 shows the pathway from uric acid to CO_2 .

Excessive Accumulation of Uric Acid: Gout

Uric acid and its urate salts are quite insoluble. This property is advantageous in birds, reptiles, and insects because it provides a route for disposition of excess nitrogen that uses very little water: the waste material is excreted essentially as uric acid crystals. However, the insolubility of urates can present difficulties in mammalian metabolism, and most mammals possess an active urate oxidase to convert uric acid to allantoin (Figure 22.9). However, some 8–24 million years ago, several mutations accumulated in the urate oxidase gene during hominid evolution, leading to loss of function of this enzyme in humans and the great apes. Lack of urate oxidase activity results in >10-fold higher levels of uric acid in the blood of humans and most primates than in other mammals. Uric acid is a powerful scavenger of free radicals, providing protection against oxidative damage. Evolution might have selected for mutations in hominid urate oxidase that led to higher uric acid levels. On the other hand, these high concentrations predispose humans to crystalline uric acid deposition. Indeed, in North America and Europe, about 3 individuals in 1000 suffer from **hyperuricemia**—chronic elevation of blood uric acid levels well beyond the already high levels. Although the biochemical reasons for hyperuricemia vary, the condition goes by the single clinical name of **gout**. Prolonged or acute elevation of blood urate leads to its precipitation, as crystals of sodium urate, in the synovial fluid of joints. These precipitates cause inflammation, resulting in a painful arthritis, which, if untreated, leads ultimately to severe degeneration of the joints. Eating and drinking purine-rich foods are apt to

FIGURE 22.9

Catabolism of uric acid to ammonia and CO_2 .

stimulate acute gouty attacks in susceptible individuals. Because such foods include “rich” items such as liver, sweetbreads, anchovies, and wine, gout is historically associated with an excess of high living.

Gout results either from overproduction of purine nucleotides, leading to excessive uric acid synthesis, or from impaired uric acid excretion through the kidneys. Several specific enzymatic defects can lead to excessive purine synthesis, as shown in Figure 22.10. One form of gout is characterized by elevated activity of PRPP synthetase (defect 1). Some inherited point mutations in the PRPP synthetase gene cause the enzyme to become resistant to feedback inhibition by purine nucleotides. Because the activity of PRPP amidotransferase (E1 in Figure 22.4) is controlled in part by the concentrations of substrates, an elevation of the steady-state pool of PRPP increases flux through the amidotransferase reaction, which represents a major control point in de novo purine biosynthesis (see Figure 22.7). Another form of gout results from deficiency of the salvage enzyme **hypoxanthine–guanine phosphoribosyltransferase (HGPRT)** (defect 2 in Figure 22.10).

HGPRT salvages both hypoxanthine and guanine. This is one of two phosphoribosyltransferases in animal purine metabolism; the other enzyme, **adenine phosphoribosyltransferase (APRT)**, is specific for adenine.

How does an HGPRT deficiency increase the rate of purine nucleotide synthesis? The HGPRT reaction, when active, consumes PRPP. Decreased flux through this reaction, when the enzyme is deficient, raises the steady-state level of PRPP. Elevated levels of PRPP increase flux through PRPP amidotransferase via mass action and allosteric activation, leading to increased purine biosynthesis.

Several known genetic alterations in purine metabolism can lead to purine oversynthesis, uric acid overproduction, and gout.

Patients with glucose-6-phosphatase deficiency (glycogen storage disease type I; Chapter 13) are also gouty (defect 3 in Figure 22.10). Again, PRPP appears to be the key. Glucose-6-phosphate accumulation in the liver stimulates the

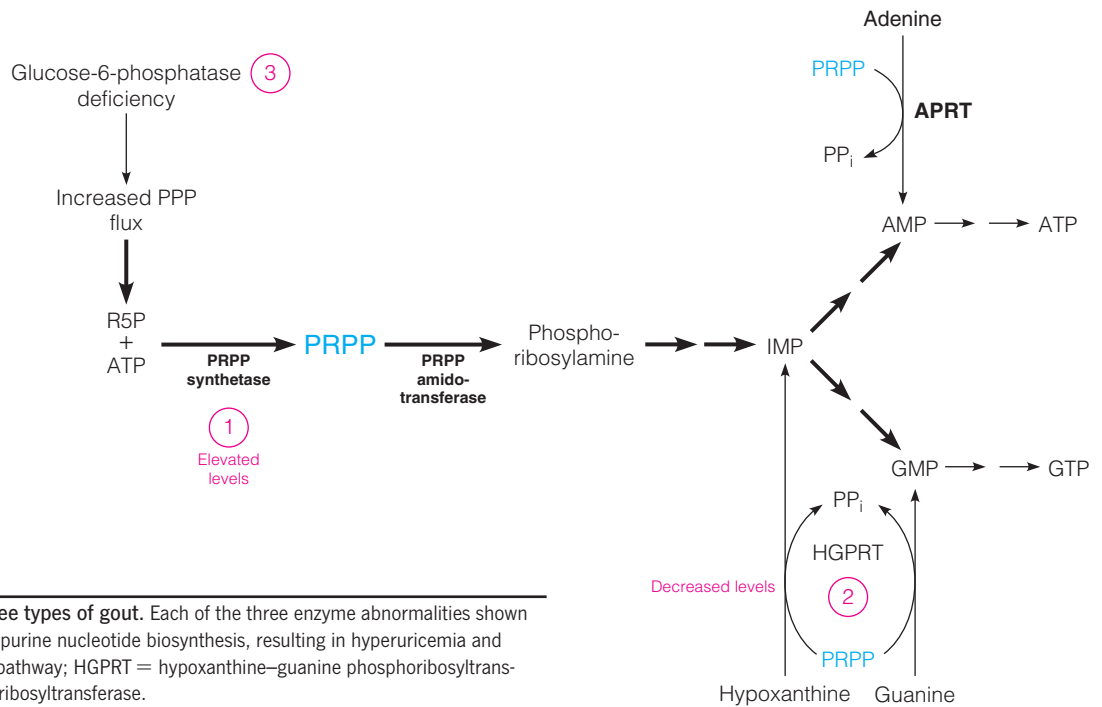

FIGURE 22.10

Enzymatic abnormalities in three types of gout. Each of the three enzyme abnormalities shown here elevates the rate of de novo purine nucleotide biosynthesis, resulting in hyperuricemia and gout. PPP = pentose phosphate pathway; HGPRT = hypoxanthine–guanine phosphoribosyltransferase; APRT = adenine phosphoribosyltransferase.

oxidative branch of the pentose phosphate pathway (Chapter 13), resulting in elevated ribose-5-phosphate, and thus PRPP, through the PRPP synthetase reaction. As noted earlier, gout also results from impaired uric acid excretion. In patients with glucose-6-phosphatase deficiency, prolonged hypoglycemia causes accumulation of organic acids (lactate and the like), and this accumulation interferes with tubular secretion of uric acid in the kidney. Gout is also a consequence of cancer chemotherapy, presumably resulting from an overload of purines caused by nucleic acid degradation after death of tumor cells.

Many cases of gout are successfully treated by the antimetabolite **allopurinol**, a structural analog of hypoxanthine in which the N7 and C8 positions are interchanged. Xanthine dehydrogenase hydroxylates allopurinol at C2 (as it does hypoxanthine), giving **alloxanthine**, which remains tightly bound to the reduced form of the enzyme. Allopurinol is thus a suicide substrate that strongly inhibits xanthine dehydrogenase. This inhibition causes accumulation of hypoxanthine and xanthine, both of which are more soluble and, hence, more readily excreted than is uric acid.

Salvage of Purines and Lesch–Nyhan Syndrome

Nucleic acids, particularly RNAs, are subject to degradation by nucleases which release nucleotides. These nucleotides are eventually enzymatically hydrolyzed to free purine and pyrimidine bases. Vertebrates can *salvage* free purine bases by converting them back into nucleotides for reuse in nucleic acid biosynthesis. The two major enzymes involved, adenine phosphoribosyltransferase (APRT) and hypoxanthine-guanine phosphoribosyltransferase (HGPRT), were described above. In humans, as much as 90% of free purines are salvaged and reused, rather than degraded or excreted. Careful analysis of patients with simple gout resulting from HGPRT deficiency reveals low but significant residual levels of the affected enzyme. Evidently the mutations involved alter the catalytic activity of the enzyme but do not abolish it completely. Far more serious consequences result from “null mutations” in the hypoxanthine-guanine phosphoribosyltransferase gene, which result in total absence of the HGPRT enzyme. Guanine and hypoxanthine are not salvaged, and are instead degraded by the pathways in Figure 22.8, leading to excess excretion of uric acid. This condition was first described in 1964 by medical student Michael Lesch and his faculty mentor, William Nyhan. Lesch–Nyhan syndrome is a sex-linked recessive trait because the structural gene for HGPRT is located on the X chromosome. Patients with this condition display a severe gouty arthritis, but they also have a dramatic malfunction of the nervous system, manifested as behavioural disorders, motor disability, learning disability, and hostile or aggressive behavior, often self-directed. In the most extreme cases, patients nibble at their fingertips or, if restrained, their lips, causing severe self-mutilation. Nyhan has likened this behavior to “nailbiting, with the volume turned up.” The biochemical reason for this bizarre behavioural pattern is unknown, but the condition, even though rare, is of great interest because all of the aberrations derive ultimately from the single well-characterized enzyme deficiency affecting HGPRT levels. At present there is no successful treatment, and afflicted individuals have such severe gouty arthritis that they rarely live beyond 20 years. Overproduction of uric acid can be blocked by allopurinol, but this treatment has no efficacy against the neurological features of Lesch–Nyhan syndrome. However, the condition can be diagnosed prenatally through amniocentesis, by molecular genetic analysis of the HGPRT gene.

Unexpected Consequences of Defective Purine Catabolism: Immunodeficiency

A surprising feature of human purine metabolism came to light in 1972, through studies on a hereditary condition called **severe combined immunodeficiency disease (SCID)**. Patients with this condition are susceptible, often fatally, to infectious diseases because of a total inability to mount an immune response to antigenic challenge. This disease was made famous by the case of David Vetter, the “bubble boy”

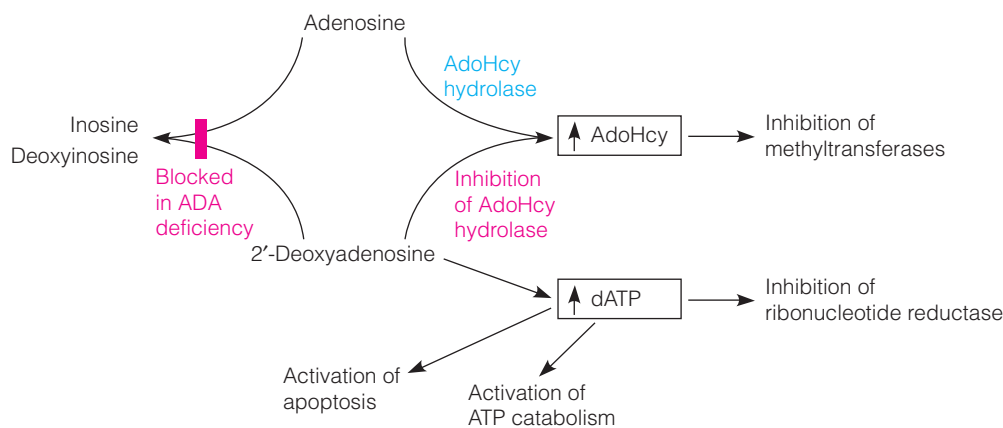

FIGURE 22.11

Metabolic consequences of adenosine deaminase (ADA) deficiency. AdoHcy, S-adenosylhomocysteine.

who lived his entire life in a sterile environment. In this condition, both B and T lymphocytes are affected; neither class of cells can proliferate as they must if antibodies are to be synthesized. In many such cases the immunodeficiency results from a heritable lack of the degradative enzyme adenosine deaminase (see Figure 22.8).

What is the basis for this unexpected relationship? First, adenosine deaminase (ADA) also acts on 2'-deoxyadenosine, which arises from the degradation of DNA (Figure 22.11). Second, white blood cells have abundant levels of salvage enzymes, including nucleoside kinases; thus, adenosine and 2'-deoxyadenosine that accumulate are readily converted in white cells to their respective nucleotides. These nucleotides include dATP, which is known to be a potent inhibitor of DNA replication because it inhibits the synthesis of deoxyribonucleotides from ribonucleotides (see page 940). White cells must proliferate for an immune response to occur. In turn, proliferation requires ample synthesis of DNA and its precursors. Additional mechanisms are involved because 2'-deoxyadenosine has been found to kill white cells even when they are not proliferating. One such mechanism came to light in 1997, when elevated dATP was reported to be a signaling agent that helped to trigger early metabolic events leading to apoptosis (Chapter 28). Finally, 2'-deoxyadenosine is an irreversible inhibitor of S-adenosylhomocysteine (AdoHcy) hydrolase, the enzyme in the methyl cycle (Figure 21.9, page 876) responsible for hydrolyzing AdoHcy to adenosine and homocysteine. This causes AdoHcy to accumulate, which inhibits S-adenosylmethionine-dependent methyltransferases, including those required for normal DNA and histone methylation reactions (Figure 22.11).

The standard treatment for ADA deficiency enzyme replacement requires frequent injections of purified bovine ADA covalently attached to the inert polymer polyethylene glycol (PEG-ADA). Although PEG-ADA often corrects the metabolic abnormalities, defects in the immune system usually persist. Partly because of the limitations of the standard therapy, adenosine deaminase deficiency was the first human disease to be treated by gene therapy. In 1990, a four-year-old girl with the condition was treated with a viral vector into which the gene for adenosine deaminase had been spliced by recombinant DNA technology, in hopes that the engineered virus would establish itself in enough cells to yield sufficient enzyme to degrade the accumulated deoxyadenosine compounds. This first gene therapy patient, now in her mid twenties, is still relatively healthy. However, she still receives periodic gene therapy and PEG-ADA to maintain the necessary levels of the enzyme in her blood. Thus, while the treatment proved safe, it is not clear how effective the gene therapy would have been alone.

A less severe immunodeficiency results from the lack of another purine degradative enzyme, purine nucleoside phosphorylase (PNP) (see Figure 22.8). Decreased activity of this enzyme leads to accumulation primarily of dGTP and 2'-deoxyguanosine. This accumulation also affects DNA replication, but less severely than does excessive dATP. Interestingly, the phosphorylase deficiency destroys only the T class of lymphocytes and not the B cells.

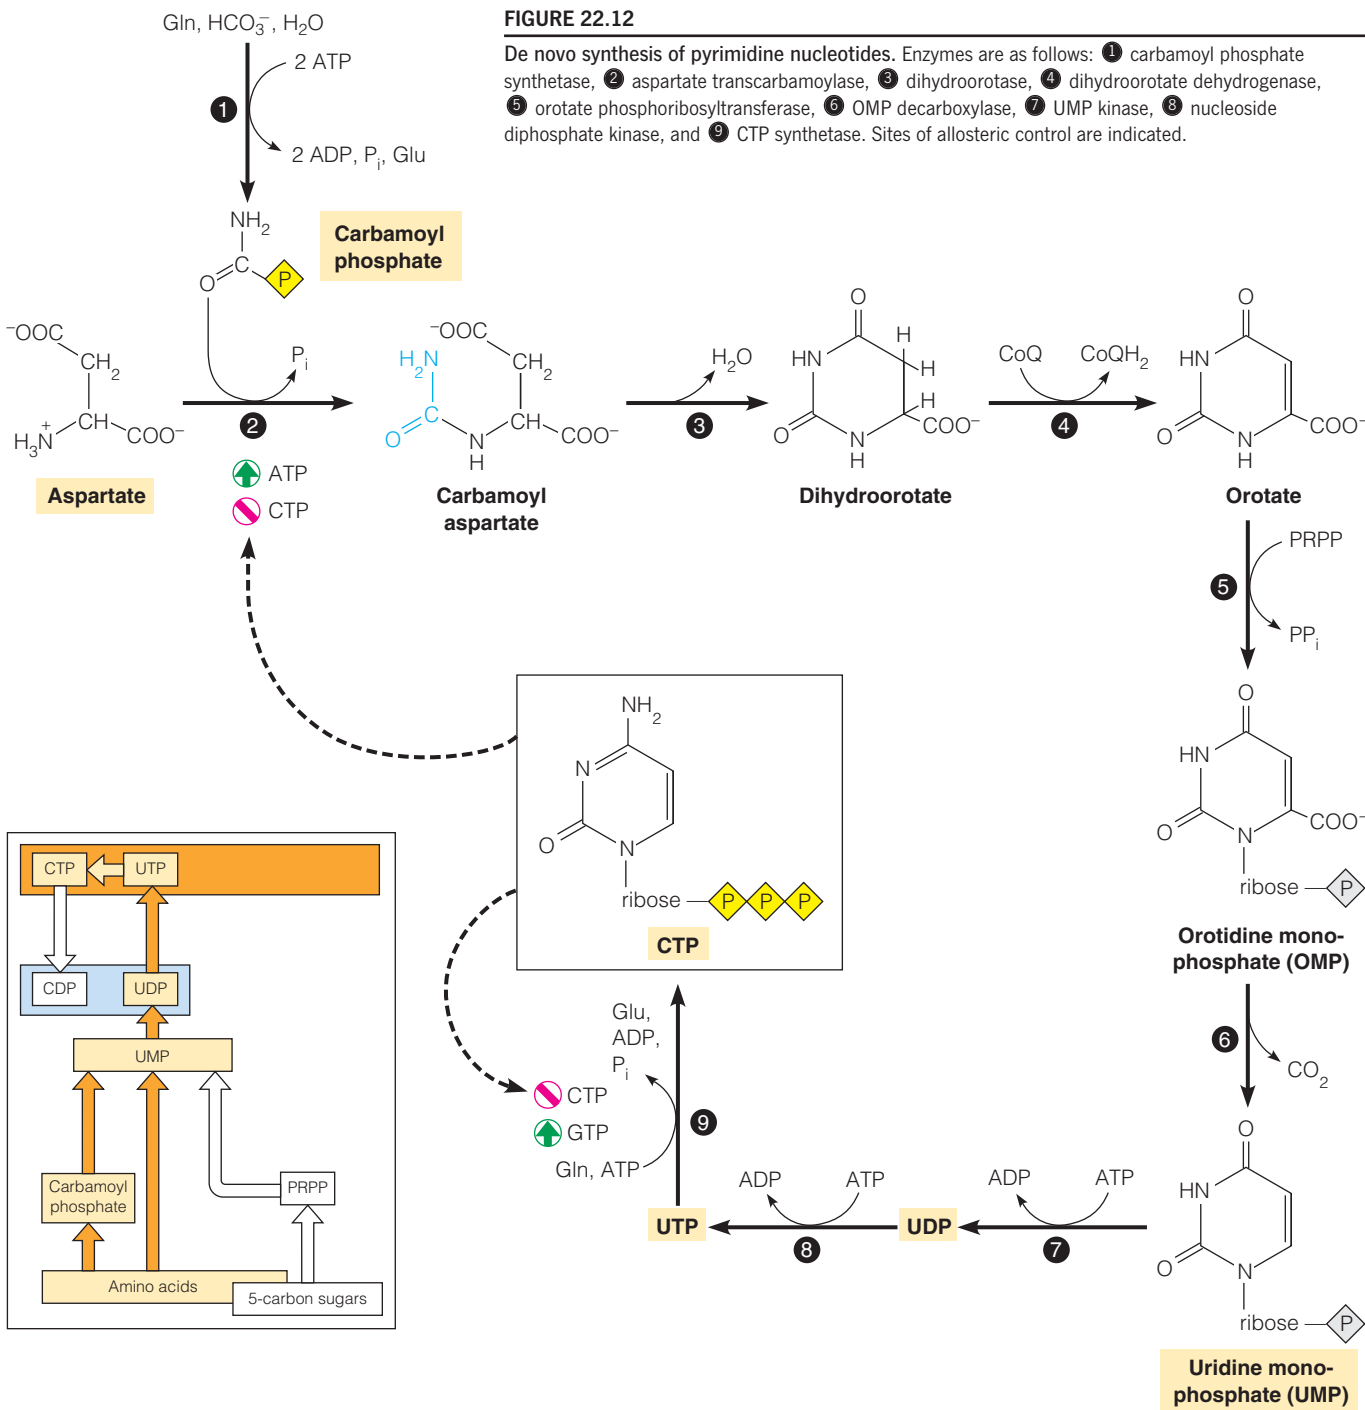

Pyrimidine Nucleotide Metabolism

De Novo Biosynthesis of the Pyrimidine Ring

Now we turn our attention to pyrimidine nucleotide biosynthesis. Pyrimidine biosynthesis is much simpler than formation of the structurally more complex purine nucleotides, with just two precursors, aspartate and carbamoyl phosphate, providing all the C and N atoms of the pyrimidine ring. As summarized in Figure 22.12, however, there are two major distinctions from the purine pathway. First, the pyrimidine ring is assembled as a free base, with conversion to a nucleotide occurring later in the pathway, when the base **orotic acid** is converted

Pyrimidine nucleotide synthesis occurs primarily at the free base level, with conversion to a nucleotide occurring late in the unbranched pathway.

to orotidine monophosphate, or OMP. Second, the pyrimidine pathway is unbranched. Uridine triphosphate, one of the two common ribonucleoside triphosphates and hence an end product of the pathway, is also the substrate for formation of cytidine triphosphate, the other end product.

Pyrimidine synthesis begins with formation of carbamoyl phosphate, a reaction catalyzed by **carbamoyl phosphate synthetase** that was first presented in Chapter 20 (see page 831 and reaction 1 in Figure 22.12). Carbamoyl phosphate is formed from ATP, bicarbonate, and the amide nitrogen from glutamine. This amidotransferase reaction involves four separate chemical steps:

Bacterial carbamoyl phosphate synthetase (CPS) is a heterodimer composed of a large subunit and a small subunit. The X-ray crystal structure of the *E. coli* CPS revealed the various substrate binding sites and the domains where the individual steps are catalyzed (Figure 22.13). The small subunit functions as a glutaminase, catalyzing the hydrolysis of glutamine to form ammonia, which is delivered to the large subunit. The large subunit contains two active sites: one binds bicarbonate, ATP, and ammonia and catalyzes carboxyphosphate and carbamate synthesis; the other active site binds a second ATP and catalyzes carbamoyl phosphate formation. The three unstable intermediates (ammonia, carboxyphosphate, and carbamate) do not diffuse from the enzyme until converted to the final product, carbamoyl phosphate. The crystal structure revealed a remarkable 96 Å tunnel in the interior of the enzyme through which the intermediates are channeled from one active site to the next (Figure 22.13). This direct transfer of reactive intermediates between active sites is a common feature in many enzymes, and is one mechanism by which enzymes increase reaction efficiency and avoid unwanted side reactions with unstable intermediates.

Recall from Chapter 20 that eukaryotic cells contain two forms of CPS. Form I, localized in mitochondria, has a preference for ammonia as substrate and is used in arginine biosynthesis (Chapter 21) and the urea cycle (Chapter 20). Form II, present in the cytosol, has a strong preference for glutamine as nitrogen donor, and is the enzyme that participates in pyrimidine biosynthesis.

Carbamoyl phosphate, preactivated by the two ATPs used in its synthesis, next condenses with aspartate to form carbamoylaspartate. This reaction, catalyzed by **aspartate transcarbamoylase (ATCase)**, involves nucleophilic attack by the α -amino

FIGURE 22.13

Channeling in carbamoyl phosphate synthetase. This figure shows the X-ray crystal structure of the heterodimeric *E. coli* enzyme (PDB ID 1C30). The small subunit (cyan) functions as a glutaminase. The two active sites in the large subunit are marked by bound ADP molecules. The N-terminal domain of the large subunit (pink) contains the active site for the synthesis of carboxyphosphate and carbamate. The C-terminal domain of the large subunit (blue) contains the active site for the synthesis of carbamoyl phosphate. The 96 Å tunnel connecting the three active sites is shown in green dotted lines.

group of aspartate on the electrophilic carbonyl C of carbamoyl phosphate, with release of P_i . The pyrimidine ring is closed in an intramolecular condensation catalyzed by **dihydroorotase**. Dihydroorotate is next oxidized to orotate (6-carboxyuracil) by **dihydroorotate dehydrogenase**. The bacterial enzymes are typically NAD^+ -linked flavoproteins, containing both FAD and FMN. Eukaryotic dihydroorotate dehydrogenase is also a flavoprotein, but is located on the intermembrane face of the mitochondrial inner membrane, where it is reoxidized by coenzyme Q (ubiquinone), directly linking pyrimidine biosynthesis to electron transport. This localization means the substrate, dihydroorotate, must enter the mitochondrial intermembrane space and the product, orotate, must exit back into the cytoplasm. Inherited mutations in the dihydroorotate dehydrogenase gene have recently been identified as the cause of **Miller syndrome**. This rare disease is characterized by developmental anomalies including cleft lip or palate, absent digits, and ocular anomalies.

The ribose-5-phosphate moiety is attached next, using PRPP as the donor, to form orotidine monophosphate (OMP). This reaction is driven forward by hydrolysis of the eliminated PP_i . **Orotate phosphoribosyltransferase**, like all the other phosphoribosyltransferases we have discussed, is stereospecific for formation of a β glycosidic linkage. The final step of the pathway is a decarboxylation, yielding uridine monophosphate (UMP). UMP is phosphorylated to UTP by sequential action of nucleoside mono- and diphosphate kinases. CTP is synthesized from UTP by a glutamine-dependent amidotransferase reaction, catalyzed by **CTP synthetase**.

Control of Pyrimidine Biosynthesis in Bacteria

The first reaction committed solely to pyrimidine synthesis is the formation of carbamoyl aspartate from carbamoyl phosphate and aspartate, catalyzed by ATCase (reaction 2). In enteric bacteria, this enzyme represents a marvelous example of feedback control, as was discussed at length in Chapter 11. Recall that the enzyme is inhibited by the end product CTP and activated by ATP, the latter possibly representing a mechanism to keep purine and pyrimidine biosyntheses in balance. Recall also that the enzyme contains six each of two types of subunits, arranged as two catalytic trimers and three regulatory dimers.

Bacteria also regulate pyrimidine metabolism through control of the *synthesis* of ATCase and the other enzymes. The rate of transcription of an operon encoding both of the ATCase subunits can vary by as much as 150-fold, depending on the intracellular level of UTP. The higher the UTP concentration, the lower the rate of transcription of these genes.

Multifunctional Enzymes in Eukaryotic Pyrimidine Synthesis

Aspartate transcarbamoylase (reaction 2 in Figure 22.12) in eukaryotes is strikingly different from the *E. coli* enzyme. This came to light through analysis of ATCase inhibition by ***N*-phosphonoacetyl-L-aspartate (PALA)**.

This compound, synthesized as an analog of the putative transition-state complex formed between the two substrates, inhibits pyrimidine synthesis in mammalian cells. However, cells eventually develop resistance to it, because levels of ATCase rise in these cells beyond the capacity of PALA to inhibit all of the activity. Surprisingly, these resistant cells contain similarly elevated levels of carbamoyl phosphate synthetase

In eukaryotes the first three reactions of pyrimidine synthesis are catalyzed by a trifunctional enzyme, the CAD protein. Similarly, the last two reactions are catalyzed by a bifunctional enzyme, UMP synthase.

FIGURE 22.14

Catabolic pathways in pyrimidine nucleotide metabolism.

(reaction 1 in Figure 22.12) and dihydroorotase (reaction 3). The explanation for this observation came with the discovery of a single protein containing 3–6 identical polypeptide chains, each with M_r of about 220,000, that catalyzes all three reactions.

George Stark has given this trifunctional enzyme the acronym **CAD** (from the first letter in the name of each enzyme). He showed that the protein accumulates in PALA-resistant cells because the gene encoding the protein becomes amplified as a consequence of the selective pressure exerted by PALA; resistant cells contain many more copies of the gene than the normal complement of two copies per diploid cell. This phenomenon of gene **amplification** has now been observed many times in eukaryotic cells exposed to prolonged and specific stresses. We discuss the mechanisms involved in Chapter 26.

In mammalian cells, reactions 5 and 6 in Figure 22.12 are also catalyzed by a single protein, which has been named **UMP synthase**. A severe deficiency in this bifunctional enzyme is responsible for a rare genetic disease in humans, **hereditary orotic aciduria**. As the name implies, patients with this defect accumulate orotic acid, exactly what you would expect for a block at the orotate phosphoribosyltransferase reaction.

In contrast to bacteria, where the six reactions of pyrimidine biosynthesis are catalyzed by six distinct monofunctional enzymes, eukaryotes combine these activities on just three proteins (one trifunctional, one bifunctional, and one monofunctional). We don't know much about how this affects regulation of pyrimidine biosynthesis, but the juxtaposition of active sites may allow channeling, as mentioned for the multifunctional proteins in purine synthesis. Recall that dihydroorotate dehydrogenase (reaction 4 in Figure 22.12) is localized at the intermembrane space side of the inner mitochondrial membrane, whereas the bifunctional and trifunctional enzymes are both cytosolic. Given that intermediates must travel into and then out of the mitochondria, the kinetic advantage provided by channeling of the first and last steps would seem to be negated. However, both CAD and UMP synthase have been detected at the cytoplasmic face of the outer mitochondrial membrane, providing a mechanism to allow direct transfer of substrates and products across the outer membrane.

Another site for control of pyrimidine nucleotide synthesis is CTP synthetase (reaction 9). This enzyme is inhibited allosterically by its product CTP and is activated by GTP.

Salvage Synthesis and Pyrimidine Catabolism

Pyrimidine nucleotides are also synthesized by salvage pathways involving phosphorylases and kinases, comparable to those already discussed for purines. The catabolic pathways for pyrimidines, summarized in Figure 22.14, are simpler than those for purines. Because the intermediates are relatively soluble, there are few known derangements of pyrimidine breakdown. One of the breakdown products, β -alanine, is used in the biosynthesis of coenzyme A.

Glutamine-Dependent Amidotransferases

Glutamine-dependent aminations that utilize ATP hydrolysis as the driving force are a common theme in purine and pyrimidine biosynthesis. Five different reactions in these two pathways are catalyzed by glutamine-dependent amidotransferases: PRPP amidotransferase and FGAR amidotransferase (steps 1 and 4 in Figure 22.4); GMP synthetase (step G-2 in Figure 22.6); and carbamoyl phosphate synthetase and CTP synthetase (steps 1 and 9 in Figure 22.12). All these enzymes are believed to use a similar mechanism (summarized in Figure 22.15), in which the glutamine amido group (unreactive, non-nucleophilic) is activated by hydrolysis at the active site to deliver nucleophilic ammonia in high local concentrations sufficient to aminate the specific acceptor (usually the carbonyl group of an amide). ATP serves as an energy

FIGURE 22.15

Proposed mechanism of glutamine-dependent amidotransferases. (a) The acceptor, usually an amide, is in tautomeric equilibrium with the isoamide form and is activated for nucleophilic attack by phosphorylation. Attack by nucleophilic ammonia, generated from glutamine hydrolysis, forms a tetrahedral intermediate, which collapses to give P_i and the aminated product. (b) Schematic of the subunit (or domain) structure of a glutamine-dependent amidotransferase. The glutaminase subunit (or domain) delivers nucleophilic ammonia to the amidotransferase subunit (or domain), which catalyzes the ATP-dependent amination of the acceptor.

input to force the equilibrium in the amination direction, generally by forming a phosphorylated derivative of the substrate that can then act as a good leaving group upon attack by nucleophilic NH_3 . Most of these enzymes can use NH_3 directly, but they exhibit a much higher K_m for ammonia than for glutamine. Note that PRPP amidotransferase, the first enzyme in purine biosynthesis, does not require ATP to aminate PRPP. However, the ribose C1 was previously activated by ATP in the PRPP synthetase reaction (page 920), as PP_i becomes an excellent leaving group in the subsequent nucleophilic substitution.

These enzymes are typically composed of two subunits (or domains) in which one catalyzes the glutaminase reaction (generation of nucleophilic NH_3) and the other catalyzes amination of the specific acceptor (recall CPS, Figure 22.13). In fact, the glutaminase subunits (or domains) are clearly evolutionarily related between various amidotransferases, within and across species.

Deoxyribonucleotide Biosynthesis and Metabolism

Most cells contain 5 to 10 times as much RNA as DNA. Moreover, as we have seen, ribonucleotides have multiple metabolic roles, while deoxyribonucleotides serve only as constituents of DNA. Therefore, most of the carbon that flows through nucleotide synthetic pathways goes into ribonucleoside triphosphate (rNTP) pools. However, the relatively small fraction that is diverted to the synthesis of deoxyribonucleoside triphosphates (dNTPs) is of paramount importance in the life of the cell. Consequently, there are especially close regulatory relationships between DNA synthesis and dNTP metabolism—more so than seen between other macromolecular biosyntheses and the pathways that provide their precursors. Overall pathways of dNTP biosynthesis are shown in Figure 22.16.

Recalling that DNA differs chemically from RNA in the nature of the sugar and in the identity of one of the pyrimidine bases, we can focus our discussion of deoxyribonucleotide biosynthesis on two specific processes—the conversion of ribose to deoxyribose, and the conversion of uracil to thymine. Both of these processes occur at the nucleotide level. Both processes are of great interest mechanistically, as target sites for chemotherapy for cancer or infectious diseases and from the standpoint of regulation. Accordingly, we shall present both processes in some detail.

FIGURE 22.16

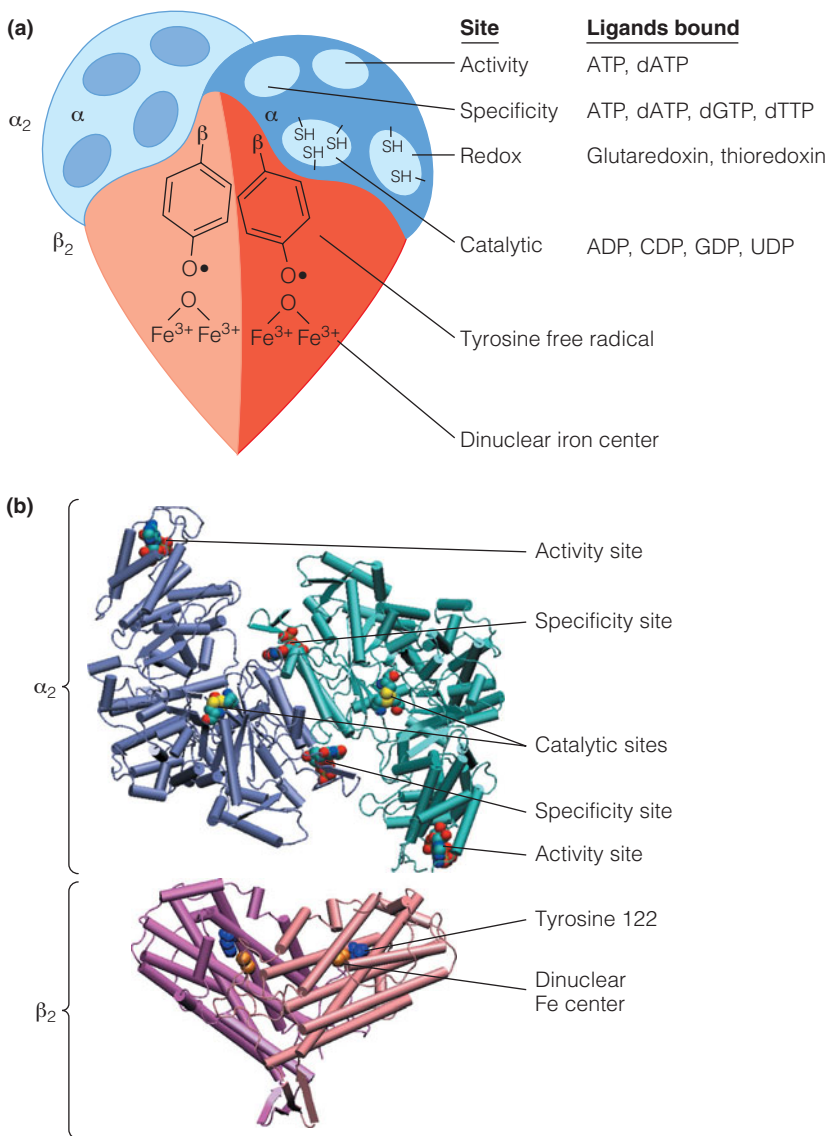

Overview of deoxyribonucleoside triphosphate (dNTP) biosynthesis.

Reduction of Ribonucleotides to Deoxyribonucleotides

One enzyme, ribonucleotide reductase, reduces all four ribonucleotides to their deoxyribose derivatives.

Mechanistically, the reduction of ribose to deoxyribose involves replacement of the hydroxyl at C-2 by a hydrogen atom, with retention of configuration. Peter Reichard showed that this difficult reaction occurs at the nucleotide level, and this led to his discovery of the important enzyme **ribonucleotide reductase**. In all organisms studied thus far, a single enzyme reduces all four common ribonucleotide substrates to the corresponding 2-deoxyribonucleotides. A protein radical mechanism is involved in the reaction. Although evolution has created three widely diverse mechanisms for generating the protein radical, the three classes of ribonucleotide reductase evidently all use the same fundamental chemistry to reduce the substrates. The most widely distributed enzyme form, called class I ribonucleotide reductase, acts upon ribonucleoside diphosphate substrates, leading it to be also called **rNDP reductase**. This enzyme generates its radical on a specific tyrosine

**FIGURE 22.17**

Structure of *E. coli* ribonucleoside diphosphate reductase. **(a)** A schematic diagram identifying the functional center of β_2 (R2)—a tyrosine free radical and a dinuclear iron center with a bridged oxygen. Shown also are the ligand-binding sites in α_2 (R1): a redox site for interaction with an external electron donor, the catalytic site, the activity site, and the substrate specificity site. The activity and specificity sites are allosterically controlled. The redox site contains two functional cysteine residues, and the catalytic site contains three. **(b)** X-ray crystal structures of the homodimeric α_2 (blue and cyan) (PDB ID 3R1R, 4R1R) and β_2 (red and pink) (PDB ID 1PFR) proteins. The catalytic sites are marked by three cysteine residues in each α_2 subunit (Cys225, 462, and 439). The activity and specificity sites are marked by bound ATP and dTTP, respectively. In the β_2 dimer, Tyr 122 (blue), which carries the free radical, and the dinuclear iron center (orange) are shown. The precise orientation of the α_2 and β_2 proteins in the tetramer is not known.

residue, with the aid of a diferric oxygen bridge (see Figure 22.17). The class II enzymes, found in cyanobacteria, some bacteria, and *Euglena*, act upon ribonucleoside triphosphate substrates and use adenosylcobalamin, a B₁₂ coenzyme (Chapter 20), to generate a free radical. The type III enzyme, found only in facultative or obligate anaerobes, also acts upon ribonucleoside triphosphate substrates. These enzymes use *S*-adenosylmethionine and an iron–sulfur center to generate the catalytically essential radical on a glycine residue. Our discussion will focus on class I, the most widespread form, whose action is shown at the top of Figure 22.16.

Structure of rNDP Reductase

As found in *E. coli* and mammalian cells, the class I rNDP reductases contain two nonidentical subunits, denoted α and β . In *E. coli*, the active form of the enzyme is composed of two 87,000-dalton α chains and two 43,000-dalton β chains. The active form of the mammalian enzyme is thought to be an $\alpha_6\beta_2$ oligomer at physiological ATP/dATP concentrations. However, the $\alpha_2\beta_2$ heterotetramer is fully active and is the form receiving the most attention regarding mechanism and regulation of the enzyme. As we shall see, regulation by allosteric modifiers involves changes in oligomerization state. The structure of the heterotetrameric form of the *E. coli* enzyme is illustrated in Figure 22.17. The catalytic site lies in the α_2 subunits. Within this site are three cysteine residues, which are conserved among

Ribonucleotide reductase contains catalytic residues on each of its subunits—redox-active thiols and a tyrosine free radical stabilized by an iron–oxygen complex.

different rNDP reductases. Two of the cysteine thiols are **redox-active**, so called because they undergo cyclic oxidation and reduction during the reaction. The third cysteine evidently functions as part of a free radical mechanism, as described in the next section.

The radical for ribonucleotide reduction is generated on a tyrosine residue in the β_2 subunits and transmitted via a radical transfer pathway over 35 Å to the subunits where the catalysis occurs. The β_2 subunits also contain an oxygen atom bridging two ferric ions near the tyrosine residues. This **dinuclear iron center** generates and stabilizes the tyrosyl radical. The α_2 subunits contain two classes of regulatory sites, which we shall discuss shortly. Finally, the α_2 subunits carry an additional pair of redox-active thiol groups, which interact with an external reductive cofactor. The mammalian enzyme is similar in structure.

Mechanism of Ribonucleotide Reduction

Although the precise mechanism of the rNDP reductase reaction is still under intense study, we can formulate a plausible mechanism based on the following observations. (1) Radiolabeling studies show that cleavage of the ribose C-3'—H bond occurs during the reaction. (2) The reaction proceeds with retention of configuration at C-2', which rules out displacement of the hydroxyl group by a hydride ion in an S_N2 reaction. (3) The thiol groups undergo oxidation during the reaction. (4) The tyrosine free radical participates in the reaction. This was shown first by the fact that **hydroxyurea**, an inhibitor of rNDP reductase, reversibly destroys the free radical. A more elegant demonstration is depicted in Figure 22.18. The free radical gives a characteristic electron paramagnetic resonance (EPR) spectrum. EPR spectroscopy detects the spin of an unpaired electron (such as that of an organic radical) as it interacts with the magnetic fields generated by the nuclei and other electrons of the molecule. Tyrosine 122, the residue that generates the radical in the *E. coli* enzyme, was changed to phenylalanine by site-directed mutagenesis of the cloned gene for β_2 . The modified protein was inactive and showed no EPR spectrum—hence, no evidence for the existence of a free radical. However, because the tyrosyl radical is more than 35 Å from the catalytic site, as shown by crystallography (see Figure 22.17), one must postulate some sort of long-range process by which the unpaired electron in the tyrosine radical attracts an electron from an active site residue. Evidence indicates that (1) this residue is cysteine 439 in the *E. coli* enzyme and (2) a specific set of amino acid residues on α_2 and β_2 participates in the long-range electron transport process.

A plausible mechanism for rNDP reductase, based on the above observations, is shown in Figure 22.19. First, cysteine 439 in the active site is converted to a **thiyl radical**, by loss of an electron in a long range proton-coupled electron transport (PCET) process over 35 Å that results in reduction of tyrosine 122 (step 1). Next, the thiyl radical participates in abstraction of a hydrogen atom from C-3' of the substrate (step 2). This is followed by loss of a hydroxide ion (water) from C-2', and migration of the radical to C-2' (step 3). Reduction at C-2' by the redox-active cysteines by a proton-coupled electron transfer step generates a **disulfide radical anion**, which then reduces C-3' (steps 4 and 5) in another PCET step. The PCET of steps 1 and 2 is then reversed (steps 6 and 7). The net result is transfer of an electron pair from the redox-active cysteine thiols (step 6), to give the nucleotide product, and regeneration of the tyrosyl radical on the β_2 subunit. The resultant cysteine disulfide is now reduced by disulfide exchange with another pair of redox-active thiols in the C-terminus of the α_2 subunit; this is not shown in the figure. The resulting disulfide is reduced by an external cofactor (shown as Grx—see the next section), regenerating the active form of the enzyme (step 8). The rate-limiting step in class I rNDP reductases is a conformational change that controls the long-range proton-coupled electron transport process.

The amazing long-range proton-coupled electron transport process that results in radical propagation from tyrosine in β_2 to cysteine in α_2 is but the first example of what turns out to be a prevalent process in enzyme chemistry. When

FIGURE 22.18

Evidence that tyrosine 122 in *E. coli* β_2 protein carries the essential free radical. The figure shows electron paramagnetic resonance spectra of *E. coli* cells containing a cloned gene that overexpresses β_2 . (a) Bacteria containing no clone (the normal level of β_2 protein is too low to create a significant spectral signal). (b) Bacteria containing the cloned wild-type gene. (c) Bacteria containing a mutant cloned gene in which tyrosine 122 has been changed to phenylalanine. Treatment of the purified enzyme with hydroxyurea yields a spectrum like that shown in (c).

FIGURE 22.19

Reduction of a ribonucleoside diphosphate by rNDP reductase. This mechanism is consistent with available evidence. N is adenine, cytosine, guanine, or uracil. **Step 1:** The reaction is initiated by propagation of the tyrosyl radical (Y122) on the β_2 subunit to a cysteine in the α_2 catalytic site (Cys 439 in *E. coli*), generating a thiyl radical. In this process, called long-range proton-coupled electron transport, the tyrosyl radical is reduced to a tyrosine residue. **Step 2:** The substrate nucleotide interacts with the radical, creating a radical at C-3. **Step 3:** Protonation of the 2'-hydroxyl by one of the redox-active cysteines (225 and 462 in *E. coli*) and deprotonation of the 3'-hydroxyl by a glutamate (E441 in *E. coli*) facilitate dehydration at C-2' and migration of the radical to C-2'. **Steps 4 and 5:** Reduction at C-2' by the redox-active cysteines generates a disulfide radical anion, which then reduces C-3'. **Steps 6 and 7:** The long-range proton-coupled electron transport of steps 1 and 2 is reversed, producing the deoxyribonucleotide product and regenerating the thiyl radical on the β_2 subunit. **Step 8:** The Cys-Cys disulfide is reduced by a low-molecular-weight protein thiol, such as glutaredoxin (Grx); see text for further explanation. dNDP dissociation (not shown) allows rNDP substrate binding for another round of catalysis.

FIGURE 22.20

Structure of thioredoxin and glutaredoxin. X-ray crystal structures of thioredoxin from *E. coli* (PDB ID 2TRX) and glutaredoxin from the yeast *Saccharomyces cerevisiae* (PDB ID 3C1S) show the locations of the redox-active cysteine residues near their surfaces. In the thioredoxin structure, Cys32 and Cys35 are in the oxidized disulfide state. In the glutaredoxin structure, Cys27 and Cys30 are reduced, and a molecule of glutathione (GSH) is bound with its cysteinyl-SH adjacent to the two cysteine residues.

Ribonucleotide reductase uses a protein cofactor—thioredoxin or glutaredoxin—to provide electrons for reduction of the ribonucleotide substrate. However, the ultimate electron donor is NADPH.

distances are short, the electron and proton may transfer together. However, when distances are long, as in the class I rNDP reductases, transfer of the heavier proton is limited to much shorter distances than that of the lighter electron. The enzyme solves this dilemma through thermodynamic and kinetic control over the individual electron and proton transport processes. Other enzymes that utilize PCET are the P450 monooxygenases (Chapter 15) and the oxygen-evolving complex (OEC) of photosystem II (Chapter 17).

Source of Electrons for rNDP Reduction

Electrons for the reduction of ribonucleotides come ultimately from NADPH, but they are shuttled to rNDP reductase by a coenzyme that is unusual because it is itself a protein (Figure 22.20). The first known member of this class of redox-active proteins is **thioredoxin**, a small protein ($M_r \cong 12,000$) with two thiol groups in the sequence Cys–Gly–Pro–Cys. These thiols undergo reversible oxidation to the disulfide, thereby reducing sulfurs in the active site of rNDP reductase (Figure 22.21). Oxidized thioredoxin is reduced by NADPH via the action of a flavoprotein enzyme, **thioredoxin reductase**.

Since its discovery, thioredoxin has been found to have many activities in vitro, suggesting an astonishing range of biological functions. Some of them are listed in Table 22.1. Whether thioredoxin is the true intracellular cofactor for ribonucleotide reduction was brought into question by the isolation of *E. coli* mutants lacking this protein. Because these mutants were capable of DNA replication, investigators looked in these cells for other redox proteins that could interact with rNDP reductase. Such a protein was found and named **glutaredoxin** because of its ability to be reduced by glutathione. Members of the thioredoxin superfamily, glutaredoxins are also small proteins with two redox-active cysteine residues (Figure 22.20). In fact, most organisms possess several species of thioredoxin and glutaredoxin. For example, *E. coli* has two thioredoxins, three glutaredoxins, and two glutaredoxin-like proteins. Eukaryotes possess distinct cytoplasmic and mitochondrial isoforms of these proteins. Recent evidence indicates that thioredoxin is the physiologically relevant electron donor for ribonucleotide reductase during DNA precursor synthesis in yeast. Whichever carrier is the principal cofactor for rNDP reductase, the ultimate electron source is NADPH.

Regulation of Ribonucleotide Reductase Activity

Because deoxyribonucleotides are used only for DNA synthesis, and because one enzyme system is used for reduction of all four ribonucleotide substrates, regulation of both the *activity* and the *specificity* of ribonucleotide reductase is essential to

FIGURE 22.21

Reductive electron transport sequences in the action of rNDP reductase. Either thioredoxin or glutaredoxin can reduce the oxidized form of the reductase. Oxidized thioredoxin and glutaredoxin are, in turn, reduced with electrons from NADPH in reactions catalyzed by thioredoxin reductase and glutathione reductase, respectively. Glutaredoxin reduction requires two molecules of glutathione (GSH), resulting in oxidized glutathione (GS-SG) (see Chapter 13, page 583).

maintain balanced pools of DNA precursors. This regulation is achieved through binding of nucleoside triphosphate effectors to two classes of regulatory sites on the α_2 subunits (two of each site per dimer in the *E. coli* enzyme—see Figure 22.17). The **activity sites** bind either ATP or dATP, with relatively low affinity, whereas the **specificity sites** bind ATP, dATP, dGTP, or dTTP, all with relatively high affinity. Binding of ATP at the activity sites tends to increase the catalytic efficiency of rNDP reductase for all substrates, whereas dATP acts as a general inhibitor of all four reactions. ATP and dATP binding affect the oligomerization status of the enzyme, shifting the equilibrium between active and inactive forms (Figure 22.22). Binding of nucleotides at the specificity sites modulates the activities of the enzyme toward different substrates, so as to maintain balanced rates of production of the four dNTPs. For example, binding of dTTP (with ATP bound in the activity site) activates the enzyme for reduction of GDP but decreases its ability to reduce either UDP or CDP. Table 22.2 summarizes the principal regulatory effects.

These effects are seen in vitro with purified enzymes. There is ample reason to conclude that similar regulatory effects also operate in intact cells. For example, either deoxyadenosine or thymidine will inhibit DNA synthesis when administered to intact cells. Measurements of intracellular pools of dNTPs show that in deoxyadenosine-treated cells the dATP pools expand (as expected from the effects of salvage pathways), while dTTP, dGTP, and dCTP pools shrink. This is probably why white blood cells cannot proliferate as needed in immunodeficiency states associated with a lack of adenosine deaminase (see page 930): dATP accumulation in these cells blocks deoxyribonucleotide synthesis and, hence, DNA replication.

Another example comes from cell biology. Researchers often **synchronize** cell cultures, that is, manipulate the cells so that all are brought to the same phase of the cell cycle. Synchrony can be accomplished by **thymidine block**, in which thymidine is added to the cells to inhibit DNA synthesis. This prevents the passage of cells from the G1 to the S phase of the cell cycle, and cells accumulate at this point, like car traffic stopped at a red light. Transferring the cells to a

TABLE 22.2 Regulation of the activities of mammalian ribonucleotide reductase

^adGTP binding inhibits the reduction of pyrimidine nucleotides by the mammalian enzyme but not by the *E. coli* enzyme.

Ribonucleotide reductase has two classes of allosteric sites. Activity sites influence catalytic efficiency, and specificity sites determine specificity for one or more of the four substrates.

Inhibition of DNA synthesis by thymidine or deoxyadenosine involves allosteric inhibition of ribonucleotide reductase by dTTP or dATP, respectively.

FIGURE 22.22

Regulation of *E. coli* ribonucleotide reductase by reversible oligomerization. All nucleotides stimulate formation of the active $\alpha_2\beta_2$ tetramer from α_2 and β_2 dimers. dATP binding at the activity sites shifts the equilibrium to formation of inactive $\alpha_4\beta_4$ octamer; ATP binding shifts the equilibrium back to active tetramer.

Journal of Biological Chemistry 283:35310–35318, R. Rofougaran, M. Crona, M. Vodnalá, B.-M. Sjöberg, and A. Hofer, Oligomerization status directs overall activity regulation of the *Escherichia coli* class Ia ribonucleotide reductase. medium containing no thymidine is like a green light, reversing the inhibition and allowing the cells to initiate DNA replication synchronously. dNTP pool measurements in thymidine-blocked cells show that dTTP accumulates, as expected from salvage synthesis, while there is a specific depletion of dCTP, as expected from the effects of dTTP on ribonucleotide reductase activity. Indeed, addition of deoxycytidine restores normal dCTP pools (by salvage synthesis) and relieves the thymidine block.

Further support for the control of rNDP reductase activity *in vivo* comes from isolation of mammalian cell mutant lines whose growth is not inhibited by deoxyribonucleosides. rNDP reductase from these altered cells shows modifications in either activity or specificity sites, which render these enzymes less susceptible to inhibition by dNTP effectors. Some of these cell lines display both dNTP pool abnormalities and **mutator phenotypes**. That is, they show increased rates of spontaneous mutation at all genetic loci tested. Comparable observations have been made with mutant cells altered in either CTP synthetase or deoxycytidylate deaminase. These findings suggest that when dNTP concentrations are altered at DNA replication sites, the likelihood is increased for replication errors, which lead to mutations. This point is discussed further in Chapter 25.

The metabolic rationale for all of the effects shown in Table 22.2 is not immediately obvious. For example, why should dATP at the specificity site activate both CDP and UDP reduction? Part of the answer is that UDP reduction is a relatively minor pathway. Most dTTP comes from deoxycytidine nucleotides, via the dCMP deaminase reaction (see below).

Biosynthesis of Thymine Deoxyribonucleotides

The previous section explored the first metabolic reaction committed to DNA synthesis—the formation of deoxyribonucleoside diphosphates through the action of rNDP reductase. Once formed, three of the diphosphates—dADP, dGDP, and dCDP—are converted directly to the corresponding triphosphates by nucleoside diphosphate kinase. Biosynthesis of deoxythymidine triphosphate occurs partly from the dUDP produced via the reductase and partly from deoxycytidine nucleotides; the ratio varies in different cells and organisms. Note that we use the terms *thymidine* and *deoxythymidine* interchangeably. That is because thymine *ribonucleotides* are not normal metabolites, so the nucleoside containing thymine and deoxyribose need not be specifically identified as a deoxyribonucleoside.

The pathways are summarized in Figures 22.16 (page 936) and 22.23. Both of the *de novo* pathways shown in Figure 22.23 lead to deoxyuridine monophosphate (dUMP), the substrate for synthesis of thymine nucleotides: (1) dUDP is phosphorylated to dUTP, which is then cleaved by a highly active diphosphohydrolase, **dUTPase**. (2) dCDP is dephosphorylated to dCMP, which then undergoes deamination to dUMP by an aminohydrolase called **dCMP deaminase**. The enzyme requires dCTP as an allosteric activator and is inhibited by dTTP. *E. coli* and some other bacteria use a different route to dUMP. Deamination is carried out at the triphosphate level by **dCTP deaminase**, and the resultant dUTP is cleaved by dUTPase to dUMP and PP_i .

However it is formed, dUMP serves as substrate for formation of thymidine monophosphate (dTMP), catalyzed by **thymidylate synthase (TS)**. This enzyme transfers a one-carbon unit, at the methylene level of oxidation, and reduces it to the methyl level (see page 852 in Chapter 20). The one-carbon donor is 5,10-methylenetetrahydrofolate, which in this unusual reaction also serves as an electron donor, to give dihydrofolate (DHF) as the other reaction product (Figure 22.24). The folate cofactor must then be reduced, by dihydrofolate reductase, and it must acquire another one-carbon group, most commonly from serine via serine hydroxymethyltransferase. Interruption of any of these steps of the cycle interferes with thymine nucleotide formation. dTMP, once formed, is converted to dTTP by two successive phosphorylations (Figure 22.23).

dUMP, the substrate for thymidylate synthesis, can arise either from UDP reduction and dephosphorylation or from deamination of a deoxycytidine nucleotide.

In the reaction catalyzed by thymidylate synthase, 5,10-methylenetetrahydrofolate donates both a single-carbon methylene group and an electron pair to reduce that carbon to a methyl group.

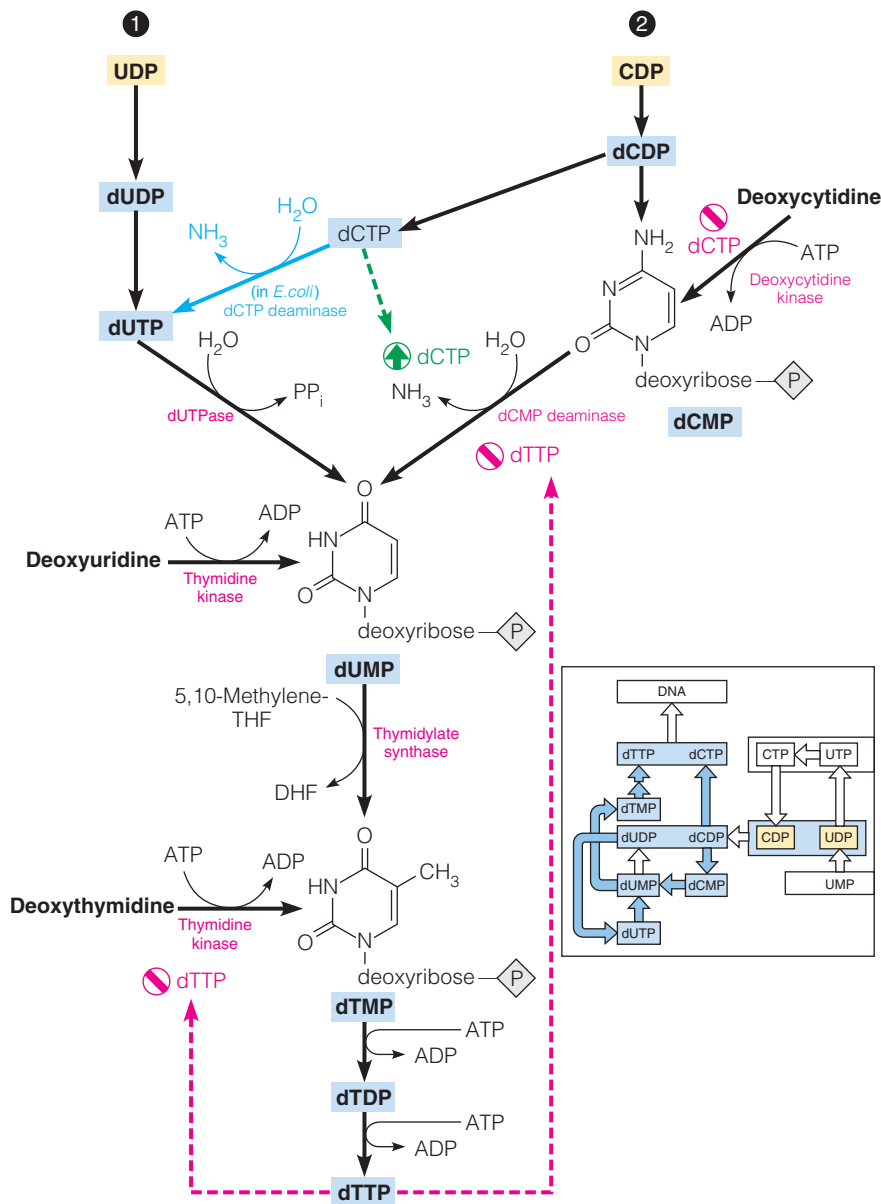

FIGURE 22.23

Salvage and de novo synthetic pathways to thymine nucleotides. The de novo pathways start with ① UDP or ② CDP, shown at the top. Dashed arrows indicate feedback regulatory loops.

Deoxyuridine Nucleotide Metabolism

In addition to the biosynthetic function of dUTPase in forming dUMP for thymine nucleotide formation, the enzyme plays an important role in excluding uracil from DNA. Were dUTP not rapidly degraded, it could serve as a satisfactory substrate for DNA polymerases. Indeed, dietary folate deficiency causes uracil misincorporation into DNA. Examination of Figure 22.24 reveals the mechanism of this effect: Folate deficiency leads to loss of 5,10-methylene-THF cofactor for the thymidylate synthase reaction, inhibiting the conversion of dUMP to dTMP. As the dUMP (and thus dUTP) levels rise at the expense of dTMP, DNA polymerase misincorporates dUTP into DNA. As discussed in Chapter 26, cells have a rather elaborate mechanism to ensure that any dUMP residues that do find their way into DNA are efficiently excised. Unfortunately, if the uracil misincorporation is severe, the repair process can lead to chromosome breaks. Because uracil is virtually identical to thymine with respect to its base-pairing properties, why is it so important for the cell to allow only thymine to be stably incorporated into DNA? The answer probably lies in the fact that dUMP residues can arise in DNA

FIGURE 22.24

Relationship between thymidylate synthase and enzymes of tetrahydrofolate metabolism. Sites of action of the chemotherapeutic drugs are indicated. See page 850 (Chapter 20) for structures of dihydrofolate reductase inhibitors. DHF, dihydrofolate; THF, tetrahydrofolate.

not only by dUTP incorporation but also by the spontaneous deamination of dCMP residues. The latter process, which occurs at an appreciable rate, would change the sense of the genetic message, so it seems advantageous for the cell to maintain genetic stability by having a surveillance system that excises dUMP residues no matter how they arise. Why thymidine was selected originally instead of uracil as a DNA base is a related question. Thermodynamic studies indicate that the methyl group of thymidine contributes significantly to hydrophobic interactions that stabilize double-helical DNA.

Cytoplasm

Mitochondria

Salvage Routes to Deoxyribonucleotide Synthesis

As noted previously, purine salvage usually involves phosphoribosyltransferase reactions, which generate ribonucleoside monophosphates from the purine bases and PRPP. After phosphorylation to the diphosphate level, these compounds enter deoxyribonucleotide metabolism via ribonucleotide reductase. However, **deoxyribonucleoside kinases**, leading directly to deoxyribonucleoside monophosphates, are widely distributed, and they involve both purines and pyrimidines. Cells and organisms vary widely in their contents of ribo- and deoxyribonucleoside kinases. Human cells contain four different deoxyribonucleoside kinases—(1) thymidine kinase 1, which is located in the cytosol; (2) deoxycytidine kinase, also a cytosolic enzyme, which phosphorylates deoxyadenosine and deoxyguanosine as well as deoxycytidine, but only at higher concentrations; and two mitochondrial enzymes: (3) deoxyguanosine kinase, which phosphorylates deoxyadenosine and deoxycytidine as well as deoxyguanosine; and (4) thymidine kinase 2, which has a broader substrate specificity than the cytosolic enzyme, acting also upon deoxycytidine. The main supply of dNTPs for mitochondrial DNA (mtDNA) synthesis in resting cells

comes from deoxynucleoside salvage, and the combined action of the two mitochondrial enzymes can supply all four dNTPs. Defects in either of these two enzymes causes mtDNA-depletion syndromes in humans, which are characterized by severe reduction in mtDNA copy number in affected tissues and progressive myopathy and encephalopathy.

As discussed later in this chapter, several nucleoside analogs are being used or tested in the treatment of cancer and several viral diseases. Invariably, these prodrugs must be converted to deoxyribonucleotides in order to be effective, and this has focused attention upon the deoxyribonucleoside kinases. For example, a side effect of **3-azido-2',3'-dideoxythymidine** (AZT or zidovudine), the first drug to receive approval for treating human immunodeficiency virus (HIV) infections (see page 951), is cardiotoxicity—damage to the heart muscle. The major route for AZT utilization involves the mitochondrial isoform of thymidine kinase, also called TK2. The deoxyribonucleotides of AZT, and most of the other nucleoside analogs in clinical use, also interfere with mitochondrial function, and this is probably the basis for the cardiotoxicity. Most of these analogs act as alternative substrates for the mitochondrial DNA polymerase, thus inhibiting mitochondrial DNA replication. However, AZT is an even more potent inhibitor of TK2, and its effect on mitochondrial function may be related to alteration of dTTP pools. Current research is aimed at developing analogs whose metabolic activation does not occur in mitochondria.

Of the four deoxyribonucleoside kinases, three are synthesized constitutively, being produced at constant rates throughout the cell cycle. The exception is cytosolic thymidine kinase (TK1), the expression of which is highest during S phase, when DNA is being replicated; in this respect TK1 resembles enzymes of de novo deoxyribonucleotide synthesis, such as ribonucleotide reductase. For reasons not yet understood, TK1 salvages exogenous thymidine extremely efficiently. Experiments with radiolabeled precursors show that dTTP derived from salvage synthesis is usually incorporated into DNA in preference to thymidine nucleotides generated by de novo synthesis. This is the basis for the widespread technique of estimating rates of DNA replication by measuring incorporation of radiolabeled thymidine into DNA. As discussed in Tools of Biochemistry 12A, however, an accurate measurement of the rate of DNA synthesis from thymidine incorporation data requires measuring the specific radioactivity of the labeled dTTP pool. Nevertheless, because of the great efficiency with which thymidine is utilized in most cells, simple measurements of thymidine incorporation often yield fairly accurate estimates of DNA replication rates.

3'-Azido-2',3'-dideoxythymidine
(AZT or Zidovudine)

Thymidylate Synthase: A Target Enzyme for Chemotherapy

A goal of **chemotherapy**—the treatment of diseases with chemical agents—is to exploit a biochemical difference between the diseased tissue and the host tissue in order to interfere selectively with the disease process. Many chemotherapeutic agents were originally discovered by chance, through testing of analogs of normal metabolites. Most of these agents are limited in their effectiveness by unanticipated side effects, incomplete selectivity, and the development of resistance to the agent. One of the most exciting areas of modern biochemical pharmacology is rational drug design—the design of specific inhibitors based on knowledge of the molecular structure of the site to which the inhibitor will bind and the mechanism of action of the target molecule. For drugs whose target is an enzyme, it is necessary to know the three-dimensional structure of the enzyme and its mechanism of action. Obtaining this information requires a fusion of classical bioorganic chemistry, structural biology (X-ray crystallography and/or NMR), and site-directed mutagenesis. Thymidylate synthase presents an excellent example of the utility of these approaches.

Inhibition of thymidylate synthase is an approach to cancer chemotherapy, by causing specific inhibition of DNA synthesis.

As noted here and in Chapter 20, the goal of chemotherapy is to attack selectively a metabolic process that is specific to the pathological condition. Because thymidylate synthase (TS) participates in the synthesis of a deoxyribonucleotide, any disease that involves uncontrolled cell proliferation can in principle be treated with inhibitors of TS: Blocking the production of an essential DNA precursor should inhibit DNA replication with minimal effects on other processes. Cells that are not undergoing rapid proliferation should be relatively immune to such agents. Thus, cancer and a wide range of infectious diseases should be amenable to treatment by this approach.

None of this was recognized in the mid-1950s. In fact, TS had not yet been discovered. It was known, however, that certain tumor cells took up and metabolized uracil much more rapidly than normal cells. Without knowing the metabolic fates of uracil in detail, Charles Heidelberger hoped to kill tumor cells selectively by treatment with analogs that would block uracil metabolism in tumor cells. To that end, he undertook the chemical synthesis of **5-fluorouracil (FUra)** and its deoxyribonucleoside, **5-fluorodeoxyuridine (FdUrd)**. Both compounds were found to be potent inhibitors of DNA synthesis. FUra and FdUrd are prodrugs—their action as inhibitors involves their intracellular conversion to **5-fluorodeoxyuridine monophosphate (FdUMP)**, a dUMP analog that acts as an irreversible inhibitor of TS.

Both fluorouracil and fluorodeoxyuridine are used in cancer treatment. However, the fluorinated pyrimidines are not completely selective in their effects. For example, fluorouracil can be incorporated into RNA by salvage routes normally used for uracil, thereby interfering with the function of messenger RNA in both cancer and normal cells. Clearly, a detailed understanding of the active site of TS could lead to the design of completely specific enzyme inhibitors.

Analysis of the binding of 5-fluorodeoxyuridine monophosphate to TS has opened the door to understanding the enzyme's reaction mechanism and the structure of the active site. FdUMP is a true **mechanism-based inhibitor**, in that irreversible binding occurs only in the presence of the other substrate, 5,10-methylenetetrahydrofolate. Binding of the coenzyme induces a conformational change in the active site that duplicates early steps in the catalytic reaction and leads to irreversible FdUMP binding. Proteolytic digestion of the **ternary complex** containing FdUMP, methylene-THF, and enzyme led investigators in the laboratories of Heidelberger and Daniel Santi to isolate a peptide fragment of the enzyme containing both the inhibitor and the coenzyme. Eventually it was shown that FdUMP was linked to the methylene carbon of the THF coenzyme through C-5 of the pyrimidine ring, and to the enzyme through a cysteine sulfur covalently bonded to C-6 of the pyrimidine. The structure of this ternary complex suggested

that the enzymatic reaction begins with nucleophilic attack by the cysteine thiol upon C-6 of the dUMP substrate.

The structure of the ternary complex between enzyme-bound FdUMP and 5,10-methylene-THF suggested the mechanism outlined in Figure 22.25. As noted previously, a cysteine thiolate ion on the enzyme initiates a nucleophilic attack on C-6 of dUMP (step 1). This step is facilitated by an active site general acid; C-5 now becomes a nucleophile, attacking the methylene carbon of the iminium cation that exists in equilibrium with 5,10-methylene-THF, forming the covalent enzyme-dUMP-THF ternary complex (step 2). Abstraction of a proton from C-5 by an active site general base (step 3) initiates an electron shift that leads to β -elimination of the cofactor (step 4), followed by hydrogen transfer from the C-6 of the cofactor to the pyrimidine (step 5), consistent with observations that this hydrogen is incorporated quantitatively into the thymidylate methyl group. This hydride transfer is accompanied by displacement of the cysteine thiolate, and also oxidizes the cofactor to dihydrofolate, which dissociates in step 5. Inhibition by FdUMP results from the electronegativity of fluorine, which generates a C—F bond at C-5 that cannot be broken. Thus, the reaction pathway cannot proceed to step 3.

Confirmation of this mechanism has come about with evidence that the substrate, dUMP, forms a covalent bond with the coenzyme during normal catalysis. More important evidence came from elucidation of a three-dimensional model of thymidylate synthase. In 1987 Robert Stroud, Daniel Santi, and their colleagues presented a model of the apoenzyme from *Lactobacillus casei*. TS is highly conserved evolutionarily, with about 20% of its residues being invariant among mammalian, bacterial, viral, fungal, and protozoal sequences. Shortly after the apoenzyme model was presented, two laboratories crystallized *E. coli* TS as a complex with dUMP and 5,10-methylene-THF (Figure 22.26). Analysis of these complexes confirmed the conformations of substrate and cofactor bound in the active site and the identification of active site residues in contact with these ligands. In these ternary complex structures, FdUMP is covalently bound to cysteine 146 (*E. coli* numbering) through C-6, and to the folate cofactor through C-5. Tyrosine 94 is thought to be the general base that abstracts the proton from C-5 in step 3, and glutamate 58 is the general acid that transfers a proton to and from the pyrimidine ring in steps 1–4. Several conserved lysine residues lie nearby and are thought to represent binding sites for the negatively charged polyglutamate tail on the folate coenzyme (see page 849). TS binds folate polyglutamates about 100-fold more tightly than folate monoglutamate.

In 1991 the crystallization of the human enzyme was reported, and this enzyme has been the focus of further drug development. Analysis of substrate binding interactions has led to design and synthesis of folate cofactor analogs (**antifolates**) that compete quite effectively with 5,10-methylene-THF for binding to TS (K_i values as low as 0.4 nM). Three such inhibitors are shown in the margin. Pemetrexed and raltitrexed are both used clinically to treat certain types of cancer. The same type of approach is underway in dozens of laboratories and companies, focused on drug targets that include membrane-bound or intracellular receptor proteins and nucleic acids, as well as enzymes. The development of specific HIV protease inhibitors as anti-AIDS drugs is an example of the potential of this approach.

Diseases other than cancer are also susceptible to attack by inhibition of thymidylate synthase. For example, parasitic protozoans, such as those that cause malaria, synthesize an unusual form of TS—a bifunctional enzyme, with both thymidylate synthase and dihydrofolate reductase activities. Knowing the structure of this enzyme's active site should allow development of inhibitors that would block this specific enzyme but not thymidylate synthase of the animal or human host.

Pemetrexed (Alimta)

Raltitrexed (Tomudex)

Nolatrexed (Thymitaq)

FIGURE 22.26

Structure of the homodimeric thymidylate synthase from *E. coli* (PDB IDs 1TLS, 1TSN). (a) Structure of the homodimer with bound folate cofactor (yellow) and FdUMP (red). (b) Active site region of the orange subunit in (a) showing the ternary complex formed between 5,10-methylene-THF, FdUMP, and Cys 146. The dashed lines indicate the covalent bonds of the ternary complex. The close proximity of Glu 58 (general acid) and Tyr 94 (general base) is also evident.

Flavin-Dependent Thymidylate Synthase: A Novel Route to dTMP

It has long been thought that the only way cells can make thymidylate is the de novo pathway via thymidylate synthase, or salvage via thymidine kinase (Figure 22.23). However, in 2002, genomics studies led to the identification of several organisms that lack both the *thyA* and *tdk* genes (encoding thymidylate synthase and thymidine kinase, respectively). How do these organisms synthesize their thymine nucleotides for DNA synthesis? Biochemists soon discovered an alternate flavin-dependent thymidylate synthase (FDTS), encoded by the *thyX* gene. This gene is present in ~30% of all microorganisms, including several serious human pathogens. The flavin-dependent TSs share no structure or sequence homology with classical TS. Whereas classical TSs are homodimers with one active site per subunit (Figure 22.26a), FDTSs are homotetramers with four active sites, located at subunit interfaces. Like classical TS, FDTS uses 5,10-methylene-THF as the one-carbon donor, but FDTS was found to require NADPH as reductant. More importantly, structural studies with FDTSs revealed that they lack the active site cysteine nucleophile conserved in all the classical TSs, suggesting that they use different chemistry to catalyze conversion of dUMP to dTMP. Figure 22.27 shows the mechanism proposed for these flavin-dependent TSs. The reaction is initiated by a hydride transfer from the reduced flavin (FADH₂) directly to C-6 of the pyrimidine ring (step 1). The resulting enolate anion nucleophilically attacks the activated iminium form of 5,10-methylene-THF, forming a folate-pyrimidine adduct (step 2). THF is eliminated (step 3), and the resulting thymine isomer rearranges to give the product dTMP (step 4). No covalent enzyme intermediate forms in this mechanism, and THF is not oxidized to DHF. The role of NADPH is to reduce the enzyme-bound oxidized flavin (FAD) back to FADH₂, readying the enzyme for another reaction cycle.

This is a beautiful example of evolution taking different routes to solve the same problem. FDTS is in a sense a bifunctional enzyme, taking the place of both classical thymidylate synthase and dihydrofolate reductase:

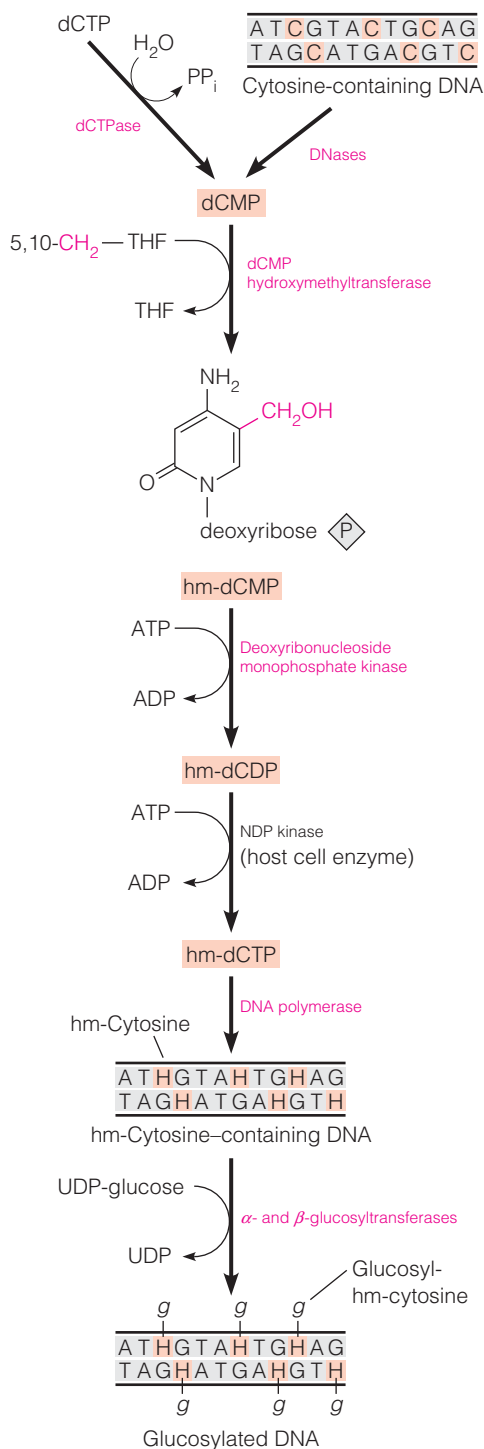

FIGURE 22.28

Metabolic pathways leading to nucleotide modifications in T-even phage-infected *E. coli*. Virus-coded enzymes are shown in red. hm = hydroxymethyl.

The mechanistic differences between these two thymidylate synthases may provide an opportunity for the development of a new class of antibiotics. It should be possible to find inhibitors of FDTS that have little effect on the classical TS used by humans.

Virus-Directed Alterations of Nucleotide Metabolism

That viruses can redirect the metabolism of their host cells first came to light in 1957 through studies of nucleotide biosynthesis in *E. coli* bacteria infected by the T-even bacteriophages—T2, T4, and T6. G. R. Wyatt and Seymour Cohen had shown in 1952 that DNA of these viruses contains no cytosine but instead contains 5-hydroxymethylcytosine, with most of the hydroxymethyl groups further modified by being in glycosidic linkage with glucose moieties.

Continuing work showed that infection initiates the synthesis of virus-coded enzymes, which carry out these modifications (Figure 22.28). The principal enzymes in T-even phage-infected bacteria include a **dCTPase**, which cleaves dCTP to dCMP; a **dCMP hydroxymethyltransferase**, which transfers a one-carbon group from 5,10-methylene-THF to dCMP at the hydroxymethyl oxidation level; and a **deoxyribonucleoside monophosphate kinase**, which can phosphorylate the resultant 5-hydroxymethyl-dCMP. The dCMP hydroxymethylase uses the same mechanism as thymidylate synthase (Figure 22.25), involving a covalent enzyme-dCMP-THF ternary complex intermediate. Phosphorylation of 5-hydroxymethyl-dCDP to the triphosphate is catalyzed by nucleoside diphosphate kinase of the host cell. The glucosylation reactions occur after the modified nucleotide has been incorporated into DNA. In T4 phage-infected bacteria there are two **glucosyltransferase** reactions, one of which transfers glucose in the α configuration and one in the β . In addition, the viral genome specifies several deoxyribonucleases, which specifically cleave cytosine-containing DNA. This process helps the virus abolish expression of host cell genes, and it also provides a source of precursors for viral DNA synthesis.

Although base substitutions in DNA are rather unusual, about a dozen instances have now come to light in which one of the four common deoxyribonucleotides is replaced, wholly or in part, by a chemically altered derivative that retains the base-pairing specificity of the replaced nucleotide. Some *Bacillus subtilis* phages, for example, substitute uracil for thymine in their DNA. Other *B. subtilis* phages contain 5-hydroxymethyluracil in place of thymine. A phage of *Xanthomonas oryzae* substitutes 5-methylcytosine for every one of its DNA cytosine residues. In each case investigated, the virus directs the nucleotide modifications through synthesis of virus-encoded enzymes that create novel metabolic pathways in the cells they infect.

Plant and animal viruses do not contain extensive nucleic acid base modifications of the type found in bacteriophages. (Most organisms contain a significant proportion of methylated nucleic acid bases, but these modifications occur after polymerization; see Chapter 26.) However, virus-coded enzymes are often produced to help the infected cell augment its synthesis of nucleic acid precursors. In some cases the virus-specified enzyme differs from its host cell counterpart sufficiently that scientists can design selective enzyme inhibitors and thereby achieve a specific chemotherapy directed against the virus-infected cell. The best current

Novel metabolic processes induced by viruses are attractive chemotherapeutic targets.

example is the use of **acyclovir** and its relative, **ganciclovir**, in treating herpes virus infections. The herpes viruses are large DNA-containing viruses whose genomes encode several enzymes, including **thymidine kinase**. This virus-encoded enzyme (HSV-TK) has extremely broad substrate specificity, capable of phosphorylating both pyrimidine and purine nucleosides. Nucleoside analogs, such as acyclovir (also called **acycloguanosine**) and ganciclovir are converted ultimately to the 5'-triphosphate, which interferes with DNA replication. Uninfected cells do not efficiently phosphorylate acyclovir and ganciclovir, so DNA replication and, hence, virus growth are inhibited selectively in the infected cells.

Biological and Medical Importance of Other Nucleotide Analogs

The previous examples have made clear the utility of nucleoside and nucleotide analogs, primarily as drugs. In this section we discuss additional analogs of medical importance, as well as several that are useful as research reagents. Nucleotides are poorly transported into cells because of the negative phosphate charge, so most of the compounds we shall discuss are introduced into cells as nucleosides or nucleoside derivatives, where they are acted upon initially by nucleoside kinases (see page 919). After uptake and conversion to nucleotides, these compounds interfere with metabolism in various ways. In this section we shall use the terms *nucleotide analogs* and *nucleoside analogs* interchangeably.

Nucleotide Analogs as Chemotherapeutic Agents

The enzymes of nucleotide synthesis have been widely studied as target sites for the action of antiviral or antimicrobial drugs. As noted earlier, the aim is to identify a biochemical distinction between comparable processes of the uninfected host and the infected host.

Antiviral Nucleoside Analogs

One of the earliest antiviral drugs approved for use in humans is **arabinosyladenine** (**araA** or **Vidarabine**). It is now being used to treat several viral diseases, including viral encephalitis, a neurological disease caused by another member of the herpes virus family. Unlike acyclovir, araA is phosphorylated to the triphosphate level by cellular kinases. The triphosphate, araATP, is a selective inhibitor of DNA polymerases encoded by herpes viruses. Thus, araA selectively interferes with viral DNA replication, even though all cells, infected and uninfected, form the triphosphate. Because araA is susceptible to degradation by adenosine deaminase, its effectiveness can be increased when administered with an inhibitor of the latter enzyme. The arabinose analog of deoxycytidine, **arabinosylcytosine** (**araC** or **Cytarabine**), is being used in cancer chemotherapy. araCTP also interferes with DNA replication after conversion to the triphosphate.

Other analogs receiving considerable attention are those being used to combat acquired immune deficiency syndrome (AIDS) caused by HIV. One such analog, 3'-azido-2',3'-dideoxythymidine (AZT; see page 945) is anabolized to the corresponding 5' triphosphate, which is an inhibitor of viral reverse transcriptase (the enzyme that makes a DNA copy of the viral RNA—see Chapter 25). Other nucleoside analogs—**2',3'-dideoxycytidine** (**ddC**), **2',3'-dideoxyinosine** (**ddI**), **3'-thiacytidine** (**3TC**), and **2',3'-didehydro-3'-deoxythymidine** (**d4T**)—act by conversion to the corresponding triphosphate, which is incorporated into DNA but then blocks further replicative chain elongation because of the absence of a 3' hydroxyl terminus. All four analogs have been approved for use in treating human HIV infections and both AZT and 3TC are components, along with HIV protease inhibitors, of the three-drug “cocktails” credited with long-term remission of HIV infections. In late 1994 two laboratories reported a synergistic effect of ddI and hydroxyurea against HIV infections, presumably starving the cell of dNTPs for reverse transcription (see Figure 25.46, page 1073).

**Formycin B****6-Mercaptopurine****6-Thioguanine**

Purine Salvage as a Target

An important biochemical anomaly is found in parasitic protozoans such as *Plasmodium*, which is responsible for malaria, and *Leishmania*, which causes a debilitating but usually nonfatal disease affecting the skin and visceral organs. Parasitic protozoans lack the capacity for de novo purine synthesis, and they depend entirely on salvage of nucleosides and bases provided by the host. Compounds such as allopurinol (see page 929) and **formycin B** inhibit the growth of these organisms in culture, partly through inhibition of salvage enzymes and partly through the ability of the salvage enzymes to anabolize the analog, an ability lacking in the corresponding host enzymes. For example, allopurinol is converted to an analog of inosinic acid and then to an AMP analog and is finally incorporated into RNA, where it interferes with messenger RNA coding in protein synthesis.

Purine salvage can also be taken advantage of, for example in the use of thiopurines as anti-cancer and immunosuppressive drugs. Like 5-fluorouracil, **6-mercaptopurine** and **6-thioguanine** are prodrugs that require metabolic activation in order to exert their cytotoxic effects. Both of these compounds are salvaged to nucleoside monophosphates by HGPRT (page 928) and then converted to triphosphates that can be incorporated into DNA or RNA. Incorporation of these thio analogs into DNA triggers cell cycle arrest and apoptosis, and these two drugs are mainstays of childhood leukemia treatment. 6-Mercaptopurine and 6-thioguanine were synthesized by Gertude Elion and George Hitchings, who also developed allopurinol and acyclovir—they received the 1988 Nobel Prize for Physiology or Medicine for their many contributions to chemotherapeutic drug development.

The thiopurines illustrate the importance of **pharmacogenetics**—understanding the genetically determined variations in responses to drugs in humans. 6-Mercaptopurine and 6-thioguanine can be metabolically inactivated by methylation of the thio group (*S*-methylation). This *S*-Adenosylmethionine-dependent methylation is catalyzed by thiopurine *S*-methyltransferase (TPMT), a cytoplasmic enzyme present in most human tissues. TPMT-deficient patients given the usual dose of thiopurines accumulate up to 10-fold higher cellular concentrations of the active thioguanine nucleotides and are thus at high risk for severe, and sometimes fatal, hematological toxicity. There are numerous variant TPMT alleles that are associated with low enzymatic activity in humans, and ~1 in 300 individuals will have low or undetectable levels of TPMT activity. These patients must be treated with much lower doses of the thiopurines to avoid these toxic side effects. There are now simple molecular genetic tests to determine a patient's TPMT genotype, and clinicians are beginning to use this information to optimize chemotherapy for each patient.

Folate Antagonists

Recall from Chapter 20 that the folic acid analog methotrexate was found long ago to induce remissions in certain acute leukemias. What is the basis for this selectivity? Given that folate cofactors play essential roles in synthesizing precursors to DNA, RNA, protein, and phospholipids, one would expect inhibition of tetrahydrofolate regeneration to be toxic to all cells. However, there is a rationale for the selective toxicity of folate antagonists against proliferating cells. Recall that the thymidylate synthase reaction oxidizes methylene-THF to dihydrofolate; this is the only known THF-requiring reaction that does not regenerate THF. From the reactions shown in Figure 22.24, one can predict that inhibition of dihydrofolate reductase blocks the recycling of DHF back to THF. Under these conditions the rate at which all of the intracellular reduced folates become oxidized is directly related to the intracellular activity of thymidylate synthase, which in turn is coordinated with the rate of DNA synthesis. Thus, proliferating cells, with rapid rates of DNA replication, will exhaust their tetrahydrofolate stores faster than nonproliferating cells.

Although antimetabolites such as fluorouracil or methotrexate do attack proliferating tissue selectively, they are still toxic to normal cells. Deleterious side effects are seen in tissues that proliferate as part of their normal function; such tissues include intestinal mucosa, hair cells, and components of the immune system. Equally serious

Cell proliferation rate is a determinant of the effectiveness of chemotherapy with dihydrofolate reductase inhibitors because thymidylate synthase reaction flux determines the rate at which tetrahydrofolate is oxidized to dihydrofolate.

is the development of drug-resistant cell variants. In such cases, levels of the target enzyme rise beyond the point that they can be controlled with inhibitors. Robert Schimke and his colleagues investigated the mechanism for the rise in dihydrofolate reductase activity, which can be several hundredfold in methotrexate-resistant cell lines. They found that prolonged incubation of cells in methotrexate often leads to selective amplification of the gene encoding dihydrofolate reductase; the number of DNA copies of this gene per cell increases many times, with a corresponding accumulation of the gene product, dihydrofolate reductase. Other resistance mutations involve more conventional mechanisms, such as altered transport of the drug into cells or alteration of the target enzyme, making it resistant to the antimetabolite.

Another class of dihydrofolate reductase inhibitors is exemplified by **trimethoprim**. This compound is a specific inhibitor of dihydrofolate reductases of prokaryotic origin. Trimethoprim and its relatives are widely used to treat both bacterial infections and certain forms of malaria. The success of these drugs derives from their being extremely weak inhibitors of vertebrate dihydrofolate reductases. Trimethoprim is often administered in conjunction with a sulfonamide drug to inhibit the synthesis of folate and hence to block sequential steps in the same pathway.

Folate antagonists have also been developed to target *de novo* purine biosynthesis. Lometrexol (5,10-dideazatetrahydrofolate) and LY309887 are both potent inhibitors (low nM K_i) of GAR transformylase (Figure 22.4). Pemetrexed, introduced previously as a thymidylate synthase inhibitor (page 947), is actually a **multi-targeted antifolate** because it also inhibits dihydrofolate reductase and GAR transformylase. It is used clinically to treat certain cancers.

Nucleotide Analogs and Mutagenesis

Some nucleotide analogs are excellent mutagens, useful both in the isolation of mutants and in studies on the mechanism of mutagenesis. Two such analogs are **2-aminopurine (2AP)** and **5-bromodeoxyuridine (BrdUrd)**. 2-Aminopurine is incorporated into DNA in place of adenine, but when a 2AP-containing template replicates, the analog occasionally base-pairs with cytosine rather than thymine. Thus, incorporation of 2AP changes an A-T pair in DNA to a G-C pair (Figure 22.29).

Bromodeoxyuridine functions similarly, but it has other uses as well. It is an excellent thymidine analog because the van der Waals radius of the bromine atom is close to that of the methyl group. Hence, it is efficiently incorporated into DNA. Mispairing of BrdUrd with a deoxyguanosine residue on replication of a BrdUrd-containing template can lead to mutagenesis by changing an A-T base pair to a G-C (see Figure 22.29). Alternatively, BrdUTP can compete with dCTP for incorporation opposite G in the template (not shown).

Because bromine is much heavier than a methyl group, it imparts an increased density to substituted DNA, thereby providing a physical basis for separating replicating from nonreplicating DNA (see Chapter 25). Finally, radiobiologists use BrdUrd as a radiosensitizing agent. Bromo-dUMP residues in DNA debrominate readily when the substituted DNA is irradiated with UV or near-UV light. This process generates free radicals, which cause various kinds of damage to the DNA structure.

Recent interest has focused upon a mutagenic nucleotide analog that is formed in normal metabolism. Recall from Chapter 15 that oxidative stress—generated, for example, by treating cells with hydrogen peroxide—damages DNA bases. The oxidation of guanine residues in DNA to 8-oxoguanine is strongly mutagenic because 8-oxoguanine base-pairs during replication with adenine almost as efficiently as it pairs with cytosine. This mispairing event could cause mutation by changing a G-C base pair to a T-A. Recently, an enzyme was discovered that specifically hydrolyzes the nucleotide 8-oxo-dGTP to 8-oxo-dGMP plus pyrophosphate (the *mutT* gene product; see Chapter 26). Mutations that inactivate this enzyme have a mutator phenotype, suggesting that a significant mutagenic pathway involves oxidation of guanine nucleotides to 8-oxoguanine nucleotides, followed by their incorporation into DNA, and that oxidative mutagenesis is minimized by the breakdown of 8-oxo-dGTP before this incorporation can occur.

Nucleotide analogs with altered base-pairing properties are mutagenic because non-Watson–Crick base pairs form when the analog is either in the template or in an incoming nucleoside triphosphate.

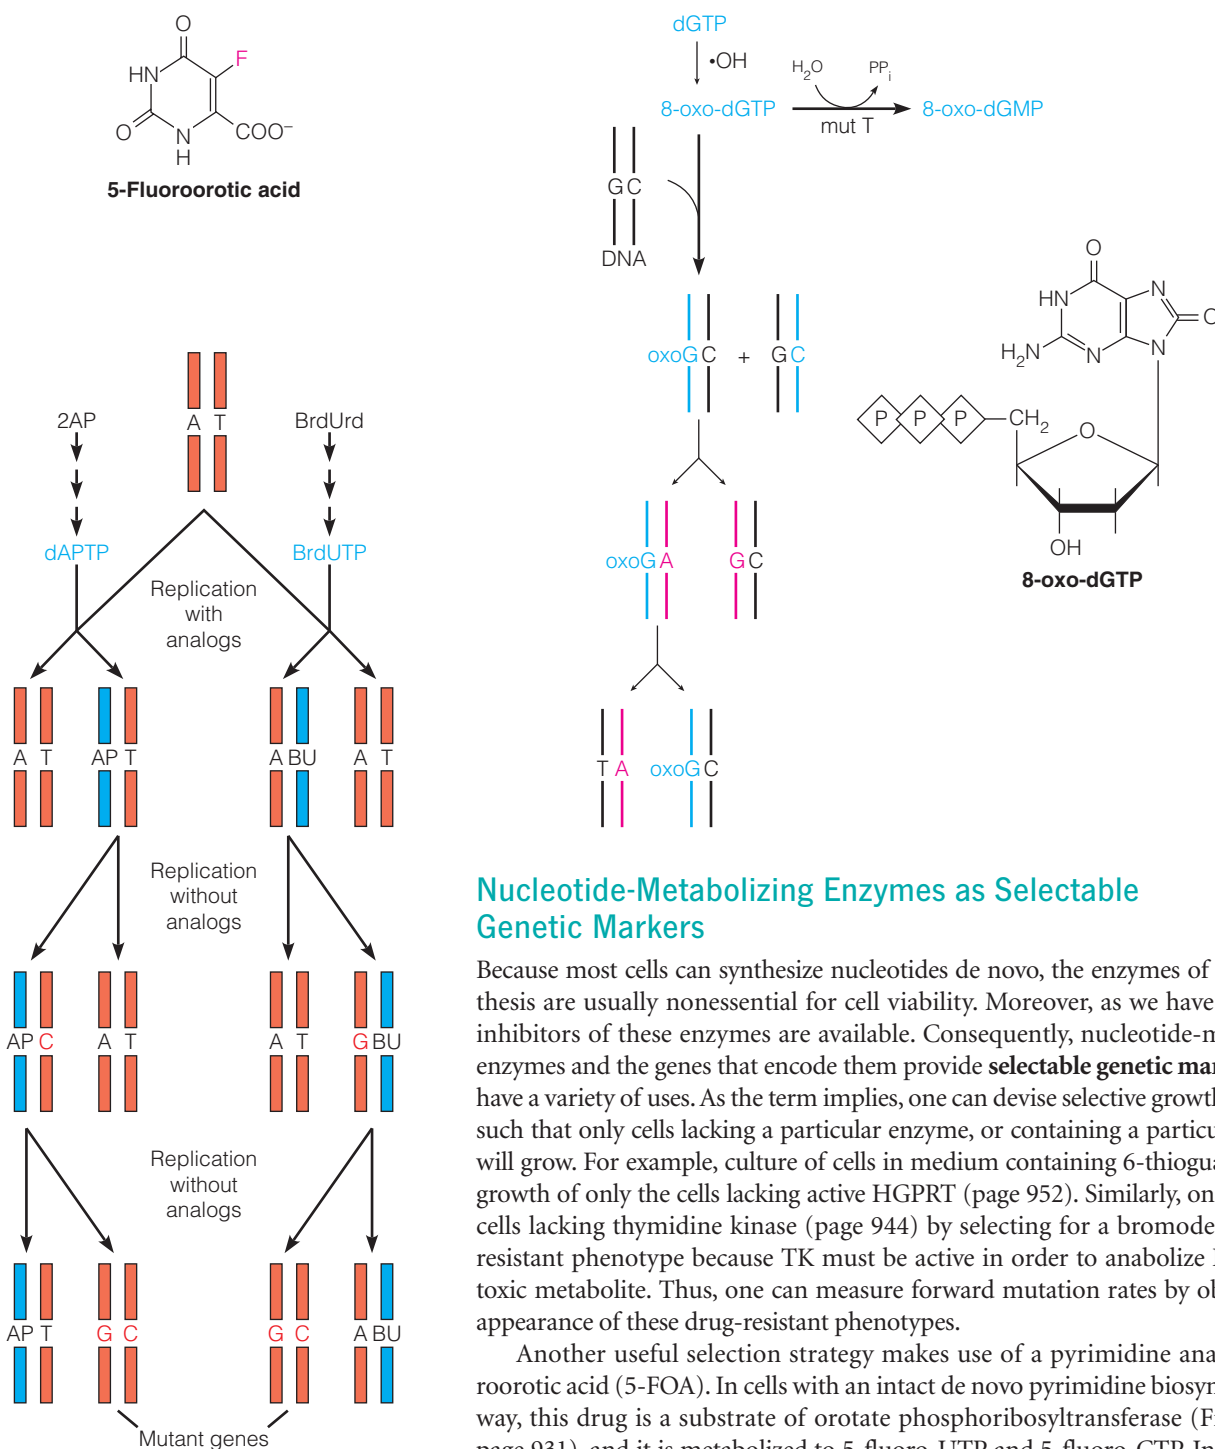

FIGURE 22.29

Mechanisms of mutagenesis by nucleotide analogs.

2-Aminopurine (2AP) is converted by salvage pathways to deoxy aminopurine triphosphate (dAPT), the dNTP analog of dATP. BrdUrd is converted to BrdUTP, the dNTP analog of dTTP. The first round of replication occurs in the presence of the analog, and the second and third rounds occur in its absence. Replication of only the analog-containing duplex is shown in the second and third rounds. AP is a 2-aminopurine nucleotide residue in DNA, and BU is a bromodeoxyuridine nucleotide residue. In the pathways shown, both analogs change an A-T base pair to a G-C base pair (red letters). Other pathways can occur as well.

Nucleotide-Metabolizing Enzymes as Selectable Genetic Markers

Because most cells can synthesize nucleotides *de novo*, the enzymes of salvage synthesis are usually nonessential for cell viability. Moreover, as we have seen, many inhibitors of these enzymes are available. Consequently, nucleotide-metabolizing enzymes and the genes that encode them provide **selectable genetic markers**, which have a variety of uses. As the term implies, one can devise selective growth conditions such that only cells lacking a particular enzyme, or containing a particular enzyme, will grow. For example, culture of cells in medium containing 6-thioguanine allows growth of only the cells lacking active HGPRT (page 952). Similarly, one can isolate cells lacking thymidine kinase (page 944) by selecting for a bromodeoxyuridine-resistant phenotype because TK must be active in order to anabolize BrdUrd to a toxic metabolite. Thus, one can measure forward mutation rates by observing the appearance of these drug-resistant phenotypes.

Another useful selection strategy makes use of a pyrimidine analog, 5-fluoroorotic acid (5-FOA). In cells with an intact *de novo* pyrimidine biosynthesis pathway, this drug is a substrate of orotate phosphoribosyltransferase (Figure 22.12, page 931), and it is metabolized to 5-fluoro-UTP and 5-fluoro-CTP. Incorporation of these fluorinated nucleotides into DNA and RNA is lethal to the cell. However, cells lacking active orotate phosphoribosyltransferase or OMP decarboxylase are resistant to 5-FOA, providing a powerful selection for these cells.

By the same token, one can select for mutation in the reverse direction by adjusting culture conditions so that the capacity for salvage synthesis is essential to cell viability. A common technique, both in somatic cell genetic analysis and in preparation of monoclonal antibodies (see Tools of Biochemistry 7A), is **cell fusion**. Two cell lines of different origins are mixed under conditions in which some of them can physically fuse, resulting in two different nuclei in one cytoplasm. One can select for these cell hybrids by adjusting culture conditions so that only the hybrids will grow in **HAT medium** (normal cell culture medium augmented with hypoxanthine, aminopterin, and thymidine). Aminopterin inhibits dihydrofolate reductase (Figure 22.24)

and hence blocks de novo purine and thymidylate synthesis. Cells can survive only if they have active HGPRT, to utilize the hypoxanthine for purine synthesis, and thymidine kinase, to utilize the thymidine for thymidylate synthesis.

Genes with selectable phenotypes represent an important adjunct to the use of recombinant DNA technology for introducing novel genetic material into cells—animal, plant, or microbial—because one can introduce recombinant DNA molecules that contain a selectable marker in tandem with a gene whose transfer is desired. Application of selective conditions then forces the growth of only those cells that have acquired the new pair of genes. An intriguing variant on this approach is described in a report of a novel treatment of brain tumors. A recombinant DNA containing the herpes simplex virus deoxythymidine kinase gene was injected into the tumor. In experimental animals the proliferating (tumor) cells took up and replicated this DNA. After several days the animals were treated with ganciclovir, which led to selective killing of the tumor cells because of selective phosphorylation of the drug in those cells.

SUMMARY

Nucleotides arise within cells from nucleic acid breakdown, from reuse (or salvage) of preformed nucleosides or nucleobases, or from de novo biosynthesis. Purine nucleotides are formed at the nucleotide level, in a 10-step pathway that leads from PRPP to inosinic acid. Beyond this branch point, separate pathways lead to adenine and guanine nucleotides. Purine catabolism yields uric acid, an insoluble compound that is formed in excess in a variety of disease states. Pyrimidines are synthesized at the base level, with conversion to a nucleotide occurring late in the pathway. An unbranched pathway leads to both UTP and CTP. In most organisms the ribonucleoside diphosphates are substrates for reduction of the ribose sugar in situ, yielding deoxyribonucleoside diphosphates, which in turn lead to the four dNTP DNA precursors. Ribonucleotide reductase is an important control site, inasmuch as it represents the first metabolic reaction committed to DNA synthesis. Biosynthesis of thymine nucleotides involves transfer of the methylene group of 5,10-methylenetetrahydrofolate to a deoxyuridine nucleotide, followed by reduction of the methylene group. Reactions of deoxyribonucleotide biosynthesis are target sites for enzyme inhibitors that have found use as anticancer, antimicrobial, antiviral, and antiparasitic drugs. Other nucleotide analogs have found use as research reagents—for example, in studies of mutagenesis or as DNA density labels.

PROBLEMS

1. Identify each reaction catalyzed by (a) a nucleotidase; (b) a phosphorylase; (c) a phosphoribosyltransferase.

2. Describe the metabolic fate of 5-bromodeoxyuridine. Would you expect BrdUrd to *inhibit* DNA replication? Briefly explain your answer.

3. Predict the effects of the following compounds on intracellular nucleoside triphosphate levels. For each answer, plot percent initial nucleotide level as a function of time after administration of the agent, for each of the four nucleotides (semiquantitatively). Consider not only the primary effect of the compound but also any indirect effects on allosteric enzymes caused by nucleotide accumulation or depletion.

- Effect of thymidine on dNTP levels
- Effect of trimethoprim on bacterial rNTP levels
- Effect of fluorodeoxyuridine on dNTP levels
- Effect of hydroxyurea on dNTP levels
- Effect of azaserine on rNTP levels

4. Radioactive uracil can be used to label all of the pyrimidine residues in DNA. Using either names or structures, present pathways for conversion of uracil to dTTP and to dCTP. For each reaction, show the involvement of cofactors, and identify sites of allosteric regulation.
5. Similarly, hypoxanthine (HX) can be used to label purine residues. As in Problem 4, write reactions showing the conversion of hypoxanthine to dATP and dGTP.
6. Leukemia is a neoplastic (cancerous) proliferation of white blood cells. Clinicians are currently testing deoxycoformycin, an adenosine deaminase inhibitor, as a possible antileukemic agent. Why might one expect this therapy to be effective?
- *7. Under what conditions might one expect a deficiency of hypoxanthine–guanine phosphoribosyltransferase to affect the rate of *pyrimidine* nucleotide biosynthesis? How might one estimate the rate of pyrimidine nucleotide biosynthesis in living animals or people?
- *8. A classic way to isolate thymidylate synthase–negative mutants of bacteria is to treat a growing culture with thymidine and trimethoprim. Most of the cells are killed, and the survivors are greatly enriched in thymidylate synthase–negative mutants.
- What phenotype would allow you to identify these mutants?
 - What is the biochemical rationale for the selection? (That is, why are the mutants not killed under these conditions?)
 - How would the procedure need to be modified to select mammalian cell mutants defective in thymidylate synthase?
9. As stated in the text, mammalian cells can become resistant to the lethal action of methotrexate by the selective survival of cells containing increases in dihydrofolate reductase gene copy number so that intracellular levels of the enzyme become very high. What other biochemical or genetic changes in cells could cause them to become resistant to methotrexate?
10. As stated in the text, bacteriophages have been discovered with the following base substitutions in their DNA:
- dUMP completely substituting for dTMP
 - 5-hydroxymethyl-dUMP completely substituting for dTMP
 - 5-methyl-dCMP completely substituting for dCMP
- For any one of these cases, formulate a set of virus-coded enzyme activities that could lead to the observed substitution. Write a balanced equation for each reaction you propose.
- *11. Radioisotope “suicide techniques” are often used in the selection of mutants. In one such technique, cells are grown in the presence of [³H]thymidine at very high specific activity. The cells are then stored
- frozen to allow for decay of some of the incorporated radioactivity. Decay of dTMP residues in DNA causes strand breakage and other potentially lethal events. Thus, cells that have incorporated thymidine into their DNA are very likely to be killed by this regimen.
- Identify an enzyme deficiency that would allow a mutant to survive such a regimen.
 - Choose any enzyme of nucleotide metabolism, and devise a suicide procedure that could select for mutants deficient in that enzyme.
- *12. For any of the multifunctional enzymes in purine or pyrimidine nucleotide biosynthesis, assume that the enzyme is available in purified form, and propose one or two experiments to determine whether the enzyme “channels” substrates through a multistep reaction sequence.
13. Write balanced equations for the three known reactions that transfer an amino group to a substrate by condensation with aspartate to give an intermediate that then undergoes α,β -elimination to give the product plus fumarate.
- *14. CTP synthetase catalyzes the glutamine-dependent conversion of UTP to CTP. The enzyme is allosterically inhibited by the product, CTP. Mammalian cells defective in this allosteric inhibition are found to have a complex phenotype: They require thymidine in the growth medium, they have unbalanced nucleotide pools, and they have a mutator phenotype. Explain the basis for these observations.
15. If thymine nucleotides are degraded by the same enzymes as those catabolizing uridine nucleotides, give the structure of the thymine metabolite that corresponds to β -ureidopropionate.
- Explain the biochemical basis for the fact that one can synchronize cell populations by treating them with deoxythymidine.
 - Explain the apparent paradox that dATP at low concentrations is an activator of ribonucleotide reductase, whereas at higher concentrations it becomes inhibitory.
17. The text states that ATP is synthesized primarily by energy metabolism, whereas other nucleoside triphosphates are formed from the action of nucleoside diphosphate kinase. What additional pathway exists for GTP synthesis?
18. A growing culture of yeast was fed with glycine labeled at the 2C position with ¹³C ([2-¹³C]glycine). After 24 hours, cells were harvested, and purine bases were extracted and analyzed by ¹³C-NMR. The following spectrum (top) was obtained (the bottom spectrum was obtained from cells grown with unlabeled glycine). Explain the metabolic pathways by which the 2-carbon of glycine is incorporated into the purine ring at the positions indicated by the resonances in the NMR spectrum.

CHAPTER 23

Mechanisms of Signal Transduction

In previous chapters—particularly Chapters 12, 13, and 18—we have discussed actions of hormones in regulating metabolism. In this chapter we focus upon mechanisms of hormone action, and we see again that hormones represent but one class of extracellular chemical messengers. Hormones are molecules that are released from controller cells in the endocrine system and travel to target cells, usually some distance away, where they interact with specific receptors in the target cell, in the process known as signal transduction. In a broader sense, signal transduction refers to reception of an environmental stimulus by a cell, leading to metabolic change that adapts the cell to that stimulus. Interaction of a hormone with its receptor, by various mechanisms, stimulates or inhibits specific metabolic events within the target cell. The examples that we have treated in most detail so far involve the effects of epinephrine and glucagon upon metabolic cascades controlling the breakdown or synthesis of glycogen in animal tissues. In fact, these are the processes that gave our earliest understanding of molecular mechanisms in signal transduction.

Insulin, glucagon, and epinephrine are all *hormones* (from Greek, “to stir up or excite”). This term was coined in 1904 to describe **secretin**, a substance that is released in the upper small intestine and that acts in the stomach to stimulate the flow of gastric juice as an aid to digestion. Early research on hormones in animals revealed little about how they act, but it did show fundamental similarities among different hormones. First, they are secreted by specific tissues, the **endocrine glands**. Second, they are secreted directly into the bloodstream, rather than being excreted through ducts or stored in bladders. Thus, the response to a hormonal signal comes as a direct and rapid result of its secretion. Figure 23.1 shows locations of the major endocrine organs in the human body.

Hormones usually stimulate metabolic activities in tissues remote from the secretory organ. They are active at exceedingly low concentrations, in the micromolar to picomolar ranges. Furthermore, many hormones are metabolized

**FIGURE 23.1**

The major human endocrine glands and their central nervous system control centers. Some other tissues also produce hormones, such as the lining of parts of the gastrointestinal tract.

rapidly, so their effects are often short-lived, allowing rapid adaptations to metabolic changes. The low concentrations of hormones and their metabolic lability initially made it difficult to assay levels of any particular hormone. Until the 1960s it was usually necessary to use a bioassay. For example, **oxytocin**, which stimulates uterine contractions in labor, was assayed by adding hormone to strips of uterine muscle and measuring the length of the strips before and after hormone addition. The introduction of **radioimmunoassay** revolutionized the field of hormone analysis. In this technique an antibody to a hormone is mixed with a sample being studied, in the presence of radioactive hormone, and the amount of radioactivity precipitated by the antibody is related to the amount of hormone in the sample.

A special class of hormones includes the eicosanoids—prostaglandins, thromboxanes, and leukotrienes—which we discussed in Chapter 19. These mediators, also called paracrine hormones, act like hormones but are distinctive in their extreme metabolic lability, their synthesis in many cell types instead of just one endocrine gland, their lower target-organ specificity, and their actions primarily on cells close to those from which they were secreted.

Hormones differ in certain ways from other intercellular messengers—**pheromones**, which are transmitted between cells of different organisms; **neurotransmitters**, which act immediately across a synaptic junction from their sites of release; and **growth factors**, which differ from hormones in that their growth-stimulating activities are continuous, rather than being short-lived in response to a burst of secretion. Another class of signaling agents, **cytokines**, bind to specific receptors and stimulate cell growth and differentiation in the immune

Signal transduction involves cell-to-cell communication, via neurotransmitters, hormones, growth factors, and pheromones.

response. Distinctions among these classes of regulators are somewhat indefinite. For example, recall that catecholamines function both as neurotransmitters and as hormones, depending upon their sites of synthesis and release.

An Overview of Hormone Action

Until the 1950s we knew little about molecular mechanisms of hormone action. A popular theory was that a hormone stimulates a metabolic pathway by binding directly to the rate-determining enzyme for that pathway and activating it. Our current understanding emerged from research discussed in Chapters 12 and 13, namely, studies of the effect of epinephrine in stimulating glycogen mobilization. These investigations, carried out largely in the laboratories of Earl Sutherland and Edwin Krebs, showed that epinephrine does not enter cells, as it must if a rate-limiting enzyme is to be activated directly. Instead, as shown in Figure 13.31 (page 567), epinephrine binds to a macromolecular receptor at the cell surface and stimulates the formation of cyclic AMP, which acts as a second messenger and in turn stimulates the phosphorylation of target enzymes. The hormone itself is the first messenger. Today we know that all hormones so far investigated act through binding to specific receptors, whether those receptors are located inside the target cell or on the cell surface. An exception is gaseous signaling agents, such as nitric oxide, which interact directly with a target enzyme. The presence of specific receptors on specific cell types determines how hormones, secreted into the bloodstream, affect only certain tissues. For example, the preferential action of glucagon in stimulating glycogenolysis in liver derives from the density of glucagon receptors on the surface of liver cells. Second messengers are often used to transmit the message to the target metabolic pathway, though not all hormone actions involve a second messenger.

Hormone action can influence (1) enzyme activity (via second messengers), (2) synthesis of specific proteins, or (3) membrane permeability to ions or small metabolites.

Chemically, the hormones in vertebrate metabolism include (1) *peptides* or polypeptides, such as insulin or glucagon; (2) *steroids*, including glucocorticoids and the sex hormones; and (3) *amino acid derivatives*, including the catecholamines and thyroxine. Hormonal mechanisms include (1) enzyme activation or inhibition via second messengers, as noted for epinephrine and glucagon; (2) stimulation of the synthesis of particular proteins, through activation of specific genes; and (3) selective increases in the cellular uptake of certain metabolites. Among this last category are some receptors that serve directly as ion channels, with hormone binding causing a conformational change that opens the channel, and other receptors that stimulate uptake, such as the effects of insulin upon glucose uptake and subsequent utilization.

Membrane receptors include (1) proteins that influence second-messenger synthesis, (2) ion channels, and (3) proteins with intrinsic enzyme activity.

The receptor to which a hormone binds may be located either in the plasma membrane or inside the cell. Most hormones interacting with *intracellular receptors* (also called nuclear receptors) exert their effects at the gene level. The hormone–receptor complex migrates to the nucleus, where it interacts with specific DNA sites and affects rates of transcription of neighboring genes. These hormones include steroids, thyroid hormones, and the hormonal forms of vitamin D. In addition, **retinoids**, derived from retinoic acid (related to vitamin A), exert regulatory effects in embryonic development, through interactions with intracellular receptors (see Chapter 19).

We recognize three major classes of *membrane-bound receptors*. First are receptors, like those introduced in Chapter 13, that interact with G proteins and influence the synthesis of second messengers. Second are receptors that are themselves ion channels—comparable to the nicotinic acetylcholine receptor (page 991). Peptide hormones and epinephrine act primarily through these two classes of receptors. A third category, exemplified by the insulin receptor, is a

transmembrane protein with a ligand-binding site on the extracellular side and a catalytic domain on the cytosolic side. In the insulin receptor, that catalyst is a protein kinase, which is stimulated by insulin binding to the extracellular domain to phosphorylate tyrosine residues on target proteins.

Mechanisms of hormones that act through membrane-bound receptors by the first and third mechanisms are summarized in Figure 23.2. Note that the end result of most interactions between a hormone and a membrane receptor is activation of one or more protein kinases, whether or not a second messenger is involved. When Edwin Krebs and Edmond Fischer described in the late 1950s the sequence of reversible protein phosphorylations in the epinephrine-induced glycogenolytic cascade, there was no indication of the extent to which protein phosphorylation would turn out to dominate cell signaling mechanisms. At present more than 500 different protein kinases have been shown to exist in human cells, all of them related, as determined by amino acid sequence homologies. The importance of protein phosphorylation was recognized with the 1992 Nobel Prize for Medicine or Physiology to Krebs and Fischer. More recent work is uncovering a host of specific protein *phosphatases*, also subject to control by cell-signaling mechanisms. As noted in Chapter 18, protein acetylation is becoming recognized as a reversible protein modification that might be comparable to protein phosphorylation in its wide usage.

The end result of many signal transduction events is the phosphorylation or dephosphorylation of target proteins.

FIGURE 23.2

Eukaryotic signal transduction systems involving membrane receptors (1–5) and/or second messengers (1–4). Nitric oxide is shown, even though it lacks a membrane receptor because it diffuses into the cell and interacts with second-messenger systems. The end result of each pathway is phosphorylation of one or more proteins, some but not all of which have been identified. Recent evidence shows that some pathways engage in cross-activation, as shown here by the dashed arrow indicating control of PK-G by cyclic AMP. PK-A, cyclic AMP-dependent protein kinase; PK-G, cyclic GMP-dependent protein kinase; PK-C, protein kinase C. Protein kinases are shown in dark orange, including the intrinsic protein tyrosine kinase domain in system 5.

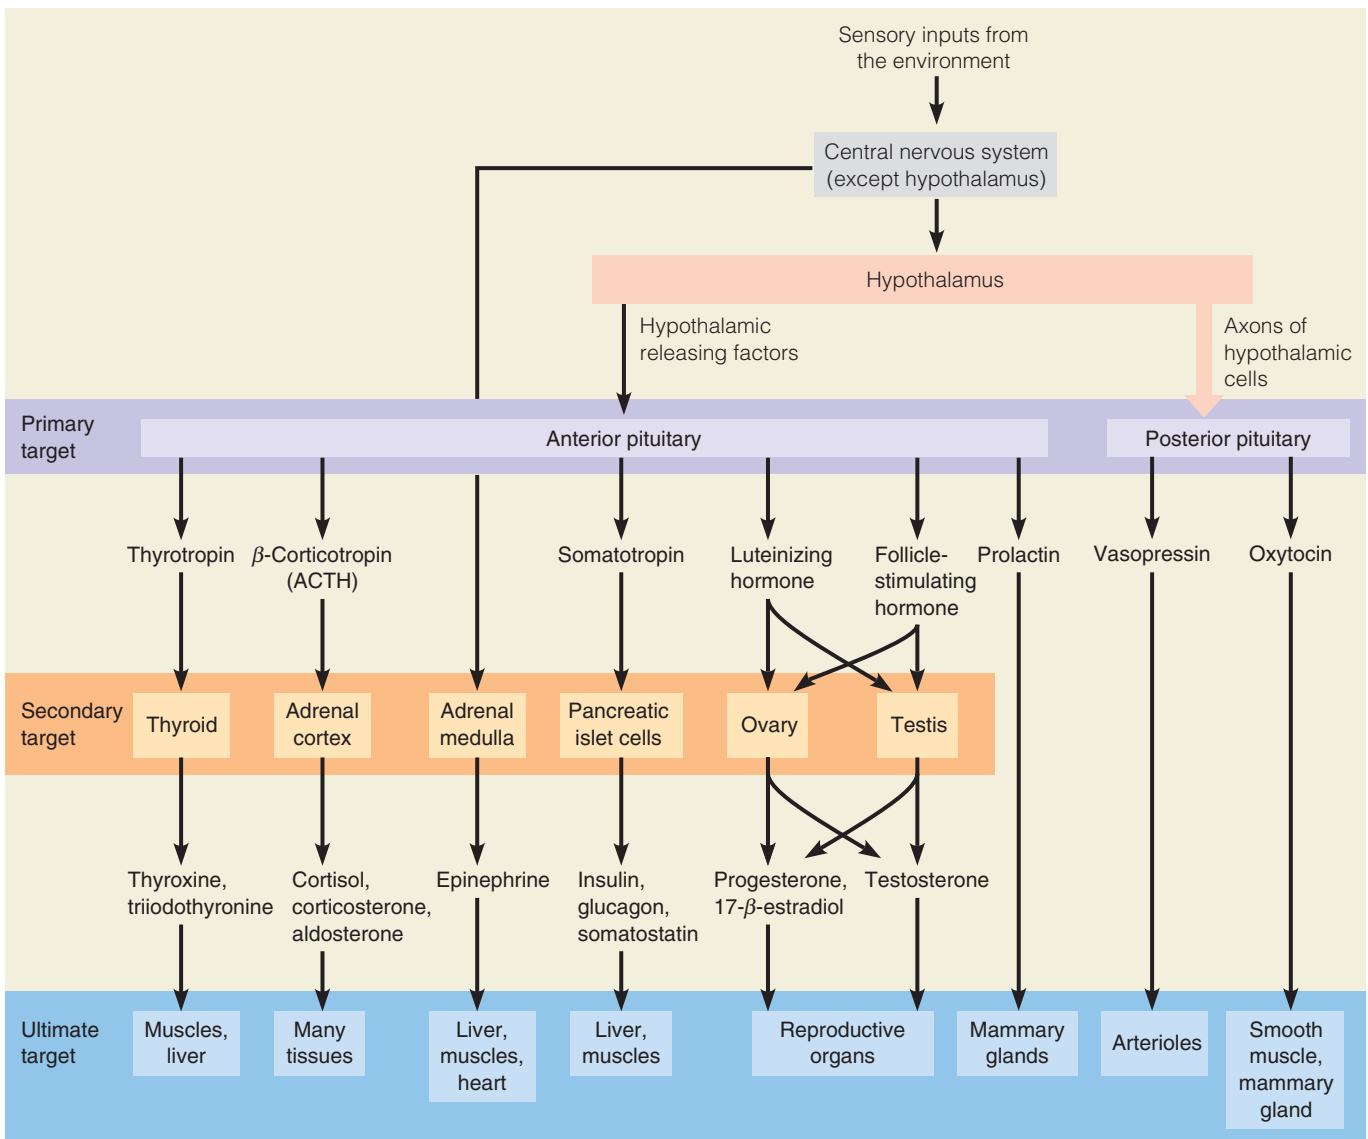

Specific hormone releasing factors from the hypothalamus control the release—and thus the action—of other hormones.

Hierarchical Nature of Hormonal Control

Hormonal regulation involves a hierarchy of cell types acting on each other either to stimulate or to modulate the release and action of a hormone. In vertebrates, the secretion of hormones from endocrine cells is stimulated by chemical signals from regulatory cells that occupy a higher position in this hierarchy (Figure 23.3). Hormonal action is controlled ultimately by the central nervous system. The master coordinator in mammals is the **hypothalamus**, a specialized center of the brain. The hypothalamus receives and processes sensory inputs from the environment via the central nervous system. In response it produces a number of hypothalamic hormones, some of them called **releasing factors**. These factors act on the pituitary, which is located just beneath the hypothalamus. Releasing factors stimulate the anterior portion of the pituitary to release specific hormones. Other hypothalamic hormones inhibit the secretion of particular pituitary hormones. Some pituitary hormones stimulate target tissue directly. For example, **prolactin** stimulates mammary glands to produce milk. However, most pituitary hormones act on endocrine glands that occupy an intermediate, or secondary, position in the

FIGURE 23.3

Hierarchical nature of hormone action in vertebrates. The pituitary represents the first target, being under hypothalamic control. Pituitary hormones then act on secondary targets, principally other endocrine glands, the hormone products of which collectively influence essentially all of the other organs and tissues. Neural stimulation of the adrenal medulla controls release of epinephrine.

hierarchy, stimulating them to produce hormones that exert the ultimate actions on target tissues. Pituitary hormones that act on other endocrine glands are called **tropic hormones** or **tropins**. An example is **adrenal corticotropic hormone (ACTH)**, also called **β -corticotropin**. This peptide is secreted from the anterior pituitary, and it stimulates the adrenal cortex to produce glucocorticoids and mineralocorticoids, which in turn act on a number of tissues, including kidney, muscle, and the immune system.

The action of a hormone is self-limiting because of the existence of feedback loops, in which secretion of a hormone sets in motion a series of events that leads to inhibition of that secretion. As shown in Figure 23.4, for example, the secretion of β -corticotropin from the pituitary is stimulated by **corticotropin releasing factor (CRF)**, a hypothalamic hormone that is a 41-residue polypeptide. Hypothalamic cells contain glucocorticoid receptors, which sense the elevated levels of circulating glucocorticoids, such as cortisol, that result from stimulation of the adrenal cortex. Binding of glucocorticoids to these receptors inhibits the further release of CRF, thus completing a feedback loop.

Synthesis of Peptide Hormone Precursors

We have already presented the biosynthesis of steroid hormones (see Chapter 19) and of catecholamines and thyroid hormones (see Chapter 21), both of which occur via straightforward metabolic pathways. Nearly all peptide hormones are synthesized as inactive precursors and then converted to active hormones by proteolytic processing. Studies of the synthesis of insulin provided the first evidence for this phenomenon. Recall that this hormone contains two polypeptide chains, of 21 and 30 residues, with two interchain disulfide bridges and one intrachain bridge (see Figure 5.21, page 154). These chains are formed by cleavage from an 81-residue polypeptide, called **proinsulin**. The first product of translation of the insulin gene is the 105-residue **preproinsulin**. Cleavage from preproinsulin of a 24-residue N-terminal “signal sequence” gives proinsulin, which undergoes folding, disulfide bond formation, and cleavage to give the active hormone, insulin. The signal sequence is involved in transport of proteins through membranes (see Chapter 28).

All known polypeptide hormones are synthesized in “prepro” form, with a signal sequence and additional sequence(s) that are cleaved out during maturation of the hormone. In some cases a single precursor polypeptide sequence contains two or more distinct hormones. The most complex known example is a pituitary multihormone precursor that contains sequences for β - and γ -lipotropin, α -, β -, and γ -melanocyte-stimulating hormone (MSH), endorphin, and enkephalin, as well as ACTH. This precursor, called **pro-opiomelanocortin**, derives its name from its role as precursor to endogenous *opiates*, *melanocyte*-stimulating hormone, and *corticotropin*. A remarkable fact about pro-opiomelanocortin is that its cleavage at different sites in different cells means that different cell types produce distinct ensembles of hormones derived from this one precursor. Cleavage sites are shown in magenta in Figure 23.5. In the anterior pituitary, cleavage generates ACTH and β -lipotropin, and further processing in the central nervous system yields endorphin and enkephalin (page 994), among other products. Synthesis of peptide hormones almost always involves proteolytic cleavage of a protein precursor.

Signal Transduction: Receptors

As noted earlier, our first insights into molecular mechanisms of hormone action came from analysis of glycogenolysis, stimulated either by epinephrine or by glucagon. In Chapter 13 we described the modular nature of this system,

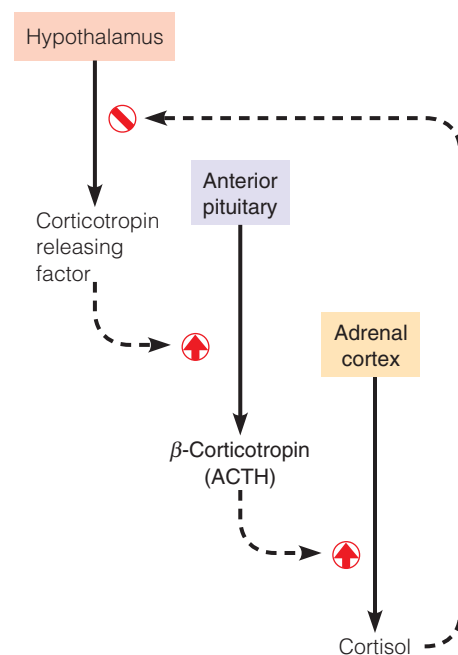

FIGURE 23.4

An example of feedback regulation of a hormone. Corticotropin releasing factor (CRF) stimulates the release of β -corticotropin (ACTH) from the anterior pituitary. ACTH stimulates the adrenal cortex to release cortisol, which feeds back on the hypothalamus to inhibit further release of CRF.

Hormone action is self-limiting because of the existence of feedback loops.

The central nervous system transmits signals to the hypothalamus, which produces releasing factors that act upon endocrine glands to control secretion of hormones with specific metabolic effects upon target tissues.

**FIGURE 23.5****Structure and properties of pro-opiomelanocortin.**

The structure shown is the primary translation product, *prepro-opiomelanocortin*. A signal peptide is cleaved off to give pro-opiomelanocortin, the prohormone, which is cleaved differently in different tissues to yield distinct assemblages of hormones and neurotransmitters. Cleavage sites are marked by red lines; most are pairs of basic amino acids. The number of residues in each polypeptide product is indicated.

including three components—a receptor (the hormone receptor), a transducer (a G protein), and an effector (adenylate cyclase). In this section we discuss in more detail the nature and action of each of these components.

With the exception of gaseous signaling agents such as nitric oxide, hormones interact with target cells by initially binding to a macromolecular receptor, located either in the plasma membrane or in the interior of the cell. Because the receptor participates in transduction of the signal from the external messenger to some component of the metabolic machinery, it must have at least one additional functional site. The activity of this site is altered by hormone binding, just as the catalytic site of an allosteric enzyme is altered by the binding of effectors at remote sites.

Experimental Study of Receptors

Binding of hormones to receptors is saturable, comparable to the binding of substrates to enzymes.

Molecular interactions involving hormone receptors can be studied experimentally by methods comparable to those used in enzymology. Binding of a hormone to its receptor is saturable, and the kinetics resembles Michaelis–Menten kinetics. Most hormones bind tightly, with dissociation constants in the range of $0.1\mu\text{M}$ to 1.0 pM . The ability of a tissue to respond to hormonal stimulation is a function of the receptor density of cells in that tissue.

Binding of radioactive hormone or an analog can be used to identify and quantify receptors, either as an assay when purifying receptors or in determining receptor density in a given cell type. The tight binding between hormones and their receptors can also be exploited in designing purification protocols involving affinity chromatography (Chapter 5). In fact, one of the earliest applications of this technique was purification of the insulin receptor, using columns of immobilized insulin. This development eased a task that is normally difficult for two reasons. First, membrane-bound receptors must be solubilized prior to purification, without irreversible inactivation. Second, most hormone receptors are present in exceedingly small amounts. For example, adipose tissue contains only about 10^4 insulin receptor molecules per cell.

Another useful technique is photoaffinity labeling, which creates a covalent bond between a hormone analog and a receptor. In this technique, a hormone molecule is modified with a photoreactive group, such as an azido moiety

($-N_3$). Mixing a radiolabeled hormone analog with a cell extract, followed by UV light irradiation, covalently binds the analog to its receptor, creating a radioactive tag that can be used to isolate the receptor.

Agonists and Antagonists

Often the ligand used in receptor-binding assays or in affinity chromatographic purification is not the hormone itself but an analog that happens to bind to the receptor, sometimes more tightly than the natural hormone. The analog may show little or no structural resemblance to the natural ligand, but it may show a stereochemical relationship that is evident in three-dimensional models. An example is the synthetic hormone analog **diethylstilbestrol**. This compound is 3 times more potent as an estrogen than 17- β -estradiol, which in turn is 10 times more potent than other natural estrogens. Diethylstilbestrol has been used in purifying and characterizing estrogen receptors. The synthetic hormone has had its uses outside the laboratory as well, including its addition to feed to stimulate growth of beef cattle, until it was found to be carcinogenic.

Diethylstilbestrol is an example of a hormone **agonist**—an analog that binds productively to a receptor and mimics the action of the endogenous hormone. An agonist is comparable to an alternative substrate for an enzyme: Its binding to a receptor is productive, in that it evokes a metabolic response comparable to that of binding the hormone. By contrast, a hormone **antagonist** binds to receptors but does not provoke the normal biological response. An antagonist is to a receptor as a competitive inhibitor is to an enzyme, in that both antagonists and competitive inhibitors compete with a normal ligand (hormone or substrate, respectively) for binding to a specific site on a protein and, by so binding, inhibit a normal biological process.

Agonists and antagonists have been useful in studies of the stereochemistry of binding sites on receptors. In turn, these investigations are useful in drug design, with a goal of activating or inactivating certain classes of receptors. For example, the agonist **isoproterenol** is used to treat asthma because it mimics the effects of catecholamines in relaxing bronchial muscles in the lung; it does so by interacting with one specific class of **adrenergic receptors** (so-called because they bind **adrenaline**, the old name for epinephrine). Another important drug, used to control blood pressure and pulse rate in cardiac patients, is **propranolol**, an antagonist of another class of adrenergic receptors, which control blood pressure and heartbeat rate.

Classes of Catecholamine Receptors

Studies of many agonists and antagonists of the catecholamines originally revealed the existence in vertebrates of four types of catecholamine receptors, each of which has a distinctive pattern of response to these analogs (now several more are recognized). The basic four are called the α_1 -, α_2 -, β_1 -, and β_2 -adrenergic receptors. Receptors of the β type are those we encountered before, in our discussions of epinephrine-induced lipolysis and glycogenolysis (see Chapters 13 and 17). Adrenergic receptors of different types, in different tissues, have various physiological effects, some of which are summarized in Table 23.1.

Receptors and Adenylate Cyclase as Distinct Components of Signal Transduction Systems

In the early stages of hormone research the epinephrine- or glucagon-stimulated mobilization of glycogen was the only defined biochemical response to hormone-receptor interaction. Adenylate cyclase, which synthesizes cyclic AMP in response to hormone secretion, was found to be a membrane-bound enzyme. Because the receptor is also membrane-bound, it was thought for some time that the receptor *was* adenylate cyclase and that epinephrine binding activated the enzyme. However, two observations argued against that interpretation. First, other hormones

TABLE 23.1 Some biological actions associated with adrenergic receptors

Receptor Class	Target Tissue	Hormone or Agonist Response
α_1	Iris of the eye	Contraction
	Intestine	Decreased motility
	Salivary glands	Potassium and water secretion
	Male sex organ	Ejaculation
	Bladder sphincter	Contraction
α_2	Pancreatic β cells	Decreased secretion
	Stomach	Decreased motility
	Adipocytes	Increased lipolysis
β_1	Heart	Increased contractility, rate, and depth
	Adipocytes	Decreased lipolysis
	Kidney	Increased renin secretion
β_2	Heart	Increased contractility, rate, and depth
	Lung	Relaxation
	Liver	Increased glycogenolysis and gluconeogenesis
	Pancreatic β cells	Increased pancreatic secretion
	Skeletal muscle	Increased contractility and glycogenolysis

Adapted from *Goodman and Gilman's Pharmacological Basis of Therapeutics*, 10th ed., J. G. Hardman, L. E. Limbird, and A. G. Goodman, eds., pp. 119–120. © 2001 The McGraw-Hill Companies, Inc.

were found to activate adenylate cyclase; more than a dozen are now known, including glucagon, ACTH, melanocyte-stimulating hormone, and luteinizing hormone. Adenylate cyclase seemed unlikely to have that many hormone-binding sites. Second, binding of catecholamines to the α_2 class of receptors was found to *inhibit* adenylate cyclase, suggesting that different kinds of proteins interact with adenylate cyclase to produce different metabolic effects.

Both of these observations indicated that the receptor and adenylate cyclase are distinct proteins. In fact, the resolution of β -adrenergic receptors from adenylate cyclase was observed experimentally in 1977, an important development because it showed that this hormonal response system has far more flexibility and versatility than previously thought. A wide variety of hormones could exert a multitude of biological effects through a common mechanism, namely, activation or inhibition of cyclic AMP synthesis. The diversity of signals and responses was built into both the diversity of receptors and the diversity of enzymes in target cells whose activities could be increased or inhibited by cyclic AMP-stimulated phosphorylation. It was soon learned that transduction of the hormonal signal to adenylate cyclase involved a third class of proteins—the G proteins, which we also introduced in Chapter 13. These developments were recognized by the award of the 1994 Nobel Prize to Martin Rodbell, who showed that receptors are distinct from adenylate cyclase, and Alfred Gilman, for the discovery of G proteins.

Because receptors are embedded in the membrane and are present in minute amounts, their isolation in quantities sufficient for structural analysis is a Herculean task. Cloning the receptor genes was crucial in gaining complete amino acid sequence information. Among the many receptor proteins whose amino acid sequences have now been determined—including both α_2 - and β_2 -adrenergic receptors—there are some remarkable structural similarities. The proteins are of comparable size, with 415 to 480 residues, including seven conserved regions that are rich in hydrophobic amino acids. It seems clear that these represent regions of α helix that are embedded in the membrane and linked by hydrophilic loops, projecting into both the extracellular environment and the cytosol, with the recognition site for the signaling agent on the extracellular side.

Hormones that act through second messengers involve a three-protein module—receptor, transducer (G protein), and effector (adenylate cyclase or related enzyme).

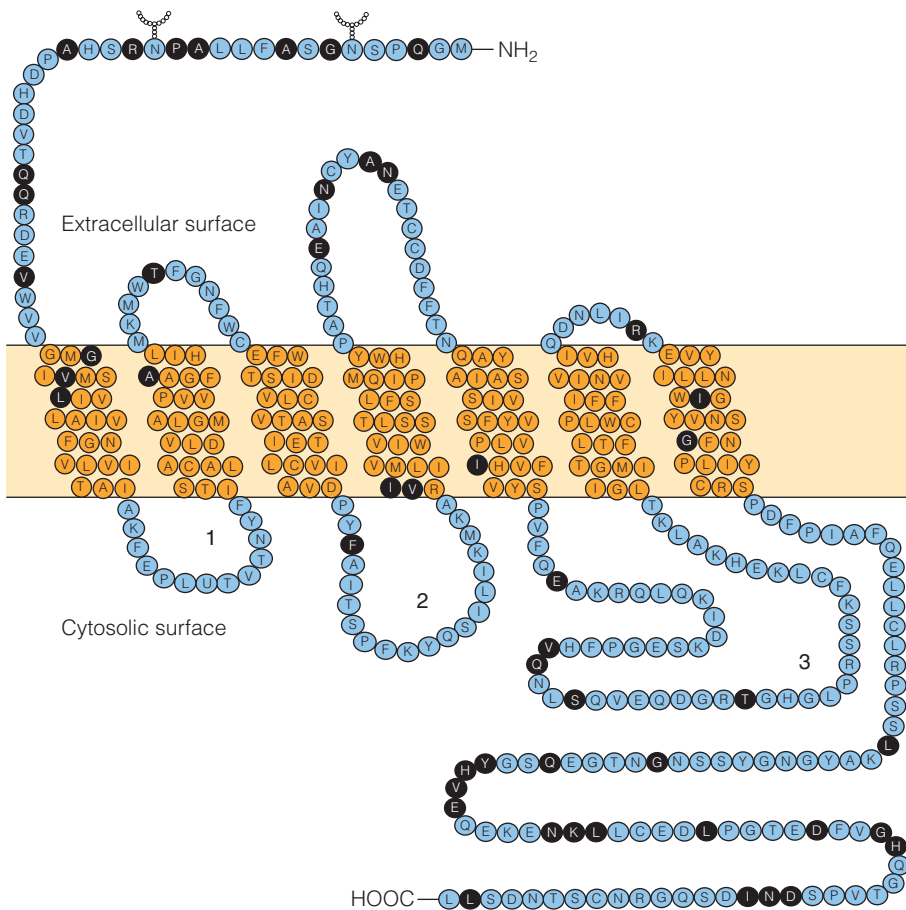

FIGURE 23.6

Amino acid sequence of the human β_2 -adrenergic receptor. The seven conserved transmembrane domains are shown in orange. Note also the three extracellular and three cytoplasmic loops and the two N-linked oligosaccharide units on the extracellular side (bound to asparagine residues). Interaction of the receptor with G proteins is controlled in part by reversible phosphorylation of serine and threonine residues near the C-terminus. The amino acids colored black are the ones that are different in the hamster β_2 -adrenergic receptor sequence.

The amino acid sequence of the β_2 -adrenergic receptor (β_2 AR) is depicted in Figure 23.6, along with the putative membrane-spanning domains. Because this class of receptor molecules snakes back and forth through the membrane, they are called serpentine receptors. Because nearly all of these receptors function in concert with G proteins they are also called G protein-coupled receptors, or GPCRs. It is estimated that half of all prescription, non-antibiotic drugs target members of this receptor class.

Structural analysis of GPCRs was challenging because of their membrane association. The first member of this class to be so characterized, in 2000, was rhodopsin, which is a G protein-coupled receptor, but which participates in light sensing in vision, rather than in hormone action (see page 809). The structure of the β_2 -adrenergic receptor was described in 2007. Figure 23.7 shows this molecule in complex with a β -adrenergic antagonist, carazolol. The figure shows a remarkable similarity between the structures of rhodopsin and β_2 AR, in placement of the seven transmembrane helices, and in the binding site for ligand (carazolol for β_2 AR, 11-*cis*-retinal for rhodopsin). A significant difference is the involvement of a helical region of one of the extracellular domains of β_2 AR in binding the ligand. Since 2007, a half dozen additional GPCR structures have been reported, and all follow the same general plan shown here for rhodopsin and β_2 AR.

Δ^9 -Tetrahydrocannabinol (THC), the active principle in marijuana, has been shown to act *via* binding to two G protein-coupled receptors. Recently, endogenous ligands for these receptors have been identified, and these molecules may play roles in adaptation to pain and inflammation. Activation of the receptors by endogenous ligands has various effects, including stimulation of appetite. Interestingly, these endogenous ligands are derivatives of arachidonic acid, with no evident structural relationship to THC.

FIGURE 23.7

Structure of the human β_2 -adrenergic receptor. (a) A model of two receptors embedded in the membrane and joined by cholesterol molecules (in yellow). The ligand carazolol is shown in green.

(b) Comparison of the top (extracellular) views of rhodopsin (PDB ID 1F88) and the β_2 -adrenergic receptor (PDB ID 2RH1), showing similarities in arrangement of the transmembrane helices. Each ligand (11-*cis*-retinal in rhodopsin, carazolol in β_2 AR) is shown in red.

A helical region of an extracellular domain, which helps to form the binding pocket for epinephrine, is shown in red.

Transducers: G Proteins

We come now to the second component of the receptor–transducer–effector signaling system first described for the β -adrenergic response: the G proteins, so designated because of their ability to bind guanine nucleotides. In 1971, guanosine triphosphate was found to be required for activation of adenylate cyclase by β -adrenergic agonists, and late in the decade the basis for this requirement emerged: GTP-binding membrane proteins interact with receptor systems that activate or inhibit adenylate cyclase. Of the several known G proteins, the two best characterized are G_s , a family of G proteins involved in *stimulation* of adenylate cyclase, and G_i , a closely related family involved in responses that *inhibit* adenylate cyclase. Although both types of G proteins interact with other receptors as well (and with target proteins other than adenylate cyclase), it is useful first to describe their functions in terms of the adrenergic receptors.

Actions of G Proteins

The G proteins are membrane proteins that in the *inactive* state bind guanosine diphosphate, GDP. As we discussed in Chapter 13, a hormone response leading to stimulation of adenylate cyclase—the binding of extracellular hormone or agonist to a receptor, typically a β -adrenergic receptor—causes a conformational change that stimulates the receptor to interact with a nearby molecule of G_s . This in turn stimulates an exchange of bound GDP for GTP—that is, the dissociation of GDP from G_s , to be replaced by GTP. G_s is thereby converted to a protein that activates adenylate cyclase, producing cyclic AMP from ATP. Cyclic AMP synthesis results in activation of cAMP-dependent protein kinase (protein kinase A), with consequent phosphorylation of target proteins, such as phosphorylase *b* kinase in cells that activate glycogen phosphorylation.

To summarize, this signal transduction pathway involves (1) hormone binding to receptor; (2) receptor interaction with G_s , stimulating release of GDP and association of GTP with G_s ; (3) stimulation of adenylate cyclase by the GTP-bound G_s ; (4) stimulation by cAMP of protein phosphorylation; and (5) stimulation or inhibition of metabolic reactions.

The initial exchange reaction (top of Figure 23.8) is usually assisted by one of a class of proteins called **guanine nucleotide exchange factors** (GEFs). Continued activation of G_s depends on the presence of bound GTP. The hormonal response is limited, and hence is controlled, by the presence of a slow GTPase activity inherent to the G protein. Thus, bound GTP is slowly hydrolyzed to GDP, with concomitant loss of ability to stimulate adenylate cyclase. This process, like the initial activation, is protein-assisted, being helped by a **GTPase-activating protein** (GAP). The G_i protein functions similarly, but in response to extracellular signals whose function is the *inhibition* of adenylate cyclase, typically α_2 agonists. Here the binding of GTP provokes an inhibitory interaction of G_i with adenylate cyclase, which decreases the synthesis of cAMP.

Structure of G Proteins

G_s , G_i , and other G proteins have an $\alpha\beta\gamma$ trimeric structure (Figure 23.8): a 39- to 46-kilodalton α subunit, a 37-kilodalton β subunit, and an 8-kilodalton γ subunit. The human genome encodes at least 24 different α proteins, 5 β , and 6 γ , allowing for a great variety of different trimeric G proteins. In most of these the γ subunit is **prenylated**; that is, it contains a covalently bound C_{20} isoprenoid moiety at the C-terminal cysteine, which helps anchor the protein in the membrane and may facilitate protein-protein interactions (see Chapter 19). The α subunit is **myristylated** in two other G proteins, G_i and G_o , and palmitylated in G_s . That is, it contains a myristic acid or palmitic acid moiety in amide linkage with C-terminal glycine. The guanine nucleotide-binding site and its associated GTPase activity are both located on the α subunit. A hormonal stimulus leads to exchange of GDP for GTP and dissociation of the G protein, with the α -GTP complex moving along the membrane until it encounters a molecule of adenylate cyclase or effector molecule. The slow GTPase activity mentioned earlier eventually reconverts α -GTP to α -GDP, and the α -GDP complex dissociates from adenylate cyclase and rejoins the $\beta\gamma$ complex.

Consequences of Blocking GTPase

The importance of the GTPase activity in controlling the hormone response can be seen in the consequences of blocking it. Blocking can be achieved in vitro by substituting GTP with **GTP γ S**, a GTP analog in which a sulfur atom substitutes for an oxygen on the γ phosphate of GTP, and which the GTPase activity cannot cleave. In a G_s -dependent system the result is irreversible activation of the target adenylate cyclase.

More dramatic are the effects of bacterial toxins that have G proteins as their biological targets. The toxin of *Vibrio cholerae* is an enzymatic protein with the ability to cleave NAD^+ and transfer its ADP-ribose moiety to a specific site in the α subunit of G_s . This modification of G_s inhibits its GTPase activity and converts α subunit to an irreversible activator of adenylate cyclase.

In the intestine the resultant cAMP accumulation promotes a physiological response controlled by cAMP—uncontrollable secretion of water and Na^+ —and

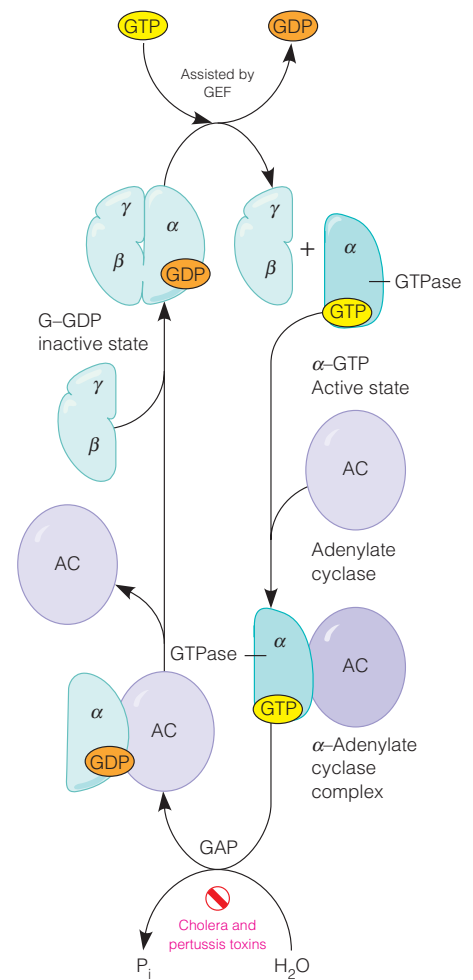

FIGURE 23.8

The cycle of G protein dissociation and reassociation. α , β , and γ are the three subunits of the G protein. The active form is the α -GTP complex (dark teal), while the inactive GDP complexes are shown in light teal. The sites of action of pertussis and cholera toxins are also shown. GEF, guanine nucleotide exchange factor; GAP, GTPase-activating protein.

Activation of G proteins involves GTP displacement of GDP bound to the α subunit and dissociation of the complex from $\beta\gamma$. Hormone action is limited by slow hydrolysis of the bound GTP.

is responsible for the severe diarrhea and consequent dehydration and loss of salt that accompany cholera. A component of the toxin of *Bordetella pertussis*, which causes whooping cough, has a similar effect on the α subunit of the G_i protein, with different physiological effects—lowered blood glucose and hypersensitivity to histamine.

G Proteins in the Visual Process

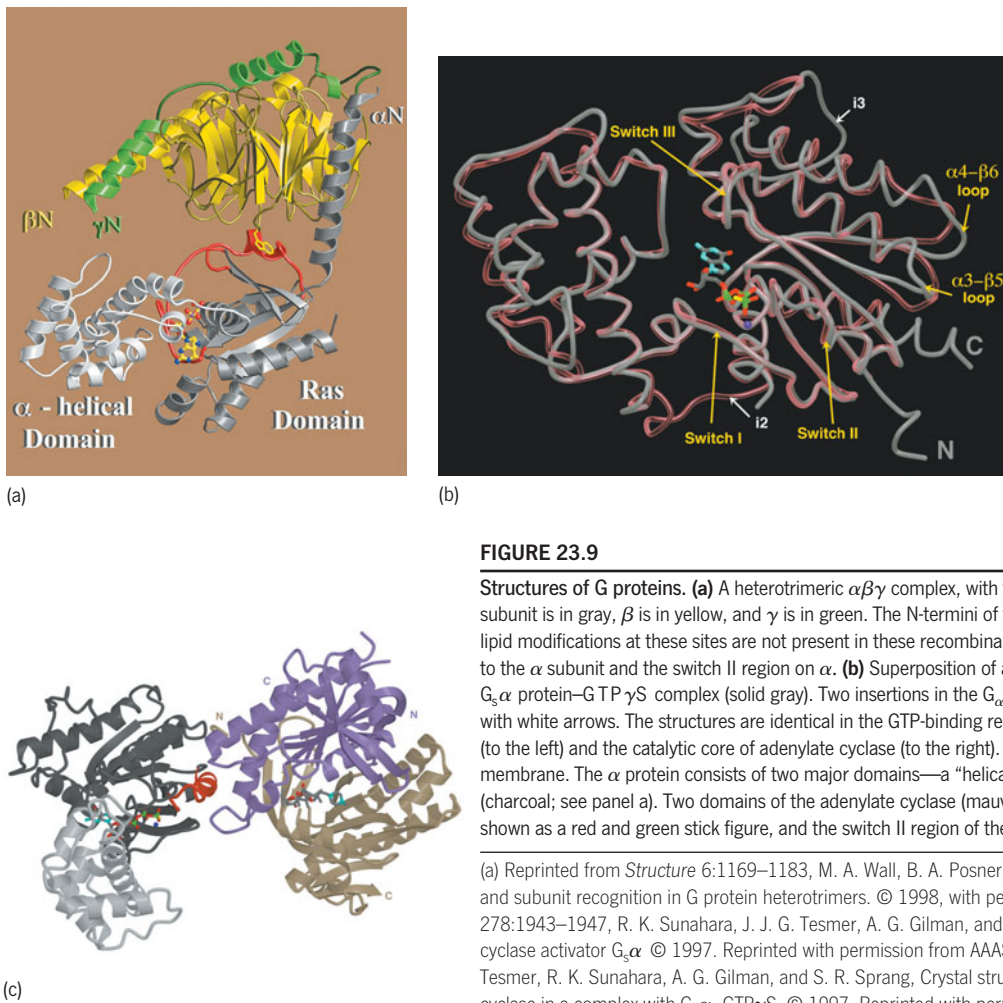

There are remarkable similarities between the actions of G proteins in transmitting hormonal signals and their actions in the transmission of signals from light. Much of our understanding of G proteins in hormonal signal transduction came from studies of a G protein called **transducin** in the visual process. The extracellular stimulus and the biochemical end point are quite different in vision from those in hormone action, but the transmembrane signaling processes are almost identical. As mentioned in Chapter 19, the extracellular signal in vision is a photon of light, and the membrane receptor is **rhodopsin**, an abundant membrane protein in the outer segment of rod cells in the retina and, as noted earlier, structurally related to adrenergic receptors. A photochemical change in the structure of rhodopsin causes it to activate transducin so that it binds GTP. The transducin–GTP complex activates a specific **phosphodiesterase**, which hydrolyzes a cyclic nucleotide, **guanosine 3,5-monophosphate** (cyclic GMP or cGMP). Cleavage of cGMP, in turn, stimulates intracellular reactions that generate a visual signal to the brain. Thus, the stimulated *hydrolysis* of cGMP is the visual analog of the stimulated *synthesis* of cAMP in β -adrenergic responses.

A Closer Look at G Protein Subunits

The G protein mechanism is used in many signal transduction pathways. Reassortment of the several α , β , and γ proteins means that a large number of different G proteins exists, giving great flexibility in response to this signal transduction element. Interaction with target enzymes is a function of the α subunits. Some interact with adenylate cyclase, some with ion channels, and some with phospholipases. One large subfamily of G proteins, called G_{olf} is present in olfactory cells in the nose and functions with a large number of receptors involved in sensory reception of odors.

The α subunits of G proteins are part of a family of small GTP-binding proteins that are active when GTP is bound and inactive in the presence of GDP. This family includes the oncogene-specified Ras proteins (see page 985) and the GTP-binding elongation factors involved in protein synthesis (Chapter 28). In recent years much has been learned from crystallographic studies about how GTP binding activates this class of proteins and how the activated protein in turn interacts with its target. Figure 23.9a shows the structure of an $\alpha\beta\gamma$ heterotrimeric G protein–GDP complex, with the α subunit derived from a G_i protein. The “switch II” region, shown in red, is a domain that changes conformation when GTP is hydrolyzed. Panel b shows the structure of a G_s α protein superimposed on that of a G_i α subunit; both proteins are binding nonhydrolyzable GTP γ S. Points of structural divergence are

**FIGURE 23.9**

Structures of G proteins. (a) A heterotrimeric $\alpha\beta\gamma$ complex, with the α subunit derived from a G_i protein. The α subunit is in gray, β is in yellow, and γ is in green. The N-termini of the three proteins are shown; note that the lipid modifications at these sites are not present in these recombinant proteins. Shown in yellow are a GDP bound to the α subunit and the switch II region on α . (b) Superposition of an α protein from G_i (transparent rose) and a $G_s\alpha$ protein-GTP γ S complex (solid gray). Two insertions in the $G_{\alpha s}$ protein relative to $G_{\alpha i}$ (i2 and i3) are shown with white arrows. The structures are identical in the GTP-binding regions. (c) A complex between $G_s\alpha$ -GTP γ S (to the left) and the catalytic core of adenylyl cyclase (to the right). The upper side is believed to face the plasma membrane. The α protein consists of two major domains—a “helical” domain (ash gray) and a “ras-like” domain (charcoal; see panel a). Two domains of the adenylyl cyclase (mauve and khaki) are also shown. GTP γ S is shown as a red and green stick figure, and the switch II region of the α protein is shown in red.

those expected to determine whether interaction of the α protein with a target enzyme, such as adenylyl cyclase, activates or inhibits that enzyme. Panel c shows a complex between a $G_s\alpha$ bound to GTP γ S and the catalytic core of adenylyl cyclase. The switch II region of the α protein is in close contact with the target enzyme and participates in its activation.

Modulating the Hormonal Stimulus

Obviously, for hormonal signaling to be effective, the response must be modulated once conditions that created it have changed. Several processes are involved. First, as hormone secretion slows, hormone–receptor complexes dissociate by mass action. Second, as mentioned above, the intrinsic GTPase activity of G protein α subunit hydrolyzes bound GTP, leading to G protein inactivation. This process is stimulated by GAP protein. Third, the receptor itself undergoes inactivation by a process that begins with the action of **β -adrenergic receptor kinase (β -ARK)**, which phosphorylates several C-terminal serines in the receptor molecule. This leads to binding of another protein, **β -arrestin**, which recognizes the phosphorylated sites and binds the receptor. This causes the receptor- β -ARK complex to become internalized in an endocytotic vesicle. Within the cell’s interior the β -arrestin- β -ARK complex dissociates, and the receptor is dephosphorylated and returned to the cell surface, effectively resensitizing the receptor to subsequent hormone release. β -Arrestin also binds to other classes of receptors, leading to their regulation by similar mechanisms.

Effectors: Adenylate Cyclase

Although G proteins have several targets involved in signal transduction, we focus here upon adenylate cyclase (AC) because of its involvement in adrenergic signaling, which, as we have observed, represents a paradigm for signal transduction mechanisms. As noted earlier, AC catalyzes the conversion of ATP to cyclic AMP plus pyrophosphate. Mammalian cells contain 10 AC isoforms that are regulated by heterotrimeric G proteins, each consisting of two transmembrane domains, M1 and M2, and two homologous cytoplasmic domains, C1 and C2. Figure 23.10 shows the structure of the cytoplasmic domains crystallized in the presence of the α subunit of G_s and **forskolin**, a diterpene from an Indian plant that activates all but one of these adenylate cyclases. The action of forskolin, as shown partly by this structure, is to draw the two cytoplasmic domains together in a catalytically active conformation. Other studies indicate that the binding site for α_1 is on the opposite side of the pseudo-symmetric catalytic domain, where it appears to prevent association of the catalytic domains (not shown). Both regulatory subunits bind to sites remote from the active site of the enzyme, indicating that complex allosteric processes must be involved in regulating AC activity.

The adenylate cyclase reaction involves activation of the 3' hydroxyl of ATP, for nucleophilic attack on the α (inner) phosphorus to create a phosphodiester bond, with pyrophosphate as a leaving group. The reaction is quite similar to that catalyzed by DNA polymerases, except that the AC reaction is intramolecular. Not shown in the figure is the fact that the constellation of amino acid residues in the active site, including strategically placed Asp residues, plus the requirement for two metal ions, supports a mechanism for adenylate cyclase that is quite similar to the two-metal mechanism now widely accepted for DNA polymerases (Chapter 25, page 1046).

Second-Messenger Systems

Cyclic AMP

As introduced in Chapter 13 and elaborated here, many signal transduction events involve the linked actions of receptor, G protein, and adenylate cyclase. These events either stimulate or inhibit the synthesis of a second messenger, cyclic AMP, inside the cell. Many intracellular processes are controlled in turn by the level of that second messenger. One such process, not yet mentioned, is the synthesis of receptor proteins themselves. Cyclic AMP binds to and activates cAMP-dependent protein kinase (PKA; see Chapter 13), which in turn phosphorylates a protein called CREB (**cAMP response element binding protein**), and the resultant phosphorylated protein controls transcription of genes, including those

FIGURE 23.10

Crystal structure of an adenylate cyclase catalytic domain. (a) The C1a and C2a catalytic domains (tan and green) were crystallized as a complex with forskolin (yellow) and α_s , the α subunit of G_s (blue-green lower left). The catalytic site where ATP is bound consists of residues from both domains. GTP bound to α_s is shown as well (gray). **(b)** Schematic diagram showing relationships of the catalytic domains to the transmembrane helical regions.

From *Science* 278:1907–1916, J. J. G. Tesmer, R. K. Sunahara, A. G. Gilman, and S. R. Sprang, Crystal structure of the catalytic domains of adenylate cyclase in a complex with $G_s\alpha$ -GTP γ S. © 1997. Reprinted with permission from AAAS. Adapted with permission from John J. G. Tesmer, University of Michigan.

encoding particular receptors. Some of these actions represent adaptation of a cell to action of a hormone. In addition, cyclic AMP acts as a second messenger in the actions of many signaling agents other than epinephrine and glucagon, including dopamine, β -corticotropin (ACTH), histamine, serotonin, and prostaglandins.

With this diversity of signaling agents acting through cAMP, how does one explain the specificity of hormone action? Part of the answer lies in distribution of hormone receptors among tissues. Glucagon receptors, for example, are located in liver and adipose tissue, explaining the preferential effects of glucagon upon these tissues. Also, the distribution of stimulatory and inhibitory G proteins within different cells determines whether binding of a hormone to that cell will increase or decrease the intracellular cAMP concentration. More recently discovered is a class of proteins, called AKAPs (**A kinase anchoring proteins**), which are bound to specific sites within a cell and are controlled by localized pools of cAMP, thereby accounting for differential effects of cAMP within the same cell. Among the thirty or so human AKAPs are forms associated with microtubules, ion channels, or mitochondria and which bind protein kinase A at those specific sites, and hence, which localize the effects of cAMP within a single cell.

Cyclic GMP and Nitric Oxide

Cyclic AMP was the first second messenger known, but is far from the only one. We have briefly mentioned cyclic GMP (see page 970) and the phosphoinositide system (Chapter 19; see page 788). Much interest has focused on cyclic GMP, particularly with respect to its role in nitric oxide metabolism. Nitric oxide ($\text{NO}\cdot$) is a gaseous signaling molecule, synthesized from arginine (Chapter 21), which plays important regulatory roles. Nitric oxide was originally identified as an agent in vasodilation of endothelial vascular cells and underlying smooth muscle. Signals that decrease blood pressure and inhibit platelet aggregation use nitric oxide as an intermediary. In inflammatory and immune responses an inducible form of nitric oxide synthase produces $\text{NO}\cdot$ at levels sufficient to be toxic to pathogenic organisms. $\text{NO}\cdot$ also regulates neurotransmission in the central nervous system.

The $\text{NO}\cdot$ synthase in endothelial vascular cells is acutely sensitive to calcium ion concentration; activation of the enzyme by Ca^{2+} causes $\text{NO}\cdot$ accumulation. Because $\text{NO}\cdot$ is a gas, it can diffuse rapidly into neighboring cells, where it exerts its control by binding to ferrous ion in a soluble form of guanylate cyclase and stimulating cyclic GMP formation. Guanylate cyclase is sensitive to inhibition by ATP at physiological concentrations, suggesting a regulatory link between nitric oxide signaling and the energetic state of the cell. Guanylate cyclase is not the only regulatory target for nitric oxide (it reacts readily with Fe^{2+} , a component of cytochrome oxidase), but cGMP elevation is probably the major cellular effect of $\text{NO}\cdot$ release.

Because $\text{NO}\cdot$ is unstable, its effects are short-lived. Because of its function in stimulating vasodilation, $\text{NO}\cdot$ plays a role in stimulating erection of the penis. The drug Viagra counteracts erectile dysfunction by inhibiting cyclic GMP phosphodiesterase, and hence, increasing the metabolic half-life of cyclic GMP.

Many cells contain a cGMP-stimulated protein kinase that, unlike the cAMP-activated enzyme, contains both catalytic and regulatory domains on one polypeptide chain of a homodimeric protein. Our understanding of the roles of cGMP in signal transduction has come more recently because its intracellular concentrations are 10- to 100-fold lower than those of cAMP.

Although the discovery of nitric oxide as a gaseous signaling molecule was unexpected, $\text{NO}\cdot$ is not the only gaseous signaling agent. It turns out that both hydrogen sulfide and carbon monoxide, released in small, subtoxic doses, also have anti-inflammatory and vasodilatory actions similar to those of nitric oxide, although different mechanisms are involved. Hydrogen sulfide, produced by desulfhydration of cysteine, activates an ATP-sensitive potassium channel in smooth muscle cells. Less is known about mechanisms of action of carbon monoxide.

Sildenafil (Viagra)

Calcium Ion

Calcium ion has also been considered a second messenger. Many cells respond to extracellular stimuli by altering their intracellular calcium concentration, which in turn exerts biochemical changes either by itself or through its interaction with calmodulin (see Chapter 13). Calcium levels themselves are controlled in large part by second messengers, including cAMP. In many nerve and muscle cells, the activation of adenylate cyclase results in an influx of extracellular calcium. cAMP activates a voltage-dependent calcium channel in the presynaptic nerve membrane, allowing calcium ions to flow into the cell and triggering synaptic transmission (see Chapter 10). That activation may involve phosphorylation, by cAMP-dependent protein kinase, of a protein component of the channel. In muscle cells, calcium influx triggers muscle contraction (see Chapter 8) and is responsible, for example, for the increased rate and force of heartbeats caused by β -adrenergic agonists. Because the second messenger cAMP regulates calcium influx, some have suggested calling calcium a third messenger rather than a second messenger.

Phosphoinositides

Cytosolic calcium levels can be increased also by release from *intracellular* calcium stores. Access to these intracellular stores is controlled by another set of messengers, the **phosphoinositide system**. Although similar in many respects to the adenylate cyclase system, the phosphoinositide system is distinctive in that the hormonal stimulus activates a reaction that generates *two* second messengers. The earliest experimental observations regarding this signal transduction system occurred in 1953, when Mabel and Lowell Hokin noted that administration of acetylcholine to pancreatic secretory cells led to rapid synthesis and turnover of the phosphatidylinositol fraction of membrane phospholipids. Similar observations were made in other systems stimulated by hormones, neurotransmitters, or growth factors. However, more than two decades elapsed before a unifying concept emerged to explain these observations.

We now know that a specific lipid in the phosphoinositide family, namely, **phosphatidylinositol 4,5-bisphosphate (PIP₂)**, is a membrane-associated storage form for two second messengers. As shown in Figure 23.11, binding of an agonist to a receptor (step 1) stimulates a G protein to bind GTP (step 2), just as occurs during the adrenergic response. However, this G protein activates not adenylate cyclase but a different membrane-bound enzyme, **phospholipase C**, which in turn cleaves PIP₂ to yield two products (step 3)—***sn*-1,2-diacylglycerol (DAG)** and **inositol 1,4,5-trisphosphate (InsP₃)**. Both of these products act as second messengers. Therefore, the cleavage of PIP₂ by phospholipase C is the functional equivalent of the synthesis of cyclic AMP by adenylate cyclase.

The second-messenger role of inositol trisphosphate is to bind to and open calcium channels in the endoplasmic reticulum (ER), thereby releasing calcium from its intracellular stores in the ER (step 4 in Figure 23.11). This release has various effects on intracellular metabolism, as noted earlier, but it also contributes to the second-messenger role of diacylglycerol, which is the activation of membrane-bound protein kinase C (step 5). This enzyme requires for its activity *calcium* (hence the “C” designation) and a *phospholipid* (specifically, phosphatidylserine). The other second messenger, diacylglycerol, stimulates protein kinase C activity by greatly increasing the affinity of the enzyme for calcium ions. This requirement is specific for the *sn*-1,2-DAG; neither the 1,3- nor the 2,3-isomer is active. The enzyme phosphorylates specific serine and threonine residues in target proteins (step 6). As with cAMP-stimulated protein kinase, the specific cellular responses to protein kinase C activation, such as the phosphorylation of calmodulin shown in Figure 23.11, depend on the ensemble of target proteins that become phosphorylated in a given cell. Other known target proteins include the insulin receptor,

β -adrenergic receptor, glucose transporter, HMG-CoA reductase, cytochrome P450, and tyrosine hydroxylase.

Now let us briefly consider the metabolism of inositol trisphosphate (InsP₃) after its release from PIP₂. Three sequential hydrolytic steps yield inositol, which is then reincorporated into phosphatidylinositol, as discussed in Chapter 19, to

FIGURE 23.11

Signal transduction pathways involving phosphoinositide turnover. DAG, *sn*-1,2-diacylglycerol; Ins, inositol; InsP, inositol monophosphate; PIP, phosphatidylinositol-4-phosphate; PIP₂, phosphatidylinositol 4,5-bisphosphate; InsP₃, inositol 1,4,5-trisphosphate; InsP₂, inositol 1,4-bisphosphate. Most of the effects of calcium result from its binding to calmodulin (CaM). A23187 is a calcium ionophore, which can be used experimentally to release calcium from intracellular stores. The release of calcium ion stimulates both protein kinase C and calmodulin kinase.

regenerate PIP and PIP₂. The last hydrolytic step, the hydrolysis of inositol monophosphate to inositol, is specifically inhibited by **lithium ion**. This block inhibits the resynthesis of InsP₃ by depleting the cell of inositol.

Given that the phosphoinositide messenger system is widely used in nervous tissue, this action of lithium may be related to its efficacy in the treatment of bipolar syndrome, formerly called manic–depressive disorder.

Because many metabolic processes are controlled by calcium fluxes and by phosphorylation of specific proteins, the phosphoinositide system has great versatility as a control mechanism. The fact that a cell can use either DAG or InsP₃ or both mechanisms as the result of a single extracellular stimulus further increases this versatility. A partial listing of processes controlled by the phosphoinositide system is presented in Table 23.2.

Several observations imply a role for the phosphoinositide system not only in metabolic regulation but also in the control of cellular growth. First is the activity of a group of natural products called **phorbol esters**, part of whose structure resembles that of DAG (shown in magenta). These compounds are called **tumor promoters**. Not carcinogenic by themselves, they stimulate the formation of tumors when applied along with a carcinogen to experimental animals. Some phorbol esters have been found to activate protein kinase C independently of diacylglycerol. This finding is consistent with the hypothesis that protein kinase C activation is part of the normal growth control process that becomes perturbed in tumorigenesis. Another indication of a link between phosphoinositide metabolism and growth control is the function of certain cell growth factors. Some of them, notably **platelet-derived growth factor (PDGF)**, are known to interact with cell surface receptors to stimulate the hydrolysis of phosphatidylinositol.

It is becoming evident that phospholipases other than phospholipase C are also stimulated by G proteins. Recall from Chapter 19 that arachidonic acid, released from phosphatidylcholine, is the major metabolic precursor to eicosanoids. Phospholipase A₂, which releases this fatty acid, is also part of a signal transduction pathway involving G proteins, and phospholipase D is thought also to participate in signal transduction via diacylglycerol formation. In addition, some phospholipases are controlled by Ca²⁺.

To recapitulate: Cyclic AMP was the earliest known second messenger. However, several comparable second messengers are now known, including cyclic GMP, calcium ion, inositol trisphosphate, and diacylglycerol. In addition,

phosphoinositides are far from the only phospholipids involved in cell signaling. In Chapter 19 we mentioned platelet-activating factor, which promotes platelet aggregation through its binding to a G protein-coupled receptor. Also, lysophosphatidic acid regulates the growth and development of cell types involved in wound healing, through its interaction with a G protein-coupled receptor. Finally, ceramide, although not a phospholipid, regulates processes involved in growth, differentiation, senescence, and apoptosis. It does this through activation of protein phosphatases, which activate growth and differentiation factors through cleavage of phosphate from specific phosphoproteins.

Second messengers include cyclic AMP, cyclic GMP, calcium ion, inositol trisphosphate, and diacylglycerol.

Receptor Tyrosine Kinases

We turn now to a family of related membrane receptors that are distinctive in having a single membrane-spanning domain, a ligand-binding site on the extracellular part of the molecule, and an intrinsic protein tyrosine kinase activity on the intracellular side. These include the **insulin receptor** (IR) and receptors for related peptide growth factors, including those for **epidermal growth factor** (EGF), **platelet-derived growth factor** (PDGF), **colony-stimulating factor 1** (CSF-1), **nerve growth factor** (NGF), and **fibroblast growth factor** (FGF), as well as a peptide **insulin-like growth factor 1** (IGF-1). These receptors represent a family of closely related proteins (see Figure 23.12), for the tyrosine kinase domains share amino acid sequence homology. With the exception of receptors for insulin and IGF-1, these are monomeric proteins that dimerize to activate the kinase activity in response to agonist binding. Some members of this class act through second messengers, but most act by initiating a protein phosphorylation cascade, similar to what we have seen in glycogenolysis. Receptors in this class include those for many peptide growth factors, as well as for insulin (which can also be considered a growth factor).

The first of this family to be characterized was the insulin receptor (Figure 23.12). This is a glycoprotein with an $\alpha_2\beta_2$ tetrameric structure, stabilized by interchain disulfide bonds. Both the α chain, of 735 residues, and the β chain, of 620 residues, are translated from a single mRNA, giving a polypeptide chain that then undergoes proteolytic processing. The α chain, which does not span the membrane, binds insulin near its C-terminus. The β chain has a single transmembrane domain, with its C-terminus in the cell interior. That C-terminal region is the site of a protein tyrosine kinase activity, which is stimulated by binding of insulin to the extracellular part of the receptor. The kinase activity is essential to the biological activity of the insulin receptor because some cases of non-insulin-dependent diabetes are associated with receptor mutations that abolish the kinase activity.

A number of more distantly related membrane receptors have other enzyme activities. Proteins of the **transforming growth factor β** (TGF- β) family bind to a receptor that has a protein serine/threonine kinase activity (similar to cAMP-dependent protein kinase). **Atrial natriuretic factor** (ANF), a peptide that controls blood volume, binds to a receptor that has both a guanylate cyclase activity and a predicted protein serine/threonine kinase activity. When excess blood volume stretches the atrium, ANF is released and travels to the kidney, where it activates cGMP synthesis, in turn increasing renal excretion of sodium and accompanying water, thereby reducing blood volume.

Signaling pathways involving receptor tyrosine kinases (RTKs) begin with binding of an agonist to the extracellular domain, and this triggers receptor dimerization (except for the insulin receptor and the IGF-1 receptor, each of which is already a dimer of $\alpha\beta$ subunits). Dimerization stimulates autophosphorylation of tyrosines in the cytoplasmic domain. Next, proteins are recruited to the intracellular domains of the RTK by virtue of containing either **SH2**

FIGURE 23.12

The insulin receptor and its structural relationship to other transmembrane receptors with protein tyrosine kinase activity. Representative proteins in each subfamily are shown. Some subfamilies have a “kinase insert domain” within the protein kinase module. VEGF, vascular endothelial growth factor; Eph, ephrins, regulators of cell movements during development. Other abbreviations presented in the text.

The insulin receptor and several related growth factor receptors contain one transmembrane domain per polypeptide chain and have an intrinsic protein tyrosine kinase activity.

(Src homology) domains or **PTB** (phosphotyrosine-binding) domains. Because of the numerous signaling pathways involved, receptor tyrosine kinases represent attractive drug targets, and the insulin receptor has been especially well characterized. Figure 23.13a shows the structure of the dimeric receptor kinase domain of the insulin receptor, complexed with one of its substrates, protein tyrosine phosphatase 1B (PTP1B), a negative regulator of insulin signaling.

Proteins associating with the tyrosine kinase domain may be either signaling agents or adaptor proteins, which create binding sites for downstream signaling proteins. As schematized in Figure 23.13b, a prominent substrate for the insulin receptor kinase is **insulin receptor substrate-1** (IRS-1), which binds to the kinase domain of the insulin receptor via its SH2 domains. One downstream effect of this phosphorylation is activation of **phosphoinositide 3-kinase**, which converts phosphatidylinositol 4,5-bisphosphate (PIP₂) to phosphatidylinositol 3,4,5-trisphosphate (PIP₃), a second messenger with a variety of intracellular targets. In the response to insulin, one effect of PIP₃ is activation of **protein kinase B** (PKB), also called Akt, by way of its attachment to the membrane. PKB then phosphorylates another protein kinase, glycogen synthase kinase (GSK3), which, in the phosphorylated form, promotes the inactivation of glycogen synthase. Therefore, as a result of insulin binding to its receptor, glycogen synthase cannot be inactivated, ensuring that glycogen synthesis continues. PKB also acts to relocalize the glucose transporter GLUT4 from internal membrane vesicles to the cell surface, where it promotes glucose uptake. Insulin also has long-term effects as a growth hormone, and these result from establishment of another phosphorylation cascade. As shown also in Figure 23.13, phosphorylated IRS-1 interacts with an adaptor protein called Grb2, which in turn activates Sos, which next binds to Ras (more about Ras on page 985). Ras is comparable to a G protein α subunit, although Ras is not a complete G protein. Sos acts like a guanine nucleotide exchange factor (GEF, page 969) in that it activates Ras by promoting binding of GTP, coupled with dissociation of bound GDP. GTP-bound Ras activates a protein kinase called Raf-1, which in turn activates another protein kinase, ERK.

**FIGURE 23.13**

Receptor tyrosine kinases, as exemplified by the insulin receptor.

(a) Structure of the tyrosine kinase domain (IRK) complexed with one of its substrates, protein tyrosine phosphatase 1B (PTP1B). The two IRK subunits are in green and yellow-green, while PTP1B is in cyan. The catalytic loops of both proteins are in red, and the IRK activation loop, near the phosphotyrosine, is in gray on both subunits. PDB ID 2B4S. From S. Li et al. (2005) *Structure* 13:1643–1651, with permission from Elsevier. (b) Signaling pathways involving the insulin receptor. Ins, insulin. Proteins with SH2 domains bind to phosphotyrosine residues. To the left, phosphorylation of IRS-1 (insulin receptor substrate) initiates a phosphorylation cascade involving kinases Raf-1, MEK, and ERK, resulting in translocation of ERK-phosphate to the nucleus, where it stimulates transcription of genes related to growth and development. To the right, phosphorylated IRS-1 activates phosphoinositide 3-kinase (PI3K), which converts PIP₂ to PIP₃. PIP₃ activates phosphorylated protein kinase B (PKB) by binding it to the membrane, where it phosphorylates glycogen synthase kinase (GSK), inactivating it. This makes it impossible for glycogen synthase (GS) to become phosphorylated and, hence, inactivated; this allows glycogen synthesis to proceed. Another action of phosphorylated PKB is release of GLUT4, a glucose transporter, from intracellular stores. Its translocation to the membrane increases glucose uptake into target cells.

Phosphorylation of ERK leads to its uptake, through nuclear pores, into the nucleus, where it phosphorylates additional proteins, which in turn bind to specific sites on the genome, promoting transcription of genes whose actions promote cell division and growth.

Steroid and Thyroid Hormones: Intracellular Receptors

Hormones acting through nuclear receptors generally have longer-lived effects than those interacting with membrane receptors.

The family of steroid receptors contains a conserved, zinc-containing DNA-binding sequence and a C-terminal hormone-binding domain.

Hormonal effects occurring via membrane receptors tend to be of short duration. Like the epinephrine-induced glycogenolytic cascade, they represent responses to rapid and urgent physiological demands, and they involve activation or inhibition of preexisting enzymes. By contrast, the effects of steroid hormones involve longer-term changes, such as the activation of a transport system or the conversion of a resting cell to a growing cell. Steroids and related hormones (thyroid, vitamin D, and retinoic acid hormones) act intracellularly. By virtue of their hydrophobic nature, they traverse the plasma membrane and exert their effects within the cell—actually, within the nucleus, where they control the activities of specific genes. In most cases, target genes are activated. Table 23.3 lists several proteins whose synthesis is regulated by these hormones.

These regulatory effects occur at the level of transcription of steroid-responsive genes. Steroid and related hormones act by binding in the cytosol to specific receptor proteins, which dimerize under the influence of the hormone. Binding in the cytosol is followed by movement of the hormone–receptor complex into the nucleus, where the complex interacts with specific DNA sites called **hormone-responsive elements (HREs)**. Binding of the complex to DNA affects transcription

TABLE 23.3 Target organs for steroid and thyroid hormones and major proteins whose synthesis is affected

Hormone Class	Target Organ	Protein ^a
Glucocorticoids	Liver	Tyrosine aminotransferase Tryptophan oxygenase α -Fetoprotein (\downarrow) Metallothionein
	Liver, retina	Glutamine synthase
	Kidney	phosphoenolpyruvate carboxykinase
	Oviduct	Ovalbumin
	Pituitary	Pro-opiomelanocortin
Estrogens	Oviduct	Ovalbumin Lysozyme
	Liver	Vitellogenin Apo-VLDL
Progesterone	Oviduct	Ovalbumin Avidin
	Uterus	Uteroglobin
Androgens	Prostate	Aldolase
	Kidney	β -Glucuronidase
	Oviduct	Albumin
1,25-Dihydroxyvitamin D ₃ Thyroid hormones	Intestine	Calcium-binding protein
	Liver	Carbamoyl phosphate synthetase Malic enzyme
	Pituitary	Growth hormone Prolactin (\downarrow)
Ecdysone (insects)	Epidermis	Dopa decarboxylase
	Fat body ^b	Vitellogenin

^aSynthesis of each indicated protein is increased by the hormone, except for the two identified by (\downarrow).

^bThe fat body is an organ in insects that plays some of the same roles as liver and adipose tissue.

rates of nearby genes, by mechanisms now under intense study. Because of their site of action, members of this protein family are also called nuclear receptors.

Nuclear receptors exist at levels of only about 10^4 molecules per cell, which makes their purification difficult. However, because they bind to hormones quite tightly, it has been possible to purify these proteins by affinity chromatography. cDNA sequence analysis has revealed structural similarities among this class of receptors, and construction of hybrid receptors by recombinant DNA technology has allowed unambiguous identification of domains of function within the receptor molecule. Each receptor protein within this family contains a central conserved domain of about 80 residues, which is involved in DNA binding (Figure 23.14). On the N-terminal side of this domain is a region essential to transcriptional activation. Toward the C-terminus are domains involved in hormone binding, protein dimerization, and transcriptional activation.

All of the known receptors in this family contain bound zinc, which is essential for DNA binding, and the DNA-binding sequences show a completely conserved distribution of cysteine residues. These observations suggested that the zinc atoms could be complexed by the cysteine sulfurs in a pattern akin to the “zinc finger” structural motif associated with a number of other eukaryotic transcriptional regulatory proteins (see Chapter 27). That prediction has been supported by high-resolution NMR studies of receptor–DNA complexes (Figure 23.15).

The utility of a set of long-term-acting regulators is evident from a couple of examples. Estrogens and progesterone regulate the female reproductive cycle. In humans these hormones interact over a 4-week cycle to prepare the uterus for implantation of a fertilized ovum. Proliferation of the endometrium, the epithelial lining of the uterus, is the major event; clearly it requires new protein synthesis and increased blood flow to the uterus. These processes stop when a pituitary signal triggers decreased release of the hormones, causing sloughing off of cells in the uterine lining and the beginning of menstrual bleeding.

FIGURE 23.14

The conserved DNA-binding domain in steroid receptors. In the center are structural domains within steroid receptors, illustrated for the estrogen receptor. Above is the DNA-binding domain of the estrogen receptor, showing conserved cysteine residues that contact the bound zinc ions (a zinc finger DNA-binding motif; see Chapter 27). At the bottom are the DNA-binding domain sequences of related human receptors, with the conserved cysteine residues highlighted. ER, estrogen receptor; GR, glucocorticoid receptor; Trb, thyroid hormone receptor; PR, progesterone receptor; VitD, vitamin D receptor; RAR, retinoic acid receptor.

The actions of glucocorticoids are comparable, in that control of the synthesis of particular proteins allows for long-term metabolic adaptation. Whereas estrogens exercise control of reproductive metabolism over a several-week period, the secretion of glucocorticoids is a means of adaptation to longer-term stress. This adaptation involves stimulation of gluconeogenesis and synthesis of a variety of proteins, including some that counteract the effects of inflammation. Unlike estrogens, which act chiefly in reproductive tissues, the glucocorticoids influence cells in a wide variety of target tissues. Recent studies show that the rate of transcription of target genes following binding of the glucocorticoid-GR complex is acutely sensitive to the nucleotide sequence in the DNA binding region of the hormone-responsive element, making this sequence a crucial determinant of glucocorticoid sensitivity of target genes.

Investigations of the action of glucocorticoids as anti-inflammatory agents and as immunosuppressants have illuminated the action of another important signaling pathway, involving a transcriptional activator called NF- κ B. This protein stimulates transcription of genes for a class of proteins called **cytokines**, which stimulate various reactions of the immune response, including proliferation of antibody-producing cells. Normally, NF- κ B is bound to an inhibitory protein called I κ B α , which prevents its translocation into the nucleus. Binding of an immune stimulator, such as **tumor necrosis factor** (TNF), to its plasma membrane receptor leads to the ubiquitination of I κ B α and its subsequent degradation by the 26S proteasome (Chapter 20). This in turn allows NF- κ B to translocate to the nucleus, where it activates transcription of about 300 genes, including those for cytokines (Figure 23.16a). Another gene activated is that for I κ B α . This sets up a feedback loop, by escorting NF- κ B out of the nucleus, followed by repeated cycles of I κ B α degradation and translocation of NF- κ B back into the nucleus. Recent fluorescent imaging studies show oscillations in NF- κ B nuclear abundance, suggesting a timed response to what might also be a pulsatile stimulus (Figure 23.16b) and possibly explaining the diverse reactions, in different cells, to immune or inflammatory stimulation.

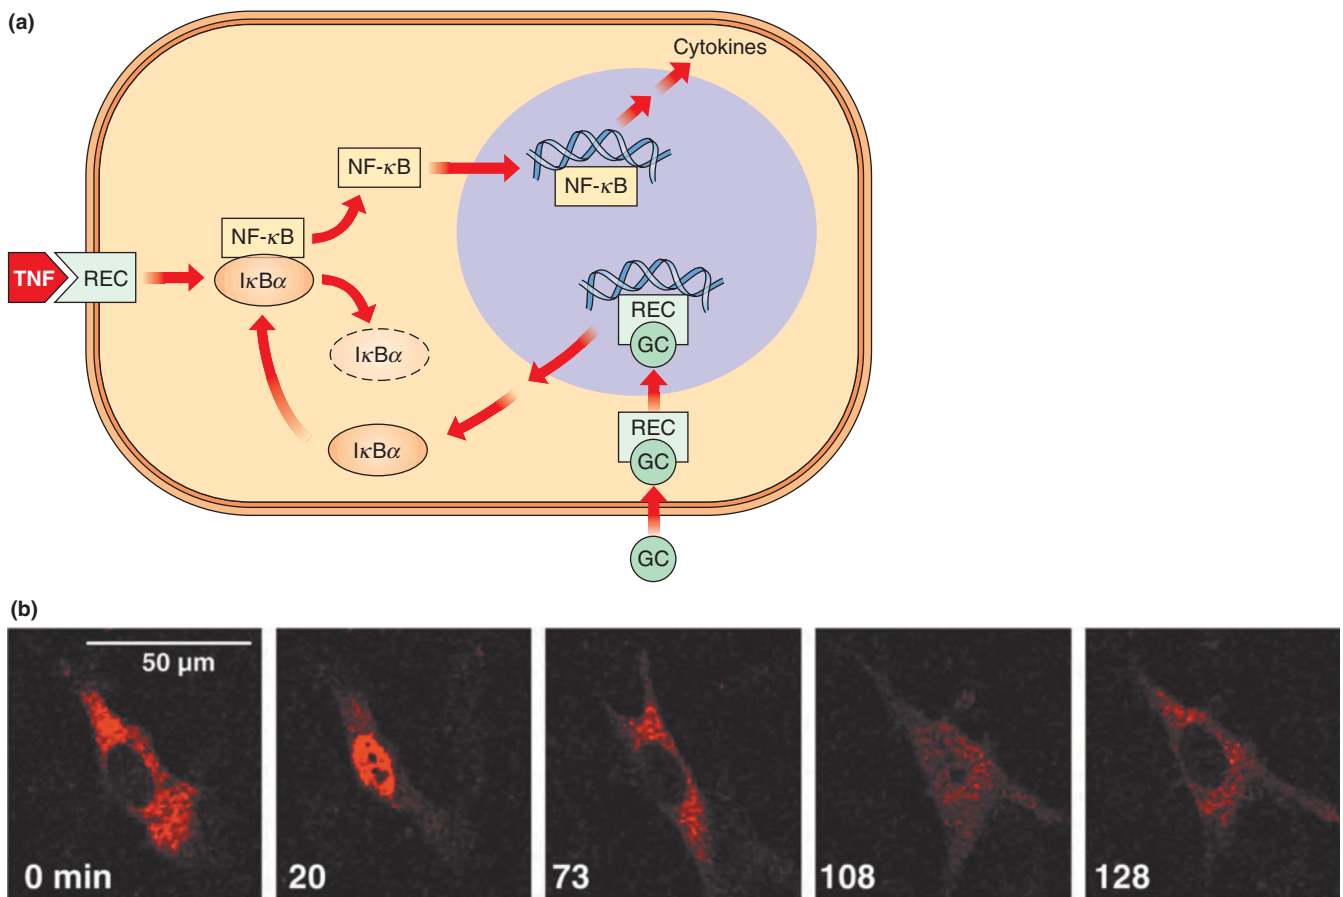

With respect to the anti-inflammatory properties of glucocorticoids, one of the target genes for activation by the glucocorticoid–receptor complex is the gene for I κ B α . By stimulating synthesis of this protein, glucocorticoids prevent further translocation of NF- κ B to the nucleus, thereby inhibiting expression of NF- κ B-stimulated genes.

Steroid hormone receptors are target sites for several important drugs. **Tamoxifen** binds to estrogen receptors but does not activate estrogen-responsive genes. The growth of some breast tumor cells is activated by estrogen. Tamoxifen treatment of patients with such tumors after surgery or chemotherapy often antagonizes estrogen binding in residual tumor cells and retards their growth. However, patients taking tamoxifen after breast cancer surgery must be monitored carefully because there is also an increased risk of uterine cancer. **RU486**, which was developed in France, binds to progesterone receptors and blocks the events essential to implantation of a fertilized ovum in the uterus. Hence, RU486 is an effective contraceptive agent, even when taken after intercourse.

Signal Transduction, Oncogenes, and Cancer

One of the most exciting areas of current research involves investigations into genetic differences between cancer cells and the normal cells from which they are derived. These investigations have revealed, in a wide variety of tumor cells, mutationally altered forms or levels of proteins involved in signal transduction—including altered protein kinases, G proteins, nuclear receptors, growth factors, and growth factor receptors. Some tumor cells contain a normal signal transduction protein, but in excessive amounts. Genes responsible for such alterations are called **oncogenes**. Investigations of protein products of oncogenes, termed

oncoproteins, have illuminated roles of the normal forms of these proteins in regulating cell metabolism and growth and have spotlighted how normal control mechanisms go awry in a cancer cell.

Viral and Cellular Oncogenes

Two developments are particularly noteworthy in the history of the study of cancer, one involving tumor viruses and the other involving genetic analysis of human tumors. Regarding the first development, it has long been known that certain viruses cause cancer in infected animals. The first known tumor virus was **Rous sarcoma virus**, discovered in 1911 by Peyton Rous and shown by him to cause tumors in chickens.

Whether a virus contains RNA (like Rous sarcoma virus) or DNA, certain features are common in viral infections leading to cancer. First, cells become **transformed**. That is, they lose normal growth control mechanisms, and in cell culture they continue to proliferate under conditions that arrest the growth of normal cells. Second, the transformed cells are themselves tumorigenic; their injection into animals causes tumors. Third, part or all of the viral genome becomes linearly inserted into chromosomes of transformed cells. For RNA viruses like Rous sarcoma virus, the viral genome must be converted to double-stranded DNA before this insertion can occur. The viral enzyme that synthesizes DNA from a single-stranded RNA template is called **reverse transcriptase**, and viruses containing this enzyme are called **retroviruses** (see Chapter 25). The product of a reverse transcriptase reaction is called complementary DNA, or cDNA, because it is complementary in sequence to its RNA template.

Viral oncogenes are errant cellular proto-oncogenes, mostly encoding signal transduction elements that have been taken into viral genomes and have undergone subsequent mutations.

A number of nontumorigenic mutants of Rous sarcoma virus exist. Mapping mutations in these strains identified *src*, the viral oncogene responsible for transforming infected cells. Some of these mutants contain extensive deletions, which permitted Raymond Erikson to use nucleic acid hybridization techniques and, in 1978, to clone a cDNA corresponding to the viral *src* gene. Two surprising findings emerged. First, expression of the cloned gene yielded a protein with a protein tyrosine kinase activity. Thus, a specific enzyme activity, which might be associated with signal transduction, was also associated with the oncogene product. Second, further nucleic acid hybridization analysis showed that sequences corresponding to the viral *src* gene were present in normal cells. This finding suggested that viral oncogenes had their origins in normal cellular genes, or vice versa. One way to explain the transfer of an oncogene, or oncogene precursor, from cells to viruses is to postulate a rare genome excision event, as depicted in Figure 23.17. If an infection had caused insertion of the viral genome next to an oncogene precursor (or **proto-oncogene**), and if a subsequent excision event removed part or all of the proto-oncogene as well as the viral genome, then this faulty excision would have created a novel viral genome, containing a cellular gene. Subsequent evolution of the virus could change the cellular gene, creating an oncogene. Action of the oncogene would contribute toward transformation in a subsequent infection.

Sequence comparison of the *src* gene from viruses and cells revealed significant differences; the 19 C-terminal amino acids in the cellular gene are replaced by 11 different residues in the viral gene, causing the viral gene to be constantly turned on, promoting cell growth. Thus, we now speak of *v-src*, the viral form of the gene, and *c-src*, the cellular form. Analysis of many other tumor viruses yielded more than two dozen additional oncogenes. The corresponding proto-oncogenes encode a variety of proteins involved in cell signaling, some of which are identified in Table 23.4. Further analysis of infections leading to tumorigenesis showed that mutational alteration of the proto-oncogene is not always necessary. In some cases the viral genome is inserted adjacent to a proto-oncogene. Elements

FIGURE 23.17

Pathways by which proto-oncogenes can become oncogenes. A proto-oncogene is a normal cellular gene that can be converted to an oncogene and cause transformation to a cancer cell. This process can occur in two ways: (1) infection by a virus, which integrates into a chromosomal site next to a proto-oncogene and carries that gene along in its own genome when the virus replicates, or (2) mutation of the cellular proto-oncogene. In the first case, once cellular DNA becomes part of a viral genome, it can undergo mutation that converts the proto-oncogene to an oncogene. The oncogene can then cause transformation when this virus infects another cell.

of the viral genome stimulate transcription of the DNA sequences flanking the integration site. Thus, tumorigenesis can result from overexpression of normal genes encoding signal transduction machinery.

Although the Src protein is a protein tyrosine kinase, it is distinct from the receptor tyrosine kinases in that it is located in the cytoplasm, rather than at the membrane. Note that by convention, the name of the gene (*src*) is italicized, while the name of the corresponding protein (Src) is not.

Oncogenes in Human Tumors

Because human tumor viruses were formerly not known to exist, the relevance of viral oncogenes in animal viruses to an understanding of human cancer was not immediately apparent. That relevance came into sharp focus in the late 1980s, from work by Robert Weinberg and others on the isolation and analysis of transforming genes from human tumors. Weinberg isolated DNA from bladder cancer tissue and used it to **transfect** normal mouse fibroblasts (connective tissue precursor cells). That is, DNA was introduced into these cells, and transformed cells were isolated after outgrowth of the cells. DNA recovered from transformed cells was shown to contain human sequences. After additional rounds of transfection, the human DNA associated with the transformed mouse fibroblasts was sequenced. The transforming gene was shown to be nearly identical with a previously described oncogene from Harvey rat sarcoma virus, called the ***H-ras*** gene. Sequence analysis showed the *H-ras* gene sequence to be identical to *c-ras*, its counterpart in untransformed cells, with but a single difference—a mutation in the twelfth codon that changed a glycine codon in *c-ras* to a valine codon in the oncogene isolated from tumor tissue. Thus, human tumors were shown to contain an oncogene that is present in some tumor viruses, and in an altered form that presumably aided the tumorigenic process.

Ras genes are now known to encode a family of proteins—all of about 21 kilodaltons, with regions homologous to sequences in the α subunit of G proteins. Like the α subunit, the Ras proteins bind guanine nucleotides. Normal Ras proteins possess a GTPase activity, as do G_{α} proteins, whereas most *ras* oncogene proteins lack this activity. The GTPase activity suggested that normal Ras proteins function like G proteins in regulating metabolism. Lending support to this model

Activated oncogenes, closely related to viral oncogenes, have been isolated from human tumors.

FIGURE 23.18

Structural basis for Ras activation by GTP. (a) The complex of human c-H-ras protein with a nonhydrolyzable GTP analog. **(b)** The Ras-GDP complex. Large conformational changes in the protein result from displacement of GDP by GTP. Most prominent changes are in the regions called switch 1 (dark blue in the figure) and switch 2 (yellow-gold in the figure), both of which are in close contact with bound guanine nucleotide (in red). PDB ID 4Q21.

Kim, Molecular switch for signal transduction: Structural differences between active and inactive forms of protooncogenic ras proteins. © 1990. Reprinted with permission from AAAS and Sung-Hou Kim.

was the determination in 1988 of the three-dimensional structure of a Ras protein, crystallized as its complex with GDP (Figure 23.18). Amino acid residues known to be changed in mutations that generate *ras* oncogenes are positioned close to the bound guanine nucleotide. This positioning supports the idea that interactions between the proto-oncogene Ras protein and guanine nucleotides are important to metabolic control and that this control is lost when a normal cell is transformed to a cancer cell.

The Ras protein, which is mutationally altered in many human tumors, is a GTP-binding protein involved in signal transduction from growth factor receptors on the plasma membrane to specific gene activation events in the nucleus.

A major difference between Ras-type proteins and the related G_{α} proteins is the far higher GTPase activity of G_{α} proteins. As suggested earlier (page 969), a set of Ras-activating proteins is required to stimulate the GTPase activity of Ras. The basis for this difference was seen in 1994, with the first structural determination of a G_{α} protein (Figure 23.19). G_{α} but not Ras, proteins contain a conserved arginine residue (R178), which interacts with the phosphates of bound GTP so as to stabilize the transition state for GTP hydrolysis.

Research on oncogenes has led to unifying theories of carcinogenesis. Work of Bruce Ames and others established that the great majority of chemical carcinogens are also mutagens. This finding suggested that chemical carcinogenesis involves mutagenesis of cellular proto-oncogenes, events that can occur in the absence of exogenous viruses (pathway 2 in Figure 23.17). Indeed, *ras* genes altered in codon 12, 13, or 61 have been detected in about 30% of spontaneous and chemically induced tumors, in both animals and humans.

A number of other genetic alterations have been detected in tumor tissue. Some are **tumor suppressor genes**. Unlike proto-oncogenes, these are genes that in the normal form suppress tumorigenesis. Loss of normal gene function, as in a deletion, leads to tumor formation because of deficient tumor suppression. One of these genes is called the **retinoblastoma gene, Rb**. Mutations in the two alleles of this gene cause a type of eye tumor, which has a familial association. The other most prominent tumor suppressor gene encodes a protein called **p53** (a protein of

53 kilodaltons). Loss of p53 function leads to tumorigenesis, and at least half of all human tumors examined display p53 gene mutations. Although its biochemical actions are not completely defined, we know that p53 is a DNA-binding protein that regulates gene expression following DNA-damaging events. If damage is moderate, the effect is to retard progression through the cell cycle from G1 into S phase until the damage has been repaired. If damage is more extensive, p53 signals that the cell shall undergo **apoptosis**, or programmed cell death (Chapter 28, pages 1221–1222). The loss of such a checkpoint would involve inappropriate cell growth, contributing toward carcinogenesis. Binding to specific DNA sequences is critical to proper functioning of p53, as shown by the structure of a p53-DNA complex, and in particular by the fact that those amino acids in closest contact with DNA are the ones most often mutated in the *p53* gene analyzed in human tumors (Figure 23.20).

Oncogenes and the Central Growth Factor Activation Pathway

Beginning in the 1990s, several lines of work converged upon the realization that the Ras protein occupies a central role in an evolutionarily conserved pathway that conveys extracellular signals to the nucleus, where specific genes are activated for cell growth, division, and differentiation. As details of that pathway emerged, they fit into a unified framework that interrelates the biochemical properties of proto-oncogene products, underscores the dominance of protein phosphorylation as a control mechanism, and rationalizes the types of mutations that lead to cancer.

Ras-related proteins have been discovered in such diverse organisms as yeast, nematode worms, and *Drosophila*, in which they control aspects of mitotic and meiotic growth and embryonic development. Research on these organisms has illuminated a central control pathway in mammalian cells (Figure 23.21), in the process richly justifying the use of simple biological model systems for cancer research.

As noted earlier, growth factor receptors with tyrosine kinase activity undergo autophosphorylation (steps 1 and 2 in Figure 23.21). In the phosphorylated state, each receptor interacts with one or more protein exchange factors, which in turn activate Ras by stimulating the GDP–GTP exchange (step 3). Also interacting with

Human tumors contain a series of mutations, affecting both signal transduction components and tumor suppressor genes and gene products.

FIGURE 23.21

Role of Ras protein in a central growth factor activation pathway. Binding of a mitogen or growth factor to a receptor stimulates the receptor tyrosine kinase (RTK), usually with dimerization of the receptor (not shown). Autophosphorylation of RTK leads to recruitment of a series of proteins (exchange factors) that stimulate GDP-GTP exchange on Ras and thereby activate it. In the scheme shown, a protein called Grb2 interacts via SH2 domains with RTK and via SH3 domains with exchange factor Sos. Ras then activates proteins of a family called MAPKKK (mitogen-activated protein kinase kinase kinase), which in turn leads to activation of MAPKK proteins and then MAPK proteins. Eventually, specific transcription factors in the nucleus undergo phosphorylation, which activates them to bind specific DNA sites and activate transcription of particular genes. The activity of Ras is curtailed by a series of GTPase-activating proteins (GAPs) that promote the hydrolysis of bound GTP.

Based on S. E. Egan and R. A. Weinberg, *Nature* (1993) 365:782, unnumbered figure, p. 782.

Ras, and limiting its activity, are GTPase-activating proteins (GAPs, see page 969). Downstream of Ras is a cascade of further protein phosphorylations (step 4), which ultimately activates transcription factors (step 5), proteins that, like nuclear receptors, stimulate transcription of specific genes (see Chapter 27).

As seen in Figure 23.21, one class of downstream kinases is called **MAP kinase (MAPK)**. The acronym *MAP* stands for mitogen-activated protein. (A mitogen is a factor that stimulates mitosis.) Upstream of MAP kinases are another family of proteins, MAPKK (MAP kinase kinase), and still further upstream are the MAPKKK proteins (MAP kinase kinase kinase). One member of the MAPKKK class is the product of the *raf* proto-oncogene (see Table 23.4). In the growth factor pathway of insulin signaling (Figure 23.13b), Sos is the GTP-GDP exchange factor, Raf-1 is the MAPKKK, MEK is the MAPKK, and ARK is the MAP kinase.

Thus, we see the growth factor response as a cascade of protein phosphorylations, analogous to the well-known glycogen breakdown cascade. We see how blocking the Ras GTPase activity can lead to uncontrolled cell growth and cancer, by keeping the signaling pathway turned on and flooding the cell with growth-stimulatory signals. What isn't immediately obvious is how this pathway can explain the distinct responses of cells to different growth factors.

Analysis of the proteins that interact with autophosphorylated growth factor receptors has identified common sequences, the SH2 domains (pages 977–978), which are involved in these interactions. A protein that binds to a phosphorylated receptor molecule recognizes not only the phosphotyrosine residue but also a critical amino acid sequence on the carboxyl side of that tyrosine. Thus, receptor phosphorylation–dephosphorylation serves as a general on–off switch, with the more subtle protein interactions governed by the SH2 domain. Downstream participants are recruited via another set of sequences called SH3 domains. These domains identify the specific proteins that will be recruited to the signaling process in response to a particular growth stimulus.

The Cancer Genome Mutational Landscape

Given what we now know about cell growth control and the biochemical functions of oncoproteins and tumor suppressor proteins in cell signaling, what are we learning about the biology of cancer? Large-scale sequence analysis of DNA from human tumors yields what is called the “mutational landscape of the cancer genome.” Figure 23.22 shows the results of combined sequence analysis of human colorectal tumors. In this plot the two horizontal axes denote chromosomal map position and the vertical axis depicts frequency with which a gene at that position is mutated in the colorectal cancers examined. The highest “mountains” on this landscape represent genes that are mutated in most cancers, which happen to include *H-ras*, *p53*, *APC*, and *PIK3* (overexpression of phosphoinositide 3-kinase, page 978). The smaller “hills” represent mutations seen in just a few of the tumors analyzed. The average colorectal cancer cell has about 80 mutations in protein-coding genes. What this landscape does not show is the considerable heterogeneity that also exists among individual cells in one tumor. Also not shown is that cancers from other tissues, such as breast, show completely different mutational landscapes. This type of information is discouraging in a sense because it suggests that there are numerous pathways by which a precursor cell population can undergo the mutations converting those cells to full-blown tumor cells, and, hence, complicating the search for single therapeutic targets that could lead to control of the process.

On the other hand, some notable successes have been achieved, based upon what has been learned. In 90% of chronic myelogenous leukemia cases, a chromosomal translocation has occurred, linking portions of chromosomes 9 and 22. This translocation fuses parts of two oncogenes, *c-abl* and *bcr*. The *c-abl* gene encodes a protein tyrosine kinase related to *src*. The gene fusion creates a novel protein kinase, which is overexpressed and stimulates growth-promoting pathways. The drug Gleevec is a specific inhibitor of this abnormal protein kinase and is a highly specific and effective treatment for this form of leukemia. Another drug, Herceptin, provides similarly specific effectiveness in treating certain forms of breast cancer. These examples suggest that the more we learn about genetic and biochemical changes in individual cancers, the better position science will be in to devise specific therapies.

FIGURE 23.22

Mutational landscape of the human colorectal cancer genome. In this study, 11 tumors were subjected to analysis of expressed genes. Map position of each gene is plotted on the horizontal axes, and percentage of tumors with a mutation in a gene at each position is plotted on the vertical axis.

Neurotransmission

In Chapter 10 we described the propagation of an action potential along a neuron as a nervous impulse is transmitted. Recall that this involves a wave of depolarization as ion channels open to admit extracellular sodium and to allow efflux of intracellular potassium. It was long thought that transmission of the impulse across a synaptic junction, from neuron to neuron or from a neuron to a muscle cell, involved an electrical impulse triggered when the action potential reached the end of a neuron. We now know that fewer than 1% of all synaptic transmission events are mediated electrically, through gap junctions between cells. The vast majority involve release of a chemical substance, the neurotransmitter, from the upstream, or **presynaptic**, cell, followed by its diffusion through a synaptic cleft and its binding to receptors in the downstream, or **postsynaptic**, cell. The postsynaptic receptor is a ligand-gated ion channel; neurotransmitter binding triggers events that allow for propagation of the nervous impulse in the postsynaptic cell. About 100 different substances, including amino acids, biogenic amines, and peptides, have been identified as neurotransmitters in the brain. The most widely used, and best understood, neurotransmitters are acetylcholine, glutamate, glycine, GABA, dopamine, serotonin, norepinephrine, and epinephrine.

The Cholinergic Synapse

Our earliest biochemical understanding of neurotransmission involved the action of acetylcholine as the transmitter at the neuromuscular junction, where nervous stimulation of a muscle cell triggers its contraction. These studies generated the scheme for neurotransmission shown in Figure 23.23. When acetylcholine is the neurotransmitter, this event is called a **cholinergic synapse**. This terminology is generally used; for example, when the neurotransmitter is dopamine, we speak of a **dopaminergic synapse**. Acetylcholine is synthesized by the coenzyme A-dependent acetylation of choline, which in turn was formed by breakdown of phosphatidylcholine.

The synaptic cleft is about 20 nm wide. Neurotransmitter is stored in vesicles within a bulb at the end of the presynaptic cell, with about 5000 molecules per vesicle. Arrival of the action potential opens voltage-gated calcium channels, triggering an influx of calcium to the bulb. This in turn causes the vesicles to fuse with the plasma membrane at the end of the bulb, spilling acetylcholine into the extracellular space of the synaptic cleft. The neurotransmitter diffuses through the cleft

FIGURE 23.23

Transmission of a neural impulse across a synapse, such as a cholinergic synapse.

and binds to receptors in the postsynaptic cell membrane. This in turn triggers the opening of channels, allowing Na^+ influx and generating an action potential. If the postsynaptic cell is a muscle cell, the action potential opens Ca^{2+} channels, and the resultant rise in intracellular Ca^{2+} concentration triggers contraction. In the meantime, on the presynaptic side some of the released acetylcholine is taken back into the cell, and an acetylcholine transporter protein is refilling vesicles with neurotransmitter, exchanging protons for acetylcholine with the help of a **vacuolar ATPase**. The remainder of the acetylcholine in the cleft is inactivated by hydrolysis (see below), terminating the signaling event. The entire process occurs about 1000 times per second. Similar events occur during neuron-to-neuron transmission, except that here the increase in Na^+ in the postsynaptic cell triggers the establishment of an action potential and its transmission down that cell.

Structural studies of a receptor called the **nicotinic acetylcholine receptor**, because it binds the alkaloid nicotine, show it to be composed of five subunits, two of which are identical and each of which has five α -helical regions that span the membrane. As shown in Figure 23.24, the subunits interact to form a channel through the membrane. Reconstitution of this multisubunit protein into membrane vesicles showed that addition of acetylcholine causes ions to flow through it. Thus, this receptor is a gated channel, which undergoes a conformational change and opens a pore in response to binding of the neurotransmitter. Our understanding of the structure and function of this receptor originally involved isolation of the receptor from organs of the electric eel (*Electrophorus*) or electric ray (*Torpedo*), both of which have the receptor densely packed in an organ, called the electroplaque, which allows the animal to shock its prey by generating potentials of several hundred volts.

Within the intersynaptic cleft acetylcholine is rapidly hydrolyzed by acetylcholinesterase, thereby destroying excess neurotransmitter and restoring the resting

FIGURE 23.24

The nicotinic acetylcholine receptor. (a) Schematic model of the receptor. Five subunits combine to form a transmembrane structure with an ion pore in the center. (b) Structure of an individual subunit. There are four different kinds of subunits, but their sequences are all similar, and each individual subunit has the kind of structure depicted here. Five α helices ($\alpha 1$ to $\alpha 5$) in each subunit traverse the membrane. The charged residues on helix $\alpha 4$, which tend to be on one surface, probably line the wall of the pore.

potential in the postsynaptic cell membrane. Acetylcholinesterase is the target for several organophosphate compounds such as the nerve gas **Sarin**, which was developed as a chemical warfare agent and which causes paralysis by reacting with an active site serine and irreversibly inactivating acetylcholinesterase (Table 11.7). Other agents act by binding to the receptor itself. **Tubocurarine**, one such agent, blocks the channel in the closed position and is considered a receptor antagonist, in contrast to **nicotine**, which activates the receptor and is an agonist. Tubocurarine is derived from curare, originally used by aboriginal people to tip poison arrows and paralyze human or animal prey. However, in the hands of qualified medical personnel, this is a useful muscle relaxant.

Fast and Slow Synaptic Transmission

For some time it was thought that the model of synaptic transmission obtained with acetylcholine receptors described all neuron-to-neuron transmission as well as transmission at the neuromuscular junction. An important difference is that some interneuronal transmission events are excitatory and some are inhibitory. In excitatory transmission, transmitter binding at the postsynaptic receptor causes sodium influx, which depolarizes the membrane and stimulates transmission of the action potential. Earlier we identified γ -aminobutyric acid, or GABA, as the principal inhibitory neurotransmitter. Binding of this agent triggers an influx of chloride ions, causing hyperpolarization and inhibiting the propagation of the action potential.

However, the situation is in fact considerably more complex. Paul Greengard has pointed out that each of the 100 billion cells in the human brain communicates directly with about 1000 other cells. The complexity is suggested in the electron micrograph in Figure 23.25, which shows multiple neuronal connections to the body of one nerve cell. Greengard shared the 2000 Nobel Prize in Physiology or Medicine with Arvid Carlsson and Eric Kandel, for their discoveries regarding slow synaptic transmission events, which occur with a timescale of hundreds of milliseconds to several minutes. In these cases neurotransmitter binding stimulates intracellular metabolic events comparable to those resulting from hormone action. Some of these events are mediated through second messengers, such as cyclic AMP, cyclic GMP, and phosphoinositides. For example, as schematized in Figure 23.26, some neurotransmitter–receptor interactions activate adenylate cyclase, causing activation of protein kinase A and triggering cyclic AMP–dependent metabolic responses in the post-synaptic cell, with time scales on the order of minutes. Persistent repetition of the transmitter–receptor interaction triggers genetic, as well as metabolic, modifications. In this longer-term response, with a time scale of days, second messenger-dependent protein kinases translocate to the nucleus,

Tubocurarine, an antagonist

Nicotine, an agonist

FIGURE 23.25

leading to stimulation of transcription of genes whose products help the cell to form new synaptic connections. Finally, prolonged neurotransmitter–receptor interaction can stimulate localized protein synthesis within the cell, to help stabilize that synaptic connection for long-term effects. Those effects that involve new protein synthesis are critically involved in learning and memory; the precise mechanisms involved are among the crucial issues of contemporary neuroscience.

Functions of Specific Neurotransmitters

Most of the fast excitatory synapses in brain use glutamate as the neurotransmitter, and most of the fast inhibitory synapses use GABA. Excessive firing of glutamatergic synapses, with consequent damage to the central nervous system, can result from overingestion of glutamate. For this reason monosodium glutamate, a major ingredient in soy sauce, was removed from baby food formulas some years ago, where it was being used as a flavor enhancer because the developing nervous system is particularly susceptible to this kind of damage.

Both glutamate and GABA participate in slow synapses as well, and it now seems clear that biogenic amines and peptide neurotransmitters participate only in slow synaptic transmission. Of particular interest are synapses for which dopamine is the neurotransmitter. Arvid Carlsson and others showed that several important psychiatric disorders involve abnormalities in dopamine signaling, including Parkinsonism, schizophrenia, drug addiction, and attention deficit–hyperactivity disorder (ADHD). Parkinsonism involves the death of dopamine-producing nerve cells in a portion of the brain called the **substantia nigra**. Success in treating some forms of Parkinsonism has resulted from treatment with massive doses of L-dopa, which can traverse a permeability blockade called the **blood-brain barrier** and undergo decarboxylation within the brain, to replenish depleted dopamine stores.

The relationship of dopamine with schizophrenia is seen by the fact that some effective anti-schizophrenic drugs have been shown to antagonize the effect of dopamine at one or more classes of receptors, by binding to the receptor and blocking the binding of dopamine. An example is **chlorpromazine**, which, although not closely related to dopamine structurally, does effectively antagonize dopamine-receptor binding. On the other hand, several drugs of abuse, including **mescaline** and **amphetamine**, are closely related to dopamine, and they act as

FIGURE 23.26

Four consequences of the action of neurotransmitters. (1) Rapid synapse, leading to opening of gated ion channels; (2) interaction of 5-hydroxytryptamine (5HT, or serotonin) with adenylate cyclase, causing activation of cAMP-activated protein kinase; (3) effect of longer-term stimulation, with protein kinases (e.g., MAPK) translocating to the nucleus and stimulating specific gene transcription by phosphorylating certain transcription factors such as CREB-1; (4) stimulation of localized protein synthesis by still undefined interactions with translation complexes.

From *Science* 294:1030–1038, E. R. Kandel, *The molecular biology of memory storage: A dialogue between genes and synapses*. © 2001. Reprinted with permission from AAAS.

dopamine agonists, binding to dopamine receptors and mimicking its effects. Dopamine is considered a “pleasure agent,” and many abused drugs stimulate the firing of dopaminergic synapses, either by raising dopamine levels or by mimicking the natural neurotransmitter. In a recent study, a targeted deletion in the mouse of D4, one of the four classes of dopamine receptors, caused the animals to become hypersensitive to ethanol, cocaine, and methamphetamine.

Synapses using serotonin as the neurotransmitter are also involved in the pathophysiology related to schizophrenia. **Lysergic acid diethylamide**, or LSD, is an indole derivative, like serotonin. LSD acts as a serotonin agonist, binding to a class of serotonin receptors and mimicking its effect. The popular (but illegal) recreational drug Ecstasy (3,4-methylenedioxy-*N*-methylamphetamine) acts by promoting the release of dopamine, serotonin, and norepinephrine from their storage sites.

Finally, **Ritalin**, used in treating ADHD (attention deficit–hyperactivity disorder), acts to promote dopamine release. This stimulant effect is paradoxical because the drug is used to calm hyperactive children. Recent research, however, suggests that its calming effect may result more from elevating levels of serotonin.

However, not all drugs of abuse involve slow synaptic transmission, and understanding dopamine and serotonin actions is only a small part of grasping the complexities of schizophrenia. Recent work has implicated glutamate receptors as well in control of addictive behavior. Inhibition of glutamate neurotransmission in rats has been shown to modulate the compulsive drug-seeking behavior after an initial drug experience, and neuroscientists are excited at the prospect of developing therapies involving glutamate antagonists, which might increase the likelihood that an addict would remain “clean” after treatment. Glutamate receptors are also strongly linked to the action of **phencyclidine** (PCP or “angel dust”). This compound blocks glutamate binding to the *N*-methyl-*D*-aspartate (NMDA) class of glutamate receptors, thereby inducing a schizophrenia-like state thought until recently to result from decreased glutamatergic neurotransmission. However, neuroscientists have found that lowering brain glutamate levels with another drug greatly diminishes the effectiveness of PCP, suggesting a possible new approach to the treatment of schizophrenia.

Ritalin
(methyl phenidylacetate)

Prozac
(fluoxetine)

Drugs That Act in the Synaptic Cleft

So far, the psychopharmacological agents we have discussed act primarily as receptor agonists and antagonists. Other important classes of drugs affect neurotransmitter metabolism in the synaptic cleft. Catecholamines are catabolized in the cleft either by methylation (**catecholamine O-methyltransferase**, COMT) or by oxidation (**monoamine oxidase**, MAO). These enzymes limit the biological effects of catecholamine neurotransmitters, just as acetylcholinesterase limits the firing of cholinergic neurons. A number of drugs used to treat depression are inhibitors of either COMT or MAO, and their action increases the effective amounts of neurotransmitter by limiting its breakdown. A more recently developed drug, **fluoxetine**, marketed as Prozac, acts as a selective serotonin reuptake inhibitor (SSRI). Secreted neurotransmitter has three possible fates—binding to postsynaptic receptors, catabolism in the cleft, or reuptake into the presynaptic cell, for re-packaging into storage vesicles. Prozac selectively blocks the reuptake of serotonin, thereby increasing the amount that reaches the post-synaptic side and potentiating serotonergic synapses. Originally marketed as an antidepressant drug, Prozac has found use against a range of psychiatric disorders.

Peptide Neurotransmitters and Neurohormones

Finally, we mention a number of peptides, including somatostatin, neurotensin, and the **enkephalins**, which act as neurotransmitters (Table 23.5). The enkephalins, along with **β -endorphin**, function also as **neurohormones**, acting to

TABLE 23.5 Some peptides that act as neurohormones (H) or neurotransmitters (T)

Name	H/T	Sequence ^a
β -Endorphin	H	YGGFMTSFKSQTPLVTLFKNAIIKNAYKKGE

Leu-enkephalin	H, T	YGGFL
Neurotensin	T	pELYENKPRRPYIL
Somatostatin	T	AGCKNFFWKTFTSC

^aThe sub-sequence YGGF, common to β -endorphin and the enkephalins, appears to be essential for their narcotic effects. The p at the N-terminal end of neurotensin signifies that the glutamate has been cyclized to the “pyro” form.

modify the ways in which nerve cells respond to transmitters. The endorphins were discovered in the 1970s, as the result of Solomon Snyder’s efforts to understand the effects of opiate drugs, such as **morphine**. After detecting morphine receptors in human brain, Snyder realized that the receptors must have a natural endogenous ligand because morphine is derived from a nonhuman source, the poppy. This work led to isolation of the endorphins, small peptides that function as natural analgesics. The modification of neural signals by these substances appears to be responsible for the insensitivity to pain that is experienced under conditions of great stress or shock. The effectiveness of opiate analgesics such as morphine is a consequence, perhaps accidental, of the recognition of these opiates by neurohormone receptors, despite their structural differences from neurohormones.

The endorphins and enkephalins are synthesized as part of the much longer hormone precursor *prepro-opiomelanocortin*. As described on page 964, this precursor is cleaved to release both the neurohormones and a number of other hormones with entirely different functions.

Signaling in Bacteria and Plants

Although the concept of signal transduction is somewhat different for single-celled than for multicellular organisms, the fact is that bacteria do respond to extracellular signals. In Chapter 21 we mentioned quorum sensing, in which bacteria respond to signals based upon cell density. In addition, bacteria respond to environmental factors, such as chemical attractants, oxygen concentration, or temperature gradients. The sensing mechanism is a **two-component system**, involving two protein kinases. The first component, a **receptor histidine kinase**, spans the plasma membrane. Interaction of this component with an environmental stimulus on the extracellular side stimulates autophosphorylation of a histidine residue on the intracellular domain. Next, the phosphate is transferred to an aspartate residue on the second protein, which is called a **response regulator**. The phosphorylated response regulator next interacts with the target; for example, if the signal is to direct response to a gradient of nutrient concentration, the flagellum undergoes a change in its rotational behavior, by mechanisms under active investigation, to move the bacterium toward a chemical attractant.

Our understanding of the molecular actions of plant hormones is less advanced than that of the vertebrate animal hormones. In part this is because some plant hormones are growth factors so that growth is the only readily measurable parameter. Furthermore, plant membranes are more difficult to isolate and study than are animal membranes.

We encountered some of the six major classes of plant hormones in earlier chapters about metabolism. To recapitulate, the six classes, illustrated in Figure 23.27, are (1) the diterpene **gibberellins**, derived from isopentenyl pyrophosphate; (2) the sesquiterpene **abscisic acid**, also derived from isopentenyl pyrophosphate; (3) the **cytokinins**, purine bases with a terpenoid side chain;

Gibberellic acid (GA3) [a gibberellin]

Abscisic acid (ABA)

Zeatin [a cytokinin]

Indole-3-acetic acid (IAA) [an auxin]

Ethylene

Brassinolide

FIGURE 23.27

Representatives of the six major classes of plant hormones.

(4) **auxins**, with the tryptophan metabolite *indole-3-acetic acid* being the most active; (5) **ethylene**, which comes from the methionyl moiety of *S*-adenosylmethionine; and (6) **brassinosteroids**, related to vertebrate steroid hormones. With the exception of brassinosteroids, these compounds are chemically quite distinct from animal hormones.

Additional differences from animal hormones lie in (1) the diversity of effects of a given plant hormone and (2) the hormonal activity of a large number of structurally related species. For example, at least a dozen different cytokinins have been characterized structurally. Though all contain adenine with a side chain on N-6, great variability occurs in the structure of that side chain.

Auxins are synthesized in apical buds (at the tip) of growing shoots. They stimulate growth of the main shoot and inhibit lateral shoot development. A class of auxin-binding membrane proteins may represent auxin receptors. Auxin action involves chemiosmotic proton gradients, which in turn establish auxin concentration gradients leading to different responses in different parts of the plant—partial cell wall degradation, necessary for growth to occur, and increased RNA and protein synthesis, necessary for differentiation. Recent evidence suggests that cyclic AMP is formed in plants and that it mediates the effects of auxin.

Cytokinins are produced in roots and promote growth and differentiation in many tissues. Cytokinins and auxins work together, and the ratio of cytokinin to auxin is often crucial in determining whether a plant will grow or differentiate. In many cases, single plant cells in tissue culture can regenerate whole plants. Here, the investigator must experiment with different proportions of cytokinins and auxins, searching empirically for the proportions that allow the best growth of normal plants.

About 100 forms of gibberellin are known. Some function as growth-promoting hormones and may stimulate expression of certain genes. Particular messenger RNAs are present in increased amounts as a result of gibberellin administration, supporting the idea that gibberellins act at the gene level.

Ethylene is considered a hormone of senescence. It stimulates fruit ripening and the aging of flowers, and it inhibits seedling growth. It also redirects auxin transport to promote transverse, rather than longitudinal, growth of plants. Abscisic acid (ABA) counteracts the effects of most other plant hormones. It inhibits germination, growth, budding, and leaf senescence and helps plants adjust to stresses such as cold or drought. Abscisic acid synthesis in leaves is stimulated by wilting. Physiological evidence suggests a role for ABA in ion and water balance. Brassinosteroids control several processes, including cell expansion, seed germination, and vascular development.

Recent work sheds light on signaling processes for these latter three hormones. Ethylene binds to a family of receptors in the ER membrane. The receptors then bind to a Raf-like protein kinase, CTR1 (Figure 23.28). This binding leads to inactivation of both receptors and CTR1, leading in turn to derepression of a positive regulatory molecule, EIN2. A MAP kinase cascade, shown in yellow, may be involved. EIN2 somehow stabilizes transcription factors EIN3 and EILs within the nucleus, leading to transcription of ethylene-responsive genes. Among these gene products are two proteins, EBF1 and EBF2, which regulate levels of EIN2, forming a feedback loop.

Brassinosteroids act similarly to steroid hormones in animals. An intracellular protein kinase called BIN2 phosphorylates two transcriptional regulators, BES1 and BZR1, targeting them for proteolytic destruction. Binding brassinosteroid to its receptor, BRI1, leads to inactivation of BIN2, which in turn leads to activation of BES1 and BZR1. BES1 joins with another protein, BIM, leading to transcriptional activation of some target genes, while BZR1 inhibits transcription of another set of target genes.

**FIGURE 23.28**

A representation of the ethylene-signaling pathway. For details see text.

From *Science* 306:1513–1515, J. M. Alonso and A. N. Stepanova, The ethylene signaling pathway. © 2004. Reprinted with permission from AAAS. Redrawn with permission from Jose Alonso.

The ABA pathway begins with binding to an extracellular receptor, followed by release of calcium from vacuoles into the cytosol. Involved with this process is a signaling component called cyclic ADP-ribose (cADPR), already known to regulate calcium release in animal cells. As in the animal system, calcium release by cADPR opens ion channels in the plasma membrane. The release of intracellular ions reduces osmotic pressure and lowers cell turgor, also allowing for preservation of cell water when insufficient water is available in the soil to meet the needs of transpiration.

SUMMARY

Hormone action is one element of signal transduction mechanisms, processes by which instructions are transmitted from cell to cell. Some hormones interact with intracellular receptors; these act at the gene level, with the hormone–receptor complex affecting transcription of specific genes in target tissue. Other hormones interact with plasma membrane receptors. Three types of such transmembrane receptors exist: (1) receptors that are ion channels, with hormone binding directly affecting membrane permeability to an ion; (2) receptors, such as the insulin receptor, that

Cyclic ADP-ribose

have a hormone-binding site on the exterior and an enzyme activity on the cytosolic side, with ligand binding stimulating that activity; and (3) receptors that act through G proteins to affect the levels of second messengers, including cyclic AMP, cyclic GMP, calcium ion, inositol trisphosphate, phosphatidylinositol bisphosphate, and diacylglycerol. Second messengers interact with a variety of intracellular metabolic processes, notably protein phosphorylation. G protein action is controlled by binding of guanine nucleotides. Stimulation by interaction with receptor causes GTP exchange for GDP, and hormone action is limited by the slow conversion of bound GTP to GDP.

Proto-oncogenes are cellular genes (most of which encode signal transduction proteins) that have been transferred to viral genomes and that subsequently undergo mutations converting them to oncogenes. Action of an oncogene, whether generated in a cell by viral infection or by mutation of a proto-oncogene, causes loss of metabolic and growth control that is associated with transformation of a normal cell to a cancer cell.

Neurotransmission involves release of neurotransmitter from storage vesicles in the presynaptic neuron, triggered when the wave of depolarization in the presynaptic neuron reaches the vesicles. Neurotransmitter is released into the synaptic cleft and a small portion of the released material is taken up in the postsynaptic neuron, where opening of ion channels leads to re-establishment of the action potential and its movement along the postsynaptic cell. At the neuromuscular junction, neurotransmitter uptake leads to muscle contraction.

Plant hormones include gibberellins, cytokinins, auxins, ethylene, brassinosteroids, and abscisic acid. Recent evidence indicates parallels between the actions of animal and plant hormones, although we know much less about plant hormones.

PROBLEMS

- G proteins show some amino acid sequence homology with bacterial elongation factors, proteins that are involved in protein synthesis. These proteins also bind and hydrolyze GTP. How might one determine whether plant tissues contain G proteins or similar entities?
- List two or three factors that make it advantageous for peptide hormones to be synthesized as inactive prohormones that are activated by proteolytic cleavage.
- Name a hormone whose concentration would probably not be amenable to analysis by radioimmunoassay, and explain your answer. (Hint: You must be able to generate an antibody to the hormone to develop such an assay.)
- Describe a mechanism by which a steroid hormone might act to increase intracellular levels of cyclic AMP.
- Signaling molecules interact with cells through specific macromolecular receptors. For each of the four receptors identified below, list all characteristics, by number, which accurately describe that receptor.
 - an adrenergic receptor _____
 - a steroid receptor _____
 - the LDL receptor _____
 - the insulin receptor _____
 - Located at the cell surface
 - Associated with the protein clathrin
 - Ligand binding stimulates the activity of phospholipase C
 - A transmembrane protein
 - A DNA-binding protein
 - Located in the cell interior
 - Receptor–ligand complex moves to the lysosome
 - Receptor–ligand complex becomes concentrated in the nucleus
 - Receptor activation can inhibit the synthesis of glycogen
 - The hormone–receptor complex activates specific gene transcription
 - Internalization decreases the synthesis of cholesterol esters
- Action of this receptor diminishes the synthesis and activity of β -hydroxy- β -methylglutaryl-CoA reductase (HMG-CoA reductase)
- This receptor activates its own synthesis
- Biological activity of this receptor involves interaction with guanine nucleotide-binding proteins
- This receptor has a protein kinase activity
- Not known to act through a second messenger
- Upon activation by a receptor, a G protein exchanges bound GDP for GTP, rather than phosphorylating GDP that is already bound. Similarly, the α subunit–GTP complex has a slow GTPase activity that hydrolyzes bound GTP, rather than exchanging it for GDP. Describe experimental evidence that would be consistent with these conclusions.
- Answer each question in about one sentence.
 - What is the biochemical basis for the action of Viagra?
 - What is the biochemical basis for the action of Prozac?
 - Oral administration of S-adenosylmethionine has been reported to be effective in treating depression. Suggest a possible explanation.
- Write a balanced equation for the hydrolysis of cyclic GMP, catalyzed by cGMP phosphodiesterase. Would you expect an inhibitor of this enzyme to potentiate or antagonize the action of Viagra? Explain.
- Lithium ion inhibits the synthesis of inositol trisphosphate by inhibiting a reaction in the breakdown of inositol trisphosphate. Explain this apparent paradox.
- Describe two general chemical features that distinguish plant hormones from animal hormones.
- Suppose that you measured binding of EGF to the isolated EGF receptor at various concentrations. Would you expect the binding curve to be hyperbolic? Explain your answer.
- Write balanced equations for reactions catalyzed by catechol O-methyltransferase and monoamine oxidase.

CHAPTER 24

Genes, Genomes, and Chromosomes

In this last major section of the book we are concerned with the storage, retrieval, processing, and transmission of biological information—processes we might call information metabolism, as distinguished from intermediary metabolism. In intermediary metabolism, the information specifying the nature of a chemical reaction lies within the three-dimensional structure of the enzyme involved. That structure determines which substrates are bound and which reactions are catalyzed. Of course, metabolic reactions are controlled ultimately by genetic information, which specifies the structures and properties of enzymes. However, the reactions we encounter from here on are distinguished by the direct involvement of genetic information—specifically, the requirement for a *template*, which functions along with an enzyme to specify the reaction catalyzed. The biological templates, nucleic acids, generally play a passive role, determining which substrates are bound and leaving catalysis to enzymes—although ribozymes (RNA enzymes) present an important exception to this generalization (Chapter 11). The basic processes—DNA replication, transcription (RNA synthesis), and translation (protein synthesis)—are described in detail in subsequent chapters. Here, however, we focus upon the organization and nature of the genes that carry and transmit that information, as well as the chromosomes and genomes within which individual genes reside. As discussed in Chapter 4, we define a gene as a chromosomal segment that encodes a single polypeptide chain or RNA molecule. Although in the past we might have called this section of our discipline genetic biochemistry, it may now be more appropriate to call it *genomic biochemistry*. That is because the powerful methods used to determine the complete nucleotide sequences of hundreds of organisms have made it possible to think of biological processes in a more global sense. Whereas the sequencing and cloning of individual genes, and the analysis of cloned genes and recombinant enzymes, allow great insight into metabolism at the level of individual or grouped reactions, we can now think of cellular and organismal function in terms of the coordinated expression of large blocks of genes—that is, as an integrated system.

Prokaryotic and Eukaryotic Genomes

Size of the Genome

With the exception of RNA viruses, the genomes of all organisms are made up of DNA sequences containing just four different nucleotides (plus small amounts of a few modified nucleotides; see pages 93 and 102). However, there is enormous variability in both genome size and in the physical state of the genome within its intracellular milieu. Single-celled organisms have relatively simple metabolic needs and so can thrive with as few as several hundred genes. Viruses, which co-opt the metabolic machinery of the cells they infect, are even simpler. The smallest DNA viruses have only 10 genes or fewer, while some RNA viruses have only three. As you can see in Figure 24.1, however, the largest viruses, such as variola, the smallpox virus, have 175,000 or more base pairs in their genomes, sufficient DNA to encode 150 proteins or more.

As you might expect, the genomes of the more complex multicellular organisms are far larger than those of bacteria or viruses. However, as you can see from Figure 24.1, there is no logical relationship between genome size and organismal complexity. The human genome, consisting of about three billion base pairs, is dwarfed by the genomes of some amphibians and some plants, which may be as much as 50-fold larger than those of humans. Because there is no basis for concluding that a bean plant is 50 times more complex than a human being, an inescapable conclusion is that eukaryotic genomes must contain considerable DNA that does not code for proteins or for the RNA machinery of protein synthesis. In the following sections, we describe several kinds of noncoding DNA sequences in eukaryotic genomes. In addition, as discussed in Chapter 29, much of the genomic DNA that does not encode proteins encodes regulatory RNA molecules.

Most eukaryotes require—and have—much larger genomes than prokaryotes.

Repetitive Sequences

The first indication that eukaryotic chromosomes contain noncoding DNA came as early as 1968, when Roy Britten and David Kohne developed a technique for analysis of DNA reassociation kinetics. In this method, the total DNA

FIGURE 24.1

Genome size. The bars show the range of haploid genome sizes for different groups of organisms. A few specific organisms are marked with vertical lines, for example 3×10^9 for humans. Note that the genome-size scale is logarithmic and that many organisms have larger genomes than humans.

FIGURE 24.2

Reassociation kinetics of *E. coli* and bovine DNA. The abscissa corresponds to reassociation time, corrected for the difference in size between the *E. coli* and bovine genomes. The curve for *E. coli* corresponds to that expected for a collection of single-copy genes in a genome of the *E. coli* size— 4.67×10^9 bp. The curve for bovine DNA exhibits two steps in reassociation. The slow step corresponds to single-copy DNA (nonrepeated sequences). The other corresponds to rapidly reassociating DNA made up of repeated sequences. Many classes of repeated DNA are represented in this phase of the reassociation.

Repetitive DNA sequences in eukaryotic genomes include satellite DNAs and scattered duplicate sequences.

**FIGURE 24.3**

Satellite DNA. Equilibrium density gradient centrifugation of total *Drosophila* DNA resolves satellite bands, surrounding the main band. These represent repetitive DNA fractions of differing base composition.

Adapted from *Journal of Molecular Biology* 96:665–674, S. A. Endow, M. L. Polan, and J. G. Gall, Satellite DNA sequences of *Drosophila melanogaster*. © 1975, with permission from Elsevier.

from an organism is cut by shear forces into pieces about 300 base pairs in length, then heated to cause strand separation, then slowly cooled, to allow strands of complementary sequence to reassociate. Sequences that are present in multiple copies will reassociate relatively quickly, whereas single sequences reassociate slowly because their abundance is low. When Britten and Kohne analyzed bovine DNA by this method, they were surprised to find that almost half the DNA reassociated much more quickly than expected for single-copy sequences in the large genome (Figure 24.2). To account for this rapid reassociation, they concluded that some DNA sequences are reiterated 10^5 – 10^6 times in one cell. Whereas practically all of the DNA of *E. coli* is single-copy, only about half of most mammalian DNAs and one third of plant DNAs fall into this category.

Satellite DNA

Further analysis has divided these reiterated DNA sequences into several categories. One type involves multiple tandem repetitions, over long stretches of DNA, of very short, simple sequences like $(ATAAACT)_n$. Such sequences can often be separated from the bulk of the DNA by shearing to break DNA into smaller fragments, followed by sedimentation to equilibrium in density gradients (see Chapter 4, page 102). Repetitive DNA sequences that are AT-rich (like the one just mentioned) have a lower density than average-composition DNA, and GC-rich sequences are more dense. Thus, in a density-gradient experiment, the reiterated, simple-sequence fragments form satellite bands around the main-band DNA (Figure 24.3). Because of this banding, clusters of repeated sequences are sometimes referred to as **satellite DNAs**. In higher eukaryotes, satellite DNA usually makes up 10%–20% of the total genome.

What function can such highly reiterated DNA sequences serve? They do not code for proteins, and most are not even transcribed into RNA. Some, at least, appear to play a structural role. Certain reiterated sequences have, for example, been found to be highly concentrated near the **centromeres** of chromosomes, the regions where sister chromatids are attached to the mitotic spindle at metaphase. In budding yeast, centromeres are AT-rich segments about 125 base pairs long, although most other organisms have shorter repeating sequences in centromeric DNA. Centromeres serve as binding sites for proteins that attach the spindle fibers in mitosis (page 1022).

Duplications of Functional Genes

There are many other classes of DNA sequences with varying degrees of repetition. Some of these sequences represent duplications of functional genes, and in some cases the repetitiveness seems to play a useful role, by allowing high levels of production of much-needed transcripts. Examples include the genes for ribosomal RNAs, of which up to several thousand copies may be present, and tRNA genes, with hundreds of copies of each type often found. The cell's continuous need for large quantities of ribosomes and tRNAs for translation is met by having multiple copies of these genes. The same is true for the genes for some much-used proteins, such as the histones that bind to eukaryotic DNA to form the chromatin structure (see page 1022). As pointed out in Chapter 26, even genes that are normally single-copy are sometimes amplified, either in response to environmental stress or in special tissues during embryonic development.

Alu Elements

Other kinds of repeated DNA sequences exist that do not code for proteins but whose true function remains mysterious. Such sequences are often scattered throughout the genome, rather than being clustered like the satellite DNAs. Some of these sequences may represent control elements of still unknown function. One of the most common such families in primates consists of the so-called ***Alu* sequences**. These sequences, of which there are more than one million copies in the human genome, are about 300 base pairs (bp) long. Their name reflects the common existence of a single site for the restriction endonuclease *AluI* in most members of this class. The *Alu* sequences can be (inefficiently) transcribed into RNA, although they are not known to be translated. *Alu* sequences are examples of **SINES**, short interspersed elements. The human genome also contains up to one million **LINES**, long interspersed elements, sequences that can be as long as 10 kbp.

The function of the large number of *Alu* sequences remains uncertain, although some of them may contain origins for DNA replication. But it is also conceivable that many repetitive sequences such as these serve no useful function. They may simply exist in the genome as “molecular parasites.” A way in which such sequences could spread through the genome has been proposed, on the basis of the observation that *Alu* sequences are flanked by short, repeated oligonucleotides resembling those of transposons (see Chapter 26). In this view, *Alu* sequences, like other mobile genetic elements, may be inserted at various places in the genome as reverse transcriptase copies of the RNA that is transcribed from them (page 1072). Recent studies suggest that the *Alu* sequences may have been derived from a small RNA (7SL RNA) involved in protein transport across membranes. We shall discuss this RNA in Chapter 28.

Introns

A second reason for the large size of eukaryotic genomes is that most eukaryotic genes are interrupted by introns. In Chapter 7 we pointed out that the coding regions of most eukaryotic genes—exons—are interrupted by noncoding regions—introns. We saw, as an example, that the β globin gene consists of three exons interrupted by two noncoding intron regions. This kind of structure is common in eukaryotes and is often more extreme than in the hemoglobin example. Consider the ovalbumin gene depicted in Figure 24.4a. This gene encodes a protein 386 amino acid residues in length, which could be accommodated by a message 1158 nucleotides long. Yet the total ovalbumin gene is about 7700 base pairs in length, containing eight exons interspersed by seven introns. The difference between the ovalbumin gene and its mRNA is dramatically displayed when hybrid DNA–RNA molecules are examined in the electron microscope (Figure 24.4b and c). The genomic DNA pairs to the mRNA along the exons, but the introns, which contain no counterpart in the mRNA molecule, are looped out, to form what are called **R loops**.

The function of many repeated sequences is unknown.

Most eukaryotic genes contain introns.

FIGURE 24.4**Exon–intron structure of the ovalbumin gene in chickens.**

(a) Map of the 7700-bp gene, showing exons 1–7 plus an untranslated leader sequence (blue) and introns A–G (brown). **(b)** Electron micrograph of a hybrid formed by renaturing chicken genomic DNA with purified ovalbumin mRNA. **(c)** Diagram showing how the intron regions loop out in R loops in such a hybrid. The RNA is shown in red, the DNA exons in blue, and the DNA introns in brown.

(b) Courtesy of Pierre Chambon, *Scientific American* (1981) 245:60–70. © 1981 by Scientific American, Inc. All rights reserved.

**(a)****(b)****(c)**

Sequence analysis shows that introns are present in most eukaryotic protein-coding genes and frequently exceed exons in total length. Lower eukaryotes like yeast usually have many fewer introns, and their genome size is correspondingly smaller. As in the case of prokaryotes, which also have few introns, the smaller yeast genome presumably reflects a need for more efficiency in cell replication.

As mentioned in Chapter 7, the function of introns is not yet wholly understood. It seems likely that they serve as loci for genetic recombination, allowing functional parts of proteins to be interchanged in evolution, a process called exon

shuffling. Such loci also allow eukaryotes to make variants of a protein from a single gene, by splicing different exons together. This **alternative splicing**, discussed in Chapter 27, page 1161, is a more efficient way to store information than having a whole gene for each variant of the protein.

Gene Families

Multiple Variants of a Gene

Despite alternative splicing, in many cases complete variants of genes for the same type of protein are found to be expressed in different tissues or at different stages in development. We encountered an example in Chapter 7, where the embryonic (ζ and ϵ), fetal (α and γ), and adult (α , β , and δ) globins of mammals were described. For each of these proteins there exists a complete gene in every cell of the mammal.

Figure 7.30 (page 261) depicts the clusters of genes for the α and β classes of hemoglobins in humans. Each of these genes has the kind of exon–intron structure shown in Figure 7.25 (page 256). In addition, the genes themselves are separated by long stretches of nontranscribed DNA. Some portions of these intervening regions must contain control signals because the expression of the globin genes is under complex and subtle regulation. In the first place, although the globin gene clusters are found in all human cells, they are expressed *only* in *erythropoietic cells*, cells that give rise to red blood cells. Furthermore, as we saw in Chapter 7, expression of each variant is strictly constrained to certain developmental stages. For example, in the early embryo, only the ζ and ϵ genes are being transcribed; all other globin genes are turned off. As development proceeds, transcription switches first to the fetal α and γ genes, and at about the time of birth the adult β variant begins to dominate and transcription of γ ceases (see Figure 7.29, page 261). This kind of developmental regulation is peculiar to eukaryotes, although bacteria show simpler developmental changes in gene expression, for example, accompanying different growth phases or during the development of biofilms. The use of multiple variant genes is expensive to copy and store in DNA: The human genome devotes about 100,000 bp of DNA just to producing different variants of hemoglobin.

Many other gene families exist. Some, like the groups of genes encoding variants of the histones, seem to play developmental roles rather like those of the globin gene family. Others, like the immunoglobulin genes, appear to exist in multiple forms in order to satisfy a multiplicity of similar but distinct needs. In each case, it seems likely that the members of a particular gene family have evolved by successive duplications of an original, ancestral gene.

As our detailed knowledge of many different genomes has expanded, it has become obvious that the concept of “gene families” has a much broader sense than that used above. We deduce, from homologies in sequence and structure, that many genes we had first thought of as unrelated belong to extended families probably descended from one common ancestor. It may be that all existing genes descend from a relatively small number (several hundred?) sufficient to serve the needs of a very primitive ancestral organism.

Pseudogenes

Gene families often include as members one or more **pseudogenes**, or nonexpressed, genes. Pseudogenes can be recognized because they bear strong sequence similarity to expressed genes, from which they undoubtedly evolved, perhaps by a reverse transcriptase mechanism as has been proposed for *Alu* elements (see page 1005). They are no longer transcribed, however, because some element required for transcription (often a flanking control region, or **promoter**, a transcriptional initiation signal) is missing or defective. Because their sequences are not expressed, pseudogenes are no longer under strong selective control in evolution. In a sense, it does not matter what

TABLE 24.1 Properties of some bacterial and viral genomes

Organism or Virus	Genome Size, bp	Number of Genes	Physical Nature of the Genome
<i>Escherichia coli</i>	4,639,221	~4400	Circular duplex
Bacteriophage T4	168,889	~175	Linear duplex, circularly permuted ^a
Bacteriophage T7	39,936	~35	Linear duplex, small repetition each end
Bacteriophage λ	48,502	~50	Linear duplex, single-stranded ends
Influenza virus	~13,500	12	Single-stranded RNA
HIV	9,749	23	Single-stranded RNA
Bacteriophage ϕ X174	5,387	11	Circular single-stranded DNA
Bacteriophage M13	6,407	11	Circular single-stranded DNA
Simian virus 40	5,226	6	Circular duplex DNA
Tobacco mosaic virus	~6,400	4	Single-stranded RNA
Bacteriophage MS2	3,689	4	Single-stranded RNA

^aCircularly permuted means that all genomes have the same linear sequence of genes, but the end points differ (see Chapter 25).

happens to them, and as a consequence they can accumulate mutations that would be selected against in functional genes. Until recently it was thought that pseudogenes play no significant biological function—that they are evolutionary remnants. However, research on a tumor suppressor called PTEN showed that a pseudogene can bind a small inhibitory RNA molecule (siRNA, see Chapter 29) intended for the functional PTEN, and hence affect expression of the functional PTEN gene. Examples of pseudogenes can be seen in Figure 7.30 (page 261), which shows the arrangement of α and β globin gene variants in human DNA.

In summary, we find that a number of quite different explanations combine to account for the very large size of the genomes of eukaryotic organisms. At the same time, we still find it hard to rationalize the extreme variations in the amount of DNA that are sometimes observed even between closely related organisms. For example, among the amphibians alone there is more than a 100-fold range of genome sizes. The function, if any, of such enormous variation is still obscure, which suggests that we still do not understand some fundamental features of the eukaryotic genome.

By contrast, prokaryotic and viral genomes are much smaller, as befits the relative simplicity of the organisms involved, and more compact, as may befit organisms that are engaged in continued rapid growth during much of their lives. Introns exist in some viral and prokaryotic genomes, but they are quite uncommon. Indeed, in some cases adjacent genes overlap and are translated in different reading frames, to give different protein products. For many years the small size of these genomes and their accessibility for genetic manipulation, owing in part to their haploid nature, made bacteria (particularly *E. coli*) and bacteriophages the favored biological systems for elucidating details of genome replication and gene expression. Table 24.1 gives information about the genomes of some of the most useful systems and some other viruses of current interest.

Restriction and Modification

We turn next to the question of how the complete nucleotide sequence of a large genome is determined. Our ability to map and determine the nucleotide sequence of genomes depended crucially upon the existence of **restriction endonucleases**, which we identified in Chapter 4 as enzymes that catalyze double-stranded DNA cleavage in a sequence-specific fashion. Before discussing the sequence determination of large genomes, we digress here to describe these remarkable enzymes and the biological processes in which they are involved—**host-induced restriction**

and modification. Bacteria use site-specific DNA methylation to mark their own DNA and to cause DNA cleavage at the same sites to inactivate the DNA of invaders, such as viruses, which lack this marking; restriction–modification could be considered a bacterial immune system.

Biology of Restriction and Modification

Although restriction and modification were first described in 1952, it was not until Werner Arber's work in Switzerland in the mid-1960s that the biochemical basis for the phenomena became clear. The basic observation was as follows. Bacteriophage λ , when grown on the K12 strain of *E. coli* (which we shall call K), grows well in subsequent infections of the K strain, with every phage particle giving rise to a **plaque**. (A plaque is a cleared area on a Petri plate seeded with excess bacteria and a limited number of phages. It results from the multiplication of one virus particle and the localized lysis of bacteria. See Figure 24.5.) However, the phage grew poorly on *E. coli* strain B, with only 0.01% of the infecting phages giving rise to a plaque; in other words, the host strain *restricted* growth of the phage. Most of the infecting phage DNA was broken down in these nonproductive infections.

Phages purified from the few plaques that formed could infect strain B with high efficiency. The same phenomenon was seen in reverse: Phages grown on *E. coli* B infected strain K with low efficiency, but the few plaques that formed yielded phages that could infect strain K with high efficiency. These experiments suggested that although most of the phages exposed to a new strain of *E. coli* are destroyed, a few underwent an adaptation that allowed them to circumvent the bacterium's defense system and become infective to that strain. Arber coined the terms *restriction* and *modification* to explain these observations, and he showed that the biochemical basis for these phenomena is a pair of enzymes specific to each bacterial strain. When phages grown on strain K infect strain B, their DNA is almost always broken down by a B-specific restriction enzyme, and the bacterium survives. However, the B strain has an additional enzyme, which modifies its own DNA by methylating specific nucleotide residues. This pattern of methylation protects DNA against its own B-specific restriction enzyme. The methylation involves transfer of a methyl group from S-adenosylmethionine (AdoMet) to a specific base within the target sequence, as schematized in Figure 24.6.

Occasionally the modification enzyme of strain B methylates phage DNA as well, and in the process creates phage DNA resistant to breakdown by the B restriction system. The resistant phages are the small proportion of phages (0.01%) that plate on strain B. Because DNA of these phages is now fully protected from B-specific restriction, all of the phages that plate on B are able to infect the B strain in subsequent infections. Note that restriction and modification are **epigenetic** phenomena, in that the phenotype is preserved through the next round of phage growth, while phage DNA *sequences* are unaltered. The ability of a phage to overcome restriction in a particular host bacterium depends not upon any changes in the phage's genotype but upon the host strain in which that phage was previously grown. Note also that any DNA within a cell is subject to restriction and modification, including transforming and plasmid DNAs, as well as chromosomal or phage DNAs.

Restriction–modification systems are widespread among bacteria. Some are encoded by chromosomal genes, and some by plasmids. In 1970 Hamilton Smith observed that a restriction nuclease he was studying catalyzed double-stranded cleavage of DNA within a specific short nucleotide sequence. Shortly thereafter, it was found that modification has the same sequence specificity, as schematized in Figure 24.6. In this example, one nucleotide within a six-nucleotide sequence is the substrate for a specific DNA methylase. When that site is methylated, the DNA

FIGURE 24.5

Bacteriophage plaques. A Petri plate was seeded with many bacteria (about 10^8) and a small number of bacteriophage particles (about 200 T4 phages). Each phage particle generates a cleared area, or plaque, by infecting and lysing all of the bacteria growing near it.

Bacteria use restriction–modification, which involves nongenetic changes in DNA structure, to distinguish their own DNA from that of invaders.

**FIGURE 24.6****Host-induced restriction and modification.**

A phage whose DNA is unmodified infects a bacterium with a restriction system that recognizes the DNA sequence 5'–GAATTC–3' (step 1). Most phage DNA molecules are cleaved by the restriction nuclease (step 2), but the few that become methylated first on the innermost A are protected from attack (step 3). The phages that emerge contain modified (methylated) DNA (step 4). Because they are not vulnerable to restriction by the host nuclease, they are able to overcome the bacterium's defense system when they reinfect the same bacterial strain.

is resistant to cleavage by a nuclease that recognizes the same hexanucleotide sequence; when that site is unmethylated, the DNA is susceptible to attack at that site. Hundreds of restriction endonucleases are now known to catalyze similar sequence-specific cleavages.

The importance of these developments was that, for the first time, scientists could isolate homogeneous DNA fragments of precisely defined length by treating DNA with a restriction nuclease *in vitro* and then resolving the fragments in the digest on an electrophoretic gel. These developments gave rise to gene cloning, as we discussed in Chapter 4. With respect to genome analysis, restriction fragments resolved by electrophoresis (Figure 24.7) can be arranged in order, so as to give physical maps of DNA molecules; the maps are called **restriction maps** because they show the physical locations of restriction sites.

**FIGURE 24.7****Fragmentation of bacteriophage λ DNA with restriction endonucleases *EcoRI* or *Bam*HI.**

(a) Experimental determination of fragmentation patterns, resulting from enzymatic digestion of the 48.5-kb linear DNA molecule from phage λ . Restriction digests are subjected to agarose gel electrophoresis, and the fragments are visualized under ultraviolet light after staining the gel with ethidium bromide, a fluorescent dye. Note that fragments with very similar sizes form but one band on a gel. (b) Maps of cleavage sites for each enzyme on the DNA molecule. By convention, the fragments are assigned letters as shown. In this experiment the 12.1 kb fragment in the *Bam*HI digest resulted from linkage of the A and F (terminal) fragments by base pairing at their cohesive ends (page 1098). Mapping the restriction sites also requires data from partial digestion or with digestion of the DNA with *EcoRI* and *Bam*HI together (not shown).

Properties of Restriction and Modification Enzymes

We now recognize three different types of restriction-modification systems—types I, II, and III. Each system consists of two distinct enzyme activities: a DNA methylase and an endonuclease that catalyzes a double-stranded DNA break. The sequence-specific endonucleases, those most widely used in molecular biology, are type II enzymes. Regardless of type, the enzymes are named with the first three letters denoting the bacterial species of origin and a fourth letter denoting an individual strain. For example, the restriction system from *E. coli* K is called **EcoK**. If more than one enzyme system is found in a given strain, the different enzymes are designated by Roman numerals. For instance, **EcoRI** is one of two known restriction systems in *E. coli* strain R, and **HindIII** is one of three enzymes from the d strain of *Haemophilus influenzae*.

Properties of each of the three types of restriction systems are discussed in the following sections and are summarized in Table 24.2.

Restriction enzymes of most use to biologists cleave both DNA strands site-specifically, depending on base methylation.

Type I

Type I enzymes have both methylase and nuclease activities in one protein molecule, which contains three subunits. One subunit contains the nuclease, one the methylase, and one a sequence-recognition determinant. The recognition site is not symmetrical, and cleavage occurs some distance (up to 10 kb) away from the recognition site, although methylation occurs within the recognition site. For cleavage, the enzyme remains bound to the recognition site, and DNA is looped out around it, with concomitant supercoiling. About 10^5 ATP molecules are hydrolyzed per cleavage event. Energy is probably needed for both translocation of the enzyme and supercoiling of the DNA. For reasons still not clear, both ATP and AdoMet are required for the cleavage activity. AdoMet may be an allosteric activator because it is not broken down during the reaction.

Type II

Type II restriction nucleases have been of greatest value to researchers because most of them cut within the recognition sequence, making the cleavage sequence-specific. Most of the type II enzymes are homodimers, with subunits of 30 to 40 kilodaltons. A divalent cation is required for cleavage, but ATP is not required. Each type II nuclease has a counterpart methylase, which binds to the same recognition sequence and methylates one nucleotide within that sequence. A **hemimethylated** DNA (with methyl group on one strand only) is a preferred substrate for the methylase but not for the nuclease, which generally cleaves only when the recognition site is unmethylated on both strands. Cleavage generates 3' hydroxyl

TABLE 24.2 Properties of restriction-modification systems

	Type I	Type II	Type III
Example	<i>Eco</i> B	<i>Eco</i> RI	<i>Eco</i> PI
Recognition site	TGAN ₈ TGCT	GAATTC	AGACC
Cleavage site	Up to 10 kbp away from recognition site	Between G and A (both strands)	24–26 base pairs 3' to recognition site
Methylation site	^m TGAN ₈ TGCT ACTN ₈ ACGA _m	^m GAATTC CTTAAG _m	^m AGACC (only one strand methylated)
Nuclease and methylase in one enzyme?	Yes	No	Yes
Requirements for cleavage	ATP, Mg ²⁺ , AdoMet	Mg ²⁺ or Mn ²⁺	Mg ²⁺ , AdoMet
Requirements for methylation	ATP, Mg ²⁺ , AdoMet	AdoMet	Mg ²⁺ , AdoMet

Note: Each methylated base is identified with the letter m. All sequences read 5' to 3', left to right.

^aThe methylated base in each site, where known, is identified with the letter m. All sequences read 5' to 3', left to right. The cleavage on the opposite strand in each case can be inferred from the symmetry of the site (except for *Hga*I and *Ple*I, each of which has an asymmetric site). Pu = purine, Py = pyrimidine, N = any base.

and 5' phosphate termini. Cleavage sites on the two strands may be offset by as much as four nucleotides (as in *Eco*RI) or more, giving cuts with short, self-complementary, single-stranded termini. Some enzymes cleave to give a 5'-terminated single-stranded end ("overhang"), whereas others generate a 3' overhang. Other type II nucleases, including *Sma*I and *Hind*II, generate blunt-ended fragments, in which the cutting sites are not offset. Most recognition sites are four, five, or six nucleotides in length, although a few type II enzymes recognize an eight-nucleotide sequence. Most show two-fold rotational sequence symmetry, suggesting that the two enzyme subunits are also arranged symmetrically. Table 24.3 shows the recognition sites for several widely used type II nucleases. Several hundred enzymes of this type have now been isolated. Not all type II nucleases are absolutely sequence specific. For example, *Hind*II recognizes four different hexanucleotide sequences, and some enzymes (such as *Hga*I) cleave at a site outside the recognition sequence.

The year 1986 saw the first crystallographic structural determination of a restriction nuclease (*Eco*RI) complexed with a double-stranded oligonucleotide containing its DNA recognition sequence. Figure 24.8 shows one polypeptide subunit of the dimeric enzyme in contact with its DNA recognition sequence. The DNA is bound in a cleft, and the protein has an N-terminal "arm" that wraps about the DNA. Sequence specificity is maintained by 12 hydrogen bonds, which link the purine residues in the site to a glutamate and two arginine residues (not shown in the figure). Binding of the DNA alters its structure to generate "kinks"; the sequences immediately flanking

**FIGURE 24.8**

Structure of the *EcoRI* nuclease complexed with its DNA substrate. The DNA helix is shown in blue, while the two subunits of the protein are shown in orange and yellow, respectively. Note the “kink” in the DNA structure, resulting from the fact that the enzyme binds the central six-base-pair cutting site in the B conformation, while the flanking sequences are bound as A-form DNA. Note also the N-terminal “arm” on each protein subunit, which wraps around the DNA. PDB ID 1ERI.

the six-nucleotide cutting site (GAATTC) adopt the A duplex conformation, and the B structure is retained within the cutting site. The other subunit, not shown in the figure, contacts the substrate identically, accounting for the ability of the enzyme to catalyze symmetrical cleavages within the cutting site.

By contrast, *BamHI* endonuclease does not kink its DNA substrate, which remains in the B form. However, as shown in Figure 24.9, the enzyme itself undergoes a major conformational change upon binding DNA. The C-terminal α helices from each subunit unwind and contact the DNA, one in the minor groove, and one along the sugar–phosphate backbone, thus introducing an unexpected element of asymmetry into the DNA–protein complex.

Structural studies on type II DNA methylases have been informative as well. Amazingly, structural studies on the *Hha* DNA methylase showed that the bases undergoing methylation rotate completely out of the DNA duplex and into a catalytic pocket within the enzyme, where methylation occurs (Figure 24.10). Since that demonstration in 1994, other enzymes that act upon specific DNA bases have been shown similarly to flip the target base, including both DNA methylases, as shown here, and glycosylases, enzymes involved in DNA repair (Chapter 26).

Type III

Type III enzymes resemble more closely the type I systems than the type II systems. Type III enzymes contain both nuclease and methylase activities in a two-subunit enzyme. They differ from type I enzymes in that they do not require ATP, they modify just one DNA strand, and the cleavage site is fairly close to the recognition site.

Modification methylases swing the target DNA base totally out of the helix in order to act upon it.

FIGURE 24.10

Structure of a complex of a type II DNA methylase with DNA. The structure is a ternary complex containing *Hha* methylase from *Haemophilus haemolyticus*, DNA, and S-adenosylhomocysteine. The loops containing the catalytic site are in white, and the rest of the enzyme is in orange. S-Adenosylhomocysteine is in yellow, the DNA backbone is magenta, and bases are green. In both views the flipped-out target cytosine base is clearly visible. **(a)** View looking down the helix. **(b)** Side view from the minor groove. PDB ID 1MHT.

Determining Genome Nucleotide Sequences

The ability to map restriction cleavage sites within a genome made it possible to determine the complete nucleotide sequence of small genomes. Once a restriction map of the genome is available, the genome is simply fragmented by restriction cleavage into relatively small pieces, each of which can be cloned into a suitable vector for subsequent sequence analysis (Tools of Biochemistry 4B). The collection of cloned genomic fragments is called a **library**, since it is a collection of separate information-containing units. Each “book” in the library is sequenced, with the final sequence being reassembled on the basis of the restriction map. Generally, digestion must be carried out with two or more restriction nucleases so that identification of overlap regions will allow alignment of adjacent fragments. Even simpler is “shotgun sequencing,” a process that yields a random set of fragments, arising either from partial digestion of the genome by a restriction nuclease or by mechanical shear so that different clones in the library contain some identical sequences, representing regions of overlap between contiguous segments. Overlapping regions can be identified on the basis of restriction fragment length patterns, which allow all of the fragments to be aligned properly. Alternatively, the fragments can be sequenced individually and aligned by use of computer programs that look for regions of sequence identity. By these means it was possible for the 5386 bases in the ϕ X174 bacteriophage genome to be sequenced as early as 1977, with the 16,569 base pairs in human mitochondrial DNA being identified a few years later. A shotgun approach yielded the first sequence of a free-living organism, the bacterium *Haemophilus influenzae*, in 1995. This genome, of 1,830,137 base pairs, encodes about 1740 proteins. Many other bacterial genomes have since been sequenced by comparable approaches.

However, these simple approaches were not practical when applied to the much larger eukaryotic genomes. Even the unicellular yeast, *Saccharomyces cerevisiae*, contains a genome of 12 million base pairs, distributed among 16 chromosomes. Much more daunting is the human genome, with more than 3 billion base pairs in 24 chromosomes (22 autosomes plus the X and Y sex chromosomes). Obviously, different approaches were needed, both for alignment of genome fragments of contiguous sequence (“contigs”) and for their assignment to specific chromosomes. In our discussion of sequence analysis of large genomes we refer primarily to the human genome, which was determined as a result of the Human Genome Project, begun in 1990 by a large international consortium under the direction of Francis Collins, and by a privately financed program directed by Craig Venter. These efforts yielded a preliminary “draft sequence” in 2000, with a “final” sequence following in 2003.

Mapping Large Genomes

What was needed first was a way to identify the chromosome from which each fragment in a total DNA digest was derived. One way to do this is **fluorescent in situ hybridization** (FISH). The investigator selects a restriction fragment containing a unique sequence, found nowhere else in the genome. This sequence, typically a few hundred nucleotides, is amplified by **polymerase chain reaction**, or PCR, a technique that allows selective amplification of any region of a genome, provided that one knows the base sequences surrounding the region of interest. PCR is described in Tools of Biochemistry 24A. The amplified DNA fragment is tagged with a fluorescent dye, then denatured and allowed to anneal in the presence of a preparation of human chromosomes arrested in metaphase, where paired, condensed chromosomes have not yet separated. Microscopic visualization under light of the appropriate wavelength for the fluorescent dye identifies the chromosome to which the probe has become annealed (Figure 24.11). FISH has other uses, including finding specific features in DNA for use in genetic counseling and medicine. FISH can also be used to detect and localize specific mRNAs within tissue samples. In this context, it can help define the spatial-temporal patterns of gene expression within cells and tissues.

By these means, sequence analysis of the human genome becomes 24 separate projects, each focused upon one chromosome. But each chromosome is still enormous, and additional landmarks are needed, landmarks that allow placement of fragments of sequence information as they became available. In classical genetics maps were constructed by recombination analysis of genes with recognizable phenotypes. For example, one could mate two strains of the fruitfly *Drosophila*, one a wild-type and the other with two mutations (both dominant)—one causing, for example, abnormal eye color and one causing abnormal wing development. If the two mutations lie in genes on different chromosomes, then they reassort randomly according to Mendel’s laws, and each of the four possible phenotypes—wild-type, double mutant, and each of the two single mutants—is represented at 25 % among the progeny. On the other hand, if the two genes under study lie on the same chromosome, then analysis of hundreds of progeny would yield relatively few with just one of the two phenotypes—abnormal eye pigment or abnormal wing development. The two genes would be shown thereby to be *linked*—carried on the same chromosome. These outcomes are schematized in Figure 24.12.

Generating Physical Maps

Even though the two genes being analyzed may lie on the same chromosome, single mutants will arise among the progeny through genetic recombination, which involves breakage and joining of homologous chromosomes during meiosis. The percentage of recombinants arising under these circumstances is a measure of the distance along a chromosome between the genes; the greater the distance, the higher the frequency of recombination. By such analysis one can assemble a genetic map in which the distance between genes on the same chromosome is reported in terms of percent recombination between mutations in those genes.

For sequence analysis what is needed, of course, is not a map of genetic distances determined by biological measurements, which are essentially statistical, but a physical map, in which markers can be placed in terms of physical distance—kilobase pairs—from one another. Such markers are also indispensable for genetic analysis. Well before investigators had shown the audacity to propose sequencing the 3-billion-base-pair human genome, geneticists were trying to locate within the genome genes in which mutations give rise to inherited diseases. For example, cystic fibrosis results from deficiency or abnormality in a chloride channel protein. When the gene for this protein was in fact mapped in 1989, it was hoped that the information might lead to a cure for this dread disease. Unfortunately, that has not yet happened. However, identification of the gene and gene product related to a disease do help immeasurably in understanding the disease, seeking prevention, and guiding therapy.

The key to locating such disease genes was to have markers on a physical genome map, and then to use association studies in family pedigrees to find markers on the physical map that lie near the gene of interest. But what might those markers be? In 1980 David Botstein realized that random variations among human

FIGURE 24.11

Mapping genes by fluorescent in situ hybridization. Four different DNA probes representing different genes were each tagged with a fluorescent dye and hybridized to human chromosome 21 in metaphase, showing hybridization signals (in yellow) at four distinct locations along the chromosome. Because metaphase chromosomes are made up of two nearly identical sister chromatids, each probe produced a pair of signals.

FIGURE 24.12

Segregation of two genetic markers, lying either on separate chromosomes (top) or linked on the same chromosome (bottom). A and B are dominant alleles of genes in which the genotype can be inferred from direct observation of a phenotype, such as eye color or wing shape. In each case, two heterozygous parents are mated, and the expected proportion of each genotype in the progeny is shown. When the genes being analyzed lie on different chromosomes, the markers assort randomly. When they lie on the same chromosome, wild-type (AaBb) or double-mutant (aabb) progeny arise only through relatively rare recombination events.

Sequencing large genomes requires prior construction of a physical map of the genome.

FIGURE 24.13

Analysis of a restriction fragment length polymorphism. For details see text. The thick line represents a hybridization probe—a labeled oligonucleotide complementary to part of the sequence toward the left end of each molecule as drawn.

FIGURE 24.14

The principle of Southern transfer and hybridization.

genome sequences could lead to the gain or loss of restriction cleavage sites, and that the resultant **polymorphisms**—variable sequences within the same region—could provide the markers needed to construct physical maps. Consider the four-base sequence 5'-GATC, the recognition site for the restriction endonuclease *MboI*. On average this site will occur at intervals of 256 base pairs ($1/4 \times 1/4 \times 1/4 \times 1/4$). Suppose that individual A has two homologous chromosomes identical within this region, containing *MboI* cleavage sites 650 base pairs apart. Both chromosomes contain an additional *MboI* site, spaced 250 nucleotides from the 5' end of this region as drawn (Figure 24.13). Now suppose that a second individual, B, has a **restriction fragment length polymorphism (RFLP)** within this region. One chromosome is identical to that just described, while the other has, 250 base pairs from the 5' end, not GATC, but GTTTC. *MboI* will no longer cleave at this site. Now, if the genome of A is digested with *MboI*, this region will yield a 250-base-pair fragment and a 400-bp fragment, while the genome of B will yield the same 250- and 400-bp fragments from one chromosome and a 650-bp fragment from the chromosome not containing the internal *MboI* site. How might these fragments be detected against the enormous background resulting from *MboI* cleavage throughout the entire genome? A powerful technique called **Southern blotting**, or **Southern transfer**, after its inventor, Edwin Southern, permits this analysis.

The Principle of Southern Analysis

Consider the example shown in Figure 24.13. We would like to examine the *MboI* fragments in the region shown. But if we simply digest total human DNA with *MboI* and resolve the fragments by agarose gel electrophoresis, the pattern of fragments on the gel will be a smear, if the gel is analyzed by the standard method—ethidium bromide staining followed by examination of its fluorescence under ultraviolet light. There are far too many fragments, with each one present in minute amounts, for any one fragment to be visualized. In the Southern technique (Figure 24.14) the contents of the gel are transferred, or “blotted,” to a sheet of

nitrocellulose, under denaturing conditions. The initial Southern technique literally involved blotting; absorbent paper was placed between the electrophoretic gel and a sheet of nitrocellulose. Nitrocellulose binds irreversibly to single-stranded DNA, so what results is a replica of the agarose gel, with all DNA fragments tightly bound. Next one prepares a single-stranded DNA fragment identical to part of the region of interest, made highly radioactive by incorporation of ³²P. This is incubated with the nitrocellulose sheet under annealing conditions, allowing the radiolabeled DNA “probe” to find complementary sequences and yield renatured radioactive double-stranded DNA molecules. After this the nitrocellulose is washed to remove unbound probe and subjected to radioautography. Only those fragments in the DNA digest containing sequences homologous to those of the probe will be detected because of the bound radiophosphorus. More recently the use of radiolabeled hybridization probes has been supplanted by the use of fluorescent nucleotide analogs, which allows examination of gels after transfer under UV light, without the need for hazardous radioisotopes. Also, the transfer from agarose gel to nitrocellulose is now done through application of an electric current.

In the example shown in Figure 24.13, suppose that the labeled probe is complementary to a unique sequence in the 250-bp fragment. Then Southern analysis of an *Mbo*I digest will show a 250-bp fragment from the DNA of individual A, and fragments of 250 bp and 650 bp in the digest from individual B.

How are the radiolabeled probes produced? One method involves automated chemical synthesis of oligonucleotides in the presence of ³²P, or a fluorescent-tagged dNTP. More often, probes are prepared by polymerase chain reaction (see Tools of Biochemistry 24A, page 1034).

Polymorphisms within genomes include not only single-base changes, as shown in Figure 24.13, but also insertions, deletions, and repetitions of short sequences. Figure 24.15 shows typical variation in a 5-kbp region of the genome for 10 individuals, carrying 20 distinct copies of the human genome. Shown are 10 single-nucleotide polymorphisms (SNPs), an insertion–deletion polymorphism (indel), and a tetranucleotide-repeat polymorphism. The six common polymorphisms on the left side are strongly correlated. Although these six could in principle occur in 2⁶ possible patterns, only three patterns are observed (shown

Southern blotting permits detection of minute amounts of DNA in the presence of a vast excess of nonspecific DNA.

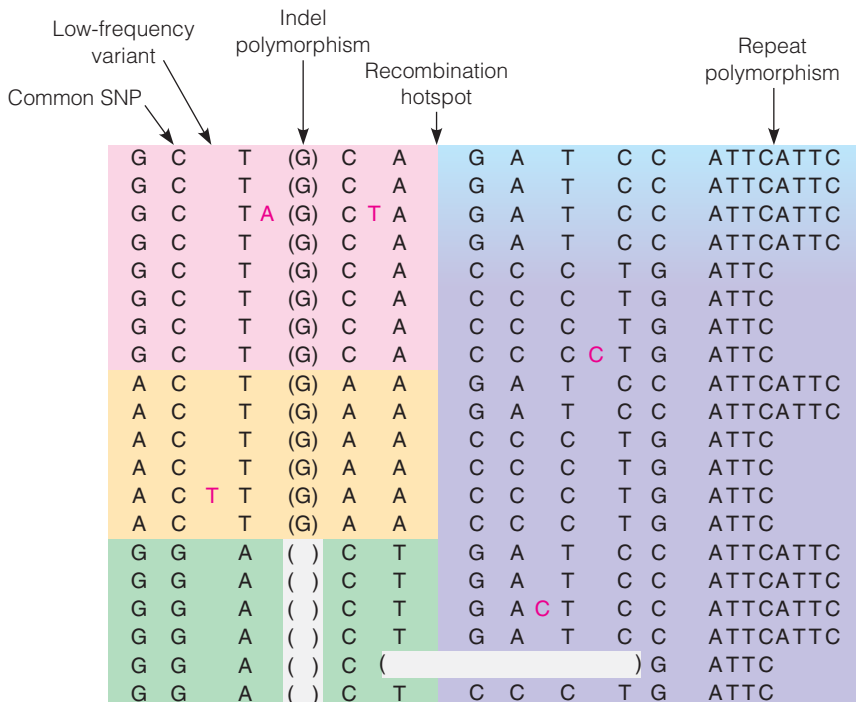

FIGURE 24.15
DNA sequence variation in the human genome. See text for description. The T insertion in the 13th line is found at low frequency.

by pink, orange, and green). These patterns are called **haplotypes**. Similarly, the six common polymorphisms on the right side are strongly correlated and exist in only two haplotypes (shown by blue and purple). There is little or no correlation between the two groups of polymorphisms because there is a “hotspot,” or region of high genetic recombination frequency, between them.

Southern Transfer and DNA Fingerprinting

Southern transfer and analysis has many applications, some of which are discussed elsewhere in this book. Best-known to the general public is DNA fingerprinting in forensic analysis. Restriction fragment–length polymorphisms (RFLPs, or “ruflups”), such as the variant sequences shown in Figures 24.13 and 24.15, exist throughout the genome. No two individuals, with the exception of identical twins, have the same pattern of RFLPs. Thus, a crime investigator who carries out Southern analysis using probes covering sufficient regions of the genome can generate a “DNA fingerprint” that establishes the identity of an individual with far more confidence than from the prints on our fingertips. Moreover, as we will see later, the power of PCR to amplify minute amounts of DNA means that DNA fingerprinting can be carried out with minuscule amounts of material left at a crime scene, such as the DNA in a single human hair. Most of the RFLPs used in forensic analysis are not single-base changes, but short tandem repeats (*repeat polymorphisms*), such as that shown in the blue portion of Figure 24.15.

Since DNA fingerprinting became routine in crime labs in the mid-1990s, hundreds of innocent criminal defendants have been acquitted and many previously convicted individuals have been exonerated. The large number of those freed, often after spending years in prison or having been sentenced to death, may yield satisfaction in the fact that molecular biology has contributed so successfully to the criminal justice system, but also sadness about years and lives unjustly sacrificed owing to deficiencies in that system.

Locating Genes on the Human Genome

The large number of known polymorphic regions in the human genome—those characterized by the presence of one or more RFLPs—provide many markers comparable to those of classical genes. Just as alleles of a gene can be recognized by observable phenotypes—eye color, for example—so also can alleles at polymorphic regions be recognized by the presence or absence of specific restriction sites. This allows disease genes to be mapped in terms of their proximity to a known polymorphic region. Consider the devastating inherited disease Huntington’s disease, which took the life of folk singer Woody Guthrie. By carrying out RFLP analysis on the DNA of members of a family afflicted with this disease, one can identify those polymorphic regions, and specific sequence variants, that remain associated with susceptibility to the disease in several individuals. By these means, the physical location of the gene responsible for Huntington’s disease can be located so that it can be sequenced, cloned, and investigated, with an eye toward identifying the mutant protein responsible for the disease and ways that this information could be used to seek treatment options. Thus, RFLPs have shown great value both in mapping the human genome and in seeking cures for genetic diseases based upon analysis of the causative genes. In the case of Huntington’s disease genetic testing can help to inform decisions on child-bearing, but unfortunately, identification of the gene has not yet led to a cure for this devastating disease. Genetic testing is now being offered directly to the public by numerous companies. This has become somewhat problematic, as discussed in one of the end-of-chapter references.

Sequence Analysis Using Artificial Chromosomes

Although recent advances in DNA sequencing technology now permit many thousands of nucleotides to be sequenced in one run of the sequencer, the original Sanger method using fluorescent-tagged dideoxynucleotides was limited to several

hundred nucleotides per sequencing run. Because a human chromosome might contain 100 million base pairs or more, there was a need for sequence analysis in DNA segments much smaller than individual chromosomes, but also much larger than typical restriction fragments. Yeast artificial chromosomes (YACs) were useful for this purpose. A YAC is a cloning vector that contains a centromere (page 1022), a DNA replication origin, telomeres (page 1022) at each end of the linear structure, a selectable marker such as a drug-resistance gene, and a cloning site. Inserts as large as 1000 kbp can be cloned into these constructs, which, after reintroduction into yeast cells, are maintained as the cell divides, just like natural chromosomes. A technique called **pulsed field gel electrophoresis**, which involves alternating voltage gradients during electrophoresis, permits resolution of the much larger DNA fragments resulting from analysis of these long DNA inserts. This approach subdivided each large sequencing project into sequence analysis of individual YACs, followed by assembly of sequences for a given chromosome. The approach is schematized in Figure 24.16, which also shows that each chromosome has a characteristic banding pattern when stained. It also illustrates that a very large number of individual restriction fragments must be cloned and sequenced to give the 130 million base pairs in the typical sequence shown here.

Size of the Human Genome

With all of these technologies in place, and with the aid of hundreds of workers, primarily from 20 institutions designated as genome centers, and from Craig Venter's privately financed effort, the entire human genome sequence, comprising some 3 billion base pairs, was determined. A surprise, given the large amount of DNA in the genome, was the relatively small number of genes that are expressed as proteins. From the size of the genome and the amount represented by noncoding structures such as satellite sequences, it was expected that the genome would contain about 100,000 genes. However, analysis of the draft sequence suggested that the true number of genes, identified as open reading frames with appropriate punctuation for initiation and termination of translation, was closer to 30,000. Further refinement of the sequence led the number of putative genes further downward, to a number between 20,000 and 25,000. However, phenomena such as alternative splicing and post-translational modification allow more than one protein product to be encoded by one gene. Nevertheless, the fact is that humans maintain organismic complexity and diversity using far fewer genes than had originally been expected.

From the first human sequence that was determined, and from analysis of RFLPs, it has become apparent that any two humans will show differences in their DNA sequences at about 1 base in 1000. In other words, any two humans, regardless of ethnic origin, are about 99.9% identical, genetically speaking.

It's interesting to consider the cost of large-scale genome sequence analysis, *vis à vis* technological innovations in sequencing methods. The government-sponsored Human Genome Project cost about \$400 million. In 1999 sequence analysis of 1 million base pairs of DNA cost about \$20,000; by 2010 that cost was 20 cents and dropping. By mid-2010, Illumina, the designer of one of the "second generation" sequence technologies (Tools of Biochemistry 4B), was offering complete sequence determination of one individual for \$9500, and a race is under way among several companies to drop that price to \$1000.

Physical Organization of Genes: The Nucleus, Chromosomes, and Chromatin

Chromosomes

As we see throughout this book, prokaryotic and eukaryotic cells differ from each other in fundamental ways. Among the most pronounced is the physical state of the genome. All organisms face the problem of compacting the genome, that is, reducing its physical dimensions to the point that it can fit into a cell of far smaller

FIGURE 24.16

The human genome contains between 20,000 and 25,000 genes, far fewer than predicted from the amount of DNA in a human cell.

FIGURE 24.17

dimensions than the length of the DNA molecules in the genome—but they solve that problem in quite different ways. Bacteria are haploid organisms, with the entire genome represented by one DNA molecule, which is usually circular. With great care, this immensely thin and fragile molecule can be teased out of the cell without being broken, so that the circular structure can be visualized. Figure 24.17 shows an *E. coli* chromosome trapped in the midst of replication. The molecule was radiolabeled by growth of the bacteria in the presence of [³H]thymidine and visualized by radioautography. The figure shows a closed circular molecule with two Y-shaped junctions, each of which is a replication fork. Compaction of this molecule occurs largely by negative supercoiling and by organization into loops of supercoiled DNA about 50 kbp in length, with each loop bound to protein (Figure 24.18). This compacted structure, called a **nucleoid**, exists free within the cytosol of a bacterial cell, with a small number of attachment points to the membrane (see also Figure 1.8, page 15).

To the extent that the ultimate proof of a molecule is its validation by synthesis, the structure of bacterial chromosomes was confirmed in 2010, with the announcement by Craig Venter's group of the complete synthesis of a bacterial chromosome, whose capacity for reproduction and expression was confirmed by its ability to replicate after transfer into a bacterial cell from which the nucleoid had been previously removed.

The situation in eukaryotes is different. First, the eukaryotic cell is usually diploid, with two copies of each chromosome in each cell. An exception is the sex chromosome; female cells have two X chromosomes, while male cells contain one X and one Y chromosome. A eukaryotic cell's genome is divided into several or many chromosomes, each of which contains a single, very large, linear DNA molecule. Although their size varies greatly among organisms and even among different chromosomes in a given species, these DNA molecules are commonly of the order of 10⁷ to 10⁹ bp in length. Different eukaryotic species contain widely varying numbers of *distinguishable* chromosome pairs—from 1 (in an Australian ant) to 190 (in a species of butterfly). Whereas most prokaryotes are haploid, containing only one copy of their chromosome, most eukaryotic cells are diploid, carrying two

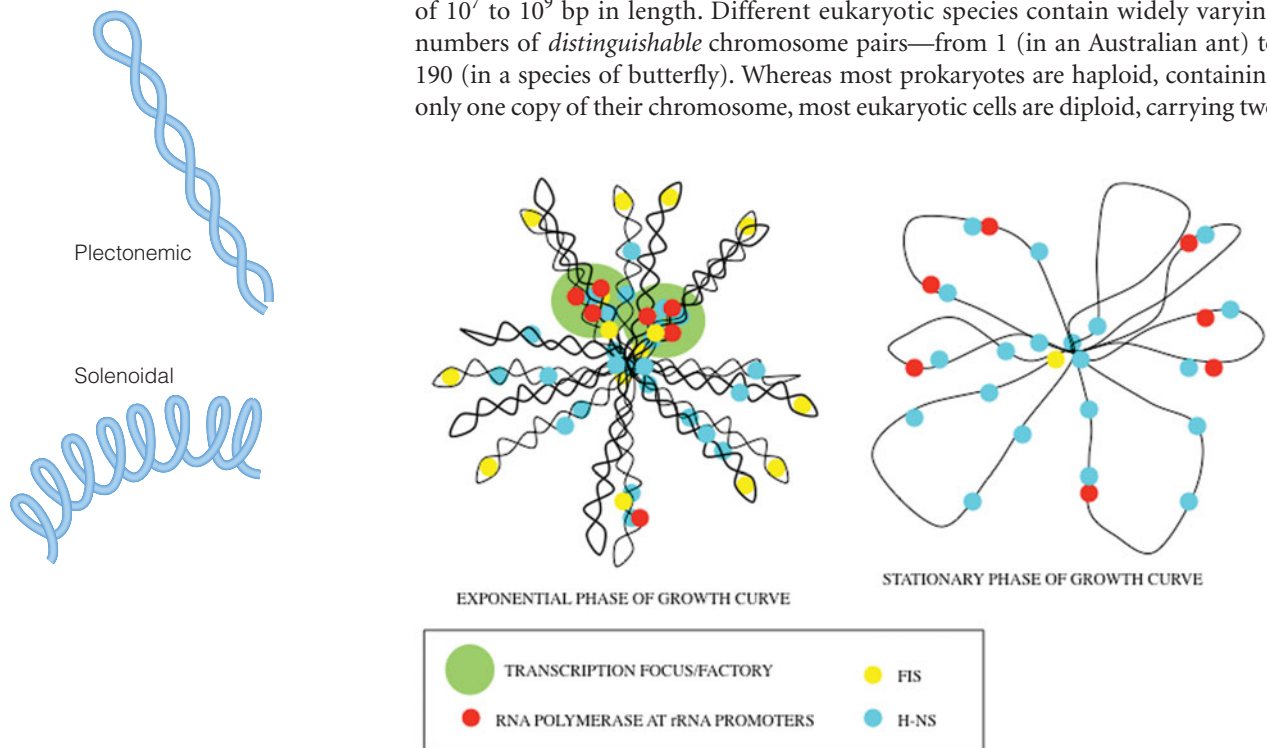

FIGURE 24.18

Structure of a bacterial nucleoid, showing independent domains of supercoiling, each stabilized by binding to protein. The term *plectonemic* refers to the type of supercoiling observed, with DNA strands intertwined in a regular way. The 1000-nm diameter of the structure allows it to fit within a bacterial cell that may be 2 to 5 μm in length. An alternative form of negative supercoiling, *solenoidal*, allows greater compaction and is seen in chromatin.

copies of each chromosome. As we have noted, the human genome is made up of 24 different chromosomes (22 autosomes plus the X and Y chromosomes) so that normal diploid human cells have a total chromosome number of 46.

An exception to the general statement that eukaryotic chromosomes are linear DNA molecules, folded into tightly packed chromatin structures, is organelle DNA—mitochondrial DNA in all eukaryotes, and chloroplast DNA in plants. Mitochondrial DNA is a circular duplex, as noted earlier, with the human mitochondrial genome containing 16,569 base pairs (see Figure 4.18, page 108). The genome is folded into a structure called the nucleoid, which is comparable to bacterial nucleoids. Human mitochondrial DNA encodes 13 proteins, all components of respiratory chain complexes. In addition, because these proteins are synthesized within the organelle, the genome also encodes a complete complement of ribosomal and transfer RNAs. Plant mitochondrial DNAs are much larger, up to two million base pairs or more. Chloroplast DNAs contain about 120,000 to 160,000 base pairs. It should not be surprising that organelle DNAs resemble prokaryotic DNAs in their structure and organization because there is now widespread agreement that these organelles evolved from primitive bacteria that infected primordial eukaryotic cells and evolved in tandem with their hosts.

Unlike the prokaryotic chromosome (nucleoid), the chromosomes of eukaryotes are not normally found free in the cytoplasm. In nondividing cells, the chromosomes are segregated within the nucleus (Figure 24.19) as an entangled mass of fibers of a DNA–protein complex called **chromatin**. The *nuclear envelope* is pierced by **nuclear pores**, which allow molecules as large as small protein and RNA molecules to pass in and out of the nucleus.

The nuclear pores are actually multisubunit complexes that provide openings of about 9 nm diameter. These allow the free diffusion of small molecules (including some small proteins) between nucleus and cytoplasm. However, the nuclear pore complex is also involved in selective transport of larger proteins and messenger RNA. In this process, two classes of assiter proteins, called **exportins** and **importins**, are involved. Protein translation in eukaryotes occurs outside the nucleus, so transcription and translation cannot be directly coupled, as they are in prokaryotes (Chapter 27). Therefore, messenger RNA must be exported from the nucleus for translation. As we shall see later, considerable processing of the mRNA occurs before this export. During *mitosis*—the separation of daughter chromosomes following DNA replication—the nuclear envelope breaks down, and the diploid chromosomes condense into compact structures like the one shown in Figure 24.20. In this electron micrograph two newly replicated chromosomes

The multiple eukaryotic chromosomes are contained within the nucleus, except during mitosis when the nuclear envelope disintegrates.

(paired **chromatids**) are joined at the **centromere**, a structure that becomes linked to the spindle fibers as chromosome pairs are drawn apart in the latter stage of mitosis (page 1027).

Not seen in the electron micrograph of Figure 24.20 are the **telomeres**, structures at each end of eukaryotic chromosomes that protect the DNA from degradation and assure that each chromosome is completely copied during replication. A telomere is a simple tandemly repeated sequence that may be several kbp in length. Usually one strand is G-rich, and, as pointed out in Chapter 4, the dGMP residues often form a G-quartet structure. In humans the telomeric repeat sequence is 5'-TTAGGG. Figure 24.21 shows a spread of human metaphase chromosomes stained with fluorescent dyes showing telomeres (pink). We discuss telomeres and their biosynthesis in Chapter 25.

The enormous amount of DNA in a eukaryotic cell poses some serious problems. First, as noted earlier, there is the issue of *compaction*. The diploid DNA content of a human cell is more than 6×10^9 bp, corresponding to a total length of about 2 m. Somehow, all this DNA must be packed into a nucleus about $10 \mu\text{m}$ (10^{-5} m) in diameter. Second is the problem of *selective transcription*. In a typical differentiated eukaryotic cell, only a small fraction of the DNA is ever transcribed. Much, as we have seen, is nontranscribable. Many genes that undergo transcription do so only in certain cell lines in particular tissues, and then often only under special circumstances. To maintain and regulate such complex programs of selective transcription, the accessibility of the DNA to RNA polymerases must be under strict control. Both compaction and the control of gene expression in eukaryotes are achieved by having the DNA complexed with a set of special proteins to form the protein–DNA complex called chromatin.

Chromatin

The DNA-binding proteins of chromatin fall into two classes. The major class, **histones**, includes five types of protein, whose properties are outlined in Table 24.4. All histones are small, highly basic proteins. The histones are the basic building blocks of chromatin structure. Some have been remarkably well conserved in amino acid sequence throughout evolution. All known histone H4 molecules, for example, contain exactly 102 amino acid residues. Histone H4 shows only two substitutions between humans and peas and only eight substitutions between humans and yeast. The nucleoids of prokaryotic cells also have proteins associated with DNA, but these proteins are quite different from the histones and do not form a comparable chromatin structure. Thus, the histone-containing chromatin structure is a uniquely eukaryotic feature. In all kinds of eukaryotic nuclei, from yeast to human, the histones are present in an amount of about 1 gram per gram of DNA, and histones H2A, H2B, H3, and H4 are always found in equimolar quantities.

The histones are accompanied by a much more diverse group of DNA-binding proteins, rather unimaginatively named **nonhistone chromosomal proteins**. The total amount of the latter proteins varies greatly from one cell type to another, ranging from about 0.05 to 1 gram per gram of DNA. They include a bewildering variety of proteins, such as polymerases and other nuclear enzymes, nuclear receptor proteins, and regulatory proteins of many kinds. It is possible to count, on two-dimensional gels, approximately 1000 different nonhistone chromosomal proteins in a typical eukaryotic nucleus. Among the most abundant are topoisomerases and a class called **SMC proteins** (for structural maintenance of chromosomes). The major proteins in this class are **cohesins**, which help to hold sister chromatids together immediately after replication and continue to hold them together until chromosomes condense at metaphase, and **condensins**, which are essential to chromosome condensation as cells enter mitosis.

The association of proteins with eukaryotic DNA has long been recognized. As early as 1888 the German chemist Albrecht Kossel isolated histones from nuclei and recognized them as basic substances that would bind to the nucleic acid.

The chromatin of eukaryotes consists of DNA complexed with histones and nonhistone proteins.

TABLE 24.4 Properties of the major histone types

Histone Type	Molecular Weight	Number of Amino Acid Residues	mol %		Role
			Lys	Arg	
H1	22,500	244	29.5	1.3	Associated with linker DNA; helps form higher-order structure
H2A	13,960	129	10.9	9.3	Two of each go to form the histone octamer core of the nucleosome.
H2B	13,774	125	16.0	6.4	
H3	15,273	135	9.6	13.3	
H4	11,236	102	10.8	13.7	

Note: All data are for calf thymus histones, except for H1, which is from rabbit.

Histones were, in fact, the first class of proteins to be recognized. However, the precise role of histones was not understood until about 1974. Then, research in a number of laboratories showed that these proteins combine in a specific way to form a repeating element of chromatin structure, the **nucleosome**.

The Nucleosome

If naked DNA (that is, DNA containing no bound proteins) is partially digested with a nonspecific endonuclease such as micrococcal nuclease, which cuts double strands almost randomly, a broad smear of polynucleotide fragments is produced. But in the early 1970s, researchers in a number of laboratories found that if the same experiment is conducted with chromatin, or even with whole nuclei (which some nucleases can penetrate through the nuclear pores), the DNA was cleaved in a quite specific, nonrandom way. On a polyacrylamide gel, the DNA from nuclease-digested chromatin gave a series of bands that were multiples of approximately 200 base pairs (Figure 24.22). This indicated that the nuclease could find easy access to the DNA only at regularly spaced points. At about the same time that these observations were made, other laboratories obtained electron micrographs of extended chromatin fibers, which revealed a regular “beaded” pattern in the chromatin structure, with one bead about every 200 bp (Figure 24.23). Still other researchers found that if nuclease digestion of chromatin was continued, it slowed down and nearly stopped when about 30% of the DNA had been consumed. The remaining protected DNA was found to be present in particles corresponding to the beads seen in the electron micrographs. These particles, called nucleosomes (or more precisely, *nucleosomal core particles*), were found to have a simple, definite composition that is practically invariant over the whole eukaryotic realm. They always contain 146 bp of DNA, wrapped about an octamer of histone molecules—two each of H2A, H2B, H3, and H4. This composition explains the equivalent amounts of these histones in chromatin. Both nucleosomes and nucleosome histone cores have been crystallized, and X-ray diffraction studies have revealed the structure shown in Figure 24.24. The DNA lies on the surface of the octamer and makes about 1.7 left-handed solenoidal superhelical turns about it. The structure of the octamer provides a left-handed helical “ramp” upon which the DNA is bound. The high-resolution data now available on the histone octamer reveal a commonality in histone structure—the *histone fold*—that was not evident from examination of sequences alone, and suggests an early common ancestor of these proteins.

Although the nucleosome itself is a nearly invariant structure in eukaryotes, the way in which nucleosomes are spaced along the DNA varies considerably among organisms and even among tissues in the same organism. The length of DNA between nucleosomes may vary from about 20 bp to over 100 bp. Exactly what determines the arrangement of nucleosomes along the DNA is still not wholly understood. However, it is now clear that at least some nucleosomes

The basic repeating structure in chromatin is the nucleosome, in which nearly two turns of DNA are wrapped about an octamer of histones.

FIGURE 24.22

The kind of evidence that first suggested a repetitive structure in chromatin. In this gel, the three lanes to the right show DNA fragments obtained after three successively longer digestions of chicken erythrocyte chromatin by micrococcal nuclease. The column to the left contains DNA restriction fragments as size markers.

occupy defined positions. The implications of this finding are discussed later. The internucleosomal, or *linker*, DNA is occupied by the H1-type (very lysine-rich) histones and nonhistone proteins. Figure 24.25 provides an overall schematic view of the fundamental elements of chromatin structure.

Histone molecules in chromatin are subject to numerous post-translational modifications, such as acetylation and methylation of lysine ϵ -amino groups. These modifications participate in regulating gene expression. In order to be transcribed, DNA must at least transiently undergo dissociation from the histone core, and histone amino acid modifications affect the strength of interactions between DNA and the histone core. Changes of this kind can bring about stable changes in the way genetic information is expressed. Inherited modifications that change genetic expression without changing DNA base sequence are termed **epigenetic**. As mentioned earlier in this chapter (page 1009), DNA methylation is an epigenetic modification because methylation patterns can be inherited. Although it has not been unequivocally established that histone modifications in chromatin are transmitted when cells divide, most workers consider histone modifications to be epigenetic. We return to these issues in Chapter 29.

Higher-Order Chromatin Structure in the Nucleus

Wrapping DNA about histone cores to form nucleosomes accomplishes part of the compaction necessary to fit the eukaryotic DNA into the nucleus because the strand is thereby shortened several-fold. However, it is clear that much of the chromatin in the nucleus is even more highly compacted. The next stage in compaction involves folding the beaded fiber into a thicker fiber like that shown in Figure 24.26. These fibers are about 30 nm in diameter and must be further folded on themselves to make the thicker chromatin fibers visible in both metaphase chromosomes (see Figure 24.20) and the nuclei of nondividing (interphase) cells.

Evidence is emerging concerning the way in which the chromatin fiber is organized in both metaphase and interphase chromatin. Dye staining of the metaphase chromosomes from a particular organism gives a reproducible banding pattern (see Figure 24.16). In situ hybridization methods, in which specific sequences are located on chromosomes by hybridization with a complementary fluorescent nucleic acid probe and then visualized microscopically (Figure 24.11), show that particular DNA sequences are always located at the same places in specific chromosomes. Given that the DNA in a eukaryotic chromosome is one long continuous strand, this implies that some kind of regular folding must be present to preserve this order. Recent evidence indicates what this folding may be. If metaphase chromosomes are treated with polyanions like dextran sulfate, which strip off the histones and loosely bound nonhistone proteins, the DNA strands emerge as enormous loops from a *scaffold* of tightly bound protein. An electron micrograph of this structure is shown in Figure 1.4 (page 9). Individual loops vary in size but may range up to 100,000 bp in length—about the size of the β globin gene cluster, for example. Approximately 1000 such loops exist in the average chromosome.

Evidence also exists for a similar but more diffuse scaffold in the interphase nucleus. Removal of histones and weakly bound nonhistone proteins from intact nuclei by high salt concentrations or detergents, together with digestion of most of the DNA by nucleases, leaves a protein structure that has been called the **nuclear scaffold**, or **nuclear matrix** (Figure 24.26). This structure includes the laminar shell that lines the inside of the nuclear membrane, plus a network of fine fibers that seem to extend throughout the nucleus. When the chemical dissection is done gently, using the specific detergent lithium diiodosalicylate to remove the histones and most other proteins, the DNA connections to the nuclear matrix are undisturbed. Cleavage of the DNA with restriction endonucleases leaves specific fragments of DNA attached to the nuclear matrix. These fragments are spaced at rather long intervals along the genome and contain characteristic *matrix attachment regions* (MARs). It appears that groups of coordinately expressed genes often lie between adjacent MARs, as Figure 24.27 illustrates for the repeated histone gene clusters in *Drosophila*.

The proteins that form the scaffold from which the loops extend include some interesting members, such as topoisomerases, enzymes that change DNA linking number (Chapter 4). It has been hypothesized that topoisomerase molecules at the base of a loop could bring about changes in the supercoiling on that particular loop. Such changes in supercoiling would be in addition to the coiling imposed by the nucleosomes. Changes in supercoiling may be involved in chromosome condensation and seem to be essential during replication and transcription. It seems likely that the structure of chromatin is dynamic, changing locally as the DNA is replicated or transcribed.

Although it has not yet been established with certainty, it is possible that at least portions of the loop-and-scaffold structures are identical in metaphase and interphase chromatin. If so, they would provide part of the mechanism necessary for the cell to “keep track” of chromatin structure through successive cell divisions. Furthermore, it now seems likely that this loop structure may play a role in the control of expression of groups of functionally linked genes.

The current view is that some loop domains—those involving the nontranscribed genes of a particular cell—may be permanently coiled into 30-nm fibers and perhaps supercompacted into even higher-order coiling. Such regions could correspond to the highly condensed regions of **heterochromatin** long recognized

FIGURE 24.25

The elements of chromatin structure. At the top is our current understanding of the extended structure of a chromatin fiber. Light digestion with nuclease releases first mononucleosomes and oligonucleosomes. Then, as linker DNA is further digested, nonhistone proteins and H1 are released, to yield the core particle whose structure is shown in Figure 24.24.

The fiber formed by the nucleosomes is folded in vivo to form higher-order chromatin structure.

**FIGURE 24.26**

Levels of chromatin structure. To the left is a schematic view of a portion of the nucleus, with partially condensed chromatin fibers. A closer view (to the right) shows a chromatin fiber in which part is in the condensed (30 nm) form, and part is opened up, as for transcription.

Loops of chromatin, often containing individual gene clusters, are attached to the nuclear matrix.

by cytologists. The more-open chromatin regions, called **euchromatin**, may then correspond to relaxed domains within which transcription can occur. However, as we shall see in Chapters 27 and 29, the regulation of transcription is surely more subtle and complex than such a simple model would imply.

The Cell Cycle

The processes by which cells divide and DNA is replicated are somewhat more complicated in eukaryotes than in prokaryotes. As discussed further in Chapter 25, DNA replication in bacteria is an almost continuous process, at least during exponential growth, whereas in eukaryotic cells DNA replication occupies but a fraction of the time needed for a cell to divide into two identical daughter cells. In general the somatic cells of eukaryotes divide much less frequently, and some, in certain types of mature tissue, do not divide at all. Those that are dividing in growing tissues exhibit a well-defined *cell cycle*, which is almost always separated into several distinct phases, as shown in Figure 24.28. Let us follow a typical eukaryotic cell through one cycle. We can arbitrarily begin in what is called the *G1 phase* (or first gap phase), following cell division. At this point, the cell contains two copies of each chromosome, the normal diploid state of a eukaryotic cell. This

state is indicated in Figure 24.28 by a DNA content of 2C, that is, twice the haploid amount. Sometime late in G1 phase, the commitment to divide is triggered. Because division will first require doubling of the DNA content, and the new DNA will need new histones to make chromatin, synthesis of histones is one of the first indications of incipient DNA replication (see Figure 24.28).

The cell then enters synthesis, or *S phase*. During this stage, the DNA is replicated and the histones and nonhistone proteins are deposited on the daughter DNA molecules to reproduce the chromatin structures. When replication is complete, the cell enters the second gap phase, or *G2 phase*. It now has a DNA content four times the haploid amount (4C). In most eukaryotic cells, the total time required for G1, S, and G2 phases is many hours. During this whole period, which is termed **interphase**, the chromatin is dispersed throughout the nucleus and is actively engaged in transcription.

Phases of Mitosis

At the end of G2, the cell is ready to enter M phase, or *mitosis*, during which it divides. Mitosis is a multistage process, and it has been subdivided for descriptive purposes into the phases depicted in Figure 24.29. In *prophase*, the replicated chromosomes condense into the typical *metaphase* chromosome structures so often pictured (see Figure 24.20). In *anaphase* the nuclear membrane disintegrates, and the *mitotic spindle* forms. The spindle consists of contractile microtubules that pull pairs of chromatids apart so that the daughter cells each receive identical sets of chromosomes. In *telophase* the nuclear membrane then re-forms about each daughter nucleus, and the cell itself divides. This cellular division is called **cytokinesis**. After division, the chromosomes of the daughter cells decondense, and a new G1 phase begins.

In many tissues of higher organisms, the G1 phase becomes very prolonged after growth and tissue differentiation are complete. The most extreme examples are fully differentiated nerve cells, most of which never divide again in mature organisms. Such nondividing cells are in a permanently arrested G1 phase, which is often called G₀. On the other hand, some specialized stem cells, such as those found in the bone marrow and intestinal epithelium, undergo continuous division throughout the life of the organism. These stem cells continually provide new differentiated cells to replace cells that have been lost or damaged.

The Centromere and Kinetochores

Earlier, we mentioned the centromere as the chromosomal site at which the chromosome becomes attached to the microtubules in spindle fibers, before sister chromatids become drawn apart. Figure 24.30 shows an electron micrograph of a chromosome attached to the microtubules of the mitotic spindle. The structure linking the centromere on the chromosome to the spindle fibers is the **kinetochore**.

What structural features describe the centromere? This is an important question because it is critical for correct chromosome segregation that each chromosome be drawn away at one, and only one, site. DNA sequences in centromeres differ from those in the rest of the chromosome, but in a nonconserved way. In budding yeast the centromere forms at a defined 125-bp sequence, while in higher eukaryotes centromeric sequences consist of much longer repetitions of a much shorter sequence. Chromatin structure is altered within the centromere, partly because of the replacement of histone H3 by a variant H3, called CenH3. Unlike the standard histones, CenH3 is quite divergent throughout evolution, evidently matching the variability seen among centromere DNA sequences. Although the structure of this modified chromatin has not yet been described in detail, there is evidence that DNA within the centromere is positively supercoiled, rather than negatively, as in the rest of the chromosome.

Further variability in centromeric chromatin is seen in the nucleosome structure. Often the replacement of H3 by CenH3 is the only change, yielding core particles with (CenH3/H4/H2A/H2B)₂ octamers. As suggested in Figure 24.31, modified

The eukaryotic cell passes through a cycle of phases: G1 (gap 1), S (DNA synthesis), G2 (gap 2), and M (mitosis).

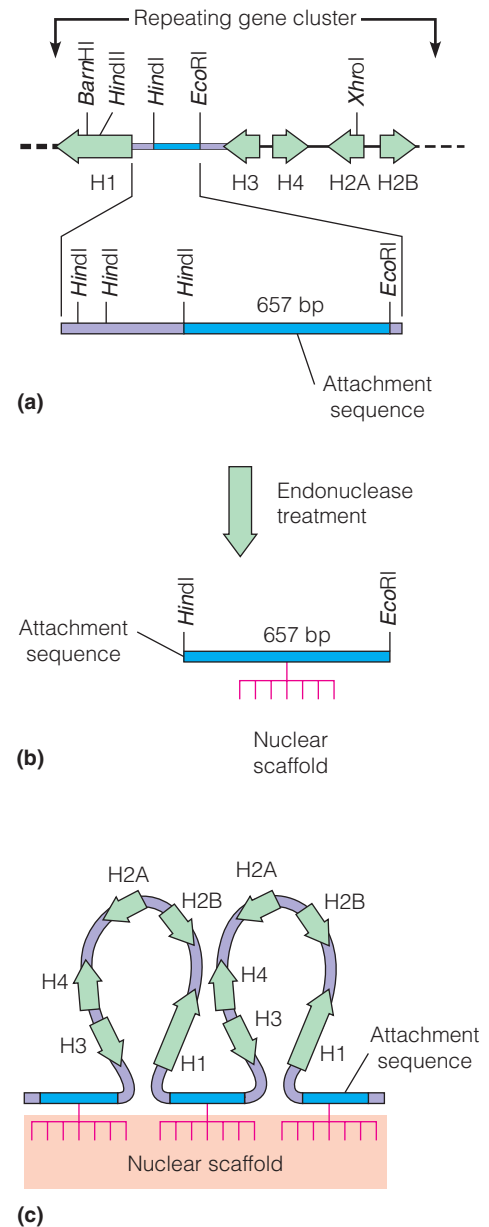

FIGURE 24.27

Attachment of gene clusters to the nuclear matrix. **(a)** A map of the repeating histone gene cluster in *Drosophila*, where each green arrow is a histone gene (arrowheads indicate direction of transcription). A number of restriction sites are also shown. **(b)** If *Drosophila* nuclei are extracted with lithium diiodosalicylate, to remove proteins gently, and are then digested with a collection of the restriction endonucleases shown, only the 657-bp HindIII-EcoRI DNA fragments are left attached to the matrix. **(c)** The interpretation is that the gene clusters exist in individual loops, the bases of which are tied to the matrix.

FIGURE 24.28

The eukaryotic cell cycle. Changes in the amount of DNA (blue line) and rate of histone synthesis (red line) with time during two cell cycles. The DNA content is measured in units of the haploid genome (C). The time scale is typical of many eukaryotic cells.

FIGURE 24.29

Mitosis. The cell entering the pathway was originally diploid. It has undergone DNA replication and is now in G₂, with a DNA content of $4C$. After the process is complete, each daughter cell will again be $2C$.

chromatin is on the outside of the chromatin coil within the centromere, available to interact with proteins in the kinetochore, which will draw the two paired chromatids apart at anaphase. Unmodified nucleosomes are in the interface between sister chromatids, which are transiently held together by proteins called *cohesins*. The figure also shows predominant histone methylation patterns within and adjacent to the centromere.

The kinetochore is a complex structure consisting of two “plates,” one in contact with the centromere and one with a microtubule. As shown in Figure 24.32, the inner and outer plates are joined by a protein complex called Ndc80. There is evidence that the protein complexes in the inner plate of each kinetochore contact just one CenH3 nucleosome. Because each kinetochore contacts just one microtubule, several kinetochores are involved in formation of each mitotic spindle.

FIGURE 24.30

An electron micrograph of a condensed chromosome pair linked via their kinetochores to microtubules (MTs). The region of the chromosome in contact with the kinetochore is the centromere.

Control of the Cell Cycle

Progression through the cell cycle is controlled by a series of protein phosphorylations. Major features of the regulatory program were elucidated by Lee Hartwell through studies on temperature-sensitive mutants of yeast blocked at high temperature in progression through the cycle. Key players in the program are small proteins called **cyclins** and the protein kinases that they activate, called **cyclin-dependent kinases (Cdks)**. The system is designed so that the cell can assess at various stages whether conditions are right to move to the next phase. Each stage at which this assessment occurs is called a **checkpoint**. A checkpoint during G1 involves a G1-Cdk, and it acts to assure that the environment—availability of nutrients, and so on—is favorable for entry into S phase and commitment to DNA replication. A series of G1/S-Cdks and S-Cdks acts to detect DNA damage, exerting a hold on the cycle until that damage is repaired. The tumor suppressor protein p53 (Chapter 23) is involved in this process. A later checkpoint, involving M-Cdk, checks both for DNA damage and completion of replication, both of which are obviously essential before cells commit themselves to mitosis. Later, during mitosis, control is exercised by the **anaphase-promoting complex (APC/C)**, which checks to ensure that all chromosomes are attached to spindles before the cell proceeds to anaphase. These processes are schematized in Figure 24.33.

The Cdks are protein serine/threonine kinases. Each one is activated by a specific cyclin, and then phosphorylates one or more target proteins. A major target of the G1-Cdk is the **Rb protein**, a molecule that controls the expression of proteins needed to pass the cell into S phase. Mutations in the gene for Rb give rise to **retinoblastoma**, a tumor affecting the eye. Once a checkpoint has been activated,

FIGURE 24.32

A model for kinetochore structure and organization. The model is based upon electron microscopic and proteomic analysis of kinetochores in yeast (*S. cerevisiae*). Cse4 and CENP-A are alternative names for the modified nucleosomes in the centromere.

the cyclin–Cdk complex dissociates, and the cyclin is marked for degradation in the proteasome, a large protein complex, described in Chapter 20, which is involved in intracellular protein degradation. One of the functions of the APC complex is targeting proteins for degradation. Another Cdk target is p53, which becomes activated as a transcription factor by phosphorylation of key serine residues and blocks advance through the cycle until the DNA is repaired. If the damage is too great, then p53 promotes events leading to **apoptosis**, or programmed cell death (Chapter 28). Mutations in the gene for p53 have been implicated in Li-Fraumeni syndrome, which carries a predisposition to early breast cancer. And, as noted in Chapter 23, p53 gene mutations are found in a large proportion of all cancers.

SUMMARY

Most of the DNA in a prokaryotic genome encodes proteins or RNA or serves a regulatory function. However, 50% or more of the DNA in a eukaryotic genome consists of repeated sequences that do not have protein or RNA gene products. In eukaryotes there is no apparent relationship between the size of a genome and the complexity of the organism harboring that genome. Sequence determination of complex genomes, notably those of humans, depended crucially upon the development of new technologies, including use of type II restriction endonucleases, fluorescent in situ hybridization, Southern transfer, polymerase chain reaction, and use of yeast artificial chromosomes as vectors for cloning huge amounts of DNA. Viral genomes, either RNA or DNA, encode as few as 3 proteins or as many as 175. Bacterial genomes usually consist of one circular double-stranded DNA molecule encoding about 1500–2000 proteins, while the human genome encodes between 20,000 and 25,000 proteins, considerably fewer than predicted from the amount of DNA in the genome. Most eukaryotic cells are diploid, with two of each chromosome. An exception is the sex chromosomes, where a male typically has one X and one Y chromosome. Chromosomal DNA is compacted by folding about histone octamers, to form

nucleosome core particles. These particles plus linker DNA make up chromatin, which refolds to form 30-nm fibers. Further compaction processes fold these fibers into the highly condensed form seen in chromatin. Eukaryotic cells divide *via* a well-defined cell cycle, involving G1, in which the chromosome number is 2; S, in which DNA replicates and histones are synthesized and chromatin assembled; G2, in which the chromosome number is 4; and M, a multistage process in which the cell undergoes mitosis. Structural analysis of centromeres and kinetochores is yielding insight into mechanisms of chromosome segregation during mitosis. The cell cycle is controlled by a complex series of protein phosphorylation events, in which protein kinase activities are constant throughout the cycle, but levels of kinase-activating proteins, the cyclins, rise and fall cyclically.

PROBLEMS

- The exponential nature of PCR allows spectacular increases in the abundance of a DNA sequence being amplified. Consider a 10-kbp DNA sequence in a genome of 10^{10} base pairs. What fraction of the genome is represented by this sequence; i.e., what is the fractional abundance of this sequence in this genome? Calculate the fractional abundance of this target sequence after 10, 15, and 20 cycles of PCR, starting with DNA representing the whole genome and assuming that no other sequences in the genome undergo amplification in the process.
- Of the restriction enzymes listed in Table 24.3, which enzymes generate flush, or blunt-ended, fragments? Of those that recognize offset sites and generate staggered cuts, which of these cuts cannot be converted to flush ends by the action of DNA polymerase? Why is this so?
- The following diagram shows one-half of a restriction site.

(a) Draw the other half.

- Use heavy arrows (\updownarrow) to identify type II cleavage sites that would yield blunt-ended duplex DNA products.
 - Use light arrows ($\uparrow\downarrow$) to identify type II cleavage sites yielding staggered cuts that could be converted directly to recombinant DNA molecules by DNA ligase, with no other enzymes involved.
 - If this were the recognition site for a type I restriction endonuclease, where would cutting of the duplex occur?
 - If DNA sequences were completely random, how large an interval (in kilobase pairs) would you expect between identical copies of this sequence in DNA?
- pBR322 DNA (4.32 kb) was cleaved with *Hind*III nuclease and ligated to a *Hind*III digest of human mitochondrial DNA. One recombinant plasmid DNA was analyzed by gel electrophoresis of restriction cleavage fragments, with the following results: lane A = *Eco*RI-treated recombinant, lane B = *Hind*III-treated vector, and lane C = *Hind*III-treated recombinant.

- Why was the recombinant plasmid treated with *Eco*RI for determination of its size?
 - How might you explain the discrepancy between the size of the recombinant molecule and the sum of the sizes of the *Hind*III cleavage fragments?
 - Draw a diagram of the recombinant showing the locations of the *Hind*III cleavage sites.
- A small DNA molecule was cleaved with several different restriction nucleases, and the size of each fragment was determined by gel electrophoresis. The following data were obtained.

Enzyme	Fragment Size (kb)
<i>Eco</i> RI	1.3, 1.3
<i>Hpa</i> II	2.6
<i>Hind</i> III	2.6
<i>Eco</i> RI + <i>Hpa</i> II	1.3, 0.8, 0.5
<i>Eco</i> RI + <i>Hind</i> III	0.6, 0.7, 1.3

- Is the original molecule linear or circular?
 - Draw a map of restriction sites, showing distances between sites, that is consistent with the data presented.
 - How many additional maps are compatible with the data?
 - What would have to be done to locate the cleavage sites unambiguously with respect to each other?
- pApGpApTpCpT
 - pGpGpApTpCpC
 - pGpTpCpGpApC
 - pCpTpGpCpApG
 - pGpTpTpApApC
 - pGpApGpTpCpNpNpNpN

- Using the same shorthand as in Problem 3, show the complete structure of any one of the foregoing restriction cleavage sites (both strands and cutting sites).
 - Which two of the cleavages shown will yield fragments that *cannot* be rejoined by *E. coli* DNA ligase? Why not? (Note: In vitro DNA ligase shows strong preference for sealing a staggered, rather than blunt-ended, cut.)
 - Cleavage products from two of these reactions can readily be joined to one another by DNA ligase, even though the two enzymes recognize different sites. Which two?
 - If you wished to linearize a newly isolated plasmid DNA, which one of the sites shown would be *least* likely to be represented only once in that DNA molecule? Assume that the DNA has equal proportions of the four nucleotides.
- The average human chromosome contains about 1×10^8 bp of DNA.

- (a) If each base pair has a mass of about 660 daltons, and there are about 2 grams of protein (histones plus nonhistones) per gram of DNA, how much does such a chromosome weigh, in grams?
- (b) If the DNA were extended, how long would it be?
- (c) An actual chromosome is about 5 mm in length. What is the approximate compaction ratio?
- (d) You have about 10^{12} cells in your body. If you have 46 chromosomes in each cell, what is the approximate extended length of *all* of your DNA? For comparison, the distance from the earth to the sun is about 1.5×10^8 km.
8. Formation of nucleosomes and wrapping them into a 30-nm fiber provide part of the compaction of DNA in chromatin. If the fiber contains about six nucleosomes per 10 nm of length, what is the approximate compaction ratio achieved? Comment on the comparison of this answer with that of Problem 7.
- *9. It is possible to “reconstitute” nucleosomes by mixing DNA and histone octamers in 2M NaCl and then dialyzing to low salt. When such experiments were carried out using a specific 208-bp fragment of sea urchin DNA, the following results were obtained: Digestion of the product with micrococcal nuclease gave quantitative production of 146-bp DNA. Upon cleavage of this DNA with a restriction nuclease having a single site in the fragment, several sharp bands were obtained, with sizes as follows: 29 bp, 39 bp, 107 bp, 117 bp. How would you interpret these data in terms of nucleosome positioning on this DNA?
10. A sample of chromatin was partially digested by the enzyme staphylococcal nuclease. The DNA fragments from this digestion were purified and resolved on a polyacrylamide gel. A set of DNA restriction fragments was used as markers. Distances of migration are given below. From these data, estimate the nucleosome repeat distance in the chromatin.
- | Marker DNA Fragment | | Chromatin DNA Fragment |
|---------------------|----------|------------------------|
| Size (bp) | d (cm) | d (cm) |
| 94 | 40 | 30.5 |
| 145 | 34.2 | 19.2 |
| 263 | 25.2 | 14.4 |
| 498 | 16.7 | 11.5 |
| 794 | 11.5 | — |
- *11. Pancreatic deoxyribonuclease I (DNase I) is a nuclease that makes single-strand nicks on double-stranded DNA. It has been observed that treatment of nucleosomal core particles with DNase I yields a peculiar result. When DNA from such a digestion is electrophoresed under denaturing conditions, the single-stranded fragments are observed to occur in a regular periodicity of about 10 bases. Suggest an explanation of this result in terms of the structure of the nucleosome.
12. Some viruses, like SV40, are closed circular DNAs carrying nucleosomes. If the SV40 virus is treated with topoisomerase, and the histone is then removed, it is found to still be supercoiled. However, if histones are removed *before* topoisomerase treatment, the DNA is relaxed. Explain.

13. Histone genes are unusual among eukaryotic genes in that they do not have introns, and histone mRNAs do not have poly(A) tails (see Chapter 27). Furthermore, in almost all eukaryotes, histone genes are arranged in multiple tandem domains, each domain carrying one copy of each of the five histone genes. Suggest an explanation for these features in terms of the special requirements for histone synthesis.
14. Consider the λ bacteriophage DNA molecule, as shown in Figure 24.7. Total digestion with the two restriction endonucleases used does not allow unambiguous placement of restriction sites, as shown in the map. Describe restriction patterns—either from partial digestion or digestion with both *Bam*H1 and *Eco*R1—that would help to establish the specific map of restriction sites shown in Figure 24.7(b).
15. RFLPs can include sequence changes created by single-base change, single-base insertion, single-base deletion, or tetranucleotide repeat, as shown in Figure 24.15. For each polymorphism, show a specific sequence change that would alter the restriction fragmentation pattern at that site and describe how the pattern would change—i.e., addition or loss of a site for a specific restriction endonuclease. Refer to Table 24.3 for the cleavage sites of several common restriction nucleases.

DNA renaturation curves occasionally show three distinct phases of renaturation. In this plot, DNA renaturation is plotted against “ C_0t ” (initial concentration times time of renaturation, essentially a measure of relative renaturation time).

- (a) Identify each part of this plot that corresponds to reannealing of (1) unique sequences, (2) moderately repetitive sequences, and (3) highly repetitive sequences.
- (b) Suppose that you cloned a single-copy gene, such as the gene for dihydrofolate reductase (DHFR), and subjected this to renaturation analysis. Sketch the curve you might expect.
- (c) Suppose that you cloned the DHFR cDNA instead of genomic DNA. Would you expect this to reanneal (1) more slowly, (2) more rapidly, or (3) at the same rate as genomic DNA? Briefly explain your answer.
17. Refer to Figure 24.28, which shows the time spent in each of the four phases of the cell cycle for a typical eukaryotic cell. If a culture of these cells was inspected microscopically, what proportion of the cells would you expect to show condensed chromosomes?

This cycle is repeated 30 or more times in an automated temperature-regulating device (a *thermal cycler*), with each cycle increasing the abundance of duplex DNA species bounded by the oligonucleotide primers. Eight such molecules have been formed by the end of cycle III, and the number doubles with each successive cycle. About 1 billion copies are present after 32 cycles (2^{n-1} to be exact, where n is the number of cycles).

Innumerable applications of this technique have been developed, including forensic analysis (as mentioned in the chapter), in which DNA can be amplified from exceedingly small samples of biological material (for instance, blood, semen, or hair) for identification of criminal suspects or of fathers in paternity cases. PCR-based forensic analysis focuses upon parts of the genome with variable numbers of tetranucleotide repeats (see Figure 24.15). Some parts of the human genome have a particular tetranucleotide sequence repeated variable numbers of times up to 30. Analyses of these regions by PCR can determine the number of repeats in one individual's genome. By analyzing several of these regions, an individual can be identified with great confidence, beginning with a DNA sample as small as one nanogram.

The field of "molecular anthropology" has developed from PCR and sequence analysis of human mitochondrial DNA, with the results used to formulate models of human evolution. Mitochondrial DNA is particularly useful because it undergoes mutation more rapidly than nuclear DNA, meaning that the amount of sequence variation is a more sensitive indicator of evolutionary time than is seen in nuclear DNA. A comparable field of "molecular paleontology" exists, with minute amounts of DNA being extracted from long-preserved biological samples, such as organisms frozen in ice or insects trapped in amber. The recent sequence analysis of DNA from specimens of Neandertals has generated new insights into human evolution. Of historical interest was the 1998 report describing PCR analysis of descendants of Thomas Jefferson, which showed that America's third president or a close relative fathered at least one child with Sally Hemings, one of his slaves. The DNA came from living people (descendants), but the results led to important historical conclusions. PCR is used in environmental microbiology, to detect microbial populations by searching for sequences unique to the organism being sought. In the same way, PCR can be used for diagnosis of microbial or viral infections. PCR is used also for prenatal diagnosis of genetic diseases, using primers specific for the gene sequence alteration responsible for a disorder. Similarly, oncogene mutations leading to cancer can be detected by PCR, and this has allowed extensive analysis of the sequence of genetic alterations leading from a precancerous lesion to a metastatic tumor.

PCR is not without its technical problems, however. For example, because some thermostable DNA polymerases, such as the commonly used *Taq* polymerase, lack a proofreading 3' exonuclease, the DNA synthesis in PCR can be relatively inaccurate. This is not usually a problem if one wants to sequence the PCR product because errors are uniformly distributed over the length of DNA being amplified, with the abundance at each site being too low to affect sequencing operations. Also, proofreading polymerases from thermophilic organisms are now available. However, precautions must be taken (such as limiting the number of cycles) if one wants to clone PCR products, with the expectation that a natural sequence is being cloned. Another problem is the great sensitivity of the technique, which can lead to amplification of minute amounts of DNA contaminants in the sample. Again, a number of controls and modifications of the technique can be used to minimize this problem.

A number of variants of the original PCR technique have been devised. In quantitative, or "real-time," PCR, one of the nucleotides has a fluorescent label on it, which permits following the reaction in real time and relating the data to abundance of the target DNA in the original sample. Another variation of the technique, called RT-PCR, can be used to monitor gene expression, by analysis of the levels of a particular mRNA species. The sample is treated first with reverse transcriptase (RT), an RNA-dependent DNA polymerase (Chapter 25), which converts an mRNA molecule to a DNA of complementary sequence, which can then be amplified by PCR.

CHAPTER 25

DNA Replication

Our focus for the remainder of this book is upon processes in genome replication, genome maintenance, and gene expression. In this chapter we discuss DNA replication. Next, Chapter 26 focuses upon DNA repair and recombination and on various processes in genome rearrangement. In Chapter 27 we discuss the readout of information encoded in DNA—transcription and RNA processing. Chapter 28 focuses upon protein synthesis—how information encoded in the four-letter nucleic acid language is translated into the 20-letter amino acid language and how the polypeptides resulting from translation undergo processing and trafficking to their destinations as mature proteins, in the correct intracellular or extracellular location. Finally, Chapter 29 revisits these process-oriented chapters to consider how gene expression is regulated. Each process of gene expression involves a defined initiation step, followed by movement of an enzyme complex along a nucleic acid template as a product is elongated, followed in turn by a defined termination step. We will see that events controlling each process—replication, elongation, and translation—occur primarily at the level of initiation.

Biosynthesis of nucleic acids and proteins is carried out through the processes of replication, transcription, and translation. Most regulation occurs at the level of initiation.

Early Insights into DNA Replication

Three central features of DNA replication were predicted in 1953 from Watson and Crick's model. First was their explicit prediction that DNA replication is semiconservative—that each of the two identical daughter DNA molecules contains one parental strand and one newly synthesized strand. This prediction was confirmed in 1957 by the elegant experiment of Meselson and Stahl, as we discussed in Chapter 4 (Figure 4.14, page 104). Not explicitly required by the model, but implied, was the idea that parental strand unwinding and synthesis of new DNA occur simultaneously, in the same microenvironment. In other words, replication occurs at a **fork**, in which parental strands are unwinding and both daughter strands are undergoing elongation, as suggested by the diagram. Also suggested by

the Watson–Crick model was the premise that replication begins at one or more fixed sites—**replication origins**—on a chromosome.

The first images of replicating DNA were consistent with the idea that replication occurs within a fork structure. In Chapter 24 we showed John Cairns' radioautogram of a replicating *E. coli* DNA molecule (Figure 24.17, page 1020). That circular molecule contains two Y-shaped structures, either or both of which could be a replication fork; this is called a theta structure, from the Greek letter θ . The figure cannot indicate whether replication is unidirectional, with one Y junction representing the site of replication initiation, or bidirectional, with two forks, which are moving from a fixed origin halfway between the two Ys. These alternatives are shown at the top of Figure 25.1. An elegant variation of Cairns' experiment established for *E. coli* that replication is bidirectional from one fixed origin. In this experiment DNA was radiolabeled by growth of cells in the presence of [^3H]thymidine. Just as cells were terminating one round of replication and initiating the next, the specific radioactivity of the thymidine was increased several-fold, so that areas of active DNA synthesis could be distinguished in a radioautogram by increased blackening of the film. If replication were unidirectional, termination and reinitiation would have to occur at the same site. Examination of individual DNA molecules, such as that shown in Figure 25.1, showed clearly that termination of one round of replication and initiation of the next occurred about 180° apart from each other, which could occur only if replication is bidirectional.

Another elegant radioautographic experiment gave further support to the idea of bidirectional replication from a fixed origin. Investigators wondered how *E. coli* cultures could double their cell numbers in 20 minutes, while the shortest time measured for replication of the entire circular chromosome was 40 minutes. The experiment, depicted in Figure 25.2, showed that *E. coli* responds to conditions favoring rapid growth by initiating a new round of chromosome replication while a previously initiated round is still in progress. Thus, when a cell divides, each daughter cell receives a chromosome that is far along in its next round of replication. Hence, the cell adapts to rapid growth by timing its replication events earlier in the cell cycle. This provides strong evidence that replication is controlled largely at the level of initiation.

Partially replicated DNA molecules can also be visualized in the electron microscope. Bacteriophage λ has a linear genome, 48,502 base pairs long, as isolated from phage particles. However, at each 5' end there is a 12-nucleotide single-stranded extension. During infection of *E. coli* these “cohesive ends,” which are complementary in sequence, pair with each other to form a circular duplex, and the ends become covalently joined. Partially replicated molecules can be seen electron microscopically as theta structures, as depicted in Figure 25.3. Again, this picture by itself doesn't establish that replication is occurring in each fork, but a technique called denaturation mapping established that this molecule indeed was undergoing bidirectional replication at the time it was isolated.

What about eukaryotic cells, which have huge linear molecules in their chromosomes? Typically, a mammalian cell in culture will replicate all of its DNA in an eight-hour S phase (as compared to 40 minutes for doubling of the *E. coli* chromosome). Radioautographic and other evidence shows that individual

FIGURE 25.1

Demonstration of bidirectional replication by radioautography. This *E. coli* chromosome was labeled by long-term growth in [^3H]thymidine, and the specific activity was increased four-fold just as a synchronized culture completed one round of replication and commenced another. The diagrams show the labeling patterns that would be expected for unidirectional replication, where the terminus (t) and origin (o) are adjacent, and for bidirectional replication, where they are on opposite sides of the chromosome.

In bacteria DNA replication initiates from a fixed origin and proceeds in both directions from that origin.

DNA chains in eukaryotic cells grow an order of magnitude more slowly than do bacterial chromosomes—about 100 nucleotides per second. Radioautographic studies show that replication initiates bidirectionally on linear eukaryotic chromosomes, but from numerous fixed origins on each chromosome. Forks advance in both directions until they meet forks proceeding in the opposite direction from adjacent origins, as schematized in Figure 25.4. A typical mammalian cell has between 10^3 and 10^4 origins distributed among its chromosomes. Remarkably, each origin is programmed to initiate replication at a fixed time within S phase; in other words, “origin firing” is programmed.

Because eukaryotic chromosomal DNA is linear, we must concern ourselves with events at the ends of these molecules; we deal with that later in this chapter. The main point, however, is that even before much had been learned about the enzymology of DNA replication, several important features of the process were evident—bidirectionality, fixed origins, simultaneous strand unwinding and chain elongation within a fork, and control at the level of chain initiation.

**FIGURE 25.3**

A partially replicated bacteriophage λ DNA molecule. (a) The original linear DNA circularizes by base pairing between the cohesive ends. After covalent closure replication begins. Partial replication yields a theta structure, resulting from bidirectional replication from an origin equidistant between the two forks. (b) An electron micrograph of partially replicated phage DNA. Examination of intermediates like these after partial denaturation showed that replication is bidirectional from a fixed origin.

DNA Polymerases: Enzymes Catalyzing Polynucleotide Chain Elongation

The biochemical elucidation of DNA replication began in the mid-1950s, with Arthur Kornberg's discovery of DNA polymerase. Kornberg realized, from his experience in bioenergetics, that the substrates for DNA replication should be activated derivatives of the DNA nucleotide residues. Thus, the endergonic synthesis of phosphodiester bonds between nucleotide residues could be coupled to the exergonic breakdown of activated substrates, just as occurs in synthesis of other macromolecules, such as glycogen. Kornberg correctly predicted that these activated nucleotides would be the 2'-deoxyribonucleoside 5'-triphosphates. When he incubated radioactively labeled dNTPs with an extract of soluble proteins of *E. coli*, radioactivity was incorporated into high-molecular-weight material, which could be quantified by acid precipitation and radioactive counting; the radiolabeled product was shown to be DNA. The enzyme required added DNA, plus Mg^{2+} . As we have mentioned earlier (Chapter 4, page 111), two DNA molecules are required for the reaction—the template and the primer, the latter becoming covalently extended from its 3' hydroxyl group. Also, the polarity of the product DNA strand (that is, the extended primer) is opposite to that of the template strand, as expected from the antiparallel orientation of DNA strands in the Watson–Crick model.

As shown in Figure 25.5, the DNA polymerase reaction involves nucleophilic attack by the 3' hydroxyl group of the primer terminus on the α -phosphate of the deoxyribonucleotide substrate, which leads to covalent bond formation. The 3' hydroxyl is a weak nucleophile, and the pyrophosphate provides a good leaving group. The reaction is readily reversible. In cells and in crude preparations, therefore, the reaction is drawn to the right by pyrophosphatase action on the other product of the reaction ($PP_i + H_2O \rightarrow 2 P_i$). Thus, two energy-rich phosphates are expended per nucleotide incorporated.

Structure and Activities of DNA Polymerase I

The DNA polymerase discovered by Kornberg in *E. coli* was later shown to be one of three different DNA polymerases in most bacterial cells (revised upward to five in 1999). The Kornberg enzyme is now called DNA polymerase I. We shall use this term henceforth and describe the other polymerases later in this chapter.

DNA Substrates for the Polymerase Reaction

As noted above, DNA polymerase I requires both template DNA and a primer, either DNA or RNA. In vitro, these roles can be played either by two distinct nucleic acids or by one molecule. As shown in Figure 25.6c, a single-strand DNA with self-complementary sequences can fold itself into a **hairpin** or **stem-loop** structure whose 3' end can be extended by polymerase, using the 5' end as the template. The figure shows other polymerase activities that can be demonstrated in vitro. The enzyme can copy around a circular single-strand template, such as the DNA extracted from small bacteriophages, like ϕ X174 or M13, so long as a primer is present, but it cannot join the ends (Figure 25.6a). When the template is linear, polymerase copies only to the 5' end of the template and then it dissociates (Figure 25.6b and c). In similar fashion the enzyme can fill in a gap (Figure 25.6d), dissociating when the gap is reduced to a nick. Under some conditions the enzyme can also extend from a 3' hydroxyl group at a nick. Typically, when this occurs, the 5' end of the preexisting DNA is displaced in advance of the nick. This is called **strand displacement** synthesis (Figure 25.6e). Under conditions where the displaced strand is degraded, there is no net DNA accumulation, and the reaction is called **nick translation**.

FIGURE 25.4

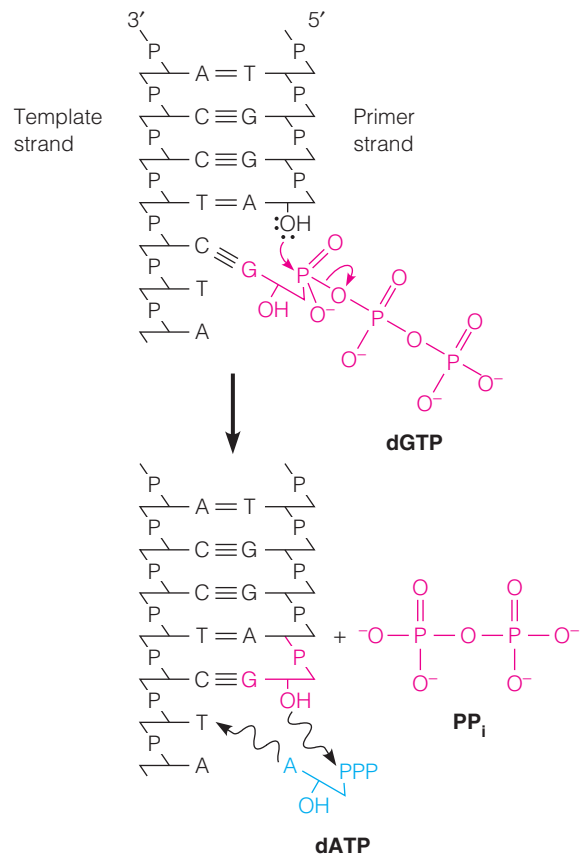

Bidirectional replication from several fixed origins (O) on a linear eukaryotic chromosome.

DNA polymerase catalyzes nucleophilic attack by the 3' hydroxyl at the primer terminus upon the α -phosphate of an incoming dNTP, base-paired with its template.

FIGURE 25.5

The DNA polymerase reaction. Each incoming dNTP is positioned by base pairing with the appropriate template nucleotide, and a phosphodiester bond is created by nucleophilic attack of the primer-strand 3' hydroxyl group on the α -phosphate of the dNTP.

The DNA polymerase I molecule contains three active sites: a polymerase and two exonucleases.

(strand displacement synthesis)**FIGURE 25.6**

DNA substrates that can be acted upon by purified DNA polymerase. Each blue arrowhead marks a 3' hydroxyl terminus at which chain extension is occurring.

Multiple Activities in a Single Polypeptide Chain

When DNA polymerase I was purified from *E. coli*, it was found to consist of a single polypeptide chain ($M_r = 103,000$). In addition to its polymerase activity, the purified enzyme has two nuclease activities: The 3' exonuclease degrades single-strand DNA from the 3' end, and the 5' exonuclease degrades base-paired DNA from the 5' terminus. The enzyme also cleaves RNA from a duplex containing one strand each of DNA and RNA. The 3' exonuclease serves a “proofreading” function, to improve the accuracy with which a DNA template is copied. The activity will remove an improperly base-paired nucleotide from the growing 3' end of a polydeoxynucleotide chain, giving the polymerase activity a second chance to insert the correct nucleotide specified by the template. We say more about the 3' exonuclease later, when we discuss the fidelity of DNA replication. The 5' exonuclease activity plays roles both in replication and in DNA repair as discussed later in this chapter and the next.

Structure of DNA Polymerase I

The three catalytic activities of DNA polymerase I have been localized to regions of the long polypeptide chain, partially through limited proteolysis of the enzyme by subtilisin or trypsin. As shown by Hans Klenow, this treatment splits the 103-kilodalton polypeptide into a small N-terminal fragment ($M_r = 35,000$) and a large C-terminal fragment ($M_r = 68,000$). The large fragment (also called the **Klenow fragment**) contains the polymerase and 3' exonuclease domains; the small fragment contains the 5' exonuclease domain. How the three catalytic sites are arranged in space is important to an understanding of how each of the two nuclease activities functions in concert with the polymerase.

Crystallographic study of the large fragment revealed a striking feature of the structure—a deep crevice, just large enough to accommodate B-form DNA, with a flexible subdomain that might allow bound DNA to be completely surrounded

(Figure 25.7). The protein molecule has been likened to a hand, with palm, thumb, and fingers. CocrySTALLIZATION of the Klenow fragment with a short duplex DNA shows that this is indeed the DNA-binding site and that bound DNA is almost completely surrounded by protein, which wraps around the DNA like a hand holding a cylinder. An interesting feature of the structure, revealed by study of mutant forms of the enzyme, is that the 3' exonuclease active site is quite far—about 3 nm—from the polymerase active site. This suggests that about eight base pairs of DNA must unwind to move the 3' terminal nucleotide from the polymerase to the 3' exonuclease active site (see page 1071). Because the 5' exonuclease activity is absent in the Klenow fragment, this unnatural enzyme is a useful laboratory reagent for synthesis of DNA *in vitro* when the researcher wishes specifically to avoid DNA degradation.

Functions of DNA Polymerase I

For his discovery of DNA polymerase, Arthur Kornberg was awarded the Nobel Prize in 1959. Although this discovery was monumental, several properties of the enzyme as isolated from *E. coli* were different from those expected for an enzyme catalyzing the major nucleotide incorporation reactions in biological DNA replication. First, the enzyme *in vitro* is too slow, with a V_{\max} of about 20 nucleotides per second; in contrast, replicative chain growth occurs *in vivo* at around 800 nucleotides per second or more. Second, with about 400 molecules of enzyme per cell, the enzyme is present in great excess over the small number (fewer than 10) of replication forks per cell, suggesting that its function(s) is carried out elsewhere. Third, as noted earlier, DNA polymerase can extend chains only in a 5' → 3' direction. A complete understanding of replication requires knowing how both of the antiparallel chains of a DNA duplex are replicated within the same fork. Fourth, DNA polymerase cannot initiate the synthesis of new DNA chains but can only extend from preexisting 3' hydroxyl termini. Finally, genetic evidence (page 1044) suggested the existence of other polymerases, as well as additional enzymes and proteins essential to DNA replication—proteins involved, for example, in DNA strand unwinding, chain initiation, and keeping polymerase bound to its template. Much of the genetics was done with *Escherichia coli* and bacteriophage T4, which infects *E. coli*. At this point we digress to say a bit about the genetics of these important biological systems.

A Brief Review of Microbial Genetics

To a greater extent than in intermediary metabolism, our present understanding of information metabolism has come from the field of genetics. Hence, it is useful to review several key genetic terms before more detailed discussions of mechanisms and control of replication. As discussed elsewhere in this book, the totality of genetic information in an organism, the **genome**, can be thought of most directly as the base sequences of all of the DNA molecules in a cell. These sequences consist of individual genes, each on a chromosome or on a small piece of extrachromosomal DNA. A **genetic map** identifies the relative positions of genes on chromosomes. As discussed in Chapter 24, one can generate a **linkage map** by measuring recombination frequencies or a **physical map**, which identifies the physical locations of genes on a chromosome.

Any characteristic of an organism that can be detected in terms of appearance, structure, or some measurable property is called the **phenotype**. The genetic composition of an individual, which specifies phenotypic properties, is the **genotype**. Individuals with different genotypes may have the same phenotype. In Chapter 17, for example, we learned that humans with different mutations affecting the LDL receptor can have a common phenotype—the elevated serum cholesterol levels that are associated with familial hypercholesterolemia.

An **allele** is a particular form of a gene. For example, phenylketonurics have two defective alleles of the gene for phenylalanine hydroxylase that encode inactive

FIGURE 25.7

The Klenow fragment of *E. coli* DNA polymerase I. α -Carbon backbone representation of the Klenow fragment complexed with DNA, in an editing configuration. That is, the 3' end of the growing strand (light blue) is bound at the 3' exonuclease active site of the enzyme (yellow). The locations of the polymerase and 3' exonuclease active sites have been identified by site-directed mutagenesis. The template strand is shown in green, and bound dCTP in red. PDB ID 1KFD.

forms of the enzyme—one on each chromosome. A **marker** is any allele whose frequency can be determined quantitatively. **Copy number** refers to the number of copies per cell of a gene or other DNA sequence. Most eukaryotic cells are **diploid**, meaning that the copy number of most chromosomal genes is two, while most prokaryotic cells have a **haploid** genotype, and thus a single allele for most genes. Extrachromosomal genes can have much higher copy numbers, whether they are carried on organelle DNA in eukaryotic cells or on an extrachromosomal DNA element such as a bacterial **plasmid**. A plasmid is usually a small circular DNA molecule whose copy number may be controlled independently of the regulatory mechanisms affecting chromosomal DNA replication.

A diploid individual in a natural environment usually has at least one functional copy, or allele, of each gene and normally displays a **wild-type** (normal) phenotype (unless the gene is recessive, in which case a homozygous individual has a mutant phenotype). A wild-type gene in an organism can undergo a mutation, thereby generating a mutant genotype, which may be detected as a mutant phenotype. For example, albinism represents a readily observable phenotype, resulting from mutations that inactivate tyrosinase (see Chapter 21). A mutant site within a gene can infrequently reverse the process that caused the mutation and restore the wild-type genotype. This type of mutation is called a **reversion**. More frequently, a wild-type phenotype can be restored by a mutation at a different site; this occurrence is called **second-site reversion**, or **suppression**. Suppression can occur either by mutation within the gene undergoing the original mutation (intragenic suppression) or within a different gene (intergenic suppression). Note that many mutations are **silent**; if a mutant protein retains some biological activity, there may not be an observable phenotype.

Because much of our discussion focuses upon replication in *E. coli* and its phages, you should understand some conventions in the naming of prokaryotic genes and gene products. Let us review these conventions in the context of the *E. coli* genetic map. Mapping genes in *E. coli* became possible after the discovery by Joshua Lederberg of sexual reproduction in bacteria. This process, termed **conjugation**, involves the transfer of DNA from a donor cell (the “male”) to a recipient cell (the “female”), as schematized in Figure 25.8. About 100 minutes is required for complete chromosome transfer. Mapping is carried out by “interrupted mating” experiments. At intervals a conjugating culture is disrupted mechanically, to separate the donor and recipient cells. The researcher then analyzes the recipient cells, correlating the transfer of marker genes from the donor with the time at which mating was interrupted. Thus, map positions of genes were originally reported as “minutes,” which identified the time at which a marker of interest was transferred by conjugation. Finer-scale mapping could be done by transduction, a process described in Chapter 26. With the complete genome sequence of *E. coli*, reported in 1997, we now know the physical locations of all *E. coli* genes.

Figure 25.9 shows part of the *E. coli* genetic map, identifying genes known to participate, either directly or indirectly, in DNA replication. The large number of these genes underscores the complexities of DNA replication, and we shall refer frequently to the genes shown on this map. Our purpose here is to describe the conventions. Each gene has an italicized lower-case three-letter designation that refers either to the gene product or to the phenotype of mutants defective in that gene, followed by a capital letter denoting the order of discovery of the gene or gene product. For example, *E. coli* was shown early to contain three DNA polymerases, named I, II, and III. The structural genes encoding these enzymes are *polA*, *polB*, and *polC*, respectively. Other genes were named from the defective phenotype. For example, all genes designated *dna* were originally identified from temperature-sensitive (*ts*) mutations in which DNA replication occurred normally when cells were grown at 30 °C but was blocked at 42 °C. Some of the gene products have been identified. For example, the *dnaG* gene product was found to be primase (page 1048). By convention, gene *products*, which are usually proteins, are given the corresponding nonitalicized and capitalized designations. For instance, DnaG is identical to primase; both terms refer to the product of the *dnaG* gene.

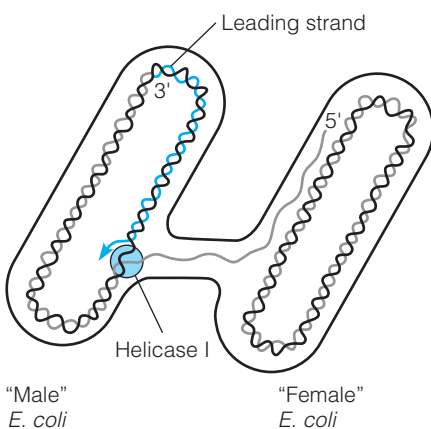

FIGURE 25.8

Bacterial conjugation. After a nick is made in the donor (male) chromosome, a helicase (page 1048) unwinds the two strands. The nicked strand (gray) is elongated (blue) at the 3' end, displacing the 5' end and transferring it into the recipient (female) cell. Later, the transferred DNA strand can undergo recombination with the recipient chromosome, thereby transferring genetic markers to the female.

FIGURE 25.9

Partial genetic map of *E. coli*. Genes whose products are involved in DNA replication or repair are shown. Gene product names are given in blue. The *dna* genes play essential roles in DNA replication. The *mut* genes specify proteins that, when mutated, can cause elevated rates of spontaneous mutation. *ori* and *ter* are sites of initiation and termination of genome replication, respectively.

Much of what we know about the functions of other proteins in DNA replication has come from investigations with bacteriophage T4 (Figure 25.10). This virus contains a duplex DNA genome, about 169,000 base pairs in length. Although large for a virus, this genome is less than 5% of the size of the *E. coli* genome, making it simpler to work with. Phage T4 encodes nearly all of its own replicative proteins and enzymes. T4 mutants are readily isolated and mapped. In fact, T4 was the first biological system in which replication-defective mutants were described. This occurred in 1965, when gene 43 on the T4 map (Figure 25.11) was identified as the structural gene for a virus-coded DNA polymerase. Figure 25.11 shows locations on the T4 genome of 15 genes whose products play essential roles in DNA replication. Three of these gene products are enzymes that carry out synthesis of the modified DNA base 5-hydroxymethylcytosine (Chapter 22). However, the remaining proteins participate in replication of the T4 genome, by mechanisms similar to those in cellular DNA replication.

Multiple DNA Polymerases

In 1969 John Cairns isolated an *E. coli* mutant that was deficient in DNA polymerase I activity. With this very abundant enzyme absent from the cell, it became possible to detect two additional DNA polymerase activities in *E. coli* cells. These were named DNA polymerases II and III, and the original Kornberg polymerase was named DNA polymerase I. The properties of these three DNA polymerases are summarized in Table 25.1. Some time later two additional polymerases were described in *E. coli*, named IV and V. We say more about these enzymes in Chapter 26.

FIGURE 25.10

Bacteriophage T4. DNA is packed into the head of this virus particle. Infection begins with attachment of the particle to an *E. coli* cell, followed by contraction of the tail and injection of the DNA through the tail into the interior of the infected cell.

FIGURE 25.11

Partial map of the T4 genome. Genes whose products participate in DNA metabolism are shown on the outside of the circle. The inner numbers represent distances in kbp. The reference point (0) represents the divide between two genes not shown—*rIIA* and *rIIB*.

DNA polymerase III was assigned the major role in nucleotide incorporation during replication, on the basis of its high V_{max} . Note also that there are few molecules of the enzyme per cell, as expected if it functions only at replication forks. More definitive evidence of this role is the existence of temperature-sensitive mutant cells that contain a thermolabile form of DNA polymerase III and in which DNA replication *in vivo* is blocked at high temperature. Both of these phenotypes can be traced to a single mutation, powerful evidence that polymerase III plays an essential role in DNA replication. The gene encoding the catalytic subunit of polymerase III was named *polC*.

There are also *polB* mutants, lacking polymerase II. Although these mutants displayed no other obvious phenotype, recent evidence suggests that the enzyme participates in DNA repair (see Chapter 26). But what about polymerase I? In the original *polA* mutant described by Cairns, DNA replication occurred normally. However, the bacteria were abnormally sensitive to ultraviolet irradiation and to alkylating agents that react with DNA, suggesting a role for polymerase I in DNA repair. Further study of the Cairns mutant revealed a role in replication. Although lacking the *polymerase* activity of DNA polymerase I, the mutant

TABLE 25.1 The classical DNA polymerases of *E. coli*

Characteristic	Polymerase I	Polymerase II	Polymerase III

^cMMS (methylmethane sulfonate) is an agent that alkylates DNA.

bacteria did synthesize the small N-terminal fragment of the protein, which contains the 5' exonuclease activity. Still later it was found that mutants lacking this 5' exonuclease activity are also defective in DNA replication. Thus, it was established that two polymerases, I and III, play essential roles in DNA replication.

Structure and Mechanism of DNA Polymerases

Sequence and structural analysis of DNA polymerases has revealed that, although there is considerable diversity at the level of primary structure, all enzymes in this family show structural features in common. Like polymerase I, all of the polymerases described so far have a structure described for the Klenow fragment, with domains identified as “palm,” “thumb,” and “fingers,” as shown in Figure 25.12. Analyses of DNA–enzyme complexes, conserved amino acid residues, and targeted mutations have indicated that the polymerase active site lies in the palm domain, and the 3' exonuclease site lies at the base of the palm. High-resolution polymerase structures show two magnesium ions, bound to nucleotide phosphates and to conserved aspartate residues already known to be essential for catalysis. These features support a general polymerase mechanism proposed by Thomas Steitz, on the basis of the Klenow fragment structure (Figure 25.13). The mechanism is similar to that more recently proposed for adenylate cyclase, which we mentioned in Chapter 23. In the Steitz mechanism one metal ion polarizes the hydroxyl group at the 3' primer terminus, facilitating nucleophilic attack of that moiety upon the α -phosphate of the

FIGURE 25.12

Comparison of DNA polymerase structures with primer and template bound. The four structures shown are oriented with respect to each other by superposition of the first two base pairs at the primer terminus. Palm, thumb, and fingers are shown for each structure. *Taq* polymerase is a thermostable enzyme used in PCR (PDB ID 1TAU). dNTP substrate. Both metals stabilize a trigonal bipyramidal transition state, in which the α -phosphorus is linked to five oxygens, and the second metal facilitates leaving by the pyrophosphate. Extensive contacts occur between the enzyme and the DNA minor groove—contacts that could occur only with a properly base-paired duplex. Also, structures of polymerase–DNA complexes show that DNA near the primer terminus adopts a conformation more like that of A form than B form and that this conformational change facilitates the minor groove interactions. Moreover, the incoming dNTP was shown to fit snugly into a pocket that favors correct base-pairing with the template. Thus, these structures reveal both how the reaction is catalyzed and how the enzyme copies its template DNA with high accuracy.

We now know that most bacteria carry five DNA polymerases, and we see later in this chapter that human cells contain fifteen. Analysis of amino acid sequences and structural data from dozens of DNA polymerases revealed similarities that have led to their classification in seven families—A, B, C, D, X, Y, and reverse transcriptase (RT). Bacterial polymerase I is a family A enzyme, while polymerase III is in family C. RB69 gp43, shown in Figure 25.12, is in family B. Archaeal DNA polymerases are in family D, while family X and Y polymerases include enzymes involved in DNA repair, including pol β , shown also in Figure 25.12 (X), and bacterial pol IV and pol V, which we discuss in Chapter 26 (Y). Reverse transcriptase (page 1072) and telomerase (page 1068) are in the RT family.

Other Proteins at the Replication Fork

Although the discovery of DNA polymerase revealed the biochemical process by which DNA chains are elongated in replication, important questions remained. How are two antiparallel DNA chains extended in the same fork if polymerase can extend in only one direction? How is the synthesis of new chains initiated if polymerase is capable only of adding nucleotides to preexisting 3' termini? How are parental DNA chains unwound?

Discontinuous DNA Synthesis

The first two questions were answered primarily through the work of Reiji Okazaki, who proposed that DNA replication could be discontinuous. In principle one parental strand (the **leading strand**) could be extended continuously, with polymerase moving 5' to 3' (from the 5' terminus to the 3' terminus), in the same direction as fork movement. Synthesis on the **lagging strand** would be discontinuous; chain extension along the leading strand would expose single-strand template on the lagging strand. This template could be copied in short fragments (later named Okazaki fragments), with polymerase moving opposite to the direction of fork movement. Thus, lagging strand synthesis would occur in short pieces. These could then be joined to high-molecular-weight DNA by the enzyme **DNA ligase**.

But how might these short DNA fragments be initiated, if DNA polymerase can only extend preexisting chains? Evidence suggested that Okazaki fragments could be initiated not with DNA, but with *RNA* oligonucleotides, which could serve as primers, for extension by DNA polymerase. The enzyme synthesizing these RNA primers was called **primase** and shown to be a special form of RNA polymerase, designed to function in a replication fork. These events are illustrated in Figure 25.14.

To support this model, Okazaki carried out a “pulse-chase” experiment with isotopic precursors (see Tools of Biochemistry 12A), which showed that DNA is synthesized as low-molecular-weight fragments (Okazaki fragments). Radiolabel was subsequently chased into high-molecular-weight DNA, presumably through the action of DNA ligase, an enzyme that closes nicks (single-strand breaks) in double-stranded DNA. In phage T4 DNA ligase is encoded by gene 30 (see Figure 25.11). When *E. coli* was infected at 42° with a gene 30 temperature-sensitive mutant, Okazaki fragments accumulated and were not incorporated into high-molecular-weight DNA until the temperature of the culture was dropped. This provided strong support for the postulated function of DNA ligase in processing Okazaki fragments.

DNA ligase requires that the nick to be sealed must contain 3' hydroxyl and 5' phosphoryl termini, and the nucleotides being linked must be adjacent in a duplex structure and properly base paired. DNA ligase is activated by adenylation of a lysine residue in the active site (Figure 25.15). The enzyme in turn transfers the adenylyl moiety to the 5' terminal phosphate of the DNA substrate, thereby activating it for nucleophilic attack by the 3' hydroxyl group, with phosphodiester bond formation and displacement of AMP. The T4 phage enzyme uses ATP to adenylylate the enzyme, as do eukaryotic DNA ligases. However, the enzyme from *E. coli* and other bacteria uses NAD⁺. Instead of being a redox cofactor, the dinucleotide in this enzyme is cleaved, to yield adenylylated enzyme plus nicotinamide mononucleotide (NMN).

RNA Primers

If short RNAs indeed serve as primers for lagging-strand replication, it should be possible to demonstrate covalent attachment of RNA to DNA during replication. Reiji and Tuneko Okazaki made *E. coli* cells permeable to exogenous nucleotides by brief treatment with a buffer containing toluene. DNA synthesis occurred when these treated bacteria were incubated with a mixture of α -[³²P]dNTPs and unlabeled ribonucleoside triphosphates (Figure 25.16). DNA was then isolated and treated with mild alkali, which hydrolyzes RNA to nucleoside 2' and 3' monophosphates, but does not degrade DNA (see Chapter 4, page 95). If DNA synthesis starts from 3' RNA termini, then for each Okazaki fragment there should exist one RNA–DNA junction, or deoxyribonucleotide residue covalently linked via a radioactive phosphate group to a ribonucleotide residue. Treatment with mild alkali, which hydrolyzes RNA but not DNA (Chapter 4) would then *transfer* that phosphate from the 5' position of the original deoxyribonucleotide substrate to the 3' position of the ribonucleotide at the junction. Sure enough, for

FIGURE 25.14

A model for DNA replication involving discontinuous synthesis on the lagging strand. A short RNA primer (red) is used to initiate synthesis of low-molecular-weight DNA fragments on the lagging strand (blue). RNA primers are replaced by deoxyribonucleotides (see text), and the fragments are sealed to high-molecular-weight DNA by DNA ligase. Each arrowhead on a nucleic acid strand identifies a 3' hydroxyl group that can undergo polymerase-catalyzed chain extension. The replication fork is moving to the right.

FIGURE 25.15

The reaction catalyzed by DNA ligase.

FIGURE 25.16

The transfer experiment that demonstrated the existence of RNA primers in DNA replication. Each Okazaki fragment generated one radiolabeled ribonucleotide from its RNA-DNA junction after alkaline hydrolysis.

each Okazaki fragment formed in this system, one radiolabeled phosphate was transferred to a ribonucleotide.

The enzyme that synthesizes RNA primers is called **primase**. In *E. coli* this enzyme is the product of the *dnaG* gene, and the comparable reaction in phage T4 is carried out by gp61, the product of gene 61. Priming involves pairing a ribonucleoside 5'-triphosphate opposite a deoxyribonucleotide residue in template DNA, followed by sequential ribonucleotide additions to the 3' hydroxyl termini, just as occurs with DNA polymerases. At some point, RNA synthesis stops, and DNA polymerase continues to extend from the 3' hydroxyl terminus of the RNA primer, but now with incorporation of deoxyribonucleotides. RNA primer structure has been described in some detail. For instance, in T4 and *E. coli* DNA replication the primer lengths are 5 and 11 nucleotides, respectively, and most primers have ATP as the 5' terminal nucleotide.

For Okazaki fragments to be ligated to high-molecular-weight DNA, the RNA primers must be excised and replaced with corresponding deoxyribonucleotides. In *E. coli* DNA polymerase I is involved in this process, through its nick translation activity. The removal of ribonucleotides from the 5' end of the primer, by the 5' exonuclease of polymerase I, is coordinated with their replacement by deoxyribonucleotides (see Figure 25.17). An alternative means for digesting RNA primers is **ribonuclease H**, an enzyme that specifically hydrolyzes RNA base-paired with DNA of complementary sequence.

Now we are in a position to consider all of the proteins in a replication fork, as well as the functions of each. Figure 25.18, an idealized fork, includes proteins we have discussed, including DNA polymerases, primase, and ligase. Note that the replicative polymerase is dimeric, with one polymerase molecule each assigned to the leading and lagging strands. The primase is complexed with a **helicase**, one of several enzymes that can use the energy of ATP hydrolysis to drive parental strand unwinding. The helicase-primase complex is called a **primosome**. Attached to each polymerase molecule is a circular **sliding clamp**, which keeps polymerase bound to DNA over thousands of catalytic cycles. As DNA unwinding exposes single-strand template DNA, that DNA is coated with **single-strand DNA-binding protein** (SSB), which holds DNA in an extended conformation so that it can base-pair efficiently with incoming nucleotides. Finally, because unwinding the parental duplex creates torsional stress, a **topoisomerase** moves ahead of the fork, acting to relieve that stress. Ultimately, a topoisomerase plays a crucial role in introducing negative supercoiling into replicated DNA. Not shown in the figure is

the **clamp-loading complex**, which both fastens and unfastens the sliding clamp to DNA. The complex of proteins supporting replication is called the **replisome**. However, it is unlike a static complex, such as pyruvate dehydrogenase because individual proteins within the replisome are in constant motion, dissociating from the complex and reassociating as parts of this dynamic machine.

The DNA Polymerase III Holoenzyme

The *E. coli polC* gene encodes a single polypeptide chain, with M_r of about 130,000. This protein has an intrinsic polymerase activity, but it is quite low. Within cells, the PolC protein functions as part of a multiprotein aggregate called the **DNA polymerase III holoenzyme**. As shown in Figure 25.19, the holoenzyme contains ten different polypeptide chains, each identified with a Greek letter. The α , ϵ , and θ subunits make up the “core polymerase,” with α being the *polC* gene product, the protein with polymerase activity, and ϵ having a 3' exonuclease activity comparable to the 3' exonuclease domain of the DNA polymerase I polypeptide

Primase, a special class of RNA polymerase, synthesizes short RNA molecules as primers for lagging strand DNA replication.

FIGURE 25.17

Nick translation in removal of RNA primers by coordinated action of the 5' exonuclease and polymerase activities of DNA polymerase I. The figure shows replacement of base-paired UMP in the RNA primer by dTMP in the growing DNA chain. The template DNA is the lagging strand.

FIGURE 25.18

Schematic view of a replication fork. Note that polymerases catalyzing leading- and lagging-strand replication are linked together. See text for details.

DNA polymerase III holoenzyme, a complex bacterial enzyme containing at least 10 subunits, plays the predominant role in replicative chain elongation.

chain. The function of θ is unknown, but it may act to improve the catalytic efficiency of α . The dimeric τ protein dimerizes the holoenzyme, holding leading and lagging strand polymerases together, ensuring that both DNA strands are elongated at the replication fork, even though the lagging strand polymerase moves in the direction opposite that of fork movement. χ mediates the switch from RNA primers to DNA.

Sliding Clamp

The β subunit was originally recognized as a protein essential for the *processivity* of DNA polymerase; in other words, its ability to remain bound to the template through many cycles of nucleotide addition. The core polymerase, once bound to template DNA, remains bound only long enough to extend a primer strand by 10–20 nucleotides. However, β tethers the enzyme to DNA, allowing it to incorporate several thousand nucleotides per binding event. We say that β converts DNA polymerase III from a highly *distributive* enzyme, which incorporates just a few nucleotides per binding event, to a highly *processive* enzyme, which remains bound through thousands of incorporation reactions. Crystallography showed β to be a circular molecule with a 3.5-nm opening, capable of completely surrounding double-stranded DNA. As shown in Figure 25.20, six α -helical domains (three per subunit) face the interior of the circle, with the hydrophobic residues in these helices having little attraction for DNA. Thus, the molecule acts as a sliding clamp, permitting polymerase to slide readily along DNA, but not to dissociate. The structure is remarkably well conserved evolutionarily, even though most other forms of this protein are trimers of dimers, not dimers of trimers.

**FIGURE 25.19**

Subunit structure of the *E. coli* DNA polymerase III holoenzyme. Greek letter designations for the subunits are identified in the text.

Clamp-Loading Complex

How does a circular molecule wrap itself around DNA to begin processive synthesis? That is the function of the remaining five proteins, which form the γ complex, an assembly also called the **clamp loader**. This pentameric complex contains three copies of the γ protein and one copy each of the related δ and δ' subunits. χ and ψ are considered part of the clamp loader complex, but they do not participate directly. These proteins associate the γ complex with primase, and regulate the termination of RNA primer synthesis. The two N-terminal domains of each pentamer subunit form an AAA + ATPase module (ATPases associated with a variety of cellular activities).

Figure 25.21 shows the crystal structure of the γ complex bound to DNA and a schematic view of the clamp loading cycle. ATP is required, but not for opening the clamp. Instead, a conformational change driven by ATP binding leads the complex to bind the β clamp and to open it; this is followed by DNA binding. Once DNA has been encircled, the bound ATP is hydrolyzed, and the β ring closes. This event happens only once per round of replication on the leading strand. However, on the lagging strand, polymerase must rebind at the initiation of synthesis of each Okazaki fragment and must dissociate when the 5' end of the preexisting daughter DNA strand is reached. In *E. coli* Okazaki fragments are 1 to 2 kb long. Because DNA chains are extended at about 800 nucleotides per second, this means that the clamp loading and unloading cycle must occur almost every second. And this remarkable process must all occur with the lagging strand core polymerase unit remaining bound to its leading strand partner, at the fork.

Single-Strand DNA-Binding Proteins: Maintaining Optimal Template Conformation

One of the earliest replication proteins to be identified, other than DNA polymerase itself, was a T4 protein called either *single-strand DNA-binding protein* (SSB) or *helix-destabilizing protein*. In an early application of affinity chromatography, Bruce Alberts immobilized DNA by binding it to cellulose and analyzed the T4 proteins that were retained by a column of this material. One protein was shown to be the product of gene 32 because the protein isolated from a *ts* gene 32 mutant was unable to bind to DNA at a restrictive temperature. Because gene 32 mutants were known to be defective in DNA repair and genetic recombination, as well as in DNA replication, it was clear that the protein played multiple roles in DNA metabolism.

Analysis of the purified gp32 showed that it binds specifically to single-strand DNA. Moreover, binding is strongly *cooperative*, meaning that the protein is far more likely to bind to DNA adjacent to a site already occupied than to an isolated site. In other words, binding of one gp32 molecule facilitates the binding of others, and the protein tends to bind in clusters. Thus, gp32 promotes the denaturation of DNA. Although it does not initiate denaturation, its presence lowers the melting temperature of DNA by as much as 40 °C.

The role of gp32 is to keep the template in an extended, single-strand conformation, with the purine and pyrimidine bases exposed so that they can base-pair readily with incoming nucleotides. This function is essential for DNA repair and genetic recombination, as well as for replication. Given that all three processes also

FIGURE 25.20

Structure of the sliding clamp. Left, the *E. coli* β protein (PDB ID 2POL); center, human PCNA (proliferating cell nuclear antigen; PDB ID 1AXC); right, gp45, the sliding clamp of the T4-related phage, RB69 (PDB ID 1B77). Each protein forms a “doughnut” that can completely surround double-stranded DNA and thus keep polymerase associated with its DNA templates. The α helices on the inner surface of the subunit contact DNA but do not bind tightly enough to retard movement of the protein. The *E. coli* protein has two identical subunits with two DNA-associating domains, while the human and RB69 proteins have three subunits, each with two DNA-associating domains.

Kuriyan, The mechanism of ATP-dependent primer-template recognition by a clamp loader complex. © 2009, with permission from Elsevier.

Single-strand DNA-binding proteins are essential in DNA replication, repair, and recombination by virtue of their ability to facilitate both DNA denaturation and renaturation.

involve the re-formation of duplex structures, with one strand each of parental and daughter DNA, it is of interest that gp32 facilitates the renaturation of single-strand DNA, as well as the denaturation of duplexes.

How can a single protein promote both duplex formation and duplex unwinding? The answer seems to lie in special design features of the gp32 molecule. Note that *gp32 does not itself unwind DNA strands*. Rather, it stabilizes single-strand DNA by binding *after* a region of DNA is unwound. Limited proteolysis of gp32 removes a C-terminal fragment. This modification renders the protein a stronger DNA denaturant *in vitro*, with a small increase in its equilibrium binding affinity for DNA. As suggested in Figure 25.22, the C-terminal domain provides a “flap” that partly covers the DNA-binding domain of the protein. When a short region of single-strand DNA is exposed, through partial and reversible unwinding of the duplex (sometimes called *breathing*), gp32 can bind with the flap down, but only to a small site (3 or 4 nucleotides). Occupancy of a complete site (7 to 10 nucleotides) is thereby inhibited, rendering binding both weak and noncooperative. If continued helix unwinding occurs, the flap can move up, permitting the complete site to be occupied and promoting further denaturation.

The partially proteolyzed gp32 lacks the ability to renature DNA *in vitro*, and it seems likely that the conformation of the native gp32 determines whether the protein functions primarily as a denaturant (flap-up position) or renaturant (flap-down position). The position of the flap is determined in part through interaction with other proteins at the replication fork. Thus, the protein can act both to stabilize a single-strand template as it pairs with incoming nucleotides and to facilitate re-formation of a duplex after DNA polymerase has passed by. Partial proteolysis can also remove an N-terminal domain, which

has been shown to be essential for self-association of the protein and, hence, for cooperative DNA binding. The crystal structure of a gp32-ssDNA complex shows three domains of the protein to be involved in DNA binding, consistent with this model.

Single-strand DNA-binding proteins have now been found in many organisms. The protein of *E. coli* (specified by the *ssb* gene) also binds cooperatively to single-strand DNA. However, the mechanism of binding appears to be quite different from that in T4. In *E. coli*, DNA is wrapped about the outer surface of the tetrameric SSB protein. Moreover, under some conditions the SSB protein binding shows *negative* cooperativity, meaning that incoming SSB molecules avoid sites adjacent to bound molecules. It has been suggested that the protein binds in different modes, depending on whether it is participating in replication, DNA repair, or recombination.

In eukaryotic cells a heterotrimeric protein called replication factor A (RFA) serves the role of SSB in DNA replication. This protein undergoes phosphorylation during S phase or after DNA damage, suggesting a role in cellular coordination of DNA metabolism.

Helicases: Unwinding DNA Ahead of the Fork

Single-strand DNA-binding proteins do not themselves denature DNA. As noted, they stabilize single-strand DNA but cannot actively unwind duplex DNA strands. Such unwinding must occur if single-strand templates are to be exposed for polymerase action. The helicase proteins have this ability. They catalyze the ATP-dependent unwinding of double-strand DNA. *E. coli* cells contain at least a half dozen different helicases, some of which participate in DNA repair and some in bacterial conjugation. The principal helicase in DNA replication is DnaB (the protein product of the *dnaB* gene), which interacts with DnaG and other proteins to form the primosome (see Figure 25.18). The comparable roles in T4 DNA replication are played by gp41 (helicase) and gp61 (primase). In phage T7 a single protein (gp4) has both helicase and primase activities.

All known helicases are multimeric proteins. Most are homodimers, but a few, like DnaB, are homo-hexamers. In vitro, each helicase binds initially to single-stranded DNA, adjacent to a duplex region, and proceeds in a fixed direction ($5' \rightarrow 3'$ or $3' \rightarrow 5'$), displacing the unbound DNA strand as it moves, and with ATP hydrolysis coupled to movement. Although the helicases are homo-oligomers, they are structurally asymmetric when bound to DNA. For example, in the well-studied dimeric Rep helicase of *E. coli*, the ATP-binding and DNA-binding properties of the two subunits are quite different. This suggests a rolling or “hand-over-hand” mechanism, in which each subunit alternates between tight-binding and loose-binding conformations, depending upon whether ATP or ADP is bound at a given instant (Figure 25.23). Consistent with this model, the crystal structure of the Rep helicase complexed with single-strand DNA and ADP shows a dramatic structural difference between the subunits, resulting from a 130° rotation of one domain about a hinge region.

The hexameric helicases, exemplified by the gene 4 product of phage T7, may move by a quite different mechanism. This ring-shaped protein, which uses dTTP rather than ATP as its energy source, wraps about the single strand to which it binds and along which it moves. The strand that is not bound becomes displaced by helicase action and does not pass through the central hole. Three of the six subunits bind and hydrolyze dTTP, while the other three bind dTTP in noncatalytic fashion. Data on dTTP binding and hydrolysis suggest a rotary motion for the protein, comparable to that seen in the mitochondrial F_0F_1 ATP synthase (see Figure 25.24a,b), suggesting the intriguing possibility that the helicase moves along the DNA by rotation. The major difference is that the F_0F_1 ATP synthase uses the proton motive force to drive ATP *synthesis*, while the T7 helicase uses the energy of dTTP *hydrolysis* to drive a conformational change, giving

FIGURE 25.22

gp32 facilitation of both denaturation and renaturation of DNA. When only a short length of DNA is exposed, gp32 binds weakly. The folded-down configuration of the C-terminal domain prevents cooperative binding of other gp32 molecules, and hence, strand unwinding (“breathing”). If a longer region of ssDNA is exposed after the first gp32 molecule has bound, the C-terminal domain can shift to the “up” configuration, enlarging the DNA binding site and permitting cooperative binding of other gp32 molecules, thereby further extending the denatured region. For simplicity binding is shown on only one of the two denatured DNA strands.

Helicases are multimeric proteins that bind preferentially to one strand of a DNA duplex and use energy of ATP hydrolysis to actively unwind the duplex.

FIGURE 25.23

A model for helicase action. In this model a homodimeric enzyme, such as the *E. coli* Rep helicase, shows 3' → 5' polarity. In the first step, binding of ATP activates the subunit shown in red to bind to DNA at the double-strand/single-strand junction and, in the second step, to unwind a few base pairs. In the third step, the hydrolysis of bound ATP weakens the binding of the blue subunit to DNA, causing its dissociation, and thereby positioning it to begin the cycle anew, by invading the DNA duplex ahead of the fork that has been created, once another ATP has been bound. Thus, by alternating in their binding to DNA, the two subunits cause the enzyme to “roll” counterclockwise as shown in this model, unwinding the duplex as it moves.

Reprinted from *Cell* 90:635–647, S. Korolev, J. Hsieh, G. H. Gauss, T. M. Lohman, and G. Waksman, Major domain swiveling revealed by the crystal structures of complexes of *E. coli* rep helicase bound to single-stranded DNA and ADP. © 1997, with permission from Elsevier.

the homohexameric protein the structural asymmetry needed to drive motion along the DNA lattice. Figure 25.24c shows a model of the T7 gene product translocating along DNA.

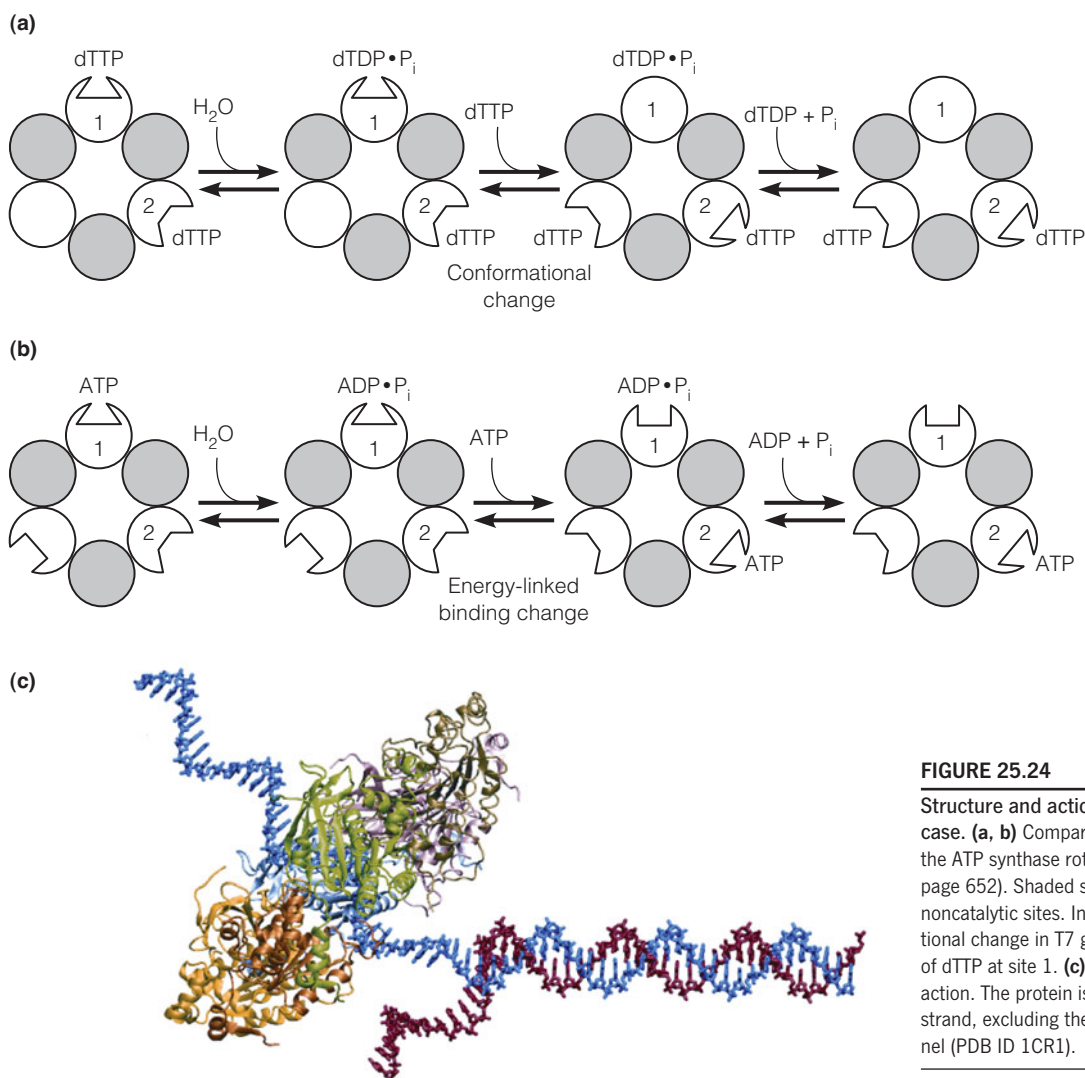

As mentioned above, the DnaB helicase of *E. coli* is also a homohexamer, which wraps around single-stranded DNA. Each subunit has two DNA-binding domains, one strong and one weak, each of which occludes about twenty DNA nucleotide residues.

As mentioned earlier, the primosome interacts with the τ and χ subunits of the γ complex to coordinate the switch from primase to polymerase on the lagging strand. Based upon the protein–protein interactions demonstrated, Figure 25.25 shows how this might occur.

Considerable excitement was engendered by recent findings that two inherited human diseases, Werner’s syndrome and Bloom’s syndrome, result from helicase defects. Both conditions involve increased susceptibility to cancer, and Werner’s syndrome patients also undergo premature aging, usually going gray in their twenties, developing cataracts, and dying of natural causes before age 50. Positional cloning (Chapter 24) of the defective genes responsible for these conditions revealed in both cases that the genes encode proteins related to the *E. coli* RecQ gene product. In *E. coli* this helicase participates in a homologous recombination pathway and may be involved in resumption of DNA replication after repair of radiation-induced DNA damage. Like the RecQ protein, the Werner’s syndrome protein has been shown to have a 3' → 5' helicase activity. These findings provide intriguing clues to understanding relationships between genomic instability and both cancer and aging.

Topoisomerases: Relieving Torsional Stress

Bidirectional replication of the circular *E. coli* chromosome unwinds about 100,000 base pairs per minute. Were there not some mechanism for relieving this torsional stress, DNA ahead of the fork would become overwound as DNA at the fork became unwound, and replication could not be sustained. Topoisomerases, a group of enzymes that can interconvert different topological isomers of DNA (see Chapter 4), provide a “swivel” mechanism for relieving this stress. Topoisomerase action is demonstrated most simply in vitro by the relaxation of supercoiled DNA. One can incubate supercoiled DNA with a purified topoisomerase and observe, by gel electrophoresis, the intermediate stages in conversion of the supercoiled substrate to relaxed circular DNA containing no superhelical turns (Figure 25.26). This analysis reveals the existence of two general classes of topoisomerases—type I enzymes, which change the linking number in units of 1, and type II enzymes, which change the linking number in units of 2.

Actions of Type I and Type II Topoisomerases

A type I topoisomerase breaks just one strand of the duplex (Figure 25.27). The enzyme remains covalently attached to the 5′ end of the broken strand, by forming a phosphodiester bond between the 5′ phosphate and a tyrosine hydroxyl. The 3′ end is then free to rotate (by one turn in the example shown). The hydroxyl group on the 3′ end then attacks the activated, covalently bound 5′ phosphate, closing the nick—in fact, *E. coli* type I topoisomerase was originally called nicking–closing enzyme. The result is that the linking number has been changed by 1. Eukaryotic topoisomerase I acts similarly, but the 3′ end, not the 5′ end, is immobilized during the reaction.

By contrast, a type II topoisomerase catalyzes a double-strand break, and the unbroken part of the duplex passes through the gap that is created (Figure 25.28). The most thoroughly studied type II topoisomerase is an *E. coli* enzyme also called **DNA gyrase** because it can not only relax a supercoiled molecule but also introduce negative superhelical turns into DNA. ATP hydrolysis is required for both activities of most type II enzymes. DNA gyrase is a tetramer, with two A and two B subunits. The A subunits bind and cleave DNA, while the B subunits carry out the energy transduction resulting from ATP hydrolysis.

As shown in Figure 25.28, gyrase action begins with DNA wrapping about the enzyme. The A subunit cleaves both DNA strands and immobilizes them, and

FIGURE 25.25

The primase–polymerase switch during lagging-strand synthesis. **(a)** DnaB helicase encircles the lagging strand, and primase has synthesized an RNA primer. Primase must contact SSB to remain bound. Core polymerase on the lagging strand is forcing that strand and the daughter strand to loop out. **(b)** The χ subunit of the γ complex interacts with SSB, leading to primase displacement. The γ complex is opening the clamp, and a newly completed Okazaki fragment is being released, along with its template. **(c)** Primase rebinds to single-strand template DNA to begin a new primer. In (b) the γ complex is also releasing a β clamp, and in (c) a new clamp is being attached. The periodic lengthening of the lagging strand loop has been likened to the playing of a trombone.

Courtesy of Dr. Michael O'Donnell.

both strands of the duplex pass through the opening. This is followed by resealing of both strands of the duplex and dissociation of the enzyme. In the example shown, a circular DNA with one positive supercoil is converted to a product with one negative supercoil. Thus, the linking number is changed by 2, the distinction between a type I and a type II topoisomerase. In Figure 25.26, note that DNA treated with a type I topoisomerase (lane 2) shows twice as many intermediates as identical DNA treated with a type II enzyme (lanes 3–5) because the type I enzyme changes linking number in units of 1.

FIGURE 25.26

Action of type I and type II topoisomerases, as shown by gel electrophoresis. Lane 1 shows a relaxed circular DNA. Lane 2 shows the pattern from treatment of supercoiled DNA with type I topoisomerase. Lanes 3–5 show relaxed circles treated with DNA gyrase, a type II topoisomerase, for different lengths of time. Note that more different topoisomers can be seen in topoisomerase I reaction mixtures, as expected if changes in the linking number (L) occur in units of 1, whereas gyrase changes L in units of 2.

From *Science* 206:1081–1083, P. O. Brown and N. R. Cozzarelli, A sign inversion mechanism for enzymatic supercoiling of DNA. © 1979. Reprinted with permission from AAAS and Pat Brown.

The action of type I topoisomerases was clarified with publication of the crystal structure of human topoisomerase I. As shown in Figure 25.29, the enzyme completely wraps around its DNA substrate. Not evident from the figure is the fact that most of the DNA–protein contacts involve the DNA sugar–phosphate backbone rather than the bases, meaning that DNA is bound as an undistorted B-form helix. Also, the contacts on the “upstream” (5′) side of the scissile bond are far more numerous than those on the downstream (3′) side. Because the 5′ nucleotide in the nick is immobilized by its binding to a tyrosine residue, the structural data indicate that the free 3′ end is relatively free to rotate, as it must do if the supercoiled DNA is to become relaxed. A useful consequence of this structure determination was clarification of the mechanism of action of anticancer drugs that act by inhibiting topoisomerases because the structure reveals how such inhibitors can be bound, and it should lead to the design of more effective inhibitors. One inhibitor in current clinical use is **camptothecin**.

The Four Topoisomerases of *E. coli*

Since the discovery of topoisomerase I and DNA gyrase in the 1970s, *E. coli* has been shown to contain four different topoisomerases. The terminology is a bit confusing because the enzymes named topoisomerase I and topoisomerase III are both type I topoisomerases, and topoisomerase II (also called DNA gyrase) and topoisomerase IV are both type II topoisomerases. Of these four enzymes, DNA gyrase plays the dominant role during replicative chain elongation, both in relieving stress ahead of the fork and in introducing negative supercoils into newly synthesized DNA. We know of this role primarily through studies of the properties of gyrase inhibitors. The gyrase A subunit is the target for binding of **nalidixic acid**, a compound long known to inhibit DNA replication. Another replication inhibitor, **novobiocin**, binds to the B subunit and inhibits ATP cleavage. Inhibitors such as these are useful as antibacterial drugs. Mutant bacteria resistant to nalidixic acid or novobiocin show structural alterations in subunit A or B, respectively.

Topoisomerase IV plays a critical role in the completion of a round of replication. Type II topoisomerases catalyze a variety of topological interconversions,

Type I topoisomerases break and resealed one DNA strand, and type II topoisomerases catalyze double-strand breakage and rejoining; hence, type I and type II enzymes change DNA linking number in units of 1 and 2, respectively.

Camptothecin

Nalidixic Acid

Novobiocin

FIGURE 25.27

Action of a type I topoisomerase. The enzyme breaks one strand and immobilizes the 5′ end by a covalent bond between the DNA phosphate and a tyrosine residue (in *E. coli* topoisomerase I). Rotation of the 3′ end is followed by resealing. The linking number is increased by 1 in the example shown (an underwound DNA). Action of a type I topoisomerase on overwound DNA would decrease the linking number, by essentially the same mechanism.

FIGURE 25.28

Action of a type II topoisomerase. DNA gyrase of *E. coli*; the example shown is a tetrameric protein with two A and two B subunits. The enzyme is shown introducing two negative turns and changing the linking number from +1 to -1. The enzyme catalyzes a double-strand break, and the two DNA ends are bound by A subunits, which move the DNA ends apart so that the unbroken duplex can pass through the gap. Resealing converts the positive super-twist to a negative one, giving the overall molecule a ΔL of -2. Type II topoisomerases can relax underwound duplexes by the reverse of the above pathway.

including knotting, unknotting, **catenation** (linking), and **decatenation** (unlinking) of circular DNAs, as shown in Figure 25.30.

A circular DNA nearing the end of a round of replication will generate two interlinked circles, so a type II topoisomerase action is necessary for separating the newly replicated molecules. As two forks approach each other at the replication terminus, steric barriers ultimately interfere with the unwinding activities of topoisomerases ahead of the two forks (Figure 25.31). At this stage the two incompletely replicated chromosomes are still interlinked. Topoisomerase IV plays a specific role in the decatenation process shown in Figure 25.31. This

finding suggests a degree of specificity in topoisomerase action that is not immediately apparent from the idea that a strained DNA conformation is being relaxed. In accord with this suggestion, studies of type II topoisomerases show that they do not generate equilibrium mixtures of topoisomers. For example, a topoisomerase IV limit digest (DNA digested until no further reaction occurs) was shown to have far fewer knotted and catenated structures than expected for an equilibrium mixture; somehow, the enzyme selectively “disentangles” DNA molecules. Also, when a mixture of topoisomers generated by topoisomerase I action was subsequently treated with topoisomerase IV under the same conditions, the average linking number—the number of supercoils—remained the same, but the distribution of topoisomers about the mean became much tighter. ATP hydrolysis is required for this selectivity to be achieved, but remarkably, these observations indicate that a topoisomerase molecule can somehow scan a DNA molecule much larger than itself and direct the specific kinds of topological changes that occur.

Additional events are involved in termination of a round of replication in *E. coli*, evidently ensuring that both replisomes reach the same point before termination can occur. As schematized in Figure 25.32, the termination region contains ten homologous 23-base-pair *Ter* sites (*TerA–J*) arranged in oppositely oriented groups of five. Each *Ter* site binds a protein called Tus, a 36-kDa terminator protein. As each replisome approaches a *Ter*-Tus complex, it encounters either a “permissive” face, which allows the replisome to displace Tus and move on, or an oppositely oriented nonpermissive face, at which the replisome stalls because it cannot displace Tus. Thus, as shown in the figure, the replisome moving counterclockwise displaces Tus and passes the sites labeled *TerJ*, *TerG*, *TerF*, *TerB*, and *TerC* before stalling between *TerC* and the oppositely oriented *TerA*. A similar sequence of events leads the other replisome to the same point. This process evidently ensures that replication terminates at the same chromosomal site, even though the two replisomes may travel at different rates. The crystal structure of a Tus-*Ter* complex, shown in Figure 25.33, provides clues to the process of Tus displacement. The actual mechanism of termination is still under investigation.

A Model of the Replisome

Strictly speaking, topoisomerases are not components of the replisome because they act at a distance from the fork. However, now that we have discussed the major proteins involved in prokaryotic fork propagation, and as a prelude to discussion of

FIGURE 25.30

FIGURE 25.31

Topoisomerase action in termination of replication. In the absence of topoisomerases, steric forces would prevent gyrase from unwinding DNA as replication forks approached each other. Topoisomerase allows the circles to decatenate. It is not known whether decatenation occurs before or after the completion of replication. Both possibilities are shown here.

comparable eukaryotic proteins, we present here a model of the *E. coli* replisome, showing relationships among the constituent proteins (Figure 25.34).

Recently it has become possible to image the *E. coli* replisome in vivo, using fluorescent-tagged proteins and single-molecule techniques (Tools of Biochemistry 26A). These experiments indicate that the replisome contains three molecules of DNA polymerase, not the two shown in Figure 25.34. Only two of the three molecules are linked to sliding clamps, but three copies of τ are present, suggesting that the unlinked polymerase is waiting its turn to have a clamp loaded so that it can catalyze synthesis of the next Okazaki fragment.

Proteins in Eukaryotic DNA Replication

DNA Polymerases

The mechanism of replicative DNA chain elongation has been found to be remarkably constant through evolution. One striking difference between prokaryotic and eukaryotic replication is the requirement for three different DNA polymerases to propagate a eukaryotic replication fork. Early fractionation of DNA polymerases from yeast or mammalian cells yielded five different enzymes, three of which are involved in nuclear DNA replication, one in mitochondrial DNA replication, and one in repair. Later work revealed the existence of at least nine additional DNA polymerases in human cells, most of which participate in specialized repair processes. Properties of the five “classical” polymerases, which include the three

replicative enzymes, are summarized in Table 25.2. The involvement of polymerases α , δ , and ϵ in replication was shown by the fact that all three are inhibited by **aphidicolin**, a fungal product with a steroid-like structure. Aphidicolin specifically inhibits eukaryotic DNA replication. Polymerases β and γ show low sensitivity to aphidicolin.

The large size and multi-subunit nature of eukaryotic DNA polymerases has made their structural elucidation more challenging than that for bacterial and phage polymerases. However, the structure of human pol γ was recently described and is of considerable interest. As shown in Table 25.2, the enzyme consists of a 137-kDa catalytic subunit (pol γ A) and a 55-kDa accessory subunit (pol γ B). Not shown is the fact that the holoenzyme contains two molecules of γ B, each of which binds differently to pol γ A. Each of the accessory subunits increases polymerase processivity, but by different mechanisms—one increasing affinity of γ A for DNA and the other stimulating the rate of catalysis.

As shown in Figure 25.35, human pol γ fairly closely resembles T7 bacteriophage DNA polymerase. T7 pol also has a processivity-enhancing subunit, which is a protein of the host cell, thioredoxin, playing a function quite distinct from its role in redox reactions. Like other polymerases, both enzymes shown in Figure 25.35 contain a thumb domain (shown in green), palm (red), and fingers (blue). The pol γ A structure shows the sites of several mutations known to be responsible for human genetic diseases. For example, the W748S mutation is associated with a condition called Alpers syndrome, which causes both cerebral cortical atrophy and liver failure in children.

Of particular interest is the fact that pol γ is responsible for the toxicity of several antiviral drugs used in HIV therapy. As pointed out in Chapter 22, nucleoside analogs such as dideoxycytidine act by conversion to their 5' triphosphates, which interfere with HIV reverse transcriptase. Several of these analogs also interfere with mitochondrial DNA replication, by inhibiting pol γ . The structure of this enzyme provides information that should be useful in designing analogs with greater selectivity toward the viral polymerase.

Other Eukaryotic Replication Proteins

Much of what we know about the enzymology of *E. coli* DNA replication came from studies in which the replication of small bacteriophage genomes was followed in bacterial extracts or in purified protein systems. The rationale was to use as the replication template a small genome, which makes possible the isolation and biophysical characterization of replicative intermediates. In the same sense, much of what we know about proteins in human DNA replication comes from similar in vitro systems using the circular duplex DNA from the tumor virus SV40 as the replication template. These studies, plus earlier work on the phage T4 system and later work with yeast, reveal striking uniformity in the kinds of proteins at replication forks and the biochemical

Pol ϵ	251	12, 17, 59	Yes	$10^{-6} - 10^{-7}$	High	Leading strand replication

functions of each, as shown in Table 25.3. One interesting difference is the requirement for two enzymes in eukaryotes for RNA primer removal—the 3' exonuclease activity of Pol δ and the 5' “flap” endonuclease activity of FEN 1 (flap endonuclease).

Replication of Chromatin

Eukaryotic cells face a DNA replication problem we have not encountered in our discussion so far focused upon bacterial and bacteriophage systems, namely, how the replisome deals with chromatin. Chromatin must be dismantled in advance of replication forks and reassembled on daughter DNA strands after a fork has passed through. And, as we discuss in later chapters, the distribution of core particles along DNA, and their modification patterns, are far from random, implying a higher-level control in the reassembly process. What we do know is summarized in

FIGURE 25.35

Structures of human DNA polymerase γ (left) and T7 phage DNA polymerase (right) holoenzymes. Both enzymes are shown complexed with DNA. The pol γ structure (PDB ID 3ILK and 3IKM) shows two unique domains (IP and AID, shown in gold), which are involved in DNA binding. Figure 25.36. Nucleosomes are disassembled ahead of the replication fork and then reassembled on both daughter strands. Both preexisting and newly synthesized histones are used in the new nucleosomes, evidently with random deposition on the daughter strands. There is mixing of old and new histone molecules on the daughter strands, but the process is not entirely random. (H3/H4)₂ tetramers tend to remain intact, as do H2A/H2B dimers. This result conforms with results of in vitro studies; (H3/H4)₂ tetramers and H2A/H2B dimers are stable when released from nucleosomes, but the octamer is not.

The much more important question of how the precise arrangement of nucleosomes and nonhistone proteins is re-established after replication is still not understood. In fact, there may be changes in this arrangement in some instances. For example, in yeast newly synthesized histone H3 specifically undergoes acetylation of Lys-56, and this is important for nucleosome assembly and genome stability during replication. Such changes could account for the observation that differentiation of cells in embryonic development usually occurs at the time of cell division. However, such changes must be *programmed* ones, so their existence only makes the problem more complex.

Recent work indicates that the preservation of specific histone modifications after replication is perturbed under conditions of replication stress—for example, damage to the DNA template or depletion of DNA precursor pools. This can lead to epigenetic changes in gene expression, and it has been suggested that such changes could be partly responsible for oncogenic transformation.

Initiation of DNA Replication

When we ask how DNA replication is initiated from an origin, we are asking three interrelated questions: (1) What are the site-specific DNA–protein interactions that trigger initiation? (2) How do proteins act after binding to origin sequences? (3) How is the process controlled? Initiation seems to be the major target for control of replication. However, we know much less about the initiation of replication than we know about the initiation of transcription or translation. It is evident that intracellular contacts, of a still undefined type, link the replication apparatus to other cellular structures so that DNA replication is coordinated with the cell cycle. In prokaryotes it is likely that replication occurs at a site attached to the cell membrane, whereas eukaryotic DNA replication may occur at a DNA-and-protein-containing structure called the nuclear matrix (see Chapter 24, page 1025). The nature and significance of these physical linkages have remained elusive. Most of the events in

**FIGURE 25.36**

Model for chromatin replication. Nucleosomes on parental DNA are dissociated as the replication fork approaches and are reformed on newly synthesized daughter strands, with both old and newly synthesized histones being used. Maturation occurs slowly, with full organization not being re-established until many kilobases behind the moving fork. For simplicity this figure does not show proteins known to be active at the replication fork.

replication have been duplicated in soluble cell-free systems, without components of the membrane or nuclear matrix. Therefore, it has been difficult to define a biochemical role for the membrane or matrix in replication.

Requirements for Initiation of Replication

Because replication proceeds from fixed origins, there are two requirements for initiation: a nucleotide sequence that specifically binds initiation proteins, and a mechanism that generates a primer terminus to which nucleotides can be added by DNA polymerase. A number of phage, bacterial, plasmid, and organelle replication origins have been isolated by gene cloning, and their nucleotide sequences have been determined. In general, these origins include repeated sequences of either identical or opposite polarity (**direct repeats** or **inverted repeats**, respectively). This finding suggests that initiation proteins bind in multiple copies.

The two most straightforward ways to generate a primer terminus at the origin are first, nicking a strand of the parental duplex to expose a 3' hydroxyl terminus and second, unwinding the parental duplex and synthesizing an RNA primer to expose a 3' hydroxyl *ribonucleotide* terminus. Phages ϕ X174 and G4, which replicate their single-stranded genomes *via* a circular duplex replicative intermediate, initiate the conversion of that intermediate DNA to single-strand progeny DNA by nicking with a site-specific endonuclease, the viral *cisA* gene product. By contrast, duplex DNA replication, where studied, occurs without nicking of the parental duplex and with the synthesis of RNA primers.

Initiation of *E. coli* DNA Replication at *ori^c*

Initiation of replication of the *E. coli* chromosome is reasonably well understood because the origin sequence has been cloned into plasmids whose replication from the origin can then be studied *in vitro*. This origin sequence, called *ori^c*, is 245 base pairs long. It contains four repeats of a 9-base-pair sequence that binds an initiation protein, the *dnaA* gene product. To the left of these sites, as shown in

Figure 25.37, are three direct repeats of a 13-base-pair sequence that is rich in A and T and thus is relatively easily denatured. The sequence also contains binding sites for several basic proteins (HU and IHF) that facilitate DNA bending, an important step in the sequence leading to initiation.

Step 1 is binding of 10 to 20 molecules of a complex of DnaA protein and ATP. The protein is activated for this step by reacting with the phospholipid cardiolipin, a process that may represent part of the coordination between DNA replication, membrane growth, and chromosome partitioning at cell division. Binding of DnaA, plus the basic proteins, bends the DNA rather sharply and creates negative superhelical tension. In turn this tension causes DNA unwinding in the 13-base-pair regions, opening up a short single-strand loop. Aided by DnaC, another initiation protein, the DnaB helicase in step 2 binds in both forks of this loop, and the helicase activity further unwinds this structure. In step 3, and subsequent steps (not shown), DnaG primase binds, and RNA primers are formed. Some of the first primers may be synthesized also by RNA polymerase, the transcription enzyme. However formed, the RNA primers are extended by DNA

Protein binding, causing DNA to bend at the origin, initiates duplex DNA replication. Stress from bending causes nearby DNA to unwind, and primosomes assemble in the forks, forming RNA primers that are extended by DNA polymerases.

FIGURE 25.37

A model for initiation of *E. coli* DNA replication at *ori^C*. HU and IHF are double-strand DNA-binding proteins that facilitate DNA bending at the origin.

polymerase III on both leading and lagging strands, and the two forks in the initiation complex mature, with a leading and a lagging strand in each fork. This may represent a general mechanism for initiation of chromosomal DNA replication.

Initiation of Eukaryotic Replication

With some exceptions prokaryotic organisms have a single origin of replication on a single chromosome. Far more complex is a typical eukaryotic cell, with thousands of replication origins distributed over multiple chromosomes, which “fire” at different times within S phase, and with not all origins firing within a single cell cycle. Moreover, there is the problem of “licensing” each origin so that it fires not more than once per cell cycle, to assure that all of the genome is replicated once and only once.

Early insight into yeast replication origins came from the identification of *autonomously replicating sequences* (ARS's), which are sequences essential for replication of plasmids after introduction into yeast cells. An ARS is typically several hundred base pairs in length, with subsequences carrying copies of the 11-base consensus sequence 5' TTTTATATTTT 3'. The AT-rich composition suggests that, as with *E. coli ori^c*, initiation involves strand unwinding at the origin.

The complexity of eukaryotic initiation can be seen by considering the number of proteins involved in preparing origins to fire in the fission yeast, *Schizosaccharomyces pombe*, and the time needed for this process. As shown in Figure 25.38, this process begins in mitosis, hours before the onset of S phase, with binding of a six-protein origin replication complex (ORC). This prepares the site for binding of two more proteins, Cdc18 and Cdt1. These proteins in turn recruit the six Mcm proteins, which constitute a putative helicase for unwinding DNA strands at the origin, to form a pre-replicative complex (pre-RC). Licensing occurs during assembly of the pre-RC; the biochemistry of this step is still undefined. Several more initiation factors bind, some of which are phosphorylated by a cyclin-dependent kinase (CDK) or Hsk1-Dfp1. Phosphorylation is thought to be required for loading Cdc45 onto the origin. This completes formation of the pre-initiation complex (Pre-IC). This prepares the origin for loading of primase and DNA polymerase, which occur in S phase, when replication actually begins. Once primase and polymerase have been loaded, all pre-RC's must be disassembled, to ensure that each licensed origin fires only once.

FIGURE 25.38

Preparing a fission yeast replication origin for initiation. Steeper steps in this process represent sites of regulation. At each step, proteins that were bound in earlier steps are shown as fainter images. For further details see text.

Mitochondrial DNA Replication

As noted earlier, the mitochondrial genome in mammalian cells is a relatively small circular duplex (16,569 bp in humans), which, unlike chromosomal DNA, should be amenable to rigorous analysis of replication mechanisms. Indeed, as early as the

1970s purified intermediates in mtDNA replication were analyzed by electron microscopy. These studies supported an unusual asymmetric process, the strand displacement model, shown in Figure 25.39. In this model replication begins from a fixed origin on the L, or light, strand. However, only one strand is copied, with the other being displaced as single-strand DNA to form a D-loop. When the replication fork has moved about two thirds around the genome, an origin is exposed on the displaced H strand, and unidirectional L-strand synthesis begins backward from the direction of H strand synthesis, which continues. The entire process requires about one hour, comparable to the relatively slow rate of nuclear DNA replication in eukaryotic cells.

In 2002 the strand displacement model was challenged on the basis of analysis of mtDNA replication intermediates in two-dimensional agarose gel electrophoresis (Tools of Biochemistry 25A), introducing controversy into the field. More recently it was reported that RNA is extensively incorporated throughout the lagging strand during mtDNA replication. This RNA might well have been lost during purification of replicating mtDNA in the early electron microscopic analyses. Whether this represents primers for lagging strand replication remains to be seen, as does the possibility that mtDNA replicates by quite different mechanisms under different conditions.

Replication of Linear Genomes

Thus far we have discussed in detail only the replication of circular DNA genomes. Linear genomes, including those of several viruses as well as the chromosomes of eukaryotic cells, face a special problem—how to complete replication of the lagging strand (Figure 25.40). Excision of an RNA primer from the 5' end of a linear molecule would leave a gap that cannot be filled by DNA polymerase action because of the absence of a primer terminus to extend. If this DNA could not be replicated, the chromosome would shorten a bit with each round of replication.

Linear Virus Genome Replication

Viruses reveal at least three strategies for dealing with this problem. Phages T4 and T7 exhibit **terminal redundancy**, the duplication of a small part of the genome at each end of the chromosome. Thus, recombination can occur at the incompletely replicated ends of two nascent DNA molecules without loss of genetic information (Figure 25.41a). This process is repeated in subsequent rounds of replication until the end-to-end linear aggregate (called a **concatemer**) is more than 20 times the length of a single phage chromosome. A virally specified nuclease then cuts this giant DNA into genome-length pieces when it is packaged into phage heads.

Bacteriophage $\phi 29$ and the adenoviruses have evolved a different strategy. The genomes of these viruses contain inverted repeat sequences at the ends. Replication begins at one end of the linear duplex, with a protein called **terminal**

FIGURE 25.39

Strand displacement model for mitochondrial DNA replication. Parental heavy (H) and light (L) chains are shown in brown. New strands are in blue and pink.

**FIGURE 25.40**

The problem of completing the 5' end in copying a linear DNA molecule.

protein serving as the primer. This protein in adenovirus reacts with dCTP to form a dCMP residue covalently linked through its phosphate to a serine residue (Figure 25.41b). The dCMP serves as primer for replication of the 3'-terminated strand, with the 5' end being displaced as a single strand. Still another mechanism is involved in the replication of poxviruses, such as vaccinia. The two strands at each end of this linear genome are covalently linked together. Such a structure, when approached by a replication fork, can support movement of the leading strand *around* the link between the strands so that the final lagging strand primer can be replaced by DNA as in a circular duplex.

Telomerase

For the linear DNA molecules in eukaryotes the end replication problem has been solved by the addition of **telomeres** at the ends of each chromosome. As mentioned in Chapter 24, telomeric DNA consists of simple tandemly repeated sequences like those shown in Table 25.4. Typically, one strand is G-rich, the other C-rich. The G-rich strand forms a 3'-terminal overhang, typically about 15 residues in length. These sequences are repeatedly added to the 3' termini of chromosomal DNAs by enzymes called *telomerases* (Figure 25.42). This elongation allows room for a primer to bind and initiate lagging-strand synthesis on the other strand, maintaining the approximate length of the chromosome and preventing the loss of coding sequences.

Note that the telomerase must add nucleotides without the use of a DNA primer. This is accomplished through the existence, in each telomerase molecule, of an essential RNA oligonucleotide that is complementary to the telomeric sequence being synthesized, and thus acts as a template. It has been speculated that telomerase is an evolutionary relic of a ribozyme that once served to catalyze DNA synthesis, a process long ago taken over by wholly protein polymerases. Because of its RNA-templated DNA synthesis, the protein portion of the enzyme, without its associated RNA, is called more descriptively TERT (**T**elomerase **R**everse **T**ranscriptase).

In 2008 the crystal structure of the catalytic subunit TERT was determined (Figure 25.43). Modeling of DNA and the RNA component into a large cleft in the protein shows a close fit, consistent with the mechanism outlined in Figure 25.42.

In recent years, it has become clear that telomeres and telomerase have wide-ranging significance in addition to their practical role in preventing chromosome shortening. First, it is possible that the G-rich strands typical of telomeres may aid in chromosome pairing by forming four-strand structures called G-quadruplexes (see Chapter 4, page 117). Secondary structure of this type has been observed many times *in vitro* with oligo-G, and it is known that a specific telomere-binding protein favors the formation of such structures. Second, there is a strong correlation between aging, cell senescence, and low levels of telomerase. Telomeres shorten with age, both in organisms and in cultured cells. Once telomeres disappear, chromosome ends are unprotected, and deleterious consequences may occur, such as end-to-end linking of two chromosomes.

Relevant to the relationship between telomerase and aging, cells in culture can be “immortalized” by introduction of active telomerase genes. These observations, together with the discovery that malignant tumor cells invariably have high levels of telomerase, have spurred intense interest in telomerase inhibition as a possible cancer therapy. The challenge, of course, is learning how to inhibit telomerase specifically in cancer cells.

Telomerase adds repeated short DNA segments to the ends of chromosomes.

Fidelity of DNA Replication

DNA replication is the most accurate of all known enzyme-catalyzed reactions, all the more remarkable given the speed of the reaction—approaching 1000 nucleotides incorporated per second in bacteria. From spontaneous mutation frequencies, which for all positions in a particular gene amount to about 10^{-6} per

generation, we can estimate the chance that a particular nucleotide will be copied incorrectly at about 10^{-9} per base pair per round of replication. About two orders of magnitude of this specificity comes from **mismatch repair**, a process that recognizes and removes mismatched nucleotides and other aberrant structures, such as looped-out nucleotides (see Chapter 26). Still, this means that the DNA polymerase reaction *per se* can have a fidelity as high as 10^{-7} errors per nucleotide incorporated, and in fact, that is what is observed (see Table 25.2).

3' Exonucleolytic Proofreading

DNA polymerase accuracy is determined at both the nucleotide insertion step and the 3' exonucleolytic proofreading step. As mentioned earlier, the 3' exonuclease is positioned to recognize and remove mispaired nucleotides before the polymerase activity can add the next nucleotide. However, crystallographic analysis of DNA polymerases shows for most DNA polymerases that the exonuclease site is far from the polymerase site. In the Klenow fragment, for example (Figure 25.7), eight base pairs must be unwound to move the 3'-terminal nucleotide in the daughter strand from the polymerase site to the exonuclease site. How, then, is a mismatched nucleotide recognized? How is a high polymerization rate maintained if each newly incorporated nucleotide must be unwound from its template in order to be inspected?

The answer comes from steady-state kinetic analysis. Experiments of the kind shown in Figure 25.44 show that the K_M for chain extension from a mismatch is about one thousandfold higher than extension from a correctly matched terminus. At physiological dNTP concentrations this means that extension from a mismatch is very slow, and the delay in extension gives time for partial unwinding of the template-primer, a process that places the primer in the exonuclease site (Figure 25.45). Hence, the 3' exonuclease activity has no specificity for a mismatched nucleotide; rather, a mismatched nucleotide has a far higher probability of reaching that site than a matched nucleotide.

Polymerase Insertion Specificity

Implicit in the Watson–Crick model was the idea that the accuracy of DNA replication is governed by the hydrogen bonds that link A to T and G to C. However, the free energy of forming a Watson–Crick base pair differs from that for forming a mismatch (A–C or G–T) by only 4 to 13 kJ/mol. This corresponds to only a 100- to 1000-fold difference in binding energy between correct and incorrect base pairs. Therefore, if DNA polymerase were completely passive, only incorporating the nucleotide that spontaneously associates with a template base, errors would be made approximately 0.1% to 1% of the time, reflecting the relative abundance of correctly and incorrectly base-paired structures, error rates far higher than observed, even when proofreading is not occurring.

Pre-steady-state kinetic analysis of DNA polymerase reactions shows that dNTP binding to a polymerase–DNA complex precedes a major conformational change that must occur before “chemistry,” that is, the formation and breakage of chemical bonds. A complete kinetic scheme for a single nucleotide addition is shown below.

^aWritten in 5' → 3' direction.

^bYeasts are unusual in having somewhat variable telomeric repeats.

FIGURE 25.42

Extension of telomeric DNA by telomerase. (a) The overall reaction. Telomerase adds simple repeat sequences to the 3' end of telomeric DNA, by the mechanism shown in part (b). Addition of an RNA primer allows lagging-strand synthesis, followed by ligation and RNA removal. **(b)** Proposed action of telomerase. The RNA carried by the telomerase matches the 3' DNA end, and allows its extension. DNA loop formation then permits further extension. Dissociation of telomerase and its RNA follows after several rounds of extension.

For a number of polymerases discrimination is shown to occur at both steps 2 (dNTP binding) and 3 (pre-chemistry conformational change). The chemistry step is not rate-limiting and does not contribute to discrimination. Evidence suggests that the conformational change occurring with a misaligned dNTP distorts catalytic residues on the enzyme so that dissociation of the misaligned dNTP becomes more likely.

Is hydrogen-bonding specificity sufficient to account for insertion specificity? This was tested by synthesis of dNTP analogs that are geometrically equivalent to natural dNTPs, but which lack hydrogen-bonding atoms. One example, a dTTP analog, is shown in the margin (next page). Although these analogs are generally poorer DNA polymerase substrates in terms of reaction rates, in many cases they show discrimination comparable to natural dNTPs; for example, the analog shown can compete with dTTP for incorporation opposite a dAMP residue in template DNA. Thus, specificity in DNA polymerase insertion reactions is seen to result from the shape of substrate molecules as well as their hydrogen bonding capacity. Base stacking interactions are probably involved as well.

Most attention in DNA replication fidelity has focused upon single-nucleotide substitution errors, in which one nucleotide is misincorporated. Less quantitative attention has been paid to other kinds of errors, including insertions and deletions. Of particular interest are errors resulting from oligonucleotide repeats along a template containing a short repeat sequence in tandem. A number of genetic diseases involve multiple tandem trinucleotide repeats within an affected gene. For example, Huntington's disease is an autosomal dominant neurological disease with a variable age of onset. In this condition a brain protein called **huntingtin** contains a stretch of consecutive glutamine residues, each encoded by 5' CAG 3'. Normal individuals contain between 6 and 31 glutamines at this site, whereas affected individuals contain as many as 80 glutamines or

**FIGURE 25.43**

FIGURE 25.44

An in vitro system for studying the fidelity of DNA replication. The primer strand is radiolabeled at the 5' end (marked with an asterisk) and is the most rapidly migrating radiolabeled species. The dTTP concentration dependence of extension from a correctly paired nucleotide (A in the A-T base pair) is shown at the top, and that of extension from a C-T mismatch is shown at the bottom. dTTP was the only dNTP present during the incubations. In each case the products after incubation and denaturation were analyzed by SDS-polyacrylamide gel electrophoresis and autoradiography. The top panel shows that the rate of extension was maximal at 1 μM dTTP and that further extension could be detected at higher dTTP levels. However, as shown in the bottom panel, dTTP concentrations in the millimolar range were required to see any chain extension from the mismatch.

Courtesy of Myron Goodman.

more. It seems likely that the number of repeats can increase if a product DNA strand undergoes slippage during an interval between successive nucleotide additions, forming a looped-out structure replication intermediate. In the example shown below, the product DNA strand (magenta) would have three more glutamine codons than the substrate.

In Huntington's disease the array of glutamine codons tends to become longer from one generation to the next, with a correspondingly earlier age of onset. The longer the array, the earlier the age of onset of this invariably fatal disease.

Until recently all investigations of DNA polymerase fidelity have focused upon incorporation of incorrect deoxyribonucleotides. However, in 2010 it was reported that yeast replicative DNA polymerases incorporate ribonucleotides at significant rates. Given the discrimination ratios seen in vitro, plus the fact that intracellular ribonucleoside triphosphate concentrations are much higher than those of deoxyribonucleoside triphosphates, one can estimate that 10,000 ribonucleotide molecules might be incorporated into yeast DNA in each round of replication. The ribonucleotides are removed by an RNase H-dependent process, which is essential for maintenance of genome stability.

FIGURE 25.45

Kinetic basis for preferential excision of mismatched nucleotides by a 3' exonuclease site distant from the polymerase site. The delay in extension from a mismatch allows for duplex unwinding at the primer terminus, placing the mismatched 3' nucleotide in the exonuclease site.

RNA Viruses: The Replication of RNA Genomes

We conclude this chapter with a few words about the replication of viral genomes consisting of RNA. Virtually all known plant viruses contain RNA instead of DNA, as do several bacteriophages and many important animal viruses, including polio virus and influenza viruses. The **retroviruses**, which are responsible for many tumors and for acquired immune deficiency syndrome (AIDS), also contain RNA genomes.

RNA-Dependent RNA Replicases

Most RNA viruses contain a genome consisting of a single molecule of single-strand RNA. Usually that RNA is the “sense” strand for expression of genetic information at the level of translation. In other words, the RNA molecule that passes from the viral particle into the infected cell can serve directly as a messenger RNA, without requiring first the synthesis of complementary-strand RNA. One of the early products of translation of this input genome is the enzyme **replicase**, or RNA-dependent RNA polymerase. After complexing with required polypeptide subunits of host cell origin, this enzyme replicates the input RNA (plus strand), starting from the 3′ end. Thus, the new strand (minus strand) is laid down from its 5′ end to its 3′ end, the same direction in which DNA polymerases work. The newly replicated minus strands then serve as templates for synthesis of plus strands, which are packaged into progeny **virions**, or virus particles. More complex mechanisms come into play when the RNA genome is double-stranded or segmented (three or four separate RNA molecules) or when the virion RNA is itself the minus strand (viruses in this latter class are called **negative-strand viruses**).

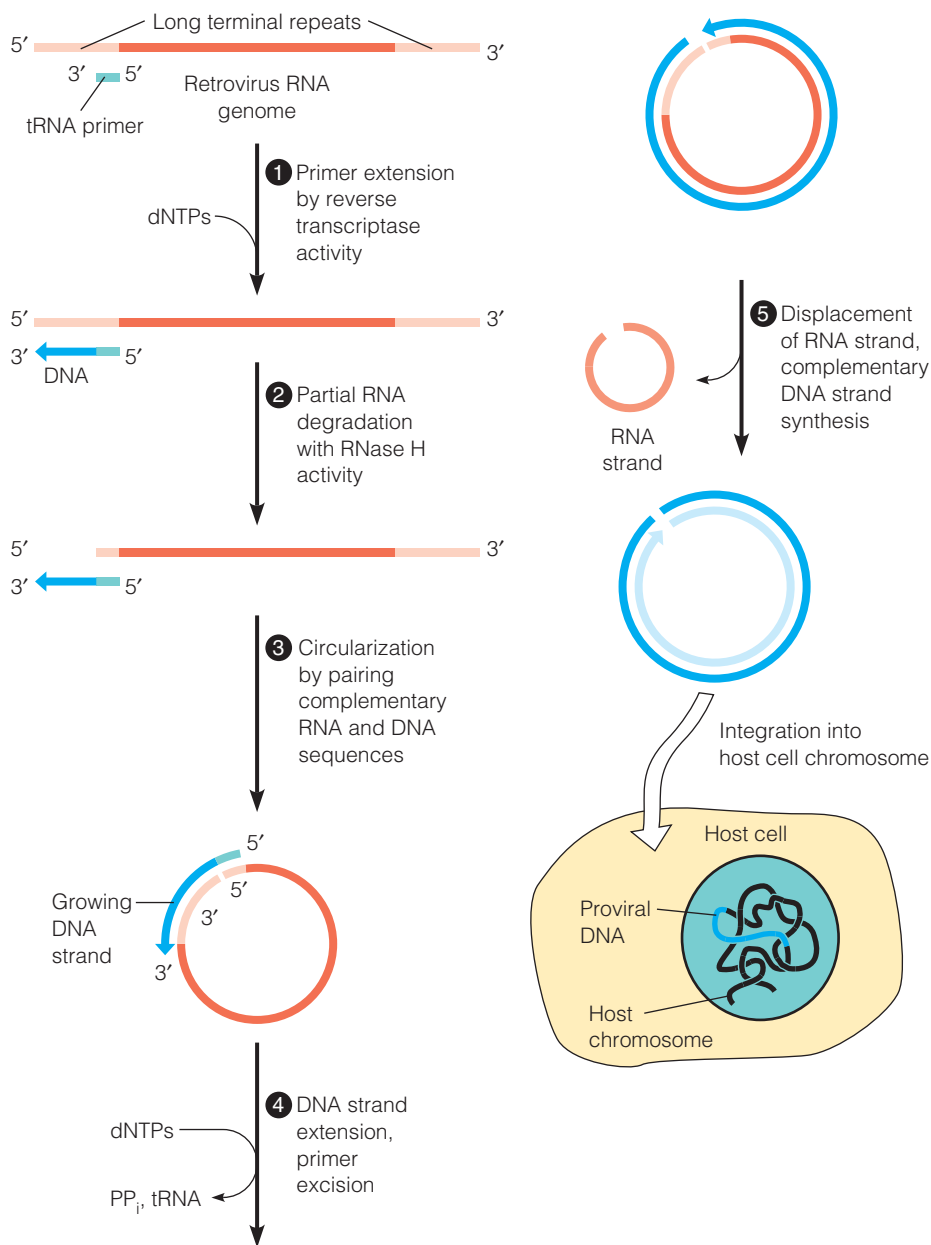

The rapid mutation rates of RNA viruses are largely due to RNA replication mechanisms that do not involve proofreading for mismatched nucleotides.

The known RNA replicases lack proofreading activity, so it is no surprise that viral RNA replication is more error-prone than DNA replication, and RNA viruses undergo mutation and evolution far more rapidly than the organisms they infect. These characteristics are clearly related to viral pathogenesis, in part because a virus population infecting a plant or an animal can undergo change so rapidly that it can evade or counteract the host’s defense mechanisms.

Replication of Retroviral Genomes

Different strategies for genome replication are involved in the action of retroviruses, so named because of the presence of a special enzyme, **reverse transcriptase**. In this class of viruses the single-strand RNA genome achieves latency—the ability to persist in a host cell for a long period without pathological effects—by making a DNA copy of itself and inserting that copy into the host cell genome. The DNA copy is made by reverse transcriptase, a multifunctional enzyme that is packaged in virions and enters the infected cell along with the viral genome. As shown in Figure 25.46, reverse transcriptase uses viral RNA as a template for synthesizing a complementary DNA strand, with a specific transfer RNA molecule serving as the primer (step 1). An RNase H activity of the enzyme then partially digests the RNA (step 2), and the structure circularizes by DNA–RNA base pairing (step 3). The nascent DNA chain is extended around the circle, and the tRNA primer is removed by RNase H activity (step 4). Strand displacement synthesis then occurs, with the RNA strand being displaced (step 5). The resultant double-strand DNA circle then recombines with a site on a chromosomal DNA and is linearly inserted into that DNA in the process. Under these conditions the integrated proviral genome can persist in a noninfectious state for many years, with most of its own genes turned off. Environmental stresses, still undetermined, can trigger excision of the integrated viral genome and return of the virus to an infectious state.

As discussed when we introduced azidothymidine (AZT) in Chapter 22, the reverse transcriptase of human immunodeficiency virus (HIV), the virus that causes AIDS, is an obvious target for antiviral therapy. Accordingly, intense

**FIGURE 25.46**

Simplified view of retrovirus life cycle. The RNA genome contains long terminal repeats, to one of which a tRNA molecule binds. Primer extension, partial RNA digestion, and circularization generate a substrate for extensive DNA synthesis. Ultimately, a circular duplex DNA molecule is formed, and it is the likely substrate for integration into a host chromosome. Evidence suggests that two viral RNA molecules must interact at step 2 or 3.

interest has focused on the structure of this enzyme, in order to design inhibitors based on the structure of the active site. The enzyme is a dimer, with one 51-kilodalton and one 66-kilodalton subunit. Both subunits are products of the same gene (see Figure 25.12). The smaller subunit, which results from proteolytic degradation of the larger subunit, collapses about the larger subunit, protecting it from degradation. As seen with DNA-dependent DNA polymerases, the large subunit forms a “hand,” which grasps DNA. Analysis of the dimer structure shows the polymerase and RNase H sites to be about 20 nucleotides apart (Figure 25.47). This structural relationship coordinates the two activities, with insertion of a new nucleotide occurring concomitantly with excision of a ribonucleotide from the RNA strand of the hybrid. One of the great difficulties in devising vaccines against HIV derives from the absence of a proofreading exonuclease in HIV reverse transcriptase. This leads to frequent uncorrected replication errors and high rates of spontaneous mutagenesis, allowing the virus to generate variants that have resistance to antiviral antibodies produced via vaccination.

FIGURE 25.47

Structure of HIV reverse transcriptase. The enzyme was crystallized in the presence of a primer–template complex and a substrate analog (a dideoxyribonucleoside triphosphate) positioned at the 3′ primer terminus. The p66 subunit is shown in color, with the fingers in red, the palm in yellow, the thumb in orange, a connector domain in blue, and the RNase H domain in purple. The p51 subunit is in gray, and the nucleotide substrate (lower left) is in brown. PDB ID 1RTD.

**SUMMARY**

DNA replication begins at fixed points on chromosomes. In most cases two replication forks are formed as a consequence of initiation. In each fork, parental DNA strands unwind, and each strand serves as template for DNA polymerase-catalyzed synthesis of a daughter strand. Both leading and lagging strands in a fork grow in a 5′ → 3′ direction, meaning that one strand must grow backward in short segments (Okazaki fragments) from the fork. That one strand, the lagging strand, elongates discontinuously, with each segment being initiated by a short RNA primer. Enzymes and proteins at the replisome, which propagates a replication fork, include DNA polymerase, which incorporates deoxyribonucleoside 5′-monophosphate moieties from dNTP substrates; sliding clamps, which enhance polymerase processivity; clamp loaders, which wrap the circular clamps about DNA and also carry out clamp unloading; helicases, which unwind parental DNA strands, using energy provided by ATP hydrolysis; primase, which synthesizes RNA primers; single-strand DNA-binding protein, which stabilizes DNA in the single-strand conformation to act as template and then facilitates renaturation with the nascent strands as deoxyribonucleotides are incorporated; and topoisomerases, which relieve torsional stress ahead of the fork and, in prokaryotes, introduce negative supercoiling into product DNA. Topoisomerases also decatenate (unlink) daughter DNA molecules at the end of a round of replication, thereby permitting chromosome segregation. Initiation of replication of duplex DNA involves binding of proteins to specific origin sequences, which leads to DNA bending and facilitates local DNA denaturation adjacent to the protein binding sites. This is followed by binding and activity of a helicase to further unwind parental DNA strands and then by primase to synthesize short RNA primers, which are extended by DNA polymerase. Replication of linear DNAs requires additional processes; in eukaryotic cells telomerase is responsible for copying chromosome ends, or telomeres. The great accuracy of DNA replication is maintained partly by substrate discrimination in the nucleotide insertion step and partly by a 3′ exonuclease activity that scans newly replicated DNA and excises mispaired 3′-terminal nucleotides. Replication of viral RNAs is far less accurate because of a lack of editing activity in RNA replicases.

One of the co-discoverers of reverse transcriptase argues that genetic variability of HIV results from more than just a lack of a proofreading exonuclease.

PROBLEMS

- Describe an experimental approach to determining the *processivity* of a DNA polymerase (that is, the number of nucleotides incorporated per chain per polymerase binding event).
- *2. After Okazaki's proposal of discontinuous DNA chain growth, there was much controversy about whether both DNA strands are synthesized discontinuously, or only the lagging strand. Clearly, there is no need for the leading strand to be synthesized in fragments, but many workers found that pulse-labeled DNA fragments hybridized to both parental DNA strands. This finding indicated that both parental strands served as the template for synthesis of short DNA fragments. Propose an alternative mechanism by which leading strand replication could generate short fragments, and propose an experimental test of your suggestion. (Hint: Look at Chapter 26.)
- The buoyant density of DNA can be increased by incorporation of either heavy stable isotopes, such as ^{15}N , or base analogs, such as 5-bromouracil. This problem asks you to calculate the density increment generated by each technique. In all calculations the density of "light" *E. coli* DNA is 1.710 g/mL. The G + C content is 51 mol % (that is, 51 moles of G + C per 100 moles of DNA nucleotides). Residue molecular weights of cesium salts of nucleotides are as follows: dAMP, 445; dTMP, 436; dGMP, 461; dCMP, 421; 5-bromo-dUMP, 501.
 - Calculate the buoyant density of *E. coli* DNA when all ^{14}N atoms are replaced with ^{15}N atoms.
 - Calculate the buoyant density of *E. coli* DNA when all thymine residues are replaced with 5-bromouracil.
- A mixture of four α - ^{32}P -labeled ribonucleoside triphosphates was added to permeabilized bacterial cells undergoing DNA replication,

and incorporation into high-molecular-weight material was followed over time, as shown in the accompanying graph. After 10 minutes of incubation a 1000-fold excess of unlabeled ribonucleoside triphosphates was added, with the results shown in the graph.

- Why was the excess of unlabeled rNTPs added?
- How could you tell that radioactivity is being incorporated as ribonucleotides, rather than an alternative such as reduction to deoxyribonucleotides, followed by incorporation?
- What does this experiment tell you about the process of DNA replication?

5. Deoxyadenylate residues in DNA undergo deamination fairly readily, as do deoxycytidylate residues.
- What is the product of dAMP deamination?
 - The deamination product is known to base-pair with A, C, or T. What would be the genetic consequences if this deaminated site in DNA were not repaired and if it paired with C on the next round of replication?
6. The *E. coli* chromosome is 1.28 mm long. Under optimal conditions the chromosome is replicated in 40 minutes.
- What is the distance traversed by one replication fork in 1 minute?
 - If replicating DNA is in the B form (10.4 base pairs per turn), how many nucleotides are incorporated in 1 minute in one replication fork?
 - If cultured human cells (such as HeLa cells) replicate 1.2 m of DNA during a 5-hour S phase and at a rate of fork movement one-tenth of that seen in *E. coli*, how many origins of replication must the cells contain?
 - What is the average distance, in kilobase pairs, between these origins?
7. DNA ligase has the ability to relax supercoiled circular DNA in the presence of AMP but not in its absence.
- What is the mechanism of this reaction, and why is it dependent on AMP?
 - How might one determine that supercoiled DNA had in fact been relaxed?
- *8. A recent paper reports that, in mammalian cells, genes that are expressed in a particular cell are replicated during the first half of S phase, and genes not expressed in that cell are replicated in the latter half of S phase. Briefly describe an experiment that could lead to this conclusion.
9. Although DNA polymerases require both a template and a primer, the following single-strand polynucleotide was found to serve as a substrate for DNA polymerase in the absence of any additional DNA.

Give the structure of the product of this reaction.

10. The 3' exonuclease activity of *E. coli* DNA polymerase I was found to show no discrimination between correctly and incorrectly base-paired nucleotides at the 3' terminus; properly and improperly base-paired nucleotides are cleaved at equal rates there. How can this observation be reconciled with the fact that the 3' exonuclease activity increases the accuracy with which template DNA is copied?
11. 2',3'-Dideoxyinosine has been approved as an anti-HIV drug. Propose a mechanism by which it might block the growth of the HIV virus.
12. Aphidicolin-resistant mutants of mammalian cells often have alterations in the structure of DNA polymerase α that render the enzyme insensitive to inhibition. However, some mutants show alterations, not in DNA polymerase but in ribonucleotide reductase. How might a change in the latter enzyme cause an aphidicolin-resistant phenotype?
13. The *E. coli* chromosome requires 40 minutes for its complete replication, even in an optimally nourished cell. However, bacterial cells can divide as frequently as every 20 minutes. How can cells divide more rapidly, apparently, than their DNA can be copied?
- *14. Supercoiled DNA is more compact than relaxed DNA of the same molecular weight, which gives supercoiled DNA greater electrophoretic mobility. Why, then, does positively supercoiled DNA migrate more slowly than relaxed in the experiment depicted in Figure 25.26? (Note: Read Tools of Biochemistry 25A before attempting to answer this question.)

15. An alternative to the model shown in Figure 25.23 for the action of homodimeric helicases is an "inchworming" model. In this model, the subunit bound to DNA moves forward by a few base pairs, unwinding as it goes, and with the 3' end bound to that subunit as it moves toward the 5' end of the bound strand. Then, ATP hydrolysis triggers a conformational change that leads to release of the 3' end of the unwound DNA so that the process can repeat, as shown.

Identify a difference between this and the hand-over-hand model of Figure 25.23 that could be used experimentally to distinguish between the two models.

16. Propose a mechanism by which a type II topoisomerase could use the energy of ATP hydrolysis to scan a large DNA molecule and, thereby, to direct that the enzyme will catalyze largely "disentangling" reactions (decatenation and unknotting).
17. The exponential nature of PCR allows spectacular increases in the abundance of a DNA sequence being amplified. Consider a 10-kbp DNA sequence in a genome of 10^{10} base pairs. What fraction of the genome is represented by this sequence; i.e., what is the fractional abundance of this sequence in this genome? Calculate the fractional abundance of this target sequence after 10, 15, and 20 cycles of PCR, starting with DNA representing the whole genome and assuming that no other sequences in the genome undergo amplification in the process.
18. Isolated rat liver mitochondria are able to carry out incorporation of added deoxyribonucleoside triphosphates into mitochondrial DNA by a semiconservative process. With this system or using a cell culture system,
- Outline an approach to determine whether RNA formed during mtDNA replication represents primers for DNA synthesis.
 - Outline an approach to determine whether mtDNA replication forks move unidirectionally or bidirectionally.
19. DNA precursor imbalances are mutagenic. For example, if dGTP accumulates, it can compete with dATP for incorporation opposite dTMP in the template, leading to a transition mutation. Recently it was reported that a modest balanced increase in all four dNTPs, three- or fourfold, stimulated mutagenesis out of proportion to the dNTP pool change. Describe a mechanism by which this could occur.
20. A plasmid DNA was isolated and shown by two-dimensional agarose gel electrophoresis to have a range of topoisomers, as shown in Tools of Biochemistry 25A.
- Sketch the expected 2D gel pattern after treatment of this DNA with topoisomerase I.
 - Sketch the expected 2D gel pattern after treatment of this DNA with DNA gyrase and ATP.

TOOLS OF BIOCHEMISTRY 25A

TWO-DIMENSIONAL GEL ELECTROPHORETIC ANALYSIS OF DNA TOPOISOMERS

When one analyzes DNA molecules resolved by agarose gel electrophoresis (see Tools of Biochemistry 2A), DNA is visualized in the gel by soaking the gel with a fluorescent dye, such as **ethidium bromide**, or EtBr.

**Ethidium bromide
(EtBr)**

This dye binds to duplex DNA by **intercalation**; the molecule is planar and about the size of one base pair, so it can fit between two adjacent DNA base pairs, forcing them apart. Intercalation greatly enhances the molecule's fluorescence, and DNA can then be visualized by observing an EtBr-treated gel under ultraviolet light.

But there is another way in which intercalators like EtBr are used in electrophoresis. If they are present *during* the electrophoresis, they can aid in distinguishing topoisomers. In forcing adjacent base pairs apart, EtBr tends to unwind a double helix. In B-form DNA, with about 10 base pairs per turn, two adjacent base pairs are rotated with respect to each other by 36° (360° per complete turn). One molecule of EtBr creates about 27° of unwinding, affecting the hydrodynamic properties of circular DNA in the following way. Recall from Chapter 4 that L , the linking number, is the sum of turns created by twist and writhe. EtBr binding decreases the number of turns needed to create an unconstrained duplex; it decreases T , the twist. Because L doesn't change unless the molecule is broken, the writhe component is affected: The number of turns devoted to writhe increases. In other words, EtBr increases the positive superhelicity of the molecule. Thus, an underwound molecule tends to

become relaxed because it loses negative superhelicity, whereas a relaxed closed duplex becomes overwound, and an overwound molecule becomes more so. Electrophoretic mobility through a gel is a function of compactness of the migrating molecule, with a relaxed duplex being least compact and, hence, most slowly migrating.

One can analyze the distribution of topoisomers in a circular DNA by two-dimensional gel electrophoresis, with the first dimension run in an ordinary agarose gel and the second dimension run in the presence of EtBr or a similar intercalating dye. For the plasmid DNA shown in Figure 25A.1a, these topoisomers include nicked duplexes, which are relaxed whether or not EtBr is present and which migrate slowly in both dimensions. For the slightly supercoiled molecules, both overwound and underwound topoisomers are present. For example, the species labeled 1 was originally overwound and has become more so, as is evident by its movement in the second dimension. Species 6, on the other hand, was underwound and moved more slowly in the second dimension, even though 1 and 6 originally had the same number of superhelical turns (writhe). The remaining species were present originally only as underwound topoisomers. At the bottom (species 18 and 22 and their neighbors) are topoisomers that could not be resolved in the first dimension but are resolved when the negative writhe is decreased, in the second dimension.

In Figure 25A.1b the plasmid analyzed was identical, except for the insertion of a 16-base-pair alternating G-C sequence, which under certain conditions forms Z-DNA (left-handed). The intercalating dye forces this DNA back to a right-hand helix, and this affects the number of superhelical turns. The topoisomers labeled 17 and 20 are species that contained the GC-rich insert in Z conformation before administration of the intercalating dye.

CHAPTER 26

DNA Restructuring: Repair, Recombination, Rearrangement, Amplification

Our focus now shifts from DNA as a *template* for its own replication to DNA as a *substrate*, in a number of processes that we categorize as **information restructuring**. DNA has long been thought to be particularly well suited to its role in storing genetic information because of its chemical stability. To be sure, the fact that DNA from prehistoric animals and humans can be isolated and sequenced attests to its stability. However, like all biomolecules, DNA is continuously exposed to damaging agents, including radiation, environmental chemicals, and endogenous agents such as reactive oxygen species. In addition, chemical change is introduced as errors during normal DNA replication. Meeting its function as a stable repository of genetic information requires that the cell be able to efficiently repair damage suffered by DNA. We will see that genetic recombination—the breakage and rejoining of DNA molecules, originally thought to be a process ensuring the diversification of the genome—is also an integral part of some repair mechanisms. Finally, we will consider the plasticity of the genome, in terms of the ability of DNA segments to move from point to point within a genome, or from genome to genome, or to undergo selective amplification.

From the biochemist's standpoint, information restructuring is less accessible than DNA replication. Replication is a central pathway that is a major metabolic event in the lifetime of all cells, and the activities of the enzymes and proteins involved are relatively high. As a result, their discovery and characterization, though elegant, were fairly straightforward. By contrast, information restructuring involves quantitatively minor pathways, with far less mass conversion per cell. Detection of the enzymes involved is correspondingly more difficult. For example, although DNA methylation has profound effects on gene integrity or expression (see Chapter 29), methylation may involve only one or a few sites per gene. Because of the low activities involved, analysis of DNA methylation requires experimental techniques much more sensitive than those used to analyze DNA replication.

The processes we consider in this chapter include (1) metabolic responses to DNA structural damage, principally mutagenesis and repair; (2) recombination,

FIGURE 26.1

A summary of the major processes in information restructuring. Restriction and modification were discussed in Chapter 24, and the other processes are presented in this chapter.

whereby the contents of a genome are redistributed, for example, during sexual reproduction; (3) gene rearrangements, including transpositions of DNA segments from one chromosomal integration site into another and the joining of DNA segments from distant parts of a genome; and (4) gene amplification, an increase in the copy number of individual segments of DNA, which occurs both as a normal developmental process and as a response to environmental stresses (Figure 26.1). Collectively, these processes are essential to the survival of cells. In broader terms, recombination and gene rearrangements are the source of most of the genetic variability in a population of cells or organisms and, along with mutation, form the basis for evolutionary changes. Other important information restructuring processes, which do not occur at the DNA level, are described elsewhere. They include alternative splicing and RNA editing (see Chapters 27 and 29).

DNA Repair

Types and Consequences of DNA Damage

Unprogrammed chemical changes occur in all biological macromolecules, either because of environmental damage or errors in synthesis. For most biomolecules, including RNA, protein, and membrane phospholipids, the effects of such changes are minimized by turnover and replacement of altered molecules. DNA is distinctive, however, in that its information content must be transmitted virtually intact from one cell to another during cell division or reproduction of an organism. Thus, DNA has a special need for metabolic stability. This stability is maintained in two ways—by a replication process of high accuracy, and by mechanisms for correcting genetic information when DNA suffers damage. In Chapter 25 we described mechanisms used to ensure high replication fidelity. Here we discuss the kinds of environmental and endogenous damage that occur and the several processes repairing that damage. These processes include (1) **direct repair**, in which a damaged DNA base undergoes a chemical or photochemical reaction to restore the original

structure; (2) **nucleotide excision repair**, in which a section of DNA that contains a damaged site is excised and replaced with normal DNA; (3) **base excision repair**, which starts with cleavage of the glycosidic bond connecting a damaged base to the DNA sugar–phosphate backbone; (4) **mismatch repair**, a process that recognizes DNA mismatches created either by replication errors, nonhomologous recombination, or damage to one DNA base and corrects the error; (5) **daughter-strand gap repair**, in which newly replicated DNA duplexes undergo genetic recombination, with ultimate removal of the damaged DNA segment; (6) **translesion synthesis**, or error-prone repair, in which DNA damage that blocks replicative DNA polymerases can be copied by specialized, but often inaccurate, DNA polymerases; and (7) **double-strand break repair**, in which severed ends of a duplex can be rejoined.

Some of the most prominent endogenous DNA-damaging reactions include (1) depurination, the hydrolytic rupture of the glycosidic bond between deoxyribose and a purine base; (2) deamination, usually the hydrolytic conversion of a DNA-cytosine residue to uracil; (3) oxidation, notably, the oxidation of guanine to 8-oxoguanine or of thymine to thymine glycol; and (4) nonenzymatic methylation by *S*-adenosylmethionine. Some of these reactions are shown in Figure 26.2, with an indication of their frequency in mammalian cells. In addition, replication errors account for many thousands of mismatched DNA nucleotides per day.

Environmental DNA-damaging agents include ionizing radiation; ultraviolet radiation; DNA-methylating reagents, such as *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine (MNNG); DNA-cross-linking reagents, such as the anticancer drug **cisplatin**; and

FIGURE 26.2

Endogenous DNA-damaging reactions. The approximate frequency of each reaction, in number of lesions per mammalian cell per day, is indicated. ROS, reactive oxygen species.

Benzo(a)pyrene

bulky electrophilic agents, such as **benzo[a]pyrene**, one of the carcinogenic hydrocarbons in tobacco smoke. We shall say more about the damage induced by such reagents and the repair processes that correct such damage. We will see that some repair processes are accurate, meaning that the original DNA sequence is restored, while some lead to mutations because the repair process is inaccurate. Because it is now clear that many cancers result from an accumulation of somatic cell mutations (see Chapter 23), the mechanisms of DNA repair are under intense study as determinants of an animal's susceptibility to cancer.

In studying mechanisms of DNA repair, one first needs to identify the chemical forms of DNA alteration that are subject to repair. Most of the early discoveries about DNA repair were made in studies with ultraviolet light-irradiated organisms. DNA was identified as the principal biological target for UV irradiation, partly through determination of **action spectra**—irradiation of bacteria or phages with UV light and determination of the wavelengths most effective in stimulating mutagenesis or death. Those wavelengths lie near 260 nm, where DNA light absorption is maximal.

When one examines either UV-irradiated DNA or the DNA extracted from a UV-irradiated organism, one detects small amounts of many different altered DNA constituents, called **photoproducts**. Prominent among them are intrastrand dimers consisting of two pyrimidine bases joined by a cyclobutane ring structure involving carbons 5 and 6 (Figure 26.3a). **Thymine dimers**, formed from two adjacent DNA thymine residues, were identified quite early as biologically significant photoproducts because the relative abundance of thymine dimers in irradiated DNA correlated most closely with death of irradiated phages or bacteria. Thus, the ability of an organism to survive ultraviolet irradiation was related directly to its ability to remove thymine dimers from its DNA. Dimerization draws the adjacent thymine residues together, distorting the helix such that replicative polymerization past this site is blocked.

FIGURE 26.3

Structures of pyrimidine dimer photoproducts.

For many years it was thought that ultraviolet light–induced *mutagenesis*, as well as cell death, was also caused primarily by cyclobutane thymine dimers. However, more recent data suggest that a different pyrimidine–pyrimidine dimer, called **6–4 photoproduct**, is probably the principal cause of UV-induced mutations. As shown in Figure 26.3b, these products are also dimers, linked via C-6 of the 5' pyrimidine (either thymine or cytosine) and C-4 of the 3' pyrimidine (usually cytosine, but occasionally thymine, as shown in Figure 26.3). The idea that 6–4 photoproducts are responsible for mutations in UV-irradiated DNA is supported by experiments in which cyclobutane thymine dimers were completely removed from UV-irradiated DNA by **photoreactivation** (see the next section). When this DNA was introduced into bacteria, the dimer removal had no effect on mutation frequency. However, the actual significance of 6–4 photoproducts in UV mutagenesis has not yet been established.

Direct Repair of Damaged DNA Bases: Photoreactivation and Alkyltransferases

Of the half dozen well-understood DNA repair processes, most involve removal of the damaged nucleotides, along with several adjacent residues, followed by replacement of the excised region using information encoded in the complementary (undamaged) strand. However, at least two processes involve reactions that *directly change* the damaged bases, rather than removing them.

Photoreactivation

A widely distributed enzyme, called **photoreactivating enzyme**, or **DNA photolyase**, repairs cyclobutane pyrimidine dimers in the presence of visible light. A wavelength of 370 nm is most effective. The enzyme binds to DNA in a light-independent process, specifically at the site of pyrimidine dimers. In the presence of visible-wavelength light, the bonds linking the pyrimidine rings are broken, after which the enzyme can dissociate in the dark. Clues to the mechanism have come with the finding that the enzyme contains two chromophores. (Recall from Chapter 16 that a chromophore is a structural moiety that absorbs light of characteristic wavelengths.) One chromophore is bound flavin adenine dinucleotide, deprotonated and in the reduced state (FADH[−]; see Figure 26.4); the second in some photolyases is 5,10-methenyltetrahydrofolate (see Chapter 20) and in others is 8-hydroxy-5-deazaflavin. Mechanistic studies suggest a process akin to photosynthesis, with the second chromophore functioning as a light-harvesting factor, and transmitting light energy by fluorescence resonance energy transfer (FRET) to FADH[−], which functions like the photochemical reaction center, transferring an electron to the dimer and breaking the pyrimidine–pyrimidine bonds by a free radical mechanism. The crystal structure of the *E. coli* photolyase shows 5,10-methenyltetrahydrofolate bound at the surface, between N-terminal and C-terminal domains, with FADH[−] bound deeply within the C-terminal domain. Figure 26.4 shows the probable reaction pathway.

Although photolyase has been detected in numerous eukaryotic systems, recent evidence indicates that human cells do not contain an enzyme for photoreactivation. Thinning of the earth's ozone layer has been blamed for population declines in certain frog species, which have been shown to lack photolyase and, hence, to suffer damage from solar ultraviolet irradiation, particularly during embryonic development in clear lakes, which are transparent to UV rays. However, other factors have also been blamed.

O⁶-Alkylguanine Alkyltransferase

Treatment of DNA with a methylating or ethylating reagent is comparable to ultraviolet irradiation in that various modified DNA bases are formed, some of which are lethal if not repaired and some of which are mutagenic. Some alkylating

Cyclobutane thymine dimers are the most lethal photoproduct in UV light–irradiated DNA. 6–4 photoproduct may be the strongest mutagenic product.

DNA can be repaired directly, by changing a damaged base to a normal one, or indirectly, by replacing a DNA segment containing the damaged nucleotide.

agents are used in cancer chemotherapy because of their ability to block DNA replication and, hence, cell proliferation. Some are widely used as mutagens in the laboratory. Three methylating or ethylating reagents are shown in the margin on page 1083.

The bases altered by these reagents are primarily purines (phosphate oxygens are also targets), and the spectrum of products formed varies with the reagent used. The most highly mutagenic of these products, O⁶-alkylguanine, is mutagenic because the modified base has a very high probability of pairing with thymine when the modified strand replicates (Figure 26.5). Thus, alkylation of a DNA-guanine stimulates a GC → AT transition (see margin, where mG is a methylguanine residue).

Repair of this type of damage involves an unusual enzyme, O⁶-alkylguanine alkyltransferase, which transfers a methyl or ethyl group from an O⁶-methylguanine or O⁶-ethylguanine residue to a cysteine residue in the active site of the protein. Remarkably, this “catalyst,” which is widely distributed in prokaryotes and eukaryotes, can function only once. Having become alkylated, it cannot remove the alkyl group, and the protein molecule turns over. Thus, the term *enzyme* is a misnomer. In bacteria the protein regulates both its own synthesis and that of another repair enzyme, a DNA-*N*-glycosylase that we shall discuss later. The regulation involves

activation of the transcription of genes encoding these two proteins. There is evidence that the *alkylated* form of the alkyltransferase is the specific form of the transcriptional activator. This allows the cell to adapt to alkylation damage by using the alkylated protein as a specific signal to produce more of the proteins needed to repair the damage.

Nucleotide Excision Repair: Excinucleases

Nucleotide excision repair (NER) was originally discovered as an enzyme system capable of repairing thymine dimers created in DNA by UV irradiation. Unlike photoreactivation, this process can take place in the dark. The enzyme system involved, which in *E. coli* includes the products of genes *uvrA*, *uvrB*, and *uvrC*, is now known to act upon a number of DNA damaged sites containing lesions that may be quite bulky, such as those created by large alkyl groups, and that distort the DNA double helix. Very similar systems exist in mammalian cells and in yeast, so the process is probably universal.

As shown in Figure 26.6 for *E. coli*, the three-subunit UvrABC enzyme recognizes a lesion (a thymine dimer in the example shown) and, with the help of ATP hydrolysis, forces DNA to bend, leading to cleavage of the damaged strand at two sites—seven nucleotides to the 5' side of the damaged site and four nucleotides to the 3' side—leaving a potential gap eleven nucleotides in length, with a 3' hydroxyl group and a 5' phosphate at the ends. Polymerase and ligase action then replace the damaged 11-mer with undamaged DNA. Helicase II, the product of the *uvrD* gene, is also required, presumably to unwind and remove the excised oligonucleotide, which is ultimately broken down by other enzymes. The UvrABC enzyme is not a classical endonuclease because it cuts at two distinct sites, and the term **excinuclease** has been proposed for it, denoting its role in *excision* repair. This system is also involved in repairing another type of DNA damage—covalent cross-linking of the two strands to each other. Here, in order to preserve an intact template strand, the two strands are repaired sequentially, one after the other.

Excision repair also occurs in mammalian cells, as shown by the discovery of a human excinuclease that cleaves at positions -22 and $+6$ relative to a thymine dimer. A significant difference is the involvement of two different endonucleases in human excision repair—one for cutting on the 5' side and one on the 3' side. Excision repair in humans originally came to light through studies of a rare genetic disease called **xeroderma pigmentosum (XP)**. XP is actually a family of diseases, in which one or more enzymes of the excision pathway are deficient. In affected humans there is at present no known way to treat the condition. The biological consequences of XP include extreme sensitivity to sunlight and a high incidence of skin cancers. Although overexposure to the ultraviolet rays in sunlight increases the risk of skin cancer for all humans, the greatly increased skin cancer frequency in XP patients highlights the importance of UV repair pathways to mammals. Because there is no known treatment for XP, affected individuals must avoid sunlight. Two other diseases—**trichothiodystrophy (TTD)** and **Cockayne's syndrome (CS)**—result from other defects in NER proteins. Although these conditions do not involve abnormal carcinogenesis, other systems are profoundly affected, and mean lifespan is only 6 years for TTD and 12 for CS.

FIGURE 26.6

Excision repair of thymine dimers by the UvrABC excinuclease of *E. coli*. A complex of A and B proteins tracks along DNA until it reaches a thymine dimer or other damaged site, where it halts and forces the DNA to bend. UvrA (a “molecular matchmaker”) then dissociates, allowing UvrC to bind to B. The BC complex cuts on both sides of the dimer. Helicase, polymerase, and ligase remove the damaged undercamer and replace it with new DNA. This system may use DNA polymerase II as well as pol I.

From *Science* 259:1415–1420, A. Sancar and J. E. Hearst, Molecular matchmakers. © 1993. Reprinted with permission from AAAS. Adapted with permission from Aziz Sancar.

Direct repair enzymes include photolyase, which uses light energy to repair pyrimidine dimers, and alkyltransferases, “enzymes” that are inactivated after just one catalytic cycle.

Excision repair involves endonuclease cleavage on both sides of a damaged site, followed by replacement synthesis.

A significant difference in NER between prokaryotes and eukaryotes is that in the latter the substrate for repair is chromatin, not naked DNA. The amount of uncoated DNA required to assemble an NER complex is estimated to be about 100 base pairs. Because this is longer than the internucleosomal spacer region (20–80 base pairs), this must mean that core particles are either displaced or else they slide out of the way in order for damage to be repaired. These processes are under intense investigation.

Recent studies of nucleotide excision repair show that active genes (those undergoing transcription) are preferred substrates for excision repair, and within these genes the template DNA strand is preferentially repaired. This **transcription-coupled repair** may initiate when a transcribing RNA polymerase becomes stalled at the site of a DNA lesion. Coupling transcription with repair helps to ensure the integrity of genes that are actually used. In mammalian cells, transcription-coupled repair is a specialized mode of NER that requires additional proteins. Cockayne's syndrome results from genetic defects in one or more of the human enzymes of transcription-coupled repair. Another human gene, BRCA1, is also implicated in transcription-coupled excision repair. Mutations in BRCA1 are associated with increased risk of breast and ovarian cancer. One mode of mammalian NER requires both DNA polymerases δ and κ , while another mode requires only pol ϵ .

As noted above, NER also corrects DNA that has been damaged by formation of bulky DNA adducts. Many chemical carcinogens of environmental significance give rise to such adducts. In the absence of repair, or following error-prone repair, these adducts can lead to mutations. For example, polycyclic aromatic hydrocarbons (PAH) are prevalent organic pollutants formed by incomplete combustion, for example, by coal burning. As with many environmental carcinogens, PAH are not directly reactive with DNA. Indeed, their lack of chemical reactivity accounts for their persistence. However, PAH can undergo *metabolic activation*, that is, *biotransformation* leading to reactive electrophilic intermediates that can bind to DNA and other macromolecules. This metabolism can occur in the liver and in other organs. The best-characterized route for metabolic activation of PAHs is the pathway for benzo[*a*]pyrene metabolism, shown (in simplified form) in Figure 26.7. First, oxygenation catalyzed by cytochrome P450 generates an epoxide intermediate. This epoxide is hydrolyzed, in a reaction catalyzed by *epoxide hydrolase*, to give a dihydrodiol product. Finally, a second cytochrome P450-catalyzed oxygenation produces the highly reactive benzo[*a*]pyrene 7,8-dihydrodiol 9,10-epoxide (BPDE). BPDE is highly reactive with DNA, forming bulky covalent adducts primarily, but not exclusively, with guanine.

Base Excision Repair: DNA N-Glycosylases

The other form of excision repair, **base excision repair**, or BER, also removes one or more nucleotides from a site of base damage. However, this process initiates with enzymatic cleavage of the glycosidic bond between the damaged base and deoxyribose.

Replacement of Uracil in DNA by BER

One of the best-understood BER systems involves scanning of DNA, to remove uracil. Uracil can base-pair with adenine in a DNA duplex, and DNA polymerases readily accept deoxyuridine triphosphate as a substrate in place of thymidine triphosphate. Yet cells possess a rather elaborate two-stage mechanism that prevents deoxyuridylate residues from accumulating in DNA. The first stage of this process, described in Chapter 22, involves an active deoxyuridine triphosphatase that cleaves dUTP to dUMP and pyrophosphate, thereby minimizing the dUTP pool and its use as a replication substrate. The second stage involves **uracil-DNA N-glycosylase** (UNG), an enzyme that removes any dUMP residues that might have arisen through incorporation of a dUTP that escaped the action of dUTPase.

As shown in Figure 26.8, uracil-DNA N-glycosylase hydrolytically cleaves the glycosidic bond between N-1 of uracil and C-1 of deoxyribose. This yields free uracil and DNA with an **apyrimidinic site**, that is, a sugar residue lacking an attached pyrimidine. Another enzyme, **apyrimidinic endonuclease** (AP endonuclease) recognizes this site and cleaves the phosphodiester bond on the 5' side of the deoxyribose moiety. This is followed in bacteria by the nick translation activity of DNA polymerase I, which inserts dTTP as a replacement for the dUMP that was removed, displacing the deoxyribose phosphate residue in the AP site. This is removed by a **deoxyribose-5'-phosphatase**. The resulting nick is sealed by DNA ligase.

Uracil N-glycosylase, like all DNA glycosylases examined to date, acts by flipping the target base out of the DNA duplex and binding it in a pocket where cleavage occurs. Structural analysis of human UNG shows that the pocket is small enough to exclude purine bases. More important, as shown in Figure 26.9, the pocket excludes thymine because of negative steric interaction between the thymine methyl group at C5 and Tyr-147. (Note: By convention eukaryotic genes and gene products are denoted with capital letters; thus, *UNG* is the human gene that encodes the protein UNG. In bacteria, gene *ung* encodes protein Ung.)

Why go to all this trouble just to replace a nucleotide that does not affect the information encoded in DNA? The likely answer is that uracil substituted for thymine (that is, base-paired with adenine) is not the true target of this DNA repair

FIGURE 26.9

The uracil-binding pocket of human UNG. The figure shows interactions with Asn-204, known to be involved in catalysis, and the negative steric interaction that would occur with Tyr-147, if the bound base were thymine instead of uracil.

FIGURE 26.8

Action of the DNA uracil repair system. Uracil-DNA N-glycosylase (also called Ung) removes uracil, leaving an apyrimidinic site. A specific endonuclease recognizes this site and cleaves on the 5' side. DNA polymerase I replaces the missing nucleotide, leaving deoxyribose-5-phosphate on the 5' side of the nick. This is removed hydrolytically, and DNA ligase seals the nick.

A base excision repair process removes uracil residues in DNA, whether they arose through deamination of cytosine residues or incorporation of deoxyuridine nucleotides instead of thymidine nucleotides.

system. Uracil residues in DNA can also arise through spontaneous deamination of cytosine residues. The latter alteration does change the genetic sense because it converts a G–C base pair to a G–U pair, and in a subsequent round of replication the U-containing strand would give rise to an A–T base pair. The uracil repair system prevents this mutation but does not discriminate between uracils paired with adenines or with guanines. Consistent with this model is the **hypermutable** phenotype displayed by mutants lacking an active uracil *N*-glycosylase. Such strains exhibit elevated rates of spontaneous mutagenesis, resulting from the accumulation of DNA dUMP residues paired with dGMP.

The replacement of uracil by thymine in DNA is one example of BER. Whereas the process always begins with cleavage of a glycosidic bond, BER proceeds via somewhat different pathways, as shown in Figure 26.10. In the center is the most common pathway, like that shown for DNA-uracil repair, with glycosylase action followed by action of an AP-endonuclease and deoxyribose-5-phosphatase. However, some DNA glycosylases have an associated **AP-lyase** activity (left pathway) in which the phosphodiester bond on the 3' side of the repair site is cleaved hydrolytically. A phosphodiesterase then removes deoxyribose-5-phosphate, leaving a gap that is filled by DNA polymerase. To the right is shown a “long-patch” repair system seen in some eukaryotic BER pathways. Here, DNA polymerase catalyzes a strand-displacement reaction, with the displaced 5'-terminated “flap” eventually being cleaved by a “flap endonuclease” (FEN1) before final DNA ligase action.

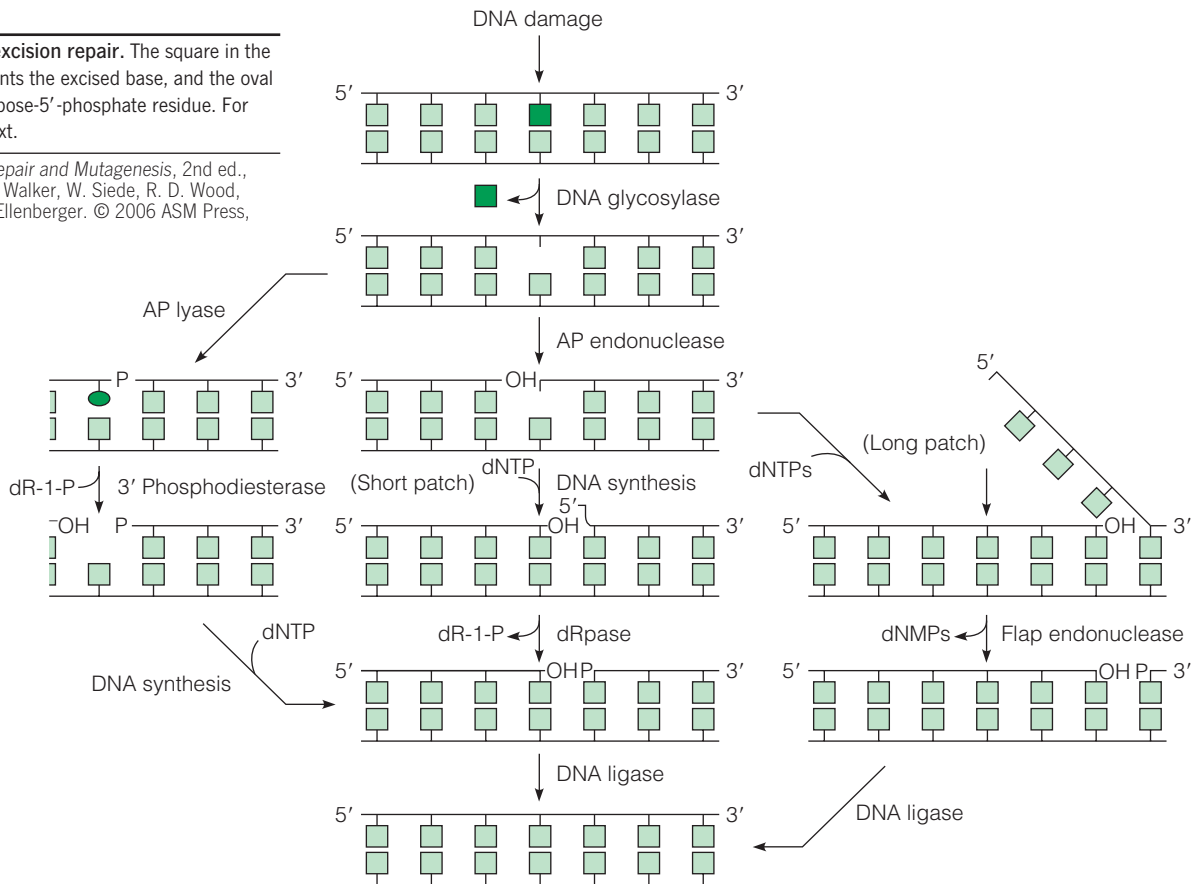

Repair of Oxidative Damage to DNA

Most cells contain several DNA-*N*-glycosylases, including those specific for the alkylated bases *N*-methyladenine, 3-methyladenine, and 7-methylguanine. Of particular interest is the BER process used to repair oxidative DNA damage. As mentioned previously, one of the most abundant oxidation products resulting

FIGURE 26.10

Pathways of base excision repair. The square in the first reaction represents the excised base, and the oval represents a deoxyribose-5'-phosphate residue. For further details see text.

from DNA exposure to reactive oxygen species is 8-oxoguanine. This is a strongly mutagenic alteration because 8-oxoguanine pairs readily with adenine, as shown below.

The A-oxoG mispair can be an intermediate in a **transversion** mutation (AT → CG or CG → AT). In *E. coli* three genes encode proteins that minimize oxidative mutagenesis: *mutM*, *mutY*, and *mutT* (the “mut” designation indicates that mutations in any one of these genes have the effect of increasing the spontaneous mutation rate). All three gene products have mammalian homologs. MutM and MutY are both DNA-base glycosylases. MutM (or its mammalian counterpart, OGG1) cleaves 8-oxoguanine from DNA, to initiate BER. MutY cleaves adenine when it is matched with 8-oxoguanine in the other DNA strand. Interestingly, MutT has nothing to do with base excision repair. Instead, it is a nucleotidase, cleaving 8-oxo-dGTP, the dNTP of 8-oxoguanine, to the corresponding nucleoside monophosphate.

This reaction is thought to “sanitize” cellular dNTP pools, by eliminating a nucleotide whose incorporation into DNA would be strongly mutagenic. Hence, as shown in Figure 26.11, two of the three *mut* gene products act to repair damage caused by the presence of 8-oxoguanine in DNA, while the third, MutT, acts to minimize incorporation of a damaged nucleotide into DNA.

FIGURE 26.11

Actions of *mutM*, *mutY*, and *mutT* gene products in countering the mutagenic effect of 8-oxoguanine (oG). Depending upon the route of introduction of oG to DNA, the pathways shown can cause either GC → AT or AT → GC transversions. MutT hydrolyzes 8-oxo-dGTP and prevents its incorporation during DNA replication. MutM excises oG from a C-G base pair to begin BER. MutY excises A from an A-oG base pair in another BER process, allowing an additional possibility for correcting an error in the next round of replication. Not all possible outcomes are shown in the figure. For example, 8-oxo-dGTP can be incorporated opposite template C, as well as opposite A. Also, MutY can excise A from an A-G base pair, thereby preventing spontaneous transversion mutagenesis. ROS, reactive oxygen species.

Structure of human OGG1 with either guanine or 8-oxoguanine bound flipped out and bound near the catalytic pocket. A combination of forces completely excludes guanine from the catalytic pocket. PDB IDm, 1YQK, 1YQR.

Based upon A. Banerjee, W. Yang, M. Karplus, and G. L. Verdine (2005) *Nature* 434:612–618, Structure of a repair enzyme interrogating undamaged DNA elucidates recognition of damaged DNA.

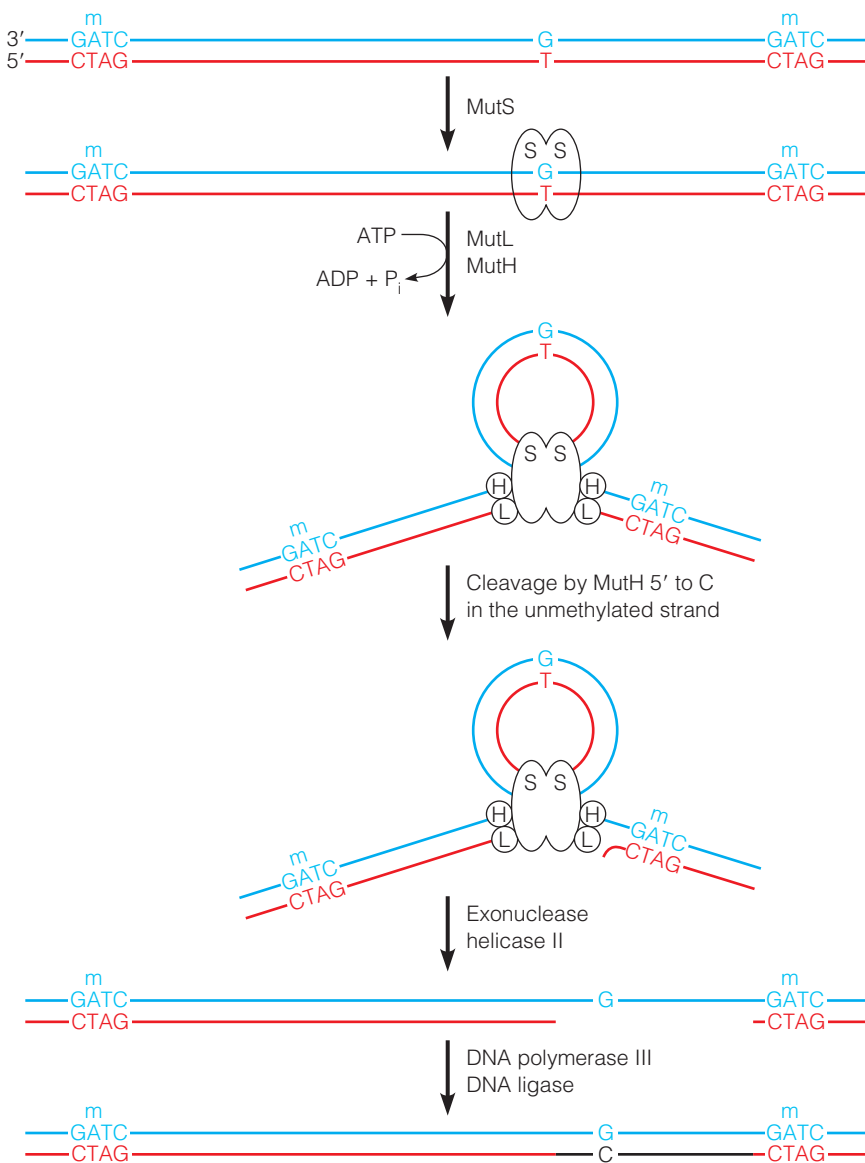

The question of how a DNA glycosylase “interrogates” its DNA substrate to distinguish target from nontarget bases is important because the enzyme must interact with thousands of dGMP residues for every 8-oxo-dGMP that it detects and removes. A cross-linking strategy was used with the human form of OGG1 to trap and determine the structures of complexes with either 8-oxoguanine or guanine flipped out from the double helix. As shown in Figure 26.12, guanine is completely excluded from the 8-oxoguanine-binding pocket. Both attractive and repulsive forces were found to contribute toward this exclusion. A remaining question pertains to the rate of the interrogation process. How much time is required to interrogate each nontarget dGMP compared to that needed for each target oxidized nucleotide?

Mismatch Repair

Mismatches, or non-Watson–Crick base pairs in a DNA duplex, can arise through replication errors, through deamination of 5-methylcytosine in DNA to yield thymine, or through recombination between DNA segments that are not completely homologous. In addition, mismatches result when DNA polymerase slides along its template, creating short loops or bulges in duplex DNA. We best understand the correction of replication errors so that is what we describe here.

If DNA polymerase introduces an incorrect nucleotide, creating a non-Watson–Crick base pair, the error is normally corrected by 3′ exonucleolytic proofreading. If the error is not corrected immediately, the fully replicated DNA will contain a mismatch at that site. This error can be corrected by another process, called **mismatch repair**. In *E. coli* the proteins that participate include the products of genes *mutH*, *mutL*, and *mutS*. Another required gene product, originally called MutU, has now been identified as DNA helicase II (also identified as the product of the *uvrD* gene).

The mismatch correction system scans newly replicated DNA, looking for both mismatched bases and single-base insertions or deletions. MutS binds to DNA at the site of the mismatch, followed by the binding of MutL and then MutH. MutS is a “motor protein,” which uses the energy of ATP hydrolysis to pull DNA from both directions until it reaches the site at which the repair process is to begin. When it finds an appropriate signal, part of one strand containing the mismatched region is cut out and replaced (Figure 26.13). How does the mismatch repair system recognize the right strand to repair? If it chose either strand randomly, it would choose incorrectly half the time and there would be no gain in replication accuracy. The answer is that the mismatch repair enzymes identify the newly replicated strand because for a short period that DNA is unmethylated. In *E. coli* the sequence — GATC — is crucial because that is the site methylated soon

**FIGURE 26.13****Methyl-directed mismatch repair in *E. coli*.**

The newly replicated daughter strand (red) contains a T mismatched to G in the template strand (blue). The mismatch repair system identifies the daughter strand because it is not yet methylated. Thus, this system must function before the newly replicated daughter strand becomes methylated, through action of the Dam methylase on the A residue in the GATC sequence.

after replication, by action of the product of the *dam* gene (DNA adenine methylase). The mismatch repair enzymes look for —GATC— sequences that are not methylated. Recognition of an unmethylated GATC can target that strand for mismatch correction at a site as far as 1 kbp between the mismatch and the GATC site, in either direction. Once the methylation system has acted on all GATC sites in the daughter strand, it is too late for the mismatch repair system to recognize the more recently synthesized DNA strand, and any advantage in total DNA replication fidelity is lost. When the system functions properly, it has the effect of increasing overall replication fidelity by about 100-fold—from about 1 error in 10^7 base pairs replicated to about 1 in 10^9 or more.

As shown in Figure 26.13, the MutHLS complex moves along DNA in both directions until it encounters the nearest 5'-GATC sequence. An endonuclease activity of MutH then cleaves on the 5' side of the G in the unmethylated strand. At that point helicase II unwinds the DNA, moving back past the mismatch, followed by an exonuclease that digests the displaced single strand—exonuclease VII or RecJ nuclease if the cut is 5' to the mismatch, and exonuclease I or X if the cut is on the 3' side (as shown in Figure 26.13). The resultant gap is filled by DNA polymerase III holoenzyme and DNA ligase, working in concert with SSB.

In bacteria the mismatch repair system uses DNA methylation to identify the strand that has a mispaired nucleotide.

Genetic deficiencies in mammalian mismatch repair are often associated with colorectal cancer.

A similar mismatch repair system exists in eukaryotic cells. However, the mismatch recognition step is somewhat more complex because three different MutS homologs (MSH proteins) are involved—MSH2, MSH3, and MSH6. These three proteins form heterodimers, with different mismatch specificities; that is, an MSH2–MSH6 complex recognizes single-base mismatches, insertions, and deletions, while an MSH2–MSH3 complex recognizes insertions and deletions of two to four nucleotides. Four heterodimeric MutL homologs exist also, but a MutH homolog has not been found. In fact, a major unanswered question is the mechanism by which the eukaryotic systems recognize and initiate repair on the newly replicated DNA strand; selective methylation is evidently not involved. Recent evidence suggests that the 5' end of Okazaki fragments may involve the strand-identifying process.

Just as seen with bacteria, mutations in eukaryotic genes that control mismatch repair confer a mutator phenotype, raising spontaneous mutation rates at all loci. How do such mutations affect the biology of human cells? As mentioned in Chapter 23, Lawrence Loeb predicted in 1974 that the progression of a normal cell to a cancer cell involves the creation of a mutator phenotype because the natural mutation rate for somatic cells seemed too low to account for the number of heritable changes that occur during tumor cell progression. Two decades later, this prediction was confirmed, when mutations in mismatch repair proteins were found in tumor cells from individuals with an inherited cancer predisposition called HNPCC (hereditary nonpolyposis colon cancer). To date, germ-line mutations in the genes for five different mismatch repair proteins have been found to be associated with HNPCC. The most common forms of the disease involve mutations affecting either hMLH1 (human Mut L homolog) or hMSH2 (human MutS homolog). The cancer predisposition is inherited in an autosomal dominant fashion, suggesting that most affected individuals are heterozygous, with one wild-type and one nonfunctional allele. Mismatch repair is normal until a somatic cell mutation inactivates the one functional allele, and mismatch repair capacity is essentially abolished, with a consequent increase in spontaneous mutagenesis. It is not clear why mutations affecting mismatch repair are associated specifically with tumors in the colon.

Tumor cells from those affected with HNPCC exhibit a phenomenon called **microsatellite instability**—a large number of mutations in regions of the genome containing repeats of single-, double-, and triple-nucleotide sequences, usually with large increases in the numbers of repeating units in such sequences. These data suggest that the product and template strands can normally slip at such sites so that DNA polymerase copies a short repeating sequence more than once, or else skips a segment. This creates a heteroduplex with a short loop, as shown for deletion mutagenesis in the margin. Normally a replication error of this type would be corrected by mismatch repair, but in a cell lacking normal mismatch repair, such errors would persist and accumulate. Studies of this type have given scientists enormous insight into the nature of cancer as a progressive genetic disease.

Daughter-Strand Gap Repair

Photoreactivation and excision repair are short-term metabolic responses. Both processes can occur within a few minutes after DNA suffers chemical or ultraviolet damage. However, if the photoreactivation and excision repair systems are defective, or become saturated by DNA damage too extensive for their capacities, longer-term systems can come into play in bacteria. One such system, **daughter-strand gap repair**, is comparable to genetic recombination, and indeed involves several of the same proteins. We shall say more about some of these proteins in the section on recombination, but we will briefly introduce the process here, as studied primarily in bacteria.

When a replicative polymerase encounters a thymine dimer or a bulky lesion, it cannot replicate past this site. If a thymine dimer is involved, polymerase III will

incorporate dAMP opposite the first thymine base in the template. The double helix is distorted because of the thymine dimer, causing the structure to be recognized as a mismatch, and the 3' exonucleolytic activity of DNA polymerase III cleaves out the newly incorporated dAMP. Thus, polymerase creates a futile cycle, “idling” at the damage site, converting dATP to dAMP by a continual process of insertion and exonucleolytic cleavage. Synthesis of an Okazaki fragment can commence on the 5' side of the damaged site, leaving a gap starting on the 3' side of the thymine dimer. This gap would be lethal if unrepaired, however, because it would generate a double-strand break in the next round of replication.

A process akin to genetic recombination can take place, not to repair the damage, but to allow replication to continue, saving the damaged site for subsequent repair by another process. Daughter-strand gap repair depends critically upon a multifunctional protein called **RecA**. Bacteria carrying mutations in *recA* were originally characterized as defective in general recombination and DNA repair. We now know that *recA*⁻ bacteria, which specify a defective RecA protein, have a complex phenotype, including defective DNA repair. We shall describe the protein later in this chapter, but for our purposes here one property is important. RecA catalyzes **strand pairing**, or **strand assimilation**—the joining of two different DNAs by homologous base pairing with each other.

Because the gap that is generated at the site of a thymine dimer is created by faulty replication, the gap is close to the replication fork. Therefore, it is also close to the corresponding region on the other daughter duplex (Figure 26.14). If that region has itself not sustained damage, the RecA protein can initiate recombination between two homologous duplexes. The uninvolved parental strand, which is complementary to the damaged parental strand, recombines into the gap, opposite the damaged site. Additional proteins are involved, as shown in the figure and discussed in the section on recombination (see page 1097). A gap now exists in the previously undamaged arm, but because it lies opposite an undamaged template, it can be filled by action of DNA polymerase and DNA ligase. The thymine dimer itself is not repaired in this process, but the process allows time for an excision system to come in later and repair this damage. RecA protein is required for daughter-strand gap repair, particularly in the first reaction, where the undamaged parental strand undergoes pairing with the parental strand opposite the gap. RecA is a bacterial protein, but a related protein, Rad51, allows this process to occur in eukaryotic cells as well.

There is evidence that the response to a blocking lesion in the leading strand template is **replication fork regression** (see Figure 26.15). The fork moves backward instead of forward, to form a “chicken-foot” intermediate. In this structure the blocked leading strand can continue to replicate, using the other daughter strand as the template, and the lesion being bypassed, for repair to occur subsequently. When damage is on the lagging strand (not shown), it need not be corrected immediately, but a gap remains, which must be repaired—usually by daughter-strand gap repair. Note that both in this process and in daughter-strand gap repair the damaged site is not repaired, but replication can continue, and time is allowed for one of the other repair processes to take over and fix the damage.

Translesion Synthesis

As mentioned in the previous section, some types of DNA lesions are noninstructive, in the sense that when a replicative DNA polymerase encounters such a site, it stalls and replication ceases. Such lesions include abasic sites, thymine dimers, and bulky adducts. If damage is so extensive that true repair systems are overwhelmed, then damage-tolerant processes come into play, including the daughter-strand gap repair just described. Another set of processes has been elucidated more recently, with discovery of additional DNA polymerases that are able to replicate past a noninstructive lesion. Most of these enzymes have very low fidelity, partly because they lack 3' exonucleolytic proofreading and partly because their catalytic sites are larger and more open than those of high-fidelity

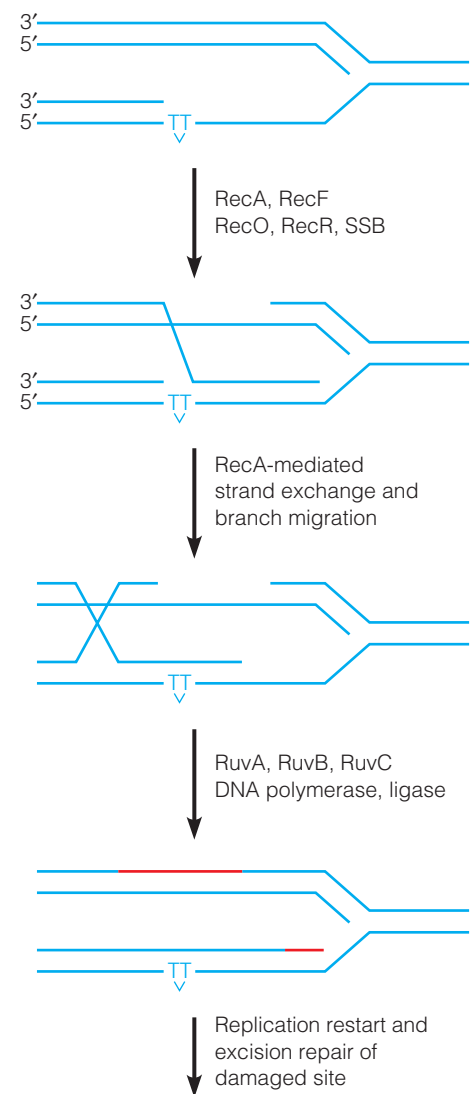

FIGURE 26.14

Daughter-strand gap repair. The undamaged parental DNA strand is transferred to the gap in the daughter strand, formed by the inability of DNA polymerase to replicate past it. The remaining steps occur by mechanisms similar or identical to those in homologous recombination, discussed later in this chapter.

FIGURE 26.15

Replication fork regression as a likely response to a blocking DNA lesion in the leading strand template. (a), (b) Regression pairs the damaged site (shown as a triangle) with its undamaged template (green). (c), (e) The daughter-strand complement of the damaged strand (brown) can then be copied from the other daughter strand (orange). The fork then reforms and replication can re-start, whether the damage has been repaired (f) or not (d).

replicative polymerases. As mentioned in Chapter 25, DNA polymerases have been classified structurally into families—A, B, C, D, X, and Y. The more recently discovered damage-tolerant enzymes comprise the Y-family DNA polymerases. The enzymes are inducible as a result of DNA damage, but the control mechanisms involved differ markedly between prokaryotic and eukaryotic organisms. We discuss the bacterial system first.

The bacterial **SOS response** is a metabolic alarm system that helps the cell to save itself in the presence of potentially lethal stresses. Inducers of the SOS response include ultraviolet irradiation, thymine starvation, treatment with certain DNA-modifying reagents such as the cross-linker mitomycin C, and inactivation of genes essential to DNA replication. Responses include mutagenesis, filamentation (in which cells elongate by growth but don't divide), activated excision repair, and activation of latent bacteriophage genomes. Mutagenesis occurs because, under SOS conditions, the gaps that are formed opposite thymine dimers or other damaged sites can be filled by replication rather than by daughter-strand transfer, and, as noted above, this replication is extremely inaccurate. In fact, this process is the principal pathway by which ultraviolet light stimulates mutagenesis in bacteria.

Induction of the SOS response by UV light or a similar damaging condition activates transcription of about forty genes in *E. coli*. We discuss the mechanism of transcriptional activation in Chapter 29 (see Figure 29.16, page 1246). Among these SOS-inducible genes are *recA*, *dinB*, *umuC*, and *umuD*. *Din* stands for damage-inducible and *Umu* stands for ultraviolet mutagenesis. Bacteria bearing a *umu* mutation can be killed by UV light, but the survivors are not enriched for mutants; in other words, Umu function is required for mutagenesis by UV light. In recent years *dinB* has been shown to encode a new polymerase, pol IV, and the *umuC* and *umuD* genes to encode another new polymerase, pol V. Both of these enzymes are highly error-prone, and both have been categorized as Y-family polymerases. The structural gene for DNA polymerase II is also SOS-controlled, but pol II is an accurate enzyme and is not involved in translesion synthesis, so it is still an enzyme in search of a function.

After SOS activation, UmuD undergoes specific proteolysis to give UmuD', and two molecules of this combine with one molecule of UmuC to give a pol V molecule. This associates with RecA bound to ATP, giving the active form of the enzyme. When the replisome containing pol III holoenzyme stalls at a damage site, pol V replaces it and binds to the sliding clamp. Once the damaged site has been copied (inaccurately), pol V steps aside, by a process under intense study, and pol III holoenzyme completes the replication process.

Considering that most mutations are probably deleterious, what is the advantage to the cell of accumulating mutations during DNA repair? Probably none, except that the alternative would be for the cell to die. In other words, extensive mutagenesis is seen as a worthwhile price for the cell to pay, if a massive UV dose has overwhelmed all other repair pathways and if error-prone replication past a dimer is necessary for the cell to stay alive.

As noted earlier, translesion synthesis is inducible in eukaryotic cells as well. Recall from Chapter 25 that eukaryotic cells were thought until recently to have only five DNA polymerases. Since the late 1990s a remarkable variety of new DNA polymerases has been discovered in eukaryotic cells, and, as mentioned in Chapter 25, the total number of human DNA polymerases now stands at 15 (including retroviral reverse transcriptases). Four of the new polymerases—Pol η , Pol ι , Pol κ , and REV1—are Y-family polymerases, and most are specialized to replicate past specific types of DNA damage. These enzymes all have generally low fidelity—high replicative error rates as shown *in vitro*. However, pol η is distinctive in being able to replicate past thymine dimers in an essentially error-free manner. Recent structural studies show how this can occur. As shown in Figure 26.16, Pol η has an active site spacious enough to accommodate a thymine dimer because the palm and fingers are rotated away from the “little finger” domain. In addition, van der Waals forces and hydrogen bonds hold the paired thymines so that both can partner with adenine on incoming dATP. All of the Y family polymerases have been shown to participate in translesion synthesis and to have additional functions as well; elucidation of these functions is an active area of current research.

Induction of some or all of the repair polymerases is part of the **DNA damage response**, a remarkably complex set of events in eukaryotic cells. Although we know little about specific regulation of each of the several Y-family polymerases, we briefly mention here some details of the DNA damage response. We will say more when we discuss events following double-strand DNA breakage.

Several different signaling pathways emanate from DNA-damaging events. The many proteins induced or activated by DNA damage have been classified as follows: (1) *sensors*, which are in contact with DNA and detect the damage, then recruit (2) *mediators*, which amplify the initial signal, and (3) *transducers*, which transmit the signal to (4) *effectors*, which stimulate cellular responses. Depending upon the severity of DNA damage, the cell type, and phase of the cell cycle, the cellular responses may lead to activation of DNA repair pathways, cell cycle arrest, or programmed cell death (**apoptosis**). We have previously mentioned p53 (Chapter 23), an effector that acts as a transcription factor whose effects include either cell cycle arrest, until damage has been repaired, or apoptosis if damage is too severe. Other effectors include cyclin-dependent kinases, which regulate the cell cycle (Chapter 24).

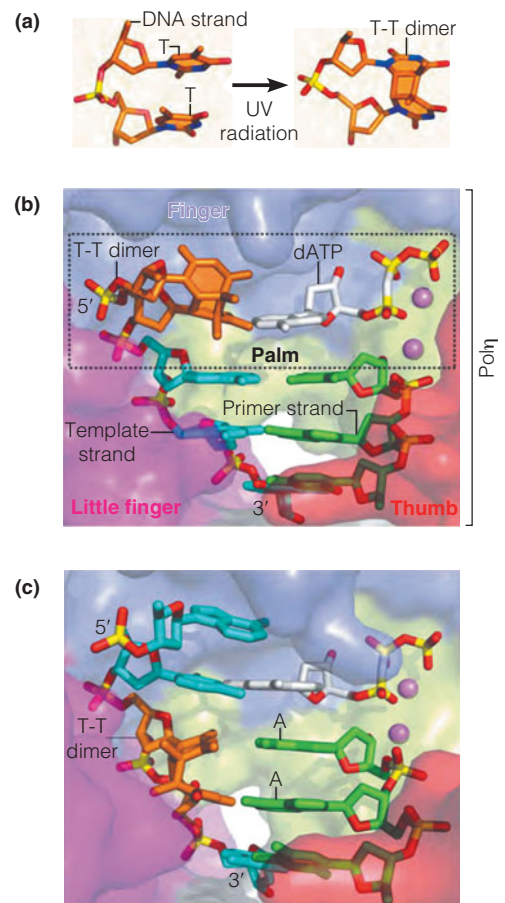

The pathway that recruits translesion polymerases to damage sites involves first continued unwinding of DNA past a damaged site, with single-stranded DNA being coated with RPA, the eukaryotic single-strand DNA-binding protein, and next, recruitment by this DNA–protein complex of Rad17, the eukaryotic clamp loader. Binding of PCNA, the sliding clamp, follows, and this leads

FIGURE 26.16

DNA can be repaired after replication, either by recombination or by inducible error-prone repair. Both processes require RecA.

ultimately to recruitment of translesion polymerases to DNA damage sites. This complex network of reactions is under active investigation.

Double-Strand Break Repair

Double-strand DNA breaks can be repaired either by homologous recombination or by nonhomologous end joining (NHEJ), a process that does not require DNA sequence homology at the ends being joined.

A double-strand break (DSB), a lesion that can be caused by ionizing radiation or as a consequence of replication stalling, is the most lethal form of DNA damage because it destroys the physical integrity of a chromosome. DSBs occur about 50 times per mammalian cell cycle. Moreover, as we see in the next section, double-strand DNA breaks occur naturally during meiotic recombination. DSBs can be repaired by either of two processes—**homologous recombination** (HR), using sequence information from an undamaged sister chromatid, or **nonhomologous end joining** (NHEJ). The latter process is more efficient, but if DNA ends are not rejoined at the precise sites where breakage occurred, genetic information will be lost or scrambled. By contrast, HR normally repairs the broken site precisely, but it can occur only during S or G2 cell cycle phases, when a homologous chromosome is available. Both processes begin with association of several signaling proteins at the severed ends, of which a principal player in vertebrates is a protein kinase called ATM (*ataxia telangiectasia mutated*). An early event in both HR and NHEJ is phosphorylation of a variant form of H2 histone, H2AX, in nucleosomes near the break. The target site is Ser-139, in the C-terminal tail of the histone. This may be part of a chromatin remodeling process that helps to move core particles out of the way, exposing DNA ends for processing.

In NHEJ a key participant is a heterodimeric protein called Ku70/80 (one 70-kDa and one 80-kDa protein). This associates with each of the severed ends. Additional end processing occurs, and a synapse is formed, which brings the two ends together. A specialized form of DNA ligase, DNA ligase IV, rejoins the ends. Ligase IV can join blunt ends or ends with compatible single-strand overhangs, and it has the ability to join DNA ends across short gaps. The actual reaction catalyzed in NHEJ has not yet been defined. The process is summarized in Figure 26.17.

FIGURE 26.17

A pathway for nonhomologous end joining. The figure shows involvement of some proteins in addition to those identified in the text, including DNA-dependent protein kinase (DNA-PK), the processing protein Artemis, and the X4-L4 complex, which includes DNA ligase IV. For more information about ATM and MRN, see text.

Homologous recombination is simple to visualize conceptually, as shown in Figure 26.18, but in fact is an extremely complex process, involving extensive signaling reactions as part of the DNA damage response. ATM activates a nuclease in a three-protein complex called MRN, as well as signaling downstream effectors via its protein kinase activity. The MRN-associated nuclease trims away 5' ends, leaving 3'-terminated single-strand ends, which are coated with RPA (replication protein A; single-strand binding protein). The BRCA1 protein is involved in this process. Another protein kinase, ATR, recognizing the single-strand ends, binds and initiates more signaling. At this point RPA is replaced by Rad51, the eukaryotic counterpart to RecA. BRCA2 is involved in this process. The Rad51-ssDNA complex searches for homology, as mentioned earlier, and invades the homologous region of the undamaged sister chromatid. Resolution to give two undamaged chromatids can occur via several pathways, one of which is shown in Figure 26.18. As mentioned, some of these events, as well as regulation of cell cycle progression, are controlled by protein phosphorylation involving ATM and ATR, central regulators in the DNA damage response. These two enzymes have at least 25 known substrates, but the total number of proteins phosphorylated during the DNA damage response exceeds 700.

Human mutations are known in a number of the proteins involved in DSB repair. Mutations in either BRCA1 or BRCA2 were identified some time ago as risk factors for development of breast or ovarian cancer, and BRCA2 mutations are also associated with Fanconi's anemia. ATM received its name from the deficiency syndrome ataxia telangiectasia, which involves premature aging, cerebellar degeneration, and enhanced cancer susceptibility.

Recombination

Population genetics teaches us that the survival of a species depends upon its ability to maintain genetic diversity so that individuals can vary in their ability to respond to unforeseen environmental pressures. Diversity is maintained through both mutation, which alters single genes or small groups of genes in an individual, and recombination, which redistributes the contents of a genome among various individuals during reproduction. In classical biology, recombination is the outcome of crossing over between paired sister chromosomes during meiosis in eukaryotes, and in fact our earliest information about recombination came from cytological and cytogenetic observations in *Drosophila*. However, recombination encompasses more processes and biological functions than those involved in sexual reproduction. Strictly speaking, **recombination** is any process that involves the formation of new DNA from distinct DNA molecules, such that genetic information from each parental DNA molecule is present in the new molecules. The daughter-strand gap repair process described earlier is a form of recombination. So also is the integration of certain bacteriophage or plasmid genomes into the chromosomal DNA of a host bacterium; many viral genomes integrate into animal host cells, as seen for HIV in Chapter 25. Recombination is also involved in **transposition**, the movement of DNA from one chromosomal integration site to another. As we see later in this chapter, recombination of this type is involved in the vertebrate immune response, in generating antibody diversity.

Classification of Recombination Processes

Different recombination processes have quite distinct requirements, both for nucleotide sequence homology between the recombining partners and for proteins and enzymes to catalyze the process. Meiotic recombination in diploid organisms requires extensive sequence homology between the recombining partners and accordingly is called **homologous recombination**. This term also applies to certain recombinational events between bacterial chromosomes. New DNA can be introduced into a bacterial cell by various processes: (1) conjugation during bacterial

FIGURE 26.18

A pathway for homologous recombination to repair DNA double-strand breaks. **(a)** MRN, aided by other proteins, trims 5' ends, and the single-strand 3' ends are coated with replication protein A, single-strand binding protein. **(b)** RPA is replaced by Rad51 (RecA counterpart), aided by the BRCA2 protein. **(c)** Strand invasion of the undamaged homologous chromosome is followed by DNA synthesis and cutting, **(d)** which can yield either recombinant (right) or nonrecombinant (left) chromosomes.

Adapted with permission from *Biochemical Journal* (2009) 423:157–168, A. Hartlerode and R. Scully, Mechanisms of double-strand break repair in somatic mammalian cells. © The Biochemical Society.

Recombination is any process that creates end-to-end joining from two different DNA molecules.

mating; (2) transformation, when DNA is taken up by cells; or (3) **transduction**, when bacterial DNA that was packaged into a phage particle is introduced by infection. Transduction results when the assembly of phage particles in an infected cell goes awry, and bacterial DNA is assembled into a phage head. Reinfection of another bacterial cell introduces that packaged bacterial DNA into the new cell.

If the introduced DNA contains a replication origin, as in a plasmid, it can replicate autonomously once inside a new bacterial cell. More often the DNA does not contain an origin, and its information can be expressed and maintained only if the DNA is taken up into the resident chromosome by homologous recombination. Biochemical analysis of homologous recombination has focused on prokaryotic systems, which in turn have provided insight into meiotic recombination. Most bacterial homologous recombination processes share a common requirement for the RecA protein or its counterpart.

Site-specific recombination, by contrast, involves only limited sequence homology between recombining partners. Sites of breaking and joining are determined by specific DNA–protein interactions. The process was first described in bacteriophage λ . After infection the linear DNA undergoes circularization, guided by its cohesive ends (see Chapter 25, page 1037). The λ chromosome can either undergo multiple rounds of replication leading to virus production or undergo integration into a specific site on the host chromosome. In the latter condition, called **lysogeny**, most of the viral genes are inactivated, and the virus can maintain a long-term, nonlethal relationship with its host (Figure 26.19). Bacteriophages that can establish lysogeny are called **temperate phages**, in contrast to **virulent phages**, such as phage T4, which always lyse their host cells after infection. In most (not all) cases of lysogeny, integration occurs at a specific site. Integrative recombination in phage λ is being studied as a model for understanding integration of tumor virus genomes into DNA of infected cells. It was earlier studied as a model for homologous recombination between chromosomes, but the processes are different, as shown when it was learned that the phage and bacterial DNA sequences in the regions undergoing recombination have only 15 base pairs of homology. Moreover, the RecA protein is not required for this process. Rather, the virus encodes a site-specific enzyme, called **integrase**, and specific DNA–protein interactions between the enzyme and the recombining partners, rather than extensive DNA–DNA sequence homology, determine the site of recombination.

FIGURE 26.19

Site-specific recombination, establishing lysogeny in bacteriophage λ . The phage chromosome circularizes between genes *A* and *R*, and recombination takes place between the *attP* site and a corresponding region, *attB*, on the *E. coli* chromosome between the *gal* and *bio* markers. The enzyme integrase carries out the site-specific recombinational event with the help of a bacterial protein. *O* and *b* are additional genetic markers.

TABLE 26.1 Characteristics of different types of genetic recombination

Type	Requirement		
	Sequence Homology	RecA Protein or Counterpart	Sequence-Specific Enzyme
Homologous	Yes	Yes	No ^a
Site-specific	Yes (about 15 bases)	No	Yes
Transposition	No	No	Yes
Illegitimate	No	No	Unknown

^aThe Chi site or its counterpart determines cutting sites (see page 1103), but initial recognition of pairing sites occurs by sequence homology.

We recognize two other forms of recombination. *Transposition* involves neither sequence homology nor the RecA protein but does require a special sequence on the donor DNA. This process is discussed in a later section. **Illegitimate recombination**, an extremely rare event that possibly occurs by chance, involves neither sequence homology nor the action of any known protein. Table 26.1 summarizes the main distinctions among the four major types of recombination.

Homologous Recombination

Breaking and Joining of Chromosomes

The most straightforward way to accomplish recombination is to break and rejoin DNA molecules. However, if recombination occurs this way, the sites of breakage must be precisely the same on both recombining chromosomes for intact genes to be regenerated. Some researchers favored alternative mechanisms, but in 1961 Matthew Meselson and Jean Weigle showed that recombination in fact occurs via breakage and rejoining of chromosomes. The demonstration, diagrammed in Figure 26.20, involved a Meselson–Stahl type of experiment (see Figure 4.14, page 104). *E. coli* was infected with two genetically marked λ phage populations, one of which had been density labeled by growth in ^{13}C – ^{15}N medium. The phage particles resulting from this cross were centrifuged to equilibrium in a cesium chloride gradient. Phages with recombinant genotypes were recovered from all parts of the gradient, whereas nonrecombinant phages were uniformly light or heavy. This result could occur only if the recombinant phages contained DNA derived from both parents, by breaking and rejoining.

This experiment had one other important result. The phage output from the crosses was analyzed in standard fashion, by visual examination of plaques. Although each plaque arises from a single phage particle, many of the plaques in the Meselson–Weigle experiment contained phages of two different genotypes, even though all arose from a single infecting phage. This suggested that recombination involves the formation of a **heteroduplex DNA** region, in which one DNA strand comes from one parent and the other from the second parent. If the heteroduplex region contains a mismatch, subsequent replication of that DNA gives rise to two progeny DNA molecules of different genotypes, as shown in Figure 26.21.

Another early observation was that recombination is stimulated by processes that nick or break DNA strands, such as thymidine starvation or UV irradiation. This suggested a role for single-strand DNA, or free DNA ends, in initiating recombination.

Models for Recombination

Putting the preceding observations together along with data on recombination in fungi, Robin Holliday proposed in 1964 a model for homologous recombination between duplex DNA molecules. That model, detailed in Figure 26.22, continues to dominate thinking and experiments about this process. You will note a marked

FIGURE 26.20

The Meselson–Weigle experiment. This experiment established that genetic recombination occurs by breakage and reunion of DNA strands.

resemblance of this model to the mechanism of homologous recombination in double-strand break repair (page 1097).

Holliday proposed that recombination begins with nicking at the same site on two paired chromosomes (step 1). Partial unwinding of the duplexes is followed by **strand invasion**, in which a free single-strand end from one duplex pairs with its unbroken complementary strand in the other duplex, and vice versa (step 2). Enzymatic ligation generates a crossed-strand intermediate, called a **Holliday junction** (step 3). The crossed-strand structure can move in either direction by duplex unwinding and rewinding (branch migration, step 4). The Holliday junction “resolves” itself into two unbroken duplexes, by a process of strand breaking and rejoining. The process leading to recombination begins with isomerization of the Holliday structure (step 5), followed by strand breakage so that the strands that break (in step 9) are those that were *not* broken in step 1. Resolution of the resulting structure (steps 10 and 11) generates two chromosomes recombinant for DNA flanking the region and each containing a heteroduplex region. However, if the original crossed strands (those that *were* broken in step 1) break and rejoin (steps 6–8), the products are nonrecombinant duplexes, each containing a heteroduplex region (that is, nonrecombinant with respect to the outside markers A and Z).

Considerable evidence now supports the central tenets of the Holliday model, particularly the electron microscopic visualization of Holliday junctions (Figure 26.23) and more recently crystallographic analysis of a synthetic Holliday junction (Figure 26.24). However, the model has been modified as new data have emerged. Matthew Meselson and Charles Radding proposed that recombination could start with a single nick (which eliminates the nagging question of how two

FIGURE 26.24

Crystal structure of a synthetic Holliday junction. This four-stranded structure was synthesized by annealing four chemically synthesized oligonucleotides [shown in (b)] designed to mimic a Holliday junction. (a) Shows the angle between the two duplexes forming the junction.

duplexes could be nicked at precisely the same point). As shown in Figure 26.25, strand displacement synthesis occurs (magenta arrow, step 1), with a displaced single-strand end of the nicked duplex, A, invading the homologous region of the unbroken duplex, B (step 2). Eventually the displaced loop on duplex B is cleaved and partially degraded (step 3), and the displaced end from duplex A is ligated to B (step 4). Isomerization then occurs, as in the Holliday model, with the originally unbroken strands crossed (step 5). An additional feature of the Meselson–Radding model is the fact that branch migration can lead the final strand cutting to occur some distance from the site of either strand invasion or the original nick (steps 6 and 7). In principle, either a 5' or a 3' end could initiate the strand invasion process. As noted below, a 3' end probably initiates recombination in *E. coli*.

Proteins Involved in Homologous Recombination

The Holliday and Meselson–Radding models explained most of the existing data on homologous recombination between paired chromosomes, particularly as studied in lower eukaryotes such as yeast. Moreover, the models could easily be adapted to explain daughter-strand gap repair or the recombination that occurs in bacteria after transformation or conjugation. Some of the proteins thought to participate, notably DNA polymerase, DNA ligase, and single-strand DNA-binding protein, had been characterized and shown to participate in recombination. What about other proteins that must function if the models are largely correct? To

answer this question, we turn back to *E. coli* and its phages and the characteristics of bacterial mutants defective in recombination. Mutations conferring a recombination-defective (*rec⁻*) phenotype map in several loci, and two important gene products are responsible for most bacterial recombination events. One of these products, the RecA protein, was introduced earlier. The other protein is called exonuclease V or the RecBCD nuclease.

RecA is an amazing multifunctional protein with M_r of about 38,000. In recombination it promotes the ATP-dependent pairing of homologous strands, as described earlier in connection with daughter-strand gap repair. In vitro the protein catalyzes both single-strand exchanges, in which ssDNA invades a homologous duplex, and double-strand exchanges, in which both strands of an invading duplex essentially change partners. However, it has become evident that in vivo only three-strand reactions occur. As schematized in Figure 26.26 (left panel), the process begins with a reaction between RecA and single-stranded (ss) DNA, to give a characteristic nucleoprotein filament. As shown by scanning-tunneling microscopy of the filament and by crystallographic analysis of the protein (Figure 26.27), RecA wraps about ssDNA as a multisubunit right-handed helix, with six RecA monomers per turn. Once ssDNA is bound, the filament searches double-strand (ds) DNA, looking for sequences complementary to those in the single strand already bound. In this process, dsDNA is also taken up within the filament, giving a structure termed a joint molecule (Figure 26.26, center panel). Binding of dsDNA requires ATP, but that ATP need not be hydrolyzed in the process. By contrast, movement of the ssDNA-protein complex with respect to the dsDNA does require ATP hydrolysis. During this process, dsDNA is underwound and stretched to about 1.5 times its normal length. Movement of the complex is polarized, in a 5'-to-3' direction along the initially bound ssDNA. During the movement, a triple-stranded structure transiently forms, with ssDNA (the red strand in Figure 26.26) wound in the minor groove of the dsDNA. The ssDNA continually tests the antiparallel strand in dsDNA (yellow) for sequence complementarity. It is not clear how this occurs, but evidently short oligonucleotide sequences swing out from the duplex structure and can pair with ssDNA if sequence complementarity is found. Once complementarity is established, branch migration occurs, with simultaneous strand exchange. A duplex is formed between the red strand (ssDNA originally) and the yellow strand (complementary to the red strand), while the displaced (green) strand is spooled out, away from the complex. ATP hydrolysis during this period may promote rotation of the DNA within the filament, facilitating the release of the displaced strand. A recent study at

RecA, a multifunctional bacterial enzyme, uses ATP to promote pairing of homologous DNA sequences.

**FIGURE 26.28**

The RecA strand exchange reaction as shown from single-molecule studies. The black strand associated with RecA at the outset is complementary to the red strand in the duplex. Synapsis occurs 5' to 3' (rightward in the center diagram), with each RecA molecule displaced after its associated DNA has base-paired with its complement. In this model reaction the displaced blue strand is wrapped around the newly formed duplex.

Reprinted from *Molecular Cell* 30:530–538, T. van der Heijden, M. Modesti, S. Hage, R. Kanaar, C. Wyman, and C. Dekker, Homologous recombination in real time: DNA strand exchange by RecA. © 2008, with permission from Elsevier.

the single-molecule level confirms the general outline shown in Figure 26.26 and shows that about 80 base pairs are actively involved in the synapsis reaction at any time, even though the total region of homology may be much longer (Figure 26.28).

Recombination occurs preferentially at or near particular DNA sequences. In *E. coli* recombination is favored near a particular octanucleotide sequence, 5'-GCTGGTCC, called Chi (for crossover hotspot instigator). How does this site act to stimulate recombination? Another important enzyme, the RecBCD protein, a multifunctional heterotrimeric enzyme encoded by the *recB*, *recC*, and *recD* genes, displays sequence specificity for Chi. This enzyme binds at a double-strand break on duplex DNA and uses two helicase activities—RecB and RecD—to unwind and partially degrade the DNA. As shown from the crystal structure of a RecBCD-DNA complex, both helicases are in contact with DNA (Figure 26.29).

RecBCD, a multifunctional enzyme, unwinds and rewinds DNA, with one strand being unwound more rapidly and then converted to a single-strand 3' end.

**FIGURE 26.29**

Crystal structure of *E. coli* RecBCD protein in complex with DNA. One strand of unwound DNA (magenta) is in contact with RecB and one with RecC. PDB ID 1W36.

Reprinted from *Cell* 131:651–653, D. B. Wigley, RecBCD: The supercar of DNA repair. © 2007, with permission from Elsevier.

The RecD helicase activity is higher than that of RecB, so as the protein moves, the 3' end is displaced as a single-strand loop ahead of RecB, and becomes coated with SSB protein. Both strands are degraded by associated nucleases, but because of the differential speeds of the protein motors, more of the 3' end is saved as the loop. When the enzyme reaches Chi, the protein pauses briefly, and a sequence-specific interaction causes RecBCD to switch speeds and switch its preferred polarity of DNA degradation. As B moves faster, the 3'-terminated loop is reeled in by RecB and coated with RecA. An associated nuclease releases the bound 3' end, as indicated in Figure 26.30, freeing it for strand invasion of a neighboring duplex.

In eukaryotic cells the RAD51 protein, as noted earlier, promotes homologous strand pairing in comparable fashion to RecA. The action of BRCA2 aids in RAD51-mediated recombination, and defective function of BRCA2 in this process may be related to the genomic instability that leads to breast or ovarian cancer in individuals with BRCA2 gene mutations.

Once a Holliday junction is formed, branch migration is essential for eventual formation of recombinant structures, as was shown in Figures 26.22 and 26.23. This is largely the responsibility of three other proteins. In *E. coli* these three proteins are products of the *ruvA*, *ruvB*, and *ruvC* genes. RuvA is a DNA-binding protein, whose specificity directs it toward the four-stranded Holliday structure. RuvB protein is an

ATP-requiring motor protein, which binds to two opposed arms of the junction. In the model of Figure 26.31, which is based upon crystal structures of the isolated RuvA and RuvB proteins, the two RuvB molecules act as twin pumps, rotating the two arms in opposite directions. This forces branch migration by driving the rotational movement of the other two strands toward the junction. Eventually RuvC binds and begins the resolution of the Holliday structure by nicking two strands.

Although Ruv protein homologs have not yet been detected in eukaryotic cells, much of the biochemistry of homologous recombination in eukaryotes is similar to what is described here. In particular, the RAD51 protein of both human cells and yeast has a strand-pairing activity similar (but not identical) to that of RecA, and the two proteins show extensive sequence homology. As noted earlier, in eukaryotic cells an essential function of homologous recombination is the repair of double-strand breaks, which can be created by ionizing radiation, oxidative stress, or other environmental damage, and would be lethal if not repaired. A broken chromosome can use the sequence information in its homolog to reconstruct the original DNA sequence at the site of the break, as was shown in Figure 26.18.

Site-Specific Recombination

As we have discussed, alignment of sites for homologous recombination is driven by DNA sequence homology. Another class of recombination reactions is directed by specific DNA–protein interactions, although a short stretch of DNA homology occurs at the actual site of cutting and resealing. Our biochemical understanding of this site-specific recombination is most advanced for the mechanism by which temperate phages such as λ become integrated at specific sites on the chromosome of the infected bacterium. This process provides an important model for studying counterpart reactions in higher organisms, such as integration of tumor virus genomes into the genomes of infected host cells.

The circularized chromosome integrates at a specific site on the *E. coli* chromosome, *attB*, which maps between genes involved in galactose utilization and biotin synthesis (the *gal* and *bio* markers), as was schematized in Figure 26.19. Integration occurs at a specific site on the phage chromosome, called *attP*. Two proteins are required for this site-specific recombination: (1) phage integrase (Int, the product of the *int* gene) and (2) an *E. coli* protein called IHF (integration host factor). IHF has been shown by X-ray crystallography to force a 90° turn when it binds to DNA (Figure 26.32a). Phage DNA must be supercoiled for the recombination to occur. This supercoiling, plus the distortion created by IHF binding to specific sites in

Recombination to integrate or excise temperate phage chromosomes involves specific DNA–protein interactions.

**FIGURE 26.32**

Integrative recombination in phage λ . (a) DNA bending by IHF, shown by X-ray crystallography.

(b) The site-specific recombination event. After IHF binding (not shown), the intasome forms, and integrase catalyzes cleavage at the sites indicated by wedges and then rejoins strands to create hybrid attachment sites. Not shown for simplicity is a short branch migration that occurs before resolution of the Holliday junction.

(a) Reprinted from *Cell* 87:1295–1306, P. A. Rice, S. Yang, K. Mizuuchi, and H. A. Nash, Crystal structure of an IHF-DNA complex: A protein-induced DNA U-turn. © 1996, with permission from Elsevier.

attP, facilitates Int binding at adjacent sites. A specialized nucleoprotein structure called the intasome is formed, with the 230-base-pair *attP* region wrapped about seven Int molecules, each bound at a specific site. This structure becomes aligned with *attB*, which is only 23 base pairs long and which binds two molecules of Int. In the core of each site is a 15-base-pair region of complete homology (Figure 26.32b). In each of these sequences, Int creates a staggered cut, with a seven-nucleotide overlap. The ends then exchange to form a Holliday junction. The bacterial and phage core sequences yield two hybrid sequences, each of which contains both phage and bacterial DNA. The multifunctional Int protein, which has already catalyzed site-specific cutting and strand exchanges, now completes the process with a DNA ligase reaction to join the ends covalently.

When a phage chromosome becomes integrated, it is essentially dormant. Almost all of its genes are turned off, and it replicates only as a part of the bacterial chromosome in which it resides. However, changes in gene expression (see Chapter 29) can activate the integrated chromosome, or **prophage**. When this occurs, the above sequence of steps is reversed, with excision of a circular phage chromosome. An additional protein, called Xis, is required in addition to Int and IHF. Xis provides binding specificity for the hybrid phage-bacterial attachment sites that flank the prophage so that excision occurs only under conditions where both Int and Xis are present.

Gene Rearrangements

Until the mid-1970s the genetic information content of an organism or population was considered to be static. All cells of a differentiated organism were thought to have identical DNA contents, with variations among different cells arising at the level of gene expression. Supporting this idea was the fact that in some plants, such as carrots, a single differentiated cell can be manipulated in culture so as to give rise to a complete and normal plant. However, more recent developments have shown a plasticity to DNA that had not been expected. In normal eukaryotic development, segments of DNA can be deleted from the genome, can move from one site to another within a genome, or can duplicate themselves manyfold. In addition, mobile genetic elements have been described in both prokaryotes and eukaryotes. These segments of DNA can move from one chromosomal integration site to another, apparently unrelated to developmental processes. As noted earlier, these processes represent a specialized form of recombination.

Actually, the plasticity of DNA was predicted, but by very few scientists. Barbara McClintock's work on maize genetics, starting in the 1940s, led her to postulate genetic regulatory mechanisms effected through the action of mobile genetic elements. However, some three decades passed before the physical demonstration of such elements in bacteria focused attention on McClintock's pioneering work. For the remainder of this chapter we shall discuss three widely studied aspects of genome plasticity: the genetic basis for antibody variability in vertebrates, gene transposition, and gene amplification.

Immunoglobulin Synthesis: Generating Antibody Diversity

Recall from Chapter 7 that antibodies are proteins manufactured by vertebrate immune systems that aid in defense against infectious agents and other substances foreign to the animal. The immune response, resulting from introduction of an antigen, elicits the production of several highly specific antibodies. It is estimated that a human is capable of synthesizing more than 10 million distinct antibodies. Most of this great diversity is generated through the action of precisely controlled gene rearrangements, involving but a small fraction of the coding capacity of the genome. These rearrangements occur during differentiation of many individual clones of cells, each clone specialized for the synthesis of one and only one antibody. Other large protein families, notably T-cell receptors, are diversified by similar mechanisms. The immune response involves proliferation of clones of cells that produce antibodies specialized to bind the specific antigen, or immunogen, provoking that response. This clonal expansion allows large-scale production of specific antibodies, needed to combat infection or another challenge to the immune system.

To see how immunological diversity is generated, let us consider one type of antibody, the immunoglobulin G, or IgG, class. Recall from Chapter 7 that these proteins consist of two heavy chains and two light chains. Each chain comprises two distinct segments—a domain of variable polypeptide sequences and a constant domain, which is virtually invariant among different IgG light or heavy chains. We focus on the light chains and in particular the λ class of light chains. (Another class, κ , has somewhat different sequences in its constant region, but its development involves similar mechanisms.) Much of what we know about this process comes from the work of Susumu Tonegawa, who in 1987 was awarded the Nobel Prize in Physiology or Medicine for this work.

Figure 26.33 shows the organization of the precursor genes to κ chains in germ-line cells, undifferentiated for antibody formation, and the rearrangements leading to one such gene in a differentiated antibody-producing cell. Each light chain is encoded by DNA sequences that are noncontiguous in the genome of undifferentiated cells but are all in the same chromosome. These sequences are called V (variable), C (constant), and J (joining). The human genome contains

FIGURE 26.33

Gene rearrangements in antibody gene maturation. The rearrangements of C, V, and J sequences produce one mature κ light chain gene, and the transcription, processing, and translation of this gene produce an antibody κ light chain.

**FIGURE 26.34**

Generation of diversity by variable V-J joining mechanisms. Four crossover events are possible at a V-J junction, giving rise to codons for any three possible amino acids in this example. Only one DNA strand is shown.

about 300 different V sequences, each of which encodes the first 95 amino acids of the variable region; four different J sequences, each of which encodes the last 12 residues of the variable region and which join it to the constant region; and one C sequence, which encodes the constant region. In an embryonic cell the V sequences, each preceded by a leader sequence containing a transcriptional activator that is not expressed, form a tight cluster; the J sequences form another cluster some distance away; and the C sequence follows shortly after the J cluster. Each J sequence is flanked by nonexpressed spacer sequences.

In the differentiation of one antibody-forming clone of cells, a gene rearrangement links one of the approximately 300 V sequences with one of the 4 J sequences. All of the DNA that lies between these two spliced sequences is deleted in this rearrangement and disappears from all progeny of this cell line. Any upstream V sequences (on the 5' side, to the left in Figure 26.33) and downstream J sequences (on the 3' side, to the right) remain in these cells but are not used in antibody synthesis.

Additional diversity is provided by the way in which the V and J sequences recombine. The cutting and splicing can occur within the terminal trinucleotide sequences of V and J in any way that yields one trinucleotide sequence in the spliced product (Figure 26.34). This increases the total number of different light chain sequences by

about 2.5 (the average number of different amino acids encoded by four random triplets). Thus, the total number of possible light chain sequences that can be formed from 300 V sequences and 4 J sequences is about 3000 ($300 \times 4 \times 2.5$).

Related DNA sequences are found to the 3' side of each V sequence and to the 5' side of each J sequence, and they represent recognition sites for the enzymes involved in the joining reaction. Those sequences, which are called recognition signal sequences, are as follows:

Note that the homologous regions of these sequences are inverted repeats.

Recombination begins with two proteins called RAG1 and RAG2 (Figure 26.35). These proteins act similarly to the bacterial proteins involved in gene transposition (page 1110), beginning the process by catalyzing double-strand breaks between the two recognition signal sequences involved and the respective V and J coding sequences. Cellular DNA-repair proteins process the double-strand DNA breaks, creating a *coding joint*, in which the V and J sequences are fused in the appropriate reading frame, and a *signal joint*, which fuses the intervening DNA into a circular molecule. The nearly identical seven-base palindromic sequences and nearly complementary eight-base AT-rich regions in these segments allow alignment of distant regions of the chromosome, with a process akin to that in phage λ integration, recombining the sequences and excising the intervening DNA. In addition, sequence analysis indicates that the DNA joining reactions are imprecise, with nucleotides removed from one or both ends, creating additional diversity.

Still another mechanism acts to introduce sequence diversity into antibody chains—**somatic hypermutation**. The spontaneous mutation rate becomes very high, but specifically within sequences related to antibody formation. These sequences undergo a high rate of deamination of cytosine residues, leaving uracil residues paired incorrectly with guanine. Upon replication these mutant strands pair with adenine, completing the transition from G-C base pairs to A-T. The enzyme involved, **activation-induced deoxycytidine deaminase (AID)**, evidently acts at paused transcription complexes, with the nontemplate DNA strand, which is single-stranded, serving as the deamination substrate.

The final step in producing a light chain polypeptide involves joining of the C and J segments (see Figure 26.33). This occurs not at the DNA level but at the level of messenger RNA. As discussed in Chapters 7 and 27, eukaryotic gene expression usually involves cutting and splicing of the messenger RNA, with excision of sequences that are not represented in the final gene product. In this case, transcription yields an RNA molecule extending from the 5' side of the V gene that is spliced to J to the 3' side of C. Depending on which J region has been spliced to V in this cell, the RNA excised during splicing may contain sequences corresponding to other J regions.

Heavy chains are formed similarly—from V sequences, J sequences, and a class of sequences called D. In addition, there are eight different C sequences, which are also involved in the synthesis of other antibody classes. The total number of possible IgG heavy chains is about 5000. Because any light chain can combine with any heavy chain to form a complete IgG, the total possible number of IgG molecules is 3000×5000 , or 1.5×10^7 . In this way, enormous diversity can be generated from a very small fraction of the total DNA in germ-line cells. Even further diversity arises from the high rate of V sequence mutation by somatic hypermutation, during development of the antibody-producing cell. This allows the same V-J joining event to produce different IgGs.

It is not clear whether both of the homologous chromosomes in a diploid antibody-forming cell undergo identical rearrangements. However, given that each cell produces only one type of antibody, either that must occur, or else one chromosome is silenced after the other has completed its rearrangement.

FIGURE 26.35

Site-specific recombination event catalyzed by RAG1 and RAG2.

The diversity of the immune response involves recombination among thousands of different DNA sequences, to yield a vast array of antibodies.

Transposable Genetic Elements

In this section we discuss transposable genetic elements—genes that do not have a fixed location in a genome but can move from place to place within the genome, albeit with low frequency. Transposition occurs without benefit of DNA sequence homology, but the enzymes catalyzing transposition recognize short sequences of about a half dozen nucleotides. Although the existence of gene transposition had been predicted by Barbara McClintock's work on maize genetics, the first physical characterization of transposable elements arose from studies of antibiotic-resistant strains of bacteria. By the early 1970s it was known that genes conferring resistance to drugs such as tetracycline or penicillin were usually carried on plasmids, whose DNA sequences bore no detectable homology with chromosomal DNA sequences of the host. Nevertheless, the genes for antibiotic resistance would appear, with low frequency, in the chromosome of the bacterium or in the DNA of a phage that had infected that cell. The presence of new DNA inserted into the host or phage chromosome could be confirmed by restriction cleavage analysis of the DNA or by heteroduplex analysis in the electron microscope. The existence of these “jumping genes,” which move from one chromosome to another in seemingly random fashion, greatly altered our views on gene organization and evolution. The new concepts were of much more than academic interest because they relate to the use of antibiotics to treat bacterial infections—specifically, to the ease with which populations of antibiotic-resistant bacteria can arise.

Transposable genetic elements include insertion sequences, transposons, and certain bacteriophages that can insert at various locations.

Transposable elements have been demonstrated in many eukaryotes, including maize, *Drosophila*, and yeast. However, we shall concentrate on bacteria, whose physical structures and transposition mechanisms are best understood. Let us first point out several distinctions between bacterial transposition and other recombinational mechanisms we have discussed. First, transposition does not require extensive DNA sequence homology. Furthermore, transposition occurs normally in a *recA*⁻ host, suggesting that homologous recombination events are not involved. Second, DNA synthesis is involved in bacterial transposition. Transposition always involves duplication of the target site, the short sequence (3–12 base pairs) at which the transposable element is inserted. In many instances the transposable element is itself replicated, with one copy being deposited in the new sequence and one remaining in the donor sequence. Finally, transposable elements can restructure a host chromosome. A transposable element can move from one site to another within the same chromosome, producing two homologous sequences resident in the same chromosome. Depending upon whether these sequences are oriented identically or in reverse, homologous recombination between them can yield a deletion or an inversion, as shown in Figure 26.36. Transposable elements also have other effects on the chromosomes they move to—either inactivation of any gene into which they move (where insertion interrupts the coding sequence) or activation of adjacent genes (where a promoter, or transcriptional activator, might be created next to the gene). Abortive transpositional events can cause deletions or inversions in the chromosome. Because such events are often lethal, evolution has selected for organisms with low rates of transposition. In the laboratory, insertional inactivation of genes is useful for isolating mutants defective in specific functions and for mapping genes.

We recognize three different classes of transposable elements in bacteria, with general structures as shown in Figure 26.37. In classifying these elements, we consider the involvement of two enzymes, **transposase** and **resolvase**, whose functions are discussed shortly. Class I elements, which encode a transposase but not a resolvase, are of two types. The simplest transposable element, called an **insertion sequence** (IS), consists simply of a gene for transposase, flanked by two short inverted repeat sequences of about 15 to 25 base pairs. A less simple structure called a **composite transposon** consists of a protein-encoding gene, such as a gene conferring antibiotic resistance, flanked by two insertion sequences, or IS-like elements. These elements may be in either identical or inverted orientations. Class II transposons contain only one set of short flanking direct repeat sequences. In addition to a protein-encoding gene (often conferring antibiotic resistance) and a transposase

FIGURE 26.36

Genome rearrangements that can be promoted by homologous recombination between two copies of the same transposable element. Depending on the orientation of the two copies, either (a) inversion or (b) deletion can result.

gene, these elements include a gene for resolvase. Finally, class III elements belong to a small group of bacteriophages, of which the best-known is phage Mu. This phage is known to insert its chromosome at random in the host chromosome by a transpositional mechanism and also to replicate its genome by a transpositional

TABLE 26.2 Structures of some transposable elements of *E. coli*

Element	Size (bp)	Target DNA (bp)	Resistance Conferred
Insertion sequences

mechanism, similar to that of type II elements. One gene of this phage, A, encodes a transposase. Another gene, B, encodes a protein with DNA-dependent ATPase activity. Whereas class I and class II transposable elements synthesize transposase at such low levels that transposition occurs at frequencies of only 10^{-7} to 10^{-5} per generation, phage Mu integrates about 100 times per lytic infection. The B gene product is partially responsible for this far greater efficiency of transposition. Other genes encode structural and other proteins of the virus.

Table 26.2 summarizes the properties of a number of transposons and insertion sequences. Note that each transposon (conventionally referred to with the abbreviation Tn) and IS inserts at a specific target sequence of five or nine base pairs in the examples shown. Insertion involves a duplication of that site, and it results in two copies of the target sequence, one on each side of the integrated element (Figure 26.38). It seems likely that this results from the action of transposase, which generates a staggered cut that brackets the target sequence.

FIGURE 26.38

Model of how direct repeats are generated during the insertion of a transposon or an insertion sequence.

Attachment of the mobile element (Tn or Is) to each end results in gaps, which are then filled and ligated to generate the flanking direct repeats.

Because the transposable element never exists as free linear DNA, how are ends of the element generated, to join with the ends of the staggered cut? The currently favored model, shown in Figure 26.39, involves transposase introducing

FIGURE 26.39

Models of simple transposition and replicative transposition.

both the staggered cuts in the target site and a nick at each of the 3' ends of the element—precisely between the transposon sequence and the flanking direct repeat. Next, the free 5' ends in the recipient DNA target sequence are joined to the 3' ends of the element. Two outcomes are then possible. In simple transposition the joining is followed by cutting of the 5' ends of the transposon, also immediately adjacent to the flanking sequences. This gives a gapped structure like that shown in Figure 26.38, which can be filled and closed by DNA polymerase and ligase. In this form of transposition, only the target sequence is copied; the donor chromosome suffers a lethal double-strand break. Tn10 (Table 26.2) transposes by a conservative mechanism, meaning that both original strands are somehow transferred to the new location.

The other process, **replicative transposition**, requires the enzyme resolvase, so it occurs only with class II and class III elements. The 3' ends of the target chromosome, after the first cutting and splicing, serve as replicative primers for copying both the gaps, as shown in Figure 26.39, and the two strands of the transposable element itself. Ligase action generates a **cointegrate**, a large circular structure containing both donor and target chromosomes with two freshly replicated copies of the transposable element. The other enzyme, resolvase, now catalyzes site-specific recombination between the two elements, resulting in one copy of the transposable element inserted into each of the two chromosomes. Structural analyses of the *E. coli* enzyme, called $\gamma\delta$ resolvase, are yielding important clues to this complex process.

Retroviruses

Gene transposition in eukaryotic systems presents some strong similarities to and some distinct differences from transposition in bacteria. The first major distinction is that integration and excision are distinct processes in eukaryotes. Thus, the transposable element can be isolated in free form, often as a double-strand circular DNA. Second, replication of that DNA often involves the synthesis of an RNA intermediate. Both of these properties are seen in the retroviruses of vertebrates, perhaps the most widely studied class of eukaryotic transposable elements. As we noted in Chapter 25, these RNA viruses use reverse transcriptase to synthesize a circular duplex DNA, which can integrate into many sites of the host cell chromosome. The integrated retroviral genome bears remarkable resemblance to a bacterial composite transposon, as you can see by comparing Figure 26.40 with

FIGURE 26.40

Structure of retroviral genomes in the integrated state. (a) A nononcogenic virus. **(b)** An oncogenic virus such as Rous sarcoma virus, showing the viral oncogene downstream (rightward) from the viral replication genes. **(c)** A defective oncogenic virus, such as Moloney murine sarcoma virus, with the viral oncogene replacing part or all of a gene (*env*) essential to viral replication. In each case the LTRs are direct repeats, flanked by short inverted repeats.

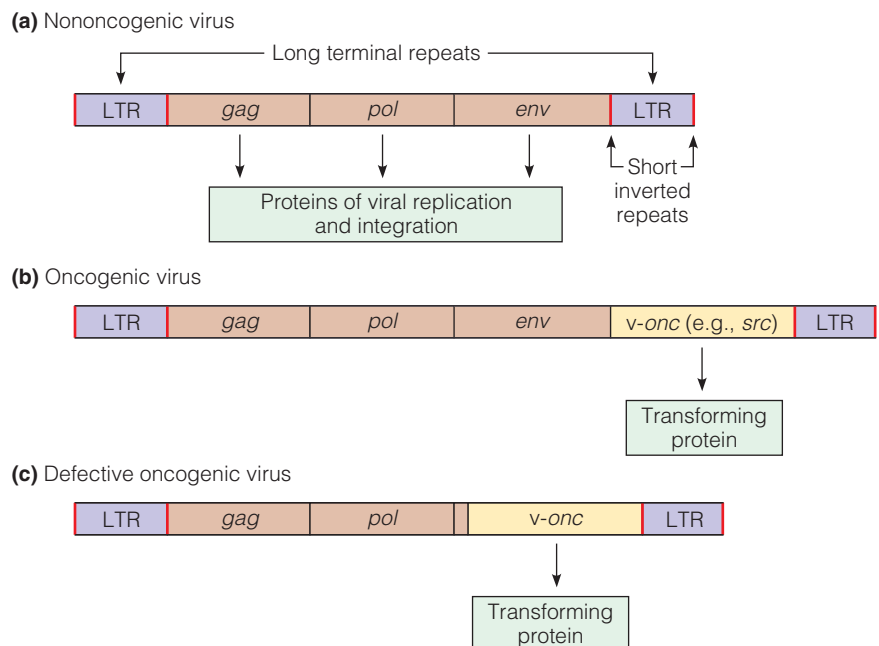

Figure 26.37. The prototypical retroviral genome has three structural genes—*gag*, which encodes the polyprotein that undergoes cleavage to give virion core proteins; *pol*, which encodes the viral polymerase, or reverse transcriptase; and *env*, the major glycoprotein of the viral envelope. Flanking these structural genes are two direct repeats, the **long terminal repeats (LTRs)** of about 250 to 1400 base pairs each. Each LTR is flanked in turn by short inverted repeat sequences, 5 to 13 base pairs in length. Integration occurs by a mechanism that duplicates the target site so that the integrated viral gene, called a provirus, is flanked by direct repeats of 5 to 13 base pairs each of host cell DNA.

Just as bacterial transposons can carry passenger genes, so also can retroviruses. The earliest known retrovirus, Rous sarcoma virus, was also the first virus shown to contain an oncogene (see Chapter 23). Rous sarcoma virus was isolated in 1911 and shown to cause tumors in chickens. Not until 1978, however, was the *src* gene identified and shown to be responsible for tumorigenesis. The *src* gene product is a 60-kilodalton protein with a protein tyrosine kinase activity. A related but distinct sequence can be detected in the host genome. In Rous sarcoma virus the *src* oncogene lies to the 3' side of the *env* gene. Other tumorigenic viruses contain the oncogene either inserted into or substituting for one of the genes *gag*, *pol*, and *env*. Because the loss of an essential gene makes it impossible for the virus to replicate, the latter class of virus can grow only in a cell coinfecting with a *helper virus*, a related retrovirus that provides the missing function(s).

By various means, one can show that the action of an oncogene is essential for the virus to effect oncogenic transformation, the change of a normal cell to a cancerous cell (see pages 982–989 in Chapter 23). For example, mutational inactivation of the *src* gene of Rous sarcoma virus does not affect the ability of the virus to replicate, but it does render the virus unable to cause tumors in infected animals. Because each viral oncogene is related in sequence to a cellular counterpart, it is presumed that the viral oncogene originated in a cell many generations ago and underwent independent mutations after being picked up by a viral genome. Moreover, because many of the oncogene products, like the Src protein, have protein kinase activity, they may be aberrant forms of normal cellular regulatory elements, and their expression may be involved in the abnormal growth control that characterizes tumor cells. An additional mechanism may be related to activation of cellular genes by insertion of proviral DNA. The leftmost LTR in an integrated provirus (i.e., to the 5' side as usually drawn) contains the transcriptional activator, or promoter, for the adjacent *gag* gene and the downstream *pol* and *env* genes. Because the LTRs are direct repeats, the rightmost LTR can activate transcription of cellular genes downstream from the integration site. If these genes include those involved in metabolic regulation, their overexpression may unbalance metabolism in some still undefined way and, hence, contribute to oncogenesis.

Transposable elements in eukaryotic cells show striking resemblances to retroviruses in sequence organization. Indeed, the term **retrotransposon** is used to denote this class of elements. These similarities are illustrated in Figure 26.41 for two retroviruses, plus Ty, a transposon of yeast; *copia* and 412, transposable elements in *Drosophila*; and IAP, a transposon found in the mouse genome.

Gene Amplification

The final process we discuss in information restructuring is the selective amplification of specific regions of the genome, principally in eukaryotic cells. This occurs in normal developmental processes and as a consequence of particular metabolic stress situations.

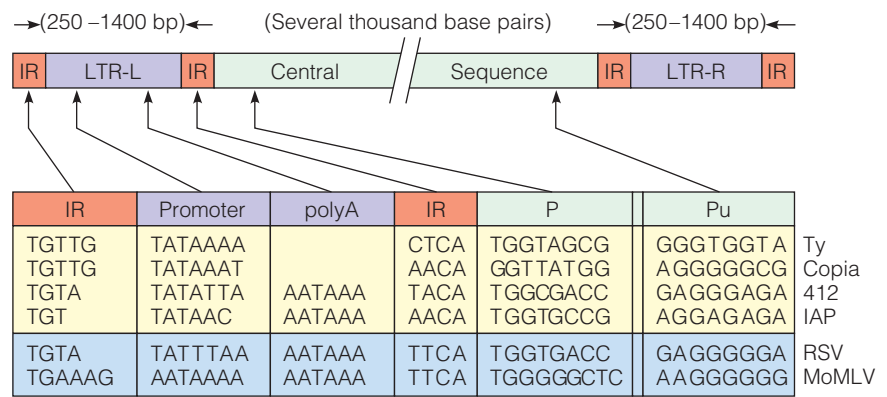

It has long been known that during oögenesis in certain amphibians the genes encoding ribosomal RNAs increase in copy number by some 2000-fold, in preparation for the large amount of protein synthesis that must occur in early development. The amplified DNA is in the form of extrachromosomal circles, each of which

Retroviral genomes and eukaryotic transposable elements have sequence similarities, to each other and to bacterial transposons.

FIGURE 26.41

Common sequence features in integrated retroviruses and other eukaryotic transposable elements. All these elements are bounded on the left and right sides by long terminal repeat sequences (LTR-L and LTR-R, respectively). Each LTR is flanked by short inverted repeat (IR) sequences (arrows). The approximate locations of various structural features are indicated, and the table gives some specific sequences associated with each feature in several transposable elements—IRs; promoter, a transcription start signal in each LTR; polyA, an adenine-rich sequence (absent from the yeast transposon Ty and the copia element in *Drosophila*); P, a sequence that anneals to an RNA that serves as a primer for replication; Pu, purine-rich sequence. 412, like copia, is a transposable element of *Drosophila*; IAP is a transposon found in the mouse genome; and RSV and MoMLV are retroviruses (Rous sarcoma virus and Moloney murine leukemia virus, respectively).

contains several copies of the ribosomal DNA repeat and a replication origin. A similar situation has been analyzed in *Drosophila*, in which genes encoding egg proteins are amplified at a particular developmental stage. In the latter case, however, the amplification results from repeated rounds of replication initiation within the amplified region, and the amplified sequences remain within the chromosome of origin.

Both types of mechanisms apparently occur during development of certain drug-resistant mammalian cell lines in culture. This process has been studied most widely in cells that become resistant to methotrexate, a dihydrofolate reductase inhibitor. As discussed in Chapter 22, treatment of leukemia with methotrexate often leads to the emergence of drug-resistant leukemic cell populations, which contain vastly elevated levels of the target enzyme, dihydrofolate reductase (DHFR). As shown originally by Robert Schimke, overproduction of the enzyme usually results from specific amplification of a large DNA segment that includes the DHFR gene. In one process, tandem duplication of the DNA segment generates a giant chromosome with multiple gene copies, in what is called a **homogeneously staining region (HSR)**, because it lacks the typical chromosome banding pattern. Alternatively, a DNA segment containing the DHFR gene can be excised, apparently by a recombinational process, to form minichromosomes called **double-minute chromosomes**, as shown schematically in Figure 26.42. Some resistant cells contain both types of amplified genes. Double-minute chromosomes are maintained within a cell only so long as selective pressure is maintained by growth of the cell in methotrexate. However, the chromosomally amplified phenotype is stable through many generations of cell growth. Figure 26.43 shows a fluorescence micrograph of metaphase chromosomes from a stably amplified Chinese hamster ovary cell line. DHFR sequences were visualized by in situ hybridization with a fluorescent-tagged DNA containing DHFR sequences. This technique is sufficiently sensitive to allow detection of single-copy sequences (white arrows). Note also the giant chromosome containing many gene-equivalents of DHFR gene sequences.

Amplification of genes under selective conditions has been widely observed—for example, in development of pesticide-resistant forms of insects. The mechanism of amplification is not yet clear. However, evidence such as that of Figure 26.43 shows that the amplified sequences are on the same chromosome as the original single-copy gene site, but at a significant distance away from that site. Such structures could arise either through recombination with unequal sister-chromatid exchange, schematized in Figure 26.44, or by a conservative transposition process. Later, homologous recombination within an amplified region can lead to excision of sequences containing one or more amplified sequences. In order to replicate autonomously, these excised sequences must have a centromere. Such elements probably represent the double-minute chromosomes.

The presence of selective pressure, such as the continuous presence of methotrexate, promotes specifically the survival of cells that can respond to that pressure, for instance, by overproducing DHFR. Once two or more copies of the gene are present

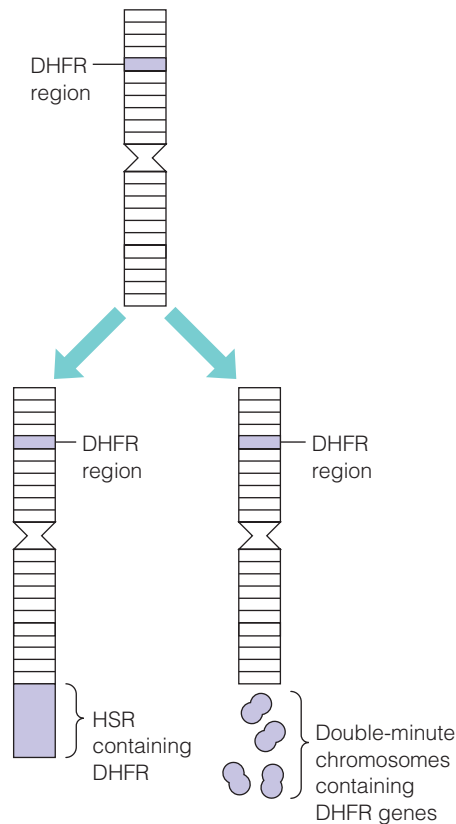

FIGURE 26.42

Two modes of gene amplification leading to drug resistance.

Gene amplification generates multiple copies of DNA sequences at a separate site on the same chromosome. Recombination among homologous segments yields extrachromosomal amplified sequences.

FIGURE 26.43

Chromosome structural changes that accompany dihydrofolate reductase gene amplification. The micrograph shows metaphase chromosomes from Chinese hamster ovary cells that are highly resistant to methotrexate. Chromosomal DNA was subjected to hybridization in situ with a fluorescence-labeled DHFR gene probe. White arrows point to single-copy genes. The amplified chromosomal sequences are on a giant form of the chromosome that also contains one of the original single-copy sequences.

Genes & Development 3:1913–1925, B. J. Trask and J. L. Hamlin, Early dihydrofolate reductase gene amplification events in CHO cells usually occur on the same chromosome arm as the original locus. © 1989 Cold Spring Harbor Laboratory Press. Reprinted by permission of Dr. Barbara Jo Trask and Dr. Joyce Hamlin.

on a chromosome, additional copies can be generated by further recombinational events or by abnormalities of replication. Resistance is thus developed in stepwise fashion and occurs over many generations of growth. These findings have immense practical significance because cancer chemotherapy often involves long-term treatment with low doses of an antimetabolite—precisely the conditions most likely to nullify the effect of treatment by generating drug-resistant cells. Findings on gene amplification not only have changed the way in which anticancer drugs are administered but also have been extended to the tumorigenic process itself. Investigators have found that specific oncogenes become amplified during the clinical progression of certain human tumors. Thus, gene amplification is seen as a mechanism in normal development, in cellular adaptation to stress, and in abnormal developmental processes. Also, the gene duplications that have occurred during evolution (see Chapter 7, page 258) probably have taken place by similar pathways.

SUMMARY

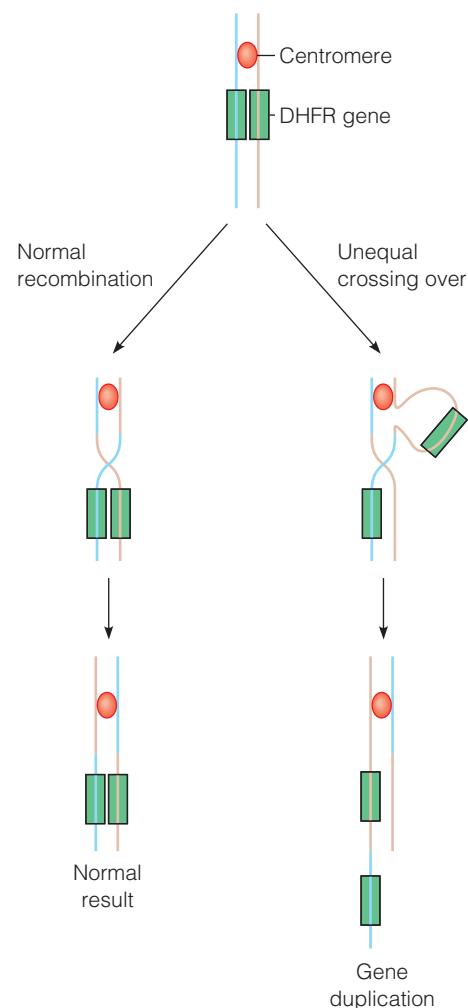

A variety of information restructuring processes affect DNA, to protect it from environmental damage or foreign organisms, to diversify the individuals in a species, or to diversify the genetic constitution of somatic cells in differentiation. DNA repair encompasses several processes, including photoreactivation, in which light energy is captured to reverse pyrimidine dimer formation, and the removal of alkylguanines by “enzymes” that act only once. Nucleotide excision-repair systems recognize damaged nucleotides and cleave out and replace a patch containing 12 to 30 nucleotides that flanks the damaged segment. Base excision repair begins with an *N*-glycosylase reaction, followed by repair enzymes that excise one or more nucleotides at the abasic site. Damage can also be repaired by a recombinational process or by induced (error-prone) repair. Mismatch repair systems correct occasional errors arising during replication. Double-strand DNA breaks are repaired either by recombination or by nonhomologous end-joining. Genetic recombination between homologous DNA segments involves helicase-catalyzed duplex unwinding, site-specific DNA cutting, duplex-strand invasion by single-strand 3' hydroxyl termini, chain extension, branch migration, and resolution of Holliday structures. Some recombinational events, such as integration of bacteriophage λ , are site-specific and governed by DNA–protein interactions. A wide range of gene rearrangements includes the joining reactions in differentiation of the immune response, gene transposition, retroviral genome integration, and gene amplification, which probably occurs by a recombinational mechanism. Gene amplification can either be a normal developmental process or occur in response to a specific environmental stress.

PROBLEMS

- Predict whether a *dam* methylase deficiency would increase, decrease, or have no effect upon spontaneous mutation rates, and explain the basis for your prediction.
- For each DNA repair process in column I, list *all* characteristics from column II that correctly describe that process.

I	II
(a) Nucleotide excision repair	1. RecA protein participates.
(b) Photoreactivation	2. Damaged nucleotides are removed by nick translation
(c) Base excision repair	3. A free radical mechanism is involved.
(d) Recombinational repair	4. The repair enzyme functions only once.
(e) SOS-driven error-prone repair	5. The key enzyme contains a bound folate cofactor.
(f) Alkyltransferase repair	6. No bases or nucleotides are removed from the DNA.
(g) Mismatch repair	7. Deficiency of this enzyme in humans greatly increases the risk of skin cancer.
(h) Double-strand break repair	8. This system is chiefly responsible for the mutagenic effect of ultraviolet light.
	9. The first enzyme in this pathway cleaves two phosphodiester bonds.
	10. This process begins up to 1 kbp away from the site to be repaired.
	11. DNA ligase catalyzes the final reaction.
	12. This process also occurs in meiotic recombination.
	13. Replication fork regression might occur during this process.

3.

For each of the following characteristics, list all of the bases (A, B, C, or D) to which they apply.

- A signal that identifies a parental DNA strand in the MthL, L, S mismatch correction system
- Most likely to be involved in cyclobutane dimer formation after ultraviolet irradiation of DNA
- A methylated base found immediately to the 5' side of dGMP residues in eukaryotic DNA

- (d) Created by treating DNA with alkylating agents that transfer methyl groups and repaired by an “enzyme” that functions only once in its lifetime
- (e) Created by AdoMet-dependent methylation of a nucleotide residue in DNA
- (f) A substrate for deamination at the DNA level, which would lead to a GC → AT transition
4. Homologous recombination in *E. coli* forms heteroduplex regions of DNA containing mismatched bases. Why are these mismatches not eliminated by the mismatch repair system?
 5. Deficiencies in the activity of either dUTPase or DNA ligase stimulate recombination. Why?
 6. Suppose that you wanted to study retroviral integration mechanisms by determining the nucleotide sequence at the integration site—several dozen nucleotides on each side of the viral–cellular DNA junction. Describe how to isolate DNA containing a junction site in amounts sufficient for sequence analysis.
 7. Analysis of p53 gene mutations in human tumors shows that a large proportion of these mutations involve GC → AT transitions originating at sites of DNA methylation. Propose a model to explain preferential mutagenesis of this type at these sites.
 8. A paper in the *Journal of Bacteriology* reported that a *mutT* mutant strain of *E. coli* displayed a mutator phenotype when the bacteria were cultured anaerobically. Is this a surprising result? Briefly explain your answer. Present one or two possible explanations for this observation.
 9. It is thought that the signal for eukaryotic mismatch repair, for identifying the strand to be repaired, could be nicks in the DNA to be repaired. If so, would you expect the nicked strand or the intact strand to be the strand to be repaired? Briefly explain your answer.
 10. Identify and briefly describe three of the processes by which deamination of DNA-cytosine residues by AID could lead to mutagenesis.
 11. In what ways can insertion of a transposon affect the expression of genes in the neighborhood of the insertion site?

TOOLS OF BIOCHEMISTRY 26A

GENE TARGETING BY HOMOLOGOUS RECOMBINATION

From the earliest years of recombinant DNA research, in the early 1970s, it was apparent that potential applications for research and for practical purposes were limitless. In short order it became routine to express exogenous genes in bacterial cells at high levels and to introduce any desired mutation into those genes (see Tools of Biochemistry 4A). It soon became possible to inactivate any desired gene in a bacterial genome. These “gene knockout” techniques took advantage of high activities of recombination enzymes in bacteria. A vector could be designed with sequences homologous to the chromosomal site in which exogenous DNA was to be inserted. Depending upon the design of the vector, recombination between vector sequences and homologous chromosomal sequences could lead either to insertion of new sequences into the genome or excision of chromosomal sequences adjacent to the targeting sequence used. In either case, expression of the target gene would be knocked out.

Comparable applications in eukaryotic organisms were less straightforward, partly because of their diploid genomes and partly because of technical difficulties in introducing exogenous DNA into nuclei. However, in 1983 Ralph Brinster and Richard Palmiter and their colleagues caused a sensation when they engineered the rat gene for pituitary growth hormone into the germ line of mice, and expression of the gene caused those mice to double in size. A vector was prepared that contained the growth hormone gene downstream from the promoter for metallothionein, a protein involved in heavy metal detoxification. The vector was microinjected into fertilized mouse eggs. A small proportion of animals stably incorporated the vector into their genomes. Supplementation of these animals’ diets with cadmium or zinc activated the metallothionein promoter, turning on the growth hormone gene.

Although this generation of the first transgenic animals was a signal achievement, it involved addition of an exogenous gene, inserted at random sites on the genome. Could similar technology be used to alter an animal’s own genotype, by insertion of DNA sequences at the site of a targeted gene? Beginning in the late 1970s, Mario Capecchi and Oliver Smithies began experimenting with gene transfer to mouse embryonic stem cells, and their efforts were rewarded with the Nobel Prize in 2007. Keys to their success were both high rates of homologous recombination between exogenous vectors and endogenous genes, and powerful techniques for selection of the desired recombination events. What is done is to introduce a targeting vector into embryonic stem cells by microinjection or electroporation (application of an electric field). Those rare cells that undergo recombination of the vector with cognate genomic sequences are selected for in culture and then injected into an early mouse embryo, which is next surgically implanted in a foster mother. The offspring are mosaics because they contain cells derived both from the manipulated stem cells and the recipient embryo. Breeding these chimeras with wild-type mice leads to homozygous transgenic animals, showing that the transgene was transmitted through the germ line.

Early gene-targeting experiments in the Capecchi laboratory used a neomycin resistance gene and the gene for hypoxanthine phosphoribosyltransferase (*hprt*) as selectable markers. The *neo^r* marker confers resistance to the antibiotic G418 (an inhibitor of protein synthesis), while expression of *hprt* sensitizes cells to 6-thioguanine, an unnatural HPRT substrate (see Chapter 22). The approach is schematized in Figure 26A.1. The targeting vector contains the *neo^r* gene inserted within a fragment of the *hprt* gene that extends from exon 7 to exon 9. Homologous recombination

**FIGURE 26.A.1**

Targeted insertion of the *neo*^r gene into the chromosomal *hprt* gene.

between the vector and the chromosomal *hprt* gene leads to insertion of *neo*^r between exons 7 and 9 of the *hprt* gene. Thus, recombinants are resistant both to G418 (because they express *neo*^r) and to 6-thioguanine (because the *hprt* gene has been disrupted). The fact that the *hprt* gene is carried on the X chromosome makes this selection particularly effective because only one insertion event is required to generate resistance to 6-thioguanine.

However, analysis of this system showed that almost all of the insertion events occurred at random sites, not at the target site. Accordingly, a more rigorous selection was devised. This was based on the finding that most random insertion events occur at the ends of the targeting vector, while insertions via homologous recombination occurred at regions of sequence homology that were usually not at the ends. An approach to target an insertion in any gene “x” is shown in Figure 26A.2. Included at the end of the targeting vector is the herpes simplex virus gene for thymidine kinase, HSV-tk. Expression of this gene sensitizes a cell to the nucleoside analog 2'-fluoro-2'-deoxy-1-β-D-arabinosyl-5-iodouracil (FIAU); HSV TK phosphorylates this nucleoside, whereas the cellular thymidine kinase does not. As shown in part A of the figure, homologous insertion at the target site does not bring the HSV-tk gene into the recipient cell. Therefore, the recipient cell is resistant to G418 because of *neo*^r expression, and resistant to FIAU because HSV-tk is not being expressed. On the other hand, random integration, occurring at molecular ends, brings the HSV-tk gene into the recipient cell and converts the cell to FIAU sensitivity.

Powerful selection techniques such as that described here make it possible to introduce new genetic material into any gene in the mouse genome, and, by extension, into other vertebrate genomes. Normal gene expression can be knocked out, and in a mutant with defective gene expression, activity of the wild-type gene can be “knocked in” by similar approaches. There is excitement about using this approach to cure genetic diseases in humans. However, the principal applications to date involve targeted disruption of mouse genes. More than 11,000 mouse genes have been disrupted, in many different laboratories, to allow analysis of the function of

**FIGURE 26.A.2**

Double selection technique to insure insertion at the homologous chromosomal site.

the respective missing gene. Many of these “knockout mouse” strains provide useful models of specific human diseases.

Gene disruption by homologous recombination has been used in other organisms. For example, in yeast a systematic study involved deletion of 6925 genes, one at a time, for analysis of the deleted gene function. In plants, by contrast, the principal means of genetic engineering do not involve homologous recombination. Most of the manipulations that generate, for example, “Roundup-Ready” seeds, use a bacterium, *Agrobacterium tumefaciens*, to provide a gene delivery vector (see Chapter 21). This bacterium causes tumors in infected plants because of expression of genes on a plasmid, the *Ti* plasmid. Part of the DNA of this plasmid, called T-DNA, becomes inserted into the infected plant genome as part of the tumorigenesis process. Transgenes are introduced into plant genomes by cloning them into vectors adjacent to T-DNA so that the transgene becomes inserted at the site of T-DNA insertion. For monocotyledonous plants, which cannot be infected by *Agrobacterium*, an alternate means of transformation involves the “gene gun,” a device that physically fires DNA-coated pellets into cells. Not nearly as elegant as targeted gene transformation, but effective under certain circumstances.

TOOLS OF BIOCHEMISTRY 26B

SINGLE-MOLECULE BIOCHEMISTRY

For many years chemists and biochemists alike have had to understand the behavior of molecules by observing large numbers of molecules and assuming that the behavior of individual molecules was similar to that of the average values observed. To be sure, it has long been possible to visualize single macromolecules, for example, by electron microscopy or atomic force microscopy (Tools of Biochemistry 1A). However, these are static measurements that do not allow analysis of molecular movements. Obviously, the ability to monitor single molecules might allow direct observation of fluctuations in behavior that are smoothed out by analysis of average behaviors. Within the past two decades a host of new techniques have become available that allow visualization of movements of single molecules. Some of these techniques use scanning electron microscopy, powerful fluorescence microscopes to detect fluorophores placed on protein molecules, or optical tweezers to immobilize single macromolecules. An optical tweezer is an instrument that uses a focused laser beam to provide a minute attractive or repulsive force, depending on the refractive index mismatch, to physically hold and move microscopic dielectric objects in solution.

An excellent example of single-molecule biochemistry is the experiment depicted in Chapter 15 (Figure 15.24, page 653), which provided direct evidence that the mitochondrial F_0F_1 complex is a rotary engine. In that experiment a molecule of the F_1 complex was immobilized in a microscopic field by means of a histidine tag. A fluorescent tag was attached to the γ subunit of the complex. Fluorescence microscopy allowed visualization of rotation of the γ subunit, its speed, direction, and dependence on ATP.

An early example of single-molecule visualization pertained to facilitated movement of a site-specific DNA-binding protein along a DNA lattice. It was observed in vitro that such proteins, including RNA polymerase, transcriptional repressors, and restriction enzymes, bind to a site more rapidly when the site is embedded in a long DNA molecule than a short one. Does this mean that the protein slides along the DNA, without dissociating, while it searches for its binding site? Or must other models be considered, such as intersegment transfer? As shown in Figure 26B.1, N. Shimamoto's laboratory devised an approach to the problem. DNA molecules containing a strong promoter, which binds RNA polymerase

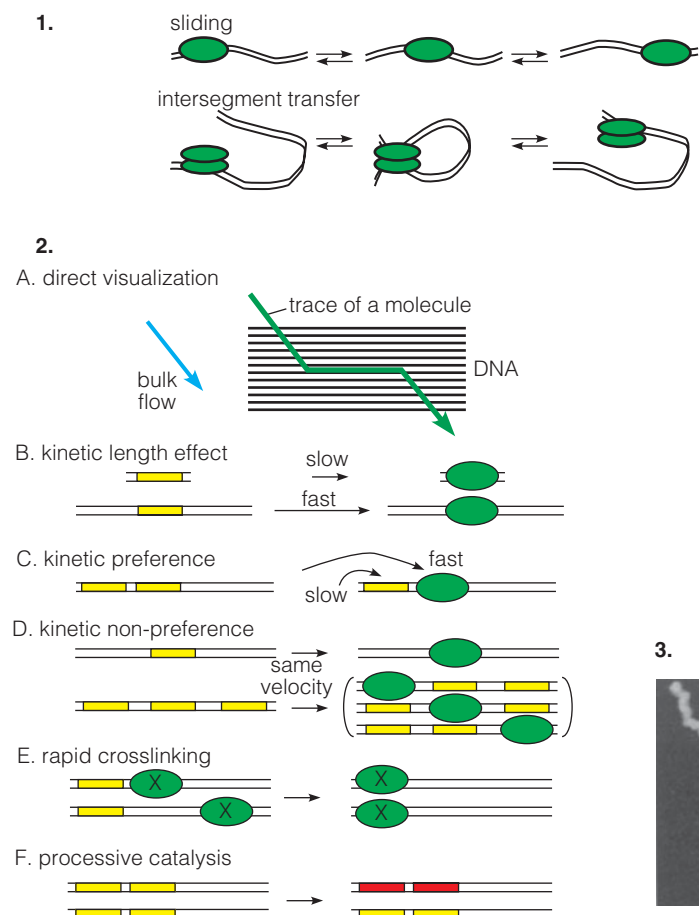

FIGURE 26B.1

Analysis of RNA polymerase sliding along DNA containing one or more strong promoter sites. **1.** In principle, facilitated movement along DNA can occur either by sliding or intersegment transfer. **2.** The experimental setup. Sliding is seen as horizontal deviation from the direction of bulk fluid flow. **B.–D.** Predicted kinetic behaviors. In **B** protein binds more rapidly to a site in a long than a short DNA molecule. In **C** protein binds more rapidly to a site adjacent to nonspecific DNA than to an identical site in the same molecule not adjacent to such DNA. In **D** protein binds equally rapidly to any site on the same molecule, so long as they are equally spaced. **3.** Experimental data showing either sliding (**right**) or simple drift through the DNA belt without binding. Interpretation of the data shown below.

tightly, were aligned in an electric field. Tangential to the DNA orientation, fluid flow carried across this “DNA belt” molecules of fluorescent-tagged RNA polymerase. Sliding would be seen as horizontal flow, as indicated in the diagram, and that in fact was seen.

Another excellent single-molecule study was mentioned in the body of this chapter (see Figure 26.28). In this study double-stranded DNA was immobilized at one end at the bottom of a flow cell. To the other end was attached a magnetic bead placed near a pair of magnets (“magnetic tweezers,” see Figure 26B.2). Rotation

of the magnets can introduce supercoils, and movement parallel to the DNA length can stretch the molecule. The number of magnet rotations needed to keep the DNA fully stretched shows how supercoiling is changing, as shown in panel B of the figure. Binding RecA-coated single-strand DNA stretches the duplex, relieving some of the supercoils. Typical data are shown in Figure 26B.3. Binding a RecA-ssDNA filament in the presence of ATP γ S, a non-hydrolyzable analog, stretched the DNA irreversibly (upper trace), while addition of ATP caused the stretched fiber to contract, con-

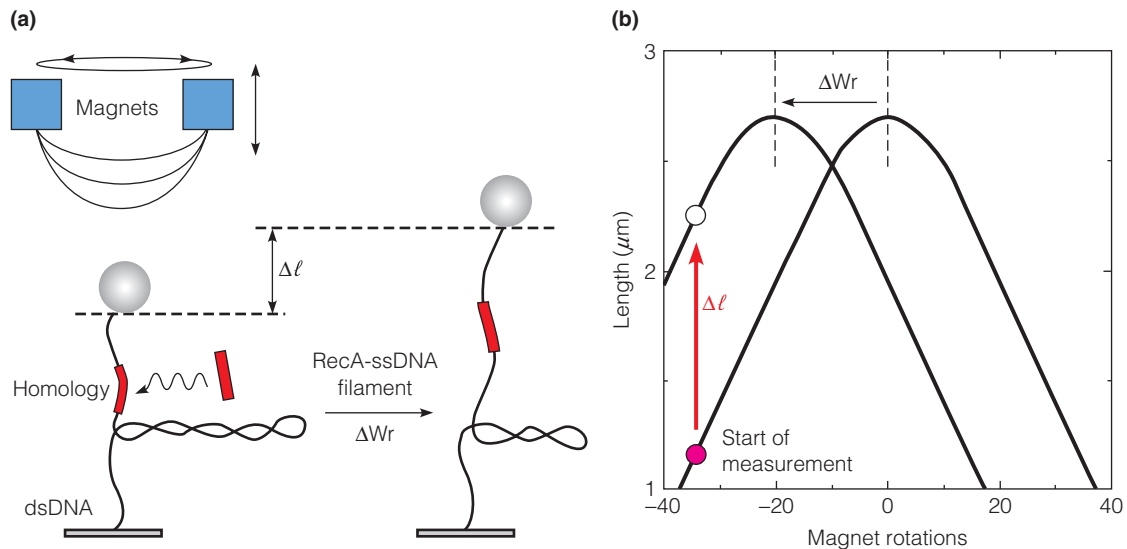

FIGURE 26B.2

Experimental setup for single-molecule analysis of RecA-mediated strand exchange. (a) The bead position, and hence, DNA length, is monitored by video microscopy and image analysis. The interaction of RecA-coated ssDNA (red bar) can be followed in real time because binding changes the end-to-end distance of the tethered DNA. **(b)** Binding RecA-ssDNA stretches the target DNA, thereby increasing its length; this can be determined from the number of rotations of the magnet needed to keep the target DNA fully stretched.

sistent with the conclusion that ATP hydrolysis is not essential for strand invasion, but is needed for strand exchange. Controls (right panel) in which there was no supercoiling of the target DNA (upper trace) or no region of homology (lower trace) showed no changes in length. By varying the length of homologous regions and other parameters, it was possible to generate the schematic view of RecA-mediated strand exchange shown in Figure 26.26.

It should be apparent from the examples shown here that the use of single-molecule techniques to study DNA–protein interactions, motor proteins, and physical movements of proteins and enzymes is limited only by the experimenter’s imagination.

CHAPTER 27

Information Readout: Transcription and Post- transcriptional Processing

We turn now to *transcription*, in which information stored in the nucleotide sequence of DNA is read out, by the template-dependent synthesis of polyribonucleotides. Mechanistically, transcription is similar to DNA replication, particularly in the use of nucleoside triphosphate substrates and the template-directed growth of nucleic acid chains in a 5' → 3' direction. There are, however, two major differences. First, with few known exceptions, only one DNA template strand is transcribed for a particular gene, and second, only part of the entire genetic potential of an organism is realized in one cell. In a differentiated eukaryotic cell, little of the total DNA is transcribed (although the proportion of DNA that is transcribed is larger than previously thought—see Chapter 29). Even in single-celled organisms, in which virtually all of the DNA sequences can be transcribed, only a small proportion of all genes may be transcribed at any time. Therefore, much of the interest in transcription involves regulation—the mechanisms used to select particular genes and template strands for transcription because this selection in large part governs the metabolic capabilities of a cell. Those mechanisms operate largely at the levels of initiation and termination of transcription through the actions of proteins that contact DNA in a highly site-specific manner (Figure 27.1). This figure shows a preview of what we have learned about transcriptional regulation through analysis of DNA-protein interactions. We discuss this important topic both here and in Chapter 29.

FIGURE 27.1

DNA–protein complexes that regulate transcription. Gene expression is controlled by proteins that recognize particular DNA sequences and bind at those sites. Shown here are two regulatory proteins of bacteriophage λ , which bind to the same *operator* sites in λ phage DNA and control the viral reproductive cycle by regulating transcription of genes adjacent to those sites. Above, the λ *cl* repressor; below, the Cro protein. In each graphic, DNA is in gold, and the protein is in green, except for the α -helical regions in contact with DNA in the major groove, which are in red. These proteins and their functions are described in Chapter 29.

The products of transcriptive RNA synthesis are rarely used directly. Almost always, transcription products are subject to further processing, such as trimming, cutting, splicing, and modifications at 3' and 5' ends. Therefore, this chapter deals also with post-transcriptional processing. We will be concerned here primarily with synthesis and processing of messenger RNA, ribosomal RNA, and transfer RNA, the species most directly involved in gene expression. However, we are learning that RNA is a far more versatile molecule than was thought until recently. We have already mentioned RNA enzymes—ribozymes—and their roles in RNA processing and splicing (Chapter 11), and we have described the involvement of RNA in the telomerase reaction (Chapter 25). In Chapter 29 we shall discuss the regulatory functions of RNA editing, riboswitches, small interfering RNAs, long noncoding RNAs, and microRNAs.

DNA as the Template for RNA Synthesis

The concept that RNAs are generated by template-directed copying of DNA base sequences is so firmly ingrained that we tend to forget about the critical experiments that led to our current understanding. This topic merits discussion because it involves a fascinating intellectual history, with many participants and some brilliant deductive reasoning. Even some of the false starts yielded important contributions. Also, the experimental systems used in the early work are some of those that continue to be useful, such as the lactose operon and bacteriophages T4 and λ .

The involvement of RNA in information transfer was suspected from the time DNA was first identified as the genetic storehouse—both from the chemical similarity of RNA to DNA and from the knowledge that proteins are synthesized on ribosomes. The latter fact meant that, in eukaryotic cells, information must somehow be transferred from the nucleus, where information is stored in DNA, to the cytoplasm, where most of the ribosomes reside. However, the nature of that information transfer was not clear until messenger RNA was shown to exist. This demonstration was far from straightforward because messenger RNA is quite unstable. Moreover, it constitutes such a small proportion of total cellular RNA (1% to 3% in bacteria) that in ordinary fractionations its presence is masked by the much more abundant ribosomal and transfer RNAs.

The Predicted Existence of Messenger RNA

Until about 1960 it was thought that ribosomal RNA (rRNA) represented the set of templates for protein synthesis. François Jacob and Jacques Monod, at France's Pasteur Institute, questioned this idea, in part because rRNAs are homogeneous in size (5S, 16S, and 23S in bacteria, as discussed in Chapter 28), whereas the molecular weights of proteins vary over at least two orders of magnitude. From analyzing *E. coli* mutants that are altered in the control of lactose metabolism, Jacob and Monod predicted the existence of messenger RNA (mRNA), an RNA species that is synthesized from a DNA template and is used in turn as the template for protein synthesis.

Lactose utilization in *E. coli* was known to be controlled by three enzymes, whose genes are adjacent on the chromosome. One of these is **β -galactosidase**, which hydrolyzes lactose and other β -galactosides. When bacteria are grown with glucose as the sole carbon source, the levels of the lactose-utilizing enzymes are very low, with less than one molecule of β -galactosidase per cell on average. However, substitution of lactose or a related β -galactoside for glucose in the medium leads to rapid enzyme **induction**, or synthesis of the three enzymes. β -Galactosidase ultimately represents as much as 6% of the total soluble protein of the cell. Removal of lactose from the culture slows the further synthesis of enzyme molecules. The rapid changes in β -galactosidase-forming capacity suggested that

Our original concepts of RNA synthesis came from genetic studies that predicted the existence of messenger RNA.

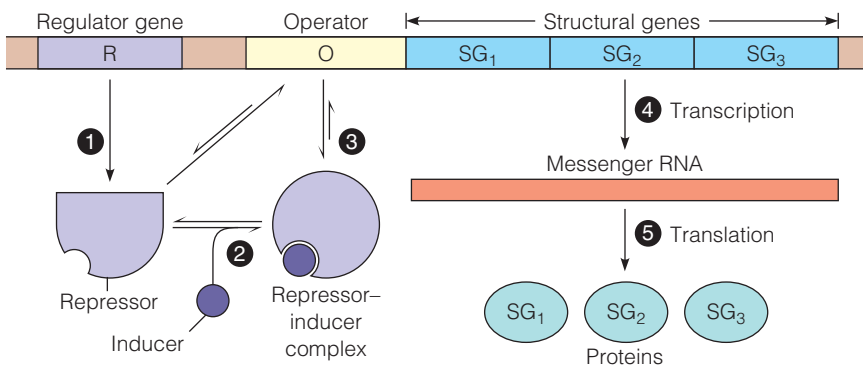

FIGURE 27.2

The operon model, as proposed in 1961 by Jacob and Monod. **Step 1:** The regulator gene R encodes a repressor molecule, which can bind to the operator (O) and thereby inhibit transcription of the adjacent structural genes SG_{1,2,3}. **Step 2:** A small-molecule inducer complexes with the repressor, thereby altering the equilibrium between the conformational states of the repressor. **Step 3:** The repressor–inducer complex binds less tightly to the operator. **Step 4:** This loosening facilitates transcription of the structural genes, resulting in production of messenger RNA—that is, an RNA copy of the structural genes. **Step 5:** The mRNA sequence is translated into proteins.

the template for synthesizing this enzyme is metabolically unstable—synthesized rapidly on demand and degraded when a continued stimulus to induction is absent (alternatively, control could be exercised at the translational level). Because rRNAs are quite stable, these species were unlikely to be intermediates in information transfer.

Jacob and Monod analyzed numerous *E. coli* mutants that displayed faulty control over induction of the lactose-utilizing enzymes. Some expressed all three genes at high levels even when lactose or a similar inducer was absent, and others could not induce any of the enzymes, even after addition of lactose. These experiments led to the notion of a macromolecular *repressor* that regulated the level of a messenger RNA by binding to a specific *operator* sequence on DNA and thereby turning off the synthesis of an RNA that encoded all three enzymes (see Chapter 29, pages 1233–1235).

Based on these studies, and on parallel work by Andre Lwoff with bacteriophage λ , Jacob and Monod in 1961 proposed a unifying hypothesis of gene regulation, in which transcription was regulated specifically at the level of initiation. Hypothetical regulatory elements called repressors and operators controlled the synthesis of other hypothetical entities called messenger RNAs (mRNAs). mRNA was postulated to be a complementary copy of the DNA that encompassed a set of structural genes, which encode proteins, as schematized in Figure 27.2. A set of contiguous genes plus adjacent regulatory elements that control their expression was termed an **operon**, and the Jacob–Monod hypothesis thus came to be known as the **operon model**.

Jacob and Monod correctly predicted several characteristics of the hypothetical messenger RNA. First, they predicted a high rate of mRNA synthesis followed by rapid degradation, which would explain the fast turn-on of the genes after induction and turn-off after removal of the inducer. Second, because of rapid synthesis and degradation, they expected mRNA to accumulate rapidly but not to high steady state levels. Third, because they thought that the messenger was a copy of two or more contiguous genes, they expected it to be fairly large and part of a heterogeneous size class of RNA. Finally, if the messenger RNA was a complementary copy of DNA, its nucleotide sequence should be identical to that of one of the template DNA strands.

T2 Bacteriophage and the Demonstration of Messenger RNA

The first physical demonstration of mRNA came from work with T2 and T4 bacteriophages. Infection by these large DNA viruses arrests all expression of host cell genes, and no accumulation of RNA can be detected after infection. However, in 1956 the use of radioisotopes led to detection of a distinctive RNA in T2-infected *E. coli*. When infected cultures were pulse-labeled with [³²P]orthophosphate for 3 or 4 minutes, about 2% of the total RNA became radioactive. This radiolabeled RNA had two properties that led to its eventual identification as viral messenger RNA.

Bacterial genetics predicted messenger RNA to be a collection of metabolically active RNAs that are present in low abundance, heterogeneous in size, and complementary in sequence to DNA.

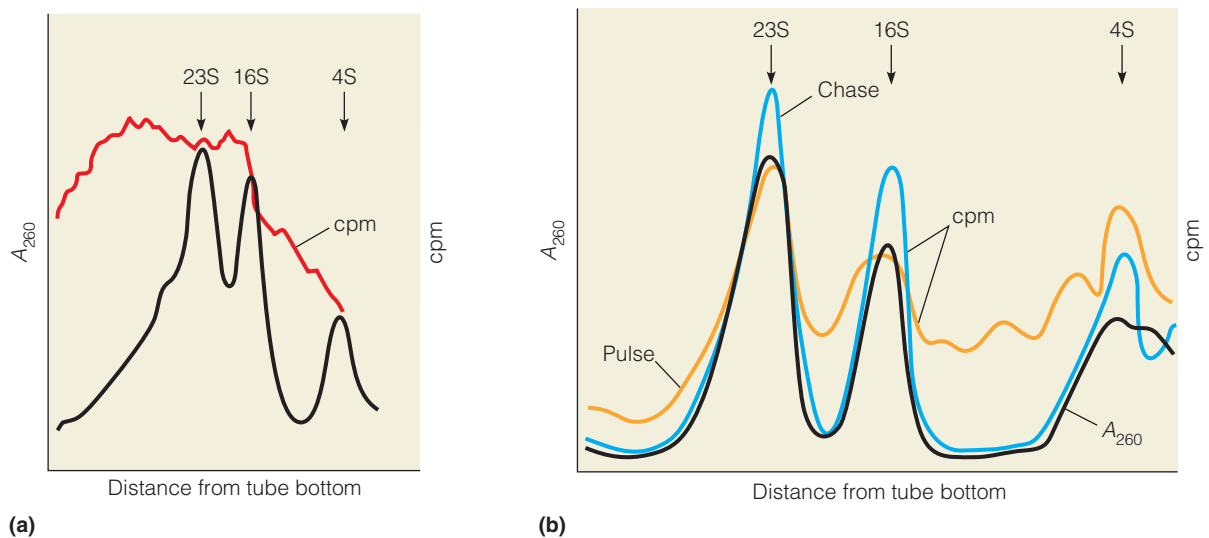

FIGURE 27.3

Demonstration of mRNA by pulse-labeling and sedimentation. (a) Sedimentation profile of total and pulse-labeled RNAs in T2 phage-infected *E. coli*. Total concentration of RNA in each fraction (black) was determined by ultraviolet absorbance (A_{260}). The peaks labeled 23S and 16S represent the major ribosomal RNA species. The radioactivity profile (red) shows the heterogeneous distribution of species synthesized during the pulse. (b) Pulse-labeled RNA species in uninfected bacteria and their fate in a chase. The orange line represents cells labeled for 3 minutes, the blue line depicts an identical culture with the label chased by 0.7 generation of growth in nonradioactive medium after the pulse, and the black line is the A_{260} profile. Again, the 23S and 16S peaks represent ribosomal RNA and the 4S peak is mostly transfer RNA.

(a) Data from *Journal of Molecular Biology* 14:71–84, K. Asano, Size heterogeneity of T2 messenger RNA. © 1965, with permission from Elsevier; (b) Data from *Proceedings of the National Academy of Sciences of the United States of America* (1961) 47:1564–1580 M. Hayashi and S. Spiegelman, The selective synthesis of informational RNA in bacteria.

The ability of T2 phage RNA to hybridize with T2 DNA and to associate with ribosomes made before infection was evidence for the existence of messenger RNA.

First, it was metabolically labile; in pulse-chase experiments (see Tools of Biochemistry 12A), radioactivity was rapidly lost from this RNA. Second, the RNA seemed to be a product of viral DNA metabolism because its nucleotide composition was close to that of T2 DNA; the RNA was rich in adenine and uracil and low in guanine and cytosine.

Important additional evidence came from sucrose gradient centrifugation of pulse-labeled RNA, which showed that the labeled material sediments heterogeneously and distinctly from any of the known rRNA or tRNA species (Figure 27.3a). Benjamin Hall and Sol Spiegelman established that this RNA is a viral gene product when they carried out the first DNA–RNA hybridization experiment, which showed that the labeled RNA was complementary in sequence to phage DNA. The earliest experiments were based on the fact that RNA is of higher density than DNA. Thus, a DNA–RNA hybrid could be detected in equilibrium gradient centrifugation as a species of intermediate density containing label derived from both DNA and RNA. Such a hybrid was formed when T2 RNA was heated and slowly cooled along with T2 DNA, but not when the DNA came from *E. coli*.

Additional support for the existence of phage messenger RNA came from a density shift experiment carried out by François Jacob, Matthew Meselson, and Sydney Brenner. *E. coli* was grown in dense medium (^{13}C – ^{15}N) and infected with T2 in light medium. The rationale is similar to that of the Meselson–Stahl experiment on DNA replication (Chapter 4). After pulse labeling with radioactive amino acids, density analysis on CsCl gradients showed that phage proteins were synthesized on dense ribosomes, that is, ribosomes synthesized before infection. The fact that only phage proteins were being made ruled out any possibility that ribosomal RNA provided a template. Instead, this experiment pictured the ribosome as a nonspecific workbench, upon which any protein could be assembled, depending on which messenger template became associated with that workbench.

RNA Dynamics in Uninfected Cells

The experiments described above demonstrated the existence of mRNA in phage-infected *E. coli*. What about uninfected bacteria? Spiegelman and his colleagues showed that pulse-labeled RNA from uninfected *E. coli* hybridized to *E. coli* DNA. At very short labeling intervals the sedimentation pattern showed incorporation into both rRNA and tRNA species and a heterogeneously sedimenting species. After a chase (Figure 27.3b), the radioactivity profile followed the absorbance profile, showing that all RNA species had become labeled to equivalent specific activities. This finding is consistent with the postulated short

lifetime of messenger RNA ($t_{1/2}$ of 2 or 3 minutes). mRNA would reach its maximal radioactivity within just a few minutes, but during the chase, mRNA turnover would release nucleotides that could flow into stable RNA species. Because those species do not turn over, label accumulates, and the fraction of total label in the stable RNA species continues to increase. Consistent with this idea, Spiegelman also showed that highly labeled ribosomal and transfer RNAs hybridize to *E. coli* DNA, demonstrating that all three major classes of RNA are synthesized from template DNA strands.

As noted previously, the earliest DNA–RNA hybridization experiments involved equilibrium gradient centrifugation, a time-consuming and expensive technique. Spiegelman and his colleagues made the important discovery that single-strand DNA binds irreversibly to membrane filters, made of material such as nitrocellulose. This technique allowed rapid hybridization analysis of a large number of samples because a radiolabeled RNA could hybridize to denatured DNA immobilized on a filter. After suitable treatment and washing of the filter, the extent of hybridization could be determined simply by placing the filter in a liquid scintillation counter and counting its radioactivity. The same principle—immobilization of nucleic acid on nitrocellulose followed by analysis of bound radioactivity—underlies Southern blotting and northern blotting (described in Chapter 24, page 1016), which are now more widely used to analyze gene organization and expression. These findings led also to microarray technology, in which thousands of DNA–RNA hybridization reactions are analyzed on a single DNA chip (see Tools of Biochemistry 27A).

The final chapter in the messenger RNA saga was the demonstration that isolated mRNAs have template activity *in vitro*. That is, they can program the synthesis of specific protein molecules in the presence of 20 amino acids and other factors. The translation of defined RNA templates, both synthetic and natural, was critical to deciphering the genetic code (see Chapter 28).

Enzymology of RNA Synthesis: RNA Polymerase

We now know that RNA synthesis involves the copying of a template DNA strand by RNA polymerase. However, the earliest description of an enzyme capable of synthesizing RNA *in vitro* occurred in the late 1950s, at about the same time as the discovery of DNA polymerase I. This RNA-synthesizing enzyme, called **polynucleotide phosphorylase**, was quite different from DNA polymerase. The enzyme required no template, and it used ribonucleoside *diphosphates* (rNDPs) as substrates to produce a random-sequence polynucleotide whose base composition matched the nucleotide composition of the reaction medium.

Initially it was thought that polynucleotide phosphorylase might be the major RNA-synthesizing enzyme, but the lack of a template requirement was troubling, as was the apparent absence of the enzyme in eukaryotic cells. Ultimately, polynucleotide phosphorylase turned out not to play a role in RNA synthesis *in vivo* but instead to participate in the *degradation* of bacterial messenger RNAs. However, the enzyme was of great value in the synthesis of polynucleotides used as templates for *in vitro* protein synthesis, when the genetic code was being elucidated (see Chapter 28).

Investigators continued to search for an enzyme that would copy a DNA template *in vitro*. In 1961 such an enzyme was discovered almost simultaneously in four different laboratories. The enzyme, **DNA-directed RNA polymerase**, resembled DNA polymerases in the nature of the reaction catalyzed.

The reaction product is a complementary RNA copy of the DNA template.

Polynucleotide phosphorylase catalyzes the reversible, template-independent synthesis of random-sequence polyribonucleotides.

Biological Role of RNA Polymerase

A single RNA polymerase catalyzes the synthesis of all three bacterial RNA classes—mRNA, rRNA, and tRNA. This was shown in experiments with **rifampicin** (Figure 27.4a), an antibiotic that inhibits RNA polymerase in vitro and blocks the synthesis of mRNA, rRNA, and tRNA in vivo. Rifampicin-resistant mutants of *E. coli* were found both to contain a rifampicin-resistant form of RNA polymerase and to be capable of synthesizing all three RNA classes in vivo in the presence of rifampicin. Because a single mutation affects both the RNA polymerase and the synthesis of all RNA types in vivo, RNA polymerase must be the one enzyme catalyzing all forms of transcription in bacteria.

In contrast, eukaryotes contain three distinct RNA polymerases, one each for synthesis of rRNA, mRNA, and small RNAs (tRNA plus the 5S species of rRNA)—RNA polymerases I, II, and III, respectively. The existence of separate enzymes was revealed partly because they differ in their sensitivity to inhibition by α -amanitin (Figure 27.4b), a toxin from the poisonous *Amanita* mushroom. RNA polymerase II is inhibited at low concentrations, RNA polymerase III is inhibited only at high concentrations, and RNA polymerase I is quite resistant.

Figure 27.4 shows the structures of two additional inhibitors. **Cordycepin**, or 3'-deoxyadenosine, is a transcription chain terminator because it lacks a 3' hydroxyl group from which to extend. The nucleotide of cordycepin is incorporated into growing chains, confirming that transcriptional chain growth occurs in a 5' \rightarrow 3' direction. Another important inhibitor is **actinomycin D**, which acts by binding to DNA. The tricyclic ring system (phenoxazone) intercalates between adjacent G-C base pairs in DNA; the cyclic polypeptide arms fill the nearby narrow groove.

Because DNA polymerases and RNA polymerases catalyze similar reactions, it is interesting to compare some of their kinetic features. V_{\max} for DNA polymerase III

FIGURE 27.4

Some inhibitors of transcription. Rifampicin is an inhibitor of bacterial transcription initiation, and α -amanitin is an inhibitor of eukaryotic RNA polymerases. Cordycepin is a transcription terminator because the 3' position on the sugar is occupied by H (magenta), rather than a hydroxyl group. The tricyclic ring system of actinomycin D (blue) intercalates between adjacent G-C base pairs in DNA; the R groups of the molecule (magenta) are cyclic polypeptides and fill in the narrow grooves of the helix.

holoenzyme, at about 500 to 1000 nucleotides per second, is much higher than the chain growth rate for bacterial transcription—50 nucleotides per second, which is the same as V_{\max} for purified RNA polymerase. Although there are only about 10 molecules of DNA polymerase III per *E. coli* cell, there are some 2000 molecules of RNA polymerase, of which half might be involved in transcription at any instant. This fits in with observations that replicative DNA chain growth is rapid but occurs at few sites, whereas transcription is much slower but occurs at many sites. The result is that far more RNA accumulates in the cell than DNA. Like the DNA polymerase III holoenzyme, the action of RNA polymerase is highly processive. Once past the initial stages of transcription, RNA polymerase rarely, if ever, dissociates from the template until the specific signal to terminate has been reached. Although this discussion is based primarily upon prokaryotic transcription, these characteristics of transcription are similar in eukaryotic cells.

Another important difference between DNA and RNA polymerases is the accuracy with which a template is copied. With an error rate of about 10^{-5} , RNA polymerase is less accurate than replicative DNA polymerase holoenzymes, although RNA polymerase is much more accurate than would be predicted from Watson–Crick base pairing alone. Given that RNA does not carry information from one cell generation to the next, an ultrahigh-fidelity template-copying mechanism is evidently not needed. However, recent observations suggest the existence of error-correction mechanisms. In *E. coli*, two proteins, called GreA and GreB, promote the hydrolytic cleavage of nucleotides at the 3' ends of nascent RNA molecules. These processes may be akin to 3' exonucleolytic proofreading by DNA polymerases, but there are important differences: First, cleavage of 3' ends of RNA molecules usually removes dinucleotides, rather than single nucleotides. Second, cleavage occurs within the polymerase catalytic site, whereas DNA polymerase proofreading occurs at a distinct exonuclease site. Finally, the rate of hydrolysis is much slower than the rate of RNA chain extension by RNA polymerase. As discussed below, 3' transcript cleavage probably plays a different role, in escaping blocks to continued elongation. However, there is evidence indicating that a misincorporated nucleotide is preferentially cleaved before continuation of chain elongation.

DNA replication involves rapid chain growth at few intracellular sites, and transcription involves slower growth at many sites. More RNA accumulates than DNA.

Structure of RNA Polymerase

When highly purified *E. coli* RNA polymerase is analyzed in denaturing electrophoretic gels, five distinct polypeptide subunits are observed. Their properties are summarized in Table 27.1. Two copies of the α subunit are present, along with one each of β , β' , σ , and ω , giving M_r of about 450,000 for the holoenzyme. ω may be involved in regulation, but its precise role is not yet clear. However, much has been learned about the functions of the other subunits, partly from **mixed reconstitution** studies, in which the dissociated subunits are renatured and allowed to reassociate, with formation of active enzyme. For example, when β from a rifampicin-resistant

The functions of the various RNA polymerase subunits can be determined by reconstitution of active enzyme from isolated subunits.

TABLE 27.1 Subunit composition of *E. coli* RNA polymerase

Subunit	M_r	Number per Enzyme Molecule	Function
α	36,500	2	Chain initiation, interaction with regulatory proteins and upstream promoter elements
β	151,000	1	Chain initiation and elongation
β'	155,000	1	DNA binding
σ	70,000 ^a	1	Promoter recognition
ω	11,000	1	Unknown

^aThe 70-kDa σ subunit is one of several alternative σ subunits.

form of RNA polymerase was recombined with α , β' , and σ from wild-type cells, the reconstituted enzyme was seen to be rifampicin-resistant. This finding establishes β as the target for rifampicin inhibition. Furthermore, rifampicin is known to inhibit the initiation of transcription, so β must also play a role in initiation. The fact that β is also the target for inhibition by an inhibitor of elongation called **streptolydigin** points to β as a subunit directly involved in chain elongation.

The σ subunit is easily dissociated from RNA polymerase—for example, by passing the purified enzyme through a carboxymethylcellulose column. The σ -free enzyme, called **core polymerase**, is still catalytically active, but it binds to DNA at far more sites than does the RNA polymerase holoenzyme, and it shows no strand or sequence specificity. The σ subunit plays an essential role in directing RNA polymerase to bind to template at the proper site for initiation—the **promoter** site—and to select the correct strand for transcription. The addition of σ to core polymerase reduces the affinity of the enzyme for *nonpromoter* sites by about 10^4 , thereby increasing the enzyme's specificity for binding to promoters.

These discoveries about σ , which were made in the early 1970s, suggested that gene expression might be regulated by having core polymerase interact with different forms of σ , which would in turn direct the holoenzyme to different promoters. In many instances, this does occur. For example, when *Bacillus subtilis* is induced to **sporulate** (that is, to generate metabolically inert cells capable of later outgrowth), new forms of σ are produced. These forms combine with core polymerase to redirect cellular metabolism for transcription of the genes involved in sporulation. Another example is apparent when an *E. coli* culture is stressed by a sudden temperature increase. In these heat-shocked cells a new form of σ appears and directs the modified RNA polymerase to a different set of promoters, thereby activating transcription of a block of genes called heat-shock genes. The most abundant σ in *E. coli*, and the one that will frame our discussions, is called σ^{70} because of its 70-kDa molecular weight. As shown in Table 27.2, seven different σ factors are known in *E. coli*, each designed to direct RNA polymerase to a functionally related set of genes.

Eukaryotic RNA polymerases show similarity with the prokaryotic enzymes, but they have a much more complex subunit structure. RNA polymerase II from yeast has twelve subunits. However, the common ancestry among RNA polymerases is evident, as can be seen in Figure 27.5. For example, the two proteins in the pol II catalytic core in all three eukaryotic multisubunit polymerases are related to β and β' of the bacterial enzyme. Shown also in the figure is the subunit composition of archaeal RNA polymerases, which shows them to be much more closely related to eukaryotic than to prokaryotic polymerases. Eukaryotic RNA polymerases have no direct counterpart to bacterial σ . Instead, a series of proteins called **transcription factors** functions in comparable fashion, helping to direct RNA polymerase to promoter sites and to form an initiation complex, as discussed later (page 1135). Bacteria have transcription factors also, as we describe in Chapter 29.

Although the multisubunit motif for RNA polymerases is the dominant structural theme, it is not universal. Exceptions include single-subunit polymerases

TABLE 27.2 σ Factors in *E. coli*

Name	Structural Gene	Genes Whose Transcription Is Stimulated by Binding to Core Polymerase
σ^{70}	<i>rpoD</i>	“Housekeeping genes” (those involved in central pathways)
σ^N	<i>rpoN</i>	Genes involved in adaptation to nitrogen stress
σ^S	<i>rpoS</i>	Genes involved in adaptation to stationary phase

encoded by some bacteriophage genomes, including T7 and SP6, and a mitochondrial RNA polymerase found in vertebrates. Plant chloroplasts also contain an organelle-specific RNA polymerase. Figure 27.6 shows crystal structures of a prokaryotic multisubunit RNA polymerase, from *Thermus aquaticus*, and RNA polymerase II from yeast (*pol II*), as determined in the laboratories of Seth Darst and Roger Kornberg, respectively. We shall describe relations between these structures and the RNA polymerase reaction presently.

Mechanism of Transcription

Like DNA replication and protein synthesis, transcription occurs in three distinct phases—initiation, elongation, and termination. Initiation and termination signals in the DNA sequence punctuate the genetic message by directing RNA polymerase to particular genes and by specifying where transcription will start, where it will stop, and which strand will be transcribed. The signals involve both instructions encoded in DNA base sequences and interactions between DNA and proteins other than RNA polymerase. Most of our initial discussion focuses on prokaryotic RNA polymerases, exemplified by the widely studied *E. coli* enzyme, but the basic mechanics of transcription are similar in all organisms. Action of the eukaryotic enzymes is discussed later.

Initiation of Transcription: Interactions with Promoters

The overall processes of initiation and elongation are summarized in Figure 27.7. The first step in transcription is binding of RNA polymerase to DNA, followed by migration to an initiation DNA site, the promoter. In *Tools of Biochemistry 27B*, we describe *footprinting*, a technique used to locate DNA sites in contact with sequence-specific DNA-binding proteins, and we discuss promoter recognition on pages 1138–1140. For now, let us concentrate on the mechanistic details of synthesizing polyribonucleotide chains.

Bacterial RNA polymerase finds promoters by a search process (Figure 27.7, step 1), in which the holoenzyme binds nonspecifically to DNA, with low affinity, and then moves along the DNA until it reaches a promoter sequence, to which it

FIGURE 27.7

Initiation and elongation steps of transcription by bacterial RNA polymerase.

binds with much higher affinity. σ factor is essential for this search because, as noted earlier, the core enzyme does not bind to promoters more tightly than to nonpromoter sites. Biophysical evidence suggests that RNA polymerase slides along the DNA, without dissociating from it. Evidence for sliding of the enzyme along DNA comes partly from single-molecule studies, of the type described in Tools of Biochemistry 26B. Binding to DNA and then moving along it reduces the complexity of the search from three dimensions to one, just as finding a house becomes simpler once you find the street upon which that house is located.

The initial encounter between RNA polymerase holoenzyme and a promoter generates a **closed-promoter complex** (step 2). Whereas DNA strands unwind later in transcription, no unwinding is detectable in a closed-promoter complex. This complex forms with a K_a between 10^7 and 10^8 M^{-1} at 0.1 M NaCl. Binding is

primarily electrostatic, for K_a is dependent on ionic strength. The complex is relatively labile, dissociating with a half-life of about 10 seconds. Footprinting studies show that polymerase is in contact with DNA from about nucleotide -55 to -5 , where $+1$ represents the first DNA nucleotide to be transcribed.

Next, as shown by analysis with chemical reagents that react specifically with single-stranded DNA, RNA polymerase unwinds several base pairs of DNA, from about -10 to -1 , giving an **open-promoter complex**, so-called because it binds DNA whose strands are open, or unwound (step 3). This highly temperature-dependent reaction occurs with half-times of about 15 seconds to 20 minutes, depending upon the structure of the promoter. The open-promoter complex is extremely stable; it is not easily disrupted by high ionic strength, and it forms with a K_a as high as 10^{12} M^{-1} . An Mg^{2+} -dependent isomerization next occurs, giving a modified form of the open-promoter complex with the unwound DNA region now extending from -12 to $+2$. Analysis with scanning force microscopy (Tools of Biochemistry 1A), later confirmed by X-ray crystallography (Figure 27.8) indicates that DNA bending in the promoter region accompanies the transition from a closed-promoter to an open-promoter complex (Figure 27.7). This could be related to the fact, as noted later, that activation of the transcription of certain genes often involves interaction between the promoter and its associated proteins and with proteins bound at upstream regulatory sites, far to the 5' side of the gene being transcribed.

Initiation and Elongation: Incorporation of Ribonucleotides

Having located a promoter and formed an open-promoter complex, the enzyme is ready to begin the synthesis of an RNA chain. Binding of the first ribonucleoside triphosphate (usually ATP or GTP) occurs with a half-saturating concentration of about $100 \mu\text{M}$. Since binding of later rNTPs occurs with half-saturating concentrations of about $10 \mu\text{M}$, this may represent a control process, favoring initiation only at relatively high rNTP concentrations. RNA polymerase contains two nucleotide-binding sites near the catalytic center. Current evidence suggests that rNTP binding at the low-affinity site is allosteric, and functions to drive the reaction in a forward direction.

Chain growth begins with binding of the template-specified rNTP (Figure 27.7, step 4), followed by binding of the next nucleotide. Next, nucleophilic attack by the 3' hydroxyl of the first nucleotide on the α (innermost) phosphorus of the second nucleotide generates the first phosphodiester bond and leaves an intact triphosphate moiety at the 5' position of the first nucleotide. Nucleotide incorporation occurs via the two-metal mechanism described for DNA polymerases in Chapter 25 (page 1046) and now thought to be universal for nucleic acid-synthesizing enzymes. The transcript is bound unstably during the first several phosphodiester bond-forming reactions, as shown by the fact that most initiations are abortive, with release of oligonucleotides two to nine residues long. The basis for this low efficiency of initiation is not fully understood, although structural analysis of RNA polymerases is yielding clues (page 1136).

During incorporation of the first 10 nucleotides, the σ subunit dissociates from the transcription complex, and the remainder of the transcription process is catalyzed by the core polymerase (steps 5 and 6). Once σ has dissociated, the elongation complex becomes quite stable. Transcription, as studied *in vitro*, can no longer be inhibited by adding rifampicin, and virtually all transcription events proceed to completion.

During *elongation* (steps 5 and 6), the core enzyme moves along the duplex DNA template. As it moves, it simultaneously unwinds the DNA, exposing a single-stranded template for base pairing with incoming nucleotides and with the nascent transcript (the most recently synthesized RNA), and it rewinds the template behind the 3' end of the growing RNA chain, as suggested in Figure 27.9. In this model, about 18 base pairs of DNA are unwound to form a moving "transcription

Transcription begins with sequence-specific interaction between RNA polymerase and a promoter site, where duplex unwinding and template strand selection occur.

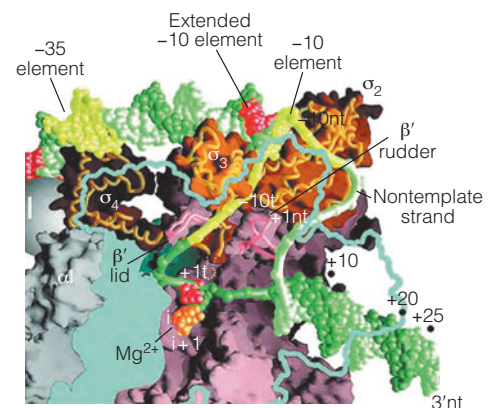

FIGURE 27.8

DNA bending in an open-promoter complex. This image is taken from the crystal structure of *Taq* RNA polymerase. Parts of β have been removed to show interior structure; outline of β is shown as a cyan line. The template DNA strand is shown in green, and the nontemplate strand is in yellow. Note the sharp bend in the template strand. The first two ribonucleotides to be incorporated (i and $i + 1$) are shown in orange and pink, respectively, close to a catalytically essential Mg^{2+} . Much of the α and β' subunits are rendered transparent, with the interior α -carbon chains shown in gold. The -10 and -35 regions of the DNA, which comprise the promoter, are shown in yellow. PDB ID, 1L9U.

FIGURE 27.9

The transcription bubble. The lengths of unwound DNA and DNA–RNA hybrid were originally estimated from reactivities of transcription complexes with reagents such as KMnO_4 , which oxidizes bases in single-strand nucleic acids. The length of DNA in contact with the enzyme is determined by footprinting (see Tools of Biochemistry 27A). Six or seven nucleotides of RNA behind the DNA hybrid are protected from ribonuclease attack by binding to the enzyme. Nt = nucleotide.

bubble.” As one base pair becomes unwound in advance of the 3' end of the nascent RNA strand, one base pair becomes rewound near the trailing end of the RNA polymerase molecule. About 9 base pairs of the 3' end of the nascent transcript are hybridized to the template DNA strand. During elongation RNA polymerase functions as a true molecular motor. Techniques for analysis of single complexes show that RNA polymerase generates forces exceeding those of well-studied cytoskeletal motor proteins, such as myosin and kinesin (Chapter 8).

Figure 27.10 shows a stylized picture of an elongation complex. Although this model was derived from the structure of yeast RNA polymerase II, it shows generally applicable features of transcriptional elongation, such as the large wall, which forces DNA to bend, almost at right angles.

High-resolution structures of a bacterial RNA polymerase, from *Thermus thermophilus*, in the presence of a nonhydrolyzable rNTP analog, give a detailed picture of the nucleotide addition cycle. Critical to this process, as schematized in Figure 27.11, is a 20-residue sequence called the trigger, part of the bridge structure seen in Figure 27.10, which can exist either as a disordered loop or as two helices. After insertion of a nucleotide into the growing RNA chain followed by translocation, the loop is disordered and the rNTP entry channel is open. Entry of an rNTP is followed by folding of the trigger loop into two helices, constraining the rNTP and giving an opportunity for the enzyme to somehow test its shape and reject an incorrectly base-paired nucleotide. At this point the nucleotide, even though not yet incorporated, serves as a ratchet, to prevent backtracking by the enzyme. After catalysis the trigger helices unfold and the channel reopens.

FIGURE 27.10

Cutaway view of the RNA polymerase II elongation complex. Cut surfaces of the protein are lightly shaded, and the remainder, at the back, is darkly shaded. Direction of polymerase motion is left to right as shown. The template DNA strand is in blue. The nontemplate strand, in green, is not shown because it is disordered, except when paired with template DNA. RNA that is hybridized to the template DNA strand is in orange. DNA entering the enzyme is gripped by protein “jaws” (upper jaw not shown in this cutaway model). The 3' end of growing RNA is adjacent to one of the catalytically essential Mg^{2+} ions. The wall forces the DNA to turn, almost at right angles. rNTPs probably enter the active site, as shown, through a funnel structure and pore. The 5' end of the growing RNA chain is diverted from the DNA template by a protein loop called the rudder, which limits the length of RNA hybridized to template DNA. The rudder and lid, which guide the exit of RNA, emanate from a large clamp that swings from back to front, as shown, over the catalytic site and contribute to the binding of nucleic acids, and hence, to the high processivity of transcription.

Structural features of the single-subunit T7 phage RNA polymerase, as well as eukaryotic RNA polymerase II, suggest that this process is widespread. In this study the antibiotic streptolydigin, a well-known RNA polymerase inhibitor, was shown to freeze the enzyme in the preinsertion state.

The concept of a transcription bubble as a central intermediate in transcription, as depicted in Figure 27.9, suggests that the enzyme moves along the DNA template in register with the growing RNA transcript, with the footprint advancing by one base pair for each ribonucleotide incorporated into the transcript. In fact, footprinting of numerous initiation and elongation complexes has shown that the enzyme often advances discontinuously, holding its position for several cycles of nucleotide addition and then jumping forward by several base pairs along the template. Similar conclusions come from single-molecule studies and other contemporary approaches. These observations suggested that the means of RNA polymerase translocation are fundamentally different from the continuous movement implied by a picture of the transcription bubble. However, the “transcription bubble” paradigm can be at least partially reconciled with the footprinting data. It has long been known that some DNA sequences are difficult to transcribe, and RNA polymerase “pauses” when it reaches such a site in vitro, often sitting at the same site for several seconds before transcription is resumed. Recent experiments indicate that at such sites, RNA polymerase often translocates backward, and in the process the 3' end of the nascent transcript is displaced from the catalytic site of the enzyme, giving a 3' “tail,” which may be several nucleotides long and is not base-paired to the template, protruding downstream of the enzyme (Figure 27.12). In order for transcription to resume, an RNA 3' end must be positioned in the active site. This is evidently a primary function of the RNA 3' cleavage reactions, which we mentioned on page 1131 as possible events in optimizing transcriptional fidelity. The “backtracking” shown in Figure 27.12 was observed initially only in transcription complexes obtained from a *greA greB* double mutant; otherwise, the displaced 3' RNA end was cleaved and could not be detected. The GreA and GreB proteins have been shown to stimulate a transcript cleavage activity that is intrinsic to the polymerase itself. These observations suggest that RNA polymerase generally moves forward until one of these special sequences is reached or, perhaps, until a

**FIGURE 27.12**

Backtracking in an elongation complex. Above, the 3' terminus of the transcript is in the active site (denoted by Mg^{2+}). Below, the enzyme has slipped backward, leaving the 3' transcript terminus at the end of a non-base-paired RNA tail, some five nucleotides long. Transcription can resume either by forward sliding of polymerase back to the structure depicted above or, more likely, by cleavage of the non-base-paired part of the transcript, creating a new base-paired 3' terminus. DBS and RBS, DNA-binding and RNA-binding site, respectively.

Reprinted from *Cell* 89:33–41, E. Nudler, A. Mustaev, E. Lukhtanov, and A. Goldfarb, The RNA–DNA hybrid maintains the register of transcription by preventing backtracking of RNA polymerase. © 1997, with permission from Elsevier.

transcription insertion error generates a DNA–RNA mispairing that weakens the hybrid and allows backtracking. Until recently the mechanism and significance of pausing were obscure. Single-molecule studies with defined DNA templates show general similarity between some pausing sites and other sites at which pausing plays a known regulatory function. And, as noted, pausing and 3' cleavage evidently do function to improve transcription accuracy.

Punctuation of Transcription: Promoter Recognition

Promoter recognition is a crucial step in transcription, from the standpoint of regulation as well as mechanism. In *E. coli* it is estimated that the most frequently transcribed genes initiate transcription about once every 10 seconds, whereas some genes are transcribed as infrequently as once per generation (30 to 60 minutes). Promoter recognition is a rate-limiting step for transcription. Because all genes in bacteria are transcribed by the same core enzyme, variations in promoter structure must be responsible in large part for the great variation in the frequency of initiation. Information about promoter structure is of practical value in designing vectors for expression of cloned genes.

What structural features in DNA direct RNA polymerase to bind at a promoter site and to form an open-promoter complex? The first hint of an answer came in 1975, when David Pribnow and Heinz Schaller independently examined the limited DNA sequence data then available, which revealed that each gene transcribed in *E. coli* shared a short adenine- and thymine-rich sequence, centered about 10 nucleotides to the 5' side of the transcriptional start site (Figure 27.13). (Identification of transcriptional start points is described in Tools of Biochemistry 27C.) There was some variation among the promoters analyzed, but a **consensus sequence** emerged within this conserved region. A consensus sequence comprises those bases that appear most frequently at each sequence position in a series of sequences thought to have a common function. Among the different initiation sequences analyzed in *E. coli*, that consensus sequence was TATAAT on the

The frequency with which a gene is transcribed in *E. coli* genes is largely determined by the similarity between the gene's promoter sequence and the consensus sequence.

FIGURE 27.13

Conserved sequences in promoters recognized by *E. coli* RNA polymerase. Lengths of spacer sequences are also shown. Red arrows indicate transcription start site.

sense strand. The sense strand is the nontranscribed DNA strand. Because it is complementary in sequence to the template strand, the sense strand is identical in base sequence to the RNA product within the region transcribed, but with T instead of U. Later, another region of conserved nucleotide sequence was found centered at nucleotide -35 , with a consensus sequence of TTGACA.

The two conserved sequences are called the -35 region and the -10 region (see Figure 27.13; the -10 region is also called the *Pribnow box*). No known natural promoter has -35 and -10 regions that are identical to the consensus sequences, but, in general, the more closely these regions in a promoter resemble the consensus sequences, the more efficient that promoter is in initiating transcription. Variations in promoter structure represent a simple way for the cell to vary rates of transcription from different genes. Figure 27.13 indicates the extent to which different nucleotides are conserved. Among 114 *E. coli* promoters examined in an early study, 6 or more of the 12 nucleotides in the two consensus sequences were found in more than 75% of the promoters.

What evidence points to a functional role for these conserved sequences in binding RNA polymerase and initiating transcription? First, a variety of mutations map in promoter regions and affect transcription efficiency in vivo. As shown in Figure 27.14, most of the promoter mutations that have been sequenced change the structure of either the -35 region or the -10 region, pointing directly to those sequences as having the greatest effect on transcriptional initiation efficiency. In general, the mutations that increase promoter strength (**up-promoter mutations**) change either the -35 or the -10 region to more closely resemble the consensus sequences. **Down-promoter mutations**, which decrease promoter strength, change the sequence away from the consensus. Similar conclusions have been drawn from site-directed mutagenesis of promoters and analysis of their efficiency in vitro. The latter studies have confirmed the importance of spacing between the two regions. Although most natural promoters have a 17-nucleotide spacer between the 35 and 10 regions, many have 16 or 18. In vitro studies show that a 17-nucleotide spacer yields the most efficient promoter structure.

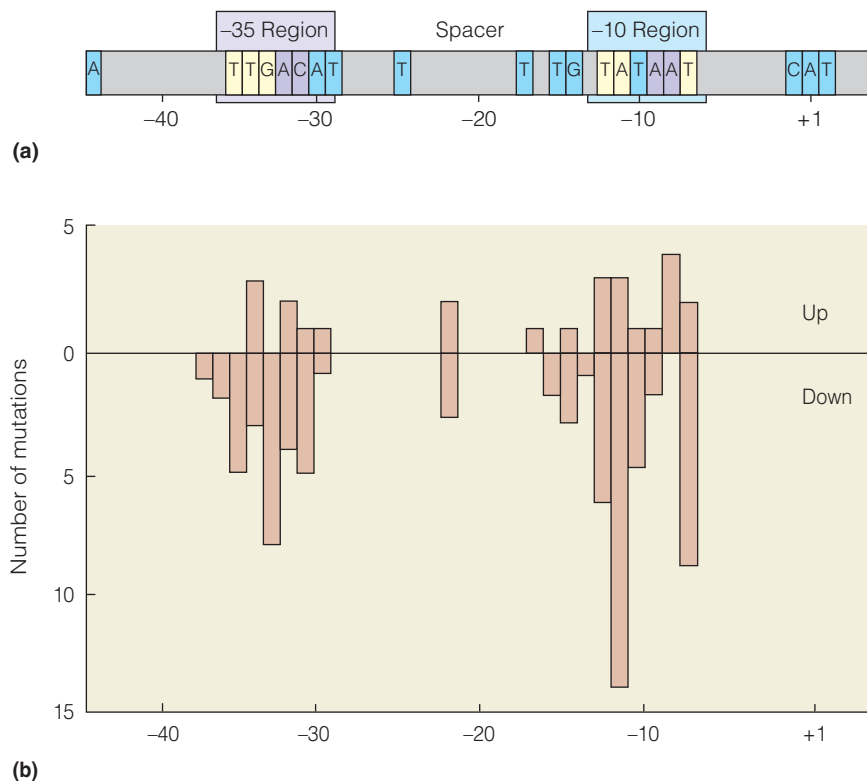

FIGURE 27.14

Survey of conserved nucleotides in *E. coli* promoters. Nucleotide sequences were compared among 114 known *E. coli* promoters. **(a)** Nucleotide positions that were invariant in at least 75% of the promoters are shown in yellow, moderately conserved nucleotides (50%–75%) in purple, and weakly conserved nucleotides (40%–50%) in blue. **(b)** The number of known promoter mutations affecting each site. Up-promoter mutations increase promoter strength; down-promoter mutations have the opposite effect.

Yanofsky, *Escherichia coli* RNA polymerase and *trp* repressor interaction with the promoter-operator region of the tryptophan operon of *Salmonella typhimurium*. © 1980, with permission from Elsevier.

The other evidence for the importance of the -35 and -10 regions is that most of the DNA nucleotides in close contact with RNA polymerase are those in or near these two conserved sequences. This was originally ascertained by comparing the susceptibilities of particular nucleotides to chemical modification, in the presence or absence of RNA polymerase. For example, dimethyl sulfate can be used to determine the susceptibility of guanine residues to methylation. First one treats a restriction fragment containing the sequence of interest with γ [^{32}P]ATP and **polynucleotide kinase**, an enzyme that transfers phosphate to the free 5' -hydroxyl group on the fragment. This end-labeled fragment is then incubated with RNA polymerase and treated with dimethylsulfate, which reacts with guanine residues and can cleave the DNA at that site. The DNA fragment is then subjected to gel electrophoresis and radioautography. Cleavage products from the DNA–protein complex are compared with those from naked DNA. Figure 27.15 shows data from analysis of the *trp* promoter, which controls transcription of genes involved in tryptophan synthesis. Cleavage at some sites, -34 and -37 , was enhanced by RNA polymerase binding, as seen by comparison of band intensities, while at other sites, -32 , -14 , and -6 , reactivity was decreased. All of these susceptible guanines lie within the -10 and -35 boxes. Reagents causing chemical cleavage at other bases give similar results. Other techniques, such as DNA footprinting (Tools of Biochemistry 27A), lead to the same conclusion. Experiments of this type show that RNA polymerase also contacts bases upstream from the -35 box, in the -40 to -60 region. These contacts involve the polymerase α subunit, while the contacts with -35 and -10 boxes involve σ . The upstream contacts (-40 to -60) are particularly important in the promoters for ribosomal protein genes, which are very actively transcribed.

Another factor affecting transcriptional efficiency, in addition to the base sequence of the promoter, is the superhelical tension on the DNA template. The relation between DNA topology and transcriptional efficiency is now receiving considerable attention. The relationship is not clear because transcription of some genes is activated *in vivo* when the template is highly supercoiled—for example, by inactivating topoisomerase I. Transcription of other genes, by contrast, is inhibited under these conditions. Interestingly, the promoter for transcription of DNA gyrase subunits becomes activated when the gene is in a relaxed state. Given that gyrase introduces superhelical turns, this finding seems to represent a feedback mechanism in which the cell responds appropriately to a signal that intracellular DNA is becoming too relaxed.

Punctuation of Transcription: Termination

Because of the great stability of transcription complexes, termination of transcription, with release of the nascent transcript, is an involved process. In bacteria we recognize two distinct types of termination events—those that depend on the action of a protein **termination factor**, called ρ (rho), and those that are ρ factor-independent.

Factor-Independent Termination

Sequencing the 3' ends of genes that terminate in a factor-independent manner reveals two structural features shared by many such genes and illustrated in Figure 27.16: (1) two symmetrical GC-rich segments that in the transcript have the potential to form a stem-loop structure, and (2) a downstream run of four to eight A residues. These features suggest the following as elements of the termination mechanism. First, RNA polymerase slows down, or pauses, when it reaches the first GC-rich segment because the stability of G–C base pairs makes the template hard to unwind. *In vitro*, RNA polymerase does pause for several minutes at a GC-rich segment. Second, pausing gives time for the complementary GC-rich parts of the nascent transcript to base-pair with one another, thereby displacing this part of the transcript from its template or from its enzyme binding site. Hence, the ternary complex of RNA polymerase, DNA template, and RNA is weakened. Further weakening, leading to dissociation, occurs when the A-rich segment is transcribed to give a series of A–U bonds (very weak), linking transcript to template.

DNA sequences that promote factor-independent termination include a run of four to eight A residues and a GC-rich region that forms a stem-loop.

The actual mechanism of termination is more complex than just described, in part because DNA sequences both upstream and downstream from the regions shown in Figure 27.16 also influence termination efficiency. Moreover, not all pause sites are termination sites. However, the scheme shown includes key elements of factor-independent termination.

Factor-Dependent Termination

Factor-dependent termination sites are less frequent, and the mechanism of this type of termination is still more complex. The ρ protein, a hexamer composed of identical subunits, was originally discovered in studies on termination of λ phage DNA transcription in vitro. This protein, which has been characterized as an RNA–DNA helicase, contains a nucleoside triphosphatase activity that is activated by binding to polynucleotides. Apparently ρ acts by binding to the nascent transcript at a C-rich site near the 3' end, when RNA polymerase has paused (Figure 27.17). Then ρ moves along the transcript toward the 3' end, with the helicase activity unwinding the 3' end of the transcript from the template (and/or the RNA polymerase molecule) and causing its release.

In factor-dependent termination, ρ protein acts as an RNA–DNA helicase, unwinding the template–transcript duplex and facilitating release of the transcript.

FIGURE 27.16

A model for factor-independent termination of transcription. (a) An A-rich segment of the template (orange segment on right) has just been transcribed into a U-rich mRNA segment. (b) RNA–RNA duplex, stabilized by G–C base pairs (yellow), eliminates some of the base pairing between template and transcript. (c) The unstable A–U bonds linking transcript to template hybrid dissociate, releasing the transcript.

FIGURE 27.17

ρ factor–dependent termination. ρ binds to a site on the nascent transcript and unwinds the RNA–DNA duplex. Once ρ reaches RNA polymerase, interaction with bound NusA protein (not shown) leads to termination.

ρ has been studied intensively as a model for understanding helicase action. Figure 27.18 shows the crystal structure of *E. coli* ρ complexed with RNA and an ATP analog (ADP + BeF_3). In the schematic (b) four of the six subunits bind ATP tightly. At the instant shown, the 5' RNA nucleotide (orange circle) is being released from the protein as the result of ATP hydrolysis at site D, and the nucleotide shown with a small circle and a dashed line is about to be bound, just as a catalytic site is being formed between the protein subunits labeled “free” and “locked,” by insertion of an “arginine finger” motif into site E. The ρ structure is very similar to those of helicases of opposite polarity, and it appears that polarity

FIGURE 27.18

Crystal structure of *E. coli* ρ . (a) RNA is shown in the central channel in orange. ADP is in magenta, BeF_3 is in black, and Mg^{2+} is in green. (b) Schematic diagram of the helicase reaction. For details see text. PDB ID, 3ICE.

is determined largely by the order of “ATP firing,” that is, the order in which the individual protein subunits hydrolyze ATP. One ATP is hydrolyzed per RNA nucleotide unwound.

It is not clear what causes RNA polymerase to pause at ρ -dependent termination sites. The action of another protein, NusA, is somehow involved. NusA was discovered during studies of **antitermination** in phage λ . Antitermination occurs early in the phage transcription program, when two ρ -dependent termination sites are inactivated so that RNA polymerase can move past these sites and transcribe genes essential to phage development (see page 1239). For this inactivation to occur, a viral protein, the product of gene *N*, must interact with NusA (*N* utilization substance) by a mechanism as yet unknown. Mutations in either the *N* or the *E. coli nusA* gene interfere with antitermination and block phage development. The NusA protein is recruited to elongation complexes, where it binds to hairpin structures in nascent RNA, possibly facilitating termination this way.

Further insight into termination mechanisms has come from an extensively studied regulatory mechanism called **attenuation**. Attenuation controls the rate of transcription of certain operons by terminating the synthesis of a nascent transcript before RNA polymerase has reached the structural genes. Attenuation, which has been investigated as a model for end-of-transcript termination, is discussed in Chapter 29.

Transcription and Its Control in Eukaryotic Cells

Transcription in eukaryotes is a much more complex process than in prokaryotes. Not only is there much more discrimination in what is to be transcribed and what is not, but this transcription is precisely programmed during development and tissue differentiation. Furthermore, the transcription machinery must somehow deal with the complex levels of structure in eukaryotic chromatin. Reflecting this complexity is the fact that eukaryotic cells have several different RNA polymerases, each with a specialized function, as described earlier in this chapter. For each polymerase, several proteins must assemble at promoters and other upstream sites on the template DNA, along with RNA polymerase, in order to form a functional transcription complex. None of the three nuclear RNA polymerases (I, II, and III) has a counterpart to the σ factor of prokaryotic complexes. However, all three require a set of transcription factors that play roles comparable to that of σ , in addition to proteins that might be specialized for transcription of a particular gene. By convention, transcription factors are named TFI, TFII, or TFIII, depending upon whether they function with RNA polymerase I, II, or III, respectively. Within one class of transcription factors, each individual factor is identified with a letter; thus, TFIIA is one of several transcription factors functioning with RNA polymerase II.

Other differences pertain to the fact that bacterial genomes are organized into blocks of functionally related genes—operons, such as the lactose operon mentioned earlier in this chapter—that are cotranscribed to give multigenic mRNAs, while eukaryotic genes are almost always transcribed as monocistronic mRNAs. In addition, as we see later in this chapter, post-transcriptional processing is far more complex for eukaryotic than for prokaryotic genes.

Eukaryotes have three kinds of nuclear RNA polymerases, each requiring additional protein factors to initiate transcription.

RNA Polymerase I: Transcription of the Major Ribosomal RNA Genes

The eukaryotic ribosome contains four rRNA molecules (see Chapter 28). The small subunit has an 18S rRNA, whereas the large subunit contains 28S, 5.8S, and 5S rRNA molecules. Of these, the 28S, 18S, and 5.8S subunits are all produced from an initial 45S pre-rRNA transcript, and it is the special function of RNA polymerase I (pol I) to carry out this transcription.

As was shown in Figure 27.5, pol I is a complex enzyme, containing 14 subunits totaling over 600,000 daltons. At least two transcription factors are known to be required (UBF1 and SL1). However, because only a single kind of gene is transcribed, there is no need for the elaborate apparatus, including multiple regulatory sites and multiple transcription factors, that we will find characteristic for pol II transcription.

The nucleolus is the site of ribosomal subunit assembly in eukaryotes. The gene for the 45S pre-rRNA is present in the nucleolus as multiple, tandemly arranged copies, as shown in Figure 27.19. After transcription, the 45S pre-rRNA is processed to yield 18S, 5.8S, and 28S rRNA molecules. About 6800 nucleotides are discarded in this process. The rRNAs are then combined with 5S rRNA from other regions of the nucleus and ribosomal proteins synthesized in the cytosol. The resulting ribosomal subunits are exported from the nucleolus back into the cytosol.

Transcription of the tandem copies of 45S pre-rRNA can be beautifully visualized in the electron microscope (Figure 27.19b). The structure of the nucleolar chromatin has been a subject of some controversy, but it appears most likely that nucleosomes are not present, at least in the transcribed regions. This absence of nucleosomes may be a specific chromatin modification to allow rapid and continuous transcription of these genes.

In some lower eukaryotes, like the protozoan *Tetrahymena*, the 28S rRNA contains an intron near its 3' end. Excision of this intron and splicing of the RNA are carried out by a remarkable process in which the RNA *itself* acts as the catalyst, via the series of reactions described in Chapter 11 (see in particular Figure 11.41 on page 452). In higher eukaryotes we know less about the mechanism of rRNA processing, the assembly of ribosomes, or the coordination of synthesis of ribosomal proteins and ribosomal RNA.

FIGURE 27.19

Transcription and processing of the major ribosomal RNAs in eukaryotes. The genes exist in tandem copies, separated by nontranscribed spacers. **(a)** The 45S transcripts first produced are processed by removal of portions shown in tan, to yield the 18S, 5.8S, and 28S products. These are then assembled into ribosomal subunits, through addition of proteins. **(b)** Electron micrograph of spread nucleolar rRNA genes undergoing transcription. Tandemly arranged genes are being transcribed from bottom to top.

RNA Polymerase III: Transcription of Small RNA Genes

RNA polymerase III (pol III) is the largest and most complex of the eukaryotic RNA polymerases. It contains 17 subunits, totaling 700,000 daltons. All of the genes it transcribes share certain features. The RNAs are small, they are not translated into proteins, and they are unique in that their transcription is regulated by

certain sequences that lie *within* the transcribed region. The major targets for pol III are the genes for all the tRNAs and for the 5S ribosomal RNA. Like the major ribosomal genes described in the previous section, these small genes are present in multiple copies, but they are usually not grouped together in tandem arrays, nor are they localized in one region of the nucleus. Rather, they are scattered over the genome and throughout the nucleus.

Of all the genes transcribed by pol III, the most thoroughly studied are those for 5S ribosomal RNA. In vitro experiments have revealed that at least three protein factors in addition to polymerase III are needed for expression of the 5S rRNA genes. Two of these transcription factors (TFIIIB and TFIIIC) appear to participate in the transcription of tRNA genes as well, but one, called TFIIIA, is specific for the 5S genes. The interaction of the three transcription factors, the polymerase, and the gene is shown in Figure 27.20. The molecule of TFIIIA

Pol I transcribes the major ribosomal RNA genes; pol III, small RNA genes; and pol II, protein-encoding genes and a few small RNA genes.

FIGURE 27.20

Preparation of a 5S rRNA gene for transcription. At least the three protein factors shown, plus RNA polymerase III, must assemble on the gene before transcription can occur. TFIIIA must bind to the gene before factors TFIIIC and TFIIIB can bind. Once the stable complex II has been formed, it will recycle with pol III to produce many RNA copies. An excess of 5S rRNA will form a complex with TFIIIA, inhibiting further transcription.

makes contact with DNA over a length of about 40 bp. Recognition of the sequence occurs in two blocks of about 12 bp each, at either end of the contact region. This somehow makes the gene accessible to TFIIB, TFIIC, and polymerase III. TFIIA can also complex with 5S RNA. This propensity limits 5S RNA production when the RNA product is in excess, by removing TFIIA from availability to bind to DNA.

TFIIIA is an example of an abundant class of sequence-specific DNA-binding proteins, in which metal-binding *zinc fingers* make contact with and identify DNA sequences (Figure 27.21). This class of proteins has conserved histidine and cysteine residues, which complex with zinc, as shown in Figure 27.21b. This DNA-binding protein motif was mentioned earlier, as a structural element in steroid hormone receptors (page 980).

Although TFIIA is a monomer and TFIIB is dimeric, TFIIC is an enormous complex, involving six polypeptide chains and covering the whole 5S rRNA or tRNA gene. Just how the polymerase manages to repeatedly transcribe through such a protein complex is still unclear. Nonetheless, once pol III is attached, it can produce multiple transcripts before dissociating.

In later sections we shall encounter a variety of transcription factors, for the control of eukaryotic gene expression is almost entirely dependent on the site-specific interaction of these proteins with DNA. A typical transcription factor contains a DNA-binding domain and one or more regulatory domains, which can interact with other nuclear proteins to convey regulatory signals.

FIGURE 27.21

Zinc fingers. (a) The transcription factor TFIIA binds to the 5S RNA gene via zinc fingers inserted into the major groove. The two major recognition regions, A block and C block, are contacted by fingers 7–9 and 1–3, respectively. (b) Structure of a zinc finger. The structure shown is for a synthetic polypeptide with sequences found in a zinc finger protein. The α helix and β -sheet motifs are shown in deep blue and green, respectively. The α helix binds within the major groove, as shown in panel (a). The two histidine residues and two cysteines that coordinate the zinc (red) are depicted in detail. Sulfur is in yellow.

**FIGURE 27.22**

Structures of four common types of DNA-binding motifs from eukaryotic transcription factors.

(a) The zinc finger motif, showing the way the fingers fit along the major groove. **(b)** A helix–turn–helix motif. Note that the helix–turn–helix fits into the DNA major groove in a way similar to that of a zinc finger.

(c) A leucine zipper protein. The coiled coils are held together by hydrophobic residues, usually leucines. At their ends, they present a pair of recognition helices to the DNA major grooves.

(d) A helix–loop–helix motif. The two monomers are held together in a four-helix bundle. Each monomer contributes parts of two α -helices held together by a flexible protein loop, shown in red. The N-termini of the two longer helices form specific contacts in the major groove of the DNA binding site.

In addition to the zinc finger proteins, three other major DNA-binding structural motifs are known, as depicted schematically in Figure 27.22 b, c, and d. In *helix–turn–helix* proteins, one α helix (called the recognition helix) lies in the major groove of the DNA, its side chains making specific contacts with the DNA bases. The helix–turn–helix motif was originally discovered in studies on sequence-specific prokaryotic transcriptional regulators, discussed in Chapter 29 and shown in Figure 27.1. A quite different class of DNA-binding proteins is called *leucine zipper* proteins. These are dimers, held together in a coiled-coil structure by hydrophobic interactions. They typically exhibit a regular pattern (seven-fold periodicity) of leucine or other hydrophobic residues in the helical tail regions, which favors side-by-side hydrophobic interaction. The N-terminal regions are recognition helices, lying in adjacent major grooves. The special feature of leucine zipper proteins is that they can form either homologous or heterologous dimers, thus allowing many combinatorial pairings between transcription factors. As seen with the leucine zipper proteins, the *helix–loop–helix* (HLH) motif is also one that allows either homologous or heterologous dimerization (Figure 27.22d). In this motif a short α helix is connected by a loop to a second, longer α helix. Because of the flexibility of the loop, one helix can fold back and pack against the other. As shown in the figure, the two-helix structure permits binding both to DNA and to the HLH motif of a second HLH protein, either the same (forming a homodimer) or different (forming a heterodimer).

RNA Polymerase II: Transcription of Structural Genes

All of the structural genes (those coding for protein products) in the eukaryotic cell are transcribed by polymerase II. This enzyme also transcribes some of the small nuclear RNAs involved in splicing (see page 1158). Like other RNA polymerases, pol II is a complex multisubunit enzyme. However, not even its 12 subunits are sufficient to allow pol II to initiate transcription on a eukaryotic promoter. Because the expression of many eukaryotic genes is either tissue-specific or developmental stage-specific or both, eukaryotic promoter structure is much more complex than that of prokaryotes. Protein factors in addition to RNA polymerase are required for promoter recognition, recruitment of RNA polymerase to a promoter, and generation of an active elongation complex. A typical eukaryotic promoter contains an initiator region (Inr) with the sequence $YYAN^T_AYY$, where N is any nucleotide, Y is a pyrimidine, and N represents the +1 initiation site. A counterpart to the bacterial Pribnow box, called the TATA box, positioned between -20 and -30 , has the sequence TATAAAA. Upstream from that box are arrayed both general and gene-specific control elements—binding sites for transcription factors and other regulatory proteins, such as the hormone receptors that we introduced in Chapter 23. Additional regulatory sites may exist several hundred base pairs upstream from the initiation site; these are called **enhancer** regions. Although these far-upstream activator sites are involved in transcriptional regulation, they are not considered part of the promoter per se. Table 27.3 gives the sequence of several general and gene-specific promoter and enhancer elements, and Figure 27.23 shows the placement of these elements in several well-studied eukaryotic promoters.

Having introduced some of the control elements involved in eukaryotic promoters, let us now introduce or reintroduce the protein players—RNA polymerase II and the general transcription factors; these are presented in Table 27.4.

Before describing the roles of these proteins in transcription, we point out that TFIID is an example of a “moonlighting protein,” one with two or more different functions. TFIID participates in transcription-coupled DNA repair (page 1086). When DNA synthesis is blocked at the site of a lesion, TFIID can interact with DNA at that site and recruit other proteins of the nucleotide excision repair process. The significance of this function is seen in the fact that genetic deficiencies in one or more of the TFIID subunits are responsible for some forms of xeroderma

TABLE 27.3 Some important pol II control elements and their corresponding transcription factors

Sequence Name	Consensus Sequence	Transcription Factor(s)	Comment
Some General Promoter and Enhancer Elements			
TATA box	TATAAAA	TBP, TFIID	The most common promoter element
CAAT box	GGCCAATCT	CP1	A common upstream element
GC box	GGGCGG	SP1	Often found in TATA-less promoters
Octamer	ATTTGCAT	Oct1, Oct2	Oct1 and Oct2 contain homeo domains ^a
Some Special Promoter and Enhancer Elements^b			
HSE	GNGAANNTCCNNG	Heat shock factor	Involved in heat-shock response
GRE	TGGTACAAATGTTCT	Glucocorticoid receptor	Mediates response to glucocorticoids
TRE	GAGGGACGTACCGCA	Thyroid receptor	Mediates response to thyroid hormones

^aHomeo domains are discussed in Chapter 29 (page 1261).

^bAbbreviations: HSE, heat-shock element; GRE, glucocorticoid response element; TRE, thyroid response element.

FIGURE 27.23

Structures of a few typical eukaryotic promoters. The colored boxes represent different regulatory elements: TATA = red, GC = blue, CAAT = yellow, and octamer = purple.

pigmentosum (page 1085) and others for Cockayne's syndrome, which involves arrested development, neurological disorders, and photosensitivity.

To form a minimal complex capable of initiation, at least five additional protein factors are needed, as shown in Figure 27.24 and listed in Table 27.4. The order of addition is not known with certainty but starts, in the example shown, with binding to the TATA box, the most common initiation signal (and one that is used by all three nuclear RNA polymerases). As noted above, this usually lies about 20–30 bp upstream from the start site at Inr. Note that a *minimal* transcription unit involves the TATA-binding protein (TBP), whereas *in vivo* formation of an initiation complex probably always uses TFIID, a multisubunit structure incorporating both the TATA-binding protein and TATA-binding associated factors (TAFs). The TAFs interact with *activation factors* associated with upstream sites on specific genes,

Transcription can be modified by binding of trans-acting factors, either in the promoter or in distant enhancers.

TABLE 27.4 General transcription initiation factors from human cells^{a,b}

Factor	Number of Subunits	Molecular Weight (kDa)	Function	
TFIID	TBP ^c	1	38	Core promoter recognition (TATA); TFIIB recruitment
	TAFs	12	15–250	Core promoter recognition (non-TATA elements); positive and negative regulation
TFIIA	3	12, 19, 35	Stabilization of TBP binding; stabilization of TAF–DNA interactions; antirepression functions	
TFIIB	1	35	RNA pol II–TFIIF recruitment; start-site selection by RNA pol II	
TFIIF	2	30, 74	Promoter targeting of pol II; destabilization of nonspecific RNA pol II–DNA interactions	
RNA pol II	12	10–220	Catalytic functions in RNA synthesis; recruitment of TFIIE	
TFIIE	2	34, 57	TFIIH recruitment; modulation of TFIIH helicase, ATPase, and kinase activities; direct enhancement of promoter melting (?)	
TFIIH	9	35–89	Promoter melting using helicase activity; promoter clearance (?) by CTD kinase activity	

^aThe subunit compositions and polypeptide sizes are those described for the human factors, but homologs for virtually all have also been identified in rat, *Drosophila*, and yeast.

^bAbbreviations used: CTD, carboxy-terminal domain of pol II; RNA pol II, RNA polymerase II; TAFs, TATA-binding protein–associated factors; TBP, TATA-binding protein.

^cTBP, the TATA-binding protein, is also part of TFIIB and of SL1, a pol I transcription factor.

FIGURE 27.24

A model for formation of a minimal preinitiation complex (PIC) for pol II on a TATA promoter. In the simplest situation, binding of TATA-binding protein (TBP) initiates the sequence. Alternatively, *in vivo* TFIID, which includes both TBP and associated factors (TAFs), is used. This will also result in binding of TFIIA. The series of dots indicates phosphorylation of the C-terminal domain (CTD) of Rpb1, the largest subunit of pol II. Phosphorylation is necessary for release of the enzyme from the initiation site.

Reprinted from *Trends in Biochemical Sciences* 21: 327–335, R. G. Roeder, The role of general initiation factors in transcription by RNA polymerase II. © 1996, with permission from Elsevier.

thereby providing communication for gene regulation. The structure of the complex containing the TATA site, TBP, TFIIB, and TFIIA has been deduced from X-ray diffraction and modeling studies. A remarkable feature that emerges is the pronounced kink induced in the DNA around the TATA site (Figure 27.25).

Essential to the formation of an elongation complex is phosphorylation of the carboxyl terminus of the largest subunit of RNA pol II. This protein contains several dozen repeats of the heptapeptide sequence $-YSPTSPS-$, as many as 52 repeats in the mammalian enzyme. Many or most of the serine residues in this sequence must undergo phosphorylation in order for RNA polymerase to escape the promoter. Recent studies show site-specific methylation of arginine residues in this domain as well.

TFIIB plays a particularly important role in converting the initial closed-promoter complex to an open-promoter complex, comparable to the complexes we have discussed for bacterial RNA polymerase. Recently Patrick Cramer and colleagues described a crystal structure for the complex between yeast RNA polymerase II and TFIIB, expanding our understanding of the biochemical steps

**FIGURE 27.25**

Computationally assembled model of the TFIIA–TBP–TFIIB–promoter complex based on crystal structures of TBP–TFIIB–TATA and TFIIA–TBP–ATA complexes. The amino- and carboxy-terminal direct-repeat domains of TBP are shown, respectively, in blue and purple; the amino- and carboxy-terminal direct-repeat domains of core TFIIB are shown, respectively, in red and magenta; and portions of the large and small subunits of yeast TFIIA are shown, respectively, in green and yellow. The transcription initiation start site (+1) is indicated in white. The view of the complex is from the top, showing TBP sitting astride the distorted TATA element and adjacent, but laterally displaced, upstream and downstream DNA segments (in standard B form) extending, respectively, leftward and below the plane of the figure and rightward and below the plane of the figure.

Reprinted from *Trends in Biochemical Sciences* 21: 327–335, R. G. Roeder, from the work of S.K. Burley, The role of general initiation factors in transcription by RNA polymerase II. © 1996, with permission from Elsevier.

involved. In Figure 27.26 the structure of the TATA box-binding protein (TBP) has been modeled in, to provide a picture of the initiation process. In forming the closed-promoter complex, TBP bends the DNA by 90 degrees. The C-terminal domain of TFIIB binds to TBP and flanking DNA regions. The N-terminal domain recruits RNA polymerase to promoter DNA near the transcription start site, forming the closed-promoter complex. Next a TFIIB structural element called the B-linker is involved in opening DNA before the the transcription start site, leading to the open-promoter complex. TFIIB is involved here in threading the template DNA strand into the active center. For this TFIIB uses another structural element, the B-reader, which consists of a helix followed by a mobile loop. Next, DNA is scanned for an initiator (Inr) motif. Following this, the first two ribonucleotide substrates are positioned opposite a conserved motif called Inr, and the first phosphodiester bond is formed. Just as seen with bacterial RNA polymerase, most of the early chain initiation events are abortive, possibly because of interference of the growing RNA chain with the B-reader loop. Finally, growth of RNA chains beyond seven nucleotides triggers release of TFIIB, and this completes the process of promoter escape. The process as described is actually similar to transcription initiation as studied with bacterial RNA polymerases, even though the proteins other than RNA polymerase are quite different.

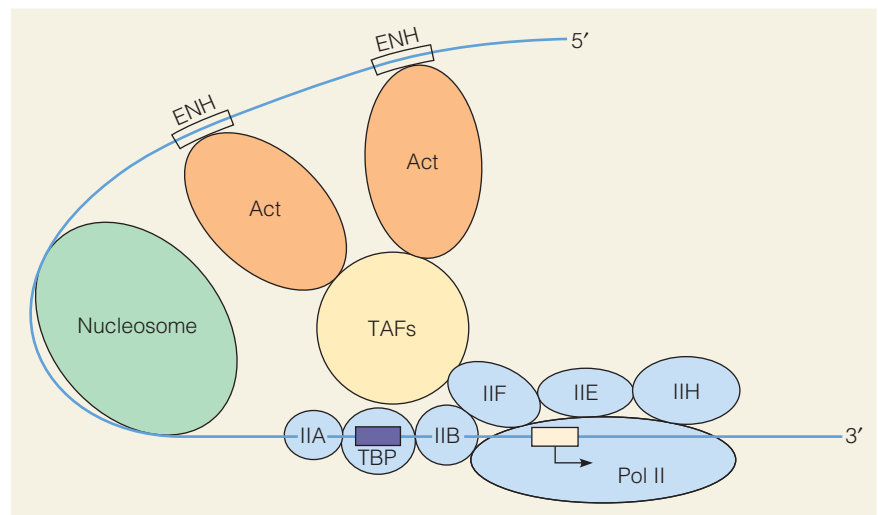

**FIGURE 27.26**

A model of transcription initiation as deduced from the crystal structure of TFIIB complexed with RNA polymerase II RNA. Polymerase is in silver-gray, with other participants as shown. Once the closed- and open-promoter complexes have formed, as described in the text, a clash between the growing RNA chain and the B-reader helix, and between nontemplate DNA and the B-linker helix, are responsible for TFIIB dissociation as elongation begins.

FIGURE 27.27

A schematic representation of how DNA looping (perhaps mediated by nucleosomes) can bring enhancer-bound activator (or repressor) proteins into contact with TAFs associated with the core complex.

As mentioned earlier, trans-acting factors binding at sequences far removed from the promoter itself—by as much as several kilobase pairs—can influence transcription. Such sequences are called enhancers, and their mode of action appears to involve DNA looping, perhaps mediated by nucleosomes, which can bring enhancer-bound proteins into close physical contact with proteins bound to the promoter. Some of the transcription factors shown in Table 27.4 can bind in either promoter or enhancer regions. It is now evident that the TAF proteins shown in Figure 27.24 can act as intermediates between activator or repressor bound to enhancer and the core transcription complex (see Figure 27.27). Also involved in communication between upstream control elements and proteins bound at the promoter is a multiprotein complex called **mediator**. This will be discussed in more detail in Chapter 29.

The trans-acting factors tend to fall into a small number of classes, each defined by the kind of structural motif that interacts with the DNA. Schematic drawings of four of the better-known motifs were shown in Figure 27.22.

Chromatin Structure and Transcription

The complex interplay of transcription factors and polymerases we have described occurs not on naked DNA but on chromatin. The chromatin structure presents two major problems: First, how can the transcription factors and initiation complex bind to DNA in the presence of nucleosomes? Second, how can the actively transcribing polymerase pass through arrays of nucleosomes? This is an area of intense research interest. We present the current views of the first problem with a few examples and then briefly comment on the second problem.

The Problem of Initiation

As an example, consider the human β globin genes, which were described in Chapter 7. Although present in every human cell, these genes are expressed *only* in erythroid cells and in a fixed developmental sequence. In embryonic cells that have not yet begun synthesis of any globin, the chromatin of the β globin gene cluster appears much the same as in any other cell in the embryo and is quite densely covered with nucleosomes. But when differentiation of these cells commits them to globin synthesis, the whole β globin gene cluster undergoes changes in chromatin structure. One such change is the appearance of *hypersensitive sites*, regions particularly susceptible to digestion by nucleases. At early stages in developing human embryos, these sites appear in the 5' flanking regions of the embryonic genes, which are the first to be transcribed. Later, hypersensitive sites shift to

Nuclease hypersensitive sites disrupt chromatin to allow initiation.

the 5' flanks of the adult genes. It is now clear that many of these sites represent regions a few tens or hundreds of base pairs in length in which nucleosomes have either been removed or "remodeled" so as to make the DNA contained therein more accessible. They provide points at which transcription factors and other trans-acting proteins can gain access to promoters and enhancers, thereby allowing the initiation and stimulation of transcription.

How are hypersensitive sites established in previously unresponsive genes? In some cases, for example the globin genes, it seems that the chromatin structure is rearranged at the time of replication. In other instances, protein factors seem to be able to interfere with chromatin structure at specific loci, opening hypersensitive sites.

Particularly interesting examples of this kind are found in hormonal regulation of transcription. A well-studied case involves the genes for the chicken egg-white proteins—ovalbumin, ovomucoid, and lysozyme. Transcription of these genes occurs only in the tubular cells of the hen oviduct. Even in immature chicks, the genomic domain containing the ovalbumin gene appears to have a somewhat different chromatin structure in these oviduct cells from that in other tissues. But only on stimulation by estrogen (either on sexual maturation of the chick or following hormone administration) does transcription of ovalbumin genes commence. Specific hypersensitive sites 5' to some of the egg-white protein genes are opened by the presence of estrogen. Withdrawal of administered hormone from an immature chick leads to loss of hypersensitive sites and an immediate cessation of transcription of the genes.

There are many other examples of hormonal control of transcription. In each case the target cells contain specific proteins that are hormone receptors. When these proteins bind the hormone, they become capable of interacting with specific DNA sites or with nonhistone regulatory proteins bound to such sites. Thus, both positive and negative regulation is possible. In some cases, the hormone-binding receptor acts as a positive regulatory factor, for example, by binding to an enhancer element. In others, the hormone-binding receptor can interact with a repressor protein to augment or relieve the repression. Recent evidence suggests that the latter model may describe the response of chicken oviduct cells to estrogens.

Chromatin Remodeling

How are hypersensitive sites generated, and how is chromatin structure altered to make the DNA accessible? Only recently have pieces of evidence begun to fit together to answer these questions. First was the discovery, in yeast and then in higher eukaryotes, of **chromatin remodeling factors**. These are proteins that enable promoter regions to be able to accept the complex and bulky machinery depicted in Figure 27.24. The SWI/SNF and RSC complexes from yeast and the NURF complex from *Drosophila* are probably the best studied; significantly, all three require ATP hydrolysis to carry out their task. Exactly what such factors do is still unclear. They seem not to remove nucleosomes but rather to "open" them in some fashion. Recent in vitro work with the yeast RSC complex indicates that nucleosomes are, in fact, dissociated, at least transiently, to aid in the generation of transcription complexes. Other recent investigations using single-molecule techniques indicate that polymerase II does not separate template DNA from the histones in chromatin. Instead, polymerase takes advantage of conformational fluctuations in chromatin, pausing until partial opening allows it to move forward, acting like a ratchet in forcing its way around the nucleosome, a process that has been called "nudging through a nucleosome." Whether both processes—transient dissociation and nudging—occur regularly in eukaryotic transcription is an issue now being intensively pursued. We shall say more about chromatin remodeling complexes in Chapter 29.

Another and perhaps equally important role is played by histone acetyltransferases and deacetylases. It has long been known that the histones of the

the unwinding it is doing. Such torsion would tend to destabilize nucleosomes because they contain negatively wrapped DNA.

Termination of Transcription

Even the termination of mRNA transcription is different in eukaryotes. Whereas the prokaryotic RNA polymerase recognizes terminator signals, which sometimes function with the aid of the ρ protein, the eukaryotic polymerase II usually continues to transcribe well past the end of the gene. In doing so, it passes through one or more AATAAA signals, which lie beyond the 3' end of the coding region (Figure 27.29). The pre-mRNA, carrying this signal as AAUAAA, is then cleaved by a special endonuclease that recognizes the signal and cuts at a site 11–30 residues 3' to it. At this point, a tail of polyriboadenylic acid, poly(A), as many as 300 bases long, is added by a special nontemplate-directed polymerase. The functions of the poly(A) tails of eukaryotic mRNAs include mRNA stabilization and facilitation of transport from nucleus to cytoplasm. We know that they cannot be essential for all messages because some mRNAs (for example, most histone mRNAs in higher eukaryotes) do not have them. However, as noted above, poly(A) tails relate to message stability, for the tail-less messages typically have much shorter lifetimes in the nucleus.

Post-transcriptional Processing

Bacterial mRNA Turnover

A major aspect of messenger RNA metabolism in eukaryotes is the events occurring *after* transcription, events that are necessary for messages to move from the nucleus to their sites of utilization in the cytosol. We discuss these events later in this chapter. In prokaryotes, by contrast, mRNAs are used in protein synthesis directly. In fact, a nascent mRNA can serve as a template for translation at its 5' end while still in the process of being synthesized toward the 3' end. In other words, transcription is coupled directly to translation.

The major post-transcriptional event in metabolism of prokaryotic mRNA is its own degradation, which in most cases is quite rapid. A few bacterial mRNAs, notably those encoding outer membrane proteins, are long-lived; however, most bacterial messages have half-lives of only 2 to 3 minutes. This short life span means that genes being expressed must be transcribed continuously and that most mRNA molecules are translated only a few times. Although this might seem energetically wasteful, it is consistent with prokaryotic lifestyles, which necessitate rapid adaptation to environmental changes. Earlier we noted the selective advantage to bacteria of expressing the genes for lactose utilization only when an inducer is present. By the same token, it would be wasteful for the cell to continue producing these proteins after lactose or a related sugar was exhausted from the milieu. Rapid degradation of *lac* mRNA ensures that the energetically wasteful synthesis of these proteins will cease soon after the need for these proteins is gone.

Although we have known about the instability of bacterial mRNA for more than five decades, we still understand surprisingly little about the pathway of degradation. There are probably overlapping mechanisms, involving hydrolysis by nucleases and phosphorolysis by polynucleotide phosphorylase. We do know that degradation starts from the 5' end, which is important because translation also starts from the 5' end. If degradation were to start from the 3' end, a ribosome starting from a 5' end might never reach an intact 3' end. There is reason to think that mRNA degradation sometimes starts with the action of ribonuclease III, an enzyme specific for duplex RNA, which could cleave in stem-loop structures and create sites for exonucleolytic attack. RNase III is actually involved in the maturation of certain phage mRNAs as they undergo post-transcriptional processing, but this involvement is not known to occur with bacterial mRNAs.

FIGURE 27.29

Termination of transcription in eukaryotes: addition of poly(A) tails. There is an AATAAA sequence near the 3' end of most eukaryotic genes. When this is transcribed to AAUAAA, it provides a signal for endonuclease cleavage and poly(A) tail addition.

Post-transcriptional Processing in the Synthesis of Bacterial rRNAs and tRNAs

Both ribosomal RNAs and transfer RNAs are synthesized in the form of larger transcripts (pre-rRNA and pre-tRNA, respectively), which undergo cleavage at both ends of the transcript, en route to becoming mature RNAs. This process is comparable to the processing of 45S pre-rRNA in eukaryotic cells (page 1144). However, as discussed in Chapter 28, the rRNA components in bacteria are somewhat smaller than in eukaryotes—23S, 16S, and 5S. The total amount of DNA encoding these rRNAs and tRNAs amounts to less than 1% of the *E. coli* genome, but because of the instability of mRNA (which is encoded by the remaining 99%), rRNA and tRNA constitute about 98% of the total RNA in a bacterial cell. It is important to realize also that transcription of rRNA genes is extremely efficient when cells are growing rapidly. The intracellular concentrations of ribonucleoside triphosphates are important control elements here; ATP, whose level is high in rapidly growing cells, activates rRNA gene transcription by stabilizing the relevant open-promoter complexes.

rRNA Processing

The *E. coli* genome contains seven different operons for rRNA species. Each one encodes, in a single 30S transcript, sequences for one copy each of 16S, 23S, and 5S rRNAs (Figure 27.30). Because the three species are used in equal amounts, the logic of this organization is apparent. Less easy to explain is that each transcript also includes sequences for one to four tRNA molecules, which vary among the seven different operons. Because rRNAs and tRNAs are all used in protein synthesis, the interspersion of rRNA and tRNA sequences may represent a means of coordinating the rates of synthesis of these RNAs, but specific mechanisms have not yet been revealed.

What enzymes are involved in processing the 30S pre-rRNA species? The abnormal accumulation of this species in bacterial strains defective in RNase III first suggested a role for this enzyme in rRNA processing. In fact, one double-strand cut in each of two giant stem-loop regions releases precursors to 16S and 23S rRNAs, and the same probably occurs for 5S rRNA. Further maturation steps require the presence of particular ribosomal proteins, which begin to assemble on the precursor RNAs while transcription is still in progress. The embedded tRNA sequences are processed to give mature tRNAs, along the same routes used for other tRNA species, as discussed next.

Bacterial transcripts undergo post-transcriptional processing, involving both endonucleolytic and exonucleolytic cleavage.

tRNA Processing

Aside from the tRNAs embedded in pre-rRNA transcripts, the other tRNAs are synthesized in transcripts that contain one to seven tRNAs each, all surrounded by lengthy flanking sequences. The maturation steps are summarized in Figure 27.31, using as an example the well-studied case of the *E. coli* tyrosine tRNA species (tRNA^{Tyr}). In this case, maturation starts (step 1) with an endonuclease that cleaves

FIGURE 27.30

Structure of *E. coli* 30S pre-rRNA. Sequences complementary to two promoter sites (P_1 and P_2), RNase III cleavage sites (RIII) that release 16S and 23S species, and the locations of tRNA sequences embedded within the transcript are shown.

FIGURE 27.31

Modification steps (1–4) that occur in maturation of *E. coli* tRNA^{Tyr} from its transcript and modified bases (5) seen in the mature tRNA. The sequence of the mature tRNA is shown in purple.

next to a stem–loop structure on the 3' side of the tRNA sequence. This is followed by action of **ribonuclease D** (step 2), which carries out exonucleolytic cleavage to a point two nucleotides removed from the CCA sequence at the 3' end. Next (step 3), the 5' end is created by **ribonuclease P**, which cleaves to leave a phosphate on the 5' terminal G. This enzyme creates the 5' terminus of all tRNA molecules. It is not clear what structural features are recognized by RNase P, for different sequences are contained in the cleavage sites. As pointed out in Chapter 11, ribonuclease P was one of the first identified ribozymes. The enzyme consists of one RNA molecule of 377 nucleotides and one protein molecule with M_r of about 20,000. Both components are necessary for full catalytic activity, but under nonphysiological conditions the RNA molecule alone can catalyze accurate cleavage. Despite the involvement of RNA as the catalytic element in ribonuclease P, the enzyme in human mitochondria was recently found to consist entirely of three protein subunits.

Once the proper 5' terminus has been created, ribonuclease D removes the remaining two nucleotides from the 3' end (step 4). Should excessive “nibbling” occur through faulty control of RNase D activity, there is an enzyme (CCA nucleotidyltransferase) that will restore the CCA end to any tRNA in a nontranscriptive fashion. This enzyme specifically recognizes the 3' terminus of tRNAs that lack the CCA end and catalyzes sequential reactions with a CTP, another CTP, and an ATP.

Creation of the modified bases (see Chapters 4 and 28) occurs at the final stage, including methylations, thiolations, reduction of uracil to dihydrouracil, and so forth. In the specific example shown, the modifications include formation of two pseudouridines, one 2-isopentenyladenosine, one O²-methylguanosine, and one 4-thiouridine (step 5). These modifications serve to stabilize the tRNA molecules against intracellular degradation. The modifications are not essential for tRNA function in translation because many tRNAs lacking them are fully active *in vitro*. Pathways for eukaryotic tRNA synthesis are similar, including the involvement of ribonuclease P.

Despite the evident nonessentiality of these modifications for tRNA function in translation, cells expend a great deal of energy carrying them out. More than

90 different base modifications have been described. In the yeast *Saccharomyces cerevisiae*, more than 40 different tRNA-modifying enzymes, made up of nearly 100 protein subunits, carry out those modifications. The average tRNA molecule has more than 12 of its bases modified.

Post-transcriptional processing in bacteria involves cleavage of the primary transcript, modification of bases (in tRNA synthesis), nontranscriptive nucleotide addition, and (in a few cases) intron splicing.

Gene Splicing in Prokaryotes

An additional post-transcriptional process, namely intron splicing, is almost exclusively confined to eukaryotes, although intron self-splicing has been well defined in a few bacteriophage genes. Interestingly, the phage genes subject to splicing are often those encoding enzymes of DNA or DNA precursor biosynthesis. For example, the three introns in the phage T4 genome are in genes encoding thymidylate synthase, the class I ribonucleotide reductase small subunit, and class III (anaerobic) ribonucleotide reductase. Also, prokaryotic introns sometimes encode a “homing endonuclease,” an enzyme that in mixed infection can facilitate transfer of an intron to a cognate intronless gene.

Processing of Eukaryotic Messenger RNA

Prokaryotic and eukaryotic cells differ significantly in the ways that messenger RNAs for protein-coding genes are produced and processed. Recall that prokaryotic mRNAs are synthesized at the bacterial nucleoid in direct contact with the cytosol and are *immediately* available for translation. A specific nucleotide sequence at the 5' end recognizes a site on the prokaryotic ribosomal RNA, allowing attachment of the ribosome and initiation of translation, often even before transcription of the message is completed. Hence, there is little or no post-transcriptional processing of bacterial mRNAs.

In eukaryotes, mRNA is produced in the nucleus and must be exported to the cytosol for translation. Furthermore, the initial product of transcription (*pre-mRNA*) includes all of the introns and substantial flanking regions; the introns must be removed before correct translation can occur. Finally, there is no ribosomal attachment sequence like the Shine–Dalgarno sequence in prokaryotes (see Chapter 28). For all these reasons, eukaryotic mRNA requires extensive processing before it can be used as a protein template. This processing takes place while mRNA is still in the nucleus.

Capping

The first modification occurs at the 5' end of the pre-mRNA. First, one phosphate is removed hydrolytically from the triphosphate moiety at the 5' terminal nucleotide. Next the resulting 5' diphosphate end attacks the α (inner) phosphate of GTP; in essence the guanine nucleotide is added in *reverse* orientation (5' \rightarrow 5'). Together with the first two nucleotides of the chain, it forms what is known as a *cap* (Figure 27.32). The cap is further decorated by addition of methyl groups to the N-7 position of the guanine and to one or two sugar hydroxyl groups of the cap nucleotides. This cap structure serves to position the mRNA on the ribosome for translation, and it probably contributes also to stabilization of the message.

Splicing

After being capped, the pre-mRNA becomes complexed with a number of *small nuclear ribonucleoprotein particles* (*snRNPs*, often called “snurps”), which are themselves complexes of *small nuclear RNAs* (*snRNAs*) and special splicing proteins. The snRNAs are all less than 300 nucleotides in length. The snRNP–pre-mRNA complex is called a **spliceosome**, and it is here that the most elegant part of the processing takes place—the cutting and splicing that is necessary to excise introns from the pre-mRNA and join the ends of the two exons. In forming a spliceosome, snRNAs recognize and bind intron–exon splice sites by means of complementary sequences (Figure 27.33). Precise recognition of splice sequences is essential, for

FIGURE 27.32

Structure of a processed mRNA 5' end. Details of the 5' cap region are shown. Methyl groups that are added are in magenta.

FIGURE 27.33

even a single-base error would disrupt the sense of the genetic message. Table 27.5 shows some representative splice-site sequences and the consensus sequences common to most introns. A schematic view of the chemical aspects of the splicing mechanism is shown in Figure 27.34.

Excision of a single intron involves assembling and disassembling a spliceosome. Figure 27.35 depicts the overall process. The sequence begins with binding of the U1 snRNP to the G site at the 5' end of the intron. The U2 snRNP then binds at the branch site. With continued assembly of the spliceosome, including addition of several more snRNPs, the lariat loop in the intron is formed and the two exons are joined. RNA in the U6 snRNP probably plays a catalytic role. Splicing has now been accomplished, and the products—a ligated mRNA and a looped intron—are released. As the spliceosome disintegrates, the looped intron is degraded, and the mRNA is exported from the nucleus. Exactly how this happens is still not known with certainty, but it may be in conjunction with some of the snRNP proteins.

TABLE 27.5 Representative sequences at splice junctions

Protein, Intron	5' Splice Site Exon ↓	Branch Site Intron ↓	3' Splice Site ↓ Exon
Ovalbumin, intron 3	···UCAG	GUACAG···A···UGUAUUCAG	UGUG
β globin, human, intron 1	···CGAG	GUUGGU···A···CACCCUUAG	GCUG
β globin, human, intron 2	···CAGG	GUGAGU···A···CCUCCACAG	CUCC
Immunoglobulin I, L-VI	···UCAG	GUCAGC···A···UGUUUCGAG	GGGC
Rat preproinsulin	···CAAG	GUAAGC···A···CCCUGGCAG	UGGC
Consensus sequences ^a	___AG	GURAGY···A···YYYYY___AG	_____

^aHere R stands for purine and Y for pyrimidine. Residues listed for the consensus sequence (in magenta) are those found in two-thirds or more of over 100 cases analyzed. The residues shown in magenta are invariant in all cases analyzed. Shown in blue is an AMP residue, the branch site, which is located 20 to 50 nucleotides upstream from the 3' splice site. A pyrimidine-rich sequence lies just upstream from the 3' splice site.

**FIGURE 27.34****A schematic view of the mechanism of mRNA**

splicing. (a) The overall process. Exons (E1 and E2) are indicated by red lines, the intron by a black line or sequence. The E1 splice site, presumably with the aid of the small RNA U1, pairs with a sequence at the branch site to form a loop. The 2' hydroxyl on the branch-site AMP carries out a transesterification reaction by attacking the phosphate of a GMP residue (blue) at the 3' end of the exon 1 (the E1 splice site). This frees the adjacent G (red) to attack with its 3' hydroxyl the phosphate 5' to the C at the 5' end of exon 2. The products are a spliced message and a looped intron "lariat" structure, which is then degraded. (b) The first transesterification reaction. The second reaction (not shown) involves nucleophilic attack of the GMP 3'-hydroxyl group (in red) upon the phosphate 5' to a CMP residue, as seen schematically in part (a).

In 2011 Jeff Gelles and Melissa Moore and their colleagues described a novel technique for kinetic analysis of the individual steps in spliceosome formation. Key to their approach was development of intensely fluorescent tags for participants in spliceosome assembly, which enabled the investigators to follow individual steps at the single-molecule level and in real time. As shown in Figure 27.36, this approach described an ordered sequential pathway. Every step in spliceosome assembly was shown to be reversible, with no single step generating commitment to the entire pathway. Instead, commitment increases as assembly proceeds. The reversibility of each step may mean that alternative splicing can be regulated at any one of these steps. The approach described should help to illuminate poorly understood aspects of alternative splicing.

Because of the obvious importance of correct splicing for correct expression of genetic information, it should not be surprising that splicing errors are responsible for many genetic diseases; in fact, it is estimated that 15% of all genetic diseases arise from splicing errors. An example is some forms of thalassemia, a family of diseases arising from defective synthesis of hemoglobin chains (page 265). Mutations have been found in both the 5' and 3' splice sites of both genes for the β chain of human hemoglobin. Usually, an incorrect mRNA chain is formed, which leads to premature termination of translation of the message. In some cases a new 5' splice site is created, and this may lead to a mixture of correctly and incorrectly spliced messages, a condition that may be less severe clinically.

Alternative Splicing

Once investigators had discovered and described mRNA splicing, they were surprised to learn that the same pre-mRNA can undergo splicing in several different ways. The existence of **alternative splicing** means that different combinations of exons from the same gene can be processed into different mature mRNAs and then undergo translation into quite different proteins in different tissues or at different developmental stages of the same organism. Alternative splicing made it easier to accept our surprise when the Human Genome Project revealed the existence of far fewer genes than had been expected given the size of the genome and the complexity of *Homo sapiens*. Alternative splicing greatly enlarges the repertoire of proteins that can be encoded by a genome. We mentioned one example of this phenomenon in Chapter 7, where we pointed

FIGURE 27.35

The overall process of splicing. The pre-mRNA plus assorted snRNPs assemble and disassemble a spliceosome, which carries out the splicing reaction. The snRNPs are designated U1, U2, and so on. In step 1 U1 is bound, which together with U2 binding (step 2) leads to a looped structure. Factors U4/6 and U5 then bind (step 3) and cleavage and transfer then occur (steps 4, 5). The spliceosome disassembles, releasing the ligated product (6) and the looped intron (7). This is degraded into small oligonucleotides (step 8).

FIGURE 27.36

Kinetic analysis of spliceosome assembly. Each step in the assembly pathway was shown to be reversible, with rate constants in the forward direction as shown. Reversibility has not yet been detected in the activation step shown nor in mRNA release. SF3b is a protein splicing factor and NTC is a multiprotein complex called Prp19.

Alternative splicing allows one gene to specify several proteins.

out that the heavy chains of immunoglobulins may or may not carry a hydrophobic membrane-binding domain.

A more dramatic example of alternative splicing is shown in Figure 27.37. The protein α -tropomyosin is used in different kinds of contractile systems in various cell types (see page 293). Apparently, the need for functional domains coded for by different exons differs among the various uses of α -tropomyosin. Rather than having different genes expressed in different tissues, a single gene is employed, but the specific splicing patterns in different tissues provide a variety of α -tropomyosins. As the figure shows, there are two positions at which alternative choices can be made for which exon to splice in. The 3' member of each of these pairs is the *default exon*; it will be chosen unless a specific cellular signal dictates otherwise.

In principle alternative splicing can be explained by differential regulation of any step in the spliceosome assembly pathway. In Figure 27.38a a ribonucleoprotein complex called hnRNPL (L in the figure) is the key player. To the left, binding of L to variable exons blocks assembly after formation of a cross-exon complex, possibly to prevent U1 and U2 from interacting across the flanking introns. To the right, binding of L away from the splice sites in an intron promotes splicing, perhaps by stabilizing interactions of flanking U1 and U2 snRNPs. Figure 27.38b shows models of exon repression caused by binding of hnRNPs to flanking introns. Left, dimerization of flanking hnRNPs promotes interaction of U1 and U2 bound to distal exons. To the right hnRNP bound to an intron blocks pairing of proximal U1- and U2-bound exons. In Figure 27.38c, a model of regulation during catalysis, binding of a complex called SXL to an RNA-bound complex, SF45, inhibits use of the adjacent 3'-splice site in the second catalytic step, thereby favoring use of a downstream exon.

RNA Editing

Another form of eukaryotic RNA processing, called **RNA editing**, actually changes the nucleotide sequence of mRNA, by converting one base to another in a completed transcript. Because editing can be seen as a process in gene regulation, we postpone discussion of this process to Chapter 29.

FIGURE 27.37

α -Tropomyosin gene organization (rat) and seven alternative splicing pathways. Exons (red, constitutive; green, smooth muscle-specific; yellow, striated muscle-specific; white, variable) are indicated with their encoded amino acids (numbered). Experimentally documented splicing pathways (solid lines) and others (dotted lines) inferred from nuclease protection mapping are shown. The smooth (SM) and striated (STR) exons encoding amino acid residues 39–80 are mutually exclusive, and there are alternative 3'-terminal exons as well. UT signifies untranslated regions.

SUMMARY

All RNA is synthesized by the template-dependent copying of one DNA strand within a gene, catalyzed by RNA polymerase. RNA polymerases use 5′-ribonucleoside triphosphates as substrates, and they transcribe in a 5′ → 3′ direction. Prokaryotes synthesize all RNA classes with one polymerase, while eukaryotic cells have different polymerases—I, II, and III—for synthesis of ribosomal, messenger, and transfer RNA species, respectively.

Strand selection and duplex unwinding and rewinding are carried out by RNA polymerase. The enzyme binds at a promoter site, by formation of specific DNA–protein contacts, largely involving the enzyme’s σ subunit in bacteria and by a host of transcription factors and regulatory proteins in eukaryotes. Most transcription initiations are abortive, but after a productive initiation, involving different factors in pro- and eukaryotes, elongation continues. In bacteria this is carried out by the core polymerase, $\alpha_2\beta\beta'\omega$. Transcription is highly processive and is terminated by specific DNA sequences, sometimes in bacteria with the participation of ρ protein. Structural analyses have identified common features in prokaryotic and eukaryotic RNA polymerases, which have helped to reveal common mechanistic features.

Post-transcriptional RNA processing includes cutting of pre-rRNA transcripts, which encode large and small ribosomal RNA components, and trimming of tRNA precursors in both prokaryotic and eukaryotic cells with the aid of the ribozyme ribonuclease P, followed by modification of several nucleotides in each tRNA molecule and nontranscriptive addition of the 3′ terminal CCA sequence. Bacterial mRNAs undergo little if any post-transcriptional processing, whereas eukaryotic messages are extensively processed, with polyadenylation at the 3′ end, capping at the 5′ end with an inverted and modified guanine nucleotide residue, and splicing throughout the

gene. Splicing is carried out by small nuclear ribonucleoprotein particles, guided by complementary base sequence interactions between splice sites and base sequences in the small nuclear RNA components. Alternative splicing is a process that expands the information content of a genome by directing quite different mRNA splicing patterns in different tissues and at different developmental stages.

12. Introns in eukaryotic protein-coding genes are rarely shorter than 65 nucleotides in length. What might be a rationale for this limitation?
13. Heparin is a polyanionic polysaccharide that blocks elongation by RNA polymerase. But heparin inhibits only when added before the onset of transcription and not if added after transcription begins. Explain this difference.
14. Estimate the time needed for the *E. coli* RNA polymerase at 37 °C to transcribe the entire gene for a 50-kilodalton protein. What assumption or assumptions must be made for this estimate to be accurate?

TOOLS OF BIOCHEMISTRY 27A

FOOTPRINTING: IDENTIFYING PROTEIN-BINDING SITES ON DNA

Transcription is controlled in large part through interactions of proteins with specific sites on DNA molecules, including operators and promoters. Such sites were initially identified through genetic analysis in the lactose system and phage λ . Biochemical analysis requires the identification and nucleotide sequence determination of a site, along with structural determination of the DNA–protein complexes that form. A technique called **footprinting**, usually involving protection against DNase I cleavage, is widely used to identify such sites. Footprinting can identify any DNA site that binds a protein specifically, as long as the protein binds sufficiently tightly.

The principle of the method, outlined in Figure 27A.1, is that binding of a protein to a specific DNA sequence should protect the protein-bound DNA from attack by DNase I (pancreatic deoxyribonuclease). The investigator first uses γ -[^{32}P]ATP and T4 polynucleotide kinase to prepare a 5' end-labeled fragment of DNA containing a protein-binding site. One aliquot of the end-labeled DNA is mixed with the protein under study (step 1) and then incubated with DNase I under conditions in which most chains are cleaved only once (step 2). Another aliquot is incubated with DNase I under identical conditions, except that the protein is absent (step 2). Next, the two incubation mixtures are analyzed in adjacent lanes of a sequencing gel (step 3). The result is a ladder of fragments similar to that seen in a sequencing gel, except that there is little sequence specificity; the bands on the gel are spaced uniformly at one-nucleotide intervals, although band intensity varies considerably. Any sites protected from DNase attack because of interaction with

the DNA-binding protein under study yield either no band or a low-intensity band in the ladder from the DNA–protein complex, indicating that little or no cleavage occurred at that site. The blank region on the gel pattern from the DNA–protein complex (the “footprint”) identifies the location and the size of the fragment in contact with the DNA-binding protein (such as RNA polymerase).

Recent improvements in footprinting technology involve cleavage with chemical agents such as **methidiumpropyl-EDTA-Fe²⁺ (MPE—Fe²⁺)**.

This compound intercalates between DNA bases, as does ethidium bromide, and catalyzes oxidation leading to cleavage at a nearby site. Because there is some sequence selectivity in DNase I attack and virtually none with $MPE - Fe^{2+}$, the latter technique gives cleaner footprints. A related technique, described in the reference section following, generates hydroxyl radicals as a reactive but nonspecific DNA cleavage reagent.

Footprinting shows that *E. coli* RNA polymerase binds to a region about 60 base pairs long, extending from about 40 nucleotides upstream of (5' to) the transcriptional start site to about 20 nucleotides past that site. In other words, the binding site extends from nucleotide -40 to $+20$, where the template for the first nucleotide in the transcript is $+1$. That first nucleotide, the 5' end of the transcript, can be identified by various methods. A widely used technique is S_1 nuclease mapping, which is described in Tools of Biochemistry 27B.

TOOLS OF BIOCHEMISTRY 27B

MAPPING TRANSCRIPTIONAL START POINTS

Studies of transcriptional initiation and its control require methods for the accurate identification of transcriptional start points, specifically the DNA template nucleotide that encodes the 5' nucleotide of the transcript. The low abundance of specific mRNAs and the high turnover of nearly all bacterial mRNAs make this a challenging task.

Prokaryotic transcripts all have a 5' triphosphate terminus on the first nucleotide, as do eukaryotic transcripts before processing; in principle these could provide a handle for their identification. Given that this identification requires purification of the transcript, less laborious methods are preferable. One such method, **S₁ nuclease mapping**, uses the fungal enzyme S₁ nuclease, which specifically and quantitatively cleaves single-strand DNA and RNA (Figure 27B.1). The necessary materials are the cloned gene and a restriction fragment thought to contain the template for the 5' end of the transcript. The fragment is 5' end-labeled, as in the Maxam–Gilbert sequencing procedure, and cleaved asymmetrically with another restriction enzyme so that only the template DNA strand is labeled. In Maxam–Gilbert sequencing, 5' end-labeled DNA is subjected to chemical reagents that cleave in a base-specific fashion. One reagent cleaves at sites occupied by either A or G, one cleaves in a strictly G-dependent fashion, one cleaves at T and C sites, and one cleaves specifically at C. Thus, by treating four aliquots of the same DNA with the four reagents and displaying the cleavage fragments on a sequencing gel, one can read the sequence of the DNA, as you can see in Figure 27B.1. Partly because Maxam–Gilbert sequencing is not completely base-specific, it has been largely supplanted by dideoxy sequence analysis, which uses replicative chain terminators to generate base-specific 3' termini (see Tools of Biochemistry 4B). However, because S₁ mapping uses a 5' end-labeled DNA fragment, it is useful to employ the Maxam–Gilbert approach, which also uses a 5' end-labeled DNA fragment, to locate the 5' end of the transcript precisely.

Next, the 5' end-labeled DNA fragment is denatured and hybridized to mRNA, under conditions (high formamide) that favor the formation of DNA–RNA hybrids over DNA–DNA duplexes (Figure 27B.1, step 1). The only double-stranded nucleic acid, then, should be a DNA–RNA hybrid with 3' single-stranded extensions from the 5' end of the transcript and the labeled 5' end of the restriction fragment. Treatment with S₁ nuclease (step 2) yields a fully duplex structure, with a labeled DNA strand whose length precisely measures the distance from the 5' end of the transcript to the relevant restriction site. This distance can be identified by denaturing the DNA–RNA hybrid and running it on a sequencing gel, alongside a set of Maxam–Gilbert cleavage fragments (step 3).

The advent of PCR led to more reliable methods for isolating and identifying RNA 5' ends. One such method is called rapid amplification of 5' cDNA ends (5'-RACE). Partial sequence

information is needed to carry out this technique. As shown in Figure 27B.2, an oligonucleotide complementary to a region of the mRNA downstream from the 5' end is annealed to the mRNA molecule. Reverse transcriptase is used to extend this primer to the 5' end of the mRNA molecule. Excess primers are removed, and terminal deoxynucleotidyltransferase plus dATP adds a polyA tail to the 3' end of this first-strand cDNA. Next, oligo(dT) is annealed to the polyA tail, and a heat-stable DNA polymerase extends this second-strand DNA to the 5' end of the original

primer. Additional cycles of PCR follow until there is enough of the product to be cloned into a suitable vector for sequence analysis.

TOOLS OF BIOCHEMISTRY 27C

DNA MICROARRAYS

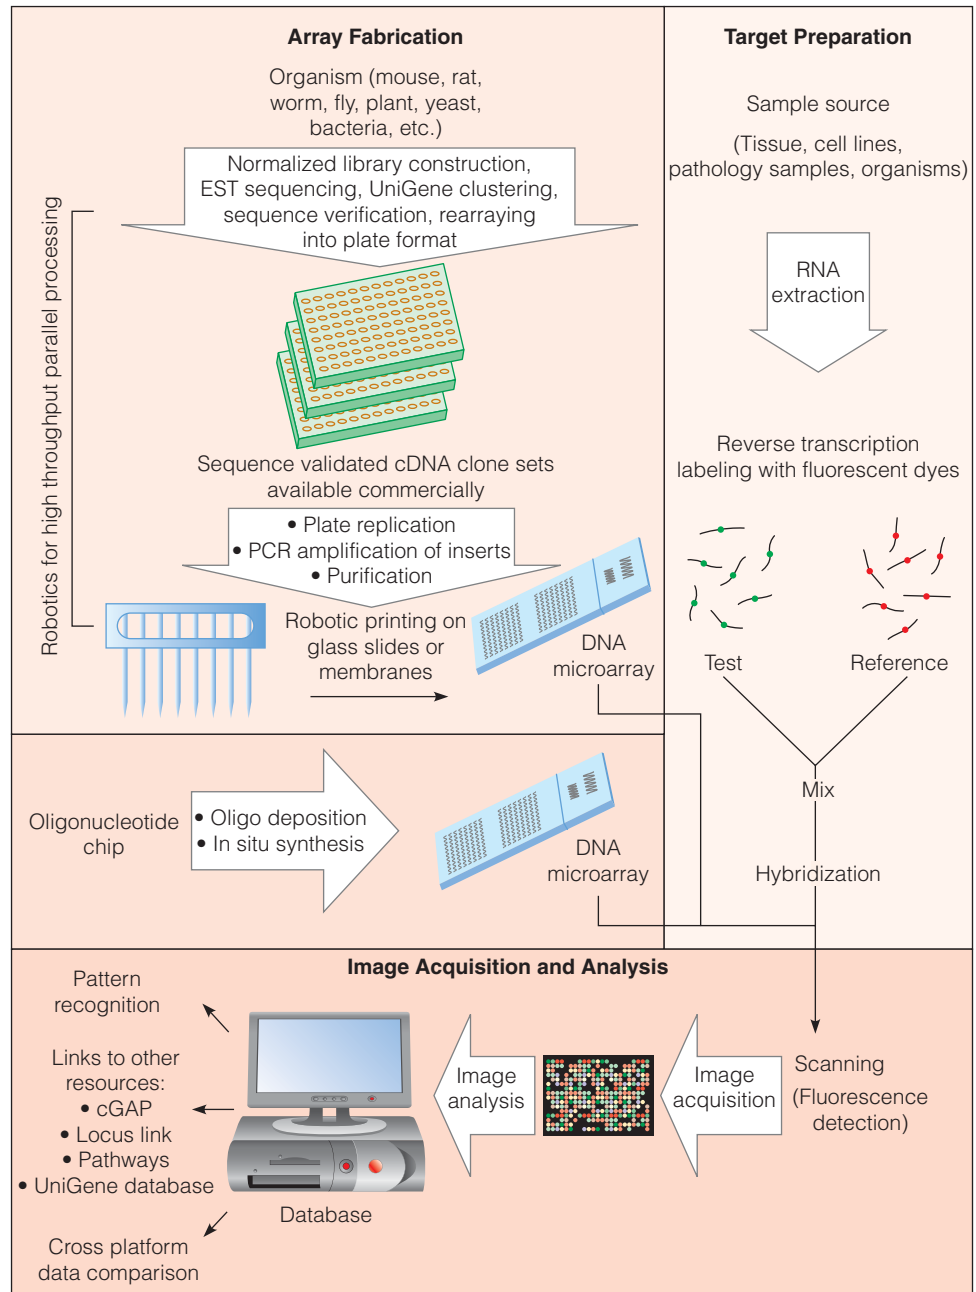

The finding in the 1960s that single-stranded DNA binds irreversibly to membrane filters, and the development of recombinant DNA technology in the 1970s, led to a number of techniques for analysis of gene expression, that is, measuring levels of transcripts of particular genes in living cells. RNA could be radiolabeled *in vivo* and hybridized to gene-specific DNA—a cloned gene or a restriction fragment—and the bound radioactivity analyzed by radioautography or in a liquid scintillation counter.

Several techniques, such as northern analysis, were based upon these developments. However, such approaches allow the analysis of just one or a few genes in each experiment. With the availability of complete genome sequences, it became desirable to analyze levels of transcripts from many genes in a single experiment, that is, patterns of gene expression, that could be compared under different physiological conditions. Microarray technology allows such analysis.

FIGURE 27C.1

Flowchart: Performing a microarray experiment.

From *Molecular Cloning: A Laboratory Manual*, 3rd ed., J. Sambrook and D. W. Russell, eds. © 2001 Cold Spring Harbor Laboratory Press with permission from Vivek Mittal.

In a microarray experiment, minute amounts of gene-specific DNAs—usually several thousand—are immobilized on a substrate, such as glass or a membrane filter. The gene-specific DNAs are either cloned cDNAs or oligonucleotides. Using robotic technology, the investigator “prints” the DNAs onto the substrate, which may be a microscope slide, suitably coated to bind the applied DNAs. The DNAs are printed as a large array, which allows the investigator to identify each gene from its location on the array. The DNAs are fixed irreversibly on the substrate so that the “DNA chip” can be used repeatedly, by stripping the annealed RNA targets off the chip after each experiment.

Typically a microarray experiment involves comparison of gene expression profiles under different conditions—comparing a tumor with the tissue of origin, for example, or comparing a hormone-stimulated tissue with unstimulated tissue (see Figure 27C.1). The investigator wishes to learn which genes are activated under the conditions being analyzed, and which are repressed. Total mRNA is isolated from each tissue or cell culture and converted to a population of cDNAs by reverse transcriptase action. During the enzymatic synthesis of the cDNAs, one of the deoxyribonucleoside triphosphates is tagged with a fluorescent dye. Typically the reference sample is labeled with a red fluorophore and the test sample is labeled with a green fluorophore. After cDNA synthesis is complete, the two samples are mixed and subjected to annealing conditions in the presence of

the microarray. Unhybridized cDNAs are washed off, and the array is then scanned. Scanning at wavelengths corresponding to emission maxima of the fluorophores reveals which transcripts are more abundant in the test than in the reference (more green fluorescence) and which are less abundant (more red fluorescence). Analysis of the image reveals which genes were stimulated and which repressed under the conditions being tested.

Microarray technology has numerous applications in addition to measuring patterns of gene expression. For example, by use of arrayed oligonucleotides representing different mutant forms of a gene of interest, one can carry out DNA–DNA hybridization on the gene chip and identify mutations or single-nucleotide polymorphisms in biological samples.

TOOLS OF BIOCHEMISTRY 27D

CHROMATIN IMMUNOPRECIPITATION

So far the techniques we have discussed for identifying and characterizing binding sites for proteins such as RNA polymerase and repressors have involved single binding sites, whereas regulatory proteins such as nuclear hormone receptors act through a host of binding sites. Moreover, techniques such as footprinting are carried out *in vitro*, although our main interest is characterizing attachment sites for DNA-binding proteins in intact cells. Chromatin immunoprecipitation allows for identification of *in vivo* binding sites on a genome-wide basis.

The principle of the technique is that any DNA-binding protein can be covalently attached to its DNA-binding site(s) *in vivo* by use of a cross-linking reagent that can penetrate cell membranes and react covalently with both protein and DNA in a reversible manner. Formaldehyde is most commonly used, as

shown in Figure 27D.1. After formaldehyde treatment of whole cells, chromatin is isolated and subjected to sonication under conditions reducing the length of each DNA molecule to fragments several hundred base pairs in length. The mixture is treated with antibody to the protein of interest, and the immunoprecipitated DNA–protein complexes collected. At this point the cross-links are broken, and the DNA that was precipitated along with the protein is subjected to sequence analysis. Originally this was done most often by PCR amplification of the DNA followed by conventional sequence analysis. But this approach allows analysis only of known and suspected DNA sequences. An alternate approach involves cloning all DNA fragments in the mixture and then using PCR primers corresponding to flanking sequences on the vector, followed by sequence analysis of each clone. With

**FIGURE 27D.1**

Chromatin immunoprecipitation. In this figure a transcription factor (TF) is cross-linked to the DNA sites to which it binds in chromatin. After fragmentation and immunoprecipitation using antibody to TF, the TF-bound DNA fragments are identified either by microarray analysis, in which the DNA is bound to a red fluorophore and subjected to hybridization analysis with an array of genomic fragments (ChIP-chip), or subjected to massive parallel sequence analysis (ChIP-seq).

the advent of microarray technology it became possible to screen the DNA fragments against a DNA microarray containing hundreds or thousands of DNA sequences. This technique is called ChIP-chip because the immunoprecipitated DNA fragments are identified on a gene chip. A still more recent innovation, called ChIP-seq, involves parallel sequencing of all of the immunoprecipitated DNA using a next-generation sequencing technology that permits simultaneous sequence analysis of hundreds or thousands of DNA molecules.

CHAPTER 28

Information Decoding: Translation and Post-translational Protein Processing

We turn now to the most complex process in biological information transfer—the decoding of genetic messages in the four-letter nucleic acid language to amino acid sequences in proteins, expressed in the 20-letter amino acid language. In DNA replication, transcription, and reverse transcription, information transfer is guided strictly by Watson–Crick base pairing between the template nucleic acid and the product, whether it be DNA or RNA. By contrast, when a messenger RNA sequence directs the synthesis of a specific protein, base sequence complementarity is still crucially involved, but a more complex overall process converts information encoded in a nucleotide sequence to information expressed as a specific amino acid sequence.

In terms of the number of components involved—ribosomal RNAs and proteins, transfer RNAs, amino acid activating enzymes, and soluble protein factors—and the number of different proteins in each cell—protein synthesis may well be the most complex of all metabolic processes, and it certainly involves the dominant fraction of a cell's metabolic effort. In a logarithmically growing bacterial cell, as much as 90% of the total metabolic effort may be devoted to protein biosynthesis, with the metabolic machinery for translation accounting for 35% of the cell's dry weight.

When we think of protein synthesis, we consider not only translation, which yields a specific amino acid sequence, but also post-translational processing and traffic, with each protein properly modified and transported to its ultimate intracellular or extracellular destination. We have already seen, for example, that protein processing involves cleavage, as in the conversion of preproinsulin to insulin, and modification of individual amino acids, as in the hydroxylation of proline residues in collagen synthesis or the phosphorylation of specific amino acid residues. We must also consider protein trafficking—how mature, or maturing, proteins are moved to their ultimate destinations, whether inside or outside the cell.

An Overview of Translation

The earliest evidence for the role of ribosomes in protein synthesis came from experiments in which radiolabeled amino acids were injected into rats, followed by isolation of the liver and fractionation of a liver homogenate. The label was shown to be incorporated earliest into ribosomes, either free or membrane-bound in the endoplasmic reticulum. This and related experiments established that the ribosome is the site of protein synthesis. Experiments with cell-free systems soon established the requirements for amino acid activation and for the involvement of small, stable RNAs (transfer RNAs).

In Chapters 4 and 5 we painted an introductory picture of translation. In Figure 4.23 (page 112) we showed how translation involves movement of a ribosome along an mRNA molecule, three nucleotides at a time, with each trinucleotide sequence in mRNA pairing with one specific transfer RNA charged with an amino acid, and with the polypeptide chain growing stepwise, one amino acid per step, from the N-terminus to the C-terminus. Figure 28.1 shows a somewhat

FIGURE 28.1

Translation of an RNA message into a protein. As the ribosome moves along the message, it accepts specific aminoacyl tRNAs in succession, selecting them by matching the trinucleotide anticodon on the tRNA to the trinucleotide codon on the RNA message (**step 1**). The amino acid (in this example, the second one of the chain, Val) accepts the growing polypeptide chain (in this example the previously bound fMet) (**step 2**), and the ribosome moves on to the next codon to repeat the process, while releasing the deacylated transfer RNA that held the growing peptide in the previous cycle (the tRNA for fMet, **step 3**). The preceding steps are repeated, adding more amino acids to the chain, until a stop signal is read (**step 4**), whereupon a protein release factor causes both the polypeptide and the mRNA to be released. The polypeptide shown here is unrealistically short, to illustrate both initiation and termination.

more detailed picture of this process and serves as an overview of translation. In Figure 5.18 (page 152) we showed the genetic code, that is, the correspondence between each of the 64 possible trinucleotide sequences and the 20 amino acids encoded by these sequences. In this chapter we expand upon both the process of protein synthesis and the elucidation and nature of the genetic code.

In 1958, several years before elucidation of the genetic code or the demonstration of messenger RNA, Francis Crick predicted the existence of *adaptor molecules*, each of which would function in translating the genetic message by binding to a specific amino acid and linking it to a molecular code word in the translation machinery. These adaptor molecules turned out to be transfer RNAs. As discussed in Chapter 4, each transfer RNA, or tRNA, molecule is 75–80 nucleotides in length (although some are as large as 93 nucleotides), folded by intramolecular hydrogen bonding into a three-loop structure. Each tRNA molecule is designed to bind one of the 20 amino acids, through the specificity of an amino acid–activating enzyme, more properly called an *aminoacyl-tRNA synthetase*. As shown in Figure 28.2, amino acid activation proceeds at the expense of ATP hydrolysis and results in esterification of the amino acid carboxyl group with the 3' hydroxyl of the 3' terminal tRNA nucleotide, yielding an aminoacyl-tRNA.

Each tRNA contains, in a region known as the **anticodon loop**, a trinucleotide sequence called the **anticodon** that is complementary to the appropriate trinucleotide codon in the message. Thus, the whole set of tRNAs contained in a cell composes a kind of molecular dictionary for the translation—it defines the correspondences between words in the four-letter nucleic acid language (gene sequence) and words in the 20-letter amino acid language (protein amino acid sequence).

The messenger RNA is bound to a ribosome, as shown in Figure 28.1. The aminoacyl tRNAs also bind here, one by one, matching their anticodons to the codons on the message, as shown in Figure 28.1, step 1. The growing peptide chain is transferred from the tRNA to which it is bound to the incoming aminoacyl-tRNA (step 2). The first tRNA is then released, and the ribosome moves one codon length along the message, allowing the next tRNA to come into place, carrying *its* amino acid (step 3). Again, expenditure of energy from high-energy phosphate hydrolysis is required at each step in the movement. As the ribosome moves along the messenger RNA, it eventually encounters a “stop” codon. At this point, the polypeptide chain is released. Step 4 shows a completed, although short, protein. In every cell, of every kind of organism, this remarkable machinery translates the information coded in thousands of different genes into thousands of different proteins. The cellular apparatus that binds all of these components and catalyzes the formation of peptide is the ribosome, a particle composed of both RNA and proteins. A ribosome can bind to mRNA and “read” it, as it moves along the RNA, accepting the charged tRNAs in the order dictated by the message and

Transfer RNAs are the adaptor molecules that match amino acid to codon.

FIGURE 28.2

Activation of amino acids for incorporation into proteins. A specific enzyme, aminoacyl-tRNA synthetase, recognizes both a particular amino acid and a tRNA carrying the corresponding anticodon. This synthetase catalyzes the formation of an aminoacyl tRNA, with accompanying hydrolysis of one ATP to AMP.

incorporating their amino acid residues one by one and in proper order within the growing polypeptide chain.

Messenger RNA is read 5' → 3'. Polypeptide synthesis begins at the N-terminus.

The mRNA message is always read in the 5'→3' direction, and the polypeptide chain is synthesized starting with its N-terminal residue. The direction of polypeptide synthesis was established in 1961 in a classic experiment. Howard Dintzis gave reticulocytes (hemoglobin-producing cells) a short pulse of [³H] leucine and isolated the completed hemoglobin molecules at various times after the pulse. After cleaving these molecules into peptides with trypsin, he compared the radioactivity of peptides from various points in the chain. Immediately after the pulse label was added, radioactivity was seen only in chains that were undergoing synthesis before the pulse began and were just being completed during the pulse; the label at this time was found only in the C-terminal peptides. At longer times after the pulse, radioactivity was found to be incorporated into parts of the polypeptide closer and closer to the N-terminus, as synthesis of new protein molecules continued to be initiated. Dintzis therefore concluded that amino acids are added to a polypeptide chain starting at the N-terminus and working toward the C-terminus.

The simple picture of translation we have presented so far leaves a host of questions unanswered. How are tRNA and amino acid matched? How does the ribosome attach to the mRNA and move along it? How does it catalyze peptide bond formation? How does it start and stop translation correctly? How does it avoid making mistakes? Where does the energy for all of this activity come from? To answer such questions, we must dissect the whole process of translation, with careful examination of each of its parts. First, let us consider the genetic code in more detail.

The Genetic Code

We introduced the genetic code in Chapters 5 and 7. Here, we describe the key experiments that led to deciphering of the code, and we discuss some features of the code, including whether it is universal throughout biological systems.

By the late 1950s it was generally accepted that a protein's amino acid sequence is encoded by the sequence of bases in a nucleic acid template. A triplet code seemed most likely, with three nucleotides specifying one amino acid. Clearly, a doublet code wouldn't work because there are only 16 possible dinucleotide sequences (4×4), and we need at least 20 code words if each amino acid is to have its own code word. So a triplet code seemed the simplest; 64 possible trinucleotides ($4 \times 4 \times 4$) made it likely that some amino acids would have more than one code word.

Genetic experiments supported the idea of a triplet code and also a code that is *nonoverlapping* and *unpunctuated*. Figure 28.3 illustrates what we mean by these terms and suggests reasons why overlapping and punctuated codes were rejected.

How the Code Was Deciphered

Biochemical elucidation of the code began in 1961 by Marshall Nirenberg and Heinrich Matthaei, with their use of artificial RNA templates for in vitro protein synthesis. Recall from Chapter 27 (page 1129) that the enzyme polynucleotide phosphorylase will catalyze the nontemplate-dependent synthesis, from a mixture of ribonucleoside diphosphates, of a random-sequence RNA whose nucleotide composition matches that of the medium. Nirenberg and Matthaei polymerized UDP with the enzyme to synthesize polyU, a polyribonucleotide containing only UMP residues. When this artificial RNA was placed in a cell-free system containing a bacterial extract, ATP, GTP, and the 20 canonical amino acids (i.e., those commonly found in proteins), the product was a polypeptide containing only phenylalanine. Thus, the genetic code word for phenylalanine was shown to be a

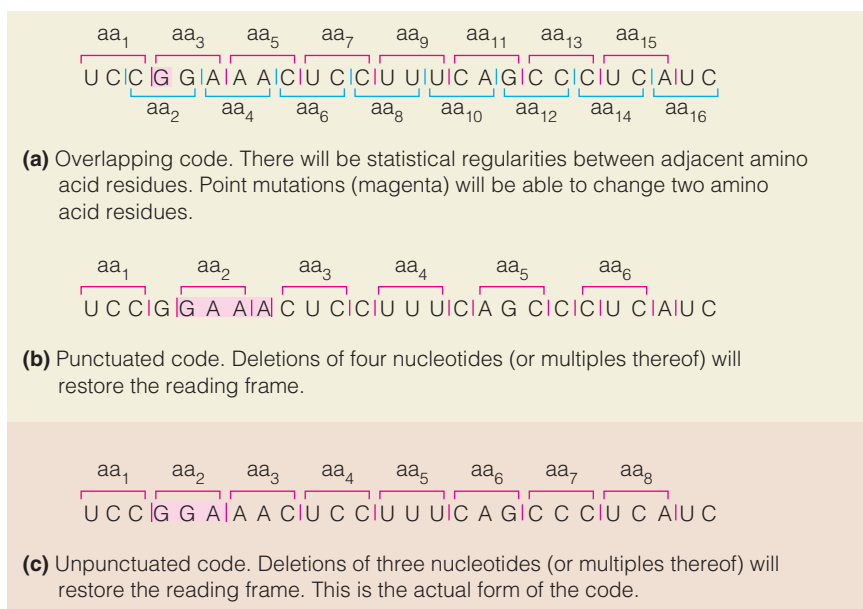

FIGURE 28.3

Three conceivable kinds of genetic codes. Early research on the nature of the code quickly showed that a nonoverlapping, unpunctuated code **(c)** fit all experimental observations.

specific sequence of UMP residues—three if we are really dealing with a triplet code. In short order, polyC was shown to encode only proline and polyA only lysine.

Establishing code words for the other 17 amino acids was trickier. For example, consider the enzymatic synthesis of a polyribonucleotide from a nucleotide mixture containing CDP and ADP in a 5:1 molar ratio. Because the base composition of the polymer reflects the substrate ratio, the polymer contains eight trinucleotide codons, with CCC 125 times more abundant than AAA ($5 \times 5 \times 5$). Codons with two A and one C (2A1C—AAC, ACA, CAA) are five-fold more abundant than AAA, and those with one A and two C (2C1A—CCA, CAC, ACC) are 25-fold more abundant. When this polymer was used by Nirenberg and Matthaei, it stimulated the incorporation of proline, histidine, threonine, glutamine, asparagine, and lysine in molar ratios of 100, 23.4, 20, 3.3, 3.3, and 1, respectively. The data were best explained by assuming that the polymer contained two codons for Pro (CCC and 2C1A) and two for Thr (2A1C and 2C1A). The codon for lysine was already known to be AAA. Codons assigned for Asp and Gln were both 2A1C and, for His, 1A2C. This and other experiments with random-sequence polymers were able to establish the nucleotide *composition* of most codons, but not their *sequence*.

Two approaches led to the identification of codon sequences. First, H. Gobind Khorana synthesized polyribonucleotides of regular repeating sequence. For example, the polymer UCUCUCUC... was shown to direct synthesis of an alternating copolymer, Ser-Leu-Ser-Leu-Ser-Leu... If the code is triplet and nonoverlapping, this means that UCU is the codon for either serine or leucine and CUC encodes the other amino acid. Because serine was known to have a 2U1C codon and leucine a 2C1U codon, this established UCU as a serine codon and CUC as a leucine codon. When a trinucleotide was used as the repeating unit, a different result was seen, as shown in Figure 28.4. The polymer AAGAAGAAG... directed synthesis of three homopolypeptides—polylys, polyarg, and polyglu. This experiment didn't give codon sequences, but it did establish the triplet and nonoverlapping nature of the code. Here, the nature of the product was set by the initial **reading frame**—the trinucleotide sequence chosen for the first amino acid incorporation event. If GAA was selected, for example, every subsequent codon would also be GAA, making all amino acids in the product identical. The experiment did establish GAA, AGA, and

**FIGURE 28.4**

Use of synthetic polynucleotides with repeating sequences to decipher the code. This example shows how polypeptides derived from the $(AAG)_n$ polymer were used to confirm the triplet code and help identify codons. The polymer $(AAG)_n$ can yield three different polypeptides, depending on which reading frame is employed.

AAG as codons for the three amino acids, but could not lead directly to assignment of each amino acid to one codon.

Experiments of this kind identified many code words, but in 1964 Philip Leder and Marshall Nirenberg developed a new and rapid method for codon assignment that made it possible to complete the deciphering of the code. Leder and Nirenberg found that synthetic trinucleotides would bind to ribosomes and specify the binding of specific tRNAs. For example, UUU and UUC stimulated binding of phenylalanine tRNAs to ribosomes, and CCC and CCU stimulated binding of proline tRNA. Such experiments provided unequivocal evidence for the *redundancy* of the code because several different codons were found to correspond to a single amino acid. By the combined use of these techniques, the entire genetic code was established within a few years after demonstration of polyU-directed Phe incorporation.

Features of the Code

In the genetic code, as shown in Figure 28.5, 61 of the 64 trinucleotides are “sense” codons, that is, they code for one amino acid. The remaining three are normally “nonsense” codons in that they do not code for an amino acid (with some exceptions, see Table 28.1 and discussion on page 1180). When a ribosome encounters a nonsense codon (UAG, UAA, or UGA) in the correct reading frame, there is no aminoacyl-tRNA in the cell containing a matching anticodon, and translation ceases. As we see later, these codons are used as part of the normal machinery for terminating translation of a message. The code is *degenerate* (or redundant) in the sense that most amino acids have more than one codon and *unambiguous*, in the sense that a particular trinucleotide encodes one and only one amino acid. There are some exceptions to this generalization, as summarized in Table 28.1 and discussed later (see page 1180). In other words, the genetic code is almost, but not quite, universal.

The code is almost, but not quite, universal.

Biological Validity of the Code

As described above, the assignment of genetic code words to amino acids was carried out strictly through the use of *in vitro* systems—amino acid incorporation directed by synthetic templates and assays of aminoacyl-tRNA binding to ribosomes. How could we be assured that these codon assignments are valid for translation of messages in living cells? Some of the validation came from amino acid sequence analysis of mutant human hemoglobins (Chapter 7). Most of the amino acid sequence changes could be accounted for by substitution mutations involving a single base, the most frequent spontaneous mutation. For example, the Glu → Val substitution seen with sickle-cell hemoglobin could be accounted for by changing a GAA Glu codon to a GUA Val codon, or GAG to GUG.

FIGURE 28.5

The genetic code (as written in RNA). We show here the genetic code as used in most organisms. Chain termination, or “stop,” codons are shown in orange, and the usual start codon, AUG, is dark green. Other, rarely used, start codons are shown in light green. When AUG is used as a start codon, it codes for *N*-formylmethionine (fMet) in prokaryotes or methionine (Met) in eukaryotes; see page 1182. Otherwise, it codes for Met. Exceptions to these codon assignments are given in Table 28.1.

TABLE 28.1 Modifications of the genetic code

Codon	Usual Use	Alternate Use	Where Alternate Use Occurs
AGA AGG	Arg	Stop, Ser	Some animal mitochondria, some protozoans
AUA	Ile	Met	Mitochondria
CGG	Arg	Trp	Plant mitochondria
CUU CUC CUA CUG	Leu	Thr	Yeast mitochondria
AUU GUG UUG	Ile Val Leu	Start (<i>N</i> -fMet)	Some prokaryotes ^a
UAA	Stop	Glu	Some protozoans
UAG	Stop	Pyrrolysine Glu	Various archaea Some protozoans
UGA	Stop	Trp Selenocysteine Selenocysteine and Cys	Mitochondria, mycoplasmas Widespread ^a <i>Euplotes</i>

^aDepends on context of message, other factors.

The code is redundant. Several codons may correspond to a single amino acid, sometimes via wobble in the 5' anticodon position.

Other important validation experiments were carried out by George Streisinger, using the T4 bacteriophage lysozyme system. Lysozyme is a phage-coded enzyme responsible for rupture of the host bacterium after a cycle of phage reproduction. Lysozyme mutants are easy to detect because they can produce phage but cannot lyse the host cell. Mutations were induced by treating phage-infected cells with **proflavin**, a large planar molecule that can fit, or *intercalate*, between successive base pairs in DNA and induce *frameshift* mutations, that is, additions or deletions of a single base, which alter the reading frame (Figure 7.26, page 257). In one such frameshift mutation, wild-type function was restored by a second mutation. Sequence analysis of the double-mutant lysozyme showed five changes from the wild-type sequence. The data were consistent only with the assumption that the double mutant was created by a single-base insertion and a single-base deletion, which restored the reading frame (Figure 28.6). All of the codons used experimentally to infer the nucleic acid sequence (long before DNA sequencing had been developed) were consistent with the codon assignments as determined *in vitro*.

Deviations from the Genetic Code

Why has the genetic code remained almost unchanged over so vast an evolutionary span? Perhaps it is simply because even small codon changes could be devastating. A single codon change could alter the sequence of nearly every protein made by the organism. Some of these changes would almost certainly have lethal effects. Therefore, codon changes have been opposed by intense selective pressure during evolution. They represent changes in the most basic rules of the game.

Yet significant deviations do occur, most notably, differences in the mitochondrial code and coding for the “21st and 22nd” amino acids, namely, selenocysteine and pyrrolysine (Chapter 5, page 144). A significant change in the mitochondrial code, as shown in Table 28.1, is the change in AUA from an isoleucine to a methionine codon. It has been argued that this represents an adaptation within mitochondria to oxidative stress. Methionine, whether free or as a residue in a protein, is readily oxidized, but just as readily reduced by methionine sulfoxide reductase. Hence, it is argued that it is advantageous for a mitochondrion to have increased methionine abundance in its proteins, to absorb reactive oxygen species that otherwise would be attacking less resilient targets. Indeed, mitochondrial proteins do have methionine in higher abundance than do proteins from other cell compartments.

Selenocysteine (21st amino acid) and pyrrolysine (22nd amino acid) are translated differently. Both use codons that are otherwise used in translation termination—UGA for selenocysteine (Sec) and UAG for pyrrolysine (Pyl). A special transfer RNA, tRNA^{Sec}, is a substrate for a seryl-tRNA^{Sec} synthetase, which charges serine directly, to give Ser-tRNA^{Sec}. (Note the convention; Ser refers to the amino acid bound and superscript Sec denotes the amino acid corresponding to the anticodon on that tRNA molecule.) The tRNA-linked Ser is then converted to Sec by a two-step process beginning with phosphorylation of the serine hydroxyl group. The resultant Sec-tRNA^{Sec} responds to a UGA codon. For a particular

FIGURE 28.6

Validation of the genetic code by amino acid sequence analysis of T4 phage lysozyme mutants. *e* is the gene for lysozyme, a portion of whose amino acid sequence is shown. One of two proflavin-induced mutations, either eJ42 or eJ44, disrupted the reading frame by deleting one base pair, and a second mutation restored the wild-type reading frame by inserting a base pair, but altering the amino acid sequence between the two mutant sites. The mRNA sequences encoding these five altered amino acids are inferred from the genetic code and the known action of the mutagen.

Adapted with permission from Eric Terzaghi from *Proceedings of the National Academy of Sciences of the United States of America* 56:500-507, E. Terzaghi, Y. Okada, G. Streisinger, J. Emrich, M. Inouye, and A. Tsugita, Change of a sequence of amino acids in phage T4 lysozyme by acridine-induced mutations, 1966.

UGA to be translated as Sec rather than for termination, that UGA must have a special Sec Insertion Sequence (SECIS) available, usually in the 3'-untranslated region (3'UTR). Although selenocysteine is rather rare among proteins, the human proteome has been shown to contain 25 selenoproteins. As mentioned earlier (Chapter 15), some of these proteins participate in oxidant protection.

Pyrrolysine, by contrast, has a much narrower distribution, having been found so far in only about 1% of all sequenced genomes, mostly methanogenic archaea. Pyrrolysine is converted directly to a pyrrolysyl-tRNA by its own amino acyl-tRNA synthetase. The resultant Pyl-tRNA^{Pyl} has an anticodon that pairs with UAG, normally used in chain termination. So far it is not clear whether any of the UAGs in these genomes are read as stop codons or whether all encode Pyl.

Finally, although we say that the code is unambiguous, that concept may need revision in light of recent work with ciliated protozoa of the genus *Euplotes*. This organism uses UGA as one of three cysteine codons (the others are UGU and UGC). At least one gene in *E. crassus* has UGA triplets encoding both cysteine and selenocysteine. Sequence context is obviously key to ensuring correct insertional specificity. Because this organism also uses UGA as a tryptophan codon in its mitochondria, UGA is busy indeed.

The Wobble Hypothesis

If you examine the codon table shown in Figure 28.5, you will note that, in general, each amino acid is characterized by the first two codon letters. For example, all four Pro codons start with CC, and all four Val codons start with GU. Thus, redundancy is usually expressed in the third letter—ACU, ACC, ACA, and ACG all code for threonine. Soon after the code was deciphered, it was recognized that a single tRNA may recognize several different codons. The multiple recognition always involves the 3' residue of the codon and therefore the 5' residue of the anticodon.

In 1966, Francis Crick proposed that the 5' base of the anticodon was capable of “wobble” in its position during translation, allowing it to make alternative (non-Watson–Crick) hydrogen-bonding arrangements with several different codon bases. An example is shown in Figure 28.7. G in the 5' anticodon position can pair with either C or U in the codon, depending on the relative orientation of the pair. Considering both base-pairing possibilities and the observed selectivity of tRNAs, Crick proposed the set of “wobble rules” given in Table 28.2. This hypothesis nicely explains the frequently observed degeneracy in the 3' site of the codon. The rather uncommon nucleoside, *inosine* (I, Chapter 22), is found in a number of anticodons, where it shows the ability to pair with A, U, or C.

Not all cases of multiple codon use involve translation of a single tRNA using wobble. As an example, consider the six leucine codons. Four of the six begin with CU and in principle could be translated by two different tRNAs, using wobble. However, the remaining two codons, UUA and UUG, will require a different anticodon, such as 3'-AAU-5', which could translate both codons. In fact, *E. coli* contains five different leucine tRNAs and multiple **isoaccepting tRNAs**—tRNAs accepting and translating the same amino acid are common.

Codon Bias

Redundancy of the genetic code means that several nucleotide triplets can encode the same amino acid—leucine, for example, with six codons. In principle, a silent mutation, such as CUA → CUG, should have no biological consequences because both triplets encode leucine. Yet we find that use of degenerate codons by certain organisms is highly selective. In an extreme case, about half of all 64 codons are used either negligibly or not at all by the bacterium *Thermus thermophilus*. Although we don't know the evolutionary mechanisms leading to such

FIGURE 28.7

The wobble hypothesis. As an example, we show how the anticodon base G can pair with either C or U in a codon. Movement (“wobble”) of the base in the 5' anticodon position is necessary for this capability (see arrow).

TABLE 28.2 Base-pairing capabilities in wobble pairs

Base at 5' Position in Anticodon		Base at 3' Position in Codon

asymmetry in codon selection, knowledge of codon bias has practical significance, for those wishing to express recombinant eukaryotic proteins in bacteria. Consider *E. coli*, a frequently used host for recombinant gene expression. Of the six arginine codons, two, AGA and AGG, are rarely used in *E. coli*, meaning that each of these triplets represents fewer than 1% of the arginine codons in the entire genome. Related to this is that the intracellular concentration of the tRNA with the anticodon, 3'-TCA-5', which can translate these two rare codons, is quite low. This means that a recombinant gene with more abundant representation of these codons will be poorly expressed after transfer into *E. coli*. This situation can be remedied by site-directed mutagenesis of the recombinant genes to change these rare codons to arginine codons that are more abundant, and more efficiently translated, in the *E. coli* genome. An alternative approach is to engineer the *E. coli* host for overexpression of the rare tRNA so that the codons AGA and AGG can be efficiently translated.

An advantage of a code design that has synonymous codons with similar structures is that many mutations involving single-base changes are silent because a codon change such as the CUA → CUG mentioned above doesn't change the sense of the genetic message. Not only are many single-base changes silent, but many more are conservative, in the sense that a mutation may substitute a structurally similar amino acid that can be tolerated by the protein with no loss of function. For example, each of six leucine codons can be converted to a codon for the closely related valine by a single-base change. This suggests that the code has evolved to maximize genetic stability.

Stopping and Starting

Because the messenger RNA is invariably longer than the open reading frame that is to be translated, specific start and stop signals are required to begin and end translation. In almost all organisms, UAA, UAG, and UGA are used for stop signals and do not code for any amino acid (with the exceptions discussed above). A stop signal indicates that translation is to terminate and the polypeptide product is to be released by the ribosome. Clearly, three stop signals are more than is absolutely necessary, so it is not surprising to find that these codons are also used for designating amino acids in mitochondria and in other special cases (see Table 28.1).

Although nature has been generous in designating stop signals, it has been stingy in apportioning starts. The start signal commonly used in translation is AUG, which also serves as the single methionine codon. How does the ribosome know how to interpret this triplet properly so as to distinguish between internal Met sites and start sites? The answer is that the 5' end of any message contains specific sequences to ensure that it is correctly attached to the ribosome (see page 1183). As the message begins to be read, the *first* AUG encountered is interpreted as a start signal, and translation begins. Although prokaryotic and eukaryotic cells handle this situation somewhat differently, the consequence is that *N*-formylmethionine (in prokaryotes) or methionine (in eukaryotes) is usually the first amino acid incorporated into a polypeptide chain. Therefore, all proteins start with *N*-fMet or Met, at least when they are first synthesized. However, in most cases this residue is either deformylated or removed as translation proceeds. Any AUG encountered after the start is treated as a signal to incorporate methionine within the sequence at that point. Very occasionally, GUG (normally valine), UUG (normally leucine), or AUU (normally isoleucine) serves as a prokaryotic start codon when located near the 5' end of a message (see Table 28.1). When they do, however, they code for *N*-formylmethionine in the first position. In other positions these triplets are read as normal codons.

Prokaryotic messengers contain translational start and stop signals, as well as a sequence that aligns the mRNA on the ribosome.

N-formylmethionyl-tRNA

The Major Participants in Translation: mRNA, tRNA, and Ribosomes

mRNAs

As we indicated in Chapter 27, eukaryotic messenger RNAs are quite different from prokaryotic mRNAs. Prokaryotic mRNAs are more complex because many or most are *polycistronic*; they encode two or more polypeptide chains. This means that the mRNA sequence must be punctuated so that translation of the RNA corresponding to each gene is controlled by its own initiation and termination signals. Eukaryotic messages almost always encode just one protein, but the mRNA structure is the result of post-transcriptional processing far more extensive than that seen in prokaryotic systems.

As a good example of a prokaryotic mRNA, consider that produced by transcription of the *E. coli lac* operon, which was introduced in Chapter 27 and receives further attention in Chapter 29. This group of three linked genes—*lacZ*, *lacY*, and *lacA*—controls the utilization of lactose and related sugars by bacteria. As shown in Figure 28.8, these three genes are expressed as a single mRNA molecule some 5300 nucleotides in length. Within this mRNA are three **open reading frames**, corresponding to the *lacZ*, *Y*, and *A* genes. An open reading frame is a sequence within a messenger RNA, bounded by start and stop codons, that can be continuously translated. Each open reading frame has its own start and stop signals, and you can see that these signals vary considerably. There is extra, untranslated RNA between the reading frames and at the ends. The regions 5' to each start signal contain sequences rich in A and G, which help to align the mRNA on the ribosome so that translation can begin at the proper points and in the correct reading frame. Such attachment sequences, found on all prokaryotic mRNAs, are called *Shine–Dalgarno sequences*, after J. Shine and L. Dalgarno, who first described them. A Shine–Dalgarno sequence can base-pair with a sequence contained in the ribosomal RNA, as shown in Table 28.3, to produce a proper alignment for starting translation. The different attachment sequences appear to have different affinities for ribosomes. For example, the three genes of the *lac* operon (Figure 28.8) are not translated to equal extents—*lacZ* is translated much more frequently than *lacY* or *lacA*.

Shine–Dalgarno sequences help align ribosomes on mRNAs to properly start translation.

FIGURE 28.8

The *lac* operon mRNA. The mRNA for the *E. coli lac* operon is about 5300 nucleotides long and contains the open reading frames for the *lacZ*, *lacY*, and *lacA* genes, each flanked appropriately by start, stop, and Shine–Dalgarno (SD) sequences.

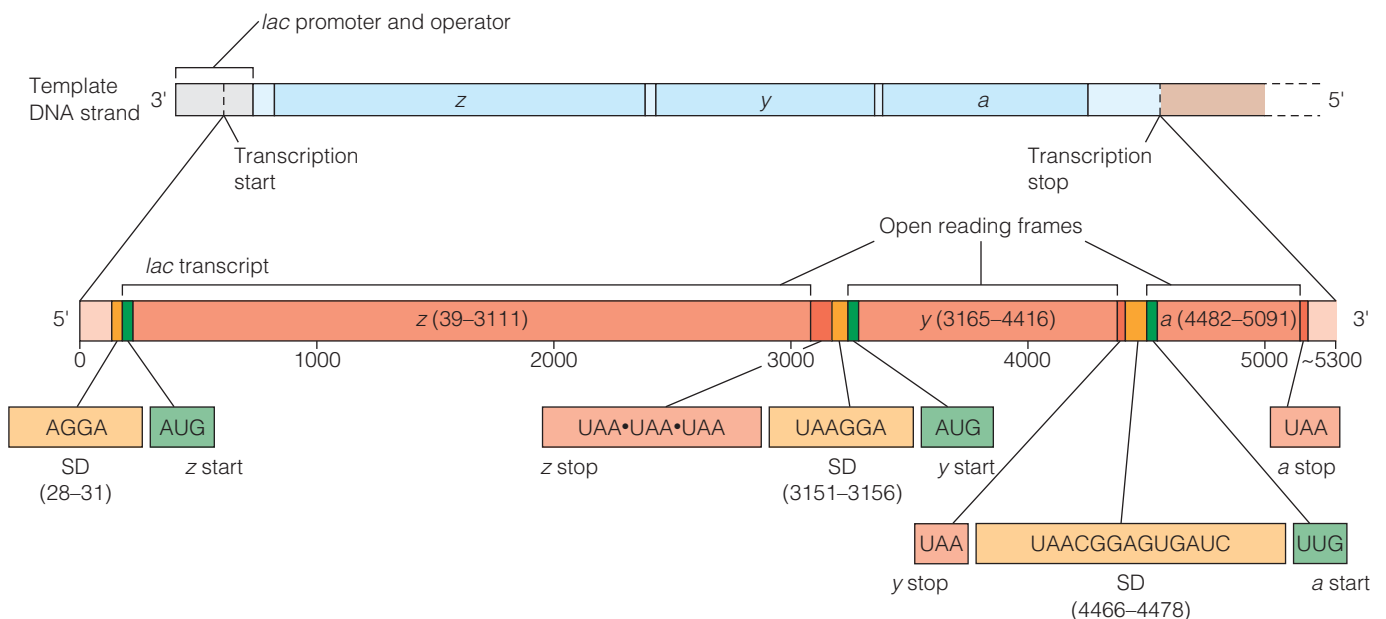

TABLE 28.3 Representative Shine–Dalgarno sequences

Message for	Shine–Dalgarno Sequence
Ribosomal protein L10	<p>5' AGGAGCAAAGCUA AUG 3' mRNA</p> <p style="text-align: center;">SD sequence Start</p> <p style="text-align: center;"> </p> <p>3' AUUCCUCCA 5' Complementary 3' end of 16S ribosomal RNA</p>
<i>E. coli lac z</i>	<p>5' AGGAAACAGCUA AUG 3'</p> <p style="text-align: center;"> </p> <p>3' AUUCCUCCA 5'</p>
λ phage Cro	<p>5' UAAGGAGGUUGU AUG 3'</p> <p style="text-align: center;"> </p> <p>3' AUUCCUCCA 5'</p>

The mRNA produced from the *lac* operon has all the basic elements necessary for its function: sequences to align it properly on the ribosome and sequences that start and stop translation at the proper points. Many mRNAs also have possibilities for forming three-dimensional secondary and tertiary structures, which can participate in regulating the relative production of the various protein products. We shall return to this point in Chapter 29.

Transfer RNA

Any cell, prokaryotic or eukaryotic, contains a battery of different types of tRNA molecules sufficient to incorporate all 20 amino acids into protein. This does not mean that there need be as many tRNA types as there are codons, for, as noted earlier, some tRNAs can recognize more than one codon, when the difference is in the third, or wobble, position. *E. coli*, for example, has about 40 different tRNAs—plenty to code for all amino acids, but not as many as the 61 amino acid codons. As noted on page 1180, the tRNA specific to a given amino acid is designated by writing the amino acid as a superscript, for example, tRNA^{Ala}.

Transfer RNA was the first natural polynucleotide sequence to be determined, in a pioneering study of yeast tRNA^{Ala} by Robert Holley in 1965. Since then, thousands of tRNAs have been sequenced. All have the general structure shown schematically in Figure 28.9a and have similar sequences of about 70 to 80 nucleotides or more. There is, however, considerable variation in detail, as shown in the examples in Figure 28.9b and c. Furthermore, the tRNAs are unique among RNA molecules in their high content of unusual and modified bases, three of which are shown in Figure 28.10. Biosynthesis of the modified bases always occurs *post-transcriptionally*, as mentioned in Chapter 27. For example, an isomerase converts a uridine residue (1-ribosyluracil) to the unusual C-glycoside pseudouridine (5-ribosyluracil), and S-adenosylmethionine-dependent methyltransferases are responsible for converting standard bases to their methylated derivatives.

Cloverleaf models of the kind shown in Figure 28.9 are useful for showing the general pattern of hydrogen bonding and denoting the functional parts of the tRNA. The *anticodon triplet* in the loop at the bottom is complementary to the mRNA codon and will make base pairs with it. Because the codon and anticodon, when paired, constitute a short stretch of double-stranded RNA, their directions must be antiparallel. In Figure 28.9 we have written the tRNA molecules with their 5' ends to the left. Therefore, the messenger RNA, when shown in such figures, is written with its 5' end to the right, opposite to the normal convention.

(a)

FIGURE 28.9

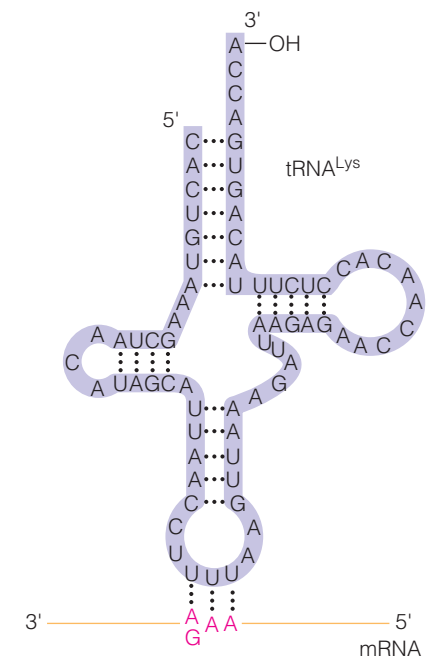

Structure of tRNAs. (a) Generalized tRNA structure. The positions of invariant and rarely varied bases are shown in purple. Regions in the D loop and the variable loop that can contain different numbers of nucleotides are shown in blue. The anticodon is shown in orange. (b) A leucine tRNA from *E. coli*. (c) A human mitochondrial tRNA for lysine. Code for bases: Y = pyrimidine, R = purine, ψ = pseudouridine, T = ribothymidine, and D = dihydrouridine (see Figure 28.10).

The *acceptor stem* at the top of the cloverleaf figure is where the amino acid will be attached, at the 3' terminus of the tRNA. This stem always has the sequence 5'...CCA—OH 3'. Other common features of tRNA molecules are the *D loop* and the *T ψ C loop*, regions that contain a substantial fraction of invariant positions and frequently contain modified or unusual bases as well. The so-called *variable loop* is indeed variable, both in nucleotide composition and in length, as Figure 28.9 demonstrates.

Although cloverleaf models are convenient for depicting the primary structure and some elements of secondary structure, they are not good three-dimensional representations of tRNA molecules. X-ray diffraction studies of tRNA molecules

All tRNAs share a general common structure that includes an anticodon loop, which pairs with codons, and an acceptor stem, to which the amino acid is attached.

have revealed that the real molecular shape is more complex, as you can see in Figures 28.11 and 4.20 (page 109). As these figures show, a tRNA molecule looks rather like a hand-held drill or soldering gun. The anticodon loop is at the bottom of the grip, and the acceptor stem is at the working tip. The D loop and the T ψ C loop are folded inward in a complex fashion near the top of the grip, to provide a maximum of hydrogen bonding and base stacking. Some of the hydrogen-bonding patterns required to produce this folding are rather unusual (Figure 28.12). The three-dimensional shapes of the tRNAs are highly conserved even though the primary structures vary. A likely explanation is that such conservation is necessary so that each tRNA can fit equally well onto the ribosome and carry out its function.

FIGURE 28.12

Unusual base pairings in tRNA. All are from the yeast tRNA^{Phe} shown in Figure 28.11. (a, b) Some unusual pair matches. (c, d) Some examples of triple interactions. R represents the ribosyl residue of the RNA chain. The bases prefixed by m are methylated at the carbon atom corresponding to the superscript. Numbers following the letters designating bases show the position in the sequence.

Coupling of tRNAs to Amino Acids and Formation of Aminoacylated tRNAs: The First Step in Protein Synthesis

Amino acids are attached to tRNAs by a covalent bond between the carboxylate of the amino acid and a ribose 3' hydroxyl group of the invariant 3' terminal adenosine residue on the tRNA. Pairing of the correct amino acid residues and the tRNAs is accomplished by a set of enzymes called **aminoacyl-tRNA synthetases** (abbreviated AARS). In *E. coli* there are 21 synthetases, each of which recognizes one amino acid and one or more tRNAs. Lysine is unique in having two synthetases. The reaction linking the two molecules, shown in Figure 28.13, proceeds in two steps. First, the amino acid, which is bound to the synthetase, is activated by ATP to form an **aminoacyl adenylate**. While still bound to the enzyme, this intermediate reacts with one of the correct tRNAs to form the covalent bond and release AMP.

Because all of the synthetases perform essentially the same function, one might expect them to represent minor variations on a common theme. This is, however, not the case; there are two general classes of aminoacyl-tRNA synthetases (I and II). Their active sites are completely different, and the two classes bind their cognate tRNAs from opposite sides. Furthermore, the class I enzymes tend to function as monomers, whereas the class II enzymes function as dimers or tetramers. Moreover, the enzymes differ mechanistically. Class II enzymes link the aminoacyl moiety in the aminoacyl adenylate intermediate directly to the 3' hydroxyl in the tRNA acceptor, while class I enzymes synthesize first a 2'-aminoacyl-tRNA intermediate, which then undergoes intramolecular transesterification, giving the 3'-aminoacyl-tRNA product.

The reasons for these extreme differences are unknown, but they may reflect the utilization of some amino acids in proteins before others in the very early evolution of protein synthesis. A recent observation that may bear on this question is that some members of some classes of organisms (Gram-positive bacteria and archaea, for example), as well as some organelles, use an indirect transamidation route for charging some tRNAs. For example, tRNA^{Gln} is charged first with Glu, which is then replaced by Gln.

Thus, these organisms do not require (although they may have) a Gln-tRNA^{Gln} synthetase, as do Gram-negative bacteria and eukaryotes. It has been suggested that glutamine was one of the last amino acids to be added to the protein repertoire and that it was initially incorporated by this route.

In higher organisms nine aminoacyl-tRNA synthetases are organized into a high-molecular-weight complex, along with three accessory proteins. The biological function of this complex is unknown, but it is assumed to contribute toward coordinating amino acid synthesis with protein synthesis.

You might expect that the synthetase would identify the correct tRNA on the basis of its anticodon, but many studies indicate that the identification process is more complex, and various nucleotides act as *identity elements*. In 1988, Ya-Ming Hou and Paul Schimmel showed that changing a single base pair (between residues 3 and 70 in the acceptor stem) of tRNA^{Cys} or tRNA^{Phe} to the G-U pair found in tRNA^{Ala} caused the alanine synthetase to accept the tRNA^{Cys} or tRNA^{Phe} and couple it to alanine. Other tRNAs appear to be recognized by their synthetases at many different locations (see Figure 28.14). No simple rule has emerged, although it is

Amino acids are coupled to their appropriate tRNAs by aminoacyl-tRNA synthetases.

FIGURE 28.13

Formation of aminoacyl tRNAs by aminoacyl tRNA synthetase. In step 1 the amino acid is accepted by the synthetase and is adenylated, with the aminoacyl adenylate remaining bound to the enzyme. In step 2 the proper tRNA is accepted by the synthetase, and the amino acid residue is transferred to the 3' OH of the 3'-terminal residue of the tRNA (class II enzymes) or to the 2' hydroxyl, followed by isomerization to the 3' aminoacyl-tRNA (class I enzymes). For class I enzymes the 2' hydroxyl of the 3'-terminal AMP residue is the nucleophile for reaction 2.

**FIGURE 28.14**

Major "identity elements" in some tRNAs. Red circles represent the positions that have been shown to identify the tRNA to its cognate synthetase. Shown also is a synthetic polynucleotide containing the G-U alanine identity element (in red), which is a good substrate for alanyl-tRNA synthetase.

From *Science* 240:1591–1592, L. Schulman and J. Abelson, Recent excitement in understanding transfer RNA identity. © 1988. Reprinted with permission from AAAS. Adapted with permission from John Abelson.

clear that identity elements are clustered in the anticodon loop and the acceptor stem. A dramatic illustration of the importance of identity elements is shown by the fact that the yeast tRNA^{Ala} shown in the figure can be trimmed to just a single-hairpin molecule, as shown, and, so long as a critical G-U base pair (shown in red) is present, the molecule can be efficiently and accurately aminoacylated.

Aminoacyl-tRNA synthetases contribute toward the fidelity of translation by a process akin to proofreading by DNA polymerases. In the instant between formation of an enzyme-bound aminoacyl adenylate and its conversion to aminoacyl-tRNA, the enzyme can sense the improper fit of the amino acid side chain and hydrolyze the intermediate before the amino acid can be linked to tRNA. Moreover, even if the wrong aminoacyl-tRNA is synthesized, the enzyme has a short time in which it can identify the mischarged amino acid as incorrect and hydrolyze it before it can be released to participate in translation. In these ways, aminoacyl-tRNAs contribute toward an overall error frequency for protein synthesis of about 10^{-4} , less accurate than DNA replication, to be sure, but with the consequences of error being much lower because the error is not propagated to the next generations. Most of the work on AARS proofreading has been done with isoleucyl-tRNA synthetase and its ability to mischarge valine, which differs from isoleucine by only one methylene group. Despite this small structural difference, the mischarging frequency is only 3×10^{-4} .

Insight into the recognition of tRNAs by their synthetases has been provided by crystallographic analysis of the complexes formed. Figure 28.15 shows the structure of a class I synthetase-tRNA complex, *E. coli* glutamyl-tRNA. As shown in the figure, the tRNA lies across the protein, making a number of specific contacts, including crucial ones in the anticodon region and in the acceptor stem. Both of these regions are distorted in the complex, with the acceptor stem being elongated and inserted into the active site pocket. This pocket is formed by a common protein structural motif called the *dinucleotide fold*, which frequently acts as a nucleotide-binding region. In this case it also binds the ATP required for acylation. It provides a binding site for glutamine as well. Thus, all three participants in the reactions are grouped close together.

FIGURE 28.15

A model of the *E. coli* glutamyl tRNA synthetase coupled with its tRNA and ATP. The tRNA is represented by a detailed atomic model, the protein by its solvent-accessible surface (blue). The ATP (green) and the 3' acceptor stem of the tRNA fit into a deep cleft in the synthetase. This cleft will also accommodate the amino acid. This is a monomeric class I synthetase. PDB ID 1GSG.

FIGURE 28.16

Yeast aspartyl tRNA synthetase complexed with two molecules of tRNA^{Asp}. This is a dimeric class II synthetase. Protein subunits are in white and pale green. tRNA molecules are in blue and gold. PDB ID 1ASY.

From *Science* 252:1682, M. Ruff, S. Krishnaswamy, M. Boeglin, A. Poterszman, A. Mitschler, A. Podjarny, B. Rees, J. C. Thierry, and D. Moras, Class II aminoacyl transfer RNA synthetases: Crystal structure of yeast aspartyl-tRNA synthetase complexed with tRNA(Asp). © 1991. Reprinted with permission from AAAS and Marc Ruff.

Similar interactions are seen with a class II synthetase. Figure 28.16 shows the dimeric yeast aspartyl tRNA synthetase complexed with two molecules of tRNA^{Asp}. Note that the tRNA is bound to the enzyme in opposite orientation from that seen with class I synthetases. Only one of the two tRNA molecules is bound in a catalytically productive conformation.

One other feature of aminoacyl-tRNA synthetases deserves comment. In higher eukaryotes most of these enzymes are “moonlighting proteins”—proteins that evolved initially to play their well-known function in protein synthesis, but which in further evolution acquired additional functions. In humans, aminoacyl-tRNA synthetases are involved in functions as diverse as autoimmunity, control of apoptosis, regulation of ribosomal RNA synthesis, vascular development, and coordination of the DNA damage response. In all cases studied the catalytic machinery for aminoacyl-tRNA synthesis has remained undisturbed, and evolutionary modifications to convey additional functions occur elsewhere on the protein molecule.

The Ribosome and Its Associated Factors

We have now described two of the participants that must be brought together to carry out protein biosynthesis—the mRNA and the set of tRNAs charged with the appropriate amino acids. The actors are in the wings, and all that is needed is a proper director and a stage on which the events can unfold. Both are provided by the ribosome, and the typical cell requires many. An *E. coli* cell, for example, contains as many as 20,000 ribosomes, accounting for about 25% of the dried cell mass. Thus, a cell devotes a large part of its energy to producing ribosomes and to using them in protein synthesis.

Soluble Protein Factors in Translation

Before describing ribosomes in detail, however, we mention one more set of participants, whose functions will be described in detail later. These are the soluble proteins that participate in the three stages of translation—initiation factors, elongation factors, and release factors. Table 28.4 introduces these factors as initially studied in bacteria, as well as their eukaryotic counterparts. We shall refer back to the information in this table as we discuss mechanisms in translation.

TABLE 28.4 Soluble protein factors in translation

Function	Factor (Bacteria)	Factor (Eukaryotes)	Role in Translation
Initiation	IF1	eIF1, eIF1A	Promotes dissociation of preexisting 70S ribosome
	IF2	eIF2, eIF2B	Helps attach initiator tRNA
	IF3	eIF3, eIF4C	Similar to IF1; prepares mRNA for ribosome binding
		eIF4A, eIF4B, eIF4F	Same as eIF1, eIF1A
		eIF5	Helps dissociate eIF2, eIF3, eIF4C
		eIF6	Helps dissociate 60S subunit from inactive ribosomes
Elongation	EF-Tu	eEF1 α	Helps deliver aminoacyl-tRNA to ribosomes
	EF-Ts	eEF1 $\beta\gamma$	Helps recharge EF-Tu with GTP
	EF-G	eEF2	Facilitates translocation
Termination	RF1	eRF	Release factor (UAA,UAG)
	RF2		Release factor (UAA, UGA)
	RF3		A GTPase that promotes release

Components of Ribosomes

The ribosome is a large ribonucleoprotein particle containing 60–70% RNA and 30–40% protein. Ribosomes and their subunits are characterized in terms of their sedimentation coefficients in ultracentrifugation. Thus, the individual bacterial ribosome is called a 70S particle and has a molecular mass of about 2.5×10^6 Da. Eukaryotic ribosomes are somewhat larger, with a sedimentation coefficient of 80S and a molecular mass of 4.2×10^6 Da. When isolated ribosomes are placed in a buffer containing low Mg^{2+} ion, they dissociate into two smaller subunits. As shown in Figure 28.17, bacterial 70S ribosomes dissociate into 30S and 50S subunits. We shall see later that dissociation and reassociation of these subunits are crucially important during translation. Figure 28.17 also shows the number of RNA and protein components in each subunit. Note that the 50S bacterial subunit contains two rRNA molecules (5S and 23S) and 34 different proteins, while the

FIGURE 28.17

Components of bacterial and eukaryotic ribosomes. Bacterial (to the left) and eukaryotic (to the right) ribosomes are assembled along the same structural plan, with eukaryotic ribosomes being somewhat larger and more complex. The shapes of the ribosomal subunits were determined by electron microscopy.

Modified from *Molecular Biology of the Cell*, 4th ed., B. Alberts et al. Garland Science, New York, 2002.

30S subunit contains just one rRNA (16S) and 21 proteins—all different from those in the 50S subunit. Proteins from the small subunit are called S1, S2, S3...S21, while those from the large subunit are called L1, L2, L3...L34. All proteins are present in one copy per ribosome, except for L12, which is present in four copies. Eukaryotic ribosomes are significantly larger, with larger rRNAs and more proteins. We shall be discussing primarily bacterial ribosomes, whose structures and functions are known in much greater detail.

Once the complexity of the ribosome was revealed, particularly the large numbers of proteins in each subunit, it seemed a daunting task to determine the structure of the particle and to understand the function of each protein. However, Peter Traub and Masayasu Nomura learned as early as 1968 that they could reassemble 30S ribosomal subunits from the separated RNA and protein components. The product, when combined with 50S subunits, was active for *in vitro* protein synthesis. An obligatory order of assembly was seen, with some proteins being incorporated only after binding of certain other proteins. As expected if transcription and translation are coupled, the proteins bound earliest in the pathway are those linked to the 5' end. The ability to assemble ribosomes *in vitro* allowed analysis of the function of individual ribosomal proteins because ribosomal subunits could be assembled with specific proteins missing, followed by functional analysis of these deliberately altered particles.

More recent analysis shows that the pathway of ribosome assembly *in vivo* differs from the pathway *in vitro* in significant ways. In this analysis, carried out by James Williamson and colleagues, assembly intermediates accumulated in *E. coli* treated with the antibiotic neomycin and were analyzed by ^{15}N pulse labeling and mass spectrometry. Additional information was obtained from electron micrographic analysis of individual assembly intermediates. Distinctions between the *in vitro* and *in vivo* pathways include the following. First, ribosome assembly *in vivo* occurs via parallel pathways, with one pathway adding proteins initially at the rRNA 5' domain and another at the 3' domain. Second, some proteins bound to central domains are incorporated before proteins binding to the ends of 16S rRNA. Third, the ribosomes are assembled both from newly synthesized proteins and from proteins that originated in previously synthesized intact subunits. Figure 28.18 summarizes principal features of the *in vitro* and *in vivo* pathways.

Sequence analyses reveal no significant homologies among the different proteins in a ribosome, but comparison of sequences between corresponding proteins in the ribosomes of different organisms reveals considerable evolutionary conservation. Thus, the ribosome is a complex object that evolved early in the history of life and has remained relatively unchanged. Although the ribosomes of eukaryotes differ significantly from those of prokaryotes, the evolutionary continuity is clear. The sequences of many ribosomal RNAs tell the same story. Indeed, because of their relatively slow evolutionary rates of change, rRNAs are useful as evolutionary yardsticks over vast phylogenetic distances. In fact, it was sequence analysis of 16S rRNAs that led Carl Woese to propose the existence of a third domain of life, the archaea.

Ribosomal RNA Structure

When the sequences of 16S rRNAs were originally determined, they were found to contain many regions of self-complementarity, which are capable of forming double-helical segments. A pattern like that shown in Figure 28.19 may seem so complex as to appear almost arbitrary, but comparison with other, even distantly related, 16S RNA sequences shows that the potentially double-stranded regions are highly conserved. Indeed, the secondary structure seems more highly conserved than is the primary structure, for it is often found that there are compensatory mutations in double-helical regions so as to maintain base pairing. A schematic illustration like that in Figure 28.19 is analogous to the cloverleaf

Despite their complexity, ribosomal subunits can be assembled *in vitro*.

**FIGURE 28.18**

Assembly map for the 30S subunit. (a) Assembly pathway *in vitro*, as determined by Traub and Nomura. Arrows indicate the obligatory nature of some protein-binding events. For example, S7 must bind before S9, S13, or S19, but once S7 is bound, any of these three proteins can be added. The earliest protein-binding events occur near the 5' end of the 16S rRNA, and an intermediate to which 5'- and central-domain proteins are bound must be formed before addition of 3' domain proteins. **(b)** *In vivo* assembly map, as determined by Williamson and colleagues. Parallel pathways begin, with proteins added at either the 5' domain or the 3' domain of 16S rRNA.

visualization of a tRNA (Figure 28.9). The actual rRNA is folded into a three-dimensional structure, just as is the tRNA. In the case of the ribosomal subunit, however, the structure is further complicated by the presence of ribosomal proteins bound to the RNA. However, it is now clear that the pattern shown in Figure 28.19 faithfully describes the secondary structure of 16S rRNA. 23S rRNA has a comparable secondary structure, actually more complex, reflecting its larger size.

Internal Structure of the Ribosome

Although EM images of intact ribosomes and their subunits were obtained some time ago, high resolution was difficult to achieve because of the necessity of staining or shadowing the particles. Nor could such techniques hope to tell us how the proteins and RNA were positioned inside the ribosome. Nevertheless, the overall

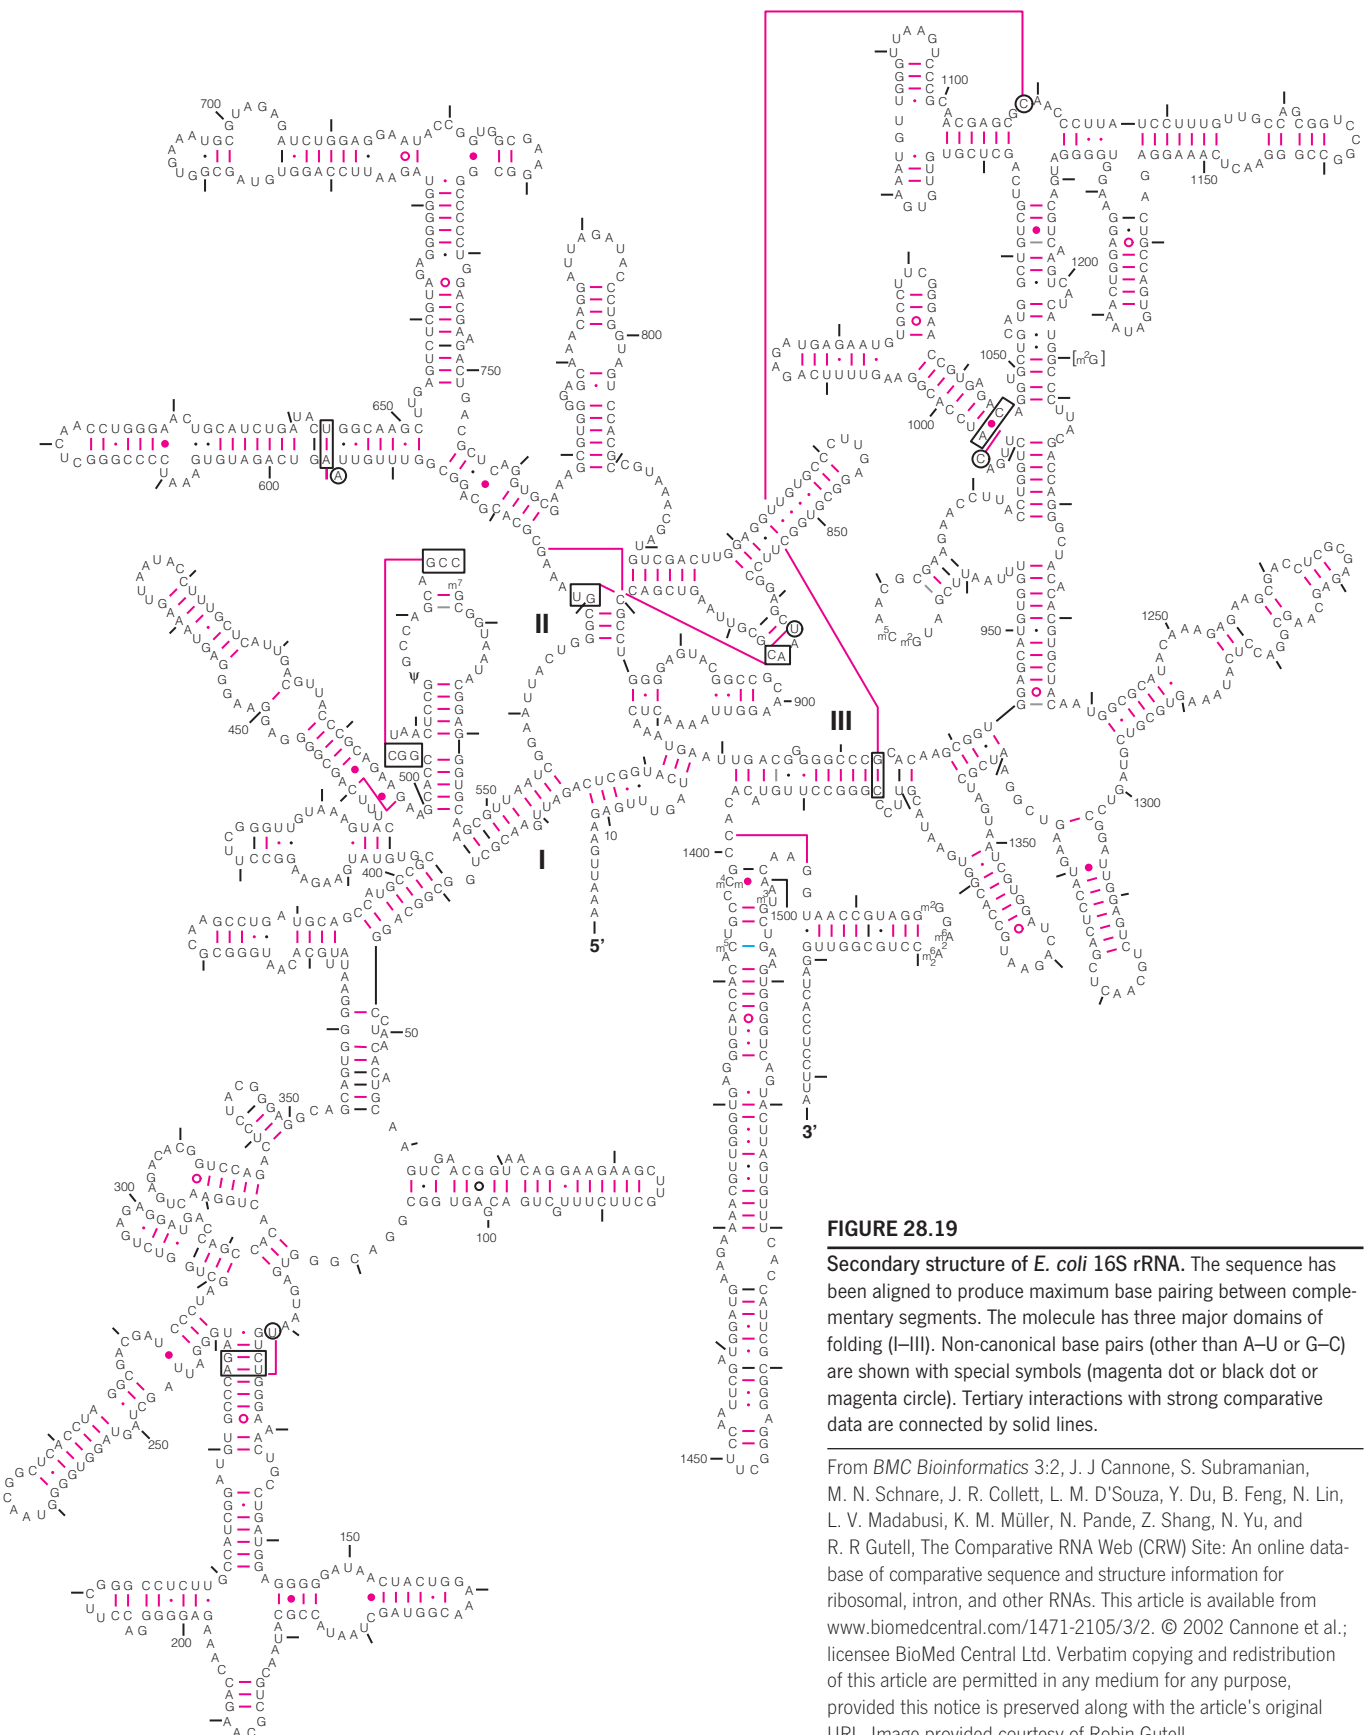

FIGURE 28.19

Secondary structure of *E. coli* 16S rRNA. The sequence has been aligned to produce maximum base pairing between complementary segments. The molecule has three major domains of folding (I–III). Non-canonical base pairs (other than A–U or G–C) are shown with special symbols (magenta dot or black dot or magenta circle). Tertiary interactions with strong comparative data are connected by solid lines.

shape of each subunit was seen as early as 1976 (Figure 28.20). Other techniques such as protein–protein or protein–RNA cross-linking, immunoelectron microscopy, cryoelectron microscopy, sequence analysis of the individual proteins, and neutron scattering gave much information about the placement of individual proteins within the overall structure.

Attempts to crystallize ribosomes began in the 1970s, but the size and complexity of these particles frustrated these early efforts. A key to the success of crystallization attempts, particularly in the laboratory of Ada Yonath, was the use of extremophilic bacteria as the source material. Although the *E. coli* ribosome was the most thoroughly studied to that point, the archaeal thermophile *Thermus thermophilus* and the halophile *Haloarcula marismortui* yielded the best crystals. Because the structure of the ribosome is well conserved evolutionarily, these bacteria made satisfactory models.

Figure 28.21 shows a model of the 70S ribosome based upon the first medium-resolution structures, in the late 1990s. Critical features known already or shown by this model are that the ribosome has three tRNA binding sites, that mRNA binding and decoding occur on the 30S subunit, that aminoacyl-tRNAs fill the gap between 30S and 50S subunits, that the newly synthesized polypeptide chain exits the ribosome through a tunnel in the 50S subunit, and that the peptidyltransferase reaction, which creates peptide bonds, occurs at a site on the 50S subunit.

Within a year after the medium-resolution structure was published, Thomas Steitz's laboratory published a high-resolution structure of the 50S subunit from *H. marismortui*, and shortly afterward Venki Ramakrishnan and colleagues described the 30S subunit from *T. thermophilus*, followed by the complete 70S ribosome from this organism. Figure 28.22 shows the Steitz 50S structure, and Figure 28.23 shows the Ramakrishnan 70S structure. Perhaps the most striking feature of both structures is that the peptidyltransferase site lies far from any protein. This structural work established conclusively that the ribosome is a *ribozyme*. We shall

return to this reaction later and to the question of how this structural work illuminated ribosome function. Yonath, Steitz, and Ramakrishnan shared the 2009 Nobel Prize in Chemistry for their contributions to ribosome structure and function.

In late 2010 Adam Ben-Shem and colleagues reported a structure for the yeast 80S ribosome at 4.15 Å resolution, and in early 2011 the large subunit of the *Tetrahymena thermophila* ribosome was reported at somewhat higher resolution. The yeast structure, which is shown on the cover of this book, was in a “racheted” state, believed to represent an intermediate in translocation, the movement from one codon to the next. A major distinction from bacterial ribosomes is the greater extent of interaction of ribosomal proteins with each other, rather than with ribosomal RNAs.

Mechanism of Translation

We now have identified all of the major participants in the translation process: a messenger RNA, charged tRNAs, soluble protein factors, and the ribosome, where the actual translation events occur. As with transcription, we can divide translation into three stages: *initiation*, *elongation*, and *termination*. Here we describe

these steps, primarily as they occur in prokaryotes, where our understanding is most detailed. Significant, though not fundamental, differences in eukaryotic protein synthesis are discussed next.

Each step in translation requires a number of specific proteins that interact with the major participants listed above. These proteins are referred to as *initiation factors* (IFs), *elongation factors* (EFs), and *release factors* (RFs). These factors, together with some of their properties and functions, are listed in Table 28.4.

Initiation

Initiation of translation is schematized in Figure 28.24. Initiation results in formation of a *70S initiation complex*, which consists of a ribosome bound to mRNA and to a charged *initiator tRNA*. In bacteria the initiator tRNA is charged with *N*-formylmethionine (fMet). First the mRNA and tRNA bind to a free 30S subunit, then the 50S subunit is added to form the entire complex. In most cases the initiation codon to which the initiator tRNA binds is AUG, also used as an internal methionine codon. As we indicated previously (page 1184), the initiator AUG is distinguished from internal methionine codons by the presence upstream of a Shine–Dalgarno sequence, which binds to a complementary sequence in 16S rRNA, thereby positioning the initiator AUG.

Binding of mRNA and initiator tRNA also requires binding of the three **initiation factors** (IF1, IF2, and IF3) to a free 30S subunit. The factors IF3 and IF1 promote dissociation of preexisting 70S ribosomes, thereby producing the free 30S subunits needed for initiation (Figure 28.24, step 1). The third factor, IF2, is bound carrying a molecule of GTP; it delivers the charged initiator tRNA in binding to the 30S subunit. IF2 is a G protein, similar to those involved in signal transduction. At about the same time that the IF2–fMet–tRNA^{fMet} complex is bound, the mRNA is bound (step 2). Although the order of these additions is still uncertain, it is clear that IF2–GTP is absolutely required for binding of the first (initiator) tRNA. With binding of the initiator tRNA and the mRNA, formation of the *30S initiation complex* is complete. The initiation complex has high affinity for a 50S subunit and binds one from the available pool (step 3), with concomitant release of IF3.

The initiator tRNA is special. It recognizes and binds to the AUG codon that would normally code for methionine, but it actually carries an *N*-formylmethionine. The formyl group is added *after* charging of the tRNA, by an enzyme (*transformylase*) that recognizes the particular tRNA^{fMet} and transfers a formyl group from 10-formyltetrahydrofolate (see Figure 20.17, page 852). *Only* tRNA^{fMet} is accepted to form the 30S initiation complex; all subsequent charged tRNAs require the fully assembled 70S ribosome. Therefore, most (not all) prokaryotic proteins are synthesized with the same N-terminal residue, *N*-formylmethionine. In almost all cases, the formyl group is removed during chain elongation. For many proteins the methionine itself is also cleaved off later.

The mRNA attaches to the 30S subunit near the 5' end of the message, which is appropriate because all messages are translated in the 5' → 3' direction. As mentioned above, an AUG initiation codon is recognized by an upstream Shine–Dalgarno sequence, which is complementary to the sequence, 3'...UCCUCC...5' in 16S rRNA. This will pair with any Shine–Dalgarno sequence (for example, those shown in Table 28.3). This pairing aligns the message correctly for the start of

Translation involves three steps—initiation, elongation, and termination—each aided by soluble protein factors.

In initiation, the correct attachment of mRNA to the ribosome is determined by binding of the Shine–Dalgarno sequence to a sequence on the 16S rRNA of the ribosome.

FIGURE 28.24**Initiation of protein biosynthesis in prokaryotes.**

The ribosome contains three tRNA binding sites, shown here as E, P, and A; these are called the exit, peptidyl-tRNA, and aminoacyl-tRNA binding sites, respectively. The initiator AUG codon is positioned so that fMet-tRNA binds in the P site.

translation. In particular, it places the initiator codon next to the P site, one of three tRNA binding sites in the ribosome (see below).

Translation cannot start until the 50S subunit has bound to the 30S initiation complex. The ribosome has three sites for tRNA binding, called the P (peptidyl) site, the A (aminoacyl) site, and the E (exit) site. The AUG initiator codon, with its bound fMet-tRNA^{Met}, aligns with the P site. At this point, the GTP molecule carried by IF2 is hydrolyzed, and IF2-GDP, P_i, and IF1 are all released. The 70S initiation complex so formed is ready to accept a second charged tRNA and begin elongation of the protein chain.

The locations of the P, A, and E binding sites for tRNAs were originally established by chemical cross-linking (Figure 28.25), but are now confirmed by X-ray crystallography (Figure 28.23). The anticodon ends of the tRNA molecules contact the 30S subunit, whereas the acceptor ends interact specifically with the 50S subunit. All of the ribosomal proteins contacted lie in the cavity between the 30S and 50S subunits. The tRNA molecules are oriented with their anticodons reaching the mRNA at the bottom of the cavity close to the 30S subunit and their acceptor ends contacting the peptidyltransferase region on the 50S subunit, near the top of the cavity.

Elongation

Growth of the polypeptide chain on the ribosome occurs by a cyclic process. Figure 28.26 illustrates a single round in this cycle. In this particular example, the fifth amino acid from the N-terminus is being linked to the sixth. However, all cycles are the same until a termination signal is reached.

At the beginning of each cycle, the nascent polypeptide chain is attached to a tRNA in the P (peptidyl) site, and the A (aminoacyl) and E (exit) sites are empty. Aligned with the A site is the mRNA codon corresponding to the *next* amino acid to be incorporated. The charged (aminoacylated) tRNA is escorted to the A site in a complex with a protein, the elongation factor EF-Tu, which also carries a molecule of GTP. (Note the parallel to IF2-GTP here.) EF-Tu plays an active role in ensuring that the correct aminoacyl-tRNA is fitted to its codon. As schematized in Figure 28.27, which results from work in the Ramakrishnan laboratory, the aminoacyl-tRNA is distorted in its complex with EF-Tu. Initial binding puts the tRNA anticodon loop into the decoding center on the 30S subunit, with the acceptor stem near the EF-Tu site. Nucleotides in the decoding site probe the major groove of the anticodon loop, specifically in positions 1 and 2. This structural work confirmed the wobble hypothesis, by showing that codon-anticodon fitting is more stringent in the first two positions. GTP hydrolysis by EF-Tu results in conformational changes that move the aminoacyl-tRNA entirely into the A site and cause dissociation of EF-Tu itself. The EF-Tu-GTP complex is then regenerated by the subsidiary cycle shown in Figure 28.28. After the charged tRNA is in place, it is checked both before and after the GTP hydrolysis and rejected if incorrect.

The next, and crucial, step is peptide bond formation (Figure 28.26, step 2). The polypeptide chain that was attached to the tRNA in the P site is now transferred to the amino group of the amino acid carried by the A-site tRNA. This step is catalyzed by *peptidyltransferase*, an integral part of the 50S subunit. As mentioned previously, the structure determination of the 50S subunit established conclusively that catalysis is carried out by the RNA portion of the subunit. This finding was crucial to acceptance of the “RNA world” model for the origin of life, for it indicates how progenitors to living cells could exist in the presence of RNA but the absence of protein.

Analysis of the 50S subunit in the Steitz laboratory showed that a conserved AMP residue (2486 in *H. marismortui* and 2451 in *E. coli*) exists in an environment that makes the purine ring unusually basic, probably resulting from hydrogen bonding to a nearby GMP. This suggests a process in which N3 abstracts a proton from the amino group of the aminoacyl-tRNA, converting the amino group to a better nucleophile that attacks the carboxyl carbon of the C-terminal amino acid, linked to peptidyl-tRNA, as shown in Figure 28.29. The protonated

FIGURE 28.25

Environment of tRNAs at the ribosome as determined by cross-linking. Cross-links from defined nucleotide positions in the tRNA to ribosomal proteins are shown. Proteins were differentially cross-linked depending on the location of the tRNA (A site, triangles; P site, circles; E site, squares; S = small subunit, L = large subunit).

FIGURE 28.26

Chain elongation in prokaryotic translation. The process is depicted as a cycle. Following translocation (step 3) and tRNA release (step 4), the ribosome is ready to accept the next aminoacyl tRNA ($aa\sim tRNA$) and repeat the cycle. The cycles will continue until a termination codon is reached. The first reaction in the overall elongation process would have been reaction between $aa_2\sim tRNA$ in the A site and fMet-tRNA in the P site (fMet is aa_1).

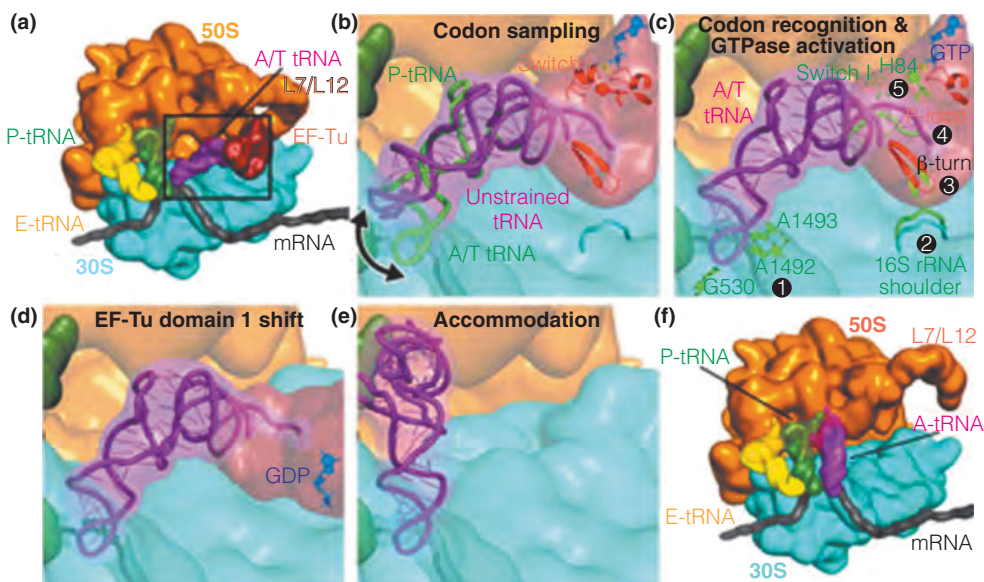

FIGURE 28.27

The ribosomal decoding pathway. (a) L7/L12 stalk on 50S subunit recruits ternary complex (aminoacyl-tRNA-EF-Tu-GTP) to a ribosome with deacylated tRNA in E site and peptidyl-tRNA in P site. The black frame is enlarged in subsequent panels. A/T tRNA is a tRNA molecule temporarily distorted, to interact simultaneously with the decoding center of the 30S subunit and EF-Tu, bound at a site in the intersubunit space. (b) tRNA samples codon-anticodon pairing. (c) The match is sensed by specific nucleotides in coding site (G530, A1492, A1493). Codon recognition triggers 30S subunit domain closure. A chain of conformational changes (shown as 2–5) opens a hydrophobic gate, allowing His84 on EF-Tu to initiate hydrolysis of GTP. (d) GTP hydrolysis and P_i release cause conformational change in EF-Tu, leading to its release from the ribosome. (e) and (f) EF-Tu release leads to relaxation of aminoacyl-tRNA structure and its accommodation at both the coding site and the peptidyl-transferase site. PDB ID 2WRN, 2WRO, 2WRQ, and 2WRR.

FIGURE 28.28

Regeneration of EF-Tu-GTP by Tu-Ts exchange. This figure gives details of the regeneration cycle shown at the top of Figure 28.26. Binding of the factor EF-Ts to EF-Tu allows the release of GDP and binding of a new GTP to prepare EF-Tu for another cycle.

FIGURE 28.29

A mechanism for peptidyltransferase involving A2451 (*E. coli*) as a general base.

This mechanism is based on the structure of the 50S subunit, as put forth by P. Nissen et al. (2000) *Science* 289:920–930.

N3 then stabilizes a tetrahedral carbon intermediate by binding to the oxyanion. The proton is then transferred to the peptidyl-tRNA 3' hydroxyl as the newly formed peptide deacylates. Concomitant with this transfer is a switch from the simple P and A states to hybrid states, in which the acceptor ends of the two tRNA molecules move into the leftward positions while the codon ends remain fixed as before. These hybrid sites are indicated as E/P and P/A. This can be considered the first half of the *translocation* step (step 3 in Figure 28.26).

To complete the translocation step, the anticodon end of the now uncharged tRNA in the P site is transferred to the E site, and the tRNA in the A site (the tRNA that now has the nascent polypeptide chain attached to it) is moved completely to the P site. In the process, the ribosome moves a three-nucleotide step in the 3' direction along the mRNA, placing a new codon adjacent to the now empty A site. Like peptidyl transfer, this step requires a protein factor (EF-G) bound to GTP and requires GTP hydrolysis. Crystallographic studies reveal a remarkable “molecular mimicry” between EF-G–GTP and the ternary complex aa-tRNA–EF-Tu–GTP. As Figure 28.30 shows, the protein and the RNA–protein complex have almost exactly the same shape, even though they differ entirely in composition and sequence. It is speculated that the reason for this similarity is to allow EF-G–GTP to move temporarily into the A site, facilitating the displacement of the peptidyl-tRNA complex. Structural studies support this model.

During translation the ribosome is “ratcheted” along the mRNA molecule by a process involving rotation of the two ribosomal subunits with respect to each other. Based on structural analysis of the ribosome in intermediate states of rotation, the ratcheting process has been schematized as shown in Figure 28.31.

At this point the E and P sites are occupied, but A is empty. As the deacylated tRNA is released from E (step 4, Figure 28.26), the A site gains high affinity and accepts the aminoacyl tRNA dictated by the next codon. A cycle of elongation is now complete. All is as it was at the start, except that now:

1. The polypeptide chain has grown by one residue.
2. The ribosome has moved along the mRNA by three nucleotide residues—one codon.
3. At least two molecules of GTP have been hydrolyzed.

The whole process is repeated again and again until a termination signal is reached, with the newly synthesized polypeptide chain being forced to exit the ribosome through the tunnel mentioned previously.

Termination

The completion of polypeptide synthesis is signaled by the translocation of one of the *stop codons* (UAA, UAG, or UGA) into the A site. Because there are no tRNAs that recognize these codons under normal circumstances, termination of the

In elongation, the growing peptide chain at the P site is transferred to the newly arrived aminoacyl tRNA in the A site. Translocation then moves this tRNA to the P site and the previous tRNA to the E site.

chain does not involve binding of a tRNA. Instead, protein *release factors* participate in the termination process. The three release factors found in prokaryotes are listed in Table 28.4. Two of these factors can bind to the ribosome when a stop codon occupies the A site: RF1 recognizes UAA and UAG, and RF2 recognizes UAA and UGA. The third factor, RF3, is a GTPase that appears to stimulate the release process, via GTP binding and hydrolysis. Structural analysis of the ribosome complexed with RF2 show that the release factor interacts directly with a UGA termination codon (Figure 28.32).

The sequence of termination events is as shown in Figure 28.33. After RF1 or RF2 has bound to the ribosome, the peptidyltransferase transfers the C-terminal residue of the polypeptide chain from the P-site tRNA to a water molecule, releasing the peptide chain from the ribosome. The chemistry of this reaction is similar to peptide bond formation (Figure 28.29), except that water replaces the α -amino group as the attacking nucleophile. The RF factors and GDP are then released, followed by the tRNA. The 70S ribosome is now unstable. Its instability is accentuated by the presence of a protein called *ribosome recycling factor*, and also by the initiation factors IF3 and IF1, and the ribosome readily dissociates to 50S and 30S subunits prepared for another round of translation.

When the ribosomal subunits separate, the 30S subunit may or may not dissociate from its mRNA. In some cases in which polycistronic messages are being translated, the 30S subunit may simply slide along the mRNA until the next

Termination requires protein release factors that somehow recognize stop codons.

Termination of translation in prokaryotes.

Shine–Dalgarno sequence and initiation codon are encountered and then begin a new round of translation. If the 30S subunit does dissociate from the message, it will soon reattach to another one.

Suppression of Nonsense Mutations

Understanding the process of termination helped clarify some peculiar observations concerning nonsense mutations. Recall from Chapter 7 that a *nonsense mutation* is one in which a codon for some amino acid has been mutated into a stop codon so that the polypeptide chain terminates prematurely. These mutations were originally discovered because their phenotypic expression could be *suppressed* by a class of mutations located in other genes. Recall from Chapter 25 that suppression is defined genetically as restoration of wild-type function by a second mutation at a different site. When this second mutation occurs in a different gene, the phenomenon is called **intergenic suppression**. Upon examination, the suppressors of nonsense mutations were found to lie in tRNA genes.

Consider the example shown in Figure 28.34. A nonsense mutation has changed a codon that normally specifies the amino acid tyrosine into a stop codon, causing premature termination of the polypeptide chain. If, however, one of the several tyrosine tRNAs mutates in its anticodon region so as to recognize

The effects of nonsense mutations can sometimes be suppressed by suppressor mutations, in which a tRNA mutates to recognize a stop codon and inserts an amino acid instead.

FIGURE 28.34

How an intergenic suppression mutation can overcome a nonsense mutation. A nonsense mutation in a protein-coding gene changes a codon for an amino acid into a stop codon, causing translation to terminate prematurely. Another mutation, in a tRNA gene, can circumvent the first mutation by altering the tRNA anticodon so that it will base-pair with the mutant mRNA. A functional protein is produced in this situation, even though suppression might not restore the original amino acid at that site.

the stop codon, translation can sometimes proceed in the normal fashion. Thus, a mutation that might otherwise be lethal can be suppressed by such a change, and the organism can survive. Clearly, it will still have problems, for the presence of such a mutated tRNA will interfere with the normal termination of other proteins. That they can survive at all depends on the fact that the suppressor mutation usually involves a minor tRNA species, little used in normal translation. Furthermore, such effects may be minimized by the frequent occurrence of two or more different stop signals in tandem in mRNAs. Even if the first stop codon is suppressed, the “emergency brake” still holds.

Suppressor mutations are by no means confined to correction of nonsense mutations. Some mutated tRNAs correct missense mutations, and some even contain two or four bases acting as the anticodon. These can therefore serve as **frameshift suppressors**.

Inhibition of Translation by Antibiotics

Many antibiotics have been shown to act by inhibiting specific steps in bacterial protein synthesis. Some of these antibiotics have proven to be useful reagents in analyzing mechanisms in translation, as well as in combating infections. We have already described the action of some kinds of antibiotics. In Chapter 9, we saw that the penicillins inhibit bacterial cell wall synthesis, and in Chapter 10 we discussed antibiotics such as gramicidin and valinomycin, which interfere with the ionic balance across membranes. Other antibiotics, such as rifampicin and streptolydigin (Chapter 27), block transcription in prokaryotes.

A host of naturally occurring substances interfere with various stages of protein synthesis. Some of these are shown in Figure 28.35. Each inhibits translation in a different way. Their importance to medicine stems largely from the fact that the translational machinery of eukaryotes is sufficiently different from that of prokaryotes that these antibiotics can be used safely in humans. In some cases (for example, the tetracyclines), antibiotics that would also inhibit eukaryotic translation are nevertheless harmless to eukaryotes because they cannot traverse the cell membranes of higher organisms.

A major problem with the therapeutic use of antibiotics is that microorganisms can develop resistance to many of them. An important example is *erythromycin* resistance. The erythromycin-binding site on the ribosome includes a specific region of the 23S RNA, and binding of the antibiotic can be inhibited by an enzyme that methylates a specific adenine residue in this region. Molecular biologists use erythromycin resistance in screening bacterial clones in recombinant DNA research. Resistance to erythromycin can be conferred to a bacterium by the insertion of a resistance gene coding for the methyltransferase on a bacterial plasmid. Bacteria containing the plasmid carrying the methylase gene will grow in an erythromycin-containing medium, whereas those lacking the plasmid will be killed. Thus, growth on such a medium automatically selects for only those clones that carry the plasmid. Because many such resistance genes are carried on plasmids, which are easily transferred from bacterium to bacterium, the frequency with which antibiotic-resistant strains arise is far higher than if the elements were carried on chromosomal genes. Another problem is the widespread use of antibiotics in animal husbandry, not to cure an infection, but rather to suppress any possible infections for improved animal weight maintenance and to prevent the spread of infection from animal to animal, under the crowded conditions in feedlots. That may be fine in the short run, but the resultant increased emergence of antibiotic-resistant strains makes many question the wisdom of this practice.

Structural studies on ribosomes have given enormous impetus to the development of new classes of antimicrobial agents to which resistance might not develop. In the same sense that knowledge of enzyme and receptor structure makes it possible to design entirely new inhibitors with therapeutic properties, the

A number of important antibiotics act by inhibiting translation in bacterial cells.

FIGURE 28.35

Some antibiotics that act by interfering with protein biosynthesis. Erythromycin is one of the polyketide antibiotics whose biosynthesis was discussed in Chapter 17.

ribosome, because of its many activities and its structural conservation among bacteria, is an extremely attractive target for drug development.

Translation in Eukaryotes

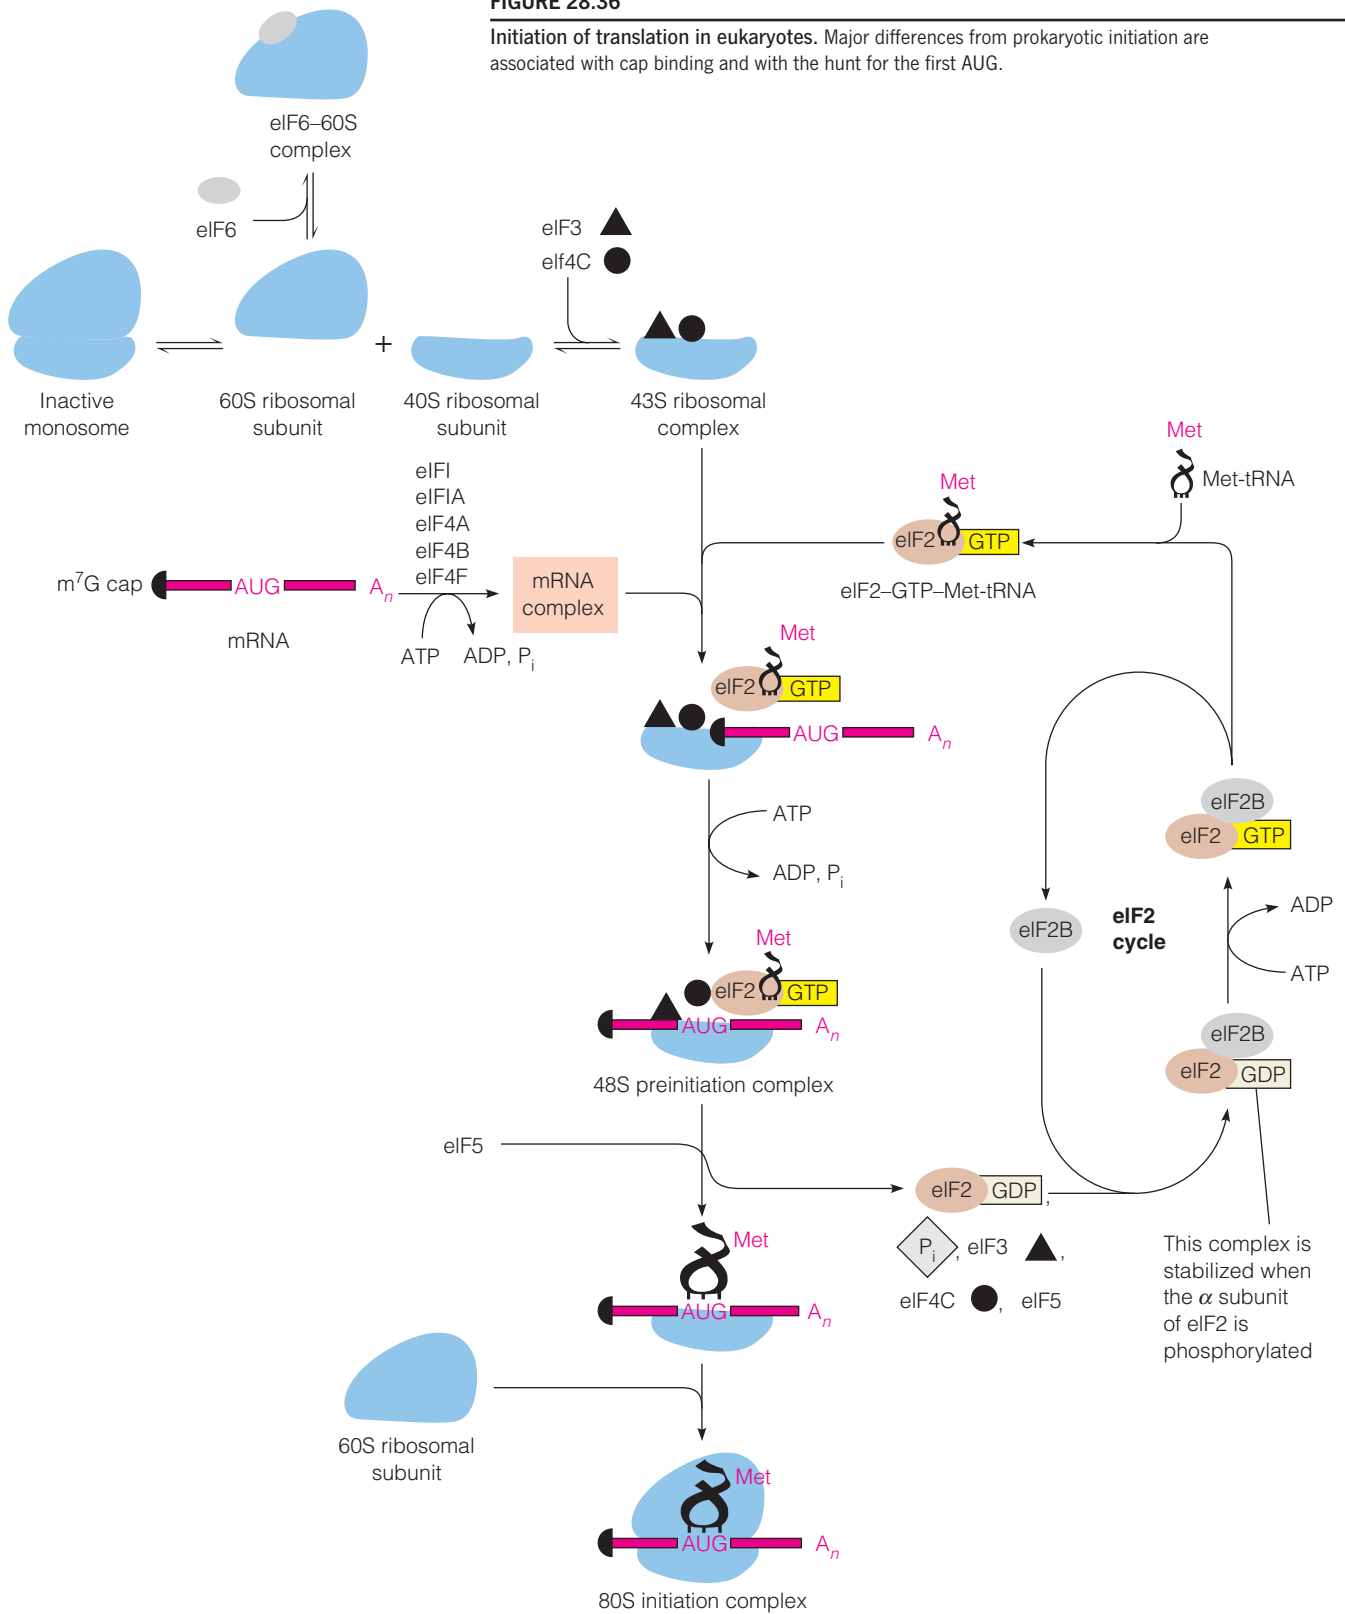

The mechanism for translating messenger RNA into protein in eukaryotic cells is basically the same as in prokaryotes. In eukaryotes the ribosomes are larger and more complex, and virtually all mRNAs are monocistronic. There are more

In eukaryotes, translational initiation is more complex and requires more protein factors than in prokaryotes.

soluble protein factors, as we saw in Table 28.4, but the functions performed are comparable to those we have discussed for bacteria. The most significant differences are in initiation mechanisms; these are schematized for eukaryotic cells in Figure 28.36. Aside from the greater complexity of the ribosome and soluble

FIGURE 28.36

Initiation of translation in eukaryotes. Major differences from prokaryotic initiation are associated with cap binding and with the hunt for the first AUG.

protein factors, the major differences are (1) that the 5' end of a message is sensed not by a Shine-Dalgarno sequence, but by the 7-methylguanine cap, and (2) the N-terminal amino acid, inserted at the initiator AUG, is methionine, not *N*-formylmethionine. After detecting the 5' cap, the ribosomal 40S subunit then scans along the mRNA (an ATP-dependent process) until the first AUG is found. At this point the initiation factors are released, and the 60S subunit is attached to begin translation.

A number of the common inhibitors of prokaryotic translation are also effective in eukaryotic cells. They include pactamycin, tetracycline, and puromycin. There are also inhibitors that are effective *only* in eukaryotes. Two important ones are *cycloheximide* and *diphtheria toxin*. Cycloheximide inhibits the translocation activity in the eukaryotic ribosome and is often used in biochemical studies when processes must be studied in the absence of protein synthesis. Diphtheria toxin is an enzyme, coded for by a bacteriophage that is lysogenic in the bacterium *Corynebacterium diphtheriae*. It catalyzes a reaction in which NAD^+ adds an *ADP-ribose* group to a specially modified histidine in the translocation factor eEF2, the eukaryotic equivalent of EF-G (Figure 28.37). Because the toxin is a catalyst, minute amounts can irreversibly block a cell's protein synthetic machinery; pure diphtheria toxin is one of the deadliest substances known.

Protein Synthesis in Organelles

As described in Chapter 15, the mitochondrial genome (mtDNA) contains 37 genes that encode 13 proteins (in humans), all of which are subunits of the respiratory chain complexes. The remaining mtDNA genes encode 22 tRNAs and 2 rRNAs. These tRNAs and rRNAs are part of the mitochondrial protein synthesis machinery, required to translate the 13 proteins encoded in mitochondrial DNA. Reflecting its evolution from an ancient alpha-proteobacterium, the mitochondrial protein synthesis machinery is more closely related to the bacterial system than to the eukaryotic cytosolic system. Like the prokaryotic process, translation initiates with formylated Met-tRNA in mitochondria and requires only a handful of initiation and elongation factors. Also, mitochondrial protein synthesis is inhibited by some antibiotics that interfere with steps in bacterial protein synthesis. However, mitochondrial ribosomes have undergone a major remodeling during mitochondrial evolution. The rRNAs of mammalian mitochondrial ribosomes are smaller than their bacterial counterparts, and the large subunit of mitochondrial ribosomes completely lacks a 5S rRNA component. On the other hand, mitochondrial ribosomes have more protein subunits so that mitochondrial ribosomes have a protein:RNA ratio of 2:1, compared to a 1:2 ratio for the bacterial ribosome. Chloroplasts also possess their own protein synthesis machinery, but much less is known about the chloroplast system.

Rates and Energetics of Translation

Translation is a rapid process in prokaryotes. At 37 °C an *E. coli* ribosome can synthesize a 300-residue polypeptide chain in about 20 seconds. This means that a single ribosome passes through about 15 codons, or 45 nucleotides, in each second. This rate is almost exactly the same as our best estimates of the rate of prokaryotic *transcription*, which means that mRNA can be translated as fast as it is transcribed. That equality is not a coincidence. Recent studies with *E. coli* show that a ribosomal protein, NusE, interacts in the cell with an RNA polymerase component, NusG, and that through this interaction transcription and translation are physically coupled, as shown in Figure 28.38, with the rate of transcription being controlled by the rate of translation. Direct coupling of this type cannot occur in eukaryotic cells because the two processes take place in separate compartments.

FIGURE 28.37

ADP-ribosylated diphthamide derivative of histidine in eEF2. Synthesis of this derivative of a modified histidine in eEF2 using NAD^+ is catalyzed by diphtheria toxin. eEF2 is inactivated, and protein synthesis is therefore blocked. ADP ribose from NAD^+ is shown in blue. Diphthamide is in black.

But the rate mentioned above represents the growth of individual polypeptide chains and does not account for the total rate of protein synthesis in the cell because many ribosomes may be simultaneously translating a given message. In fact, if we were to carefully lyse *E. coli* cells, we would observe **polyribosomes** (also called polysomes) like those shown in Figure 28.39. Apparently, as soon as one

FIGURE 28.38

Coupling of transcription to translation in *E. coli* via the interaction between NusE and NusG.

Polyribosomes. (a) Electron micrograph showing *E. coli* polyribosomes. The ribosomes are closely clustered on an mRNA molecule. (b) Schematic picture of a polyribosome like that shown in (a). Each ribosome is to be imagined as moving from left to right.

(a) Courtesy of Barbara Hamkalo; (b) *Molecular Biology of the Gene*, 4th ed., James D. Watson, Nancy H. Hopkins, Jeffrey W. Roberts, Joan Argetsinger Steitz, and Alan M. Weiner. © 1987. Reprinted by permission of Pearson Education Inc., Upper Saddle River, NJ.

ribosome has moved clear of the 5' region of the mRNA, another attaches. Under some conditions, as many as 50 ribosomes may be packed onto an mRNA, with one finishing translation every few seconds. Because each *E. coli* cell contains 15,000 ribosomes or more, all of them operating at full capacity can synthesize about 750 protein molecules of 300 residues each second.

The energy cost for this process is high. If we examine the individual steps in protein synthesis described earlier, we can make the following estimate of the total energy budget for synthesizing a protein of N residues:

The equivalent of

$2N$	ATPs are required to charge the tRNAs because the ATP is cleaved to AMP and PP_i , and PP_i is subsequently hydrolyzed.
1	GTP is needed for initiation.
$N-1$	GTPs are required to form the $N-1$ peptide bonds, in the EF-Tu-GTP hydrolysis step.
$N-1$	GTPs are necessary for the $N-1$ translocation steps.
1	GTP is required in termination.
<hr/>	
Sum	$= 4N$

Altogether, then, about $4N$ high-energy phosphate molecules must be hydrolyzed to complete a chain of N units. This is a minimal estimate, for it does not include the energy required to formylate methionine, nor any extra GTPs that may be expended in proofreading and replacing incorrectly bound tRNAs. Furthermore, there have been persistent, although debated, reports that *two* GTPs must be hydrolyzed for every aa-tRNA bound to the A site. But even at the conservative estimate, a typical protein of 300 residues costs the cell about 60,000 kJ of free energy per mole, if we assume ATP or GTP hydrolysis yields about 50 kJ/mol under cellular conditions. Proteins are expensive!

If we express the same data in terms of the energy requirement for synthesis per mole of *peptide bond*, we obtain a cost of about 200 kJ/mol. Given that the free energy change required to form a peptide bond in dilute aqueous solution is only about +20 kJ/mol, the price seems exorbitant. Why does the cell have no mechanism for making peptide bonds for a few dozen kilojoules each? Certainly, an input of even 40 kJ/mol would be enough to make the synthesis process very favorable—with an equilibrium constant of about 3000.

The key to this great energy expenditure is found in the fundamental nature of life. The cell is making polypeptides of *defined* sequence. If it were simply throwing together amino acids at random, the free energy price could be much cheaper. But a chain of 300 residues, made from 20 different amino acids, can be put together in 20^{300} different ways, whereas the cell needs *one* specific sequence. There is, in other words, a large entropy price to be paid in making specific sequences—and making them correctly. What this means at the mechanistic level is that every step in the assembly not only must be done with a free energy excess but also must involve a specific *choice*. Furthermore, the product must, at critical points, be checked by a proofreading mechanism, which in turn costs more energy. It is expensive to get a good translation of a book, for not only must the translators be expert and careful but their work must also be rechecked with great care.

Translation is fast but energy-expensive. About four ATP equivalents are needed for each amino acid added.

The Final Stages in Protein Synthesis: Folding and Covalent Modification

The polypeptide chain that emerges from the ribosome is not a completed, functional protein. It must fold into its tertiary structure, and it may have to associate with other subunits. In some cases, disulfide bonds must be formed, and other covalent modifications, such as hydroxylation of specific prolines and lysines

must take place. Complexation with carbohydrate or lipid occurs after translation. In addition, many proteins are subjected to specific proteolytic cleavage to remove portions of the nascent chain.

Chain Folding

The cell need not wait until the entire chain is released from the ribosome to commence its finishing touches. The first portion of the nascent chain (about 30 residues) is protected as it passes through the tunnel in the ribosome. However, changes begin almost as soon as the N-terminal end emerges. There is good evidence that folding into the tertiary structure starts during translation and is nearly complete by the time the chain is released. For example, antibodies to *E. coli* β -galactosidase, which recognize the tertiary folding of the molecule, will attach to polyribosomes synthesizing this protein. This enzyme displays catalytic activity only as a tetramer. It has been demonstrated that nascent β -galactosidase chains, still attached to ribosomes, can associate with free subunits to form a functional tetramer. Thus, even quaternary structure can be partially established before synthesis is complete.

This behavior should not be surprising, if we recall (from Chapters 6 and 7) that formation of the secondary, tertiary, and quaternary levels of protein structure is thermodynamically favored. However, as we have seen in Chapter 6, in some cases this spontaneous folding must be aided by chaperone proteins.

Covalent Modification

Some of the covalent modifications of polypeptide chains also occur during translation. We mentioned earlier that the *N*-formyl group is removed from the initial *N*-fMet of most prokaryotic proteins. A specific *deformylase* catalyzes this reaction. In many cases, deformylation seems to happen almost as soon as the N-terminus emerges from the ribosome. Removal of the N-terminal methionine itself can also be an early event, but whether it happens or not apparently depends on the cotranslational folding of the chain. Presumably, in some cases this residue is “tucked away” and protected from proteolysis in the folded structure.

Some prokaryotic (and many eukaryotic) proteins experience much more severe proteolytic modifications. These proteins are usually the ones that are going to be exported from the cell or are destined for membrane or organelle locations. We discuss the more complicated eukaryotic protein processing in the next section and concentrate here on what happens in prokaryotes.

Bacterial proteins that are destined for secretion (**translocation** across the cell membrane) are characterized by highly hydrophobic **signal sequences** or **leader sequences** in the N-terminal regions. Representatives are listed in Table 28.5. After the protein has passed through the membrane, the leader sequence is cleaved off at the point indicated by the arrow in the table.

A current model for translocation in bacteria is shown in Figure 28.40. In many, but not all, cases the protein to be translocated (the pro-protein) is first complexed in the cytoplasm with a chaperone—the SecB protein in the example shown. This complexing keeps the protein from folding prematurely, which

Translation is immediately followed by various kinds of protein processing, including chain folding, covalent modification, and directed transport.

Note: Hydrophobic residues are in magenta. The cleavage site is designated by the arrow.

FIGURE 28.40

A current model for protein secretion by prokaryotes. The new polypeptide chain (the pro-protein) complexes with SecB, which prevents complete folding during transport to the membrane. At the membrane an ATPase, SecA, drives translocation through the membrane with the aid of SecYEG, which forms a membrane pore. The leader sequence is then cleaved off the secreted protein by a membrane peptidase.

would prevent it from being passed through a secretory pore in the membrane. This pore is composed of a heterotrimeric protein made up of SecE, SecY, and SecG—the “SecYEG translocon.” The secretory pore is also a target for a fourth protein component, SecA. SecA is an ATPase, and both ATP hydrolysis and the electrochemical potential gradient across the membrane help drive translocation. Structural analysis of the SecA protein with and without bound adenine nucleotide suggests a mechanism comparable to that of DNA-dependent helicases in driving the protein through the membrane. After the pro-protein has been translocated, the leader peptide is cleaved off by a membrane-bound protease, and the protein can fold. The cleavage site, as shown in Table 28.5, usually lies between a small amino acid (often Gly or Ala) and an acidic or a basic one.

Protein Splicing

A small, but significant, number of proteins, mostly from single-celled organisms—bacteria, archaea, and eukaryotic microbes—undergo post-translational splicing, in a process comparable to the RNA splicing discussed in Chapter 27. In protein splicing an **intein** (internal protein segment) is cleaved from within the polypeptide sequence, yielding a mature protein, the **extein** (external protein). Embedding an intein into a normally nonspliced protein retains its splicing activity for the new protein host, indicating that amino acid residues for catalysis of splicing lie within the intein.

Although we know little about the biological functions of protein splicing, we do know that the mechanism is comparable to that of RNA splicing, with, of course, different functional groups involved. As shown in Figure 28.41, an N-terminal serine or threonine hydroxyl (or cysteine thiol; serine as shown) attacks the C-terminal peptide carbon of the upstream intein segment (N-extein), and this is followed by a transesterification involving a thiol or hydroxyl in the N-terminal residue of the downstream extein segment (C-extein) upon that same

**FIGURE 28.41**

An outline of the mechanism of protein splicing.

carbon in the N-extein. This yields a branched intermediate, in which the C-terminal Asn or Gln of the intein (Asn as shown) remains linked to the N-terminal Ser of C-extein. Spontaneous rearrangement of the ester or thioester linkage between the ligated exteins yields the more stable peptide bond linking N-extein to C-extein. Most inteins encode a homing nuclease comparable to that seen in introns, suggesting that the functions of RNA and protein splicing are similar, in promoting their ability to move from gene to gene.

Protein Targeting in Eukaryotes

The eukaryotic cell is a multicompartmental structure. Its several organelles each require different proteins, only a few of which are synthesized within the organelles themselves. Most mitochondrial and chloroplast proteins, for example, are encoded by the nuclear genome and synthesized in the cytoplasm. They must be carefully distinguished from other newly synthesized proteins and selectively transported to their appropriate addresses. Other new proteins are destined for export out of the cell or into vesicles like lysosomes. The diversity of destinations for different proteins implies the existence of a complex system for labeling and sorting newly synthesized proteins and ensuring that they end up in their proper places. And, as seen with bacteria, there must be a process by which protein molecules, which may be hydrophilic, engage the hydrophobic membrane and find a way either to pass through or, as in the case of integral membrane proteins, to become embedded within the membrane.

Proteins Synthesized in the Cytoplasm

Proteins destined for the cytoplasm and those to be incorporated into mitochondria, chloroplasts, or nuclei are synthesized on polyribosomes free in the cytoplasm. The proteins targeted to organelles, as initially synthesized, contain specific signal sequences. These sequences probably aid in membrane insertion, but they also signal that these polypeptides will interact with a particular class of chaperones. These chaperones are members of the “heat-shock” Hsp70 family, and they act to ensure that the newly synthesized protein remains unfolded and is delivered to a receptor site on the organelle membrane. The unfolded protein then passes through membranes, through gates containing transport proteins that discriminate among proteins destined for the lumen, the membranes, or an organelle matrix. If it passes into an organelle matrix, the protein may be taken up by intraorganelle chaperones for final folding. The N-terminal targeting sequence is also cleaved off during this transport.

Transport of proteins into mitochondria is schematized in Figure 28.42. First, the Hsp70-bound protein attaches *via* a basic N-terminal signal sequence to a receptor protein as part of a structure called the TOM complex (translocation of outer membrane). An ATP-dependent reaction releases the protein from the receptor and inserts it into a pore, another part of the TOM complex. The signal sequence then interacts with another complex, the TIM complex (translocation of inner membrane), in the inner membrane. The electrochemical gradient across the inner membrane pulls the signal sequence through. A mitochondrial Hsp70 binds to the protein as it becomes exposed within the mitochondrial matrix and, in another energy-dependent reaction, pulls the rest of the protein through. The signal sequence is removed by a specific protease (MPP, matrix processing peptidase) within the matrix. Note that this process pulls the protein through both outer and inner mitochondrial membranes.

A quite different process occurs in nuclear transport. Originally it was thought that these proteins simply diffused into the nucleus through the nuclear pores and were then bound to chromatin. However, it is becoming clear that the nuclear pores are complex gates, rather than open channels. Proteins destined for the nucleus contain *nuclear localization sequences* (NLS) that help these proteins select the nucleus

FIGURE 28.42

Transport of newly synthesized mitochondrial proteins into the matrix. Upper left, signal sequence of Hsp70-bound protein inserts into import receptor of the TOM complex (TOM20) in the outer membrane. Hsp70 dissociation is coupled to ATP hydrolysis. Insertion of the protein into the outer membrane (via TOM22) puts signal sequence in position to interact with TIM complex (TIM23) in the inner membrane. Potential across the inner membrane drives protein into intermembrane space. Signal sequence is cleaved off by MPP. Mitochondrial Hsp70 binds to protein in the matrix and uses the energy of ATP hydrolysis to pull the rest of the protein through.

Modified from *The Cell: A Molecular Approach*, 4th ed., G. M. Cooper and R. E. Hausmann (2007). American Society for Microbiology.

as their destination. Nuclear localization sequences can be found anywhere within the polypeptide sequence, not only the N-terminus. Moreover, the NLS is not removed as a consequence of transport. This is important because the nuclear membrane breaks down in each cell division cycle, and each nuclear protein must be re-transported into the nucleus after re-establishment of the nuclear envelope.

The nuclear localization signal on a prospective cargo protein interacts with a protein called **importin**, which carries the protein through the nuclear pore complex, as schematized in Figure 28.43. Energy for transport is provided by a monomeric G protein called **Ran** (**R**as-**r**elated **n**uclear protein). Ran is similar to other G proteins we have encountered, in that the protein becomes activated by exchange of Ran-bound GDP for GTP, by a guanine nucleotide exchange factor (GEF), and inactivated by GTPase-activating protein (GAP), which hydrolyzes bound GTP to GDP. Ran passes the nuclear pore freely. Because GEF is localized to the nucleus and GAP to the cytoplasm, Ran-GTP predominates in the nucleus and Ran-GDP in the cytoplasm.

Once the importin-cargo protein complex has passed into the nucleus, Ran-GTP binds to that complex, which displaces the cargo. The Ran-GTP complex is returned to the cytoplasm, where bound GTP is converted to GDP. Ran-GDP returns to the nucleus, where it exchanges GDP for GTP, and importin seeks a new NLS-containing cargo protein.

Proteins destined for the cytoplasm, nuclei, mitochondria, and chloroplasts are synthesized in the cytoplasm; those destined for organelles have specific targeting sequences.

FIGURE 28.43

A schematic view of delivery of a protein, synthesized in cytoplasm, into the nucleus. A protein with a nuclear localization signal (NLS) binds to importin. The complex binds to a nuclear pore and passes through. Within the nucleus Ran-GTP binds to the importin-cargo complex and displaces the cargo. The resultant Ran-importin complex is returned to the cytoplasm, where Ran-bound GTP is hydrolyzed to GDP. Ran-GDP returns to the nucleus, and its bound GDP is exchanged for GTP (not shown).

Proteins Synthesized on the Rough Endoplasmic Reticulum

Proteins destined for cellular membranes, lysosomes, or extracellular transport use a quite different distribution system. The key structures in this system are the **rough endoplasmic reticulum (RER)** and the Golgi complex (see also Chapter 9). The rough endoplasmic reticulum is a network of membrane-enclosed spaces within the cytoplasm. The RER membrane is heavily coated on the outer, cytosolic surface with polyribosomes; this coating is what gives the membrane its rough appearance. The Golgi complex resembles the RER in that it is a stack of thin, membrane-bound sacs. However, the Golgi sacs are not interconnected, nor do they carry polyribosomes on their surfaces. The role of the Golgi complex is to act as a “switching center” for proteins with various destinations.

Proteins that are to be directed to their destinations via the Golgi complex are synthesized by polyribosomes associated with the RER. Synthesis actually begins in the cytoplasm (Figure 28.44, step 1). The first sequence to be synthesized is an N-terminal *signal sequence*, part of a mechanism for attaching the ribosome and nascent protein to the RER. *Signal recognition particles (SRPs)*, containing several proteins and a small (7S) RNA, recognize the signal sequences of the appropriate nascent proteins and bind to them as they are being extruded from the ribosomes (step 2).

The SRP has two functions. First, its binding temporarily halts translation so that no more than the N-terminal signal sequence extends from the ribosome. This pause prevents completion of the protein in the wrong place—that is, in the cytosol—and also inhibits premature folding of the polypeptide chain. Thus, the SRP is acting as a kind of chaperone. The second function of the SRP is to recognize a docking protein in the RER membrane. This is the trimeric Sec61 complex, homologous to the bacterial SecYEG. The docking protein binds the ribosome to the RER, and the signal sequence is inserted into the RER membrane (step 3). The SRP is then released (step 4), allowing translation to resume (step 5). The protein

Proteins destined for cell membranes, lysosomes, or export are synthesized on the rough endoplasmic reticulum, then modified and transported via the Golgi apparatus.

FIGURE 28.44

The sequence of events in synthesis of proteins on the rough endoplasmic reticulum. The time sequence of events is from left to right. Recent cryo-electron microscopic analysis of ribosome-Sec61 complexes shows that the Sec61 functions as a monomer. Model building allowed investigators to trace the path of newly synthesized protein from the tRNA through the ribosomal tunnel through the monomeric Sec61 embedded in the membrane, as shown in Figure 28.45.

being synthesized is actually *pulled* through the membrane by an ATP-dependent process. Before translation is complete, signal sequences are cleaved from some proteins by an RER-associated protease. These proteins are released into the lumen of the RER and further transported (step 6). Proteins that will remain in the endoplasmic reticulum have resistant signal peptides and thereby remain anchored to the RER membrane. A model of the protein translocation process, based upon the structure of Sec61, is shown in Figure 28.45.

Role of the Golgi Complex

The proteins that enter the lumen of the RER undergo the first stages of glycosylation at this point. Vesicles carrying these proteins then bud off the RER and move to the Golgi complex (Figure 28.46). Here the carbohydrate moieties of glycoproteins are completed (see pages 339–343 in Chapter 9 for details), and a final

FIGURE 28.46

Transfer from the rough endoplasmic reticulum (RER) to the Golgi complex.

Note that vesicles bud off the RER and move to the *cis* face of the Golgi. Primary lysosomal vesicles bud from the *trans* portion of the Golgi.

sorting occurs. The multiple membrane sacs that constitute the Golgi complex represent a multilayer arena for these processes. Vesicles from the RER enter at the *cis* face of the Golgi (that closest to the RER) and fuse with the Golgi membrane. Proteins are then passed, again via vesicles, to the intermediate layers. Finally, vesicles bud off from the *trans* face of the Golgi complex to form lysosomes, peroxisomes, or glyoxysomes or to travel to the plasma membrane. All of this transport of vesicles, from the RER to the *cis* face of the Golgi, to successive levels of the Golgi and on to their final destinations, requires high specificity in targeting. Transport of vesicles to the wrong destinations would cause cellular chaos. This sorting is accomplished by having each kind of protein cargo packed in a vesicle marked by specific vesicle membrane proteins. In some cases, the target membranes contain complementary proteins that interact with these and cause membrane fusion. These complementary pairs are called *SNARES* (soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors)—*v*-SNARES on vesicles, *t*-SNARES on target membranes. The interaction of specific *v*- and *t*-SNARES, aided by cytosolic fusion proteins, leads to fusion of the vesicle and target membranes and delivery of the cargo (see Figure 28.47).

The Fate of Proteins: Programmed Destruction

In Chapter 11 we pointed out that one mechanism for control of enzymatic function is the selective degradation of certain enzymes. However, not only enzymes need to be destroyed in a programmed way. Regulatory proteins that are essential in certain parts of the cell cycle and deleterious in others must be eliminated at some point. Consider the cyclins (Chapter 24), for example, which must be broken down and resynthesized during each cell cycle. Proteins that have become damaged must also be removed. In some developmental processes, it is necessary to remove whole organelles or even entire cells and tissues.

Eukaryotic cells have two distinct methods for protein degradation. The lysosomes contain among their hydrolases proteolytic enzymes that will degrade any protein trapped within the organelle. Parallel to this process is a cytosolic degradation system, which is of necessity highly selective. The danger inherent in having nonspecific proteases loose in the cytosol should be evident. Both of these processes were described briefly in Chapter 20, and we supplement that information here.

The Lysosomal System

The lysosomal particles budded from the Golgi complex, known as **primary lysosomes**, are essentially bags of degradative enzymes. Over 50 different hydrolytic enzymes are contained in lysosomes, including proteases, nucleases, lipases, and carbohydrate-cleaving enzymes. The lysosomes play a number of important roles in cellular metabolism, as schematically depicted in Figure 28.48.

In some cell types, such as those in the pancreas that secrete degradative enzymes, primary lysosomes migrate to the cell surface and release their contents into the exterior medium (path A). Primary lysosomes may also fuse with *autophagic vesicles*, formed when smooth ER engulfs organelles destined for destruction (path B). The combined vesicle is called an *autophagic lysosome*. In some kinds of cells—mainly certain white blood cells—primary lysosomes may fuse with *phagocytic vacuoles* that have engulfed nutrient materials at the cell surface (path C). In these heterophagic lysosomes, the nutrients are digested and their amino acids, nucleotides, lipids, and other low-molecular-weight constituents released into the cytosol. Residual, undigested material is excreted when the heterophagic lysosomes and autophagic lysosomes find their way to the plasma membrane.

Cytosolic Protein Degradation

In contrast to the lysosomal enzymes, which are usually safely sequestered in their vesicles, any protease activity that is free in normal cytosol must be under rigid control. It must attack only the proteins whose destruction is needed. These may include

**FIGURE 28.47**

A schematic, and somewhat hypothetical, view of SNARE-pin fusion. Specific v-SNAREs and t-SNAREs dictate interaction, and form coiled-coil structures. After fusion, these are broken up by the factor NSF, using the energy of ATP hydrolysis.

**FIGURE 28.48**

Formation of primary and secondary lysosomes and their role in cellular digestive processes. The primary lysosomes that bud from the Golgi can take several pathways.

Path A: Exocytosis—transport of enzymes to outside of cell.

Paths B and C: Phagocytosis—formation of phagic lysosomes for digesting organelles (autophagocytosis) or ingested matter (heterophagocytosis).

Path D: Autolysis—destruction of the cell itself.

damaged proteins, incorrectly synthesized proteins, or proteins no longer required at a particular stage in the cell cycle. If we recall that protein hydrolysis is a thermodynamically favored reaction, it becomes clear that the enzymes participating in such cytosolic degradation must be more than simple catalysts for the hydrolytic process—otherwise, destruction would be wholesale. Basically, there must be some means of distinguishing the proteins to be attacked from those to be left alone.

As described in Chapter 20, the major proteolytic system in cytosol uses ubiquitin to mark proteins destined for destruction. Recall that ubiquitin is a small, heat-stable protein that is transferred to lysine residues of proteins destined for breakdown or other processing. Although some ubiquitinated proteins are simply marked for translocation to specific cellular sites, and others are marked for reasons yet unknown, most are marked for ATP-dependent proteolytic digestion in the proteasome.

Apoptosis

Previously in this book we have mentioned *apoptosis*, which is a form of programmed cell death. It has long been known that cell death occurs on a substantial scale as part of normal embryonic development. For example, when a tadpole undergoes metamorphosis to a frog, its tail disintegrates as the result of the death

Protein degradation occurs via lysosomes—vesicles filled with hydrolytic enzymes—or intracellularly, often involving the marker ubiquitin and/or a multicatalytic complex.

of its constituent cells. Another example is development of toes and fingers, where the webbing that originally holds digits together also falls away as a result of programmed cell death. Both these and other developmental processes occur in close coordination with the growth and division of adjoining cells, such that the release of possibly toxic intracellular contents does not damage nearby cells. In addition, we now know that cells suffering irreversible damage, whose continued existence could threaten the organism, also undergo programmed cell death. Apoptosis (from Greek, “falling off,” as of leaves from a tree) is distinguished from *necrosis*, a form of cell death caused by trauma or anoxia (lack of oxygen) or lack of blood supply. Necrotic cells rupture spontaneously, spilling their contents and causing inflammatory responses in neighboring cells.

By contrast, events in apoptosis occur on schedule. Receipt of appropriate signals causes collapse of the cytoskeleton, disassembly of the nuclear membrane, and condensation of chromatin, followed by its breakdown. The cell surface becomes chemically altered, attracting neighboring cells such as macrophages, which engulf membrane-enclosed bits of the apoptotic cell and further degrade them, ensuring that contents of the dying cell are not released directly to the extracellular environment, where they could, as in necrosis, provoke an inflammatory response. The principal cell surface change is migration of phosphatidylserine from the inner leaflet of the plasma membrane to the outer leaflet. This particular phospholipid on the cell surface serves as a signal to neighboring phagocytic cells that they can proceed to engulf and degrade fragments of the apoptotic cell.

Understanding apoptosis is crucial to understanding cancer, because tumor cells lose the ability to undergo apoptosis.

Understanding apoptosis is critical to understanding cancer because a defining characteristic of tumor cells is their inability to undergo apoptosis. In Chapter 23, for example, we described p53, a sentinel protein that senses DNA damage and, depending upon the extent of that damage, either delays cell cycling until the damage is repaired, or triggers apoptosis, thereby insuring that the damaged cell will not survive to harm the organism. Loss of p53 function, as seen in many tumors, is responsible for the continued proliferation of abnormal tumor cells.

Among various ways to identify cells undergoing apoptosis is to observe the pattern of chromatin degradation. Among the degradative activities unleashed during apoptosis is an endonuclease activity that cleaves chromatin-associated DNA at linker regions between nucleosomes. Hence, analysis of chromatin by gel electrophoresis reveals a “ladder” pattern, with each band representing a particle containing an integral number of nucleosomes, as seen when purified chromatin is digested with an endonuclease (see Figure 24.22, page 1023). Another means of apoptotic detection involves the use of fluorescent dyes that register the loss of mitochondrial membrane potential.

Apoptosis can be triggered either extracellularly (*extrinsic* pathway) or intracellularly (*intrinsic* pathway). The extrinsic pathway predominates during normal development, whereas the intrinsic pathway is activated as a result of intracellular damage. Although the two pathways are triggered by different events, both pathways proceed via a series of conversions of inactive precursors to active proteolytic enzymes called **caspases**. The name refers to the fact that each of these enzymes has an active-site cysteine residue, and each attacks target proteins at specific aspartate residues; hence, *c-asp*-ases. These proteins are synthesized as inactive *procaspases*, which undergo proteolytic cleavage and dimerization, yielding enzymatically active $\alpha_2\beta_2$ heterotetramers.

The extrinsic pathway begins with recognition between a trimeric death receptor on the surface of the pro-apoptotic cell and a homotrimeric ligand on a cell, such as a killer lymphocyte. In the example schematized in Figure 28.49a, the ligand is a protein related to *tumor necrosis factor* (TNF), also mentioned in Chapter 23. An intracellular domain of the death receptor recruits an adaptor protein, which in turn recruits either procaspase-8 or -10, as shown, *via* a death effector domain, thereby forming DISC (death-inducing signaling complex). This brings procaspase molecules into close proximity, activating them and allowing them to cleave one another, forming activated caspases. Next these cleave and activate other procaspases, setting in motion the chain of events that results in death of the cell.

The intrinsic pathway, by contrast, is activated by signals that respond to intracellular events, such as DNA damage or lack of nutrients (Figure 28.49b). In mammalian cells the signaling agent is a protein, either *Bak* or *Bax*, which interacts with the mitochondrial outer membrane and triggers the release of cytochrome *c* from the intermembrane space, as we mentioned also in Chapter 15. Cytochrome *c* then binds to a protein called *Apaf1* (Apoptotic protease activating factor), triggering the hydrolysis of dATP bound to *Apaf1*. This in turn stimulates *Apaf1* to oligomerize into the heptameric *apoptosome*, a pinwheel-like structure that recruits and activates procaspase-9. Cleavage and activation of procaspase-9 creates active caspase-9, which cleaves and activates downstream procaspases, ultimately activating the events of apoptosis. In both the intrinsic and extrinsic pathways, the downstream events resulting from the caspase cascade are areas of active current investigation.

Apoptosis, the major form of programmed cell death, is triggered by either an extrinsic or intrinsic pathway, both of which initiate a series of proteolytic activations of procaspases to active caspases.

FIGURE 28.49

Extrinsic and intrinsic signaling pathways leading to apoptosis. (a) The extrinsic pathway. As shown, the interaction between a trimeric death cell receptor on the pro-apoptotic cell with a trimeric ligand in a killer cell stimulates assembly of DISC (the death-inducing signaling complex), which includes inactive procaspase-8 or -10 or both. Activation of the bound procaspase triggers a cascade of activation of downstream (“executioner”) caspases. **(b)** The intrinsic pathway. A protein such as *Bak* or *Bax* interacts by unknown mechanisms with the mitochondrial outer membrane, releasing cytochrome *c* and other proteins in the intermembrane space. Cytochrome *c* binds to *Apaf1*, stimulating hydrolysis of bound dATP and triggering assembly of the heptameric apoptosome. Activation of procaspase-9 within the apoptosome stimulates the cleavage of downstream executioner caspases, as seen in the extrinsic pathway.

Morgan, J. E. Heuser, X. Wang, and C. W. Akey, Three-dimensional structure of the apoptosome: Implications for assembly, procaspase-9 binding and activation. © 2002, with permission from Elsevier.

SUMMARY

The connection between gene (or mRNA) sequence and protein sequence is dictated by the genetic code. The code is almost, but not quite, uniform in all living creatures. The code is redundant, with multiple codons for most amino acids, and it includes start and stop signals.

Translation of mRNAs into polypeptide chains involves a number of steps. First, the appropriate tRNAs must be coupled to the corresponding amino acids, using a set of aminoacyl-tRNA synthetases. The site of translation is the ribosome—an RNA–protein complex composed of two subunits, each with its individual RNA and protein components. Translation of an mRNA on ribosomes involves three stages—initiation, elongation, and termination. Each stage requires certain protein factors in addition to the ribosome. In prokaryotic initiation the mRNA is fixed to the 30S subunit in proper register via its Shine–Dalgarno sequence, and the initiator *N*-formylmethionyl tRNA is matched to its AUG codon at the P site. The 50S subunit is then attached. The second tRNA enters the A site, and the incipient chain is transferred to it. Next, the mRNA is translocated so as to move the chain again into the P site, while the now unoccupied tRNA moves into the E site and is released. These steps involve intermediate hybrid states.

The chain continues to elongate in this fashion until a stop codon is reached, whereupon release factors bind to the ribosome and aid in releasing the polypeptide chain. The entire process of translation requires about 4 ATP equivalents for each amino acid added. Numerous antibiotics have their antibacterial effect by inhibiting various stages of the translation process.

Eukaryotic protein synthesis differs from that in bacteria in significant ways, starting with the fact that eukaryotic mRNAs are highly processed templates for single genes; ribosomes are larger and more complex, and more soluble protein factors are involved; different mechanisms are used for initiation because *N*-formylmethionine is not involved; and translation is coupled only indirectly with transcription because the two processes occur in different cell compartments.

As translation is being completed, folding and covalent modification of the polypeptide chain begin. The chain as synthesized may contain an *N*-terminal sequence that targets it for passage through membranes. Distinct transport processes involve uptake into organelles, uptake into the nucleus, or sorting for transport into lysosomes, membrane interiors, or the extracellular milieu.

PROBLEMS

- The following synthetic polynucleotide is synthesized and used as a template for peptide synthesis in a cell-free system from *E. coli*.
 $\cdots\text{AUUAUAUAUAUAU}\cdots$
 What polypeptide would you expect to be produced? Precisely what information would this give you about the code?
- If the same polynucleotide described in Problem 1 is used with a *mitochondria-derived* cell-free protein-synthesizing system, the product is
 $\cdots\text{Met-Tyr-Met-Tyr-Met-Tyr}\cdots$
 What does this say about differences between the mitochondrial and bacterial codes?
- When polynucleotides are synthesized with repeating triplets of nucleotide residues, from one to three kinds of polypeptide chains will be produced in cell-free synthesis.
 - Explain why these different results are possible.
 - Predict polypeptides produced when the following are used with an *E. coli* system: $(\text{GUA})_m; (\text{UUA})_n$
- What kind of repeating polynucleotide would yield a single polypeptide with a tetrapeptide repeating unit?
- Although the Shine–Dalgarno sequences vary considerably in different genes, they include examples like GAGGGG that could serve as code—in this case, for Glu–Gly. Does this imply that the sequence Glu–Gly cannot ever occur in a protein, lest it be read as a Shine–Dalgarno sequence? Speculate.
- According to wobble rules, what codons should be recognized by the following anticodons? What amino acid residues do these correspond to?
 - $5' - \text{ICC} - 3'$
 - $5' - \text{GCU} - 3'$
- In the early days of ribosome research, before the exact role of ribosomes was clear, a researcher made the following observation. She could find, in sedimentation experiments on bacterial lysates, not only 30S, 50S, and 70S particles but also some particles that sedimented at about 100S and 130S. When she treated such a mixture with EDTA, everything dissociated to 30S and 50S particles. Upon adding divalent ions, she could regain 70S particles, but never 100S or 130S particles.
 - Suggest what the 100S and 130S particles might represent, in light of current knowledge of protein synthesis. What important discovery did the researcher miss?
 - Why do you think reassociation to 100S and 130S particles did not work?
- The E site may not require codon recognition. Why?
- What is the minimum number of tRNA molecules that a cell must contain in order to translate all 61 sense codons?
- Suppose that the probability of making a mistake in translation at each translational step is a small number, δ . Show that the probability, p , that a given protein molecule, containing n residues, will be completely error-free is $(1-\delta)^n$.
- Assume that the translational error frequency, δ , is 1×10^{-4} .
 - Calculate the probability of making a perfect protein of 100 residues.
 - Repeat for a 1000-residue protein.
- Devise an experiment, based on sucrose gradient sedimentation (see Figure 27.3, page 1128), that would demonstrate that proteins are synthesized on polyribosomes.
- Assuming that glucose is burned to CO_2 as an energy source, how many amino acid residues can be incorporated into a protein molecule for each glucose consumed by a cell? Is this a maximum or minimum estimate?
- Why might you expect a small dose of puromycin to be less effective in repressing bacterial growth than an equivalent number of molecules of erythromycin?
- The antibacterial protein colicin E3 is an effective inhibitor of protein synthesis in prokaryotes. This protein is a nuclease, specifically attacking a phosphodiester bond near the 3' end of the 16S RNA. Suggest a mechanism for the effect of colicin E3 on translation.
- If a nonsense mutation can be suppressed by a tRNA mutation that changes an anticodon so that a nonsense codon can be translated, describe a mechanism for suppression of a frameshift mutation.
- Compare and contrast the metabolic pathways leading to thymine in DNA and thymine as a modified base in tRNA.
- Refer to Figure 28.6, which showed restoration of a proper reading frame by a frameshift mutation. In another experiment with the T4 lysozyme system, the Streisinger group found that a second frameshift mutation in T4 gene *e* restored wild-type function. Sequence analysis of wild-type and double-mutant lysozymes were identical except for the amino acid sequences shown here. Describe the mutations that could have generated this result in terms of the base sequences in the *e* gene and known codon assignments.
 Wild-type: $\cdots\text{Lys-Ser-Pro-Ser-Leu-Asn-Ala}\cdots$
 Mutant $\cdots\text{Lys-Ser-Val-His-His-Leu-Met-Ala}\cdots$
- The earliest work on the genetic code established UUU, CCC, and AAA as the codons for Phe, Pro, and Lys, respectively. Can you think of a reason why polyG was not used as a translation template in these experiments?

TOOLS OF BIOCHEMISTRY 28A

WAYS TO MAP COMPLEX MACROMOLECULAR STRUCTURES

As we continue to probe the structure of the cell, using ever gentler and more discriminating techniques, it becomes apparent that much of the cellular machinery is organized in complicated structures that are *assemblies* of macromolecules. The ribosome, with its several kinds of RNA and many kinds of proteins, is an excellent example. Although ribosomes, with their large size and complexity, have finally yielded to X-ray crystallography, some of the techniques used in earlier investigations are still important in learning about other complex biological structures. We describe several of these methods here.

Chemical Cross-linking

One way to learn about the arrangement of components in a particle is to investigate spatial relationships, through chemical **cross-linking** (see also Tools of Biochemistry 13A, page 588).

Consider an idealized particle (like that shown in Figure 28A.1) that contains three different protein molecules. If we have a bifunctional reagent (like one of those shown in Table 28A.1) that can react with side chain residues to form cross-links between adjacent protein molecules, we can allow them to react lightly, and then we can extract the protein as a mixture of cross-linked particles. Covalently linked partners that have formed can be identified in various ways. If we have antibodies to the different proteins, we can identify partners that have formed by using Western blotting (method 1 in Figure 28A.1; also see Tools of Biochemistry 7A). Alternatively, we might use one of the “cleavable” cross-linkers shown in Table 28A.1, together with two-dimensional gel electrophoresis (method 2 in Figure 28A.1). In any event, in the simple example shown, it is clear that protein A must lie between B and C because A can be linked to either of the other proteins but B and C do not form cross-linked dimers.

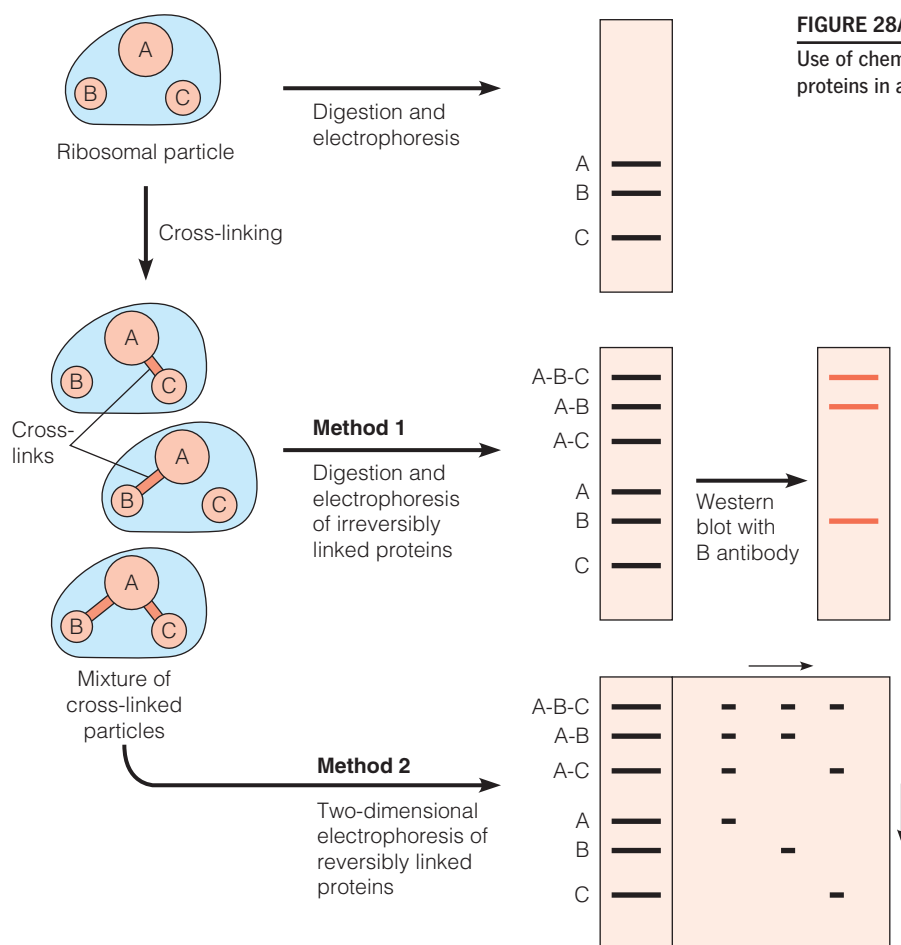

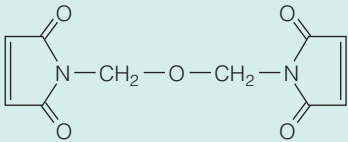

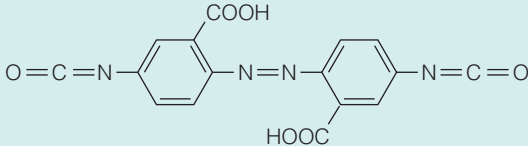

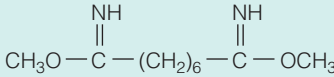

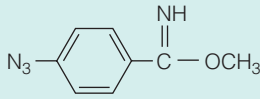

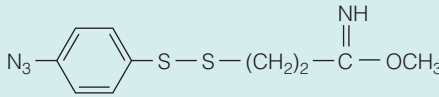

TABLE 28A.1 Some protein cross-linking reagents

Reagent	Formula	Reacts Primarily with	Cleavable?
Bis(<i>N</i> -maleimidomethyl) ether		Sulfhydryl group	No
2,2'-Dicarboxy-4,4'-azophenyldiisocyanate		Amino groups	Yes, by reduction of —N=N—
Dimethyl suberimidate		Amino group	Yes, by ammonia
Tetranitromethane	$C(NO_2)_4$	Phenolic groups (tyrosine)	No
Methyl-4-azidobenzoimidate ^a		Amino groups and others	No
Methyl[3-(<i>p</i> -azidophenyl)dithio]propionimidate ^a		Amino groups and others	Yes, by reduction of —S—S—

^aThese reagents are photoactivatable. They may be first reacted, in the dark, through the imidate group to the right and then coupled to another group by activating the azide (N₃) with a flash of light.

In addition to the protein–protein cross-linking techniques described here, methods for RNA–protein and RNA–RNA cross-linking are now available (see References). These methods have played a large part in determining the detailed ribosomal models that led ultimately to crystal structures shown in this chapter.

Immunoelectron Microscopy

In **immunoelectron microscopy**, components that lie on the surface of a particle can be localized in a direct manner by using antibodies prepared against them. The Y-shaped antibody molecules form bridges between two particles, connecting points at which the particular component is accessible to the surface. In Figure 28A.2, we show the same idealized particle used in Figure 28A.1. The fact that protein B lies near the pointed end of the particle is made clear by the way in which anti-B antibodies tie two particles together. When appropriate hapten groups are attached at specific points on RNA molecules, the same method can be used to show

FIGURE 28A.2
Locating proteins on a particle surface by antibody binding.

when these RNA sequences are near the ribosomal surface. The ends of the ribosomal RNAs have been located in this way, as has the position at which the nascent peptide emerges from the ribosome (see Figure 28A.3).

Cryoelectron Microscopy

Conventional techniques of transmission electron microscopy (Tools of Biochemistry 1A) suffer from a number of serious

**FIGURE 28A.3**

Use of antibodies to detect where the polypeptide chain emerges from the ribosome. Antibodies to β -galactosidase were used to interact with β -galactosidase chains at the point where they emerge from the ribosomes. The 70S ribosomes were found to be tied together by such antibodies at sites near the back of the 50S subunit, at the location of a pore in this unit.

drawbacks in the study of delicate biological structures. First, the necessity of complete dehydration in the vacuum chamber of the microscope can greatly modify structures. Second, to produce enough contrast, samples have traditionally been stained with heavy metals or metal-shadowed, producing an inherent loss in resolution.

A relatively new technique that avoids these artifacts is *cryoelectron microscopy* (or *electron cryomicroscopy*). The idea is simple: A sample is very rapidly frozen in ice; the freezing is so rapid that the water does not crystallize but becomes *vitrified* (glassy). The sample can be vitrified in the interstices of an EM grid or vitrified in bulk and then thin-sectioned for examination. Because no stain is used, contrast is low, and methods of image enhancement are needed. For particles such as ribosomes, this is accomplished by combining the information from a number of faint images of particles in the ice to develop a picture. Because they will, in general, be randomly rotated, this random orientation must be taken into account in the computer analysis. The advantage, of course, is that the final generated image can be viewed “from all sides” and can be examined from any angle in computer display.

If particles (viruses, for example) have elements of symmetry, or if the structures of subunits are known, the analysis becomes easier. But even irregular particles like ribosomes can be analyzed with resolution approaching 1–2 nm. Last, but not least, the

sample has remained in an aqueous environment throughout the study, so damage to the structure should have been minimized.

Low-Angle Scattering of X-Rays and Neutrons

Although crystal diffraction studies of enormous particles like ribosomes are still challenging, we can learn much from studying the scattering of radiation from suspensions of such particles. When electromagnetic waves are scattered from a particle with dimensions much greater than the wavelength of the radiation, the scattering intensity depends on the angle of observation. As shown in Figure 28A.4, waves scattered from different regions within the particle at any angle other than 0° are out of phase, resulting in mutual interference and decreased intensity. At large angles the phase difference increases, causing partial cancellation of the scattered waves. This interference may be used to measure average dimensions of the particle. The intensity of scattering at angle θ (I_θ) compared with the scattering at angle 0 (I_0) is given (for small angles) by the following:

$$\frac{I_\theta}{I_0} = e^{-(16\pi^4 R_G^2/3\lambda^4)\sin^2(\theta/2)} \quad (28A.1)$$

Here λ is the wavelength of the radiation, and R_G is a quantity called the *radius of gyration*, a kind of average dimension of the

FIGURE 28A.4

Principle of X-ray or neutron scattering. Scattering of X-rays or neutrons from different small regions within a large particle produces mutual interference in the scattered waves.

particle. According to Equation 28A.1, a graph of $\ln(I_\theta/I_0)$ versus $\sin^2(\theta/2)$ should be a straight line at low angles, with initial slope of $(16\pi^4 R_G^2/3\lambda^4)$. Thus, measurement of the scattering at very low angles gives a measure of average particle size. At higher angles, the I_θ/I_0 curves have a more complex shape, with maxima and minima. These can be used to give additional information about the shape of the particle and its internal distribution of matter.

Although low-angle scattering of X-rays has been useful in studying particles in solution, a much more powerful technique is **low-angle neutron scattering**. It may seem strange at first to think of neutrons as radiation, but we must remember that, according to quantum mechanics, any elementary particle has wavelike properties as well. The wavelength of a particle with

mass m moving at velocity v is given by $\lambda = h/mv$, where h is Planck's constant. It turns out that "thermal neutrons" emerging from a nuclear reactor have a wavelength of a few tenths of a nanometer. Thus, they are of the right length for examination of details of macromolecular structure. Still more important, neutrons interact primarily with atomic nuclei and are therefore scattered differently by different atoms. Thus, nucleic acids and proteins scatter neutrons differently, and even hydrogen and deuterium have different scattering powers. Because H_2O and D_2O differ in scattering, it is possible to use as solvents H_2O/D_2O mixtures that match the neutron-scattering power of either the nucleic acid or protein portion of a nucleoprotein particle. Then, as shown in Figure 28A.5, we can make either nucleic acid or protein "disappear" into the background and measure the radius of gyration of either component. In the example shown, the greater R_G observed for nucleic acid than for protein tells us that the nucleic acid is concentrated on the outside of the particle.

An even more powerful variant of the technique has been used to "map" the distances between particular pairs of proteins in complex particles. Suppose, as in Figure 28A.6, we have reconstituted particles containing just two proteins (among the many in the particle) that have been prepared from deuterium-fed bacteria. These two proteins will be heavily deuterated and will have a neutron-scattering power much different from that of the rest of the particle. If the H_2O/D_2O solvent is now mixed so as to match the average background in the nondeuterated portion of the particle, the two deuterated proteins will stand out in contrast. The neutron-scattering pattern obtained will be dominated by the interference in scattering between these two proteins and can be used to measure their separation. In addition, the

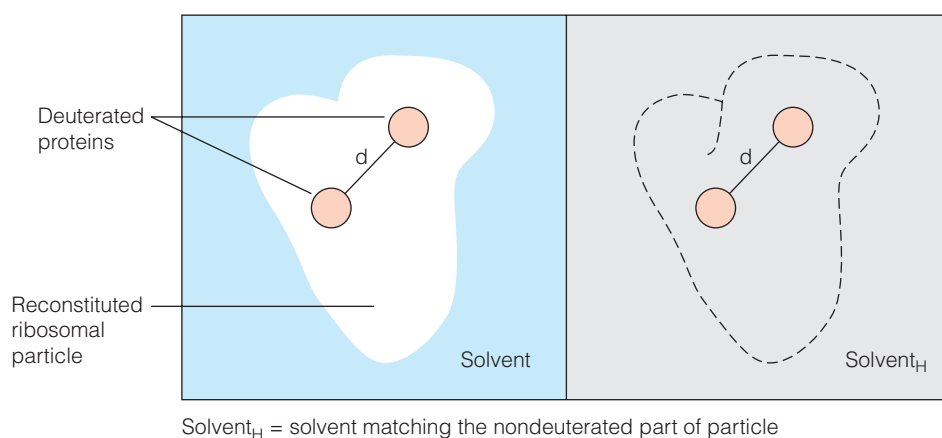

Solvent_p = solvent that matches the scattering properties of the protein
 Solvent_N = solvent that matches the scattering properties of the nucleic acid
 R_G = radius of gyration of the nucleic acid-protein complex
 R_{GN} = radius of gyration of the nucleic acid
 R_{GP} = radius of gyration of the protein

FIGURE 28A.5

Use of selective solvent matching to show, by neutron scattering, that the nucleic acid is on the outside of a nucleoprotein particle.

**FIGURE 28A.6**

Use of solvent matching to determine the distance between two selectively deuterated proteins in an undeuterated particle.

method allows measurement of the radius of gyration of a particular protein in situ.

Although neutron scattering can give much useful information, it is not a technique the average biochemist can use in the laboratory. Only a few locations in the world have large research reactors that are fitted to do neutron-scattering studies.

CHAPTER 29

Regulation of Gene Expression

A key to understanding life is understanding how the expression of genes is controlled. Why is hemoglobin present only in red blood cells? How does addition of lactose to a bacterial culture initiate a several thousand-fold increase in the rate of β -galactosidase synthesis? What causes enzymes of the urea cycle to appear during metamorphosis of a tadpole to an adult frog? What factors orchestrate the pattern of sequential gene expression during embryonic differentiation? These are just a few questions whose answers demand an understanding of gene regulation.

As we mentioned in Chapter 27, seminal insights into genetic control were presented in 1960, when François Jacob and Jacques Monod of France's Pasteur Institute proposed the operon model of gene regulation, based upon their genetic analysis of lactose utilization in *E. coli*. Contributing equally to the success of Jacob and Monod were parallel investigations by Andre Lwoff of the genetic regulation of reproduction of the temperate bacteriophage λ in *E. coli*. We shall return to this important biological system later. Based upon similarities in regulatory mechanisms between these two quite different systems, Jacob and Monod proposed that regulation of gene expression occurs primarily at the level of transcription, and specifically, at the level of transcriptional initiation. Their model was largely correct, but subsequent years have shown that regulation can occur at any stage in the expression of a gene. For example, we have seen in Chapter 26 that regulation can occur at the level of gene copy number, when environmental stresses cause amplification of genes whose products deal with the stress.

However, Jacob and Monod were correct; most regulation does occur at the transcriptional level, and that is what we focus upon in this chapter. We will begin with prokaryotic systems, which provide historical context, then move to the more complex eukaryotic regulatory processes. Along the way, we will present some examples of regulatory processes occurring at other levels of gene expression, particularly translation. We will also discuss recent discoveries that identified functions of small RNA molecules in gene regulation.

Regulation of Transcription in Bacteria

The Lactose Operon: Earliest Insights into Transcriptional Regulation

Recall from Chapter 27 that lactose utilization in *E. coli* is controlled by three contiguous genes—*lacZ* (β -galactosidase), *lacY* (β -galactoside permease, a transport protein), and *lacA* (thiogalactoside transacetylase, an enzyme of still unknown function). In the presence of an inducer, all three proteins accumulate simultaneously, but to different levels. Lactose itself leads to induction of the lactose operon, but the true intracellular inducer is **allolactose**, Gal β (1 \rightarrow 6)Glc, a minor product of β -galactosidase action. In the laboratory one usually uses a synthetic inducer such as **isopropyl thiogalactoside (IPTG)**, which induces the lactose operon but is not cleaved by β -galactosidase. Hence, its concentration does not change during an experiment.

A mutation in a structural gene—*lacZ*, for example—can inactivate its product (β -galactosidase) without affecting control of the other two genes. However, mutations in the regulatory regions mapping *outside* genes *lacZ*, *lacY* and *lacA* can affect expression of all three structural genes. In their early work, Jacob and Monod recognized two distinct mutant phenotypes—**constitutive**, in which all three gene products are synthesized at high levels even when inducer is absent, and **noninducible**, in which all three enzyme activities remain low even after addition of an inducer. These mutations mapped in two sites, termed *o* and *i*. Importantly, Jacob and Monod were able to establish dominance relationships involving regulatory mutations, by using interrupted bacterial mating (Chapter 25) to create partial diploids. Problem 7 at the end of this chapter should help you to understand relationships among regulatory mutations, mutant phenotypes, and levels of *lac* operon enzymes.

The original Jacob–Monod model for gene regulation, based upon this system, was presented in Figure 27.2 (page 1127). A more contemporary map of the *lac* operon is shown in Figure 29.1. As Jacob and Monod correctly proposed, transcription of the three structural genes is initiated near an adjacent site, the **operator**. Transcription yields a single **polycistronic messenger RNA**; that is, it yields an RNA copy of all three genes. (The term **cistron** has genetic significance. For our purposes it is a region of a genome that encodes one polypeptide chain.) The *i* gene product is a macromolecular **repressor**, which in the active form binds to the operator, blocking transcription (Figure 29.2a).

The repressor protein also has a binding site for an inducer. Binding of IPTG, allolactose, or some other inducer at this site inactivates repressor by vastly decreasing its affinity for DNA (Figure 29.2b). This repressor inactivation stimulates transcription of *lacZ*, *Y*, and *A* because dissociation of the repressor–inducer complex from the operator removes a steric block to binding of RNA polymerase at the initiation site. Thus, the introduction of lactose activates synthesis of the gene products involved in its catabolism by removing a barrier to their transcription. This mode of regulation is essentially negative because the active regulatory element (the repressor) is an *inhibitor* of transcription. Positive control was later discovered, involving the CRP site shown in Figure 29.1. We shall discuss this shortly.

FIGURE 29.1

A map of the lactose operon. The CRP site is the binding site for cAMP receptor protein, a regulatory factor (page 1237). The promoter also includes binding sites for RNA polymerase and *lac* repressor. Synthesis of repressor initiates at its own promoter (*i* promoter). Additional repressor-binding sites exist, 82 nucleotides upstream and 432 nucleotides downstream, respectively, from the transcriptional start point (not shown).

**FIGURE 29.2**

Configurations of the lactose operon. (a) Binding of the repressor to the operator inhibits transcription of the structural genes. **(b)** The inducer binds to the repressor, decreasing the affinity of the repressor for the operator. Dissociation of the inactive repressor–inducer complex from the operator permits transcription of the structural genes.

As mentioned above, essential for developing the operon model was the ability to analyze regulation in partial diploids—bacteria containing one complete chromosome plus part of another, transferred in by conjugation. One copy of the operon resides in the chromosome, while another lies on an incomplete chromosome, introduced into a cell as part of the bacterial mating process. Noninducible mutations that mapped in *i* had a dominant phenotype, meaning that expression of the structural genes was low when both wild-type and mutant alleles of *i* were present. Jacob and Monod proposed that the mutant alleles give rise to mutant repressors that are unable to bind inducer. These mutant repressors would remain bound to DNA at operator sites on both the mutant and the normal chromosomes, even when inducer is present.

Constitutive mutations that mapped in *i* had a recessive phenotype. That is, they resulted in high gene expression, but only when two mutant alleles were present. These mutant alleles generated repressors that were defective in operator binding and thus could not turn off gene expression. Such mutations are recessive because a normal repressor in the same cytosol can bind to all operators and inhibit transcription. These observations showed that repressor mutations are **trans-dominant**, meaning that the *i* gene product encoded by one genome can affect gene expression from other genomes in the same cell. This finding led to the conclusion that repressor is a diffusible product, capable of acting on any DNA site in the cell to which it could bind. On the other hand, the constitutive mutations mapping in *o* had a **cis-dominant** effect. That is, in a cell with one wild-type operator and one mutant operator, only the genes on the same chromosome as the mutant operator were expressed constitutively. Given that a protein would be capable of diffusing through the cytosol and acting on other chromosomes, this finding suggested that the operator does not encode a gene product.

The phenotypes of partial diploids involving *lac* regulatory genes gave indispensable clues to mechanisms of transcriptional regulation.

For a molecular mechanism based almost entirely on the indirect evidence of genetic analysis, the operon model as advanced by Jacob and Monod has stood the test of time remarkably well. Three major modifications to the model occurred as the system was subjected to further analysis. First, the promoter was discovered as an element distinct from the operator (although the two sites overlap). Second, although the repressor was first thought to be *i*-gene RNA, its isolation proved that it is protein. Third, Jacob and Monod proposed that all transcriptional regulation was negative; that is, binding a regulatory protein always inhibits transcription. However, the lactose operon, like many other regulated genes, also exhibits *positive* control of transcription (that is, *activation* of transcription by binding of a protein), as described on pages 1236–1238.

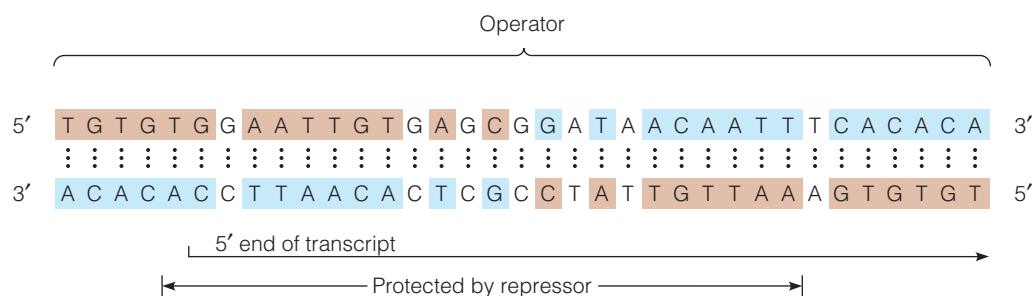

Isolation and Properties of Repressor

The *lac* repressor was isolated in 1966 by Walter Gilbert and Benno Müller-Hill. Because this repressor comprises only 0.001% of the total cell protein, Gilbert and Müller-Hill used mutants designed to overproduce it, so as to maximize its synthesis, to about 2% of total protein (this was several years before the gene could have been easily overexpressed by cloning). They then purified the protein on the basis of its ability to bind the synthetic inducer IPTG. The purified *lac* repressor is a tetramer, formed from four identical subunits, each with 360 amino acids ($M_r = 38,350$). The protein binds IPTG with a K_a of about 10^6 M^{-1} , and it binds nonspecifically to duplex DNA with a K_a of about $3 \times 10^6 \text{ M}^{-1}$. However, its specific binding at the *lac* operator is much tighter, with a K_a of 10^{13} M^{-1} . Like RNA polymerase, repressor seeks its operator site by first binding to DNA at any site and then moving in one dimension along the DNA. It moves either by sliding or by transfer from one site to another, when the two sites are brought next to each other on adjacent loops of DNA.

Control by the *lac* repressor is exceedingly efficient, particularly in view of the minute amount of repressor present in an *E. coli* cell. The *i* gene is expressed at a low rate, giving about 10 molecules of repressor tetramer per cell. Although this corresponds to a concentration of only about 10^{-8} M , this value is several orders of magnitude higher than the *dissociation* constant, meaning that in a *noninduced* cell the operator is bound by repressor more than 99.9% of the time—hence, the very low levels of *lac* operon proteins in uninduced cells (less than one molecule per cell). However, binding of inducer decreases the affinity of the repressor–inducer complex for operator by many orders of magnitude. Under these conditions, nonspecific binding of the repressor–inducer complex at other DNA sites becomes significant so that in *induced* cells the operator is occupied by repressor less than 5% of the time.

The Repressor Binding Site

The DNA site bound by *lac* repressor has been analyzed by footprinting and methylation-protection experiments of the type described earlier for RNA polymerase (see Figure 27.15, page 1140). As shown in the diagram below, the operator comprises 35 base pairs, including 28 base pairs of symmetrical sequence; that is, it includes a sequence that is identical in both directions (shaded in the diagram). Thus, the operator is an imperfect palindrome—imperfect because of the seven base pairs that do not show this symmetry.

A repressor–inducer system provides negative control of the *lac* operon. The repressor binds to operator, interfering with transcription initiation. An inducer binds to repressor, reducing its affinity for operator.

**FIGURE 29.3**

The 122-base *lac* regulatory region. The inverted repeat sequence in the CRP binding site is shaded in blue, and the palindromic areas of the operator are shaded in pink. The binding sites for all three proteins (CRP, repressor, and RNA polymerase), as determined by DNase I footprinting, are boxed. The sequence changes encountered in promoter and operator mutations are shown, as well as the start codon for the *lacZ* protein (*Z* gene) and the stop codon for repressor protein (*i* gene). Nucleotides are numbered from 0 at the *lac* transcriptional start point (the first mRNA nucleotide is +1).

The transcriptional start point is included within the repressor-binding sequence, as shown in the diagram. Twenty-four of the 35 base pairs of the operator are protected from DNase attack by repressor binding. Operator-constitutive (o^c) mutations involve changes in the central portion of this sequence of nucleotides. Figure 29.3 shows how the operator and promoter overlap, as determined by the regions of DNA protected by binding either repressor or RNA polymerase, respectively.

Once the *lac* operon had been sequenced, it became apparent that two additional *lac* repressor-binding sites are located nearby, one centered upstream, at position -82, and one within the *lacZ* gene itself, at position +432; the original operator is centered at +11. Genetic analysis indicated that both additional sites participate in *lac* operon regulation. Although the significance of the downstream site is not clear, mutations affecting the upstream (-82) site led to incomplete repression of the operon. Evidence indicated that a looped DNA structure was essential for complete repression, with repressor contacting both the -82 and +11 sites. Confirmation came in 1996, with the crystal structure determination of the complete tetrameric *lac* repressor by itself, as a complex with a defined oligonucleotide fragment, and as a complex with IPTG. As shown in Figure 29.4a, the tetrameric protein consists of two dimeric units, joined by a hinge region. Each dimer binds DNA separately, suggesting that the tetrameric protein binds to both the +11 and -82 sites, creating a DNA loop of 93 base pairs between them. The DNA-binding domain of the protein is an α -helical region that contacts bases within the major groove of the operator DNA. This helical binding motif has been seen in other sequence-specific DNA-binding proteins, as we shall discuss shortly.

Figure 29.4b suggests the mechanism of induction. The repressor is an allosteric protein which, upon binding inducer, significantly increases the angle at which two monomeric units in a dimer relate to one another. This drives the DNA-binding helices apart by 3.5 Å so that they can no longer contact DNA binding sites, as they must in order to bind tightly.

Regulation of the *lac* Operon by Glucose: A Positive Control System

The *lac* repressor-operator system keeps the operon turned *off* in the absence of utilizable β -galactosides. An overlapping regulatory system, summarized in Figure 29.5, turns the operon *on* only when alternative energy sources are unavailable. *E. coli* has long been known to use glucose in preference to most other energy substrates. When grown in a medium containing both glucose and lactose, the cells metabolize glucose exclusively until the supply is exhausted. Then growth slows, and the lactose operon becomes activated in preparation for continued growth using lactose. This phenomenon, now known to involve a transcriptional *activation* mechanism, was originally called glucose repression or catabolite repression. Transcriptional activation occurs when glucose levels are low; control is exerted through intracellular levels of cyclic AMP.

Recall that in animal cells a rise in cAMP levels stimulates catabolic enzymes, which increase the levels of energy substrates. Those effects are mediated metabolically, through hormonal signals and triggering of metabolic cascades. In bacteria cAMP activation involves control of gene expression, but the end results are

**FIGURE 29.4**

Structure of the *lac* repressor. **FIGURE 29.5**

Activation of the *lac* operon. Repressor is inactivated by binding inducer, and cAMP receptor protein (CRP) is activated by binding cyclic AMP. Binding of the CRP–cAMP complex to DNA facilitates initiation of transcription by RNA polymerase.

similar. In *E. coli*, cAMP levels are low when intracellular glucose levels are high. The actual regulatory mechanism is not yet known. Adenylate cyclase apparently senses the intracellular level of an unidentified intermediate in glucose catabolism—hence, the current name for the regulatory process, **catabolite activation**. When glucose levels drop, as shown in Figure 29.5, cAMP levels rise, triggering activation of the lactose operon by its interaction with a protein called **cAMP receptor protein (CRP)**, formerly called **catabolite activator protein (CAP)**. This protein is a dimer, each of whose identical polypeptide chains contains 210 amino acid residues. When it binds cAMP, CRP undergoes a conformational change. The change greatly increases its affinity for certain DNA sites, including a site in the *lac* operon adjacent to the RNA polymerase binding site. The binding of cAMP–CRP

at this site protects a DNA sequence from -68 to -55 , as shown in Figure 29.3. This binding facilitates transcription of the *lac* operon by stimulating the binding of RNA polymerase to form a closed-promoter complex or by increasing the rate of open-promoter complex formation.

Our understanding of CRP action is still incomplete, partly because the cAMP–CRP complex activates several different gene systems in *E. coli*, all of them involved with energy generation. They include operons for utilization of other sugars, including galactose, maltose, arabinose, and sorbitol, and several amino acids. Among the operons that have been analyzed, the DNA-binding site of the cAMP-activated dimer varies considerably with respect to the transcriptional start point, suggesting that regulatory mechanisms involving this protein are complex.

Cyclic AMP receptor protein (CRP) provides positive control of *lac* and several other catabolite-repressible operons. The cAMP–CRP complex binds at the *lac* promoter when glucose levels are low and facilitates initiation of transcription.

The CRP–DNA Complex

The structure of the CRP–cAMP–DNA complex, as revealed by X-ray crystallography (Figure 29.6), shows how the protein binds to DNA. Each CRP subunit contains a characteristic pair of α helices, which are joined by a turn. One helix of each pair, shown as perpendicular to the plane of the figure, lies within the major groove of DNA. This **helix–turn–helix** structural motif, which was observed at about the same time as the structure of the λ phage Cro repressor (see Figure 27.1 and pages 1239–1244), is found in several DNA-binding regulatory proteins, suggesting common evolutionary origins for this family of proteins. Helix–turn–helix was the earliest-described DNA-binding structural motif, earlier than those we discussed in Chapter 27 (page 1147). We shall return to this motif and its regulatory significance when we discuss the repressors of phage λ .

Analysis of the DNA–protein complex shows also that CRP induces DNA to bend quite sharply when it binds. This bending may facilitate the initiation of transcription by bringing parts of RNA polymerase that are bound upstream into direct contact with the promoter or transcriptional start site. Evidence indicates that an important interaction between the polymerase α subunit and DNA occurs as a result of DNA bending.

FIGURE 29.6

Bending of DNA by binding to CRP–cAMP. This model was deduced from the crystal structure of the DNA–protein–cAMP complex. The DNA bases are in light blue, and the sugar–phosphate backbone is in yellow. The DNA-binding domains of the protein—two α helices that contact DNA bases in the major groove (see text)—are in purple and are perpendicular to the plane of the page. The cAMP-binding domain is in blue, and two bound cAMP molecules are in red. On the DNA molecules, those phosphates that are in closest contact with the protein and whose ethylation interferes with protein binding are in red. Those phosphates whose reactivity to ethylation is enhanced (on the outer edge of the bend) are in blue. PDB ID 1CGP.

Bacteriophage λ : Multiple Operators, Dual Repressors, and Models for DNA Binding Specificity

We now return to phage λ , a larger and more complex genetic system than the lactose operon, but one that is regulated by similar factors—binding of proteins to specific DNA regulatory sites, just upstream from the genes that they control, with binding leading to either activation or inhibition of transcriptional initiation. However, because of the variety of relationships between the virus and its host bacterium, the specific controls used are more complex and more subtle than those we have been discussing. Recall from Chapter 26 that infection can have one of two possible outcomes—a lytic cycle of growth, comparable to that of phage T4, or lysogenization, in which the viral chromosome circularizes and undergoes site-specific integration into the host-cell chromosome (see Figure 26.19, page 1098), with consequent repression of nearly all viral genes. Once lysogeny has been established, the phage chromosome can be maintained as a transcriptionally repressed prophage for many generations. This state of repression can be broken, leading to excision of the viral chromosome as a circular DNA, followed by replication of viral DNA, followed by activation of genes needed to assemble virus particles. The virus must rely on four distinct patterns of gene expression needed for its four physiological states—(1) infection leading to lytic growth, (2) infection leading to establishment of lysogeny, (3) long-term maintenance of lysogeny, and (4) breaking of lysogeny with subsequent lytic growth.

The critical events in λ transcriptional regulation involve two different repressor proteins, called *cI* and *Cro*, each of which binds at two different operators. Each operator contains not one repressor-binding site (as in the lactose operon) but three, and each contains promoter sites interspersed with the repressor-binding sites. Transcription from the two promoter-operator sites takes place in opposite directions along the genome (see Figure 29.7). The repressors bind to each of the six operator sites with varying affinities, leading to varying occupancy of each binding site by each repressor under different physiological conditions. To add to the complexity, the *cI* repressor also serves, under certain conditions, as a transcriptional *activator*, promoting the expression of some genes while repressing that of others. To understand the biochemistry involved, we must first consider the genes and their positions on the λ genome (Figure 29.7), as well as the phenotypes of mutants altered in these regulatory genes.

Genes and Mutations in the λ System

Phage mutants defective in establishing or maintaining lysogeny have phenotypes comparable to those defective in *lac* regulation, and these similarities helped Jacob and Monod make the generalizations embodied in the operon model. The lysogenic

FIGURE 29.7

The early regulatory region of phage λ . The sites of action of several regulatory proteins are shown (brown bands on tan ribbon). These proteins are the *cI* and *Cro* repressors, the *cII* activator, *cIII* (which acts to stabilize *cII*), the antiterminator *N*, and the integration and excision proteins *Int* and *Xis*. The RNA transcripts colored green and red are synthesized under different conditions and in the directions shown by the arrowheads.

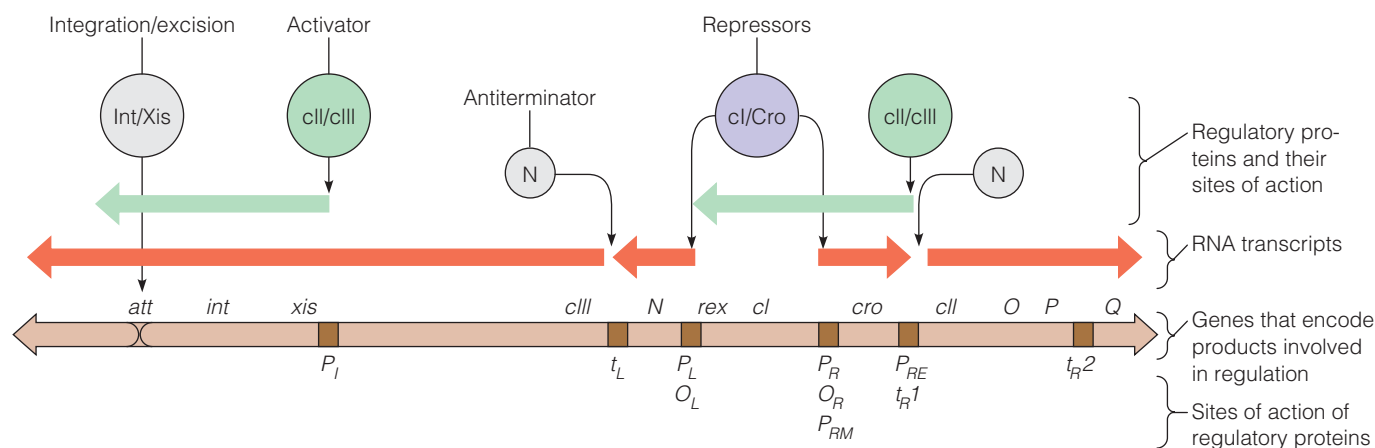

TABLE 29.1 Phenotypes of comparable *lac* and λ mutations

<i>lac</i> Phenotype	Corresponding λ Phenotype	Regulatory Abnormality
Inducer-constitutive, recessive	Clear-plaque; cannot establish lysogeny	Repressor defective in operator binding
Operator-constitutive, <i>cis</i> -dominant	Virulent; can replicate in a superinfected immune lysogen	Operator unable to bind repressor
Noninducible, <i>trans</i> -dominant	Noninducible (cannot be induced by UV or other treatments)	Repressor cannot bind inducer or be inactivated

response involves processes of viral gene inactivation, accomplished by the binding of a repressor to an operator, comparable to the one that keeps the *lac* operon turned off when inducer is absent. The major λ phenotypes and the counterpart *lac* mutations are summarized in Table 29.1.

When a defective repressor cannot bind to operators, the mutant phages give clear plaques when they are plated. Normally a λ plaque is turbid because it contains not only phage but also lysogenized bacteria, which continue to grow because they are *immune* to infection by additional phage. By contrast, mutants that cannot establish lysogeny give clear plaques because all of the cells are lysed. Clear-plaque mutants in λ map in three different genes—*cI*, *cII*, and *cIII*. *cI* is the structural gene for one of the repressors mentioned above, and the other two genes control the synthesis of the cI protein.

Virulence mutations, which map in operators, also exhibit a clear-plaque phenotype, but there is an important distinction. Bacteria lysogenic for λ are immune to infection by a second λ phage because repressor in the cell binds to the operators of any input phage. This is true for *cI* mutants because they contain normal operators, which can bind repressors. However, virulent mutants can produce progeny phage following infection of an immune lysogen because their operators cannot bind repressor after entry into the cell. These observations are similar in principle to those resulting from the experiments with partial diploids in the *lac* operon.

Regulation of lysogeny in λ phage is similar to regulation of the lactose operon but is more complex.

FIGURE 29.8

Model of λ *cI* repressor binding to DNA. The repressor is a dimer and binds to a 17-base-pair region in a λ operator.

A Genetic Switch: Gene Control and Phage λ , M. Ptashne. © 1986 John Wiley & Sons Inc. Reproduced with permission of Blackwell Publishing Limited.

The λ *cI* Repressor and Its Operators

In 1967 Mark Ptashne isolated the λ repressor encoded by *cI*. The *cI* repressor is a dimeric protein, with a subunit M_r of 27,000; it binds through its N-terminal sequences to operator sites with a K_a of about $3 \times 10^{13} \text{ M}^{-1}$ (Figure 29.8). Repressor–DNA interactions have been used to map and characterize what turned out to be two operator regions, one on each side of *cI*. The two operators control divergent transcriptional events from a central regulatory region—leftward (O_L) and rightward (O_R); see Figure 29.7. As shown by footprinting, each operator contains three separate repressor-binding sites, each about 17 base pairs long. The three repressor-binding sites are homologous, but not identical (Figure 29.9), and they are separated by spacer regions of three to seven base pairs. Mutations that confer virulence map within the repressor-binding regions. A fully virulent mutant has at least two mutations—one in O_L and one in O_R .

The λ operators are remarkable in several respects other than their multiple repressor-binding sites. (1) Mutations that affect promoter activity lie between the repressor-binding sites. Thus, operators and promoters are *interspersed*, so the regulatory regions are more properly called $O_L P_L$ and $O_R P_R$. (2) As seen in Figure 29.9, $O_R P_R$ controls transcription from *two distinct promoters*—one rightward (P_R) and one leftward (P_{RM}). (3) Transcription from $O_L P_L$ and $O_R P_R$ is controlled by *two different repressors*—cI and Cro (the *cro* gene is an acronym,

**FIGURE 29.9**

The $O_R P_R$ region. The upper diagram shows the nucleotide sequence of the $O_R P_R$ region, including the three repressor-binding sites (O_{R1} , O_{R2} , and O_{R3}), the leftward promoter P_{RM} , and the -35 and -10 regions for the two promoters (shaded purple and blue, respectively). The thin horizontal arrows mark the operator half-sites. Below are the consensus sequences for the -35 and -10 regions and a chart that shows the partial homology among the operator half-sites (that is, the repressor-binding sites).

from cI repressor off). (4) Under certain conditions the cI repressor is a transcriptional *activator*, not an inhibitor. Another novel feature of this regulatory system is that cI transcription is initiated from different promoters under different physiological conditions. All of these complexities are related to the need for orderly and efficient phage gene control under quite different physiological conditions, as we shall see.

Early Genes in Phage λ

To understand the significance of cI gene regulation, we must identify several λ genes that are expressed early in infection (see Figure 29.7). cI and cro code for repressors, as just noted, and cII and $cIII$ both stimulate cI synthesis. rex is a gene of still unknown function, the only gene aside from cI known to be expressed during lysogeny. We encountered int , xis , and att in Chapter 26, when we discussed site-specific recombination. O and P function in the initiation of λ DNA replication. The N gene product interacts with NusA (see page 1142) to prevent transcription termination. The Q product activates late gene transcription.

Interactions between the Two λ Repressors

The interspersed $O_L P_L$ controls transcription of N , through interaction of its repressor-binding sites with the cI protein. However, most of the regulatory action occurs at $O_R P_R$, and it is here that the decision is made between lytic and lysogenic infection. This decision involves interactions of the two repressors, cI and Cro.

Quantitative footprinting experiments show that of the three repressor-binding sites in $O_R P_R$, cI binds most tightly to site O_{R1} , less tightly to O_{R2} , and still less tightly to O_{R3} . Moreover, cI binding is *cooperative*, so that when one repressor dimer is bound at O_{R1} , affinity for a second molecule is increased at O_{R2} . Cro protein is a dimer of identical 66-residue subunits. It binds considerably less tightly to any of the sites than does cI and in the reverse order of affinity. That is, site O_{R3} is favored, followed by approximately equal binding at O_{R2} and O_{R1} . Binding of Cro is noncooperative.

Although Cro is a repressor, it can also be considered an **antirepressor** because it antagonizes the action of cI in a very specific way. To understand how this works, we must first consider the transcriptional events occurring in the presence of varying levels of cI , illustrated in Figure 29.10. Because of the cooperative binding of cI to its operators, both sites O_{R1} and O_{R2} are usually occupied in the lysogenic state (Figure 29.10a), even though the intracellular concentration of cI is quite low (about 200 molecules per cell, or 10^{-7} M). This inhibits the rightward transcription of cro from its own promoter, but it *activates* the leftward transcription of cI from the promoter P_{RM} (the M stands for “maintenance,” because this is the promoter from which cI is transcribed during maintenance of lysogeny).

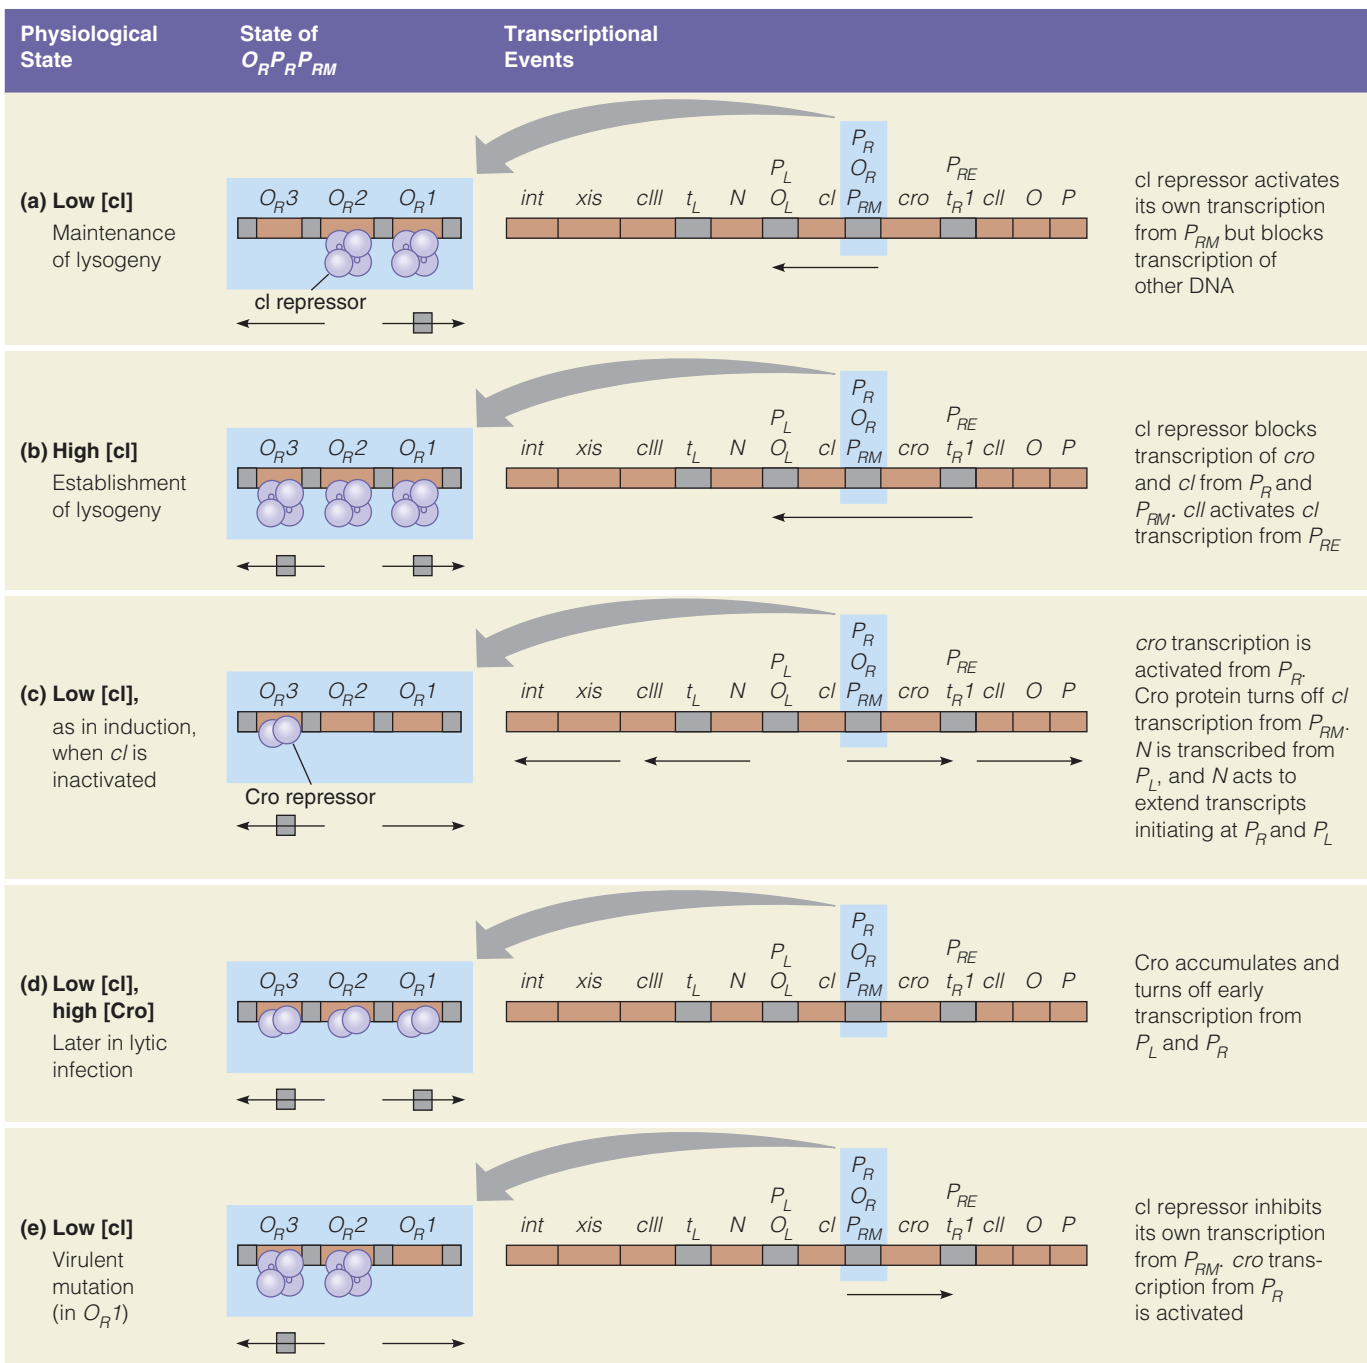

FIGURE 29.10

cI–Cro interactions in the $O_R P_{RM}$ region. Different physiological conditions lead to different interactions, with varying effects upon transcription of the rest of the λ genome. Gray boxes indicate blocked transcriptional events. Gene *rex*, which does not participate in regulation, is omitted for simplicity.

The -10 and -35 regions for the P_{RM} promoter lie within the operators. The evidence that cI really does activate its own transcription in the lysogenic state lies in the existence of a special class of *cI* mutants whose repressor can bind tightly at O_{R1} and O_{R2} but cannot stimulate *cI* transcription from P_{RM} .

During *establishment* of lysogeny (Figure 29.10b), when lytic and lysogenic genes are competing to determine the fate of the viral genome, there is a need for larger amounts of cI repressor than can be transcribed from P_{RM} . At this time a different *cI* promoter, called P_{RE} , is activated (*E* stands for “establishment”). In this activation the cII protein binds specifically at the -35 region of P_{RE} and stimulates RNA polymerase binding at that site. This transcriptional event yields a longer *cI* messenger RNA that is more efficiently translated than the message synthesized

from P_{RM} . The result is sufficient cI repressor to bind all three sites in O_R and, hence, to block both transcriptional initiation events.

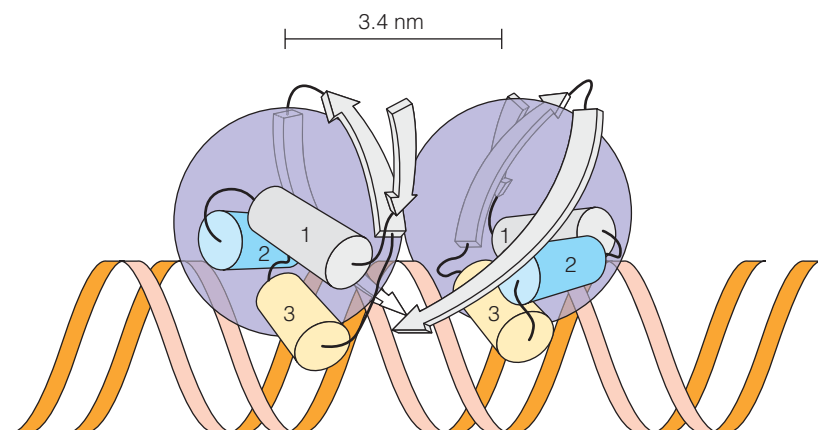

Now consider the events in prophage induction, when lysogeny is broken, leading to a lytic infection (Figure 29.10c). First, cI repressor is inactivated (we shall see shortly how this occurs), and the O_R sites become unoccupied. This permits transcription of cro from P_R , and the Cro protein blocks further transcription of cI from P_{RM} . At the same time, leftward transcription from P_L generates the N protein, blocking transcriptional termination at the sites indicated in Figure 29.10 as t_{R1} and t_L . Thus, the two early transcripts for Cro and N are extended to activate new genes. Leftward transcription generates Int and Xis proteins, necessary for prophage excision. Rightward transcription generates O and P, necessary for DNA replication.

Subsequent regulatory events, including the action of the gene Q protein, activate transcription of late-acting genes, which encode structural proteins of the virus. At this time it is desirable to suppress early gene transcription, so that the late proteins can be made at maximal rates. This involves further action of the Cro protein, which by this time has accumulated to the point that it can bind to both O_{R1} and O_{L1} , blocking transcription from P_R and P_L , respectively (Figure 29.10d). In infection by a virulent mutant (Figure 29.10e), cI transcription from P_{RM} is blocked, and this leads to activation of cro transcription from P_R .

Structure of Cro and cI Repressors and Related DNA-Binding Proteins

Studies of the three-dimensional structures of Cro and cI repressors have yielded remarkable insight into mechanisms by which proteins recognize specific DNA sequences. This in turn has greatly enhanced our understanding of how transcription is regulated through specific DNA–protein interactions.

In 1981 Brian Matthews determined the crystal structure of Cro protein. Cro is a homodimer of 66-residue subunits folded into three α -helical regions and three β strands (Figure 29.11). Model-building studies showed that two of the helices, numbered 2 and 3 in the figure, could fit within the major groove of the DNA double helix. These two helices are separated by a short β turn, forming a helix–turn–helix motif of the type we mentioned earlier for the CRP protein (see page 1238). In the Cro dimer, the two number 3 helices are 3.4 nm apart, the length of one turn of the DNA double helix. This distance suggested that the two subunits bind on the same side of the helix, in adjacent major groove sites, with the number 3 helices lying lengthwise in the grooves. This model was strongly supported by methylation- and ethylation-protection experiments, which identified the DNA functional groups in close contact with the protein. Note from Figure 29.9 that each operator site is an imperfect palindrome. Therefore, each of the two number 3 helices is in contact with a slightly different set of bases.

Lysogeny in λ phage is controlled by two repressors, cI and Cro, which bind with differing affinities to three operators in the $O_R P_R$ region of interspersed operators and promoters.

The helix–turn–helix motif is widely used in prokaryotic transcriptional regulatory proteins. Specific contacts are made between DNA major groove bases and amino acids in a recognition helix.

The amino acid sequence within and between helices 2 and 3 shows remarkable homology with corresponding sequences in a large family of sequence-specific DNA-binding proteins but *not* with DNA-binding proteins that showed no sequence preference. This observation suggested that the helix–turn–helix motif is a commonly evolved structural element in transcriptional regulatory proteins, at least in prokaryotes. Note that the *lac* repressor also contacts DNA in a helix–turn–helix motif (Figure 29.4). As indicated earlier, this was the first structural motif elaborated for a sequence-specific DNA-binding protein. In Chapter 27 we identified several other such motifs, more recently discovered, such as the zinc finger, leucine zipper, and the helix–loop–helix motif.

Helices E and F of the cAMP receptor protein adopt the helix–turn–helix motif, as mentioned on page 1147. Once the three-dimensional structure of λ cI repressor was shown also to have the helix–turn–helix motif, it seemed likely that the helix–turn–helix structure is involved in DNA binding in all of these proteins. The relevant structural similarities for Cro, CRP, and cI repressor are shown in Figure 29.12. Amino acid sequence homologies among these regions are shown for Cro and cI in Figure 29.13. Note that the sequences, though similar, are not identical. If they were identical, we would not be able to explain how Cro and cI repressors differ in their relative affinities for different operators. cI repressor contains an additional binding determinant—a pair of “arms,” or short polypeptide segments, that extend from helix 1 and can be seen in Figure 29.14 extending around the helix and establishing contacts on the other side of the DNA duplex. These arms probably explain why cI binds more tightly to its operators than Cro does.

The α -3 helix is called the **recognition helix** because its position deep within the major groove allows it to contact specific DNA bases and hence to determine sequence specificity of binding. The α -2 helix is in contact primarily with DNA phosphates. These electrostatic contacts strengthen binding but do not contribute to specificity. Supporting the concept of α -3 as a recognition helix is that most cI mutations that reduce specific binding of repressor to operator DNA alter the amino acid sequence in this region of the protein.

Crystallographic analysis of the respective DNA–protein complexes explains how Cro and cI can bind to the same operator sites with different binding affinities. As shown in Figure 29.15, the residues common to both proteins are in contact with DNA sequence elements common to all of the operators. In both proteins a glutamine residue interacts with one A–T base pair. cI repressor establishes specificity through a contact in O_R1 with a unique alanine residue, whereas Cro can be in contact with three specific base pairs in O_R3 with unique asparagine and lysine residues. Also, because the two α -3 helices lie closer together in Cro (2.9 nm) than in cI (3.4 nm), the orientations of these helices with respect to the major grooves of operator DNA are quite different.

The SOS Regulon: Activation of Multiple Operons by a Common Set of Environmental Signals

How is the λ *cl* repressor inactivated when the prophage is excised and begins a cycle of lytic growth? Various DNA-damaging treatments are known to induce λ prophages, including ultraviolet irradiation, inhibition of DNA replication, and chemical damage to DNA. Evidently the virus finds it advantageous to leave a damaged cell, like rats leaving a sinking ship. Because of the similarity in genetic control between the λ and *lac* systems, investigators sought a small molecule, perhaps a nucleotide, that would accumulate after these treatments and that might be the ligand that binds to *cl* and inactivates it. Surprisingly, the λ repressor was found to be inactivated by a quite different mechanism—proteolytic cleavage. Analysis of this cleavage reaction revealed the SOS system described in Chapter 26 as one of the elements in error-prone DNA repair, in which the genes are controlled by a single repressor–operator system. Such a set of unlinked genes, regulated by a common mechanism, is called a **regulon**. The heat-shock genes, all activated by a transient temperature rise, make up another regulon.

The control elements in the *E. coli* SOS regulon are the products of genes *lexA* and *recA*. We have encountered *RecA* protein before, in its role of stimulating DNA strand pairing during recombination. Strikingly, this small protein has an enzymatic activity in addition to the activities involved in recombination. When bound to single-stranded DNA, it can stimulate proteolytic cleavage of the proteins encoded by *cl*, *lexA*, and *umuD*. *LexA* is a repressor that binds to nearly three dozen operators scattered about the *E. coli* genome (Figure 29.16). Each operator controls the transcription of one or more proteins that help the cell respond after

FIGURE 29.16

The SOS regulon. The figure shows locations on the *E. coli* chromosome of some of the genes controlled by the LexA repressor. *dinA* is the structural gene for DNA polymerase II, while *dinB* encodes DNA polymerase IV and *dinF* is a damage-inducible gene of unknown function. *umuC,D* (so-called because mutants in this gene could not undergo ultraviolet mutagenesis) encodes the highly error-prone DNA polymerase V. LexA repressor (pink) is inactivated by proteolysis, which is somehow enhanced by a complex of RecA protein (blue) and single-strand DNA.

environmental damage that might harm the genetic apparatus. About 40 known proteins are induced as a result of LexA inactivation. These proteins include the gene products of *uvrA* and *uvrB*, involved in excision repair; *umuC,D*, the genes for the error-prone DNA polymerase V; *sulA*, involved in cell division control; *dinA*, the structural gene for DNA polymerase II; *recA* itself; *lexA* itself; *dinB*, the structural gene for error-prone DNA polymerase IV; and *dinF* (function unknown).

In a healthy cell, *lexA* and *recA* are expressed at low levels, with sufficient LexA protein to turn off the synthesis of the other SOS genes completely. LexA protein does not completely abolish either *lexA* transcription or that of *recA*. The trigger that activates the SOS system after damage is single-stranded DNA. As we have seen, UV irradiation generates gapped DNA structures, and so do other conditions that induce the SOS system. RecA binding within a gap activates LexA proteolysis by a mechanism not yet clear. Intracellular levels of LexA decrease, removing the LexA barrier to *recA* transcription. RecA protein accumulates in large amounts. Simultaneously, cleavage of the LexA protein activates transcription of all genes under *lexA* control. In a λ lysogen, cleavage of λ cI repressor is stimulated as well, activating prophage excision and replication, as discussed earlier.

Sequencing of operators that respond to LexA has yielded a consensus sequence, with 7 highly conserved bases in a 20-base-pair region. However, different LexA-sensitive genes have this sequence located quite differently with respect to the transcriptional start site. The location of each LexA operator, and its similarity to the consensus sequence, control the time after DNA damage at which a particular gene is expressed. Thus, the SOS response appears to be a coordinated series of events, controlled in part by the nature and severity of the initial DNA-damaging event.

Biosynthetic Operons: Ligand-Activated Repressors and Attenuation

The lactose operon is involved with catabolism of a substrate. Therefore, the gene products are not needed unless the substrate is also present to be consumed. A different situation is encountered with genes whose products catalyze biosynthesis—of

The SOS regulon is activated by DNA damage, which stimulates RecA to cause proteolytic cleavage of the LexA and λ cI repressors.

**FIGURE 29.17**

The *trp* operon. The figure shows regulation by *trp* repressor and by attenuation. *trpA*, the attenuator site, is shown in red.

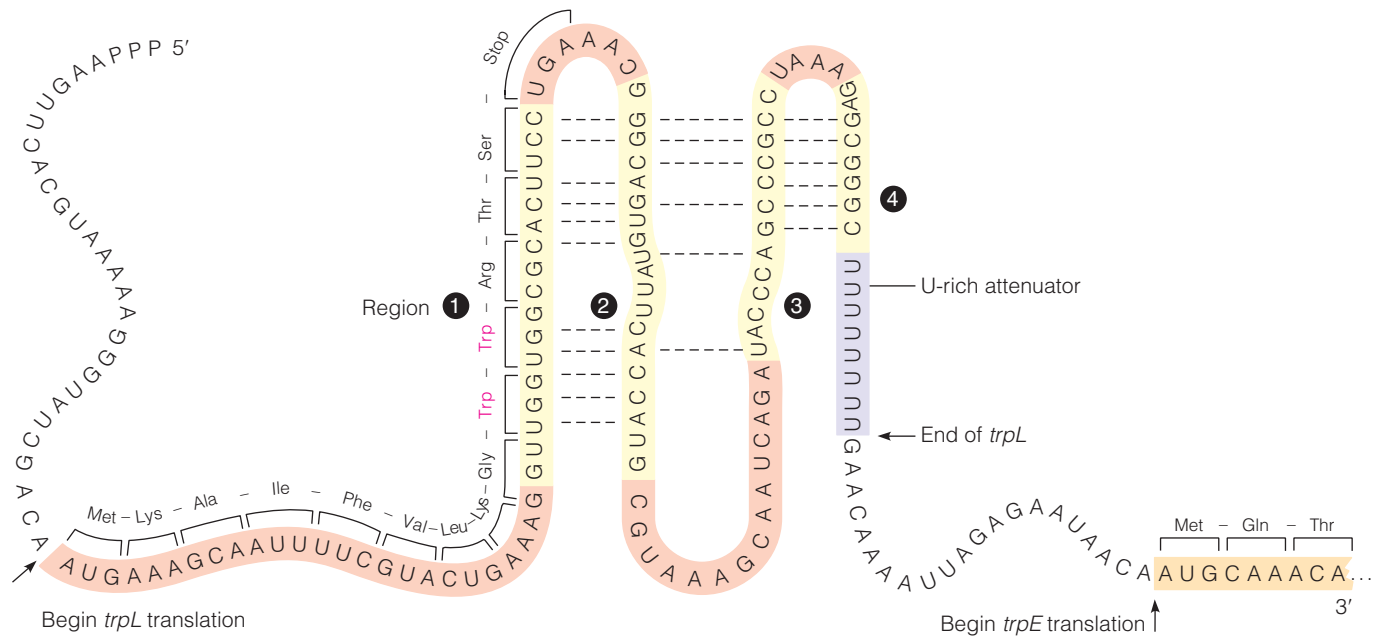

an amino acid, for example. Because biosynthesis consumes energy, it is to the cell's advantage to use the preformed amino acid, if it is available. Therefore, the regulatory goal is to repress gene activity, by turning *off* the synthesis of enzymes in the pathway when the end product is available. Regulation of the *E. coli trp* operon, which controls the five reactions transforming chorismic acid into tryptophan (see Figure 21.38, page 910), demonstrates two ways of accomplishing this shutdown: A repressor design in which binding of a small-molecule ligand *activates* the repressor, rather than inactivating it, and premature termination of transcription.

The *trp* operon consists of five adjacent structural genes whose transcription is controlled from a common promoter–operator regulatory region (Figure 29.17). The *trp* repressor, a 58-kilodalton protein encoded by the nonadjacent *trpR* gene, binds a low-molecular-weight ligand, namely tryptophan. However, in this case the protein–ligand complex is the *active* form of the protein, which binds to the operator and blocks transcription. When intracellular tryptophan levels decrease, the ligand–protein complex dissociates and the free protein (“aporepressor”) leaves the operator so that transcription is activated. If we call lactose an inducer in a catabolic system, it is appropriate to call tryptophan a **corepressor** in this anabolic system.

The crystal structure of the *trp* repressor–DNA complex shows a helix–turn–helix motif, comparable to that seen with the λ cI, Cro, and *lac* repressors; binding tryptophan to this protein reorients the helices to activate binding to DNA. Remarkably, this model shows no direct contacts between residues in the recognition helices and specific DNA bases. It has been proposed that bound water molecules make sequence-specific contacts between amino acids in the recognition helix and nucleotides in the operator.

The *trp* operon has an additional regulatory feature, now known to be involved in controlling numerous biosynthetic operons. Charles Yanofsky found that activities of the *trp* enzymes varied over a 600-fold range under different physiological conditions, more than could be accounted for by a repressor–operator mechanism alone. Analysis revealed a second mechanism, called *attenuation*, that involves early termination of *trp* operon transcription under conditions of tryptophan abundance. Note from Figure 29.17 a 162-nucleotide sequence called *trpL*, the *trp* leader region. A site called *a*, the attenuator, is 133 nucleotides from the 5' end of the *trpL* sequence. When tryptophan levels are high, transcription

The *trp* repressor inhibits tryptophan synthesis by binding as the repressor–tryptophan complex to the *trp* operator, blocking transcription.

**FIGURE 29.18**

RNA base sequence of the *trp* leader region. The four internally complementary sequences that participate in attenuation (yellow) are shown, as well as the two *trp* codons (magenta) in region 1 that act as a pause site for RNA polymerase. The translational stop codon after region 1 (see Chapter 28) may serve to prevent needless translation of those few full-length messages that are produced despite attenuation.

Attenuation is a regulatory mechanism in which ribosome positioning on an mRNA determines whether transcription of an operon will terminate before transcription of the structural genes begins.

terminates at *a*, to give a truncated 133-nucleotide transcript rather than the complete 7000-nucleotide *trp* mRNA. The structural genes are not transcribed, so tryptophan is not synthesized.

Critical to understanding the mechanism of attenuation is the presence of four oligonucleotide sequences in the *trp* leader region that are capable of base-pairing to form stem-loop structures in the RNA transcript (Figure 29.18). In the most stable conformation (Figure 29.19a), region 1 pairs with 2, and region 3 pairs with 4, to give two stem-loops. The 3–4 structure, being followed by eight Us, is an efficient transcription terminator because it resembles the factor-independent terminator structure shown in Figure 27.16 (page 1141).

When tryptophan levels are low (Figure 29.19b), formation of the 3–4 stem-loop is inhibited, and termination does not occur at the attenuation site. Note that region 1 contains two tryptophan codons (see Figure 29.18). In prokaryotes, translation is coupled to transcription, so a ribosome can begin translating a message from its 5' end while the message is still being synthesized at its 3' end. In this case, the ribosome stalls when it reaches the two tryptophan codons because there is insufficient tryptophanyl-tRNA to translate them. The presence of the bulky ribosome prevents region 1 from base-pairing with 2, leaving region 2 free to base-pair with 3. Once region 3 is unavailable to base-pair with 4, the 3–4 stem-loop transcriptional terminator cannot form, and the entire message is synthesized. Conversely, when tryptophan is abundant (Figure 29.19c), the ribosome does not stall, thereby occluding region 2 and allowing the 3–4 stem-loop structure to form, which leads to transcription termination on the 3 side of 3–4.

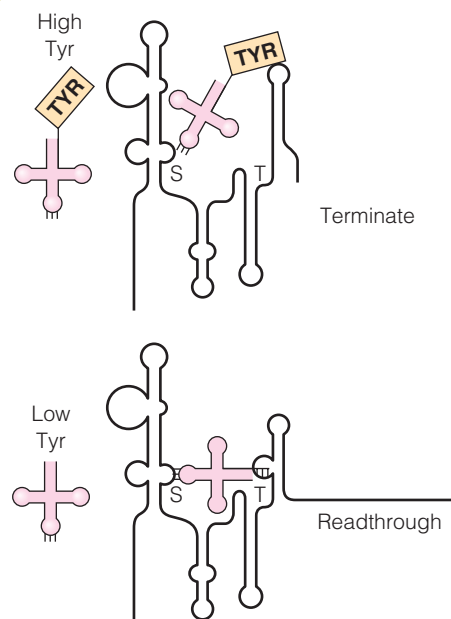

Neither the *trpR* system nor the attenuator is simply an on–off system. Both respond in graded fashion to the intracellular tryptophan level. Even though both systems are controlled by the same signal, the action of two distinct control systems greatly extends the possible range of transcription rates of the *trp* operon, giving maximum efficiency to regulation of these genes. At low tryptophan concentration the repressor–operator interaction is the principal regulatory mechanism, whereas the effects of attenuation are more significant at moderate to high tryptophan levels.

**FIGURE 29.19**

Mechanism of attenuation in the *trp* operon.
(a) Most stable conformation for leader mRNA.
(b) Conformation for leader mRNA at low tryptophan levels.
(c) Conformation for leader mRNA at high tryptophan levels.

Although the foregoing model was originally proposed simply by inspection of the *trp* leader sequence, it is now supported by several lines of evidence. Significant confirmation comes from the existence in other attenuation-controlled operons of “stalling sequences”—sequences at which movement of a ribosome is inhibited at a low concentration of the product of the operon. These include bacterial operons for synthesis of leucine, with four adjacent leucine codons in the leader sequence, and of histidine, with seven.

Transcriptional control via a quite different termination–antitermination mechanism in the leader region has been described in *Bacillus subtilis*. Synthesis of aminoacyl-tRNA synthetases is controlled by the level of aminoacylation of the cognate tRNA. For example, in cells starved for tyrosine, synthesis of tyrosyl-tRNA synthetase is activated by an antitermination mechanism that allows transcription to proceed past a potential termination site in a leader region. By contrast, termination proceeds efficiently when most of the appropriate tRNA is charged with tyrosine, and there is no need to synthesize more of the aminoacyl-tRNA synthetase. The mechanism involves a complex secondary structure of the upstream leader sequence for *tyrS*, the structural gene for tyrosyl-tRNA synthetase. As shown in Figure 29.20, uncharged tRNA^{Tyr} can stabilize an antiterminator structure in leader RNA, by means of base-pairing interactions between the anticodon and mRNA, as well as the 3' end of the uncharged tRNA. These latter interactions are hindered when the 3' end of tRNA is aminoacylated. Thus, readthrough occurs, and the gene is transcribed. By contrast, the aminoacylated tRNA cannot form these base-pairing interactions. Thus, the leader forms a terminator, which prevents transcription of the gene.

**FIGURE 29.20**

Model for induction of *B. subtilis* *tyrS* gene by uncharged tRNA^{Tyr}. Readthrough leading to gene expression is favored when tRNA^{Tyr} is in the uncharged state, as described in the text.

Control of rRNA Synthesis: The Stringent Response

The last prokaryotic transcriptional control mechanism presented here—the **stringent response**—was discovered more than four decades ago but is not yet understood in detail. The synthesis of ribosomal and transfer RNAs in bacteria is inhibited when protein synthesis is decreased by amino acid starvation. This inhibition evidently prevents the unnecessary production of translational machinery when protein synthesis is blocked. During amino acid starvation uncharged tRNAs bind to the ribosome A site. This leads to ribosomal binding of a protein called **stringent factor**, an enzyme that phosphorylates GTP at the 3' position, giving a nucleotide that we abbreviate pppGpp. Next the γ phosphate of the 5'-triphosphate moiety is cleaved off, giving a regulatory nucleotide, **guanosine 3',5'-tetrphosphate** (ppGpp). Binding of ppGpp to RNA polymerase leads to inhibition of ribosomal RNA synthesis. A class of mutants, called *relaxed*, cannot synthesize pppGpp, and therefore does not accumulate ppGpp under these conditions and does not show the stringent response. In other words, for these mutants amino acid starvation does not cause inhibition of rRNA or tRNA synthesis.

Guanosine 3',5'-tetrphosphate

Guanosine 3',5'-tetrphosphate senses amino acid starvation and responds by decreasing ribosomal RNA synthesis.

Applicability of the Operon Model: Variations on a Theme

Biochemical analyses of the *lac*, λ phage, *trp*, and SOS regulatory systems have confirmed the central features proposed by Jacob and Monod—that gene expression is regulated at the level of transcription and that specific protein–DNA interactions control the rate of transcription, primarily by regulating transcriptional initiation. These analyses have also revealed several important variations on that simple theme—including positive control of initiation, interspersed operators and promoters, dual proteins binding to the same site, multiple operons controlled by the same repressor, induction of DNA bending by regulatory proteins, and early termination as a regulatory mechanism. References at the end of this chapter will direct you to information about other well-studied operons, particularly the galactose and arabinose operons.

However, although the operon concept is well established, more recent analysis by genomic techniques, including microarray analysis and chromatin immunoprecipitation, has shown transcriptional regulation in bacteria to be more complex than earlier postulated. Many operons are controlled by more than one transcription factor— σ factors, repressors, and transcriptional activators. For example, the transcription of *nrdA* and *nrdB*, the structural genes for ribonucleotide reductase subunits, is controlled by at least five different proteins, including CRP. Eight proteins control transcription of *sodA*, the structural gene for superoxide dismutase. In addition, more than two dozen multitarget transcription factors are known, including the CRP and LexA discussed in this chapter. Findings such as these suggest hierarchical networks of transcriptional regulation.

In addition, although the operon model provides the basis for our understanding of prokaryotic transcription, developments in recent years have highlighted important regulatory processes occurring at other levels of gene expression—particularly translation. We deal with some of these processes later in this chapter.

Transcriptional Regulation in Eukaryotes

From Chapter 27 you are already aware that transcription and its regulation are far more complex in eukaryotic cells than in bacteria and viruses. Much of the added complexity stems from the fact that the transcription template in eukaryotes is chromatin, not naked DNA. Also, the complexity associated with multicellularity and highly differentiated states demands higher orders of regulation. Among the eukaryotes complexity of regulation increases with complexity of the

organism. The genome of the nematode worm, *Caenorhabditis elegans*, contains about 20,000 genes, nearly as many as humans, while the fruitfly *Drosophila* has about 14,000 genes. As we mentioned earlier, alternative splicing helps to account for the increased information content of the human genome, despite surprisingly small differences in numbers of genes. Differences in transcriptional regulation contribute as well. Both worms and flies are estimated to encode about 1000 transcription factors, while the human genome encodes about 3000. But the difference in complexity is far more than three-fold because regulation by transcription factors is *combinatorial*. Because many different factors are used in assembling a transcription initiation complex, and because each transcription factor can participate in controlling multiple genes, a nearly infinite number of transcription factor combinations is possible. By contrast, bacteria have about a half dozen RNA polymerase σ subunits, which can be considered as transcription factors because they bind to RNA polymerase and direct it to certain groups of promoters. However, a single bacterial RNA polymerase molecule contains just one σ factor. So, even though bacterial genes are regulated by multiple transcription factors, as mentioned in the previous section, the multiplicity of factors controlling transcription of a single gene is far greater in eukaryotic cells.

The importance of transcription factors in generating biological diversity is illustrated by recent studies showing interspecies variations in distribution of transcription factor binding sites. In one such study, five vertebrate species were compared by ChIP-seq with respect to distribution in one gene, *PCK1* (which encodes an isoform of protein kinase C), of binding sites for one transcription factor, CEBPA (CCAAT/enhancer-binding protein α). As shown in Figure 29.21, the binding-site distribution varied dramatically among these five species. Less dramatic, but comparable, variation has been seen in transcription factor binding among different humans, showing this as a feature both in speciation and in inter-individual variation within a species.

Additional regulatory complexity is brought about by the more recently discovered existence of small regulatory RNA molecules, called microRNA, or miRNA (page 1267). As we shall see, the number of microRNA molecules encoded by a genome is closely related to the complexity of the organism.

Chromatin and Transcription

Recall from Chapter 24 that chromatin consists of individual units—nucleosomes—with each nucleosome containing 200 or more base pairs of DNA, 147 of which are wrapped about a histone core. Within these 147 base pairs, the central 80 or so are organized by a heterotetramer of histones H3 and H4. About 40 base pairs on each side are more loosely associated with H2A/H2B dimers. Spacer DNA, which is not associated with the core histones, associates with histone H1 and other proteins. The core histones (H2A, H2B, H3, and H4) have a common helical core structure, called the *histone fold*, joined to a relatively unstructured N-terminal tail. Specific amino acid residues within the tails are subject to modification—acetylation, methylation

A large number of transcription factors helps to explain the complexity of higher eukaryotes, even though the number of genes in a genome may be smaller than originally expected.

FIGURE 29.21

Binding site variation for transcription factor CEBPA along gene *PCK1* as determined by ChIP-seq. There is one highly conserved binding site, but essentially all of the other sites are variable. To the left is an evolutionary tree showing divergence in millions of years ago (MYA) for the five species—Hsap (human), Mmus (mouse), Cfam (dog), Mdom (opossum), and Gqal (chicken).

T. Odom, Five-vertebrate ChIP-seq reveals the evolutionary dynamics of transcription factor binding. © 2010. Reprinted with permission from AAAS.

(mono-, di-, and tri-), ubiquitylation, sumoylation, ADP-ribosylation, and phosphorylation. Acetylation usually involves lysine amino groups. By neutralizing the charge, acetylation loosens the ionic bonds that link histones to DNA, and generally activates the target nucleosome as a transcription template, whereas deacetylation, conversely, tends to inhibit transcription.

Chromatin exists within cells either in a highly compacted form, called **heterochromatin**, or a more loosely structured form, called **euchromatin**. Heterochromatin is transcriptionally inactive, and genes in particular tissues, which are permanently silenced in those tissues as a result of differentiation, are often found in heterochromatin. The repressed chromatin structure is often associated with methylation of histone H3 at lysine 9 (H3K9). Methylation at this site leads to binding of HP1 (Heterochromatin Protein 1) at that methyl mark. Repression is also induced by other histone modifications, such as H3K27 or ubiquitylation of H3K119. Whether these modifications are causes or effects of the repressive structure is not yet clear. By contrast, the H3K4 mark is a transcriptional activating signal. Many biochemists believe in a “histone code” that would relate specific chromatin modifications to specific regulatory effects in a predictable and rational way, as seen with the genetic code. So far, however, the histone code has proved to be elusive, and recent evidence indicates that the effect of a particular histone modification upon gene expression is dependent upon the context, that is, the modification status of adjacent or nearby histones. This has led some investigators to suggest that the relationship between histone modification and gene expression is more akin to a “language” than a more restrictive “code.”

In order for a gene to be transcribed, the promoter must be relatively clear of nucleosomes; stated otherwise, it should lie in a nucleosome-free region (NFR). The nuclease-hypersensitive sites that we discussed in Chapter 27 probably represent NFRs. To some extent, clearing a promoter of histones is a function of chromatin remodeling complexes (Chapter 27; also see page 1254). In addition, chromatin remodeling and the binding of certain transcription factors are evidently responsible for the replacement of the canonical histones H2 and H3 by variants called H3.3 and H2A.Z. It is not clear how these replacements lead to transcriptional activation, but circumstantial evidence for an activating role is strong. Use of ChIP-seq (Tools of Biochemistry 27D) has shown that H2A.Z is specifically associated with nucleosomes near the transcription start site (Figure 29.22).

Several factors combine, including chromatin remodeling and histone modifications, to render eukaryotic transcription start sites relatively free of nucleosomes.

Transcriptional Control Sites and Genes

As in prokaryotic gene expression, transcription in eukaryotes is regulated by the interplay of *trans*-acting proteins that interact with *cis*-acting sites on the DNA template. *Cis*-acting sites within the promoter include NFR (nucleosome-free region), TSS (transcription start site), Inr (initiation region), TATA box, and BRE (TFIIB recognition element). This list is not exhaustive. Sites farther upstream are generally called enhancers in metazoans, and UAS (upstream activator sites) or

FIGURE 29.22

Distribution of H2A.Z-containing nucleosomes near a transcription start site (TSS). ChIP-seq was used to demonstrate that in humans, *Drosophila*, and yeast, the modified histone H2A.Z is most abundant in nucleosomes at positions +1 and -1 relative to the transcription start site (TSS).

URS (upstream repressor sites) in yeast. Although the TATA box, as we indicated in Chapter 27, is the most widely distributed core promoter element, only about 20% of yeast genes actually contain a TATA box. Because of the large number of proteins bound in each initiation complex, there is tremendous variability among different genes in promoter and enhancer sequences.

Trans-acting factors include not only general transcription factors but also chromatin remodeling factors, chromatin modifying factors (such as histone acetyltransferases, deacetylases, methylases, or demethylases), and a multiprotein complex called *Mediator*, which we briefly mentioned in Chapter 27. Mediator is a large multisubunit complex found in all eukaryotes. Mediator links upstream activating (or repressing) elements with RNA polymerase II—specifically, with the C-terminal domain of the largest subunit, which undergoes phosphorylation as a prerequisite to activation. Mediator in yeast contains 21 subunits plus a 4-subunit subassembly that, when linked to Mediator, represses transcription, as indicated in Figure 29.23b. The large size of Mediator can be seen in Figure 29.24, which shows image-processed electron micrographs of the complex in association with RNA polymerase II.

FIGURE 29.23

Mediator as a bridge between gene-specific regulatory factors and the general transcription machinery at the pol II promoter. (a) Activation. Mediator has three distinct structural domains—head, tail, and middle. The tail domain interacts with transcriptional activators (ACT, in red) and links Mediator with RNA polymerase. **(b)** Repression. The four-subunit complex containing Srb8, Srb9, Srb10, and Srb11, when bound to Mediator, prevents its interaction with RNA polymerase II and the basal transcription machinery.

Nucleosome Remodeling Complexes

These complexes couple the energy of ATP hydrolysis to changes in chromatin structure, usually resulting in transcriptional activation. In most cases the energy of ATP hydrolysis is coupled to translocation of the histone core particle along DNA, with the core histones either sliding along DNA or being displaced. Four families of chromatin remodelers are known, classified in terms of the structure of the ATPase-containing subunit. Additional remodelers are known, but have not yet been well characterized in terms of structure or biological function. Figure 29.25 shows the domain organization of the ATPase-containing subunit in each of the four described families.

The SWI/SNF ATPase subunit contains a **bromodomain**, a domain that interacts specifically with acetylated lysines. This draws the complex to chromatin that has already become somewhat activated by histone acetylation. Chromatin remodeler RSC, which was mentioned earlier (page 1153), is a member of the SWI/SNF family. Recent evidence indicates that this complex completely dissociates histones from DNA, beginning with disruption of DNA-histone bonds by the remodeler, followed by ATP-dependent translocation. Presumably, once transcription has been initiated and RNA polymerase has moved downstream, chromatin is reassembled. In yeast the RSC complex also functions at promoters for RNA polymerases I and III.

The INO80 catalytic subunit is distinctive in that the ATPase domain is split. This complex plays a broader role in cellular metabolism than the other remodelers in that it is found in DNA repair complexes and at sites of resolution of stalled replication forks. Recent evidence points to additional roles in telomere regulation, chromosome segregation, and cell checkpoint control. A principal action of this remodeler is replacement in chromatin of canonical histones with histone variants, specifically, exchange of H2A for H2A.Z. As mentioned earlier, H2A.Z is particularly abundant in those nucleosomes nearest to a transcription start site.

Unlike the complexes just described, the ISWI family of remodelers is associated with transcriptional repression. The domains identified in Figure 29.25 as SANT and SLIDE are thought to bind histone tails and linker DNA, respectively. Although little is known about the function of this family, recent evidence in *Drosophila* identifies a role in maintaining the higher-order structure of the male X chromosome.

Chd1, the ATPase subunit of the CHD remodeler, contains a **chromodomain**, which interacts specifically with methylated histones. In vitro studies show strong interaction with methylated H3K4, a transcription-activating methyl mark. Although CHD has been found to be associated with transcriptionally active chromatin, its specific function has not been identified. However, intense interest has focused upon the relationship between Chd1 and the ability of embryonic stem cells to maintain the pluripotent state, that is, the ability to develop into any

kind of differentiated cell. So the current picture of this family of remodelers is that, by helping to maintain all chromatin in an open conformation, CHD helps to retain in that cell the ability to express any combination of genes needed for a specific developmental pathway.

Transcription Initiation

As noted earlier, most sequence-specific regulatory sequences, such as nuclear receptor-binding sites, are found some distance upstream from transcription-start sites, and Mediator plays a key role in connecting these sites to the downstream promoters. It is estimated that each eukaryotic gene contains about five specific regulatory sites. Because of the large number of sequence-specific regulatory proteins, and their uses in controlling multiple genes, this complexity is probably necessary to prevent the accidental expression of a gene that might result if only one or two specific regulatory events needed to occur.

The action of chromatin-remodeling complexes, the modifications of histones near promoter sites, the binding of upstream sequence-specific transcriptional activators, and their relationship to Mediator set the stage for final assembly of a transcription complex—binding of RNA polymerase II and the several general transcription factors that we identified in Chapter 27, including TATA box-binding protein and TFII proteins A, B, D, E, F, and H. TFIIH contains at least two enzymatic activities—an ATP-dependent helicase that unwinds template DNA strands to expose the transcription template, and a protein kinase that converts the initiation complex to an elongation complex, by phosphorylating serine residues in the C-terminal domain of the largest pol II subunit.

Recent studies with ChIP techniques indicate that RNA polymerase II is bound at most genes, whether expressed or not, although not all genes are fully occupied by pol II. However, this finding suggests that binding of these general transcription factors, not binding of pol II itself, is rate-limiting for initiation. Although these events are largely independent of the gene being transcribed, there is some gene specificity. For example, Rap1 is a protein that binds directly to TFIID, and this interaction helps to drive the transcription of the highly expressed genes for ribosomal protein synthesis. In any event, the sequence of binding general transcription factors is as we indicated in Chapter 27 (Figure 27.24), and the final preinitiation complex can be schematized as in Figure 29.26.

As is seen also with prokaryotic transcription, many eukaryotic initiation complexes pause soon after initiation. This may involve a site for specific regulation because several protein factors are known both to promote and to overcome pausing. One such positive regulator is called P-TEFb (positive transcriptional elongation factor b). This protein phosphorylates the second serine in each of the heptapeptide carboxy terminal repeats in RNA polymerase II—perhaps augmenting the activity of the TFIIH protein kinase, which acts at the fifth serine residue in each repeat.

Chromatin-remodeling complexes use the energy of ATP hydrolysis to move nucleosomes out of the way for transcription initiation, but they participate in other functions as well.

Most, but not all, events involving general transcription-factor binding at promoters are nonspecific with regard to the gene being activated.

FIGURE 29.27

Writers, readers, and erasers of the CTD phosphorylation code. Writers (serine kinases), readers, and erasers (phosphatases) are identified under the specific serine phosphorylation pattern that most strongly stimulates binding of the respective protein to the CTD. The pattern shown here is oversimplified because evidence suggests that S7, Y1, and T4 also undergo phosphorylation and dephosphorylation during the transcription cycle.

Regulation of the Elongation Cycle by RNA Polymerase Phosphorylation

The heptad repeats in CTD, the C-terminal domain of the large RNA polymerase subunit, are unphosphorylated when the enzyme interacts with Mediator for placement at the promoter. The phosphorylation status of these repeats changes with time after initiation, in a functionally significant way that suggests a “CTD phosphorylation code.” As indicated in Figure 29.27, proteins that interact with the CTD can be classified as code “writers” (serine kinases), “readers” (proteins that interact with specific phosphorylation patterns), or “erasers” (serine phosphatases). Among the proteins binding early are those involved in modifying the RNA 5' end by synthesizing the 7-methyl guanylyl cap. Other CTD readers are enzymes that change the histone modification status, and the patterns change as the predominant CTD phosphorylation changes from Ser-5 to Ser-2 as termination approaches. Figure 29.28 shows the predominant histone and CTD modification patterns as transcription proceeds. The late modifications help to recruit protein factors involved in transcription termination. Strikingly, the CTD itself appears to participate in these changes through *cis-trans* isomerization of the proline residues in the CTD, catalyzed by the proline isomerase Ess1, which binds preferentially to the doubly phosphorylated CTD.

Time-dependent changes in CTD phosphorylation are of intense interest to investigators trying to understand the “histone code,” or “language,” mentioned earlier as a presumed relationship between specific histone modification patterns and functional consequences, such as activation or repression of specific genes, or epigenetic phenomena. Epigenetics refers to heritable changes in gene expression that do not involve changes in DNA base sequence. We discuss epigenetics in more detail in the next section, in connection with DNA methylation.

The shifting pattern of CTD phosphorylation as RNA polymerase moves through a gene controls events such as mRNA capping, histone modifications, and the recruitment of transcription termination factors.

DNA Methylation, Gene Silencing, and Epigenetics

DNA Methylation in Eukaryotes

As we discussed in Chapter 24, DNA methylation in prokaryotes is well understood. The target base for methylation is always adenine, and the processes involving methylation include restriction/modification and methyl-directed mismatch repair. The situation in eukaryotes is quite different. The only eukaryotic DNA base to undergo methylation is cytosine. In eukaryotes DNA mismatch repair does not involve methylation, and there appears to be no direct eukaryotic counterpart to restriction and modification. Instead, DNA methylation participates in still incompletely understood processes involving gene silencing.

Those cytosine residues undergoing methylation in eukaryotes are usually C's that are immediately 5' to G's, *i.e.*, C's in a CpG dinucleotide. CpG is relatively underrepresented in eukaryotic genomes, possibly because of the high frequency with which C can undergo deamination to give U. Base excision repair will normally replace the U with T, which becomes part of a G-C to A-T transition mutational pathway. Deamination of 5-methyl-C gives T directly, making the G-mC deamination an even stronger event in effecting a transition mutation.

Although CpG dinucleotides are underrepresented in DNA, there are regions of eukaryotic genomes in which CpG dinucleotides are found at the statistically expected frequency. These regions are called **CpG islands**. CpG islands are generally longer than about 500 base pairs, and they have a total GC content of 55% or greater. Generally, C's in CpG islands are undermethylated, while most CpG methylation occurs in CpG-poor regions of the genome. For unknown reasons, this distribution of methylated sites is often reversed in cancer cells, and interest is focused upon the question of whether this is related to altered patterns of gene expression seen in cancer, such as decreased expression of tumor suppressor genes.

DNA methylation patterns are heritable, making DNA methylation the best understood example of an epigenetic process. As mentioned earlier, epigenetics refers to the heritable transmission of a gene expression pattern that does not involve a change in DNA base sequence. The pattern of methylation in a particular genome is established early in embryonic development. Mammalian cells contain three different DNA-cytosine methyltransferase enzymes—Dnmt1, Dnmt3a, and Dnmt3b. *De novo* methylation, early in development, is carried out by Dnmt3a and 3b. How these enzymes generate specific methylation patterns is not yet clear. However, once an embryonic methylation pattern is established, that pattern can be faithfully reproduced by the maintenance methylase, Dnmt1, which tracks with the replication apparatus and methylates every C in the daughter strand that was methylated in the parental strand. This process is illustrated in Figure 29.29. A key finding leading to understanding this phenomenon, also shown in Figure 29.29, is the effect of **5-azacytidine** upon maintenance methylation. Azacytidine is a cytidine analog that can be metabolized to the 5-aza analog of dCTP and be incorporated into DNA. However, because the pyrimidine ring of 5-azacytidine contains N instead of C at position 5, it cannot undergo stable methylation. Hence, in the presence of 5-azacytidine, a 5-mCpG dinucleotide is converted to CpG in three rounds of replication. This treatment was found to activate previously repressed genes, a finding that constituted important early evidence that correlated DNA methylation with gene silencing. For example, adult bone marrow cells were found to reactivate the synthesis of fetal hemoglobin, which is normally repressed during development.

Recent structural analysis of Dnmt1 reveals an autoinhibitory mechanism, in which unmethylated CpG dinucleotides are occluded from the active site. Hence, only hemimethylated CpG nucleotides can be methylated, explaining how this enzyme can function only in maintenance methylation.

Abnormal DNA methylation patterns are a hallmark of cancer cells.

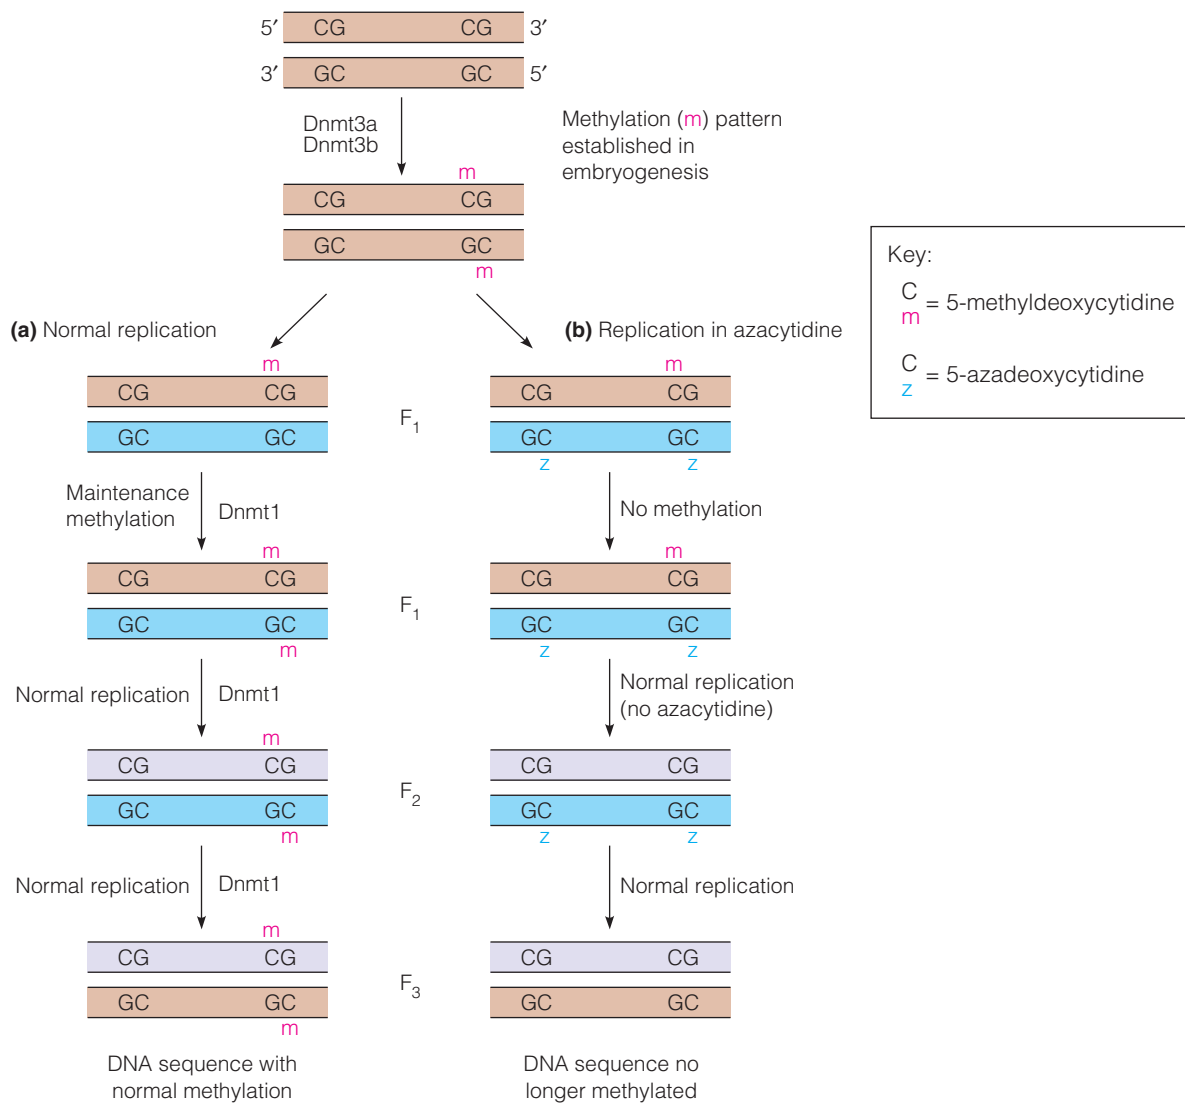

FIGURE 29.29

De novo and maintenance methylation of DNA and the effect of 5-azacytidine upon DNA methylation.

5-Azacytidine

5-Azadeoxycytidine triphosphate

More recent evidence points to a natural role of DNA demethylation in activation of repressed genes. In early 2010 two laboratories reported that deamination of DNA-methylcytosine bases by AID, a DNA-cytosine deaminase involved in antibody maturation (page 1109), also plays a role in the induced dedifferentiation of somatic cells to induced pluripotent cells, capable of differentiation in culture to any state. This is an important development in attempts to use stem cell biology for therapeutic purposes.

There seems not to be a single mechanism accounting for gene repression as a consequence of methylation. In some cases binding of transcription factors to methylated DNA is inhibited. In other cases there are effects upon histone modifications that promote transcriptional inactivation. For example, as we have seen, H3K4 methylation is associated with transcriptionally active chromatin. Some H3K4 methyltransferases (these are *protein* methyltransferases) are targeted to sites containing high levels of CpG dinucleotides, which in turn interfere with methylation of these histones and, hence, with transcriptional activation.

DNA Methylation and Gene Silencing

Whatever the mechanism in terms of effects upon chromatin structure, it is clear that DNA-cytosine methylation is responsible for permanent gene silencing. Two such phenomena are well established—*X chromosome inactivation* and establishment and maintenance of *gene imprinting*. During embryonic development in mammals, one of the two X chromosomes in female cells is permanently inactivated by DNA-cytosine methylation. As described above, this involves *de novo* methylation, followed by maintenance methylation throughout life. The significance of this modification is that the level of expression of genes carried on the X chromosome is then approximately equal for both male and female cells. In most mammals the choice of a chromosome to inactivate is random. Gene imprinting is similar, in that it involves permanent gene inactivation during embryonic development. For some genes only a single parental allele is expressed—some from the father, some from the mother. Again, DNA methylation is responsible for shutting off expression of the imprinted gene. Structural analysis of the Dnmt3a DNA methylase suggests an explanation for the specificity of this latter effect. Dnmt3a functions in concert with a regulatory protein, Dnmt3L. These proteins were found to co-crystallize as a tetramer with the structure Dnmt3L-Dnmt3a-Dnmt3a-Dnmt3L. Binding this protein to DNA showed the two methylase active sites to be about one DNA helical turn apart (Figure 29.30). Examination of several maternally imprinted genes showed them to have a periodicity in spacing of CpG dinucleotides, some 8 to 10 nucleotides apart, suggesting a basis for the specificity in choice of the genes to be imprinted.

Imprinting is affected in a rare condition called *Prader-Willi syndrome*. In this condition a region of paternal chromosome 15 is deleted or unexpressed. This region includes a gene that controls imprinting; normally paternal genes from this region are expressed, while maternal genes are silenced. The defect in imprinting means that, while most people have one working copy of each gene in this region, affected individuals have none. The condition is characterized by short stature, obesity, and delayed puberty. In a comparable condition, *Angelman syndrome*, the same region of chromosome 15 is affected in the maternally derived genetic material.

Genomic Distribution of Methylated Cytosines

Recently, the availability of second- and third-generation DNA sequencing procedures, which allow rapid generation of vast amounts of sequence data, has made it possible to analyze the entire human “DNA methylome,” that is, the distribution of 5-methylcytosine bases throughout the genome. The approach is to treat DNA with sodium bisulfite, which quantitatively deaminates cytosine to uracil, but does not affect methylcytosine. This is followed by high-throughput sequence analysis. The most intriguing finding, when this was carried out recently, was that embryonic stem cells have about one-quarter of their methylcytosines in a non-CpG

DNA methylation can lead to permanent gene inactivation by processes involving chromatin structure and histone modification.

DNA CpG methylation is responsible for at least two developmental gene inactivation processes—X chromosome inactivation and gene imprinting.

FIGURE 29.30

Structure of the Dnmt3a heterotetramer complexed with a DNA 25-mer. Although the two Dnmt3a active sites are not specifically shown in this model, they were reported to be about ten base pairs apart. Binding of multiple methylase molecules along the DNA duplex could account for preferential methylation of a gene that contained CpG base pairs at 8- to 10-base pair spacings. The two identical subunits are shown in green and the L subunits in light blue. PDB ID 2QRV.

context. When embryonic stem cells underwent differentiation, non-CpG methylation disappeared. Moreover, it is known that certain cell lines can be induced to return to a pluripotent state (able to differentiate into any state), and these induced pluripotent cell lines were found once again to contain a large proportion of non-CpG methylated sites. These findings provide important clues to the potential use of embryonic stem cells in treating diseases such as type 1 diabetes or Parkinsonism. Incidentally, techniques are now available for determining DNA base sequence and cytosine methylation status in a single operation, without a need for bisulfite treatment.

Other Proposed Epigenetic Phenomena

5-Hydroxymethylcytosine

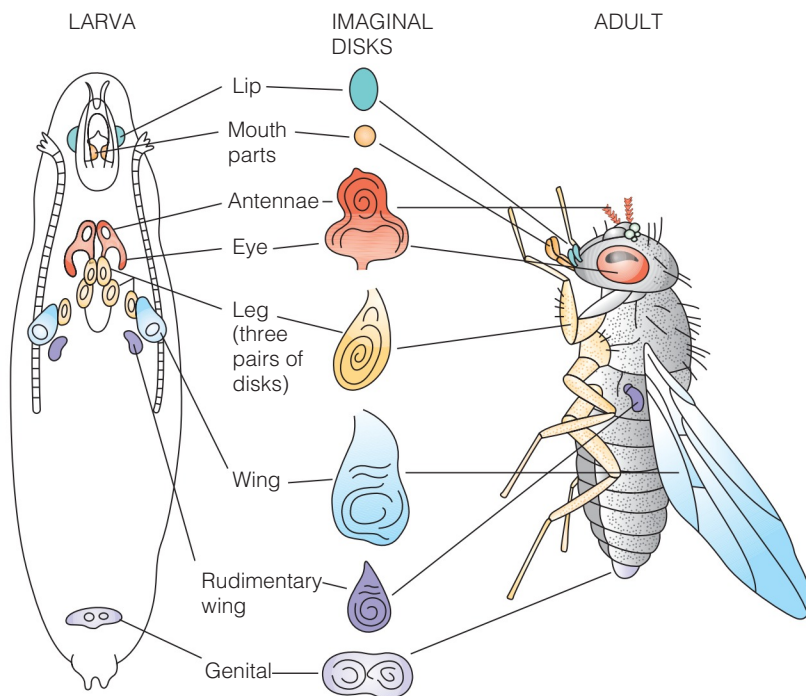

In 2009 it was reported that DNAs from some cells, mostly in nervous tissue, contain significant proportions not only of 5-methylcytosine but also of *5-hydroxymethylcytosine*. As we noted in Chapter 22, bacteriophage T4 and its relatives have 5-hydroxymethylcytosine completely substituted for cytosine (page 950). In phages the modification occurs at the nucleotide level. The situation in mammalian cells is quite different; hydroxymethylcytosine arises through oxidation of methyl groups in 5-methylcytosine. Recent evidence suggests that DNA-cytosine oxidation is a process in DNA demethylation, leading to reactivation of silenced genes.

Chromatin Histone Modifications

Intense interest is focusing upon other possible mechanisms of epigenetic inheritance, including processes involving chromatin histone side chain modification and noncoding RNA molecules. In particular, the premise that modification of histone amino acid residues is an epigenetic phenomenon is widely accepted. There is no doubt that histone side chain modifications affect gene expression, and that no changes in DNA base sequence are involved. The issue is whether patterns of histone modification are inherited from one cell generation to the next. There is evidence that daughter chromosomes after mitosis both have histone modifications characteristic of the parent cell, a concept that supports histone modification as an epigenetic phenomenon. However, as stated in a recent review article, “To date ... only DNA methylation has been shown to be stably inherited between cell divisions” (R. Margueron and D. Reinberg [2010] *Nature Reviews Genetics* 11:285–296). One possible way to account for histone-mark transmission would be for histone dimers to mix during mitosis such that, for example, the two H2A/H2B dimers in a newly replicated nucleosome would contain one parental dimer and one newly synthesized, such that the parental dimer could somehow instruct the new dimer regarding its modification pattern. However, although density labeling experiments are consistent with this concept of histone mixing, we know nothing about how a histone molecule in parental chromatin might serve as a template for the corresponding histone after replication.

Control of Higher-Order Developmental Patterns: Homeotic Genes

Throughout this chapter we have emphasized how carefully the life of an organism, whether single-celled or multicellular, is programmed in its DNA. We now realize that for eukaryotes *much* more information is stored in DNA than simply the recipes for a collection of proteins and special nucleic acids. A variety of signals are hidden within the genes themselves—signals to determine how transcripts will be cut and spliced, where gene products will go, and even how long they will last. In addition, a vast amount of information, usually coded in the sequences surrounding certain genes, specifies when, either in the course of

**FIGURE 29.31**

Imaginal disks in the development of *Drosophila*. Each of the imaginal disks shown in the larva develops into a specific segment of the adult.

From J. W. Fristrom, R. Raikow, W. Petri, and D. Stewert (1970). In *Problems in Biology: RNA in Development*, E. W. Hanly, ed. University of Utah Press. Reprinted by permission.

development or in response to environmental stresses, certain genes are to be transcribed in certain cells.

At a higher level, further genetic instructions *coordinating* these transcriptional instructions must exist because the development of an organism requires the programmed differentiation of some cells, the proliferation of certain tissues, and the death of selected cells. We have only glimpses of how such information may be encoded in the genome. Much of what we know comes from studies of development of the fruitfly, *Drosophila melanogaster*. Developmental biologists have long known that as the larva of this insect develops, groups of cells are set apart as disklike structures called **imaginal disks** (Figure 29.31). These groups of cells will form specific parts of the adult fly. As the larva metamorphoses, larval cells are destroyed by apoptosis, and each imaginal disk develops into a different portion of the adult.

Geneticists working with *Drosophila* have long recognized classes of **homeotic mutations**—mutations that scramble the whole developmental pattern in defined ways. One, called the *Antennapedia* mutation, causes perfectly formed legs to grow in the places near the eye where antennae are normally formed. Another group, termed *bithorax* mutations, leads to abnormal development of thoracic segments, producing, for example, extra pairs of wings (Figure 29.32). Recent molecular biological studies have revealed large clusters of **homeotic genes** that control these developmental processes and are the sites of homeotic mutations. Remarkably, a common sequence element of about 180 bp is repeated many times in these gene clusters. This sequence, now called the *homeo box*, codes for a 60-residue polypeptide sequence called the *homeo domain*. Proteins containing this domain are nuclear, DNA-binding proteins of the helix–loop–helix class. It seems likely that each acts as a regulator of transcription for a coordinated group of proteins.

Most remarkable is that the homeo box is not confined to insects but is found in many other organisms, including amphibians and mammals. The sequences are highly conserved over this phylogenetic range. This discovery hints at a quite unexpected uniformity in developmental mechanisms between very distantly related organisms.

Homeotic mutations that modify developmental pathways involve special protein factors carrying the homeo domain.

Regulation of Translation

As noted earlier, the Jacob–Monod paradigm dominated our thinking for many years about gene expression and its control. We have seen in the previous section how much of the operon model applies also to the more complex processes of eukaryotic gene expression, yet how many striking differences we have encountered—mRNA splicing, mRNA capping and tailing, multiple transcription factors in initiation complexes, chromatin as the transcription template, chromatin remodeling, the involvement of Mediator, control by phosphorylation of RNA polymerase, and the absence of multicistronic mRNAs, to cite a few examples. Equally striking are recent discoveries of important regulatory processes acting at the translational level. One of the most active research arenas, aided by second-generation DNA sequencing (also called deep sequencing; see Tools of Biochemistry 4A), is the discovery of many classes of RNA molecules that are themselves genetic regulators. We present examples of these regulatory processes first for prokaryotes, then for eukaryotes. Some of these RNA regulatory phenomena, such as RNA interference, operate at the level of mRNA degradation, and are treated in a separate section (page 1267). Other processes, including riboswitches (page 1269) and RNA editing (page 1270), are also treated separately.

Regulation of Prokaryotic Translation

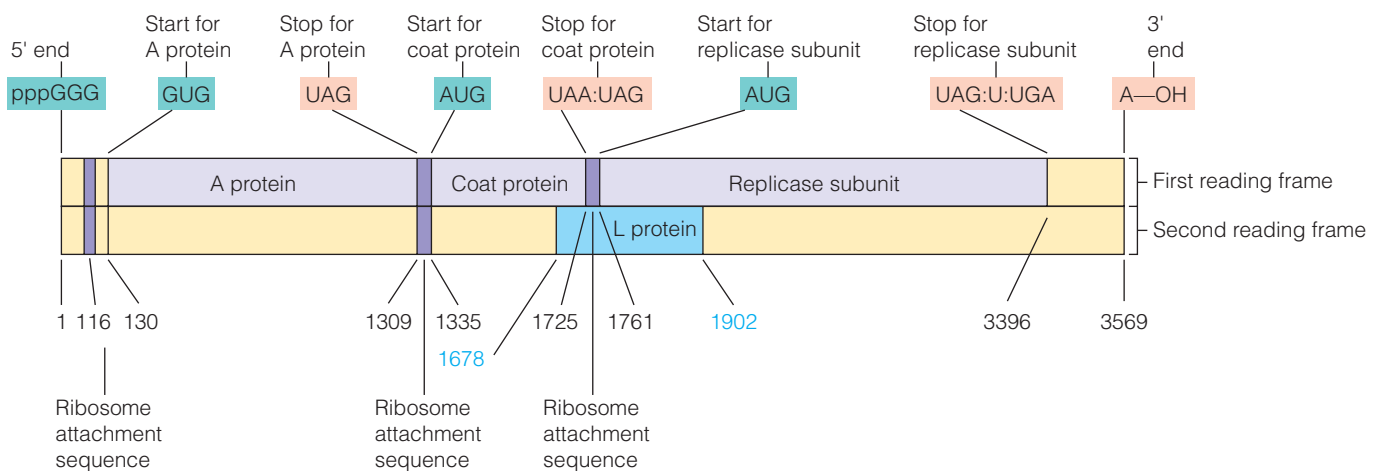

Prokaryotic translation is regulated by at least three mechanisms—ribosome occlusion due to mRNA tertiary structure, translational repression caused by protein binding to mRNA, and actions of regulatory RNA molecules, which base-pair with mRNA molecules. Particularly with respect to regulatory RNA molecules, this is a currently active research frontier, so new regulatory processes and mechanisms are likely to emerge.

Ribosome Binding Site Occlusion

This kind of control appears to explain the regulation of translation of a number of polycistronic messages. An example is found in the messenger RNA of bacteriophage MS2, shown in Figure 29.33. This complex and economical mRNA encodes four essential proteins—one of them coded from an alternate, overlapping reading frame. Consider the different requirements that translation of this message must satisfy: To make new viruses, *many* copies of the coat protein and a significant number of replicase subunits are needed. But only *one* copy of the A protein (which is used in virus assembly) and only a small amount of the lysis protein (used in viral release) are needed per virus. To simply translate the whole polycistronic message equally in all its parts would be woefully inefficient. Instead,

FIGURE 29.33

The RNA of bacteriophage MS2. This RNA molecule serves as a message for all four of the proteins required by this virus. The coding sequences for the A protein, coat protein, and replicase subunit are shown in gray. The message for the lysis protein (the L protein, shown in blue) actually overlaps the coat protein and replicase messages. It is translated in a different reading frame.

the ribosome-binding sequence at the 5' end of the mRNA (which would start translation of the A protein message) is normally blocked by tertiary folding of the mRNA molecule. Therefore, the ribosome normally begins translation by binding to an attachment sequence near the start site of the coat-protein message, translating this message efficiently and proceeding sometimes, but not always, to the replicase message. As replicase is made, it catalyzes replication of the viral mRNA itself. Copies of new plus strands that are still being transcribed have not yet folded into their final conformation. Therefore their 5' ends are still open for initiation and can attach to ribosomes to translate A protein. But this happens only once in the lifetime of each mRNA—at the time it is newly synthesized. The message for the lysis protein, which overlaps the coat protein message but in a different reading frame, is apparently translated only occasionally, as a consequence of a frameshift slip during translation of the coat protein.

Translational Repression, by Protein Binding to mRNA

An elegant example of this kind of control is found in the synthesis of the bacterial ribosomal proteins themselves. As Figure 29.34 shows, *E. coli* ribosomal proteins are encoded by polycistronic messages. In each group encoded by such a message, there is *one* protein that is capable of binding at or near the 5' end of the message and blocking its translation. This binding seems to occur because the mRNA has a tertiary structure similar to the normal binding site for that protein on rRNA.

The beauty of the system can be seen by comparing Figure 29.34 with Figure 28.18. The proteins that control ribosomal protein synthesis—S4, S7, and S8—are also among the first to bind onto the 16S rRNA in ribosome assembly. These proteins are the keys to ribosome construction, and they have a very high affinity for the target rRNAs. If ribosomal RNA is abundant in the cell, which would signal need for ribosomal proteins, the “control” proteins are incorporated into ribosomes, and synthesis of all ribosomal proteins can proceed. But if rRNA is in short supply, the unused “control” proteins will bind to the target mRNAs, shutting down the synthesis of other, currently unneeded ribosomal proteins. In other words, these proteins can be considered to act as “translational repressors.” This control of ribosome production acts in concert with stringent control of rRNA synthesis, exercised by ppGpp (page 1250) to give complementary processes by which ribosome assembly is inhibited under nutrient-limiting conditions.

Actions of Regulatory RNA Molecules

The idea that RNA molecules themselves could serve as genetic regulators has been known since the early 1980s, but the broad significance of this mechanism has only recently become evident. An early finding was the discovery of antisense

Ribosomal protein binding to mRNA is a site for regulation of translation.

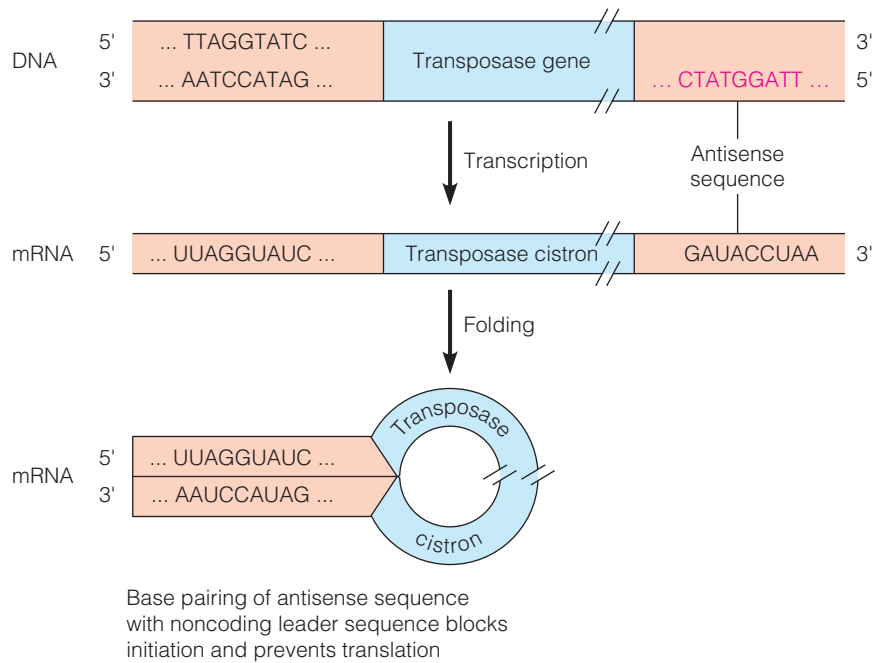

FIGURE 29.34

Regulation of synthesis of ribosomal proteins. Shown are three polycistronic messages encoding ribosomal proteins in *E. coli*. Note that these mRNAs also code for EF-G, EF-Tu, and the α subunit (in purple) of RNA polymerase. Translation of each polycistronic message is controlled by one of the ribosomal proteins it controls, shown in magenta. Arrows show the binding sites for each protein. Control extends *only* over the genes shown in teal.

FIGURE 29.35

Blocking of translational initiation by antisense RNA. The transposase gene contains an antisense sequence at its 3' end. When transcribed, this antisense segment can fold back and base-pair to block initiation of translation.

regulation, in which the mRNA for the transposase of the Tn10 transposon can base-pair with an upstream sequence, thereby blocking initiation of transposase mRNA translation (Figure 29.35).

Another example of antisense regulation involves *ompC* and *ompF*, two genes that encode outer membrane proteins in *E. coli*. These genes are osmoregulated: Cells respond to growth in a medium of high osmolarity by shutting down the synthesis of OmpF protein and activating the synthesis of OmpC so that the total amount of protein is constant and the cell's internal environment is maintained. The postulated mechanism of the *ompF* shutoff is shown in Figure 29.36. High osmolarity in some way triggers synthesis of an antisense RNA, the product of the *micF* gene. This RNA is partly complementary to sequences in the 5' end of *ompF* mRNA. The *micF* RNA inactivates the *ompF* message, by annealing to it, and thereby forming a duplex RNA in vivo. The translational initiation sequences of OmpF mRNA, which must be single-stranded to direct translation, are included in this duplex. This is responsible for blocking translation of the message. Another gene regulated by antisense RNA is *crp*, the structural gene for cAMP receptor protein.

More recently, analysis of whole genome sequences followed by confirming experimental evidence has revealed that regulation by small RNAs (now called sRNAs) is much more widespread than originally realized. In *E. coli* alone, some 80 sRNAs have been discovered. Some, like the MicF RNA mentioned above, bind

FIGURE 29.36

Inactivation of *ompF* mRNA by pairing with antisense RNA from the *micF* gene. A change in osmolarity stimulates transcription of the *micF* gene. The transcript is largely complementary to a region in *ompF* RNA that includes the translational start site. Hairpin loops within the sequences allow base pairing between complementary regions on the two mRNAs, and in this way both transcripts are prevented from serving as templates for protein synthesis.

to just one target sequence. Others bind several different sequences. Some, like the antisense examples mentioned here, act by sequence-specific binding to RNA. Others act by binding specific target proteins. Most of the regulatory effects mentioned here are exerted at the level of initiation. Again, this makes the most sense energetically. Regulation by RNAs instead of proteins also makes good metabolic sense because the energy-using reactions of translation can be avoided.

Synthesis of designed antisense RNAs is being widely used as an approach to **gene knockdown**, when an investigator wishes to block expression of a specific gene without the extensive efforts involved in creating knockout organisms by targeted gene interruption. A synthetic oligonucleotide can be introduced into cells, usually following treatment to transiently increase membrane permeability, with a sequence targeted to the gene whose expression is to be inhibited. Often the knock-down reagent is not an RNA molecule but an RNA analog, one that has been modified so as to avoid enzymatic degradation within the cell. A popular family of antisense reagents is the *morpholinos*, oligomers or polymers that use the same bases as found in natural RNA, but which have morpholine instead of ribose and a phosphoramidate bond to link adjacent “nucleotide” units; see the margin.

Antisense analogs such as morpholinos are being developed as therapeutic reagents, where a target nucleic acid can be identified, such as a viral genome, to become bound and be thereby inactivated. The stumbling block to developing this approach is the difficulty of making these reagents in a form permeable to cell membranes, something that is far easier to do with cells in culture than with cells in living organisms.

Regulation of Eukaryotic Translation

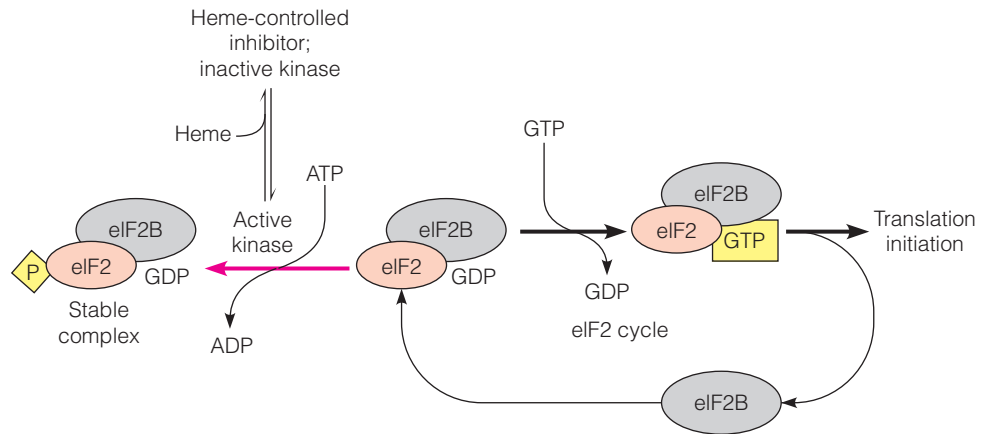

Comparable translational regulatory processes occur in prokaryotic and eukaryotic cells, although there are some significant differences, such as control by phosphorylation of initiation factors (see below). Most striking, however, are parallel developments in prokaryotic and eukaryotic cells regarding regulatory roles of noncoding RNAs. In prokaryotes these RNA molecules are generally short, as implied by the name sRNA. By contrast, this family of RNA molecules in eukaryotes is of higher molecular weight, normally over 200 nucleotide residues in length; these are usually called long noncoding RNAs, or ncRNAs. We discuss these after presenting a couple of better-understood examples of translational regulation.

Phosphorylation of Eukaryotic Initiation Factors

A number of the soluble protein-translation factors in eukaryotes are subject to control by phosphorylation. We give a couple of examples here. eIF2 is a G protein, involved in binding Met-tRNA to the P site as an essential step in initiation (Table 28.4). Four different protein kinases are known to phosphorylate the α subunit of eIF2 at Ser-51. Phosphorylation of eIF2 increases its affinity for its guanine nucleotide exchange factor, eIF2B, leading to formation of an inactive eIF2B-eIF2-GDP complex, thereby shutting down translation initiation. The four protein kinases (not all of which are universally distributed) include (1) the protein 2(GCN2), a kinase that is activated by uncharged tRNA and thereby is a sensor for amino acid starvation; (2) a double-stranded RNA-activated protein kinase, which responds to viral infection; (3) an endoplasmic reticulum protein kinase, which is activated by unfolded proteins in the ER; and (4) a heme-regulated inhibitor kinase (HRI), which is activated under conditions of heme deprivation, thereby shutting off synthesis of hemoglobin when the heme cofactor is scarce. This effect is important in reticulocytes (immature erythrocytes), which are enucleated, but which have ample mRNA for globin synthesis. As shown in Figure 29.37, the biosynthesis of hemoglobin is regulated by this process and, hence, the translation of globin mRNA is shut off unless adequate heme is available to complex with the protein. Another example, mentioned in Chapter 18, is the phosphorylation of 4EBP1 by

FIGURE 29.37

Regulation of translation in erythropoietic cells by heme levels. If heme levels fall, the heme-controlled kinase becomes active and phosphorylates eIF2 (magenta arrow). This blocks further translation by tying this factor into a stable complex with eIF2B. When heme levels are adequate, the kinase is inhibited, and eIF2 is available for translation initiation.

Phosphorylation of initiation factors is commonly used for translation-level control in eukaryotes.

mTOR. Phosphorylation relieves the binding of 4EBP1 to eIF4E, thereby freeing the initiation factor to participate in protein synthesis.

Another example is eIF4E, which is involved in recognition of the 5' mRNA cap, essential to identification of the initiating AUG codon. In eukaryotic cells one or more MAP kinase signaling pathways (Chapter 23) leads to phosphorylation (of Ser-209 in the human protein), with resultant loss of ability of eIF4E to recognize the cap. eIF4E is subject to additional regulation, involving translational repression (see above) by a family of proteins called 4E-BPs (eIF4E-binding proteins). Binding of these proteins is controlled by phosphorylation, with the phosphorylation state, again, being controlled by amino acid availability, cellular energy status, or effects of growth factors or other stimuli. Overexpression of eIF4E causes oncogenic transformation of some cell lines in culture, and levels of the protein are abnormally high in some human cancers.

Long Noncoding RNAs

Until recently it was thought that only a small proportion of the human genome, and hence, of eukaryotic genomes in general, undergoes transcription. This conclusion was compatible with results from the Human Genome Project, when it was revealed that protein-coding open-reading frames accounted for less than 2% of all genomic sequences. However, several approaches, including microarray analysis of the human transcriptome, revealed that more than 90% of the human genome is likely to be transcribed. This means that the mammalian transcriptome contains very large numbers of noncoding RNA molecules. Although some of these molecules may represent transcriptional “noise,” it is likely that many of the newly discovered transcripts are, in fact, functional. Indeed, for some of these ncRNAs that have been characterized, there is evidence for antisense as a regulatory mechanism, as we have seen for sRNAs in bacteria. However, to the extent analyzed to date, eukaryotic ncRNAs appear to act at the transcriptional level. Transcription of a noncoding region in the vicinity of a protein-coding gene can inhibit transcription of that gene, by interfering with the binding of transcription factors. An interesting example is transcription of human *DHFR*, the structural gene for dihydrofolate reductase. In this case a noncoding RNA forms a triplex structure with the *DHFR* promoter, which results in disruption of the preinitiation complex. Of course, this pushes the regulatory issue back one step; what controls expression of this regulatory ncRNA?

To date there are few indications that ncRNAs act at the translational level, for example, by occluding ribosome-binding sites, as we have seen for bacterial sRNAs. However, the phenomenon of RNA interference, which we consider next, establishes that noncoding RNAs regulate translation by controlling *degradation* of mRNA molecules.

RNA Interference

A series of striking discoveries, beginning in the late 1990s, revealed unexpected processes involving RNA-based genetic regulatory and cellular defense mechanisms. The original observations stemmed from attempts to use genetic engineering to increase purple pigmentation in petunias, by introducing into purple flowers additional genes encoding the pigment synthesis pathway. Surprisingly, the resultant transgenic plants were not purple; flowers either had highly variegated pigmentation or were white. Somehow, it appeared, the pigment-forming genes had switched each other off. At first it was thought that this could be resulting from formation of *antisense RNA*, that is, RNA transcribed from the nontemplate DNA strand, which would pair with normal sense RNA, creating nontranslatable double-stranded RNAs. Further experiments, primarily by Craig Mello and Andrew Fire, led to a different conclusion and to the discovery of **RNA interference**, or RNAi. The term covers two distinct processes, both of which involve small RNA molecules, some 21 to 24 nucleotides in length. One class of these molecules, **microRNA**, or miRNA, is involved in gene regulation, while **small interfering RNAs**, or siRNAs, are formed primarily as a cellular defense mechanism.

MicroRNAs

MicroRNAs are specific gene regulatory products; it is estimated that nearly one third of all human genes are regulated by miRNA molecules. The number of specific miRNA molecules in cells of a particular organism is related to the evolutionary complexity of the organism. In a recent study the total numbers of known miRNAs were reported as 677 for humans and 491 for the mouse. By contrast, *Drosophila* had 147, while the sponge had only 8. miRNAs are derived from partially palindromic RNA molecules. As shown in Figure 29.38, these precursor molecules result from transcription by RNA polymerase II, followed by 5' capping and 3' polyadenylation, just as in mRNA synthesis, yielding a primary transcript (pri-miRNA). Ends of the molecule meet to give a stem-loop hairpin, and complementary sequences pair up. Processing begins in the nucleus, with cleavage by an enzyme complex called *Drosha*, some 22 nucleotides from the stem-loop junction, to give a partial hairpin with a short 3' overhang. This is recognized by an exportin complex (like importin in reverse), which carries the miRNA precursor to the cytoplasm, where it is bound by another complex called *Dicer*. In conjunction with another protein called *Argonaute* (AGO), *Dicer* degrades one strand of the partial duplex miRNA precursor and transfers the remaining single strand, which is now a completed miRNA molecule, along with the Argonaute protein, to still another complex, called RISC (RNA-induced silencing complex). RISC then binds to the 3' untranslated sequences of target mRNA molecules, using sequence complementarity with the miRNA as a guide. The region along which sequence complementarity is sought is about seven nucleotides. If the miRNA sequence is completely complementary to that of the target mRNA within those seven nucleotides, that mRNA is completely degraded (not shown in the figure). This process is catalytic, in that once an mRNA has been degraded, RISC can seek further targets.

If the miRNA-mRNA sequences match only partially, then activity of the mRNA is slowed, by various mechanisms. There may be inhibition of binding of translational initiation factors, or ribosome stalling, or activation of enzymes (CCR4-NOT in the figure) that remove the 3' polyA tail. There may not always be immediate mRNA degradation, but its translational activity is slowed.

Eventually, the inhibited mRNA is transferred to a cytosolic site called the **P-body** (P for processing), where it is sequestered from ribosomes, and hence, translationally inactive. The P-body is the site for ultimate degradation of all mRNA molecules, whether or not they arrived there accompanied by RISC. By this process a single miRNA can participate in regulating as many as several hundred

Small RNAs produced from processing of double-stranded RNAs are widely used in gene regulation (miRNAs) and as a defense mechanism (siRNAs).

FIGURE 29.38

Biogenesis of miRNA. The mRNA sequence selected for processing can be either in an exon or an intron. For further details see text.

different mRNAs. Also, regulation by miRNAs can be combinatorial, in that the 3' UTR of an mRNA can be bound by two or more miRNAs, with each binding of a second miRNA yielding further repression of the translational activity of that mRNA. Although we have learned much about these processes, our understanding of what they mean in terms of specific metabolic control is still at an early stage. One fairly recent finding is that some miRNAs can *activate* translation, with the effect of the same miRNA oscillating between inhibitory and activating during the cell division cycle.

Small Interfering RNAs

RNAi as a defense mechanism arises normally as a result of virus infection of a cell. If the virus has an RNA genome but is not a retrovirus, perfectly matched double-stranded RNA molecules arise in the infected cell as intermediates in viral genome replication. These dsRNAs are cleaved in the cytosol by Dicer, to give a series of perfectly matched double-stranded RNA molecules, each about 23 base pairs long, called siRNAs (small interfering RNAs). These are targeted to viral RNA molecules, and because the nucleotide match is perfect, the RNA molecules are cleaved as indicated in our discussion of miRNA synthesis. This process is particularly effective in plants, whose cells are connected by fine channels. Hence, the RNA

interference activity can be spread from cell to cell, leading an entire plant to become virus-resistant, even though only a few cells might have been infected initially.

Although we have much to learn about particular aspects of miRNA regulation, we do know that the synthesis of specific miRNAs is tissue- and developmental-stage-specific. Initial transcription of the pre-miRNA molecule is subject to the same regulatory processes as those we have discussed for mRNA biosynthesis, and each following step is controlled, although many details remain to be elucidated.

With respect to miRNA function, we know that these molecules are involved in regulating processes as diverse as cellular proliferation, control of development, apoptosis, homeostasis, and tumorigenesis. With respect to apoptosis, an interesting connection was recently described. In *C. elegans*, Dicer is directly involved; action of a particular caspase upon Dicer converts it from a ribonuclease to a deoxyribonuclease, responsible for the chromosome fragmentation that is a hallmark of apoptosis. Another recent study described a specific role of an miRNA molecule in controlling activity of a tumor-suppressor gene called PTEN. In this case a PTEN pseudogene (Chapter 24) is transcribed, and the miRNA that would otherwise downregulate the tumor suppressor is drawn to, and inactivates, the pseudogene mRNA instead. This action of the pseudogene, in “titrating away” the PTEN miRNA, suggests an interplay between pseudogene and functional gene activities and helps to explain why “nonfunctional” pseudogenes might have been retained through evolution—to act as “decoys,” protecting the functional mRNA.

It should come as no surprise, therefore, to learn that there is tremendous interest in harnessing miRNA biology to treat or prevent diseases such as cancer. Although this field is in its infancy, RNAi has found widespread use in the laboratory for specific gene knockdown. In Tools of Biochemistry 26A, we described how genes can be knocked out in living cells or organisms by targeted gene replacement. As we mentioned also on page 1120, the most complete and specific and permanent way to study gene function involves ablation of that gene, for example, by targeted deletion, followed by investigation of the deletion mutant. However, use of RNAi is a much faster, albeit less complete and less specific, way to achieve the same goal. In this approach a short hairpin RNA (shRNA) can be prepared by chemical synthesis and introduced into target cells. These hairpin molecules are metabolized essentially identically to siRNAs, which leads to degradation of the target mRNA. In cultured mammalian cells there are several reagents that can be used to transiently increase cell permeability, allowing direct uptake into cells, followed by specific gene inactivation. With other biological systems, such as the nematode, *Caenorhabditis elegans*, the shRNA can simply be injected into the intestine, where it is more or less efficiently taken up into cells. Gene knockdown by RNAi is rarely as complete or as specific as is the creation of knockout organisms, but, as noted above, it is much simpler, and, hence, can be used to investigate the functions of several different genes as part of the same study.

Riboswitches

The discovery of gene regulatory mechanisms involving RNA molecules, along with previously mentioned findings that RNA can serve as an enzyme, strengthened belief in an RNA world—a primordial biosphere existing before proteins, in which biological functions later assumed by proteins could be carried out by primitive RNA molecules. Supporting this concept is the fairly recent discovery of **riboswitches**—mRNA molecules whose translation is controlled by specific binding of a metabolic end product of the pathway in which that mRNA is involved. These molecules were originally discovered in bacteria and have recently been found in some plants and fungi as well.

A riboswitch usually has an **aptamer** at or near its 5' end. An aptamer is a specific binding site created from an oligonucleotide or polynucleotide sequence. Aptamers were originally recognized on the basis of a laboratory technique called

SELEX, which creates such binding sites in vitro through repeated cycles of a selection process. With the discovery of riboswitches, in about 2002, it was found that aptamers of much greater binding specificity had been created by evolution. As noted above, a riboswitch RNA has a binding site for a particular metabolite at the 5' end of an mRNA that encodes an enzyme in the metabolic pathway leading to that metabolite. Many riboswitches contain sites for binding nucleotides or coenzymes—thiamine pyrophosphate, flavin adenine dinucleotide, *S*-adenosylmethionine, and so on. The earliest known riboswitch has a binding site for adenosylcobalamin (B₁₂ cofactor). Specificity of the binding sites is high, as shown by the finding that a riboswitch for *S*-adenosylmethionine was shown to bind that particular target molecule at least 100-fold more tightly than it binds the closely related *S*-adenosylhomocysteine. Figure 29.39 shows the crystal structure of a riboswitch binding site for thiamine pyrophosphate. The structure shown is part of the 3' end of the mRNA encoding one of the enzymes in TPP biosynthesis. Binding of TPP to the riboswitch evidently abolishes the template activity of this mRNA, thereby shutting off TPP biosynthesis. It is evident that a complex folding pattern has evolved to completely enfold the target molecule. The dissociation constant for the complex shown is in the range of 50 nM. It is essential that riboswitches bind their target molecules tightly because they are controlling the biosynthesis of nucleotides and coenzymes that exist within cells at very low concentrations.

A riboswitch is an mRNA molecule that has a specific binding site for a metabolic end product, which, when bound, blocks either transcription or translation of downstream genes.

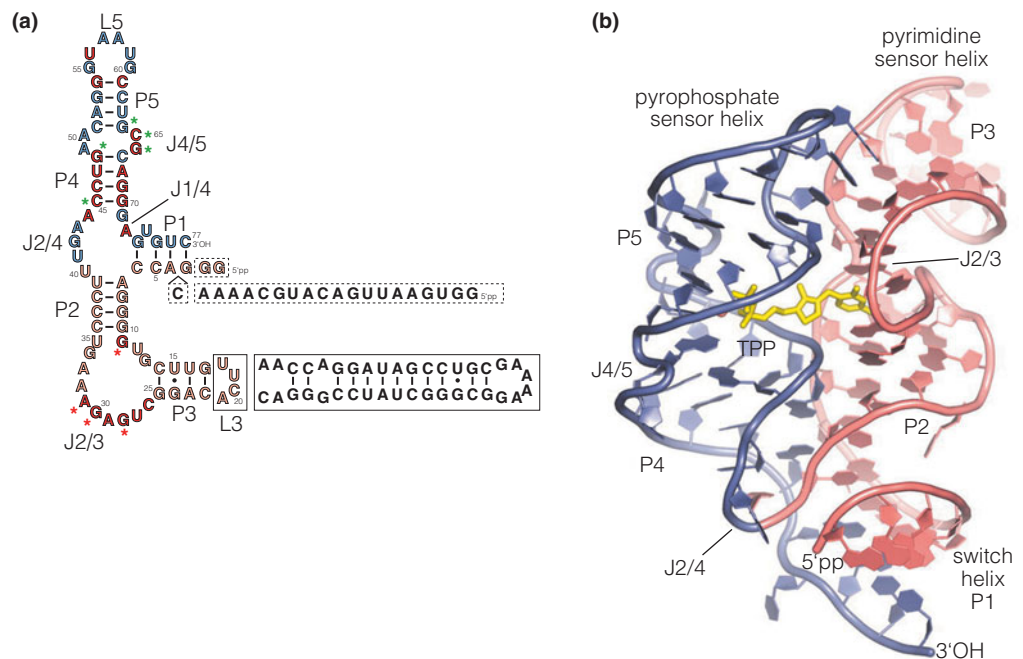

In each case, binding of the target molecule has the effect of shutting off the expression of genes involved in synthesis of the target molecule. This can occur at the level of either transcription or translation, as shown in Figure 29.40. A specific example is shown in Figure 29.41. Here the riboswitch is for a bacterial second messenger, cyclic di-guanosine monophosphate (*c*-di-GMP). This nucleotide controls synthesis of proteins in the flagellae of *Clostridium difficile*. The figure shows how binding the messenger molecule to the riboswitch alters RNA conformation to create a transcriptional terminator, causing premature termination of transcription of an operon that encodes 13 proteins, in the same sense that creation of a premature terminator controls transcription of the tryptophan operon (page 1247).

RNA Editing

RNA editing was another unanticipated process when it was first described in 1986. In this process the nucleotide sequence of an RNA molecule is actually changed post-transcriptionally. It was found that in trypanosomes the mRNAs for some mitochondrial proteins were modified by insertion and occasional removal

**FIGURE 29.40**

Mechanisms of action of a riboswitch. In the absence of effector (upper left) the ligand-binding site (L) is unoccupied, and a transcriptional antiterminator (AT) can form (see Figure 29.19, mechanism of attenuation). Alternatively, if the riboswitch functions at the level of translation (lower left), a region containing the Shine–Dalgarno sequence (SD) is not paired with its complement (anti-SD, or ASD), and translation can occur. In the presence of an effector, the mRNA tertiary structure can change to pair the antiterminator sequence with its complement (AAT), allowing a terminator loop (T) to form, leading to transcriptional termination (upper right). Alternatively (lower right), binding the ligand permits the Shine–Dalgarno sequence to pair with its complement (ASD) so that translation cannot initiate.

of UMP residues. In some cases as many as half of the nucleotides in the mature mRNA molecule were U's that had been inserted. Obviously the complete sense of the genetic message is changed. However, the process is not random. The process is directed by *guide RNAs*, which have 5' ends complementary to one end of the molecule to be edited, followed by a sequence of nucleotides identical to that which is to be inserted. Each insertion step of a single nucleotide involves cleavage, insertion, and re-ligation of the RNA chain. The biological significance of this seemingly wasteful process is still not known.

RNA editing in mammalian cells is much different, simply involving enzymatic deamination of selected AMP or CMP RNA nucleotides. As many as 1000 mammalian genes may be subject to RNA editing. The deaminase enzymes involved recognize a double-stranded RNA that is formed between the site that is to be edited and a complementary sequence elsewhere in the molecule, typically in a downstream intron. As we described in Chapter 17, the mRNA for apolipoprotein B undergoes a CMP to UMP deamination at a site that yields a premature stop codon. Hence, the apolipoprotein product is shorter in the gut (where editing occurs) than in the liver (where it does not). As a result, the lipoproteins produced in these two tissues have somewhat different properties (see Figure 17.5, page 713).

An interesting example of RNA-AMP deamination occurs in the mRNA for a neurotransmitter-gated ion channel in the brain. The edit converts a glutamine to an arginine codon; the affected amino acid lies on the inner wall of the channel and affects the calcium permeability of the channel. Although the reason for the edit is not clear, its significance was shown in knockout mice lacking the deaminase enzyme responsible for the edit. These mice were subject to repeated epileptic seizures and early death. When the gene for the ion channel was modified to contain the arginine without need for deamination of a Glu codon, the mice developed normally. So, even though the purpose of the editing step is unknown, its indispensability is established.

Editing is used by lymphocytes as a defense against HIV infection. These cells carry out large-scale deamination of CMP residues to UMP, using an enzyme similar to activation-induced deoxycytidine deaminase (AID), which is responsible for somatic cell hypermutation (page 1109). Because the RNA in this case is the genome of the virus, the extensive deamination creates multiple mutations, which cripple or kill the virus. However, the virus has evolved a defense mechanism of its own—a protein inhibitor of the deaminase, which is carried into the infected cell along with the viral genome.

SUMMARY

Gene expression is controlled primarily at the level of transcription. In bacteria, control is exercised by binding of repressors and transcriptional activators at promoter sites, thereby influencing the binding of RNA polymerase. Many or most genes are expressed as operons, in which as many as a dozen proteins or more can be translated from the same multicistronic mRNA. A common structural motif in sequence-specific prokaryotic proteins is the helix–turn–helix, in which amino acids in a recognition helix form specific contacts with nucleotides in the major groove of target DNA. The helix–turn–helix is also involved in eukaryotic gene regulation, along with additional motifs, including helix–loop–helix, leucine zipper, and zinc finger. Gene regulation in eukaryotes also occurs at the level of transcription initiation, but regulation is much more complex. As many as 50 proteins may have to assemble at a promoter and upstream enhancer in order for RNA polymerase II to bind and transcribe a protein-coding gene. These proteins include sequence-specific activators, bound at enhancers; Mediator, which connects enhancers to the transcription machinery; chromatin-remodeling complexes, which clear the transcription start region for binding RNA polymerase; and

general transcription factors. Time-dependent changes in the phosphorylation pattern of the RNA polymerase II carboxy terminal domain control timing of events in transcription. Important RNA-based regulatory processes have come to light in recent years, most notably RNA interference. Processing of small RNAs to short duplex RNAs and then to single-stranded miRNAs is becoming widely recognized as a translational regulatory mechanism. Other short RNAs, siRNAs, are formed by similar processes, but are used to degrade invading RNAs, such as those introduced by viral infection. Riboswitches are RNAs that control biosynthetic pathways by specific and tight binding of metabolic end products of those pathways.

PROBLEMS

- The active form of lactose repressor binds to the operator with a dissociation constant of 10^{-13} M for the reaction $R+O \rightleftharpoons RO$. About 10 molecules per *E. coli* cell suffice to keep the operon turned off in the absence of inducer.
 - If the average *E. coli* cell has an intracellular volume of 0.3×10^{-12} mL, calculate the approximate intracellular concentration of repressor.
 - If the average cell contains two copies of the *lac* operon, calculate the approximate intracellular concentration of operators.
 - Calculate the average intracellular concentration of free operators under these conditions.
 - Explain how a cell with a haploid chromosome could contain an average of two copies of the *lac* operon.
- Is attenuation likely to be involved in eukaryotic gene regulation? Briefly explain your answer.
- *3. Suppose you want to study the transcription in vitro of one particular gene in a DNA molecule that contains several genes and promoters. Without adding specific regulatory proteins, how might you stimulate transcription from the gene of interest relative to the transcription of the other genes on your DNA template? To make all of the complexes identical, you would like to arrest all transcriptional events at the same position on the DNA template before isolating the complex. How might you do this?
- For some time it was not clear whether *lac* repressor inhibits *lac* operon transcription by inhibiting the binding of RNA polymerase to its promoter or by allowing transcription initiation but blocking elongation past the site of bound repressor. How might you distinguish between these possibilities?
- A *lac* operon containing one mutation was cloned into a plasmid, which was introduced by transformation into a bacterium containing a wild-type *lac* operon. The three genes of the chromosomal operon were rendered noninducible in the presence of the plasmid.
 - What kind of mutation in the plasmid operon could have this effect?
 - Suppose the result of transformation was to cause the three plasmid *lac* genes to be expressed constitutively, at a high level. What type of plasmid gene mutation could have this result?
- *6. Several new genes in the SOS regulon were identified by an ingenious use of “Mud” phages. These are derivatives of phage Mu that have a promoterless β -galactosidase gene inserted at a particular point in this phage genome. How might these phages be used to identify genes whose expression is turned on after ultraviolet irradiation of bacteria?
- Partial diploid forms of *E. coli* were created, each of which contained a complete lactose operon at its normal chromosomal site and the regulatory sequences only (*i*, *p*, *o*) on a plasmid. Predict the effect of each mutation upon the activity of β -galactosidase before and after the addition of inducer. Use $-$, $+$ or $++$ to indicate approximate activity levels.

Mutation	Before	After
(a) No mutations in either chromosomal or plasmid genes	_____	_____
(b) A mutation in the plasmid operator, which abolishes its binding to repressor	_____	_____
(c) A mutation in the chromosomal promoter, which reduces affinity of promoter for RNA polymerase by 10-fold	_____	_____
(d) An <i>i</i> gene mutation in the chromosome, which abolishes binding of the <i>i</i> gene product to inducer	_____	_____
(e) An <i>i</i> gene mutation in the plasmid, which abolishes binding of the repressor to the inducer	_____	_____
(f) A chromosomal <i>o</i> mutation, which abolishes its binding to repressor	_____	_____
(g) A mutation in the gene for CRP, which abolishes its binding to cyclic AMP	_____	_____
- *8. What type of mutation of the *lac* repressor might be both constitutive and *trans*-dominant?
- It has been proposed that thiogalactoside transacetylase (LacA in the lactose operon) plays a role in detoxification—ridding the cell of potentially toxic β -galactosides by acetylating them to facilitate their diffusion out of the cell. How might you test this proposal?
- Consider Figure 29.34. Note that accumulation of EF-G and the α subunit of RNA polymerase are subject to translational repression by ribosomal proteins S7 and S4, respectively. This would seem to be disadvantageous to the organism because S4, S7, and S8 binding to ribosomal mRNAs are mechanisms to control ribosome assembly. Why might this phenomenon *not* be disadvantageous?
- Riboswitches are generally considered to have been discovered in about 2002. But a comparable regulatory process was described much earlier, when Nomura et al. ([1980] *Proc. Natl. Acad. Sci. USA* 77:7084) described the regulation of ribosomal protein synthesis carried out by binding of ribosomal proteins to their own mRNAs (Figure 29.35). Was the riboswitch actually discovered years earlier? Discuss similarities and differences in control of ribosomal protein synthesis and riboswitch regulation as discussed in this chapter.
- Describe experimental evidence that would indicate that most or nearly all of the DNA sequences in a mammalian genome are transcribed.

CHAPTER 2

- (a) 3.54 kJ/mol.
(b) 151 kJ/mol.
- $\text{CCl}_4 < \text{H}_2\text{S} < \text{H}_3\text{N}^+\text{CH}_2\text{COO}^- < \text{H}_3\text{N}^+\text{CH}_2\text{CH}_2\text{CH}_2\text{COO}^-$. CCl_4 is symmetrical, $\mu = 0$; H_2S will be comparable to H_2O ; the latter two involve separation of whole charges, and in the last, separation is greatest.
- The graph will be a reflection of the graph given, across the $E = 0$ line.

$$4. (a) K_a = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]} = \frac{x^2}{A_0 - x}$$

$$K_a A_0 - K_a x = x^2$$

or $x^2 + K_a x - K_a A_0 = 0$

$$x = \frac{-K_a \pm \sqrt{K_a^2 + 4K_a A_0}}{2}$$

(b) First, assume $x \ll A_0$ and obtain

$$x^2 \cong K_a A_0, \quad x \cong \sqrt{K_a A_0}$$

Use this approximate x to obtain a better approximation to the denominator ($A_0 - x$). Repeat calculation until change in each step is less than required precision.

If K_a is very small (acid weak), either the above or direct approximation yields

$$[\text{H}^+] \cong \sqrt{K_a A_0}$$

- (a) pH = 0.456.
(b) pH = 2.608 by approximation, 2.609 exact.
(c) pH = 3.113 (use the quadratic equation).
- (a) $K_a = 8.16 \times 10^{-5}$.
(b) pH = 2.40.
- Choose a series of about 10 points at which volumes of KOH have been added to neutralize increasing fractions of the acid. Use the Henderson–Hasselbalch equation to calculate the pH at each point.
- (a) pH = 4.46.
(b) pH = 2.57.
- (a) 0.138 M.
(b) $[\text{KH}_2\text{PO}_4] = 0.126 \text{ M}$; $[\text{Na}_2\text{HPO}_4] = 0.174 \text{ M}$.
- pH = 3.93.
- The best choice would be a mixture of H_2PO_4^- and HPO_4^{2-} , which has $\text{p}K_a = 6.86$.
- One will dissolve $2 \times 7.507 \text{ g}$ of glycine in the 2 L to make a 0.1 M solution. To obtain a pH of 9.0, the Henderson–Hasselbalch equation states that the ratio of $\text{Gly}^-/\text{Gly}^\pm$ must be 0.251. This can be achieved by adding NaOH to a concentration of 0.02 M. For 2 L, this would require 0.04 mol, or 40 mL of 1 M NaOH.
- 7.4% as H_2CO_3 . Very little CO_3^{2-} .
- (a) $B = (A_0/2.303)f(1 - f)$.
(b) When $f = 0.5$.
(c) $A_0/9.2/2$.
(d) Increasing A_0 increases B.
- Protein molecules in aqueous solution become increasingly protonated as the pH decreases. Thus, proteins become more positively charged because carboxylic acids become *less negatively charged* as pH drops, whereas amines become *more positively charged*. Proteins become more negatively charged as pH increases, because acidic groups become more negatively charged while the basic groups become less positively charged. These effects are summarized in Table 2.9.
- (a) pI = 10.7. Form I will be present at insignificant concentration at pH values above 7.
(b) +0.382
(c) Yes. When $\text{pH} < \text{pI}$ the molecule is predicted to carry a positive charge.
- Successive deprotonations increase the (–) charge density on the resulting anion. This results in unfavorable electrostatic repulsions between the carboxylate anions which reduces the likelihood that a proton would dissociate. It is more favorable for the proton to remain bound to reduce unfavorable charge repulsion. In fact, citrate has a $\text{p}K_a$ of 6.86.
- The ionic strength of 1 M $(\text{NH}_4)_2\text{SO}_4$ is 3.0.
- Lysine has a pI of about 9.5. Thus, it would not migrate at pH 9.5, whereas cysteine with a side chain $\text{p}K_a$ of 8.3 would carry a partial negative charge at this pH, and arginine, with its very high side chain $\text{p}K_a$ (12.5) would be strongly positively charged.

- (a) Isoelectric focusing. The single charge difference would make little difference in mobility in gel electrophoresis, but a detectable difference in pI.
(b) At a pH below 6.4 (e.g., pH 5) such that the His sidechain is highly (+) charged, whereas the Val sidechain would carry no charge.

CHAPTER 3

- $\Delta H_f - \Delta U_f = -0.165 \text{ J/mol}$, thus, $\Delta U_f = 6,010.165 \text{ J/mol}$,
 $\left(\frac{\Delta H_f - \Delta U_f}{\Delta U_f}\right) \times 100 = 0.003\%$.
- (a) $+926 \text{ kJ/mol}$.
 (b) 463 kJ/mol .
- (a) $\Delta S^\circ = +470 \text{ J/K}\cdot\text{mol}$.
 (b) A solid material is being transformed entirely into gases. The greater freedom of motion of gas molecules results in an entropy increase.
 (c) $\Delta U^\circ = 103.4 \text{ kJ/mol}$.
 (d) Because the system does work on the surroundings, in expanding from a solid to a gas.
- (a) $\Delta G^\circ = -2872 \text{ kJ/mol}$.
 (b) $\Delta G^\circ = -1896 \text{ kJ/mol}$.
 (c) 34% .
- (a) $1.18 \times 10^{-4} \text{ mM}$.
 (b) $\Delta G^{\circ'} = -16.7 \text{ kJ/mol}$.
 (c) 24.6 M . It is never reached because glucose-6-phosphate is continually consumed in other reactions. The system never reaches true thermodynamic equilibrium.
- (a) $K = 5.44 \times 10^{-2}$; $(f_{\text{GAP}})_{\text{eq}} = 0.052$.
 (b) $\Delta G = -4.37 \text{ kJ/mol}$.
- (a) ΔS must be positive because the increase in available states corresponds to an increase in entropy.
 (b) Since $\Delta G = \Delta H - T\Delta S$, a positive ΔS yields a negative contribution to ΔG (T is always a positive number). Thus, for proteins to be stable, which requires ΔG for the above to be positive, denaturation must involve a large positive ΔH and/or an additional negative contribution to ΔS . As we shall see in Chapter 6, both occur.
- This process should correspond to an entropy decrease ($\Delta S < 0$), since order is being established in the H_2O structure.
- (a) We expect ΔS for denaturation to be positive order is lost. If ΔH is also positive (energy required to break internal bonds), then we have the $+, +$ situation described in the first entry in Table 3.3 (p. 68).
 (b) If many hydrophobic residues are present in a protein, ΔS could be negative for unfolding (see Problem 8). If ΔH were also negative, we would have the $-, -$ situation in Table 3.3.
- Given $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$ and $\Delta G^\circ = -RT \ln K$, combination and rearrangement gives the desired equation, which is called the van't Hoff equation. According to the van't Hoff equation, if ΔH° and ΔS° are independent of temperature, a graph of $\ln K$ versus $1/T$ should be a straight line with a slope of $-\Delta H^\circ/R$.
- (a) $\Delta H^\circ = +59.0 \text{ kJ/mol}$.
 (b) $\Delta S^\circ = -103 \text{ J/K}\cdot\text{mol}$. To obtain the true K , so as to get ΔG° , one must divide K_w by 55.5, the molar concentration of pure water.
- (a) $K = 17.6$.
 (b) Toward glucose-1-phosphate.
- (a) $2.19 \times 10^3 \text{ kJ}$.
 (b) ~ 71.5 moles.
- 216 g .
- For a mole of protein molecules, $\Delta S = R \ln W - R \ln 1$, where W is the number of conformations available to each, and R is the gas constant, $8.314 \text{ J/K}\cdot\text{mol}$. Because there are 99 bonds between 100 residues, $W = 3^{99}$.
 (a) $\Delta S = 9.04 \times 10^2 \text{ J/K}\cdot\text{mol}$.
 (b) $\Delta H = 292 \text{ kJ/mol}$.
 (c) Increase, because ΔS and ΔH are both positive.
- (a) $5.93 \times 10^{-6} \text{ kJ}$.
 (b) $-5.93 \times 10^{-6} \text{ kJ}$.
 (c) In (a) 1.94×10^{-7} moles ATP, in (b) none.
- (a) 0.527 M .
 (b) -62.4 kJ/mol .

CHAPTER 4

- (a) It must be a single-strand DNA, since Chargaff's rules are not obeyed.
 (b) It should be mostly random coil, with perhaps some self-bonding into hairpins, etc.
- (a) $3' \text{ TGGCAT TCCGAAATC } 5'$.
 (b) $5' \text{ pApCpCpGpTpApApGpGpCpTpTpTpApGp } 3'$.
 (c) $3' \text{ UGGCAUUCGAAAUC } 5'$.
- The center of symmetry is indicated on the figure at right by a large black dot.

protein). This is done because the charge on the wt protein is zero when $\text{pH} = 5.5$. This analysis yields an overall charge on the mutant of

+0.559 at $\text{pH} = \text{pI}$. If a protein is positively charged the pH must be BELOW the pI ; thus, the pI of the mutant is greater than 5.5.

CHAPTER 6

- (a) Left-handed.
(b) 3.0.
- If the helix were distorted so as to give 3.5 residues/turn, a leucine would project on the same face every 2 turns. The leucines on the two chains would provide hydrophobic faces for interaction. This structure is called a *leucine zipper*.
- (a) The four helices could be arranged so that the hydrophobic side chains would all point toward the center of the bundle and would pack together there (see Problem 2). This would give a stabilizing hydrophobic core.
(b) A proline at this point would break the helix near the Fe_2 binding sites. This would probably mean that Fe_2 could not be bound, and the mutant protein would be nonfunctional.
- They are spaced about three to four residues apart. Therefore, they will all lie on the same side of the α helix. This suggests that this side of the helix may face the interior of the protein.
- In the unfolded form of the protein, most of its hydrogen bond donors and acceptors can make H bonds to water. Therefore, it is only the *difference* in hydrogen bonding energy between the folded and unfolded states that contributes to protein stability. The energy required to break the H-bonds in the unfolded state must be subtracted from the energy released when new H-bonds form in the folded state.
- (a) $3^{200} = 2.7 \times 10^{95}$.
(b) Not all of these conformations will be sterically possible. But even if only 0.1% of these are allowed, there are still 2.7×10^{92} , a very large number.
- (a) $\Delta S_{\text{folding}} = S_{\text{folded}} - S_{\text{unfolded}}$
 $= R \ln W_{\text{folded}} - R \ln W_{\text{unfolded}}$
 $= 8.314 \text{ J/K} \cdot \text{mol} \times [\ln 1 - \ln (2.7 \times 10^{92})]$
 $= -1769 \text{ J/K} \cdot \text{mol} = -1.77 \text{ kJ/K} \cdot \text{mol}$
 (b) $\Delta H_{\text{folding}} = 96 \times (-5 \text{ kJ/mol}) = -480 \text{ kJ/mol}$
 (c) $\Delta G_{\text{folding}} = \Delta H_{\text{folding}} - T \Delta S_{\text{folding}}$
 $= -480 \text{ kJ/mol} - 298 \text{ K}(-1.77 \text{ kJ/K} \cdot \text{mol})$
 $= +47 \text{ kJ/mol}$
 Since $\Delta G_{\text{folding}} > 0$ at 25°C , the protein would not be stable. It would be stable below 0°C . This points out the importance of sources of stabilization other than backbone H bonds.
- An α helix from residues 4–11, a β sheet between 14–19 and 24–30. There is very probably a β turn involving residues 20–23.
- (a) C_4 , held together by heterologous interaction, or D_2 , held together by isologous interaction.
(b) C_2 , since each $\alpha\beta$ dimer forms an asymmetric unit.
- (a) C_8, D_4 .
(b) D_4 , because it involves more subunit–subunit interactions.
(c) Both. There must be heterologous interactions about the four-fold axis and isologous interactions about the two-fold axes.
- The measurement by circular dichroism will detect only the unfolding of tertiary structure in the subunits. Calorimetry will also pick up the energy required to break down the quaternary structure.
- (a) Using data in Table 5.1, we calculate the molecular weight to be 1072. A 1 mg/cm^3 solution will be $9.33 \times 10^{-4} \text{ M}$. From Figure 5.6, we see that the molar extinction coefficient of Tyr is $\sim 1000 \text{ M}^{-1} \text{cm}^{-1}$. Phe does not contribute appreciably. Therefore, ϵ is $0.93 \text{ cm}^2/\text{mg}$.
(b) 2.8 mg/cm^3 .
(c) 5%.
- In the absence of BME, a single band of $M \cong 70,000$ is obtained. This suggests, but does not prove, that there are two identical, noncovalently linked subunits. However, the addition of BME removes this band and gives two bands of $M \cong 30,000$ and $\cong 40,000$, respectively. The sum of these is 70,000, strongly suggesting that the native molecule contains four subunits, two of $M \cong 30,000$, two of $M \cong 40,000$. The 30,000 and 40,000 units are paired by at least one disulfide bond.
- The fact that disulfide reduction has little effect means that the protein is a single chain. It must have an extended structure, which cleavage at a critical Arg residue can relax, giving faster migration; the fragments are still held together by disulfide bonds. Cleavage of these, after thrombin cleavage, yields two fragments.
- Assuming that X-ray diffraction is not practical, we have:
(a) Analysis by CD or by NMR.
(b) More than one secondary/tertiary folding can be observed for the same sequence. Therefore, sequence alone cannot dictate folding in all cases, and sequence-based predictions must sometimes fail badly.
- (a) No. DNA is charged and therefore polar, so most of the DNA-binding helix is likely to be composed of polar residues that interact with either the DNA or the solvent (this is supported by sequence analysis of the bHLH family of DNA binding proteins).
(b) The N-terminus is interacting with the DNA. Two reasons might be given for this: (1) the α -amino group of the N-terminus is positively charged and will interact favorably with the negative charge on the phosphodiester backbone of the DNA; (2) this orientation also situates the “partial positive” end of the helical macrodipole for favorable electrostatic interactions with the negatively charged phosphodiester backbone of the DNA.
- Consider how the mutation would affect the relative free energies in the folded and unfolded states of the protein. Because the mutation is on the surface, loss of hydrophobic contacts in the protein core is not an issue and the amino acid is likely to be interacting with solvent to similar extents in both folded and unfolded states; thus, effects on ΔH are predicted to be minimal. For the same reason the $\Delta S_{\text{solvent}}$ is likely to be small because side chain solvation is predicted to be similar in both the folded and unfolded states (see Equation 6.2b). $\Delta S_{\text{protein}}$ changes the most due to the conformational flexibility of Gly compared to Pro. Gly will stabilize both the folded and the unfolded states; however, it stabilizes the unfolded state more due to the dramatic increase in conformational entropy of the unfolded state as a result of this mutation. The stabilization of the unfolded state for the mutant means that $\Delta G_{\text{folding}}(\text{wt}) < \Delta G_{\text{folding}}(\text{mutant})$; thus, the mutation is destabilizing.

- The orientation of four contiguous residues is required to initiate one turn of a helical structure (Figure 6.3a). Likewise a minimum of three contiguous residues must be ordered to initiate a turn (Figure 6.21), which could then initiate H-bonding between antiparallel strands.

Nucleation of an antiparallel sheet can therefore be faster than nucleation of a helix. The initiation of a parallel sheet requires a noncontiguous sequence to form H-bonding interactions. Because the effective

concentration of contiguous residues is higher than that of noncontiguous residues, the nucleation of a parallel sheet will be significantly slower.

CHAPTER 7

- (a) ~2.6 mm Hg.
(b) About 94%.
- (a) Decrease P_{50} .
(b) Increase P_{50} .
(c) Decrease P_{50} .
- (a) (1) 98%; (2) 56%.
(b) About 42%.
(c) About 63%.
- In the absence of O_2 from the lungs, the residual O_2 bound to hemoglobin is used for continued energy production in respiring cells (such as cardiac and skeletal muscle). Underwater, the crocodile continues to generate CO_2 from metabolic activity. The CO_2 is rapidly converted to HCO_3^- by carbonic anhydrase. As $[HCO_3^-]$ increases, more will bind to hemoglobin, shifting it to greater T-state conformation. This favors O_2 release; thus, as the crocodile stays underwater its hemoglobin delivers most of the bound O_2 as a result of increased binding of HCO_3^- to the T conformation.
- (a) $P_{50} = 4.467$ mm. (Note: This very low value is a consequence of stripping, plus the fact that the temperature is lower than physiological [37 °C].)
(b) $h \cong 3.5$.
(c) $P_{50T} \sim 20.3$ mm Hg; $P_{50R} \sim 1.16$ mm Hg. These are obtained by extrapolating the limiting lines tangential to the extremes of the Hill plot.
- Hemoglobin concentration can influence affinity only if protein dissociation or association is occurring. Most likely is dissociation to $\alpha\beta$ dimers, which will have lost some of the interactions that stabilize the T state. Thus, ligand-binding affinity should rise and P_{50} should decrease.
- (a) $P_{50} = 126$ mm Hg.
(b) $h = \sim 2.6$ (the slope of the Hill plot near $Y_{O_2} = 0$ is 2.588).
(c) Since $h \sim 2.6$, there must be at least 3 sites because $h \leq n$. (Actually, this is an immense molecule, with 24 binding sites.)
- (a) Because H146 lies in the α/β interface (see Figure 7.15), mutation should be expected to interfere with the $T \rightleftharpoons R$ transition. The effect is to increase affinity. This mutation is known; it is hemoglobin Hiroshima.
(b) Because F8 is involved in heme binding (see Figure 7.17), the heme should be unstable. Leucine will not ligate to the heme iron.
(c) β_2 His is involved in BPG binding (see Figure 7.23). Changing to Asp would weaken this.
In each case, a single base change could suffice.
- (a) Faster.
(b) Probably same.
(c) Faster.
- (a) It would begin with a slope of about 1 at low values of $\log P_{O_2}$, would then show a region with slope less than 1, and approach a line with a slope of 1.
(b) MWC theory involves switching an equilibrium of all sites between two states—weak and strong. But in KNF theory, one site can modify an adjacent site in either direction—to stronger or weaker binding.
- A likely explanation: In native Hb, the binding of oxygen is actually hindered by the fact that pulling on helix F must move it against constraints within the molecule. In the imidazole replacement, there is no need to do the extra work of moving helix F. This difference shows up as a more favorable free energy for binding.
- (a) $\Delta Y_{O_2} = Y_{O_2(\text{lungs})} - Y_{O_2(\text{capillaries})} = \left(\frac{(85)^{3.2}}{(31)^{3.2} + (85)^{3.2}} \right) - \left(\frac{(25)^{3.2}}{(31)^{3.2} + (25)^{3.2}} \right) = 0.961 - 0.334 = 0.627$
(b) Living at 1460 m (~4600 ft), the Dalai Lama has adapted to a lower atmospheric P_{O_2} . These adaptations included elevated [2,3-BPG], which will shift P_{50} to higher values.
- (a) Yes, because the linkage between subunits is such that forcing one pair of helices apart favors moving the other pair apart, making O_2 binding easier in the second pair.
(b) Probably so. Deprotonation of His 13 destroys the salt bridge, allowing easier opening of the O_2 binding site.
(c) The molecule would exhibit higher O_2 affinity, and probably lesser cooperativity because the O_2 sites would be opened further. Possibly, the whole structure would become unstable.
- (a) If one multiplies both sides of the first equation by $1 + Kc$, divides through by c , and rearranges, the second equation results.
(b) According to the second equation, the slope of a graph of r/c versus r should be $-K$, and its intercept at $r/c = 0$ should give n . Using the data in this way, we get $K = 2.2 \times 10^4 \text{ M}^{-1}$ and $n = 2.1$. Because the true number of sites must be integral, we would choose $n = 2$.
- The inter-chain disulfide bond would not form, thus the H and L chains would not be stabilized by a *covalent* bond between them. Depending on the strength of the non-covalent interactions between the chains, the loss of the disulfide could result in dissociation of the chains and loss of the antigen binding.

CHAPTER 8

- (a) In the relaxed state, there is about $0.6 \mu\text{m}$ overlap on each side; in the contracted state, about $0.75 \mu\text{m}$.
(b) About 10 steps.
- (a) $0.0033 \text{ min} \cong 0.2 \text{ s}$.
(b) $0.021 \text{ min} = 1.2 \text{ s}$.
(c) That creatine phosphate must be continually produced in active muscle.
- That the growth of actin filaments (which occur at the ends) is somehow essential for cell-shape modification by nonmuscle actin.
- If the GTPase activity is slow, microtubules that happen to have GTP ends will be able to pick up GTP-tubulin and grow for a considerable time, until the GTP at the end is hydrolyzed. These will then tend to shrink as long as release of GDP-tubulin continues to reveal new GDP ends. Thus, depending on its “end state” (GTP or GDP), a

given microtubule will either grow or shrink in competition with its neighbors.

5. (a) Release of the myosin headpiece from the thin filament requires ATP binding. Until ATP binds, the myosin-actin cross-bridge will remain intact, thereby preventing extension of the sarcomeres.
 (b) Without the action of the Ca^{2+} transporter, Ca^{2+} will leak across the membrane from the side of high Ca^{2+} concentration (in the transverse tubule) to the side of lower Ca^{2+} concentration (inside the sarcomere). As $[\text{Ca}^{2+}]$ increases, it will bind TnC, thereby stimulating myosin binding to actin. The lack of ATP will

result in a persistent cross-bridge (see part [a]), characteristic of the *rigor* state.

(c) Decomposition includes cleavage of actin and myosin by intracellular proteases (e.g., enzymes such as trypsin and chymotrypsin described in Chapter 5).

6. The observation would suggest that several power strokes may occur in succession. These may, however, be on different myosin heads—the actin filament can slide a considerable distance past a single head during the portion of the ATP cycle when it is disengaged.

CHAPTER 9

2. Galactitol has the following structure:

Because it has a plane of symmetry between C-3 and C-4, it is optically inactive. Such compounds, which contain asymmetric carbons but have no net optical activity, are called *meso* forms.

3. In the chair form, there is more steric clash between the 2-OH and the 1-OH in the α form of glucose and in the β form of mannose. (Compare glucose and mannose as glucose is pictured in Figure 9.13.) Furthermore, dipole-dipole interactions will be more favorable in β -D-glucose and α -D-mannose.

4. For the reaction

we have $K = 64/36 = 1.78$. Therefore

$$\begin{aligned} \Delta G^\circ &= -RT \ln K = -8.314 \text{ J/K} \cdot \text{mol} \times 313 \text{ K} \times 0.577 \\ &= -1.50 \text{ kJ/mol} \end{aligned}$$

The explanation relates to Problem 3. As Figure 9.12 shows, the 2-OH and 1-OH come quite close in α -D-glucose. Furthermore, the dipole moments of the two OH groups are more nearly parallel in the α -anomer, and antiparallel in the β -anomer. All of these are essentially energetic considerations, so ΔG arises primarily from an enthalpy contribution.

6. Reducing: maltose, cellobiose, lactose, gentiobiose. Nonreducing: trehalose, sucrose.

Note: For simplicity, H atoms are represented by vertical bars.

8. Hyaluronic acid.

9. (a) S.

- (b) R.

10. Cleavage of the pyranose form will occur twice, producing formic acid. Cleavage of the furanose form will also occur twice (between C2 and C3 and between C5 and C6), but formaldehyde will be produced from C6.

Xylan

Glucomannan

12. Perhaps the Gal–GlcNAc linkage is not β , or not 1–4.
13. (a) a; (b) f; (c) a; (d) c; (e) d, f.
14. The influenza hemagglutinin binds to the surface of any cell that contains sialic acid. When it binds to the surface of erythrocytes, this causes the cells to aggregate, or clump.
15. Six possible tripeptide sequences involving A, B, and C.

Some possible trisaccharides: Glc α (1 \rightarrow 4)GlcUA α (1 \rightarrow 4)GlcNAc
 Glc β (1 \rightarrow 4)GlcUA β (1 \rightarrow 4)GlcNAc
 Glc α (1 \rightarrow 3)GlcUA α (1 \rightarrow 4)GlcNAc
 Glc α (1 \rightarrow 4)GlcUA β (1 \rightarrow 4)GlcNAc
 Glc α (1 \rightarrow 4)GlcUA β (1 \rightarrow 6)GlcNAc
 Glc β (1 \rightarrow 4)GlcUA β (1 \rightarrow 6)GlcNAc
 Glc α (1 \rightarrow 2)GlcUA β (1 \rightarrow 4)GlcNAc
 Glc β (1 \rightarrow 3)GlcUA β (1 \rightarrow 4)GlcNAc
 Glc α (1 \rightarrow 4)GlcUA β (1 \rightarrow 3)GlcNAc
 Glc α (1 \rightarrow 4)GlcUA β (1 \rightarrow 2)GlcNAc

This is a partial list of the trisaccharides with the sequence Glc—GlcUA—GlcNAc. There will be comparable numbers of trisaccharides with each of the other possible trisaccharide sequences—a very large number altogether.

16. Mannose and galactose: no, they differ in configuration at C2 and C4; Allose and altrose: yes, they differ only at C2; Gulose and talose: no, they differ at C2 and C3; Ribose and arabinose: yes, they differ only at C2.

CHAPTER 10

1. (a) $\text{CH}_3(\text{CH}_2)_5\text{CH}=\text{CH}(\text{CH}_2)_9\text{COOH}$.
 (b) $\text{CH}_3(\text{CH}_2)_5\text{CH}=\text{CH}(\text{CH}_2)_9\text{COOH}$. (This is called *cis*-vaccenic acid.)
 (c) According to Table 10.1, any with fewer than 10 carbons will melt below 30 °C. An example would be $\text{CH}_3(\text{CH}_2)_6\text{COOH}$, *n*-octanoic acid.
2. (a) Fatty acid, long-chain alcohol.
 (b) Glycerol, fatty acid.
 (c) Carbohydrate, long-chain alcohol.
3. From the data, 4.74×10^9 cells would have a total surface area of $4.74 \times 10^{11} (\mu\text{m})^2$, or 0.474 m^2 . The ratio of monolayer area to cell surface is $0.89 \text{ m}^2/0.474 \text{ m}^2$, or 1.89, very close to 2.00.
4. (a) 20.
 (b) The sequence MVGALLLVVALGIGILFM is 19 residues long, is very hydrophobic, and has a number of helix-forming residues.
5. The concentration ratio is 10^5 . Therefore
 (a) $\Delta G = 29.7 \text{ kJ/mol}$.
 (b) $\Delta G = 36.4 \text{ kJ/mol}$.
 In either case, hydrolysis of 1 mole of ATP (at cellular concentration) would suffice to transport 1 mole of ion.
 (c) Yes, because ΔG for ATP hydrolysis is -53.4 kJ/mol under these conditions.
6. $J = -P(C_2 - C_1)$; from Table 10.6, we have $P = 2.4 \times 10^{-10} \text{ cm/s}$. If we express $C_2 - C_1$ in mol/cm^3 , J will have dimensions of $\text{mol/cm}^2 \cdot \text{s}$. Calculation yields $J = 2.04 \times 10^{-14} \text{ mol/cm}^2 \cdot \text{s}$.

Therefore, the amount transferred in 1 min across $100 (\mu\text{m})^2$ ($= 100 \times 10^{-8} \text{ cm}^2$) will be as follows:

$$M = -1.224 \times 10^{-18} \text{ mol}$$

7. The initial concentration inside = $100 \text{ mM} = 0.1 \times 10^{-3} \text{ mol/cm}^3$. The cell volume is $100 (\mu\text{m})^3$, or $100 \times 10^{-12} \text{ cm}^3$. The amount initially present is as follows:

$$\begin{aligned} M &= 0.1 \times 10^{-3} \text{ mol/cm}^3 \times 1 \times 10^{-10} \text{ cm}^3 \\ &= 1 \times 10^{-14} \text{ mol} \end{aligned}$$

Therefore, the percentage escaping in 1 min will be

$$\frac{1.224 \times 10^{-18} \text{ mol}}{1 \times 10^{-14} \text{ mol}} \times 100 = 1.224 \times 10^{-2} \%$$

Thus, unless facilitated transport is available, “leakage” of K^+ from cells is very slow.

8. Consider mass flow from one direction only, with ligand A at concentration $[A]$ outside the membrane. It reacts with carrier X at the membrane surface to give XA:

If we say that J is proportional to the fraction of carriers occupied, then

$$J = -P(C_2 - C_1) \frac{[XA]}{[X] + [XA]}$$

and we get

$$J = -P(C_2 - C_1) \frac{K_{\text{bind}}[A]}{1 + K_{\text{bind}}[A]}$$

This approaches a limiting value ($J = -P(C_2 - C_1)$) at high $[A]$.

9. If the calcium ion is *maintained* at this concentration difference, we must have, from equation (10.2), $V_{\text{in-out}} = -92 \text{ mV}$. Because $V_{\text{in-out}}$ is defined as the potential inside minus the potential outside, the inside of the organelle is negative with respect to the outside.
10. (a) -61.5 mV (right $-$).
 (b) $+61.5 \text{ mV}$ (right $+$).
 (c) 0.
11. No in (a) and (b). Yes in (c). Concentrations will equalize.
12. (a) 0.27.
 (b) -72.8 mV .
13. The subunits traversing the membrane usually need to present different domains to the two sides. Thus, no symmetry involving

twofold axes parallel to the membrane surfaces (like D_n) should be expected.

14. 2.71 kg of K^+ , 2.39 kg of Na^+ .
15. The maximum value of $[\text{G6P}]_{\text{in}}$ will be achieved when ΔG for the glucose phosphorylation reaction inside the cell is zero. If we assume the concentrations of free glucose outside and inside the cell are equal (i.e., 5 mM), the maximum value of $[\text{G6P}]_{\text{in}} = 162 \text{ M}$. This absurdly high value is never achieved, as G6P is rapidly consumed in other metabolic reactions (see Chapter 13).
16. (a) -21.0 kJ/mol H^+
 (b) $\text{ADP} + \text{P}_i + 3\text{H}_{\text{out}}^+ \rightarrow \text{ATP} + \text{H}_2\text{O} + 2\text{H}_{\text{in}}^+$
 (c) 2.7 mM

CHAPTER 11

1. Given $\ln([A]/[A]_0) = -kt$. When $t = t_{1/2}$, we have

$$\ln\left(\frac{1}{2}\right) = -0.693 = -kt_{1/2}$$

Therefore, $t_{1/2} = 0.693/k$. The constant of proportionality is 0.693.

2. Graphing $\ln([A]/[A]_0)$ versus t gives a curved line. Therefore, kinetics are not first-order.
3. About 1.1×10^{14} .
4. The Asp must be protonated to act as a general acid catalyst; thus, activity will be higher when $\text{pH} < \text{pK}_a$ and lower when $\text{pH} > \text{pK}_a$. At $\text{pH} = \text{pK}_a$, expect 50% of maximal activity because the Asp will be 50% protonated.

5. If the protein can bind to a random location on the DNA and slide along until it finds the specific site, a more efficient one-dimensional search replaces an entropically less favorable three-dimensional search.
6. Given $d[A]/dt = -k_1[A] + k_{-1}[B]$. Noting that $[B] = [A]_0 - [A]$, we get

$$d[A]/dt = -(k_1 + k_{-1})[A] + k_{-1}[A]_0 \quad (1)$$

The second term on the right can be evaluated from the equilibrium condition

$$-k_1[A]_e + k_{-1}[B]_e = 0 \quad (2)$$

which gives, after further substitutions,

$$k_{-1}[A]_0 = (k_1 + k_{-1})[A]_e \quad (3)$$

Inserting into (1), and noting that $d[A]/dt = d([A] - [A]_e)/dt$, we get

$$\frac{d([A] - [A]_e)}{([A] - [A]_e)} = -(k_1 + k_{-1})dt \quad (4)$$

After integrating, this yields the result

$$[A] - [A]_e = ([A]_0 - [A]_e)e^{-(k_1 + k_{-1})t} \quad \text{Q.E.D.} \quad (5)$$

7. (a) From equation (11.7) we may write

$$-d[A]/dt = k[A]^2$$

Rearranging to give:

$$d[A]/[A]^2 = -kdt$$

and integrating from $[A]_0$ to $[A]_t$ and $t = 0$ to t , we obtain

$$1/[A] - 1/[A]_0 = kt$$

- (b) One way to do it is to plot $1/[A]$ versus t .
 (c) The data yield a linear graph, so the reaction is second-order.

8. (a) It is quite difficult to estimate V_{max} in this way. A value of about $150 (\mu\text{mol/L})\text{min}^{-1}$ might be guessed at. Then, by taking K_M as the substrate concentration at $V_{\text{max}}/2$, we would estimate $K_M \sim 25 \mu\text{mol/L}$.
 (b) $V_{\text{max}} = 164 (\mu\text{mol/L})\text{min}^{-1}$; $K_M = 32 \mu\text{mol/L}$. These values are considerably more reliable than those found in (a).
 (c) Best fit gives $V_{\text{max}} = 158 (\mu\text{mol/L})\text{min}^{-1}$; $K_M = 30 \mu\text{mol/L}$.
9. (a) $V_{\text{max}} = 164 (\mu\text{mol/L})\text{min}^{-1}$, $k_{\text{cat}} = 1.64 \times 10^5 \text{min}^{-1} = 2733 \text{s}^{-1}$.
 (b) Using $K_M = 32 \mu\text{mol/L}$, $k_{\text{cat}}/K_M = 8.5 \times 10^7 (\text{mol/L})^{-1}\text{s}^{-1}$. This compares favorably with the largest values of k_{cat}/K_M .

10. (a) It is necessary only to rearrange the equation to

$$\left(\frac{K_M}{[S]} + 1\right)d[S] = -V_{\text{max}}dt$$

and then integrate from $t = 0$ ($[S] = [S]_0$) to a finite time t . We obtain

$$[S]_0 - [S] - K_M \ln \frac{[S]}{[S]_0} = V_{\max} t$$

(b) When $[S]_0 \gg K_M$, the first two terms on the left will be much larger than the third, so

$$[S]_0 - [S] \cong V_{\max} t$$

or

$$[S] = [S]_0 - V_{\max} t$$

This corresponds to a situation in which the enzyme is saturated with substrate, so substrate molecules are simply being consumed at the maximum rate.

11. (a) E270 acts as a GBC in step one and as a GAC in step two.
 (b) R145 provides specific ion-ion interactions with the C-terminal carboxylate of the substrate. This confers specificity for cleavage of the C-terminal residue from the peptide substrate.
12. The change in k_{cat} between pH 6 and pH 7 must involve loss of a proton in the active site. The best candidate is His 57. The increase in K_M at higher pH must involve a change in the binding site. The group involved is probably the N-terminus on Ile 16, created by the cleavage that activates chymotrypsin.
13. (a) If we take k_{cat}/K_M ratios, we find that PAPAF would be digested most rapidly and PAPAG most slowly.
 (b) A hydrophobic residue C-terminal to the bond cleaved seems to be favored. Elastase always requires a small residue (like Ala) to the N-terminal side.
 (c) Serine and histidine.

14. (a) The enzyme must be stable both to the presence of detergents and to moderately high temperatures.
 (b) Replace the methionine, by site-directed mutagenesis, with another residue. Because methionine is quite hydrophobic, a hydrophobic replacement would seem appropriate. A single base change in the codon could yield Phe, Leu, Ile, or Val.
 (c) The oxyanion is formed after S binds; thus, for a mutation of a residue that only interacts with the oxyanion intermediate one would not expect K_M to change significantly (it does not, according to Wells et al.); however, k_{cat} should be reduced due to the loss of enthalpic stabilization of the transition state (it is—by factor of 2500).
 (d) Using Equation 11.11, and assuming that the value of γ is the same for both mutants:

$$\begin{aligned} \text{rate enhancement} &= \frac{k_{\text{catN155}}}{k_{\text{catT155}}} \\ &= \frac{\gamma_{\text{N155}} \left(\frac{k_B T}{h} \right) e^{\left(\frac{-\Delta G_{\text{N155}}^\ddagger}{RT} \right)}}{\gamma_{\text{T155}} \left(\frac{k_B T}{h} \right) e^{\left(\frac{-\Delta G_{\text{T155}}^\ddagger}{RT} \right)}} = \left(\frac{\gamma_{\text{N155}}}{\gamma_{\text{T155}}} \right) e^{\left(\frac{\Delta \Delta G^\ddagger}{RT} \right)} \end{aligned}$$

$$\frac{k_{\text{catN155}}}{k_{\text{catT155}}} = 2500 = (1) e^{\left[\frac{\Delta \Delta G^\ddagger}{(0.008314 \text{ kJ/mol K})(310 \text{ K})} \right]}$$

$$\Delta \Delta G^\ddagger = 20 \text{ kJ/mol}$$

(e) The dielectric constant, ϵ , is lower in the enzyme active site than it is in water; thus, Coulomb's law (Equation 2.2) predicts a stronger interaction between the bond donor and acceptor.

15. (a) Mixed.
 (b) No inhibitor: $K_M = 2.5 \text{ mmol/L}$, $V_{\max} = 5.1 \text{ (mmol/L)min}^{-1}$.
 With inhibitor: $K_M = 7.6 \text{ mmol/L}$, $V_{\max} = 3.0 \text{ (mmol/L)min}^{-1}$.

16. (a) Competitive.
 (b) $V_{\max} \sim 5.1 \text{ (mmol/L)min}^{-1}$ at all inhibitor concentrations.

[I] (mmol/L)	K_M^{app} (mmol/L)
0	2.5
3	3.8
5	5.4

(c) Using the data when $[I] = 3 \text{ mM}$, the apparent $K_I = 5.5 \text{ mM}$; using the $[I] = 5 \text{ mM}$ data, $K_I = 4.2 \text{ mM}$. $K_I = 4.9 \text{ mM}$ is a reasonable estimate, given the variance in the experimental data.

17. According to equation (11.33), we can write the Michaelis-Menten equation as $V = V_{\max} - K_M V/[S]$, so we plot V versus $V/[S]$. The intercept at $V/[S] = 0$ will give V_{\max} ; the slope will be K_M^{app} . Therefore, the graphs will look like the following sketches:

(a) Competitive inhibition $[I]_1 < [I]_2$

(b) Noncompetitive inhibition $[I]_1 < [I]_2$

18. One should replace the hydrophobic group in TPCK with a positively charged group. A good candidate would be

19. Find K_{eq} for $F \rightleftharpoons U$ from the ratio of rate constants; then, calculate $\Delta G^{\circ'}_{F \rightarrow U}$:

$$K_{\text{eq}} = \frac{[U]}{[F]} = \frac{k_{F \rightarrow U}}{k_{U \rightarrow F}} = \frac{3.62 \times 10^{-5} \text{ s}^{-1}}{255 \text{ s}^{-1}} = 1.42 \times 10^{-7}$$

$$\Delta G^{\circ'}_{F \rightarrow U} = -RT \ln(1.42 \times 10^{-7}) = 39.1 \text{ kJ/mol}$$

The mutant is more stable than the wild-type myoglobin.

20. (a) If we make a graph of v versus $[S]$, the data show a slightly sigmoidal curve. A more convincing demonstration is to use a Lineweaver–Burk plot or an Eadie–Hofstee plot. Neither is linear.
 (b) From the v versus $[S]$ plot, we can estimate V_{\max} to be approximately $5 \text{ (mmol/L) sec}^{-1}$.

21. The equation is

$$\log \left(\frac{v/V_{\max}}{1 - v/V_{\max}} \right) = \log [S] - \log K_M$$

The Hill plot of $\log \left(\frac{v/V_{\max}}{1 - v/V_{\max}} \right)$ versus $\log [S]$ will approach straight lines with slope = 1 at low and high values of $\log [S]$. The former will yield K_M^T , the latter K_M^R .

22.

23. In the MWC theory, the more favorable binding to the R state makes the equilibrium shift as $[S]$ is increased; the shift can only be toward R. In the KNF theory, binding to one site can have any kind of effect on another, including inhibition.

24. (a) The key to the derivation is to note that

$$Y = \frac{\text{number of sites occupied}}{\text{total number of sites}} = \frac{[RS] + 2[RS_2]}{2([R] + [R] + [RS] + [RS_2])}$$

Expressions given for $[T]$, $[RS]$, and $[RS_2]$ are inserted and the equation simplified.

(b) This must be done graphically. A large L and a small K ensure a sigmoidal curve.

25. (a) Activation of the molecule by trypsin will be greatly reduced due to removal of the R that trypsin binds in its active site.
 (b) If activation occurs, the N-terminal peptide will no longer be constrained by an S–S bond and may be released.
 (c) Automodification of π -chymotrypsin to α -chymotrypsin could be reduced, although this mutation is relatively conservative (loss of a methyl group); thus, the effect on activation might be slight.

26. The simplest technique would be to incubate the ribozyme with a radiolabeled pentanucleotide and collect samples from time to time for electrophoresis. Autoradiography should initially show only the pentanucleotide, but with time both longer and shorter labeled oligomers should appear on the gel.

27. Stable transition state mimics of amide bond hydrolysis are challenging to synthesize. A number of haptens with tetrahedral oxyanions have been used: phosphonates, sulfonamides, boronic esters. These molecules have been used to raise antibodies that show rate enhancements for amide bond hydrolysis of $\sim 10^3$ (see R. Aggarwal et al. (2003) *Chem. Eur. J.* 9:3132).

28. (a) $[E]_t = [E] + [ES] + [ESI]$. Using the expressions for α' , K_M , and K_I' :

$$[E]_t = [ES] \left(\frac{K_M}{[S]} + 1 + \frac{[I]}{K_I'} \right) = [ES] \left(\frac{K_M}{[S]} + \alpha' \right)$$

$$V = k_{\text{cat}}[ES] = \frac{k_{\text{cat}}[E]_t}{\frac{K_M}{[S]} + \alpha'} = \frac{V_{\max}[S]}{K_M + [S]\alpha'}$$

- (b) $[E]_t = [E] + [EI] + [ES] + [ESI]$. Using the expressions for α , α' , K_M , K_I and K_I' :

$$[E]_t = [ES] \left(1 + \frac{[I]}{K_I'} \right) + [E] \left(1 + \frac{[I]}{K_I} \right) = [ES](\alpha') + [E](\alpha)$$

$$[E]_t = [ES] \left(\alpha' + \frac{\alpha[K_M]}{[S]} \right)$$

$$V = k_{\text{cat}}[ES] = \frac{k_{\text{cat}}[E]_t}{\alpha' + \frac{\alpha[K_M]}{[S]}} = \frac{V_{\max}[S]}{\alpha K_M + [S]\alpha'}$$

29. (a) Enalaprilat is too polar to cross membranes; whereas enalapril is less polar and can cross membranes to get from the gut to circulation.

(b):

$$10 = \frac{\alpha K_M + [S]}{K_M + [S]}$$

$$\nu_{\text{o(inhibited)}} = \frac{0.1 V_{\max}[S]}{K_M + [S]} = \frac{V_{\max}[S]}{\alpha K_M + [S]}$$

$$\alpha = \frac{10(K_M + [S]) - [S]}{K_M} = \frac{10(12 \mu\text{M} + 75 \mu\text{M}) - 75 \mu\text{M}}{12 \mu\text{M}}$$

$$= 66.25 = 1 + \frac{[I]}{K_I}$$

$$K_I = \frac{2.4 \times 10^{-9} \text{M}}{66.25} = 3.7 \times 10^{-11} \text{M}$$

CHAPTER 12

1. Equation

- | | |
|--|-------|
| (a) $\text{C}_2\text{H}_5\text{OH} + 3\text{O}_2 \rightarrow 2\text{CO}_2 + 3\text{H}_2\text{O}$ | RQ |
| (b) $\text{CH}_3\text{COOH} + 2\text{O}_2 \rightarrow 2\text{CO}_2 + 2\text{H}_2\text{O}$ | 0.67* |
| (c) $\text{CH}_3(\text{CH}_2)_{16}\text{COOH} + 26\text{O}_2 \rightarrow 18\text{CO}_2 + 18\text{H}_2\text{O}$ | 1.0 |
| (d) $\text{CH}_3(\text{CH}_2)_{14}(\text{CH}_2)_2\text{COOH} + 25\frac{1}{2}\text{O}_2 \rightarrow 18\text{CO}_2 + 17\text{H}_2\text{O}$ | 0.69 |
| (e) $\text{CH}_3(\text{CH}_2)_{12}(\text{CH})_4\text{COOH} + 25\text{O}_2 \rightarrow 18\text{CO}_2 + 16\text{H}_2\text{O}$ | 0.71 |
| *Example: $\text{RQ} = 2\text{CO}_2/3\text{O}_2$. | 0.71 |

2. (a) >1 .
 (b) <1 .

Because NAD^+ -dependent enzymes usually act to dehydrogenate (oxidize) substrates, an $[\text{NAD}^+]/[\text{NADH}]$ ratio greater than unity tends to drive reactions in that direction. Similarly, $[\text{NADP}^+]/[\text{NADPH}]$ ratios less than unity provide concentrations that tend to drive these reactions in the direction of substrate reduction.

3. (a) 0.
 (b) 1.
 (c) 4.

4. for glucose ($C_6H_{12}O_6$): $MW = 6(12 \text{ g mol}^{-1}) + 12(1 \text{ g mol}^{-1}) + 6(16 \text{ g mol}^{-1}) = 180 \text{ g mol}^{-1}$
 Energy yield/mole glucose
 $= (15.64 \text{ kJ g}^{-1})(180 \text{ g mol}^{-1}) = 2815.2 \text{ kJ mol}^{-1}$ glucose
 Energy yield/mole carbon
 $= (2815.2 \text{ kJ mol}^{-1} \text{ glucose}) / (6 \text{ mol carbon mol}^{-1} \text{ glucose}) = 469.2 \text{ kJ mol}^{-1}$ carbon
 for palmitic acid ($C_{16}H_{32}O_2$): $MW = 16(12 \text{ g mol}^{-1}) + 32(1 \text{ g mol}^{-1}) + 2(16 \text{ g mol}^{-1}) = 256 \text{ g mol}^{-1}$
 Energy yield/mole palmitic acid
 $= (38.90 \text{ kJ g}^{-1})(256 \text{ g mol}^{-1}) = 9958.4 \text{ kJ mol}^{-1}$ PA
 energy yield/mole carbon
 $= (9958.4 \text{ kJ mol}^{-1} \text{ PA}) / (16 \text{ mol carbon mol}^{-1} \text{ PA}) = 622.4 \text{ kJ mol}^{-1}$ carbon

5. $\Delta G = \Delta G^{\circ'} + RT \ln([ADP][P_i] / [ATP])$
 $= -30500 \text{ J/mol} + (8.315 \text{ J/mol} \cdot \text{K})(310 \text{ K}) \times \ln(1 \times 10^{-3} \text{ M})(1 \times 10^{-3} \text{ M}) / (3 \times 10^{-3} \text{ M})$
 $= -51134 \text{ J/mol} = -51.14 \text{ kJ/mol}$

6. (a)

Treatment	% Change in flux
Inhibitor that reduces activity of X by 10%	10% decrease
Activator that increases activity of X by 10%	10% increase

(b) Metabolic flux rate = rate of X - rate of Y = 100 - 80 = 20 pmol/ 10^6 cells/sec in the direction of B \rightarrow C

(c)

Change in flux	Treatment	Direction of flux (B \rightarrow C or C \rightarrow B)	% Change in flux
90 - 80 = 10	Inhibitor that reduces activity of X by 10%	B \rightarrow C	50% decrease
110 - 80 = 30	Activator that increases activity of X by 10%	B \rightarrow C	50% increase
100 - 160 = -60	Doubling the activity of enzyme Y	C \rightarrow B	400% change (decrease)

(d) A substrate cycle allows amplification of a small change in an enzyme's activity; e.g., a 10% change in activity gives a 50% change in flux.

7. (a) $K = e^{\left(\frac{-\Delta G^{\circ'}}{RT}\right)} = e^{\left(\frac{16700 \text{ J/mol}}{(8315 \text{ J/mol} \cdot \text{K})(298 \text{ K})}\right)}$
 $= 845 = \frac{[ADP][\text{glucose-6-phosphate}]}{[ATP][\text{glucose}]}$

Since $[ATP] = [ADP] : [\text{glucose-6-P}] / [\text{glucose}] = 845$ under physiological conditions.

- (b) $K = [\text{glucose}][P_i] / [\text{glucose-6-P}] = 262$
 $[\text{glucose}] / [\text{glucose-6-P}] = 262 / (1 \times 10^{-3} \text{ M}) = 262,000$
 (c) Any condition where the $[\text{glucose}] / [\text{glucose-6-P}]$ ratio is between 262,000 and 0.0012 (1/845).
 (d) The relative concentrations of allosteric regulators that exert kinetic control over the enzymes in the opposing pathways.

- *8. The most direct way is to purify the enzyme to homogeneity and determine both its molecular weight and turnover number. Then, from the activity observed in a crude extract, one can calculate the number of active enzyme molecules needed to achieve that activity (assuming that the extract does not contain inhibitors of the activity). Another approach is to treat the extract with a specific antibody to the enzyme of interest and quantitate the protein immunoprecipitated. One still needs to know the molecular weight to convert this value to number of molecules of enzyme.

- *9. (a) 20% (600 cpm/pmol/3000 cpm/pmol).
 (b) 1500 cpm dTTP incorporated per minute per 10^6 cells, corrected for the 20% fraction calculated in part (a) ($1500/0.2$) = 7500 cpm/ 10^6 cells/min.

$$\frac{7500 \text{ cpm}}{10^6 \text{ cells} \cdot \text{min}} \times \frac{1 \text{ pmol}}{3000 \text{ cpm}} \times \frac{6.02 \times 10^{11} \text{ molecules}}{1 \text{ pmol}}$$

$$= 1.5 \times 10^6 \text{ molecules/min/cell}$$

- (c) Prepare an acid extract of the cells (e.g., 5% trichloroacetic acid), separate the nucleotides by ion-exchange HPLC, and determine in the dTTP fraction its radioactivity and its mass, the latter from UV absorbance.

10. (a) $N = 1 \mu\text{mol orthophosphate} = 6.02 \times 10^{17} \text{ molecules}/\mu\text{mol}$

$$\lambda = \frac{0.693}{t_{1/2}} = \frac{0.693}{14.2 \text{ days}} = \frac{0.693}{2.04 \times 10^4 \text{ min}} = 3.39 \times 10^{-5} \text{ min}^{-1}$$

$$dN/dt = (6.02 \times 10^{17} \text{ molecules}/\mu\text{mol}) (3.39 \times 10^{-5} \text{ min}^{-1})$$

$$= 2.04 \times 10^{13} \text{ dpm}/\mu\text{mol}$$

$$(2.04 \times 10^{13} \text{ dpm}/\mu\text{mol}) (1 \text{ mCi}/2.2 \times 10^9 \text{ dpm})$$

$$= 9274 \text{ mCi}/\mu\text{mol}$$

(b) $(10 \text{ mCi}/\mu\text{mol})(3.67 \times 10^7 \text{ dps/mCi})$
 $= 3.67 \times 10^8 \text{ dps}/\mu\text{mol} = dN/dt = \lambda N$

$$\lambda = \frac{0.693}{t_{1/2}} = \frac{0.693}{12.1 \text{ years}} = \frac{0.693}{3.8 \times 10^8 \text{ sec}} = 1.8 \times 10^{-9} \text{ s}^{-1}$$

$$N = (3.67 \times 10^8 \text{ dps}/\mu\text{mol}) / \lambda$$

$$= (3.67 \times 10^8 \text{ dps}/\mu\text{mol}) / (1.8 \times 10^{-9} \text{ s}^{-1})$$

$$= 2.04 \times 10^{17} \text{ atoms}$$

$(1 \mu\text{mol leucine})(6.02 \times 10^{17} \text{ molecules}/\mu\text{mol})$
 $(13 \text{ H/molecule}) = 7.83 \times 10^{18} \text{ H atoms}$
 (at physiological pH)
 % radioactive = (100%) \times
 $(2.04 \times 10^{17} \text{ atoms}) / (7.83 \times 10^{18} \text{ H atoms}) = 2.6\%$

CHAPTER 13

1. $\Delta G = \Delta G^{\circ'} + RT \ln([F6P][ADP] / [F6P][ATP])$. With the concentrations given, $\Delta G = \Delta G^{\circ'}$, since the natural log term is zero. Therefore, the reaction is neither more nor less exergonic in muscle than under standard conditions.

2. Ethanol will generate NADH, through the action of alcohol dehydrogenase, and this will reduce formaldehyde back to methanol, also through alcohol dehydrogenase. The acetaldehyde formed can be metabolized further to acetate. Ethanol may also compete with methanol for binding to alcohol dehydrogenase.

23. Because pyruvate carboxylase has two metabolic roles—replenishment of citric acid cycle intermediates (Chapter 14) and initiation of gluconeogenesis. PEPCK catalyzes the first reaction committed to gluconeogenesis.
24. (1) The liver is the most active gluconeogenic tissue. Because alanine is an important gluconeogenic precursor, its accumulation in liver is a signal that gluconeogenesis should be activated, with simultaneous inhibition of glycolysis. Also, alanine accumulates in muscle under conditions of high metabolic demand, where glycolysis must still function to provide ATP.
(2) The function of glucose-6-phosphatase is production of glucose, for exit from the cell and transport to other tissues. Therefore, the enzyme plays a role only in those tissues (primarily liver) that manufacture glucose for export.
25. PP1 inactivates phosphorylase *b* kinase, by catalyzing its dephosphorylation. This blocks the conversion of glycogen phosphorylase *b* to *a*, thereby inhibiting glycogenolysis. Inhibitor 1, by inhibiting PP1, has the opposite effect.
26. (a) The function of glucagon is to increase blood glucose concentration. Stimulation of liver glycogen breakdown and gluconeogenesis and inhibition of liver glycolysis are consistent with this function.
(b) The glucose-6-phosphatase deficiency would interfere with release of glucose from the liver for export to other tissues.
(c) Phosphorylase *b* kinase converts phosphorylase *b* to *a*, which activates glycogen breakdown, and it converts glycogen synthase *a* to *b*, the less active form of this enzyme.
(d) Glucose-6-phosphate must be hydrolyzed in order for glucose to exit the liver cell and be exported to other tissues.
27. (a) $G6P + 2NADP^+ + H_2O \rightarrow R5P + CO_2 + 2NADPH + 2H^+$
(b) $G6P + P_i + 12NADP^+ + 7H_2O \rightarrow 6CO_2 + 12NADPH + 12H^+$
28. C-1 and C-3 of fructose-6-phosphate should be labeled. Erythrose-4-phosphate should be unlabeled.
- 29.

(see Fig. 14.20, p. 619)

CHAPTER 14

1. Administer separately 1- ^{14}C]glucose and 6- ^{14}C]glucose, and measure initial rates of $^{14}CO_2$ formation. The ratio gives relative flux rates through the two pathways. For example, if the flux rates are equal, the ratio from C¹-labeled glucose to C⁶-labeled glucose is 2:1.
2. C-1: all released as CO_2 . C-2 and C-3: all retained in oxaloacetate.
3. First turn: one-quarter. Second turn: three-eighths.
4. The action of pyruvate carboxylase on the labeled pyruvate would yield oxaloacetate labeled such that, when these carbons proceed through the citric acid cycle, C-5 of isocitrate would be labeled.
5. Addition to isolated glyoxysomes of citrate, isocitrate, glyoxylate, malate, or oxaloacetate would stimulate succinate formation out of proportion to the amount added.
6. C-3 and C-4, because these become the carboxyl group of pyruvate, which is lost in the pyruvate dehydrogenase reaction.
7. First, the cytosolic location of much of the $NADP^+$ -dependent enzyme raises suspicions about its role in the citric acid cycle. More important, cells that have high or low flux rates through the cycle have high or low activities, respectively, of the $NADP^+$ -dependent enzyme. Activity of the $NADP^+$ -dependent enzyme does not vary in coordination with activities of other cycle enzymes.
8. E_1 : pyruvate + lipoyllysine \rightarrow acetyl-lipoyllysine + CO_2
 E_2 : acetyl-lipoyllysine + CoA-SH \rightarrow acetyl-CoA + dihydrolipoyllysine
 E_3 : dihydrolipoyllysine + NAD^+ \rightarrow $NADH + H^+$ + lipoyllysine
9. (a) This is a signal that levels of substrates are adequate for citric acid cycle oxidation, so that pyruvate can be shunted into gluconeogenesis instead of being oxidized. In addition, if acetyl-CoA is accumulating due to unbalanced fat vs. carbohydrate metabolism, it will divert pyruvate to OAA until balance is achieved.
- (b) This tends to inactivate pyruvate dehydrogenase (by phosphorylation) when levels of reduced electron carriers ($NADH$) are sufficient for ATP production via the respiratory chain and, hence, to make pyruvate available for other purposes.
(c) This is a signal to reduce flux through the citric acid cycle when levels of reduced electron carriers are adequate for energy generation.
(d) When the energy charge is low, the accumulation of ADP provides a signal to activate the citric acid cycle and thereby increase the oxidation of nutrients for ATP production.
(e) This is an example of product inhibition, but it also serves as a general indicator that when an energy-rich substrate (succinyl-CoA) is abundant, flux through the citric acid cycle can be reduced.
(f) Ca^{2+} mediates stimulation of PDH activity during muscle contraction. Ca^{2+} is a critical signaling molecule for contraction in vertebrate muscle, which places a huge demand on ATP production.
10. (a) An oxidation is required to convert the aldehyde to an acid. An oxidation requires an electron acceptor (e.g., NAD^+ or E-FAD):

- (b) The modified pathway bypasses the succinyl-CoA synthetase reaction of the standard citric acid cycle, which produces one ATP (GTP) by a substrate-level phosphorylation. The modified pathway therefore generates one less ATP than the standard pathway. There is no difference in the number of reduced cofactors generated (four oxidations per cycle).

11. Some possible mechanisms: substrate-level control of citrate synthase, activation of citrate lyase by acetyl-CoA or fatty acids, inhibition of isocitrate lyase by succinate (to ensure adequate flux through the citric acid cycle).
12. $2 \text{ acetyl-CoA} + 2\text{NAD}^+ + \text{E-FAD} + 3\text{H}_2\text{O} \rightarrow \text{oxaloacetate} + 2\text{NADH} + \text{E-FADH}_2 + 2\text{CoA-SH} + 4\text{H}^+$
13. The redox potential of the flavin, which does not dissociate from its enzyme, depends on its protein environment. In lipoamide dehydrogenase, its redox potential is held more negative than in other flavin

dehydrogenases, so that electrons can be passed onto NAD^+ under physiological conditions.

14. $[\text{NAD}^+]/[\text{NADH}]$ should be high, so that it can promote the oxidation of substrates, e.g., malate + $\text{NAD}^+ \rightleftharpoons$ oxaloacetate + $\text{NADH} + \text{H}^+$. Conversely, because NADPH and NADP^+ usually promote reduction of substrates, we expect $[\text{NADP}^+]/[\text{NADPH}]$ to be low.

CHAPTER 15

1. +28.95 kJ/mol (from the equation $\Delta G^{\circ} = -nF\Delta E^{\circ}$).
 $\Delta E^{\circ} = -0.32 - (-0.17)$.

2. (a) $\text{Cyt } c \rightarrow \text{Cu}_A \rightarrow \text{heme } a \rightarrow \text{heme } a_3\text{-Cu}_B \rightarrow \text{O}_2$
 (i.e., complex IV)
 (b) To block oxidation of endogenous substrates and to inhibit reverse electron flow (i.e., to prevent electrons flowing back up the respiratory chain).
 (c) Because ATP is formed, with a P/O ratio of ~1.0, complex IV must be a coupling site (i.e., a site of proton pumping).
 (d) From Table 15.1:

Coupled to:

- (e) - 78.1 kJ/mol for overall reaction (calculated as in Problem 1).
3. (a) β -hydroxybutyrate \rightarrow NADH \rightarrow complex I \rightarrow CoQ \rightarrow complex III \rightarrow cytochrome *c*.
 (b) 2, because cytochrome *c* oxidase is bypassed.
 (c) Because NADH cannot freely enter the mitochondrion.
 (d) To block cytochrome oxidase, so that electrons exit the chain at cytochrome *c*.
 (e) β -hydroxybutyrate + 2 $\text{cyt } c_{\text{ox}} + 2\text{ADP} + 2\text{P}_i + 4\text{H}^+ \rightarrow$ acetoacetate + 2 $\text{cyt } c_{\text{red}} + 2\text{ATP} + 2\text{H}_2\text{O}$
 (f) -53.8 kJ/mol β -hydroxybutyrate (calculated as in Problem 2).
4. To block succinate dehydrogenase and measure phosphorylation resulting only from the α -ketoglutarate dehydrogenase reaction. P/O ratio = ~3.5 (2.5 ATP from NADH and 1 from the succinyl-CoA synthetase reaction).
5. +67.6 kJ/mol (solved as in Problem 1). Minimum $[\text{NAD}^+]/[\text{NADH}]$ ratio = 2.5×10^{10} , calculated from Equation 3.23 (Chapter 3):

$$\Delta G = \Delta G^{\circ} + RT \ln \left(\frac{[\text{fumarate}][\text{NADH}]}{[\text{succinate}][\text{NAD}^+]} \right)$$

where $\Delta G < 0$.

6. $[\text{ADP}] = 1.44 \text{ mM}$ and $[\text{AMP}] = 0.29 \text{ mM}$, calculated from two simultaneous equations: the defining equation for energy charge, and $[\text{ADP}] = 5 \times [\text{AMP}]$.

$$\Delta G = -27.8 \text{ kJ/mol}$$

$$\text{from } \Delta G = \Delta G^{\circ} + RT \ln ([\text{ADP}][\text{P}_i])/[\text{ATP}].$$

7. 1.8×10^{17} . Calculate ΔG° as in Problem 1, and then apply $\Delta G^{\circ} = -RT \ln K_{\text{eq}}$. Use $E^{\circ} = +0.30 \text{ V}$ for H_2O_2 (see Table 15.1).
8. Add ADP in limiting amount and measure O_2 uptake. The ratio of μmol ADP consumed to μatom oxygen taken up is identical to the P/O ratio (see Figure 15.27).
9. Because the energy not used for ATP was dissipated as heat, and the subjects developed uncontrollable fevers.

10. 1.

11. (1) NADH is oxidized by FMN, not FAD.
 (2) Reduced flavin (FADH_2 or FMNH_2) is oxidized by CoQ, not CoQH_2 .
 (3) $\text{cyt } c_1$ accepts e^- from $\text{cyt } b$, and is then oxidized by $\text{cyt } c$.
 (4) O_2 is reduced to H_2O , not H_2O_2 .

12. (a) $\Delta G^{\circ} = -nF\Delta E^{\circ} = -2(96485) \times [-0.23 - (-0.32)] = -17.37 \text{ kJ/mol}$
 (b) The same, because E° for NAD^+/NADH is the same as for $\text{NADP}^+/\text{NADPH}$.
 (c) ΔG would probably be positive in vivo for an NADH-linked enzyme because the high NAD^+/NADH concentration ratio would promote the oxidation of GSH to GSSG.

13. (a) Succinate \rightarrow FAD \rightarrow Q \rightarrow $\text{cyt } b \rightarrow$ $\text{cyt } c_1 \rightarrow$ $\text{cyt } c$
 (b) succinate + 2 $\text{cyt } c_{\text{ox}} + \text{ADP} + \text{P}_i \rightarrow$ fumarate + 2 $\text{cyt } c_{\text{red}} + \text{ATP} + \text{H}_2\text{O}$.
 (c) For the redox reaction, $\Delta G^{\circ} = -nF\Delta E^{\circ} = -2(96485)(0.2 - 0.03) = -42.5 \text{ kJ/mol}$; ΔG° for synthesis of ATP = +30.5 kJ/mol; net $\Delta G^{\circ} = -42.5 + 30.5 = -12 \text{ kJ/mol}$.
 (d) To block cytochrome oxidase and force electrons to exit the respiratory chain at cytochrome *c*.
 (e) 0. No ATP would be produced because 2,4-dinitrophenol would dissipate the proton gradient.

14. DNP acts catalytically in the sense that one DNP molecule can mediate the transport of multiple protons into the matrix: after deprotonating in the matrix (due to the higher pH), DNP cycles back across the membrane to bind and bring another proton into the matrix. One important implication is that DNP is toxic in very small amounts.

15. (a) $\Delta G^{\circ'} = -nF\Delta E^{\circ'} = -2(96485)(0.82 - 0.03)$
 $= -151 \text{ kJ/mol.}$
 (b) For protons (eqn 15.5, p. 647): $\Delta G^{\circ'} = 2.3 RT \Delta \text{pH} + F\Delta\psi = 24.9 \text{ kJ/mol protons.}$
 $151/24.9 = 6 \text{ protons maximum}$
 (c) Complexes III and IV.
16. All 3 inhibitors leave d oxidized, so d must be last; all three inhibitors leave c reduced, so c must be first:

17. (a) A, 1; B, 2; C, 3; D, 4; E, 5.
 (b) 3 divided by 4 (ratio of uptakes in presence and absence of ADP, with substrate present for both measurements).
 (c) 5; O₂ depleted.
 (d) 4; ADP level low because ATP level is high.
 (e) 3; rapid ATP production and turnover demand rapid and continuous O₂ uptake.

CHAPTER 16

- $\Delta G^{\circ} = 164 \text{ kJ/mol.}$ An einstein of 700 nm light would yield 171 kJ.
- 14.7%.
- 1050 nm.
- (a) After being attached to C-2 of ribulose-1,5-bisphosphate, the ¹⁴C will become the carboxylate (C-1) of *one* of the two molecules of 3-phosphoglycerate. This becomes the carbonyl carbon (C-1) in G3P, or C-1 in DHAP. Upon condensation to form fructose-1,6-bisphosphate, the ¹⁴C will show up in carbons 3 and/or 4.
 (b) No. They may carry 0, 1, or 2 labeled carbons, depending on what combination of labeled and unlabeled trioses has been used in their formation.
- Assuming 48 photons per mole of hexose, the leaf could theoretically produce 0.0263 mol, or 4.73 g, of hexose in 1 hour. It will, in fact, produce only a small fraction of this, for not all photons are absorbed, nor do all absorbed photons serve to pass electrons through the photosynthetic pathway.
- (a) No, because plastoquinones are not involved in this process.
 (b) Addition of ferricyanide as an electron donor allows a Hill reaction.
- By using illumination at both 700 and 680 nm, either singly or together. Observe the oxidation state of plastoquinones and plastocyanin. If only p700 is involved, these will be oxidized. If only p680, they will be reduced. If both are involved, simultaneous illumination at the two wavelengths will give enhanced oxidation of the donor.
- Carbon 3.
- Competitive.
- The data suggest the strong binding of an inhibitor. It is apparently heat stable, so it is probably not a protein, but it is released on ammonium sulfate precipitation.
- (a) Decrease.
 (b) Increase.
 (c) Increase.
- (a) Because both O₂ and CO₂ are being consumed and produced by the opposing processes of photorespiration and photosynthesis, a steady-state ratio will be attained.
 (b) The relative affinity of rubisco for CO₂ and O₂.
- Most of the 3PG that is initially labeled is reused in replacing RuBP, which then reenters the cycle.

CHAPTER 17

- Palmitic acid, 106 ATP; stearic acid, 120 ATP; linoleic acid, 116 ATP; oleic acid, 118.5 ATP. The lower values for linoleic and oleic acids vs. stearic acid are due to the presence of double bonds in the former.
- $34\% [(108 \text{ ATP} \times 30.5) / (9788) \times 100\%].$
- $336.5 (106 \text{ from each palmitate, } 18.5 \text{ from glycerol}). 336.5 \text{ ATP}/51 \text{ carbons} = 6.6 \text{ ATPs per carbon atom (5.3 for glucose).}$
- Example for palmitic acid (c) follows.
 $\text{CoA-SH} + \text{palmitate} + \text{ATP} \rightarrow \text{palmitoyl-CoA} + \text{AMP} + \text{PP}_i$
 $\text{PP}_i + \text{H}_2\text{O} \rightarrow 2\text{P}_i$
 $\text{Palmitoyl-CoA} + 7 \text{ CoA-SH} + 7\text{FAD} + 7\text{NAD}^+ + 7\text{H}_2\text{O} \rightarrow$
 $8 \text{ acetyl-CoA} + 7\text{FADH}_2 + 7\text{NADH} + 7\text{H}^+$
 $8 \text{ acetyl-CoA} + 16\text{H}_2\text{O} + 24\text{NAD}^+ + 8\text{FAD} + 8\text{ADP}$

Now add the equations for the metabolic oxidation of NADH and FADH₂.

5. Acetoacetyl-CoA \longrightarrow 2 acetyl-CoA 2 Acetyl-CoA \longrightarrow 4CO ₂	0 ATP 20 ATP (two turns of citric acid cycle)
Sum: 20 ATP	
Propionoacetyl-CoA \longrightarrow propionyl-CoA + acetyl-CoA Propionyl-CoA \longrightarrow succinyl-CoA Succinyl-CoA \longrightarrow 4CO ₂	4 ATP (one cycle of β -oxidation) -1 ATP 20 ATP (two turns of citric acid cycle)
Acetyl-CoA \longrightarrow 2CO ₂	10 ATP (one turn of citric acid cycle)
Sum: 34 ATP	

6. Carnitine acyltransferase I. If inhibition occurred at a later step, then palmitoylcarnitine oxidation would be inhibited, as well as that of palmitoyl-CoA.

7. The acyl-ACP produced by one subunit undergoes the next round of reductive two-carbon addition on the other subunit.

The main point is that the carbons lost in one turn of the citric acid cycle are not the ones that entered as acetyl-CoA in that cycle.

10. 7 (during each cycle, one tritium atom is lost at the 3-hydroxyacyl-ACP dehydratase step, and the resulting double bond is reduced by unlabeled NADPH).

11. Increase in citrate levels would increase generation of acetyl-CoA in cytosol, hence stimulating fatty acid synthesis.

12. 1. Glucagon activates phosphorylation of pyruvate dehydrogenase, which inhibits the formation of acetyl-CoA, the substrate for the enzyme.

2. Glucagon promotes triacylglycerol breakdown, yielding increased levels of fatty acids, which, as acyl-CoAs, could prevent polymerization and activation of acetyl-CoA carboxylase.

13. Malonyl-CoA, a key intermediate in fatty acid synthesis, inhibits carnitine acyltransferase I, thereby blocking the entry of fatty acyl units into the mitochondrion for oxidation. Fatty acyl-CoAs, the substrates for fatty acid oxidation, inhibit fatty acid synthesis by interfering with the polymerization of acetyl-CoA carboxylase. Hormonal effects on adipocytes are opposed; insulin promotes fatty acid synthesis by several mechanisms, while glucagon promotes fat breakdown and fatty acid oxidation.

14. This could be a way for a cell to inhibit fatty acid synthesis under conditions where substrates are needed for oxidation, to provide ATP.

15. Increased glucose levels in the cytosol stimulate glycolysis, which provides pyruvate for oxidation in the mitochondrion. The resultant acetyl-CoA can return to the cytosol (as citrate) and generate precursors for increased fatty acid synthesis. The increased intracellular glucose also stimulates adipocytes to synthesize glycogen.

CHAPTER 18

1. It is presumed that starch increases blood glucose levels less than simple sugars do. Thus, there is less stimulation of insulin secretion. Insulin would tend to retard energy mobilization from intracellular stores—something not desirable during a marathon.

2. About 2.6 hours. Normal glycogen reserves are about 6800 kJ for a 70 kg person (see p. 710 in Chapter 17). Thus,

$$(6800 \text{ kJ}) \times (1 \text{ kcal}/4.183 \text{ kJ}) = 1625.6 \text{ kcal}$$

For running,

$$(15000 \text{ kcal/day}) \times (1 \text{ day}/24 \text{ hr}) = 625 \text{ kcal/hr}$$

$$\text{Time} = (1625.6 \text{ kcal}) / (625 \text{ kcal/hr}) = 2.6 \text{ hr}$$

3. About 28% at rest, about one-tenth that value during a marathon.

4. The measured proteolysis represents the sum of rates of protein synthesis and breakdown. The actual rate of protein breakdown does not rise, but in the early stage of a fast, the utilization of amino acids in catabolic pathways reduces the concentrations needed to support protein synthesis at rates that counterbalance breakdown. Later, as fatty acids and ketones are used more for energy, amino acids are spared for this purpose and are more readily available to be used for protein synthesis.

5. Glucosylated hemoglobin accumulates in the blood of diabetics and can easily be measured. Because the glucosylation reaction is covalent, the level of glucosylated hemoglobin reflects the level of blood glucose over a period of about four months (the life of an erythrocyte), whereas a single determination of glucose reflects only the value at the time of blood sampling. Thus, longer-term diabetes control can be monitored with greater accuracy if glucosylated hemoglobin is measured.

6. Liver contains low levels of the enzyme that synthesizes acetoacetyl-CoA from acetoacetate, ATP, and CoA-SH. Therefore, when liver synthesizes ketone bodies, they cannot readily be activated for catabolism within the hepatocyte. Instead, they are released and ultimately utilized by other tissues.

7. Adipose tissue lacks glycerol kinase. Glycolysis generates dihydroxyacetone phosphate, which is reduced to glycerol 3-phosphate (see Chapter 17).

8. (a) Malonyl-CoA at high levels inhibits carnitine acyltransferase I, and this inhibits ketogenesis by blocking the transport of fatty acids into mitochondria, both for β -oxidation and for ketogenesis (see Chapter 17).

(b) The high $K_{0.5}$ of hexokinase IV, a liver-specific enzyme, allows the liver to control the rate of glucose phosphorylation over a wide range of glucose concentrations. Accumulation of glucose-6-phosphate activates the *b* form of glycogen synthase and promotes glycogen deposition. By several mechanisms the liver also senses when blood glucose levels are low and mobilizes its glycogen reserves accordingly (see Chapter 13).

9. Phosphorylation of pyruvate kinase by cyclic AMP-dependent protein kinase. The phosphorylated form of the enzyme is far less active than the dephosphorylated form (see Chapter 14).

CHAPTER 19

1. ΔG is probably ~ 0 (K_{eq} close to unity) because the bond broken is identical to the bond created (a transesterification).

2. If phosphatidylserine synthase and phosphatidylserine decarboxylase (E_1 and E_2 in Figure 19.4) were kinetically and physically coupled, PS could never accumulate because once formed by E_1 , it would immediately be converted to PE by E_2 . If the two enzymes are tightly coupled in the membrane, then addition of radiolabeled PS to an enzyme system would not label PE because E_2 would act only on PS generated by E_1 .

3. By stimulating release of arachidonic acid from membrane phospholipids. These in turn would be converted to prostaglandins, which contribute to inflammation.

4. Substitution of vegetable fats for animal fats could decrease cholesterol levels. This would ultimately decrease inhibition of HMG-CoA reductase levels by cholesterol, which could result in increased mevalonate levels.

6. None, because the carboxyl C is lost in conversion to the isopentenyl pyrophosphate intermediate.

7. Because this is a nonhydrolyzable analog of glycerol-3-phosphate, you might expect it to be acylated without difficulty to give the phosphonate analog of diacylglycerol. By acting as an analog of diacylglycerol, this could competitively inhibit the synthesis of CDP-diacylglycerol from phosphatidic acid.

8. 25% from the choline utilization pathway, 75% from the phosphatidylserine pathway. If all the PC came from the PS pathway, you would expect the specific activity of PC to be $3 \times$ that of the methionine ($3 \times 2 = 6 \text{ mCi/mmol}$). Instead, it is only $1.5/6 = 25\%$, suggesting that 75% of PC was synthesized from free choline. These calculations assume that the endogenous methionine pool is small and becomes virtually completely labeled. To know true intracellular rates

of synthesis, you must also know the specific radioactivity of the final intermediate in each pathway, whether pools of intermediates are compartmentalized, and the rate of degradation of the product (see Tools of Biochemistry 12A).

10. By shutting down the pathway leading to aldosterone, this deficiency increases the supply of progesterone available for conversion to sex steroids.

11. The most straightforward route is desaturation of C16 palmitoyl-CoA to palmitoleoyl-CoA, followed by a C_2 elongation at the carboxyl group, both described on page 744, to give *cis*-vaccenyl-CoA. Alternatively, stearoyl-CoA could be an enzyme-bound intermediate in a process starting with elongation and followed by desaturation.

12. The most straightforward way is to purify one of the enzymes, such as PE methylase, to homogeneity and then to ask whether that enzyme can catalyze three methylations to give PC, or whether it can act upon the monomethylated and dimethylated intermediates. Alternatively, one could follow all three activities through a fractionation procedure.

13. Cyclic AMP promotes triacylglycerol breakdown, through activation of hormone-sensitive lipase. This probably increases intracellular levels of diacylglycerol, which could in turn increase flux through the last reactions in the salvage pathways to PE and PC (see Figure 19.7).

14. Example: 2 isopentenyl pyrophosphate to limonene:

6. One plausible theory proposes that ammonia depletes pools of α -ketoglutarate through the glutamate dehydrogenase and glutamine synthetase reactions, which convert α KG to glutamate and glutamine, and that this diminishes ATP production by reducing flux through the citric acid cycle.

7. CPS I is in mitochondria, and CPS II is in cytosol. Apparently, carbamoyl phosphate cannot cross the mitochondrial membrane, so that which is formed in mitochondria can be used only for arginine synthesis, and that formed in cytosol is used only for pyrimidine synthesis.
8. The injected enzyme should convert all circulating asparagine to aspartate. Normal cells would take up aspartate and resynthesize asparagine. However, leukemic cells would be unable to synthesize asparagine and would starve. On the other hand, an enzyme injected into the bloodstream would probably have too short a half-life to be effective. Moreover, being a foreign protein, it might cause an immunological reaction.
9. (a) True. The complete catabolism of amino acids yields CO_2 , H_2O , and ammonia. However, the ammonia must be converted to urea for detoxification and excretion, and this requires ATP, which decreases the net ATP yield.
 (b) False. Glutamate can be used to synthesize essential amino acids only if the carbon skeletons are available as keto acids.
 (c) False. Arginine is used *catalytically* in the urea cycle in liver, and thus most of the arginine that is formed is cleaved to urea and ornithine. Little arginine is left over to meet the needs of other tissues.
 (d) False. Although it is present in all proteins, alanine can be synthesized by mammalian cells and is not required in the diet.

10. Refer to Figure 20.13:

11. (a) NH_3 has an unshared electron pair that can initiate nucleophilic attack on the electron-poor carbonyl carbon atom.
 (b) $[\text{NH}_3] + [\text{NH}_4^+] = 100 \mu\text{M}$. From the Henderson–Hasselbalch equation, at pH 8.0 $[\text{NH}_3]/[\text{NH}_4^+] = 10^{-1.2} = 0.063$. Thus, $[\text{NH}_3] = 6.7 \mu\text{M}$ (and $[\text{NH}_4^+] = 93.3 \mu\text{M}$). $6.7 \mu\text{M} [\text{NH}_3]$ is $(6.7 \times 10^{-3})K_M$. The Michaelis–Menten equation can be rearranged to

$$\frac{V}{V_{\max}} = \frac{[S]}{K_M + [S]}$$

Substituting $[S] = (6.7 \times 10^{-3})K_M$ into the equation gives

$$\frac{V}{V_{\max}} = \frac{6.7 \times 10^{-3} K_M}{K_M + (6.7 \times 10^{-3})K_M} = 0.0067$$

- (c) The direction of a reaction depends both upon the equilibrium constant and the concentrations of reactants and products. The intramitochondrial $[\text{NAD}^+]/[\text{NADH}]$ ratio is high, and this drives the reaction toward α -ketoglutarate.

12. PLP forms a covalent Schiff base between the aldehyde carbon of the coenzyme and an ϵ -amino group of a lysine residue. Obviously, this bond must be broken for the coenzyme to form a Schiff base with an amino acid substrate.
13. (a) This will control the synthesis of carbamoyl phosphate by regulating the synthesis of glutamine, the preferred substrate for carbamoyl phosphate synthetase.
 (b) This will have the effect of activating the deadenylation of glutamine synthetase, which in turn activates glutamine synthetase. This would promote the utilization of α -ketoglutarate for glutamate and glutamine synthesis.
 (c) This also has the effect of activating glutamine synthetase, under conditions where the ATP needed for the reaction is abundant.
14. First, purify the enzyme from HeLa cells or another human tissue and prepare antiserum against the enzyme. Then label HeLa cell cultures by growth in a radioactive amino acid. At intervals following removal of the labeled amino acid (a pulse-chase experiment), prepare a cell-free protein extract, treat an aliquot with antiserum, and count the radioactivity in the immunoprecipitate.
15. Dihydrofolate: GTP:
- | | |
|-----|------|
| N-1 | N-3 |
| C-2 | C-2 |
| C-4 | C-6 |
| N-5 | N-7 |
| C-7 | C-1' |
| N-8 | N-9 |
| C-9 | C-3' |

16. (a) B. (b) C. (c) D. (d) E, methionine.
 (e) A. (f) F. (g) C.

17. Adenylation tends to inactivate glutamine synthetase. Therefore, the effect of glutamine is to inhibit its own synthesis when it is present in abundance.

18. The most straightforward answer is to place the two enzymes in different cell compartments—the catabolic enzyme in mitochondria and the assimilative enzyme in cytosol.

CHAPTER 21

1. Formiminoglutamate, because the next reaction in its catabolism requires tetrahydrofolate.

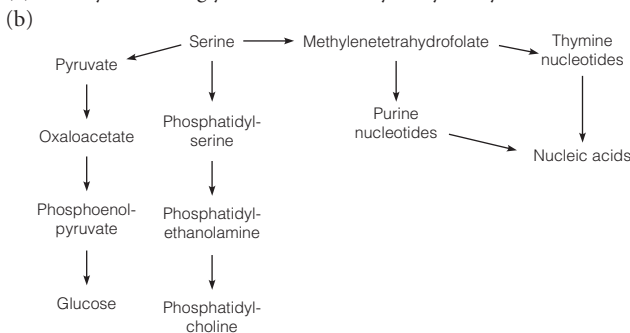

3. *N*-Acetylglutamate is an intermediate in ornithine biosynthesis. Activity of the urea cycle requires both ornithine and carbamoyl phosphate. If insufficient carbamoyl phosphate is available, ornithine will accumulate, and this could cause accumulation of the precursor, *N*-acetylglutamate. This accumulation acts as a signal to stimulate carbamoyl phosphate synthesis to increase urea cycle flux.

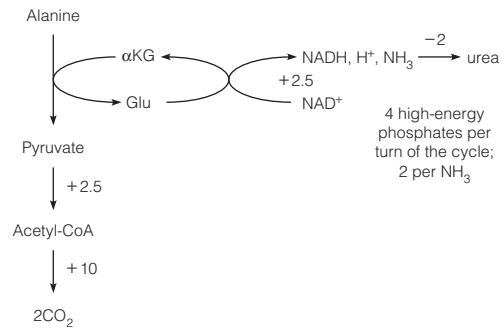

A tryptophan tolerance test

6. (a) Tetrahydrofolate, glycine, and serine hydroxymethyltransferase.

7. Alanine = 13 ATPs

You might expect all of these pathways to generate a little more energy in a fish because it is not necessary to consume ATP in converting ammonia to urea for excretion.

Isoleucine = 36 ATPs (see Figure 21.5 and Problem 5 in Chapter 17)

Tyrosine = 40.5 ATPs (see Figure 21.8)

8. One should be feedback inhibited or have its synthesis repressed by threonine, a second by methionine, and a third by lysine because the aspartokinase reaction is involved in separate biosynthetic pathways leading to each of these three amino acids.

10. Because the same enzymes are involved in comparable steps of both isoleucine and valine biosynthesis. Threonine dehydratase.

11. Threonine \rightarrow α -ketobutyrate: inhibited by isoleucine

α -ketoisovalerate + acetyl-CoA \rightarrow β -isopropyl malate: inhibited by leucine

Control of valine synthesis is more complicated because three of the enzymes are involved in synthesis of all three amino acids. One could look for cumulative feedback inhibition—by valine, isoleucine, and leucine—of the first committed reaction:

12. Histamine.

13. (a) 5. (d) None.
 (b) 2, 3, 4. (e) 5 (X3).
 (c) 3, 4. (f) 5.

14. Because a pteridine reductase deficiency would impair all tetrahydrobiopterin-dependent reactions, which include the synthesis of catecholamines, serotonin, and nitric oxide, as well as tyrosine.

17. The structure of glyphosate is similar to that of phosphoenolpyruvate, suggesting that it acts as a competitive inhibitor with respect to PEP and a noncompetitive inhibitor with respect to shikimic acid 3-phosphate.
18. Because the synthesis of bilirubin diglucuronide occurs in the liver, a chronically diseased liver would be unable to effect this conversion, and unconjugated bilirubin would accumulate. In either a bile duct obstruction or an elevated heme destruction resulting from hemolysis, there would not initially be an impairment of the conjugating system, so most of the accumulated bilirubin would be in the conjugated form.
19. Reaction 1: pyridoxal phosphate
Reaction 2 and reaction 3: O_2 and NADPH (or another two-electron donor)

21.

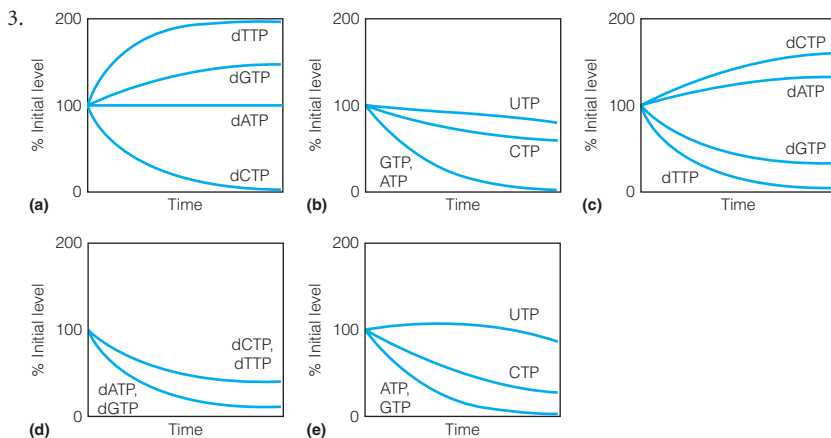

Modified from *Proceedings of the National Academy of Sciences of the United States of America* 103:13688–13693, J. Stetefeld, M. Jenny, and P. Burkhard, Intersubunit signaling in glutamate-1-semialdehyde-aminomutase. © 2006 National Academy of Sciences, U.S.A.

CHAPTER 22

1. (a) C.
(b) E, F.
(c) A, B.
2. $\text{BrdUrd} \xrightarrow[\text{ATP}]{\text{TK}} \text{BrdUUMP} \xrightarrow[\text{ATP}]{} \text{BrdUDP} \xrightarrow[\text{ATP}]{\text{Nucleoside diphosphate kinase}} \text{BrdUTP}$

Br-dUTP can be incorporated into DNA in place of dTTP. However, it might also inhibit DNA synthesis by acting as a false feedback inhibitor of CDP reduction. Because dTTP is an allosteric inhibitor of CDP reduction by ribonucleotide reductase, Br-dUTP might have a similar effect. This could inhibit DNA replication by causing a dCTP deficiency.

4. Outline answer (* = sites of allosteric regulation).

5. Outline answer (* = sites of allosteric regulation).

6. Deoxycoformycin treatment might lead to adenosine and deoxyadenosine accumulation, as in adenosine deaminase deficiency. This would cause dATP to accumulate and shut off all activities of ribonucleoside diphosphate reductase.

7. Decreased flux through HGPRT could cause the substrates to accumulate, including PRPP. This could increase pyrimidine synthesis at the orotate phosphoribosyltransferase reaction, if PRPP levels are normally subsaturating for that enzyme. Orotate incorporation into nucleotide pools or nucleic acids would give a reasonable estimate of the rate of de novo pyrimidine nucleotide synthesis.

8. (a) Either a deficiency of thymidylate synthase activity, measured in a cell-free extract, or a growth requirement of cells for thymidine would confirm that the mutants are deficient in this enzyme.

(b) Because the mutants have negligible flux through the thymidylate synthase reaction, they do not deplete their intracellular tetrahydrofolate. Thymidine satisfies the need for synthesis of thymine nucleotides.

(c) Use methotrexate instead of trimethoprim because trimethoprim is not an effective inhibitor of mammalian dihydrofolate reductase.

9. Mutation in DHFR gene that makes the enzyme resistant; mutation in transcriptional or translational control mechanism that causes overproduction of normal DHFR; transport defect that causes failure of methotrexate to be taken up by cell.

10. (a) Inhibitors of thymidylate synthase and dUTPase specified by the viral genome.

(b) Virus-specified dUMP hydroxymethylase and hm-dUMP kinase:

(c) Virus-specified dCMP methylase, e.g.,

11. (a) Mutants with a defect in DNA synthesis (no thymidine incorporated into DNA).

(b) Mutants defective in thymidine kinase, thymidylate synthase, dihydrofolate reductase, or serine hydroxymethyltransferase can be selected for by their resistance to decay of incorporated [³H]deoxyuridine.

12. If intermediates in a pathway are restricted in their ability to diffuse away from enzyme surfaces, then a multistep pathway can be catalyzed efficiently with very low steady state levels of intermediates. Thus, you could set up an assay system for such a sequence and analyze levels of intermediates at various times. Another test for channeling involves running a multistep sequence beginning with a radiolabeled substrate and asking whether addition of a large excess of an unlabeled intermediate will dilute the radioactivity of the product. A pathway channeled by an enzyme complex preferentially uses intermediates that are produced by that complex.

13. 4-carboxy-5-aminoimidazole ribonucleotide + aspartate + ATP → *N*-succinyl-5-aminoimidazole-4-carboxamide ribonucleotide + ADP + P_i

14. Uncontrolled conversion of UTP to CTP elevates pools of cytidine and deoxycytidine nucleotides, while pools of uridine and thymidine nucleotides are diminished. The depletion of endogenous thymidine nucleotide explains the growth requirement for exogenous thymidine, and the perturbed dNTP pool imbalance (dCTP/dTTP ratio is elevated) causes replication errors, principally C incorporated opposite A, that lead to mutations.

16. (a) Feeding thymidine stimulates salvage pathway synthesis and accumulation of ATP, which inhibits CDP reduction by ribonucleotide reductase and inhibits DNA replication by depleting the cell of dCTP.

(b) dATP binds to both activity and specificity sites of ribonucleotide reductase, with low and high affinities, respectively. When bound at the specificity site, dATP activates the reduction of CDP and UDP. At higher levels, dATP binds at activity sites and inhibits all four activities of ribonucleotide reductase.

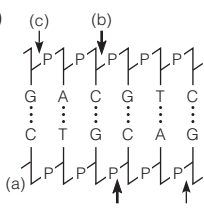

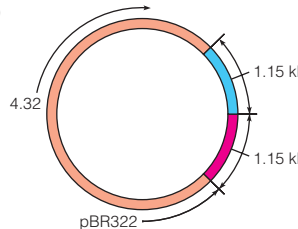

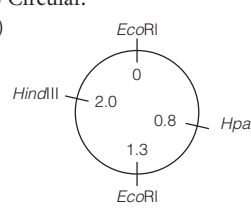

17. Succinyl-CoA synthetase.

18. Glycine is incorporated into purines as an intact molecule at the GAR synthetase reaction (step 2), accounting for labeling of the C5 position. Label at C2 and C5 comes from 10-formyl-THF (steps 3 and 9). Glycine donates its C2 to the tetrahydrofolate one-carbon pool in the mitochondrial glycine cleavage reaction (see Chapter 21), yielding 5,10-methylene-THF, which is readily converted to 10-formyl-THF for incorporation into purines. This experiment is from Pasternack, L. B., D. A. Laude, Jr., and D. R. Appling, (1994) ¹³C NMR analysis of intercompartmental flow of one-carbon units into choline and purines in *Saccharomyces cerevisiae*. *Biochemistry* 33:74–82.

CHAPTER 23

- Using recombinant DNA techniques (see Chapter 4), one could prepare nucleic acid sequences that encode either an entire subunit of a G protein or a GTP-binding domain and ask whether that “probe” can hybridize with DNA from a plant species of interest. Alternatively, one could ask whether antibodies against mammalian G proteins cross-react with any proteins in a plant extract. If so, the protein could be isolated and its properties analyzed (including its ability to bind guanine nucleotides). Another approach is to look for proteins that can be ADP-ribosylated by cholera toxin or pertussis toxin.
- Some possible factors: storage, control of activity, proper folding of the polypeptide chain, signal sequences for direction to the proper part of the cell.
- Ethylene. It would probably be difficult to prepare an antibody against it, as it is a gas.
- Because steroid hormone–receptor complexes activate the transcription of specific genes, a steroid hormone could conceivably activate the transcription of the gene for adenylate cyclase and, hence, increase the steady state level of this enzyme.
- (a) 1, 4, 9, 14.
(b) 5, 6, 8, 10, 16.
(c) 1, 2, 7, 12, 16.
(d) 1, 4, 15, 16.
- One could treat a G protein–GDP complex with γ -[^{32}P]ATP and ask whether radiolabeled GTP is synthesized. The fact that it is not indicates that the G protein cannot phosphorylate bound GDP. One can also show that radiolabeled GTP can displace bound, unlabeled GDP under various conditions. One can also show that activation of the G protein requires the presence of GTP. Finally, one can demonstrate that the isolated α subunit has GTPase activity, by showing its ability to convert GTP to GDP in the absence of GDP.
- (a) Viagra inhibits cyclic GMP phosphodiesterase, so cGMP levels remain high, thereby prolonging the effects of nitric oxide upon regional blood flow.
(b) Prozac selectively inhibits reuptake of serotonin by presynaptic neurons, thereby increasing the amount of the neurotransmitter that reaches the postsynaptic cell, increasing synaptic transmission in areas related to regulation of mood.
(c) If AdoMet could cross the blood–brain barrier, it might conceivably increase methylation of norepinephrine to give epinephrine. Because that seems unlikely, maybe one should view the initial report with skepticism.
- $\text{cGMP} + \text{H}_2\text{O} \rightarrow 5' \text{-GMP}$. Because Viagra acts by inhibiting this enzyme, any other compound acting similarly should potentiate the effect of Viagra.
- Because inositol trisphosphate is derived from phosphatidylinositol, which in turn is derived from diacylglycerol and inositol, inositol phosphates must be completely dephosphorylated in order to be reincorporated into phosphatidylinositol for another round of synthesis.
1. Most plant hormones are terpenoid compounds.
2. There are no known peptide hormones in higher plants. Steroid-like compounds have been described in plants, but it is not clear that they act like steroid hormones.
- The reaction of EGF with its receptor should be trimolecular, because EGF binding should promote dimerization of the monomeric receptor. Therefore, a simple hyperbolic curve would not be expected.
- Catechol O-methyltransferase
Norepinephrine + AdoMet \rightarrow Epinephrine + AdoHcy
Monoamine oxidase
Dopamine + $\text{O}_2 \rightarrow$ 3,4-Dihydroxyphenylacetic acid + NH_3

CHAPTER 24

- $10 \times 10^3 \text{ bp} / 10^{10} \text{ bp in genome} = 10^{-6}$
Amplification = 2^{n-1} where n is the number of cycles
After 10 cycles: $2^9 \times 10^{-6} = 1.02 \times 10^{-3}$
After 15 cycles: $2^{14} \times 10^{-6} = 3.3 \times 10^{-2}$
After 20 cycles: $2^{19} \times 10^{-6} = \text{essentially } 1.0$
- Flush ends: *EcoRII*, *HaeIII*, *HindII*, *HpaI*, *SmaI*. Not made flush by DNA polymerase (because the recessed end lacks a 3' hydroxyl): *HgaI*, *HhaI*, *PleI*, *PstI*.
- (a) 
(c) Up to 1 kb away from this site.
(e) A particular hexanucleotide sequence would arise at intervals of $1/4^6$, or every 4056 base pairs.
- (a) To linearize circular DNA, so that its electrophoretic mobility can be compared with those of other linear DNA fragments.
(b) The recombinant DNA contains two tandem 1.15-kb inserts.
(c) 
- (a) Circular.
(b) 
(c) 7.
(d) Cleave with *HpaII* plus *HindIII*.

- (b) A and B.
 (c) E and F.
 (d) E.

7. (a) $6.6 \times 10^2 \text{ g/mol} \times 2 \times 10^8 \text{ nuc. molecules/chromosome} / 6.02 \times 10^{23} \text{ molecules/mol} = 2.2 \times 10^{-13} \text{ g DNA/chromosome} + 4.4 \text{ g protein/chromosome} = 0.66 \text{ pg}$
 (b) $10^8 \text{ bp} \times 3.4 \text{ \AA /bp} \times 10^{-8} \text{ cm/\AA} = 3.4 \text{ cm}$
 (c) $3.4 \times 10^{-2} \text{ m} / 5 \times 10^{-6} \text{ m} = 6.8 \times 10^3$
 (d) $46 \text{ chrom./cell} \times 10^{12} \text{ cells} \times 3.4 \times 10^{-2} \text{ m/chromosome} = 1.56 \times 10^{12} \text{ m}$

8. If we take the average nucleosome (including linker) to contain about 200 bp, we get a compaction ratio of 40 for the 30-nm chromatin fiber. Obviously, this fiber must be greatly folded on itself to yield the overall ratio of over 7000 found in the metaphase chromosome.

9. If the nucleosome were exactly positioned (all occupying the same site on the 208-bp fragment), only a single pair of bands (summing to 146 bp) would have been obtained. The fact that two such pairs (29 + 117, 39 + 107) were observed means that there are two alternative locations, 10 bp apart.

10. Using a graph of $\log(\text{bp})$ vs. d for the markers, one can interpolate the chromatin fragments to obtain sizes of 185, 380, 578, and 772 bp. A repeat of about 195 bp is indicated, with the monosome being slightly degraded.

11. The simplest explanation comes from the hypothesis (since proved) that the DNA lies on the surface of the particle. Thus, each strand is maximally exposed approximately every 10 residues and is most susceptible to nicking at these periodically spaced points.

12. The DNA makes 1.75 left-hand superhelical turns about each nucleosome. These turns are “constrained” and cannot be removed while the histones are still present. However, if the histones are first removed, the DNA so produced will have unconstrained supercoils, which can be relaxed by topoisomerase.

13. Histones are required in very large amounts during only one brief period (the beginning of S phase) in the cell cycle. Furthermore, they are always required in equivalent amounts, to make nucleosomes. The presence of multiple copies aids in rapid transcription, and an equal number in each domain should help maintain balance in production. The absence of introns and poly(A) tails means that two of the major steps involved in processing most eukaryotic genes are avoided, so that histone mRNAs can be delivered rapidly to the cytoplasm.

14. For example, cutting with both *EcoRI* and *BamHI* would yield a digest in which fragment B in the *BamHI* digest had disappeared. That places an *EcoRI* site within the B fragment. Sizes of all of the fragments in the digest would suggest that only one *EcoRI* site lies within fragment B. Now if a partial digest with *BamHI* yielded a fragment corresponding to A + B and digestion of this fragment with *EcoRI* yielded a fragment nearly as large as A + B, this would locate the *BamHI* site toward the 5' end of B.

15. An addition or deletion or substitution of one or more bases in any symmetrical restriction site would inactivate that site. As an example, for a tetranucleotide repeat –AATT– within the *EcoRI* site: –GAATTC– → –GAATTAATTC–
 The *EcoRI* site is lost.

- (b) The red line shown in the graph.

- (c) The genomic DNA would renature more slowly than cDNA because it has greater sequence complexity among the 300-bp fragments used for the analysis.

17. Measurement of the approximate length of each phase of the cell cycle indicates that M, when cells are undergoing mitosis, accounts for about 3% of the total time in one cell cycle. That should represent the proportion of cells undergoing mitosis in a random (non-synchronized) culture, and, hence, the percentage of total cells showing condensed chromosomes.

CHAPTER 25

Use a 5' end-labeled primer, and run a polymerase reaction in DNA excess (so that any polymerase that dissociates will rebind to a new chain). Stop reactions after a brief incubation and determine the molecular weight of radioactive material by gel electrophoresis. M_t tells how many nucleotides were incorporated per chain, which gives the processivity (number of nucleotides incorporated per unit time per chain).

Incorporation of dUMP generates sites for chain breakage, as the uracil replacement process begins. If the single-strand breaks had not been fully repaired when DNA was isolated, short fragments would be seen. Fewer of these would be seen if the experiment were done with a mutant defective in uracil-DNA-N-glycosylase—and more if the experiment were done with a dUTPase-negative mutant.

3. (a) 1.725 g/cm^3 .
 (b) 1.772 g/cm^3 .
4. (a) To eliminate virtually all further incorporation of radioisotope.
 (b) If incorporated as ribonucleotides, the labeled product will be hydrolyzed by mild alkali. If incorporated as deoxyribonucleotides, the product is alkali stable.
 (c) RNA primers are metabolically unstable. They are rapidly degraded, as they are replaced by deoxyribonucleotides in DNA.
5. (a) Deoxyinosinic acid (dIMP).
 (b) Conversion of an A–T to a G–C base pair.
6. (a) 0.016 mm.
 (b) 9.79×10^4 nucleotides per fork per minute.
 (c) 1250 origins (2500 replication forks).
 (d) 2937 kilobase pairs.

7. (a) It's the reversal of the DNA ligase reaction. Single-strand interruption relaxes supercoiled DNA.

- (b) Analyze the DNA by gel electrophoresis.

8. Synchronize cells and label with 5-bromodeoxyuridine either early or late in S phase. Separate replicated DNA by CsCl equilibrium centrifugation. This can be analyzed by hybridization with cloned DNAs from genes known to be expressed or not expressed in those cells.

9.

Note: The 3' exonuclease removes the mismatched A and T before polymerase action begins.

10. The polymerase activity was found to extend more slowly from an improperly paired terminus. Thus, a mismatched base has a longer residence time at the 3' terminus than a matched base, increasing the likelihood of cleavage by the exonuclease activity.
11. Dideoxyinosine is converted to the corresponding dideoxyribonucleoside triphosphate, ddITP. Incorporation of this nucleotide in place of dGTP would block further chain elongation because of the absence of a 3'-OH terminus. If the HIV reverse transcriptase incorporates ddITP more readily than the cellular DNA polymerases do, then replication of the viral genome would be selectively inhibited.
12. If the mutation affected one of the feedback control sites of ribonucleotide reductase, the cell could overproduce dNTPs to the extent that competitive inhibition in vivo of replicative DNA polymerases by aphidicolin could be overcome.
13. They initiate rounds of replication at intervals shorter than 40 min. Thus, a cell may have two identical chromosomes, each at the same stage of replication.
14. Because ethidium bromide in the gel relaxes the positive supercoils, converting an overwound duplex to a relaxed circle, with a consequent loss of mobility.
15. The inchworming model suggests that each subunit of helicase is continuously in contact with just one DNA strand, while in the hand-over-hand model, continuous strand exchange occurs.
16. One mechanism would have the enzyme bind at two distant sites on DNA and then slide along DNA so that the two DNA contact points come closer and closer together. If any knots or links are encountered, they can be removed by topoisomerase cutting and resealing.

17. Fractional abundance: 10^{-6} .
 Abundance after 10 cycles, 1.02×10^{-3} ; 15 cycles, 3.3×10^{-2} ; 20 cycles, 1.0 (essentially 100%).

18. What is needed here is an in vitro system that will replicate mtDNA with purified proteins (polymerase, helicase-primase, single-strand DNA-binding protein, etc.) so that replication can be initiated synchronously in a population of purified mtDNA molecules. Such a system may be available soon.

(a) Incubate mtDNA in this system with unlabeled dNTPs and radiolabeled rNTPs. Determine the ability of labeled RNA to anneal to denatured mtDNA restriction fragments. If the RNA represents replication primers it should hybridize only to fragments representing replication origins. Another approach is to carry out a transfer experiment comparable to the Okazaki experiment outlined in Figure 25.16, and determine what proportion of incorporated ribonucleotides become linked to deoxyribonucleotides.

(b) If mtDNA replicates by the strand displacement model described in Figure 25.36, then all DNA synthesis is unidirectional. Label replicating DNA with radiolabeled dNTPs in the above in vitro system. Because complete mtDNA replication requires an hour, all labeled DNA formed in the first ten minutes or so should hybridize only with L strand DNA. Later in the process, DNA that becomes labeled will hybridize with both strands. Doing this experiment requires that one separate the strands of mtDNA, so that annealing to each strand can be measured separately.

19. It is likely that increasing dNTP concentrations, even modestly, will increase rates of DNA chain extension from a mismatch at the 3' terminus. This will have the effect of inhibiting proofreading because a mismatch that occurred because of incorporation of an incorrect deoxyribonucleotide will have a greater probability of undergoing chain extension than nucleolytic removal, and this seals the mismatch in place, where a mutation will occur in the next round of replication.

20. (a) Extensive treatment with topoisomerase I will relax all DNA molecules, so they should all migrate like species 6 in Figure 25A.1, a circular molecule that is neither underwound nor overwound.

(b) Treatment of underwound DNA with gyrase and ATP would make an already underwound population of molecules even more underwound. So the pattern of spots shown in Figure 25A.1 might be expected to shift downward as the figure is oriented. The most strongly underwound molecules might not change their migration because there is a thermodynamic limit to the number of superhelical turns that gyrase can introduce.

CHAPTER 26

- Increase, because mismatch repair would repair the “correct” mismatched nucleotide half the time.
- (a) 2, 7, 9, 11.
(b) 3, 5, 6.
(c) 2, 11.
(d) 1, 11.
(e) 1, 8, 11.
(f) 4, 6.
(g) 10, 11.
(h) 6, 11, 12.
- (a) A.
(b) B.
(c) C.
(d) D.
(e) A, C.
(f) C.
- Because both strands are methylated.
- dUTPase deficiency increases dUMP incorporation into DNA and increases subsequent excision repair. Ligase deficiency increases the mean lifetime of Okazaki fragments. Both conditions increase the number of single-strand interruptions, the structures that initiate recombination.
- First, clone a large number of DNA fragments from cells containing the integrated virus. Next, carry out colony hybridization on these clones, using labeled viral DNA as the hybridization probe. From Southern blot analysis of clones containing viral DNA, identify viral DNA fragments that are larger than corresponding fragments from the nonintegrated double-strand viral DNA. These should represent viral sequences fused to adjacent cellular sequences. These can now be subcloned and sequenced.
- Nonenzymatic deamination of the cytosine in a G·C base pair yields a G·U base pair, which is readily repaired by the uracil-N-glycosylase base excision repair system. However, if the C in that base pair has been methylated before deamination, then deamination of G·mC yields a G·T base pair, which is not as easily corrected. Also, it is possible that methylation of C in a G·C base pair facilitates its deamination.
- This is a surprising result because the function of the MutT protein is thought to be hydrolysis of 8-oxo-dGTP, an oxidation product of dGTP. It is not clear how this oxidation could occur in the absence of O₂. Perhaps MutT acts also on another mutagenic nucleotide not yet identified, which can be formed during anaerobic growth.
- It’s likely that repair would occur on the nicked strand, for that would be the strand containing 3’ hydroxyl termini from which repair polymerases could initiate DNA synthesis.
- The most likely pathway involves deamination of G-C to G-U, with the U specifying A on the next round of DNA synthesis. Another possibility is for UNG to create an abasic site after removing U created by deamination, with any base then being inserted opposite that site at the next round of replication, before the repair process can be completed. Or, during repair DNA synthesis after deamination of C in a G-C base pair, dUTP could be incorporated at an A-T base pair, leading to A-U, which then undergoes erroneous UNG repair, as described above.
- By inserting within a gene the transposon would interrupt expression of the gene. By inserting into an adjacent regulatory region, the result could be either enhanced or reduced transcription of the gene, depending upon the nature of the regulatory region.

CHAPTER 27

- Pulse-label cells with a radioactive RNA precursor, isolate RNA, and hydrolyze with mild alkali. This will yield one nucleoside per 3’ terminus. Total picomoles of labeled nucleotide in the hydrolysate divided by the number of picomoles of nucleosides gives the number of nucleotides incorporated per chain in the labeling interval.
- First, devise conditions under which only the cloned gene is synthesized. You could initiate transcription by adding three ribonucleotides. At time zero, add the fourth nucleotide and stop incubation after a fixed time. Use a small, measured amount of template so that the number of transcribing genes is roughly equal to the number of template molecules. Determine the average length of transcripts synthesized by gel electrophoresis.
- By gel electrophoresis of radiolabeled RNA products. Any paused species will accumulate and can be detected as a heavier-than-expected band on a radioautograph of the gel.
- A dinucleotide, complementary to the first two template nucleotides, can bypass the first nucleotide incorporation step and permit efficient transcription at low nucleotide concentrations. Then one can arrest all transcription events at one nucleotide by knowing the nucleotide sequence of the gene being transcribed and adding only two or three rNTPs, instead of all four, with the missing nucleotide being the one that would have been inserted at the site at which you desire to arrest transcription.
- Because it uses the –35 region of *trp* and the –10 region of *lac*, the hybrid *tac* promoter more closely matches the consensus –35 and –10 sequences than does either *lac* or *trp*.

	Number of identities with consensus sequence
<i>lac</i>	9/12
<i>trp</i>	8/12
<i>tac</i>	10/12
- Actinomycin is a noncompetitive inhibitor because it binds to DNA, not to a substrate-binding site on the enzyme. Cordycepin acts as the nucleotide, 3’-deoxyATP. This should compete with ATP for utilization by RNA polymerase.

7. (a) RNA 3' CUAGGAUUCAGUAAGG 5'
 DNA 5' GATCCTAAGTCATTCCCATTACCAGTATAG 3'
 3' CTAGGATTCAGTAAGGGTAATGGTCATATC 5'
- (b) Pribnow box is underlined in (a)
- (c)

 TAGCTA
 ATCGAT
 ↑

```
8. If two genes on a plasmid are oriented in the same direction and both are being transcribed, then the overwinding created ahead of gene 1 can be compensated by the underwinding created behind gene 2, and vice versa.
9. One way would be to measure the distribution of poly(A) tail lengths in bulk mRNA. If a distribution were found that cut off at a distinct minimal value, the hypothesis would be supported; all mRNA with shorter tail lengths would have been degraded.
10. There are many possible ways. One is to simply cross-link DNA to histones in an in vitro transcription system. If this blocks transcription, which proceeds in the presence of un-cross-linked nucleosomes, this provides evidence of the necessity of removal, or at least

displacement. A more critical test would be to carry out transcription in vitro in the presence of an excess of radiolabeled, nongenic DNA. If nucleosomes are found on this after transcription, removal from the genomic DNA is indicated.

11. (a) 7 exons, 6 introns.  
 (b) These two structures will be at opposite ends of the RNA (shorter strand). However, one cannot unequivocally identify the 5' and 3' ends from such a figure, unless something is known of its sequence.
12. It may be difficult to form loops shorter than 65 nucleotides.
13. Once the transcription complex is formed, it is extremely stable, and in accessible to heparin.
14. A 50-kDa protein would contain about 450 amino acid residues, and therefore would be encoded by a gene containing  $3 \times 450$ , or 1350 nucleotides. If  $V_{\max}$  for RNA polymerase is 50 nucleotides per second, this gene could be transcribed in 27 seconds, assuming that the gene contains no introns. Also the time needed for initiation and formation of a stable transcription complex would lengthen the time needed.

## CHAPTER 28

1.  $\cdots$  Ile–Tyr–Ile–Tyr–Ile–Tyr– $\cdots$ . Either AUA codes for Ile and UAU for Tyr or vice versa.
2. The mitochondrial code uses AUA to code for *Met*, not *Ile*. The experiment also tells us that UAU is a Tyr codon.
3. (a) First, codons such as UUU or AAA can yield only one polypeptide. Second, some reading frames in some polynucleotides will be read as repeats of stop codons.  
 (b)  $(GUA)_n$  Val<sub>n</sub> or Ser<sub>n</sub> (third reading frame is UAG = stop).  
 $(UUA)_n$  Leu<sub>n</sub> or Tyr<sub>n</sub> or Ile<sub>n</sub>
4. Any polynucleotide built from a tetranucleotide repeat, unless a stop codon is involved.
5. The Shine–Dalgarno sequence, like the AUG that is read uniquely as fMet, occurs near the 5' end of the message. The implication is that, in forming the initiation complex, only a region near the 5' end of mRNA can bind. That is, a Shine–Dalgarno sequence occurring by chance within a message could not bind at this site to form an initiation complex. Other explanations may be possible.
6. (a)  $5'GGU^{3'}$ ,  $5'GGC^{3'}$ , or  $5'GGA^{3'}$ . All are Gly codons.  
 (b)  $5'AGU^{3'}$  or  $5'AGC^{3'}$ . Both are Ser codons.
7. (a) The simplest explanation for particles of 100S and 130S is that they represent some kind of dimers and trimers of 70S particles (note the nonlinearity of S with mass). From what we know now, these represented small oligoribosomes on mRNA. The research missed discovering the basic mechanism of protein synthesis.  
 (b) Dissociation would have produced ribosomal subunits and free RNA. Because these were only fragments of polyribosomes, the chance that they would reassociate onto the RNA is small. Furthermore, mRNA is extremely unstable, unless precautions are taken to eliminate traces of ribonucleases (a fact that this experi-
- menter did not appreciate at that time). Thus, the mRNA was probably quickly degraded.
8. Because the tRNA is going to be released from the E-site, codon recognition and pairing with the anticodon are in no way advantageous and may, in fact, be detrimental to smooth release.
9. 32 different tRNAs with different anticodons, using wobble rules, could translate all 61 sense codons.
10. If  $\delta$  is the probability that an error is committed at each step, then  $1 - \delta$  is the probability that an error has not been made in any one step. The probability that no error has been made in *any* of the  $n$  steps is then  $(1 - \delta)^n$ . This is the probability that the protein is entirely error-free.
11. (a) 0.990.  
 (b) 0.904. In this case, nearly 10% of the proteins would contain one or more errors.
12. Bacteria are given a pulse of radioactive amino acids (e.g., [<sup>14</sup>C] leucine) to label new polypeptide chains. The cells are broken; nucleoids, cell walls, and membranes are removed by centrifugation; and the lysate is placed on a sucrose gradient. The appearance of <sup>14</sup>C in fractions sedimenting more rapidly than 70S indicates that newly synthesized protein is associated with such structures. Samples taken some time *after* the pulse will have little label in these fractions, showing that it was protein in the process of translation that was associated with the polysome fraction. Ribonuclease digestion will shift the radiolabel to 70S or lower.
13.  $36 \text{ (ATP/glucose)}/4 \text{ (ATP/residue added)} = 9 \text{ residues added/glucose}$ .  
 This is a maximum because any inefficiency in ATP production, or use of extra ATP in proofreading and so forth, will give less efficiency.

- absorbance ( $A_l$ )** A dimensionless number that indicates how well a solution of a substance absorbs light of a given wavelength. It is defined as the negative logarithm of the fraction of light of wavelength  $l$  that passes through a sample of the solution; its value depends on the length of the light path, the concentration of the solution, and the extinction coefficient of the substance at that wavelength.
- acetylcholinesterase** An enzyme found in cholinergic synapses that breaks down acetylcholine and thus terminates its action on the postsynaptic cell.
- action potential** A wave of transient depolarization that travels along the membrane of a nerve cell (or any other kind of excitable cell, such as a muscle cell) as a result of fluxes of ions across the membrane. A nerve impulse.
- activated state** With respect to a chemical reaction, a transient high-energy state of a reactant molecule (such as an unfavorable electron configuration or strained conformation) that enables the molecule to undergo the reaction.
- active site** The site on an enzyme molecule where the substrate binds and where the reaction is facilitated. It is often a cleft or pocket in the surface of the enzyme.
- active transport** The transport of a substance across a biological membrane by a mechanism that can work against a concentration (or electrochemical) gradient. It always requires the expenditure of cellular energy. Compare *facilitated transport*, *passive transport*.
- adenylate energy charge** A measure of the energy status of a cell, calculated as the ratio of the ATP concentration plus one half the ADP concentration divided by the sum of the AMP, ADP, and ATP concentrations. See *energy charge*.
- adenylation** In cells, the transfer of an adenylyl moiety from ATP to another molecule. Some enzymes are regulated by reversible adenylylation; often incorrectly referred to as adenylation.
- adipocytes** Fat cells; cells that are specialized for storing triacylglycerols and for releasing them to the blood in the form of fatty acids and glycerol as required.
- adrenergic receptors** Cell-surface receptors that bind epinephrine or norepinephrine. There are several different types with somewhat different ligand specificities and effects. (The term comes from *adrenaline*, the old name for epinephrine.)
- affinity chromatography** A protein purification technique in which a specific ligand for the protein of interest is immobilized upon a chromatographic support, so that enrichment of that protein is based upon its specific affinity for the immobilized ligand.
- affinity constant** See *association constant*.
- agonist** In molecular biology, a substance that mimics the cellular effects of a natural compound (such as a hormone or neurotransmitter) by binding to and activating the same cellular receptor. Compare *antagonist*.
- A helix** Referring to nucleic acids, a right-handed helix structure of nucleic acid duplexes that has a smaller pitch and a larger diameter than the B-DNA helix. It is the structure adopted by RNA duplexes and RNA-DNA hybrid molecules.
- AIDS (acquired immune deficiency syndrome)** A disease caused by prolonged infection with human immunodeficiency virus (HIV) and characterized by crippling of the immune system. Victims die of infections or cancers that their immune system cannot control.
- alditols** Compounds that are produced by reducing the carbonyl group on a monosaccharide.
- aldose** A monosaccharide in which the carbonyl group comes at the end of the chain and thus represents an aldehyde group. Compare *ketose*.
- alkaloids** A large group of nitrogenous basic substances found in plants. Most of them taste bitter, and many are pharmacologically active. The term can also be used for synthetic compounds of the same type. Morphine, caffeine, and nicotine are familiar alkaloids.
- alignment** Referring to sequence alignment, the comparison of nucleic acid or protein sequences by lining up identical or closely related portions of sequence in the two sequences being compared.
- allele** A specific version of a gene that occupies a particular location in the genome. It is distinguished from other alleles of the same gene by differences in nucleotide sequence.
- allosteric** With respect to enzymes, an effect that is produced on the activity of one part of an enzyme (such as an active site) by the binding of an effector to a different part of the enzyme.
- alternative splicing** The splicing of a eukaryotic RNA transcript in different ways, to include or exclude certain exons from the final mRNA.
- Alu Elements** DNA sequences about 300 base pairs long that occur in many copies scattered throughout the genome of primates; the human genome has hundreds of thousands of them. They may serve an unknown function, or they may be purely “parasitic,” spreading as mobile elements through the genome.
- Ames test** A test for the mutagenicity of a substance. A strain of the bacterium *Salmonella typhimurium* having a mutation that disables an enzyme necessary for histidine utilization is exposed to the substance in question and plated on a medium lacking histidine. A reversion mutation that activates the mutant enzyme causes the cells to grow on this medium.
- amino terminus** See *N-terminus*.
- amphipathic** For a molecule, the property of having both hydrophobic and hydrophilic portions. Usually one end or side of the molecule is hydrophilic and the other end or side is hydrophobic.
- ampholyte** A substance whose molecules have both acidic and basic groups.
- anabolism** The sum of all the metabolic processes by which complex biomolecules are built up from simpler ones. In general, these processes consume rather than produce cellular energy. Compare *catabolism*.
- anaerobic** Refers to the absence of oxygen or the absence of a need for it; processes that must or can occur without oxygen are called anaerobic processes.
- anaplerotic** Referring to pathways that replenish pools of citric acid cycle intermediates.
- androgens** The male sex hormones; specifically, the steroid hormones testosterone, dihydrotestosterone, and androstenedione, which act mainly to promote male sexual development and maintain male sex characteristics.
- anneal** Referring to a process (usually slow cooling after heat denaturation) that allows complementary nucleic acid single strands to find each other and pair up, reforming a duplex molecule.
- anomers** Stereoisomers of cyclized monosaccharide molecules differing only in the configuration of the substituents on the carbonyl carbon. (This carbon is a center of chirality in the cyclized but not in the open-chain form of the molecule.)
- antagonist** In biochemistry, a substance that counteracts the cellular effects of a natural compound (such as a hormone or neurotransmitter) by binding to the cellular receptor for the compound and blocking its action. Compare *agonist*.
- antibodies** (also called immunoglobulins) A set of related proteins that are produced by B lymphocytes and can bind with specificity to antigens. Some types are released into body fluids and mediate humoral immunity; other types are retained on the surface of the B cell or are taken up and displayed by some other cell types.

- anticodon** The nucleotide triplet on a tRNA that binds to a complementary codon on mRNA during protein synthesis and thereby mediates the translation of the codon into a specific amino acid.
- antigen** A substance that can elicit a specific immune response.
- antigenic determinant** See *epitope*.
- antimetabolite** A substance that is a structural analog of a normal metabolite or otherwise resembles it and that interferes with the utilization of the metabolite by the cell.
- antioxidant** A strongly reducing compound, such as ascorbic acid, which counteracts the tendency of a metabolite to undergo oxidation to a potentially toxic or harmful species.
- antiport** A membrane transport process that couples the transport of a substance in one direction across a membrane to the transport of a different substance in the other direction. Compare *symport*.
- antisense RNA** An RNA molecule that is complementary to an mRNA; it can block translation of the mRNA by forming a duplex with it. Gene expression can be regulated by the production of antisense RNAs.
- antiserum** Serum that contains antibodies against a particular antigen.
- apolipoproteins** The specific proteins that constitute the protein fraction of lipoproteins; they mediate the interactions of lipoproteins with tissues.
- apoprotein** For a protein with a prosthetic group (which see) the polypeptide portion of the molecule without the prosthetic group.
- apoptosis** Programmed cell death (as distinguished from necrosis; see *autolysis*).
- archaea** A group of prokaryotes that are biochemically distinct from the true bacteria (Eubacteria) and that separated from them early in the history of life. Modern archaea live mostly in extreme environments, such as acid hot springs.
- association constant (*K*)** (also called affinity constant) An equilibrium constant that indicates the tendency of two chemical species to associate with each other; it is equal to the concentration of the associated form divided by the product of the concentrations of the free species at equilibrium.
- asymmetric carbon** A carbon molecule that carries four different substituents and therefore acts as a center of chirality, meaning that the substance can occur in two different enantiomers (stereoisomers that are nonsuperimposable mirror images of each other).
- atherosclerotic plaques** The protruding masses that form on the inner walls of arteries in atherosclerotic disease. A mature plaque consists partly of lipid, mainly cholesterol esters, which may be free or contained in lipid-engorged macrophages called foam cells, and partly of an abnormal proliferation of smooth-muscle and connective-tissue cells.
- attenuation** A mechanism for regulating prokaryotic gene expression in which the synthesis of a nascent RNA transcript is terminated before RNA polymerase has reached the structural genes.
- autocatalytic** Refers to a reaction that an enzyme catalyzes on part of its own structure, such as a cleavage performed by a protease on its own polypeptide precursor.
- autoimmunity** A condition in which the body mounts an immune response against one of its own normal components.
- autolysis** Programmed cell death; the orderly self-destruction of a cell in a multicellular organism. It is the process by which unwanted cells are eliminated in the body. Also called *apoptosis* (which see).
- autonomously replicating sequences (ARSs)** Sequences in yeast chromosomes that, when incorporated into an artificial plasmid, enable the plasmid to replicate efficiently in yeast cells.
- autotrophs** Organisms that can synthesize their organic compounds entirely from inorganic precursors, in particular needing only CO<sub>2</sub> as a carbon source. Compare *heterotrophs*.
- auxotrophs** Microorganism strains that require as a nutrient a particular substance that is not required by the prototype (wild-type) strain.
- Usually the requirement results from a mutation that disables an enzyme necessary for the endogenous synthesis of the substance.
- axis of symmetry** An imaginary axis through a structure, such that rotating the structure around the axis through an appropriate angle leaves the appearance of the structure unchanged.
- axon** A threadlike process extending from a nerve cell by which impulses are transmitted to other nerve cells or to effector cells such as muscle or gland cells. Most nerve cells have one axon; shorter processes that function in receiving impulses from other neurons are called dendrites.
- base excision repair (BER)** A DNA repair process that begins with cleavage of a glycosidic bond between a damaged base and the deoxyribose to which it is linked.
- B-DNA** A DNA duplex with a specific right-handed helix structure. It is the usual form of DNA duplexes in vivo.
- Beer's law** The equation that relates the absorbance of a solution sample at a given wavelength to the length of the light path, the concentration of the dissolved substance, and the extinction coefficient of the substance at that wavelength. See *extinction coefficient*.
- bile acids** A family of amphipathic cholesterol derivatives that are produced in the liver and excreted in the bile; salts of the bile acids emulsify fat in the intestine.
- biogenic amines** A set of low-molecular-weight amino acid derivatives that contain a basic amino group and function in the body as intercellular mediators. Examples are serotonin, histamine, and epinephrine.
- bioinformatics** The quantitative and computational analysis of biological data.
- blood-brain barrier** A selective permeability barrier that is found in the walls of blood vessels in the brain and that prevents most large or polar molecules from readily entering brain tissue. Physically the barrier consists of tight junctions between endothelial cells; these cells have transporters for polar substances such as glucose that need to enter the brain.
- blood group antigens** A group of oligosaccharides that are carried in the form of glycoproteins and glycolipids on the surface of cells, including blood cells; they are encoded by a large number of polymorphic gene loci and can provoke an immune response in an individual with different blood group antigens.
- Bohr effect** The effect of pH on oxygen binding by hemoglobin, by which a decrease in pH causes a decrease in oxygen affinity. The effect promotes both the release of oxygen from hemoglobin in the tissues and the release of CO<sub>2</sub> from the blood to the air in the lungs.
- branch migration** During homologous recombination, the migration of a crossover point (Holliday junction) by simultaneous unwinding and rewinding in both duplexes.
- buffering** The ability of a mixture of an acid and its conjugate base at a pH near their pK<sub>a</sub> to minimize pH changes caused by an influx of acid or base.
- calorie** A unit of energy defined as that amount of heat energy that will raise the temperature of 1 gram of water by 1 °C. 1 calorie = 4.182 joules (which see).
- Calvin cycle** The cycle of photosynthetic dark reactions by which CO<sub>2</sub> is fixed, reduced, and converted to glyceraldehyde-3-phosphate (the precursor of hexose monophosphates).
- carbohydrates** In general, substances that have the stoichiometric formula (CH<sub>2</sub>O)<sub>*n*</sub>, where *n* is at least 3, or that are derived from such a substance by the addition of functional groups.
- carboxyl terminus** See *C-terminus*.
- carnitine** A low-molecular-weight lysine derivative that shuttles fatty acids through the inner mitochondrial membrane to the matrix. The fatty acyl moiety is transferred from CoA to carnitine for transit through the membrane and is then transferred back to CoA; the carnitine released on the matrix side of the membrane is shuttled back for reuse.

- caspases** A family of proteases involved in apoptosis (which see); (cysteine aspartate proteases) have an active site cysteine and attack bonds containing an asp residue.
- catabolism** The sum of all the metabolic processes by which complex molecules are broken down to simpler ones, including the processes by which molecules are broken down to yield cellular energy. Compare *anabolism*.
- catabolite activation** In bacteria, a transcriptional control system that induces the synthesis of enzymes for the catabolism of energy substrates other than glucose when glucose levels are low. It involves an activator protein, CRP, that binds cyclic AMP under conditions of low glucose; this complex then binds to DNA sites and promotes transcription of the appropriate genes.
- cathepsins** Lysosomal proteases that function in degrading proteins in lysosomes and are also released into the cell at large during cell autolysis (programmed cell death).
- cell wall** A rigid, protective wall around a plant, bacterial, or fungal cell that is secreted by the cell and is located outside the plasma membrane.
- center of chirality** With respect to organic compounds, a carbon atom that has four different substituents attached to it; such a group cannot be superimposed on its own mirror image and therefore can occur in two enantiomers.
- centromere** The region of a chromosome where the two sister chromatids are attached together. It is also the site of attachment for spindle fibers during mitosis and meiosis.
- C4 cycle** A cycle in some plants that minimizes the wasteful effects of photorespiration by using an enzyme other than rubisco to perform the initial fixation of CO<sub>2</sub>. This enzyme is found in mesophyll cells, where it fixes CO<sub>2</sub> into a four-carbon compound (hence *C4*). This fixed carbon is shuttled into sheltered bundle-sheath cells, where it is released as CO<sub>2</sub> and enters the Calvin cycle.
- chaotropic** The property of being able to disrupt the hydrogen bonding structure of water. Substances that are good hydrogen bonders, such as urea or guanidine hydrochloride, are chaotropic. Concentrated solutions of these substances tend to denature proteins because they reduce the hydrophobic effect.
- chaperonins** Proteins that are involved in managing the folding of other proteins. Some of them help proteins to fold correctly; some prevent premature folding; and some prevent polypeptides from associating with other polypeptides until they have folded properly.
- checkpoint** A point during the cell cycle at which the cell monitors its readiness to proceed into the next phase.
- chemical cross-linking** A technique for investigating the mutual arrangement of components in a complex. The complex is exposed to a reagent that can form chemical cross-links between adjacent components and is then disaggregated and analyzed. Components that are linked together can be assumed to be neighbors in the complex.
- chemical potential** (also called partial molar free energy) In a system, the free energy that resides in a chemical component per mole of the component present. For example, in a system consisting of *a* moles of component A and *b* moles of component B, the total free energy *G* would be the sum of the free energy in the two components:  $G = aG_{wA} + bG_{wB}$ .
- chemiosmotic coupling** The coupling of an enzyme-catalyzed chemical reaction to the transport of a substance across a membrane either with or against its concentration gradient. The outstanding example is the coupling of ATP synthesis to the movement of protons across a membrane in response to a proton gradient.
- chemotaxis** The process by which bacteria sense a concentration gradient of a particular substance in the medium and move either up or down the gradient.
- chemotherapy** The treatment of disease with chemical agents.
- chiral** With respect to a molecule or other object, the property of being non-superimposable on its mirror image. An atom that makes a molecule chiral, such as a carbon with four different substituents, is called a chiral atom or center of chirality.
- chloroplasts** The organelles in plant and algal cells that carry out photosynthesis.
- chromatin** The filamentous material of eukaryotic chromosomes, consisting of DNA with associated histones and other proteins. During interphase it is dispersed and fills most of the nucleus; during nuclear division it condenses into compact chromosomes.
- chromophore** A chemical group that absorbs light at characteristic wavelengths.
- chylomicron** A type of lipoprotein that is produced in the intestinal villi and serves to transport dietary lipids in the circulation.
- circular dichroism** The property of absorbing right circularly polarized light and left circularly polarized light to different extents. Stereoisomers exhibit circular dichroism. Also, some types of secondary structure, such as  $\alpha$  helices and  $\beta$  sheets in proteins, exhibit a predictable circular dichroism at specific wavelengths.
- circular dichroism spectrum (CD spectrum)** An optical spectrum obtained using circularly polarized light; it gives the circular dichroism of the substance over a range of wavelengths.
- cis-dominant** Refers to a mutation in a genetic regulatory element that affects the expression of appropriate genes *only* on the same chromosome, not on another homologous chromosome present in the same cell. *Cis*-dominance demonstrates that a regulatory element does not code for a diffusible factor.
- cistron** The smallest unit of DNA that must be intact to code for the amino acid sequence of a polypeptide; thus, the coding part of a gene, minus 5' and 3' untranslated sequences and regulatory elements.
- citric acid cycle** (also called tricarboxylic acid cycle and Krebs cycle) A cycle of reactions that takes place in the mitochondrial matrix and results in the oxidation of acetyl units to CO<sub>2</sub> with the production of reducing equivalents and ATP. It is a central pathway in oxidative respiration. Other substrates besides acetyl-CoA can enter the cycle at intermediate points.
- clamp loader** A multiprotein complex that opens the sliding clamp in DNA replication and allows binding and release of the sliding clamp.
- clathrate structure** The cagelike structure of organized water molecules that forms around a hydrophobic molecule in solution. The structure has lower entropy than liquid water, which helps explain why hydrophobic substances dissolve poorly in water.
- clonal selection theory** A model (proved correct) describing how the body is able to produce specific immune responses against a vast array of antigens. The B and T cells produced by the body have randomly generated antigen specificities. When a particular antigen enters the body, it induces proliferation only in B and T cells that happen to be specific for it. Thus, the antigen selects the cells that will mount an immune response against it and stimulates them to undergo clonal proliferation.
- clone** A group of cells, organisms, or DNA sequences that are genetically identical because they are all derived from a single ancestor.
- closed promoter complex** A pre-transcriptional complex of RNA polymerase and a promoter in which the promoter DNA strands have not yet unwound.
- coated pit** A cell membrane pit that is lined on its cytosolic side by a meshwork of the protein clathrin. Coated pits participate in the mechanism of receptor-mediated endocytosis, in which surface receptors that have bound specific extracellular substances are gathered into coated pits, which pinch off to become cytoplasmic vesicles.
- codon** A trinucleotide sequence corresponding to one specific amino acid in the genetic code; a "code word."
- coenzyme** An organic small molecule that binds to an enzyme and is essential for its activity but is not permanently altered by the reaction. Most coenzymes are derived metabolically from vitamins.

- colony hybridization** A technique that is used to screen bacteria for the presence of a specific recombinant DNA sequence. Colonies of the bacteria are transferred to a filter, treated to lyse the cells and denature the DNA, and then exposed to a labeled DNA probe that is complementary to part of the sequence in question. Colonies that bind the probe possess the sequence.
- competitive inhibitor** A substance that inhibits an enzyme-catalyzed reaction by competing with the substrate for the active site; the inhibitor can reversibly occupy the active site but does not undergo the reaction.
- concatemer** A DNA molecule that consists of a tandem series of complete genomes. Some phage genomes form concatemers during replication as part of a strategy for replicating the full length of a linear DNA duplex.
- confocal microscopy** A light-microscopy technique that allows high resolution in thick samples.
- conjugation** With respect to bacteria, a process in which two bacterial cells pair up and one of them passes a copy (usually partial) of its chromosome to the other. Also called bacterial mating.
- consensus sequence** For a group of nucleotide or amino acid sequences that show similarity but are not identical (for example, the sequences for a family of related regulatory gene sequences), an artificial sequence that is compiled by choosing at each position the residue that is found there most often in the sequences under study.
- constitutive** With respect to gene expression, refers to proteins that are synthesized at a fairly steady rate at all times instead of being induced and repressed in response to changing conditions.
- cooperative transition** A transition in a multipart structure such that the occurrence of the transition in one part of the structure makes the transition likelier to happen in other parts.
- copy number** The number of copies per cell of a particular gene or other DNA sequence.
- Cori cycle** The metabolic cycle by which lactate produced by tissues engaging in anaerobic glycolysis, such as exercising muscle, is regenerated to glucose in the liver and returned to the tissues via the bloodstream.
- counterion atmosphere** A cloud of oppositely charged small ions (*counterions*) that collects around a macroion dissolved in a salt solution. Counterion atmospheres partly shield macroions from each other's charges and thus affect their interactions.
- cristae** Folds in the inner mitochondrial membrane that project into the mitochondrial matrix. The enzymes of the electron transport chain and oxidative phosphorylation are located mainly on the cristae.
- crossover point** A specific site of inhibition at which an overall pathway is blocked.
- cruciform** In a DNA duplex, a structure that can be adopted by a palindromic sequence, in which each strand base-pairs with itself to form an arm that projects from the main duplex and terminates in a hairpin loop. The two arms form a "cross" with the main duplex.
- cryoelectron microscopy** A variation of electron microscopy (which see) in which samples are frozen in a glassy ice matrix.
- C-terminus** (also called carboxyl terminus) The end of a polypeptide chain that carries an unreacted carboxyl group. See also *N-terminus*.
- curie** The basic unit of radioactive decay; an amount of radioactivity equivalent to that produced by 1 g of radium, namely  $2.22 \times 10^{12}$  disintegrations per minute.
- cyclic photophosphorylation** In photosynthesis, photophosphorylation (light-dependent ATP synthesis) that is linked to a cyclic flow of electrons from photosystem II down an electron transport chain and back to photosystem II; it is not coupled to the oxidation of H<sub>2</sub>O or to the reduction of NADP<sup>+</sup>. Compare *noncyclic photophosphorylation*.
- cyclins** Proteins that regulate the cell cycle by binding to and activating specific nuclear protein kinases. Cyclin-dependent kinase activations occur at three points during the cell cycle, thus providing three decision points as to whether the cycle will proceed.
- cytokines** Compounds that regulate cell processes during the immune response.
- cytokinesis** The division of a eukaryotic cell to form two cells. It usually accompanies nuclear division, although nuclear division can occur without cytokinesis.
- cytoskeleton** An organized network of rodlike and fiberlike proteins that pervades a cell and helps give it its shape and motility. The cytoskeleton includes actin filaments, microtubules, and a diverse group of filamentous proteins collectively called intermediate filaments.
- cytosol** The fluid medium that is located inside a cell but outside the nucleus and organelles (for eukaryotes) or the nucleoid (for prokaryotes). It is a semiliquid concentrated solution or suspension.
- dark reactions** The photosynthetic subprocesses that do not depend *directly* on light energy; specifically, the synthesis of carbohydrate from CO<sub>2</sub> and H<sub>2</sub>O. Compare *light reactions*.
- denaturation** For a nucleic acid or protein, the loss of tertiary and secondary structure so that the polymer becomes a random coil. For DNA, this change involves separation of the two strands. Denaturation can be induced by heating and by certain changes in chemical environment.
- depurination** Cleavage of the glycosidic bond between C-1 of deoxyribose and a purine base in DNA. A common form of DNA damage.
- diabetes mellitus** A disease caused by a deficiency in the action of insulin in the body, resulting either from low insulin levels or from inadequate insulin levels combined with unresponsiveness of the target cells to insulin. The disease is manifested primarily by disturbances in fuel homeostasis, including hyperglycemia (abnormally high blood glucose levels).
- dialysis** The process by which low-molecular-weight solutes are added to or removed from a solution by means of diffusion across a semipermeable membrane.
- diastereomers** Molecules that are stereoisomers but not enantiomers of each other. Isomers that differ in configuration about two or more asymmetric carbon atoms and are not complete mirror images.
- dielectric constant** A dimensionless constant that expresses the screening effect of an intervening medium on the interaction between two charged particles. Every medium (such as a water solution or an intervening portion of an organic molecule) has a characteristic dielectric constant.
- difference spectrum** With respect to absorption spectra, a spectrum obtained by loading the sample cuvette with the substances under study and a reference cuvette with an equimolar sample of the same substances in a known state (for example, fully oxidized) and recording the difference between the two spectra.
- diffraction pattern** The pattern that is produced when electromagnetic radiation passes through a regularly repeating structure; it results because the waves scattered by the structure interact destructively in most directions (creating dark zones) but constructively in a few directions (creating bright spots). For the pattern to be sharp, the radiation wavelength must be somewhat shorter than the repeat distance in the structure. See also *X-ray diffraction*.
- diffusion coefficient (D)** A coefficient that indicates how quickly a particular substance will diffuse in a particular medium under the influence of a given concentration gradient.
- diploid** For a cell or an organism, the possession of two homologous sets of chromosomes per nucleus (with the possible exception of sex chromosomes, which may be present in only one copy). Compare *haploid*.
- dismutation** A reaction in which two identical substrate molecules have different fates; particularly, a reaction in which one of the substrate molecules is oxidized and the other reduced.
- dispersion forces** Weak intermolecular attractive forces that arise between molecules that are close together because the fluctuating electron distributions of the molecules become synchronized so as to produce a slight electrostatic attraction. These forces play a role in the internal packing of many biomolecules.

- dissociation constant** For an acid, the equilibrium constant  $K_a$  for the dissociation of the acid into its conjugate base and a proton. For a complex of two biomolecules, the equilibrium constant  $K_d$  for dissociation into the component molecules.
- DNA damage response** A coordinated series of events following DNA-damaging events in eukaryotic cells.
- DNA gyrase** An enzyme that is able to introduce negative superhelical turns into a circular DNA helix.
- DNAzyme** A catalytic DNA molecule, so far available only as a synthetic construct.
- domain** A portion of a polypeptide chain that folds on itself to form a compact unit that remains recognizably distinct within the tertiary structure of the whole protein. Large globular proteins often consist of several domains, which are connected to each other by stretches of relatively extended polypeptide.
- double-strand break repair** Processes in eukaryotic cells that allow repair of double-stranded DNA breakages.
- drug resistance factors** Bacterial plasmids that carry genes coding for resistance to antibiotics.
- dyad axis** A two-fold axis of symmetry.
- editing** See *RNA editing*.
- eicosanoids** A family of compounds, including prostaglandins and thromboxanes, that are derived from arachidonic acid, an eicosaenoic fatty acid.
- einstein** One mole of photons.
- electron microscopy** A form of microscopy in which electrons are used as radiation. Capable of very high resolution.
- electron spin resonance** (also called electron paramagnetic resonance, or EPR) A form of spectroscopy that is sensitive to the environment of unpaired electrons in a sample.
- electron transport chain** A sequence of electron carriers of progressively higher reduction potential in a cell that is linked so that electrons can pass from one carrier to the next. The chain captures some of the energy released by the flow of electrons and uses it to drive the synthesis of ATP.
- electrophoresis** A method for separating electrically charged substances in a mixture. A sample of the mixture is placed on a supporting medium (a piece of filter paper or a gel), to which an electrical field is applied. Each charged substance migrates toward the cathode or the anode at a speed that depends on its net charge and its frictional interaction with the medium. See also *gel electrophoresis*.
- elongation factors** Nonribosomal protein factors that are necessary participants in the chain-elongation cycle of polypeptide synthesis; they interact with the ribosome-mRNA complex or with other major cycle participants.
- enantiomers** (also called optical isomers) Stereoisomers that are nonsuperimposable mirror images of each other. The term *optical isomers* comes from the fact that the enantiomers of a compound rotate polarized light in opposite directions.
- endergonic** In a nonisolated system, a process that is accompanied by a positive change in free energy (positive  $G$ ) and therefore is thermodynamically not favored. Compare *exergonic*.
- endocrine glands** Glands that synthesize hormones and release them into the circulation. The hormone-producing gland cells are called endocrine cells.
- endocytosis** Uptake into a cell.
- endonuclease** An enzyme that hydrolytically cleaves a nucleic acid chain at an internal phosphodiester bond.
- endoplasmic reticulum (ER)** A highly folded membranous compartment within the cytoplasm that is responsible for a great variety of cellular tasks, including the glycosylation and trafficking of proteins destined for secretion or for the cell membrane or some organelles. It also functions in lipid synthesis, and the enzymes of many pathways of intermediary metabolism are located on its surface.
- endorphins** A class of endogenous brain peptides that exert analgesic effects in the central nervous system by binding to opiate receptors. They are produced by cleavage of the large polypeptide pro-opiomelanocortin.
- energy** The ability to do work. See *internal energy*.
- energy charge** A quantity that indicates the state of a cell's energy reserves. It is equal to the cell's reserves of the free energy sources ATP and ADP (taking into account that ADP stores less free energy than ATP) divided by the total supply of ATP and its breakdown products ADP and AMP:  $([ATP] + 1/2[ADP])/([ATP] + [ADP] + [AMP])$ .
- enhancer sequence** A DNA sequence that is distant from a gene but to which a protein factor that affects the gene's transcription can bind to exert its action. Enhancers are linked to RNA polymerase at the transcriptional start site by Mediator.
- enthalpy ( $H$ )** A thermodynamic quantity (function of state) that is equal to the internal energy of a system plus the product of the pressure and volume:  $H = E + PV$ . It is equal to the heat change in constant-pressure reactions, such as most reactions in biological systems.
- entropy ( $S$ )** A thermodynamic quantity (function of state) that expresses the degree of disorder or randomness in a system. According to the second law of thermodynamics, the entropy of an open system tends to increase unless energy is expended to keep the system orderly.
- enzyme** A catalyst for a biological reaction. Usually a protein molecule, but some enzymes are RNA molecules or ribonucleoproteins.
- epigenetics** The study of hereditary changes in gene expression that do not involve changes in DNA nucleotide sequence.
- epimers** Sugar isomers differing in configuration about one asymmetric carbon.
- episomes** Plasmids that can undergo integration into the bacterial chromosome.
- epitope** (also called antigenic determinant) The specific portion of an antigen particle that is recognized by a given antibody or T-cell receptor.
- equilibrium** A condition in which there are no net currents of matter or energy.
- essential amino acids** Amino acids that must be obtained in the diet because they cannot be synthesized in the body (at least not in adequate amounts).
- essential fatty acids** Fatty acids that must be obtained in the diet because they cannot be synthesized in the body in adequate amounts. Examples are linoleic acid and linolenic acid.
- eukaryotes** Organisms whose cells are compartmentalized by internal cellular membranes to produce a nucleus and organelles. Compare *prokaryotes*.
- exergonic** In a nonisolated system, a process that is accompanied by a negative change in free energy (negative  $G$ ) and therefore is thermodynamically favored. Compare *endergonic*.
- exocrine cell** A cell that secretes a substance that is excreted through a duct either into the alimentary tract or to the outside of the organism. Exocrine cells are grouped together in exocrine glands.
- exocytosis** Movement out of a cell.
- exon** A region in the coding sequence of a gene that is translated into protein (as opposed to introns, which are not). The name comes from the fact that exons are the only parts of an RNA transcript that are seen outside the nucleus. Compare *intron*.
- exportins** A class of proteins involved in transporting materials out of nuclei. See *importins*.
- extinction coefficient** A coefficient that indicates the ability of a particular substance in solution to absorb light of wavelength  $\lambda$ . The molar extinction coefficient,  $\epsilon_m$ , is the absorbance that would be displayed by a 1.0 M solution in a 1-cm light path.
- facilitated transport** (also called facilitated diffusion) The movement of a substance across a biological membrane in response to a concentration or electrochemical gradient where the movement is facilitated by membrane pores or by specific transport proteins. Compare *active transport*, *passive transport*.

- fatty acid** A carboxylic acid with a long hydrocarbon chain.
- fermentations** Processes in which cellular energy is generated from the breakdown of nutrient molecules where there is no net change in the oxidation state of the products as compared with that of the reactants; fermentation can occur in the absence of oxygen.
- fibrous proteins** Proteins of elongated shape, often used as structural materials in cells and tissues. Compare *globular proteins*.
- first law of thermodynamics** The law stating that energy cannot be created or destroyed and that it is therefore possible to account for any change in the internal energy of a system  $E$  by an exchange of heat ( $q$ ) and/or work ( $w$ ) with the surroundings.  $E = q + w$ .
- first-order reaction** A reaction whose rate depends on the first power of the concentration of a reactant. Compare *second-order reaction*.
- Fischer projection** A convention for representing stereoisomers in a plane. The tetrahedron of bonds on a carbon is represented as a plane cross, where the bonds to the right and left are assumed to be pointing toward the viewer and the bonds to the top and bottom are assumed to be pointing away from the viewer. Fischer projections of monosaccharides are oriented with the carbonyl group at the top; the chiral carbon farthest from the carbonyl group (which is the one that determines whether the sugar is the D or the L form) is then drawn with its hydroxyl to the right for the D form and to the left for the L form.
- flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN)** Coenzymes derived from vitamin B<sub>2</sub> (riboflavin) that function as electron acceptors in enzymes that catalyze electron transfer reactions.
- flavonoids** A family of plant compounds, of diverse biological functions, derived from phenylalanine.
- fluid mosaic model** A model describing cellular membrane structure, according to which the proteins are embedded in a phospholipid bilayer and are free to move in the plane of the membrane.
- fluorescence** The phenomenon by which a substance that absorbs light at a given wavelength reradiates a portion of the energy as light of a longer wavelength.
- flux** With reference to a chemical pathway, the rate (in moles per unit time) at which reactant “flows through” the pathway to emerge as product. The term can be used for the rate at which particles undergo any process in which they either flow or can be thought of metaphorically as flowing.
- flux control coefficient** For a reaction in a pathway the ratio of change in flux rate through that reaction to change in flux rate through the entire pathway.
- F<sub>0</sub>F<sub>1</sub> complex** (also called F<sub>0</sub>F<sub>1</sub> ATP synthase or complex V) The enzyme complex in the inner mitochondrial membrane that uses energy from the transmembrane proton gradient to catalyze ATP synthesis. The F<sub>0</sub> portion of the complex spans the membrane, and the F<sub>1</sub> portion, which performs the ATP synthase activity, projects into the mitochondrial matrix.
- footprinting** With respect to molecular genetics, a technique used to identify the DNA segment in contact with a given DNA-binding protein. The DNA-protein complex is subjected to digestion with a nonspecific nuclease, which cleaves at the residues that are not protected by the protein, and the protected region is identified by gel electrophoresis.
- frameshift mutation** A mutation that changes the reading frame for a gene by adding or deleting one or two nucleotides, thereby reducing the remainder of the message 3' to the mutation to gibberish.
- frameshift suppressor** A mutant tRNA that contains either two or four bases in the anticodon loop and can suppress the effects of a particular frameshift mutation in a gene.
- free energy (G)** (also called Gibbs free energy) A thermodynamic quantity (function of state) that takes into account both enthalpy and entropy:  $G = H - TS$ , where  $H$  is enthalpy,  $S$  is entropy, and  $T$  is absolute temperature. The change in free energy ( $G$ ) for a process, such as a chemical reaction, takes into account the changes in enthalpy and entropy and indicates whether the process will be thermodynamically favored at a given temperature.
- frictional coefficient** A coefficient that determines the frictional force on a particular particle (such as a molecule) in a particular medium at a given velocity. In the context of electrophoresis or centrifugation, it determines how fast a chemical species will move in a particular medium in response to a given electrical field or centrifugal force.
- furanose** A sugar with a five-membered ring, akin to furan.
- fusion proteins** Genetically engineered proteins that are made by splicing together coding sequences from two or more genes. The resulting protein thus combines portions from two different parent proteins.
- futile cycle** A pair of reactions that interconvert the same substrates and products in opposite directions, one of which consumes ATP and the other of which generates ATP. Uncontrolled operation of both reactions results in breakdown of ATP with no useful work performed.
- G proteins** A family of membrane-associated proteins that transduce signals received by various cell-surface receptors. They are called G proteins because binding of GTP and GDP is essential to their action.
- gated channel** A membrane ion channel that can open or close in response to signals from outside or within the cell.
- gel electrophoresis** A type of electrophoresis in which the supporting medium is a thin slab of gel held between glass plates. The technique is widely used for separating proteins and nucleic acids. See also *electrophoresis, isoelectric focusing*.
- genetic code** The code by which the nucleotide sequence of a DNA or RNA molecule specifies the amino acid sequence of a polypeptide. It consists of three-nucleotide codons that either specify a particular amino acid or tell the ribosome to stop translating and release the polypeptide. With a few minor exceptions, all living things use the same code.
- genetic recombination** Any process that results in the transfer of genetic material from one DNA molecule to another. In eukaryotes, it can refer specifically to the exchange of matching segments between homologous chromosomes by the process of crossing over during meiosis.
- genome** The total genetic information contained in a cell, an organism, or a virus.
- genomics** The investigation of hereditary features of biological processes and mechanisms focused upon the whole genome, as compared with focusing on the individual genes.
- genotype** The genetic constitution of an individual organism. Compare *phenotype*.
- gibberellins** A family of diterpene plant growth hormones.
- Gibbs free energy** See *free energy*.
- globular proteins** Proteins whose three-dimensional folded shape is relatively compact. Compare *fibrous proteins*.
- glucan** A glucose polymer.
- glucocorticoids** The steroid hormones cortisol and corticosterone, which are secreted by the adrenal cortex. In addition to other functions, they promote gluconeogenesis in response to low blood sugar levels.
- glucogenic** In fuel metabolism, refers to substances (such as some amino acids) that can be used as substrates for glucose synthesis.
- gluconeogenesis** The processes by which glucose is synthesized from non-carbohydrate precursors, such as glycerol, lactate, some amino acids, and (in plants) acetyl-CoA.
- glucose transporter** A membrane protein that is responsible for transporting glucose across a cell membrane. Different tissues may have glucose transporters with different properties.
- glycan** Another name for oligo- or polysaccharide.
- glycocalyx** The polysaccharide coat found on many eukaryotic cells.
- glycolipids** Lipids that have saccharides attached to their head groups.
- glycolysis** The initial pathway in the catabolism of carbohydrates, by which a molecule of glucose is broken down to two molecules of pyruvate, with a net production of ATP molecules and the reduction of two NAD<sup>+</sup> molecules to NADH. Under aerobic conditions, these NADH molecules are

reoxidized by the electron transport chain; under anaerobic conditions, a different electron acceptor is used.

**glycoprotein** A protein with a covalently linked oligosaccharide.

**glycosaminoglycans** (also called mucopolysaccharides) Polysaccharides composed of repeating disaccharide units in which one sugar is either *N*-acetylgalactosamine or *N*-acetylglucosamine. Typically the disaccharide unit carries a carboxyl group and often one or more sulfates, so that most glycosaminoglycans have a high density of negative charges. Glycosaminoglycans are often combined with protein to form proteoglycans and are an important component of the extracellular matrix of vertebrates.

**glycosidase** An enzyme that hydrolytically cleaves a glycosidic bond.

**glycosidic bond** The covalent link between the carbonyl carbon of a sugar molecule and another molecule, for example, a purine or pyrimidine in a nucleoside or another sugar in an oligosaccharide.

**glyoxysome** A specialized type of peroxisome found in plant cells. It performs some of the reactions of photorespiration, and it also breaks down fatty acids to acetyl-CoA by  $\beta$ -oxidation and converts the acetyl-CoA to succinate via the glyoxylate cycle, thus enabling plants to convert fatty acids to carbohydrates.

**Golgi complex** A stack of flattened membranous vesicles in the cytoplasm. It serves as a routing center for proteins destined for secretion or for lysosomes or the cell membrane; it performs similar functions for membrane lipids, and it also modifies and finishes the oligosaccharide moieties of glycoproteins.

**G-quadruplex** A four-stranded DNA structure stabilized by groupings of four deoxyguanylate residues, called G-quartets.

**growth factors** Peptide mediators that influence the growth and/or differentiation of cells; they differ from growth hormones in being produced by many tissues and in acting locally.

**half-life** (also called half-time) For a chemical reaction, the time at which half the substrate has been consumed and turned into product. The term can also refer to the analogous point in other processes, such as the radioactive decay of an isotope.

**haploid** For a cell or an organism, the possession of only one copy of each chromosome per nucleus. Compare *diploid*.

**haplotype** Referring to a specific grouping of restriction fragment length polymorphisms (which see) in a particular genome.

**haptén** A molecule that is too small to stimulate an immune response by itself but can do so when coupled to a larger, immunogenic carrier molecule (usually a protein).

**Haworth projection** A conventional planar representation of a cyclized monosaccharide molecule. The hydroxyls that are represented to the right of the chain in a Fischer projection are shown below the plane in a Haworth projection.

**heat-shock proteins** A group of chaperonins that accumulate in a cell after it has been subjected to a sudden temperature jump or other stress. They are thought to help deal with the accumulation of improperly folded or assembled proteins in stressed cells.

**helicases** Enzymes that catalyze the energy-dependent unwinding of duplex nucleic acids.

**helix-loop-helix motif** A binding motif that is found in calmodulin and some other calcium-binding proteins as well as in some DNA-binding proteins. It consists of two  $\alpha$  helix segments connected by a loop.

**helix-turn-helix motif** A DNA-binding motif that is responsible for sequence-specific DNA binding in many transcription factors. It consists of two  $\alpha$  helix segments connected by a  $\beta$  turn; one of the helices occupies the DNA major groove and makes specific base contacts.

**helper T cells** T lymphocytes whose role is to recognize antigens and help other defensive cells to mount an immune response. They help activate antigen-stimulated B cells (resulting in production of specific antibodies) and/or antigen-stimulated cytotoxic T cells (resulting in attack on

antigenic cells), and they also produce immune mediators that stimulate nonspecific defense responses.

**heme** A molecule consisting of a porphyrin ring (either protoporphyrin IX or a derivative) with a central complexed iron; it serves as a prosthetic group in proteins such as myoglobin, hemoglobin, and cytochromes.

**hemimethylated** With respect to DNA, refers to the condition in which one strand of the duplex is methylated and the other is not. Newly replicated DNA is hemimethylated; normally a methylase enzyme then methylates appropriate bases in the new strand.

**Henderson-Hasselbalch equation** An equation relating pH to the concentrations of two species contributing to buffering and to the  $pK_a$  of the relevant protonic equilibrium.

**heteropolymer** A polymer made up of differing monomeric units; native nucleic acids and proteins are heteropolymers, as compared with synthetic homopolymers (which see), which are assembled from identical monomeric units.

**heterotrophs** Organisms that cannot synthesize their organic compounds entirely from inorganic precursors but must consume at least some organic compounds made by other organisms. In particular, these organisms cannot use  $CO_2$  as a carbon source. Compare *autotrophs*.

**heterotropic** For proteins with multiple subunits, referring to interactions among subunits that are different in structure.

**heterozygous** In a diploid organism, the possession of two different alleles for a given gene (as opposed to two copies of the same allele). Compare *homozygous*.

**hexose** A six-carbon sugar.

**high-density lipoprotein (HDL)** A type of lipoprotein particle that functions mainly to scavenge excess cholesterol from tissue cells and transport it to the liver, where it can be excreted in the form of bile acids.

**Hill coefficient** A coefficient that indicates the degree of cooperativity of a cooperative transition; it is the maximum slope of a Hill plot of the transition.

**histones** The proteins that participate in forming the nucleosomal structure of chromatin. Four of the five kinds of histones make up the core particle of the nucleosome; the fifth is associated with the linker DNA between nucleosomes. All histones are small, very basic proteins.

**Holliday junction** An intermediate during homologous recombination; a four-armed structure in which each of the participating DNA duplexes has exchanged one strand with the other duplex.

**homeo box** A common sequence element of about 180 base pairs that is found in homeotic genes. It codes for a sequence-specific DNA-binding element of the helix-loop-helix class. See also *homeotic genes*.

**homeostasis** A steady state in living systems, usually maintained at conditions far from equilibrium by performing work upon the surrounding environment.

**homeotic genes** Genes that contain homeo box elements and typically are involved in controlling the pattern of organismal development. Homeotic mutations, which scramble portions of this pattern, affect homeotic genes. The nuclear DNA-binding proteins encoded by these genes presumably serve as transcriptional regulators for the coordinated expression of groups of genes. See also *homeo box*.

**homologous recombination** Genetic recombination that requires extensive sequence homology between the recombining DNA molecules. Meiotic recombination by crossing over in eukaryotes is an example.

**homology** Relatedness of two nucleic acid or protein sequences.

**homolytic reaction** A bond-cleavage reaction in which each of the two shared electrons in the cleaved bond ends up in a different product.

**homopolymer** A polymer that is made of only one kind of monomer. Starch, made only of glucosyl units, is an example. Polymers that include more than one kind of monomer, like polypeptides and nucleic acids, are called *heteropolymers* (which see).

- homotropic** For a multisubunit protein, refers to interactions among identical subunits.
- homozygous** In a diploid organism, the possession of two identical alleles for a given gene. Compare *heterozygous*.
- hormone** A substance that is synthesized and secreted by specialized cells and carried via the circulation to target cells, where it elicits specific changes in the metabolic behavior of the cell by interacting with a hormone-specific receptor.
- hormone-responsive element** A DNA site that binds an intracellular hormone–receptor complex; binding of the complex to a hormone-responsive element affects the transcription of specific genes.
- host-induced restriction and modification** A genetic system found in bacteria whereby a genetic element (often a plasmid) encodes both an enzyme for the methylation of DNA at a specific base sequence and an endonuclease that cleaves unmethylated DNA at that sequence. The system thus *restricts* the DNA that can survive in the cell to DNA that is *modified* by methylation at the correct sequences.
- hybridomas** Cultured cell lines that are made by fusing antibody-producing B lymphocytes with cells derived from a mouse myeloma (a type of lymphocyte cancer). Like B cells, they produce specific antibodies, and like myeloma cells, they can proliferate indefinitely in culture.
- hydrogen bond** An attractive interaction between the hydrogen atom of a donor group, such as —OH or =NH, and a pair of nonbonding electrons on an acceptor group, such as O=C. The donor group atom that carries the hydrogen must be fairly electronegative for the attraction to be significant.
- hydrophilic** Refers to the ability of an atom or a molecule to engage in attractive interactions with water molecules. Substances that are ionic or can engage in hydrogen bonding are hydrophilic. Hydrophilic substances are either soluble in water or, at least, wettable. Compare *hydrophobic*.
- hydrophobic** The molecular property of being unable to engage in attractive interactions with water molecules. Hydrophobic substances are nonionic and nonpolar; they are nonwetable and do not readily dissolve in water. Compare *hydrophilic*.
- hydrophobic effect** With respect to globular proteins, the stabilization of tertiary structure that results from the packing of hydrophobic side chains in the interior of the protein.
- hypochromism** With respect to DNA, a reduction in the absorbance of ultraviolet light of wavelength of about 260 nm that accompanies the transition from random-coil denatured strands to a double-strand helix. It can be used to track the process of denaturation or renaturation.
- immunoglobulins** See *antibodies*.
- importins** A class of proteins involved in importing molecules into the nucleus. See *exportins*.
- inborn errors of metabolism** Human mutations that result in specific derangements of intermediary metabolism. Usually the problem is an enzyme that is inactive, overactive, too scarce, or too abundant; symptoms may result from the insufficient production of a necessary metabolite and/or from the accumulation of another metabolite to toxic levels.
- induced dipole** A molecule has an induced dipole if an external electric field induces an asymmetric distribution of charge within it.
- induced fit model** A model for how enzymes interact with substrates to achieve catalysis. According to this model, the empty active site of the enzyme only roughly fits the substrate(s), and the entry of substrate causes the enzyme to change its shape so as to both tighten the fit and cause the substrate to adopt an intermediate state that resembles the transition state of the uncatalyzed reaction. This is currently the dominant model for enzymatic catalysis.
- induction** In cellular metabolism, the synthesis of a particular protein in response to a signal; for example, the synthesis of an enzyme in response to the appearance of its substrate.
- in situ hybridization** A technique for finding the chromosomal location of a particular DNA sequence by probing the chromosomes with a radiolabeled or fluorescent-tagged sequence that will hybridize with the sequence in question. The location of the probe is then visualized with radioautography or by fluorescence microscopy.
- intercalation** With respect to DNA, refers to the fitting (intercalation) of a small molecule between adjacent bases in a DNA helix.
- interferon** An antiviral glycoprotein produced in response to viral infection.
- intermediary metabolism** All the reactions in an organism that are concerned with storing and generating metabolic energy and with the biosynthesis of low-molecular-weight compounds and energy-storage compounds. It does not include nucleic acid and protein synthesis.
- internal energy (*E*)** The energy contained in a system. For the purposes of biochemistry, the term encompasses all the types of energy that might be changed by chemical or nonnuclear physical processes, including the kinetic energy of motion and vibration of atoms and molecules and the energy stored in bonds and noncovalent interactions.
- intron** A region in the coding sequence of a gene that is not translated into protein. Introns are common in eukaryotic genes but are rarely found in prokaryotes. They are excised from the RNA transcript before translation. Compare *exon*.
- in vitro** (Latin, *in glass*) Referring to the analysis of biological processes carried out outside of a living cell or organism, as in a glass test tube.
- in vivo** (Latin, *in life*) Referring to a biological process as it occurs within a living cell or organism.
- ion-exchange resins** Polycationic or polyanionic polymers that are used in ion-exchange column chromatography to separate substances on the basis of electrical charge.
- ionic strength** A quantity that reflects the total concentration of ions in a solution and the stoichiometric charge (charge per atom or molecule) of each ion. It is defined as  $I = \frac{1}{2} \sum M_i Z_i^2$ , where  $M_i$  and  $Z_i$  are respectively the molarity and stoichiometric charge of ion  $i$ . It is used, for example, in calculating the effective radius of a counterion atmosphere.
- ionophore** A substance that selectively permeabilizes membranes to particular ions or molecules.
- ion pore** A pore in a cellular membrane through which ions can diffuse. It is formed by a transmembrane protein and can discriminate among ions to some degree on the basis of size and charge. Many ion pores are gated, meaning that they can open and close in response to signals.
- isoelectric focusing** A version of gel electrophoresis that allows ampholytes to be separated almost purely on the basis of their isoelectric points. The ampholytes are added to a gel that contains a pH gradient and are subjected to an electric field. Each ampholyte migrates until it reaches the pH that represents its isoelectric point, at which point it ceases to have a net electric charge and therefore comes to a halt and accumulates. See also *gel electrophoresis*, *isoelectric point*.
- isoelectric point (pI)** The pH at which the net charge on an ampholyte is, on average, zero.
- isoenzymes** (also called isoforms or isozymes) Different but related forms of an enzyme that catalyze the same reaction. Often differ in only a few amino acid substitutions.
- isomorphous replacement** The replacement of one atom in a macromolecule with a heavy metal atom in such a way that the structure of the macromolecule does not change. It is used in the determination of molecular structure by X-ray crystal diffraction.
- isozymes** See *isoenzymes*.
- joule (J)** A unit for energy or work, defined as the work done by a force of 1 newton when its point of application moves 1 meter in the direction of the force. It is the unit of energy used in the Système Internationale (SI).
- $\alpha$ -keratins** A class of keratins that are the major proteins of hair. They consist of long  $\alpha$ -helical polypeptides, which are wound around each other to form triplet helices.

- ketogenic** Referring to fuel molecules whose catabolism generates acetyl-CoA, and, hence, which tend to increase levels of ketone bodies.
- ketone bodies** The substances acetoacetate,  $\beta$ -hydroxybutyrate, and acetone, which are produced from excess acetyl-CoA in the liver when the rate of fatty acid  $\beta$ -oxidation in liver mitochondria exceeds the rate at which acetyl-CoA is used for energy generation or fatty acid synthesis.
- ketose** A monosaccharide in which the carbonyl group occurs within the chain and hence represents a ketone group. Compare *aldose*.
- kinetic isotope effect** A change in a rate-determining step of enzyme catalysis brought about by substitution of an isotope, usually a heavy atom, at a specific position in a substrate.
- kinetochore** The structure that connects the centromere to the microtubules that will carry out chromosome separation during mitosis and meiosis.
- Krebs cycle** See *citric acid cycle*.
- lagging strand** During DNA replication, the strand that is synthesized in the opposite direction to the direction of movement of the replication fork; it is synthesized as a series of fragments that are subsequently joined. Compare *leading strand*.
- leader sequence** (also called signal sequence) For an mRNA, the non-translated sequence at the 5' end of the molecule that precedes the initiation codon. For a protein, a short N-terminal hydrophobic sequence that causes the protein to be translocated into or through a cellular membrane.
- leading strand** During DNA replication, the strand that is synthesized in the same direction as the direction of movement of the replication fork; it is synthesized continuously rather than in fragments. Compare *lagging strand*.
- leukotrienes** A family of molecules that are synthesized from arachidonic acid by the lipoxygenase pathway and function as local hormones, primarily to promote inflammatory and allergic reactions (such as the bronchial constriction of asthma).
- library** With respect to molecular genetics, a large collection of random cloned DNA fragments from a given organism, sometimes representing the entire nuclear genome.
- ligand** In general, a small molecule that binds specifically to a larger one—for example, a hormone that binds to a receptor. The term can also be used to mean a chemical species that forms a coordination complex with a central atom, which is usually a metal atom.
- light reactions** The photosynthetic subprocesses that depend *directly* on light energy; specifically, the synthesis of ATP by photophosphorylation and the reduction of  $\text{NADP}^+$  to NADPH via the oxidation of water. Compare *dark reactions*.
- lignins** Complex polymers, derived from phenylalanine, that compose the major constituents of woody tissue.
- Lineweaver–Burk plot** A plot that allows one to derive the rate constant  $k_{\text{cat}}$  and the Michaelis constant  $K_M$  for an enzyme-catalyzed reaction. It is constructed by measuring the initial reaction rate  $V$  at various substrate concentrations  $[S]$  and plotting the values on a graph of  $1/V$  versus  $1/[S]$ .
- linkage map** A map showing the arrangement of genes on a chromosome; it is constructed by measuring the frequency of recombination between pairs of genes.
- linking number ( $L$ )** The total number of times the two strands of a closed, circular DNA helix cross each other by means of either twist or writhe; this equals the number of times the two strands are interlinked. It reflects both the winding of the native DNA helix and the presence of any supercoiling. See also *twist*, *writhe*.
- lipid bilayer** A membrane structure that can be formed by amphipathic molecules in an aqueous environment; it consists of two back-to-back layers of molecules, in each of which the polar head groups face the water and the nonpolar tails face the center of the membrane. The fabric of cellular membranes is a lipid bilayer.
- lipid raft** A membrane microdomain enriched in sphingolipids and cholesterol.
- lipids** A chemically diverse group of biological compounds that are classified together on the basis of their generally apolar structure and resulting poor solubility in water.
- lipoproteins** Any lipid–protein conjugate. Specifically refers to lipid–protein associations that transport lipids in the circulation. Each consists of a core of hydrophobic lipids surrounded by a skin of amphipathic lipids with embedded apolipoproteins. Different kinds of lipoproteins play different roles in lipid transport.
- long terminal repeats (LTRs)** A pair of direct repeats several hundred base pairs long that are found at either end of a retroviral genome. They are involved in integration into the host genome and in viral gene expression.
- low-angle neutron scattering** A set of techniques that can be used to find the size of a particle in solution or to find the size or spacing of internal regions that can be distinguished by different neutron scattering power, such as the protein and nucleic acid components of a nucleoprotein particle or labeled proteins within a multisubunit complex.
- low-density lipoprotein (LDL)** A type of lipoprotein particle that functions mainly to distribute cholesterol from the liver to other tissues. Its protein component consists of a single molecule of apoprotein B-100.
- lysogeny** A latent state that can be achieved by some bacteriophages, in which the phage genome is integrated into the host bacterial chromosome and few if any viral genes are expressed.
- mass spectrometry** A method for determining the molecular mass from the velocity of ions in a vacuum.
- mechanism-based inhibitor** An enzyme inhibitor whose action depends on the enzyme's catalytic mechanism. Typically it is a substrate analog that irreversibly modifies the enzyme at a particular step in the catalytic cycle.
- mediator** A large multiprotein complex that connects upstream transcriptional activators and enhancers with transcription machinery bound near a transcriptional start site.
- membrane electrical potential** With respect to biological membranes, a voltage difference that exists across a membrane owing to differences in the concentrations of ions on either side of the membrane.
- messenger RNA (mRNA)** RNA molecules that act as templates for the synthesis of polypeptides by ribosomes.
- metabolism** The totality of the chemical reactions that occur in an organism. Compare *anabolism*, *catabolism*, *intermediary metabolism*.
- metabolome** The entire complement of low-molecular-weight compounds (metabolites) within a cell or organism.
- metabolomics** The investigation of biological processes conducted through analysis of the metabolome (which see).
- metabolon** A complex of enzymes, usually linked noncovalently, which carry out functionally related reactions and, hence, can facilitate catalysis of multistep reaction pathways.
- metastability** For a system, the condition of being in a state that does not represent thermodynamic equilibrium but is nearly stable at the time scale of interest because progress toward equilibrium is slow.
- micelles** Tiny droplets that form when an amphipathic substance that has a polar head group and a nonpolar tail region (such as a fatty acid) is added to an aqueous medium and shaken. Each droplet consists of a spherical cluster of amphipathic molecules arranged with their polar head groups facing out toward the water and their nonpolar tails facing in toward the center.
- Michaelis–Menten equation** An equation that gives the rate of an enzyme-catalyzed reaction in terms of the concentrations of substrate and enzyme as well as two constants that are specific for a particular combination of enzyme and substrate: a rate constant,  $k_{\text{cat}}$ , for the catalytic production of product when the enzyme is saturated, and the Michaelis constant,  $K_M$ .

- microarray** Also called a gene chip, a collection of several thousand gene fragments, either oligonucleotides or cDNAs, immobilized on a small slide as a precise array, so that a pattern of total RNAs from a cell can be subjected to annealing conditions, with the extent of hybridization to each gene fragment in the chip giving a global picture of transcription patterns.
- microRNA** An RNA molecule, 21 to 23 nucleotides long, also called miRNA, which regulates the activity of a specific mRNA that contains partially or completely homologous nucleotide sequences.
- microtubules** Fiberlike cytoplasmic structures that consist of units of the protein tubulin arranged helically to form a hollow tube. They are involved in various kinds of cellular motility, including the beating of cilia and flagella and the movement of organelles from one part of the cell to another.
- microtubule-associated proteins (MAPs)** A class of proteins associated with microtubules that assist in dynamic processes.
- minus strand** In viral genomes, a nucleic acid strand that is complementary to the RNA strand that serves as mRNA. Compare *plus strand*.
- mismatch repair** A system for the correction of mismatched nucleotides or single-base insertions or deletions produced during DNA replication; it scans the newly replicated DNA, and when it finds an error, it removes and replaces a stretch of the strand containing the error.
- missense mutation** A mutation that alters a DNA codon so as to cause one amino acid in a protein to be replaced by a different one.
- mitochondria** The organelles whose chief task it is to supply the cell with ATP via oxidative phosphorylation. They contain the enzymes for pyruvate oxidation, the citric acid cycle, the  $\beta$ -oxidation of fatty acids, and oxidative phosphorylation, as well as the electron transport chain.
- mixed-function oxidase** An oxygenase enzyme that catalyzes a reaction in which two different substrates are oxidized, one by the addition of an oxygen atom from  $O_2$  and the other by supplying two hydrogen atoms to reduce the remaining oxygen atom to  $H_2O$ .
- molten globule** A hypothetical intermediate state in the folding of a globular protein, in which the overall tertiary framework has been established but internal side chains (especially hydrophobic ones) are still free to move about.
- mucopolysaccharides** See *glycosaminoglycans*.
- multicatalytic proteinase complex (MPC)** A massive complex of proteolytic enzymes that is found in the cytosol of many eukaryotic cells and seems to function in the programmed destruction of cellular proteins.
- muscarinic acetylcholine receptors** A class of receptors for the neurotransmitter acetylcholine that are characterized by an ability to bind the toadstool toxin muscarine. Synapses that have these receptors may be either excitatory or inhibitory. Compare *nicotinic acetylcholine receptors*.
- mutagen** A substance that is capable of causing mutations.
- mutarotation** The spontaneous racemization about the carbonyl carbon in a sugar.
- mutation** Any inheritable change in the nucleotide sequence of genomic DNA (or genomic RNA, in the case of an RNA virus).
- myofibrils** A unit of thick and thin filaments of muscle fibers.
- Nernst equation** An equation that relates the electrical potential across a membrane to the concentrations of ions on either side of the membrane.
- neurohormones** Substances that are released from neurons and modulate the behavior of target cells, which are often other neurons. Unlike neurotransmitters, they do not act strictly across a synapse. Most neurohormones are peptides.
- neurotoxin** A toxin that acts by disrupting nerve cell function. Fast-acting neurotoxins often act by blocking the action of an ion gate necessary for the development of an action potential.
- neurotransmitter** A low-molecular-weight substance that is released from an axon terminal in response to the arrival of an action potential and then diffuses across the synapse to influence the postsynaptic cell, which may be either another neuron or a muscle or gland cell.
- nick translation** A process beginning at a nick in a DNA duplex, in which a DNA polymerase adds nucleotides one at a time to the 3' terminal nucleotide in the nick, in synchrony with cleavage of the nucleotide on the 5' side of the nick. The process causes the location of the nick to migrate (hence the origin of the term).
- nicotinic acetylcholine receptors** A class of receptors for the neurotransmitter acetylcholine that are characterized by their ability to bind nicotine. Synapses with this kind of receptor are excitatory. Compare *muscarinic acetylcholine receptors*.
- nitrogen equilibrium** Also called normal nitrogen balance, a condition in which daily nitrogen excretion equals total dietary nitrogen intake.
- noncompetitive inhibitor** An inhibitor of an enzyme-catalyzed reaction that acts by binding to a site on the enzyme different from the active site and reducing the enzyme's catalytic efficiency. Irreversible binding of a substrate analog at the active site is kinetically similar to noncompetitive inhibition.
- noncovalent interactions** All the kinds of interactions between atoms and molecules that do not involve the actual sharing of electrons in a covalent bond; they include electrostatic interactions, permanent and induced dipole interactions, and hydrogen bonding.
- noncyclic photophosphorylation** In photosynthesis, photophosphorylation (light-dependent ATP synthesis) that is linked to a one-way flow of electrons from water through photosystems II and I and finally to NADPH; it is thus coupled to the oxidation of  $H_2O$  and the reduction of  $NADP^+$ . Compare *cyclic photophosphorylation*.
- nonhomologous end joining** A process in double-strand break repair in which severed ends are linked together without a requirement for sequence homology at the severed ends.
- nonsense mutation** A mutation that creates an abnormal stop codon and thus causes translation to terminate prematurely; the resulting truncated protein is usually nonfunctional.
- Northern blotting** A technique for detecting the presence of a specific RNA sequence in a cell and determining its size. The total RNA of the cell is extracted, resolved by gel electrophoresis, and blotted onto a filter. There it is incubated under annealing conditions with a radiolabeled probe for the sequence in question, and heteroduplexes of the probe with RNA are detected by radioautography.
- N-terminus** (also called amino terminus) The end of a polypeptide chain that carries an unreacted amino group. A ribosome synthesizes a polypeptide in the direction from the N-terminus to the C-terminus. See also *C-terminus*.
- nuclear envelope** The double membrane that encloses the nucleus. It is pierced by nuclear pores that allow even quite large molecules, such as mRNAs and nuclear proteins, to enter or leave the nucleus.
- nuclear magnetic resonance (NMR) spectroscopy** A type of spectroscopy that depends on the fact that isotope nuclei having the property of spin will resonate with specific frequencies of microwave radiation when placed in a magnetic field of given strength. The resonance energy is sensitive to the local molecular environment, so NMR spectroscopy can be used to explore molecular structure. Also, different living tissues have characteristic overall NMR spectra, which are sensitive to changes in the tissue environment. NMR can thus be used in the study of tissue metabolism and the diagnosis of disease.
- nuclear matrix** (also called nuclear scaffold) A protein web that is left in the nucleus when histones and other weakly bound proteins are removed and most of the DNA is digested away. It is presumed to act as an organizing scaffold for the chromatin.
- nuclease** An enzyme that cleaves nucleic acids.
- nucleoid** The large, circular DNA molecule of a prokaryotic cell, along with its associated proteins; also sometimes called the bacterial chromosome.

- It is supercoiled and forms a dense mass within the cell, and the term *nucleoid* is often used for the cell region occupied by this mass.
- nucleolus** A region in the nucleus of a cell where ribosomal RNAs are transcribed and processed and ribosomes are assembled.
- nucleoside** A molecule that, upon complete hydrolysis, yields 1 mole per mole of a purine or pyrimidine base and a sugar.
- nucleosome** The first-order structural unit for the packing of DNA in chromatin, consisting of 146 bp of DNA wrapped 1.75 times around a core octamer of histone proteins. Successive nucleosomes are connected by stretches of “linker” DNA.
- nucleotide** A molecule that, upon complete hydrolysis, yields at least 1 mole per mole of a purine or pyrimidine base, a sugar, and inorganic phosphate.
- nucleotide excision repair** A DNA repair process in which a stretch of DNA that includes a damaged site is cut out endonucleolytically and replaced.
- nucleus** The membrane-bound structure in a eukaryotic cell that contains the chromosomal genetic material and associated components. It is also the place where RNA molecules are processed and ribosomes are assembled.
- Okazaki fragments** The discontinuous stretches in which the lagging strand is initially synthesized during DNA replication; these fragments are later joined to form a continuous strand.
- oligonucleotide** A molecule composed of nucleotide residues linked 3' to 5' but smaller than a nucleic acid, which is called a polynucleotide; often refers to a product of chemical synthesis.
- oligopeptide** A molecule composed of amino acid residues linked by peptide bonds that is smaller than a protein, which is called a polypeptide.
- oncogene** A gene that, in a mutated version, can help transform a normal cell to a cancer cell. Many oncogenes code for mutant proteins that are involved in the reception and transduction of growth factor signals.
- oncoprotein** The protein product of an oncogene.
- open-promoter complex** A complex between RNA polymerase holoenzyme and a promoter that has undergone initial unwinding (has “opened”) preparatory to the start of transcription. It is preceded by a much less stable *closed-promoter complex*, in which the promoter has not unwound, that may either fall apart or proceed to an open-promoter complex.
- open reading frame** A sequence within a messenger RNA that is bounded by start and stop codons and can be continuously translated. It represents the coding sequence for a polypeptide.
- operator** A DNA site where a repressor protein binds to block the initiation of transcription from an adjacent promoter.
- operon** A set of contiguous prokaryotic structural genes that are transcribed as a unit, along with the adjacent regulatory elements that control their expression.
- optical isomers** See *enantiomers*.
- organelles** Membrane-bound compartments in the cytoplasm of eukaryotic cells. Each kind of organelle carries out a specific set of functions. Examples are mitochondria, chloroplasts, and nuclei.
- orthologs** Homologous genes in different species that originated by vertical descent from a common ancestral gene by speciation. Compare paralogs.
- orthophosphate** The ionic form of phosphoric acid as it exists at physiological pH.
- osteoporosis** Loss of calcium from the bones resulting in porous, brittle bones.
- oxidase** An enzyme that catalyzes the oxidation of a substrate with oxygen as the electron acceptor.
- oxidative phosphorylation** The phosphorylation of ADP to ATP that occurs in conjunction with the transit of electrons down the electron transport chain in the inner mitochondrial membrane.
- oxidative stress** Actual or potential damage to cells and tissues caused by prolonged high levels of reactive oxygen species (which see).
- oxygenase** An enzyme that catalyzes the incorporation of oxygen into a substrate.
- palindrome** With respect to DNA, a segment in which the sequence is the same on one strand read right to left as on the other strand read left to right; thus, a back-to-back pair of inverted repeats.
- paralogs** Homologous genes in a single organism that originated by gene duplication. Paralogous genes often have the same or similar function, but not always. As long as one copy continues to perform the original function, the other copy can escape the original selective pressure and is free to mutate and acquire new functions. Compare orthologs.
- partial molar free energy** See *chemical potential*.
- partition coefficient (K)** A coefficient that indicates how a particular substance will distribute itself between two media if allowed to diffuse to equilibrium between them; it is equal to the ratio of the solubilities of the substance in the two media.
- passive transport** (also called passive diffusion) With respect to membrane transport, the movement of a substance across a biological membrane by molecular diffusion through the lipid bilayer. Compare *active transport*, *facilitated transport*.
- Pasteur effect** The inhibition of glycolysis by oxygen; discovered by Pasteur when he found that aerobic yeast cultures metabolize glucose relatively slowly.
- pentose** A five-carbon sugar.
- peptide bond** The bond that links successive amino acids in a peptide; it consists of an amide bond between the  $\alpha$ -carboxyl group of one amino acid and the  $\alpha$ -amino group of the next.
- peptidoglycan** A polysaccharide linked covalently to peptide or polypeptide chains.
- peptidyltransferase** During ribosomal polypeptide synthesis, the enzyme complex that transfers the polypeptide chain from the tRNA in the P site to the amino acid carried by the tRNA in the A site, thereby adding another amino acid to the chain. The active site is carried within the RNA portion of the large ribosomal subunit.
- permanent dipole** In chemistry, a molecule that has a permanent, asymmetric distribution of charge such that one end is negative and the other end positive. The water molecule is an example: The oxygen end has a partial negative charge, and the hydrogen end has a partial positive charge.
- peroxisome** A small, vesicular organelle that specializes in carrying out cellular reactions involving the transfer of hydrogen from a substrate to O<sub>2</sub>. These reactions produce the by-product H<sub>2</sub>O<sub>2</sub>, which is split to H<sub>2</sub>O and O<sub>2</sub> by the peroxisomal enzyme catalase.
- PEST sequences** A family of amino acid sequences that have been found on cellular proteins that undergo rapid turnover; they may target proteins for rapid proteolysis. They consist of a region about 12 to 60 residues long that is rich in proline, glutamate, serine, and threonine (P, E, S, and T in the one-letter abbreviation system).
- phenotype** The appearance and other measurable characteristics of an organism; it results from the interaction of the organism's genetic makeup with the environment. Compare *genotype*.
- phenylketonuria** One of the earliest-understood inborn errors of metabolism, characterized by accumulation of phenylalanine and its catabolic products.
- pheromones** Intercellular mediator compounds that are released from one organism and influence the metabolism or behavior of another organism, usually of the same species. Sex attractants, which elicit reproductive behavior in suitable recipients, are an example.
- phorbol esters** A group of natural substances that resemble *sn*-1,2-diaclyglycerol (DAG) in part of their structure and can act as tumor promoters. This effect suggests that the DAG second-messenger system may be involved in growth factor action.

- phosphate transfer potential** Refers to the thermodynamic tendency of an organic phosphate compound to transfer its phosphate to an acceptor; literally,  $-\Delta G^{\circ}$  of hydrolysis for the phosphate bond.
- phosphodiester link** The linkage that connects the nucleotide monomers in a nucleic acid. It consists of a phosphate residue that links the sugar moieties of successive monomers by forming an ester bond with the 5' carbon of one sugar and the 3' carbon of the next.
- photophosphorylation** Phosphorylation of ADP to ATP that depends directly on energy from sunlight. The light energy is captured by a pigment such as chlorophyll and is passed in the form of excited electrons to an electron transport chain; the electron transport chain uses energy from the electrons to create a proton gradient across a membrane, which drives the synthesis of ATP.
- photoproducts** The products that result when light energy causes a chemical reaction to occur in a substance. With respect to DNA, the term refers to the types of damaged DNA that can be caused by UV irradiation.
- photoreactivation** A DNA repair process in which an enzyme uses light energy to break cyclobutane pyrimidine dimers created by UV irradiation and to restore the correct bonding.
- photorespiration** The cycle of reactions that occurs in place of the Calvin cycle when the photosynthetic enzyme rubisco adds  $O_2$  rather than  $CO_2$  to ribulose biphosphate carboxylase. It takes place partly in chloroplasts, partly in peroxisomes, and partly in mitochondria; it expends ATP energy and loses a previously fixed  $CO_2$  molecule in the process of regenerating the Calvin cycle intermediate 3-phosphoglycerate.
- photosynthesis** The process by which energy from light is captured and used to drive the synthesis of carbohydrates from  $CO_2$  and  $H_2O$ .
- photosystem** A structural unit in a cellular membrane that captures light energy and converts a portion of it to chemical energy. The photosynthesis practiced by plants, algae, and cyanobacteria involves two types of photosystem, both of which capture energy in the form of high-energy electrons and transduce it via an electron transport chain.
- plaque** A clear area that is formed by a local phage infection in a lawn of cultured bacteria in a Petri dish; for purposes of experimentation, it is the phage equivalent of a bacterial colony. The term *plaque* refers also to atherosclerotic plaques (which see)—fatty deposits that line the inner surfaces of coronary arteries.
- plasma membrane** The lipid bilayer membrane that encloses the cytoplasm; it is surrounded by the cell wall if one is present.
- plasmids** Small, extrachromosomal circular DNA molecules found in many bacteria. They replicate independently of the main chromosome and may occur in multiple copies per cell.
- plus strand** In viral genomes, a nucleic acid strand that can serve as mRNA or (for a DNA strand) that is homologous to one that can; as distinct from the complementary (minus) strand. Most viruses with single-strand genomes package only the plus or minus strand in virions; the other strand is made transiently during replication. Compare *minus strand*.
- polyamines** A family of compounds, most derived from ornithine, that have several functions in growth control, including stabilization of nucleic acids and membranes.
- polymer** A large molecule that is made by linking together prefabricated molecular units (monomers) that are similar or identical to each other. The number of monomers in a polymer may range up to millions.
- polymerase chain reaction (PCR)** A technique that is used to amplify the number of copies of a specific DNA sequence through repeated cycles of heat denaturation and DNA polymerase-catalyzed replication.
- polyribosome** Several ribosomes bound to and translating the same mRNA molecule; also called a polysome.
- polytene chromosome** An extra-thick chromosome that includes many parallel copies of the original DNA molecule; it is produced by repeated rounds of DNA replication without separation of the resulting copies.
- Polytene chromosomes are found in various cell types, notably *Drosophila* salivary gland cells; they are useful in chromosome mapping because they are large and because the genes on the strands are arranged in strict register.
- P/O ratio** In oxidative phosphorylation, the ratio of P atoms consumed (in ATP synthesis) to atoms of oxygen consumed (in respiration).
- porphyrins** A family of tetrapyrrole compounds, derived from succinate and glycine, that include heme and chlorophyll.
- primary structure** For a nucleic acid or a protein, the sequence of the bases or amino acids in the polynucleotide or polypeptide. Compare *quaternary structure*, *secondary structure*, *tertiary structure*.
- primer** A short piece of DNA or RNA that is base-paired with a DNA template strand and provides a free 3'-OH end from which a DNA polymerase can extend a DNA strand. Also refers to DNA oligomers used in the polymerase chain reaction.
- primosome** An enzyme complex that is located in the replication fork during DNA replication; it synthesizes the RNA primers on the lagging strand and also participates in unwinding the parental DNA helix.
- prion** An infectious agent that contains protein but no nucleic acid.
- processivity** For a DNA or an RNA polymerase, the average number of nucleotides incorporated per event of binding between the polymerase and a 3' primer terminus. It describes the tendency of a polymerase to remain bound to a template.
- prochiral** Referring to a symmetrical molecule that becomes asymmetric as a result of binding to an enzyme.
- prokaryotes** Primitive single-celled organisms that are not compartmentalized by internal cellular membranes; the eubacteria and archaea. Compare *eukaryotes*.
- promoter** A DNA sequence that can bind RNA polymerase, resulting in the initiation of transcription.
- prophage** An inactive phage genome that is present in a bacterial cell and its progeny. It is integrated into the host chromosome.
- prostaglandins** A family of compounds that are derived from certain long-chain unsaturated fatty acids (particularly arachidonic acid) by a cyclooxygenase pathway and that function as local hormones.
- prosthetic group** A metal ion or small molecule (other than an amino acid) that forms part of a protein in the protein's native state and is essential to the protein's functioning; its attachment to the protein may be either covalent or noncovalent.
- proteases** Enzymes that cleave peptide bonds in a polypeptide. Many show specificity for a particular amino acid sequence.
- proteasome** A large, ATP-dependent protease complex that is found in the cytosol of cells and is involved in the selective degradation of short-lived cytoplasmic proteins.
- proteoglycans** Glycoproteins in which carbohydrate is the dominant element. The carbohydrate is in the form of glycosaminoglycan polysaccharides, which are connected to extended core polypeptides to form huge, feathery molecules. Proteoglycans are important components of the intercellular matrix.
- proteome** The entire complement of proteins within a cell or organism.
- proteomics** Investigation of biological processes carried out through analysis of the proteome (which see).
- protofilaments** The 13 linear columns of tubulin units that can be visualized in the structure of a microtubule; they result because each turn of the microtubule helix contains exactly 13 tubulin units. Each protofilament consists of alternating  $\alpha$  and  $\beta$  tubulin subunits.
- proton motive force (pmf)** An electrochemical  $H^+$  gradient that is set up across a cellular membrane by membrane-bound proton pumps, such as the ones in the inner mitochondrial membrane or thylakoid membrane.

As the protons flow back down their gradient across the membrane, they can drive processes such as ATP synthesis.

**proton pumping** The active pumping of protons across a cellular membrane to form a proton gradient. For example, the electron transport chains of the inner mitochondrial and thylakoid membranes incorporate proton pumps, which create the proton gradient that powers the ATP synthases of these membranes.

**provirus** An animal virus genome that is integrated into a host chromosome.

**pseudogenes** Generally nontranscribed stretches of DNA that bear a strong sequence similarity to functioning genes and obviously arose from them during evolution. Many gene families contain pseudogene members. Recent evidence indicates that some pseudogenes are, in fact, transcribed.

**pulsed field gel electrophoresis** A type of gel electrophoresis in which the orientation of the electric field is changed periodically. This technique makes it possible to separate very large DNA molecules, up to the size of whole chromosomes.

**pyranose** A sugar that forms a six-carbon ring.

**quantum efficiency (Q)** With respect to photosynthesis, the ratio of oxygen molecules released to photons absorbed.

**quaternary structure** For a protein, the level of structure that results when separate, folded polypeptide chains (subunits) associate in a specific way to produce a complete protein. Compare *primary structure*, *secondary structure*, *tertiary structure*.

**quorum sensing** A bacterial phenomenon, such as biofilm formation, that is dependent upon cell density.

**radioautography** A technique in which an item containing radioactively labeled elements (for example, a tissue slice or a chromatography gel) is laid against a photographic film; the radioactivity exposes the film to form an image of the labeled elements. Also called autoradiography.

**Ramachandran plot** A plot that constitutes a map of all possible backbone conformations for an amino acid in a polypeptide. The axes of the plot consist of the rotation angles of the two backbone bonds that are free to rotate ( $\phi$  and  $\psi$ , respectively); each point  $\phi$ ,  $\psi$  on the plot thus represents a conceivable amino acid backbone configuration.

**random coil** Refers to a linear polymer that has no secondary or tertiary structure but instead is wholly flexible with a randomly varying geometry. This is the state of a denatured protein or nucleic acid.

**rate constant** With respect to chemical reactions, a constant that relates the reaction rate for a particular reaction to substrate concentrations.

**rate enhancement** The factor by which the rate of a catalyzed reaction is increased relative to the same reaction carried out without a catalyst or with a nonbiological catalyst.

**rate equation** An equation, such as the Michaelis–Menten equation (which see), that relates velocity of an enzyme-catalyzed reaction to measurable parameters.

**reaction center** In photosynthesis, a specific pair of chlorophyll molecules in a photosystem that collect light energy absorbed by other chlorophyll molecules and pass it to an electron acceptor, normally the first compound of an electron transport chain.

**reaction coordinate** A measure of the progress of a reaction toward completion.

**reactive oxygen species (ROS)** Oxygen species intermediate in oxidation level between  $O_2$  and  $H_2O$ , which are more reactive than  $O_2$ ; ROS include superoxide, peroxide, peroxyxynitrite, and hydroxyl radical.

**receptor** A protein that binds selectively to a specific molecule (such as an intercellular mediator or antigen) and initiates a biological response.

**recognition helix** In a helix–turn–helix DNA binding motif, the  $\alpha$ -3 helix, which fits deep in the major groove and is responsible for the sequence specificity of binding.

**recombinant DNA molecule** A DNA molecule that includes segments from two or more precursor DNA molecules.

**recombination** A process in an organism in which two parent DNA molecules give rise to daughter DNA that combines segments from both parent molecules. It may involve the integration of one DNA molecule into another, the substitution of a DNA segment for a homologous segment on another DNA molecule, or the exchange of homologous segments between two DNA molecules.

**reducing equivalent** An amount of a reducing compound that donates the equivalent of 1 mole of electrons in an oxidation–reduction reaction. The electrons may be expressed in the form of hydrogen atoms.

**regulon** A group of unlinked (nonadjacent) genes that are all regulated by a common mechanism.

**release factors** Independent protein factors that are necessary participants in the release of a finished polypeptide chain from a ribosome.

**replicon** A unit in the genome that consists of an origin of replication and all the DNA that is replicated from that origin.

**replisome** A complex of DNA polymerase and other enzymes and proteins that catalyzes the multiple processes involved in replicative DNA chain elongation.

**repressor** In molecular genetics, a protein that inhibits the transcription of a gene by binding to an operator.

**residue** An amino acid or nucleotide as it exists within a polypeptide or polynucleotide chain, respectively. The structure is the same as that of the respective free compound, minus the elements of one water molecule.

**respiration** With respect to energy metabolism, the process in which cellular energy is generated through the oxidation of nutrient molecules with  $O_2$  as the ultimate electron acceptor. This type of respiration is also called *cellular respiration* to distinguish it from respiration in the sense of breathing.

**respiratory chain** The electron transport chain that is employed during cellular respiration and has  $O_2$  as the ultimate electron acceptor.

**respiratory quotient** For a metabolite undergoing complete oxidation to  $CO_2$  and water, the ratio of  $CO_2$  molecules generated to  $O_2$  molecules consumed.

**resting potential** The voltage difference that exists across the membrane of an excitable cell, such as a nerve cell, except in places where an action potential is in progress. It is a consequence of the ion gradients that are maintained across the membrane.

**restriction endonucleases** Enzymes that catalyze the double-strand cleavage of DNA often at specific base sequences. Many restriction endonucleases with different sequence specificities have been found in bacteria; they are used extensively in molecular genetics.

**restriction fragment length polymorphisms (RFLPs)** A type of genetic polymorphism that is readily detected by Southern blotting and can be used to screen for genetic diseases. It is based on the fact that alleles often have different restriction endonuclease cleavage sites and therefore produce different arrays of fragments upon cleavage with appropriate endonucleases.

**retinoids** Substances that are derived from retinoic acid (a form of vitamin A) and act as intercellular mediators; they are particularly important in regulating development.

**retroviruses** A family of RNA viruses that possess reverse transcriptase. After the virus infects a cell, this enzyme transcribes the RNA genome into a double-strand DNA version, which integrates into a host chromosome. Human immunodeficiency virus (HIV) is a retrovirus.

**reverse transcriptase** An enzyme found in retroviruses that synthesizes a double-strand DNA molecule from a single-strand RNA template. It is an important tool in molecular genetics and is the target for several antiviral drugs.

- ribosomes** Large protein–RNA complexes that are responsible for synthesizing polypeptides under the direction of mRNA templates.
- riboswitch** The 5′ end of certain mRNAs, which can fold around specific metabolites, usually end-products of a pathway, thereby inhibiting translation of that mRNA and shutting down the pathway.
- ribozyme** An enzyme containing RNA as its catalytic entity; can be either an RNA molecule or a ribonucleoprotein.
- RNA editing** A type of RNA processing that has been found in the mitochondrial mRNAs of certain eukaryotes, in which the RNA sequence is altered by the insertion of uridine residues at specific sites; more generally, any process that involves alteration of an mRNA sequence.
- RNAi** Short for RNA interference, a collection of processes in which small RNA molecules (21 to 23 nucleotides) attach to particular mRNAs by homologous base pairing and limit translation of the target RNA by various means, including stimulated degradation.
- RNA primer** During DNA replication, the short stretch of RNA nucleotides that is laid down at the beginning of each Okazaki fragment; it provides a 3′ –OH end from which DNA polymerase can extend the fragment. It is later replaced with DNA.
- rubisco (ribulose biphosphate carboxylase-oxygenase)** The enzyme that accomplishes carbon fixation in photosynthesis by adding CO<sub>2</sub> to ribulose-1,5-bisphosphate. It can also add O<sub>2</sub> in place of CO<sub>2</sub>, initiating photorespiration.
- saponification** Base-catalyzed hydrolysis of a triacylglycerol.
- sarcoplasmic reticulum** A network of membranous tubules that surrounds each myofibril in a skeletal muscle cell. It is a specialized region of endoplasmic reticulum; its main function is to sequester and then release the Ca<sup>2+</sup> that triggers myofibril contraction.
- satellite DNA** DNA consisting of multiple tandem repeats of very short, simple nucleotide sequences. It typically makes up 10% to 20% of the genome of higher eukaryotes; at least some of it may play a role in chromosome structure.
- scanning electron microscopy (SEM)** A type of electron microscopy in which a beam of electrons is scanned across an object, and the pattern of reflected electrons is analyzed to create an image of the object's surface. Compare *transmission electron microscopy*.
- secondary structure** Local folding of the backbone of a linear polymer to form a regular, repeating structure. The B- and Z-forms of the DNA helix and the  $\alpha$ -helix and  $\beta$ -sheet structures of polypeptides are examples. Compare *primary structure*, *quaternary structure*, *tertiary structure*.
- second law of thermodynamics** The law that states that the entropy in a closed system never decreases. An alternative statement is that processes that are thermodynamically favored at constant temperature and pressure involve a decrease in free energy.
- second messenger** An intracellular substance that relays an extracellular signal (such as a hormonal signal) from the cell membrane to intracellular effector proteins.
- second-order reaction** A reaction in which two reactant molecules must come together for the reaction to occur. The reaction is called second-order because the reaction rate depends on the square of reactant concentration (for two molecules of the same reactant) or on the product of two reactant concentrations (for two different reactants). Compare *first-order reaction*.
- sedimentation coefficient (S)** A coefficient that determines the velocity at which a particular particle will sediment during centrifugation; it depends on the density of the medium, the specific density of the particle, and the size, shape, and mass of the particle.
- sedimentation equilibrium** A technique for using centrifugation to measure the mass of a large molecule such as a protein. A solution of the substance is centrifuged at low speed until the tendency of the substance to sediment is balanced by its tendency to diffuse to uniform concentration; the resulting concentration gradient is used to measure the molecular mass.
- semiconservative replication** A mode of DNA replication in which each daughter duplex contains one strand from the parent duplex and one newly synthesized strand. This is the way DNA replication actually occurs.
- sense strand** For a gene, the DNA strand that is homologous to an RNA transcript of the gene—that is, it carries the same sequence as the transcript, except with T in place of U. It is thus complementary to the strand that served as a template for the RNA.
- sex factors** Plasmids that specify gene products that enable bacteria to engage in conjugation (bacterial mating).
- sickle-cell disease** A genetic disease resulting from a hemoglobin mutation. It produces fragile erythrocytes, leading to anemia.
- signal recognition particles (SRPs)** Cytoplasmic particles that dock ribosomes on the surface of the endoplasmic reticulum (ER) if the nascent polypeptide is destined to be processed by the ER. The SRP recognizes and binds to a specific N-terminal signal sequence on the nascent polypeptide.
- signal sequence** See *leader sequence*.
- siRNA** Also known as small interfering RNA, a short (21 to 23 nucleotides) double-stranded RNA that targets other RNAs with homologous sequences for degradation; involved in resistance by plants to virus infection.
- sirtuins** (For *silent information regulators*) A family of proteins with NAD<sup>+</sup>-dependent protein deacetylase activity that are involved in regulating energy metabolism.
- site-directed mutagenesis** A technique by which a specific mutation is introduced at a specific site in a cloned gene. The gene can then be introduced into an organism and expressed.
- 6–4 photoproduct** A type of DNA damage caused by UV irradiation in which a bond forms between carbon-6 of one pyrimidine base and carbon-4 of an adjacent pyrimidine base. This type of photoproduct appears to be the chief cause of UV-induced mutations.
- somatic hypermutation** A large increase in the spontaneous mutation rate of genes in the immune system, participating in the terminal stages of antibody diversification.
- somatic mutation** A mutation that occurs in a cell of an organism other than a germ-line cell; it may affect the organism in which it occurs, but it cannot be passed on to progeny.
- SOS response** A bacterial response to various potentially lethal stresses, including severe UV irradiation. It involves the coordinated expression of a set of proteins that carry out survival maneuvers, including an error-prone type of repair for thymine dimers in DNA.
- Southern blotting** A technique for detecting the presence of a specific DNA sequence in a genome. The DNA is extracted, cleaved into fragments, separated by gel electrophoresis, denatured, and blotted onto a nitrocellulose filter. There it is incubated under annealing conditions with a radiolabeled probe for the sequence in question, and heteroduplexes of the probe with genomic DNA are detected by radioautography.
- spectrophotometer** An instrument that exposes a sample to light of defined wavelengths and measures the absorbance. Different types of spectrophotometers operate in different wavelength ranges, such as ultraviolet, visible, and infrared.
- spin label** A substance that has an unpaired electron detectable by electron spin resonance and that is used as a chemical label.
- spliceosome** A protein–RNA complex in the nucleus that is responsible for splicing introns out of RNA transcripts.
- standard reduction potential (E<sub>0</sub>)** For a given pair consisting of an electron donor and its conjugate acceptor, the reduction potential under standard conditions (25 °C; donor and acceptor both at 1 M concentration). Sometimes called redox potential.
- standard state** A reference state, with respect to which thermodynamic quantities (such as chemical potentials) are defined. For substances in

- solution, standard state indicates 1 M concentration at 1 atm pressure and 25 °C.
- statins** A family of drugs that lower cholesterol levels by inhibiting HMG-CoA reductase.
- stop codons** RNA codons that signal a ribosome to stop translating an mRNA and to release the polypeptide. In the normal genetic code, they are UAG, UGA, and UAA.
- stringent response** A mechanism that inhibits the expression of all structural genes in bacteria under conditions of amino acid starvation. It involves inhibition of the synthesis of ribosomal and transfer RNAs.
- substrate** A reactant in an enzyme-catalyzed reaction.
- substrate-level phosphorylation** Synthesis of a nucleoside triphosphate (usually ATP) driven by the breakdown of a compound with higher phosphate transfer potential.
- suicide inhibitor** An enzyme inhibitor on which the enzyme can act catalytically but which irreversibly alters the active site of the enzyme in the process. (It is called a suicide inhibitor because the enzyme “commits suicide” by acting on it.)
- supercoiling** For a DNA double helix, turns of the two strands around each other that either exceed or are fewer than the number of turns in the most stable helical conformation. Only a helix that is circular or else fixed at both ends can support supercoiling. See *twist*, *writhe*.
- superhelix density** ( $s$ ) A measure of the superhelicity of a DNA molecule. It is equal to the change in linking number caused by the introduction of supercoiling divided by the linking number the DNA molecule would have in its relaxed state.
- suppression** With respect to mutations, a mutation that occurs at a different site from that of an existing mutation in a gene but restores the wild-type phenotype.
- Svedberg unit (S)** In ultracentrifugation, a unit used for the sedimentation coefficient; it is equal to  $10^{-13}$  second.
- swinging cross-bridge model** The periodic attachment and release of crossbridges, with a cross-bridge conformational change, slide the thin and thick filaments past one another.
- symport** A membrane transport process that couples the transport of a substrate in one direction across a membrane to the transport of a different substrate in the same direction. Compare *antiport*.
- systems biology** A form of biological investigation that focuses upon the operation and interactions of entire systems, such as all of the metabolic reactions occurring in a cell, as compared with the analysis of individual steps and processes.
- tautomers** Structural isomers that differ only in the location of their hydrogens and double bonds.
- Tay–Sachs disease** A genetic disease caused by a deficiency of the lysosomal enzyme *N*-acetylhexosaminidase A, which is involved in sphingolipid degradation. The deficiency results in accumulation of the ganglioside sphingolipid GM<sub>2</sub>, particularly in the brain.
- telomerase** A DNA polymerase that adds a short repeating sequence to the 3' end at either end of a chromosomal DNA molecule, thus creating a single-strand overhang. This overhang gives room for priming the origin of a final Okazaki fragment during DNA replication so that the full length of the chromosome can be copied.
- telomeres** Special DNA sequences at the ends of eukaryotic chromosomes.
- temperate phages** Bacteriophages that can establish a condition of lysogeny. See also *lysogeny*.
- template strand** A DNA or an RNA strand that directs the synthesis of a complementary nucleic acid strand.
- terpenes** A family of compounds, including the steroids, that are assembled from five-carbon units related to isoprene.
- tertiary structure** Large-scale folding structure in a linear polymer that is at a higher order than secondary structure. For proteins and RNA molecules, the tertiary structure is the specific three-dimensional shape into which the entire chain is folded. Compare *primary structure*, *quaternary structure*, *secondary structure*.
- thioredoxin** A low-molecular-weight protein with a redox-active dithiol grouping that plays a variety of roles, mostly as a biological reductant.
- thylakoids** The membrane-bound sacs within a chloroplast (which see) that contain the photosystems (which see).
- topoisomerases** Enzymes that change the supercoiling of DNA helices by either allowing the superhelical torsion to relax (thus reducing the supercoiling) or adding more twists (thus increasing the supercoiling).
- topoisomers** With respect to DNA, closed circular DNA molecules that are identical except in their sense or degree of supercoiling. DNA topoisomers can be interchanged only by cutting one or both strands using topoisomerases.
- transamination** In the cell, the enzymatic transfer of an amino group from an amino acid to a keto acid. The keto acid becomes an amino acid and vice versa.
- transcription** The synthesis of an RNA molecule complementary to a DNA strand; the information encoded in the base sequence of the DNA is thus “transcribed” into the RNA version of the same code. Compare *translation*.
- transcription factors** Proteins that influence the transcription of particular genes, usually by binding to specific promoter sites.
- transduction** A gene-exchange process that involves packaging of bacterial DNA during virus infection followed by its transfer to another cell in a subsequent round of infection.
- transfer RNA (tRNA)** A class of small RNA molecules that transfer amino acids to ribosomes to be incorporated into proteins.
- transgenic** Refers to an organism whose genome contains one or more DNA sequences from a different species (transgenes). Genetic engineering can be used to create transgenic animals.
- transition** In genetics, a substitution mutation in which a purine–pyrimidine base pair gives rise to another purine–pyrimidine base pair.
- transition state** In any chemical reaction, the high-energy or unlikely state that must be achieved by the reacting molecule(s) for the reaction to occur.
- translation** The synthesis of a polypeptide under the direction of an mRNA, so that the nucleotide sequence of the mRNA is “translated” into the amino acid sequence of the protein. Compare *transcription*.
- translesion synthesis** A form of DNA repair in which specialized DNA polymerases participate by replicating past a damaged site in the undamaged template strand.
- transmission electron microscopy (TEM)** A type of electron microscopy in which a beam of electrons passes through the object to be viewed and creates an image on a photographic plate or screen. Compare *scanning electron microscopy*.
- transposable genetic elements** Genetic elements that are able to move from place to place within a genome. A transposon is one type of transposable element.
- transposase** An enzyme that is involved in the transposition, the movement of a bacterial transposon into a target site.
- transversion** In genetics, a substitution mutation in which a purine–pyrimidine base pair gives rise to a pyrimidine–purine base pair.
- triacylglycerol** Often called neutral fat or triglyceride, a lipid that upon hydrolysis yields one glycerol and three fatty acids.
- tricarboxylic acid cycle** See *citric acid cycle*.
- tumor promoter** A compound that functions beyond the initial stage of carcinogenesis, often acting as a growth stimulator.

- turnover number** With respect to an enzyme-catalyzed reaction, the number of substrate molecules one enzyme molecule can process (turn over) per second when saturated with substrate. It is equivalent to the catalytic rate constant,  $k_{\text{cat}}$ .
- twist ( $T$ )** With respect to a DNA double helix, the total number of times the two strands of the helix cross over each other, excluding writhing. It is a measure of how tightly the helix is wound. See also *linking number*, *writhe*.
- ubiquitin** A widely distributed low-molecular-weight protein which, when linked to the C-terminal residue of another protein, marks that protein for metabolic degradation.
- ultrafiltration** The technique of filtering a solution under pressure through a semipermeable membrane, which allows water and small solutes to pass through but retains macromolecules.
- uncompetitive inhibition** A form of enzyme inhibition in which the inhibitor binds reversibly to the enzyme–substrate complex but not to the free enzyme.
- uricotelic** Referring to organisms, such as birds or reptiles, that excrete most of their nitrogen in the form of uric acid.
- van der Waals radius ( $r$ )** The effective radius of an atom or a molecule that defines how close other atoms or molecules can approach; it is thus the effective radius for closest molecular packing.
- vector** In genetic engineering, a DNA molecule that can be used to introduce a DNA sequence into a cell where it will be replicated and maintained. Usually a plasmid or a viral genome.
- very low-density lipoprotein (VLDL)** A type of lipoprotein particle that is manufactured in the liver and functions mainly to carry triacylglycerols from the liver to adipose and other tissues.
- vesicle** A spherical particle formed from a phospholipid bilayer.
- virion** A single virus particle.
- viruses** Infectious entities that contain the nucleic acid to code for their own structure but that lack the enzymatic machinery of a cell; they replicate by invading a cell and using its machinery to express the viral genome. Most viruses consist of little but nucleic acid enclosed in a protein coat; some viruses also have an outer lipid-bilayer envelope.
- wax** An ester formed from a long-chain fatty acid and a long-chain fatty alcohol.
- Western blotting** A technique for identifying proteins or protein fragments in a mixture that react with a particular antibody. The mixture is first resolved into bands by one-dimensional denaturing gel electrophoresis. The protein bands are then “blotted” onto a nitrocellulose sheet, the sheet is treated with the antibody, and any bands that bind the antibody are identified. More accurately called immunoblotting.
- wild-type** Refers to the normal genotype found in free-living, natural members of a group of organisms.
- writhe ( $W$ )** With respect to a supercoiled DNA helix, the number of times the helix as a whole crosses over itself—that is, the number of superhelical turns that are present. See also *linking number*, *twist*.
- xenobiotic** An organic compound that is not produced by the organism in which it is found.
- X-ray diffraction** A technique that is used to determine the three-dimensional structure of molecules, including macromolecules. A crystal or fiber of the substance is illuminated with a beam of X-rays, and the repeating elements of the structure scatter the X-rays to form a diffraction pattern that gives information on the molecule’s structure. See also *diffraction pattern*.
- yeast artificial chromosomes (YACs)** Artificial chromosomes used for cloning and maintaining large fragments of genomic DNA for investigational purposes. A YAC is constructed by recombinant DNA techniques from a yeast centromere, two telomeres (chromosome ends), selectable markers, and cloned DNA in the megabase range.
- Z-DNA** A DNA duplex with a specific left-hand helical structure. In vitro, it tends to be the most stable form for DNA duplexes that have alternating purines and pyrimidines, especially under conditions of cytosine methylation or negative supercoiling.

NOTE: Page numbers in boldface refer to a definition or major discussion of the entry. An *f* after a page number indicates a figure and a *t* indicates a table.

**SOME PREFIXES USED IN THE INTERNATIONAL SYSTEM OF UNITS**

|                   |       |   |
|-------------------|-------|---|
| 10 <sup>9</sup>   | giga  | G |
| 10 <sup>6</sup>   | mega  | M |
| 10 <sup>3</sup>   | kilo  | k |
| 10 <sup>-1</sup>  | deci  | d |
| 10 <sup>-2</sup>  | centi | c |
| 10 <sup>-3</sup>  | milli | m |
| 10 <sup>-6</sup>  | micro | μ |
| 10 <sup>-9</sup>  | nano  | n |
| 10 <sup>-12</sup> | pico  | p |
| 10 <sup>-15</sup> | femto | f |

**CONVERSION FACTORS**

Energy: 1 joule = 10<sup>7</sup> ergs = 0.239 cal  
 1 cal = 4.184 joule

Length: 1 nm = 10 Å = 1 × 10<sup>-7</sup> cm = 1 × 10<sup>-9</sup> m

Mass: 1 kg = 1000 g = 2.2 lb  
 1 lb = 453.6 g

Pressure: 1 atm = 760 torr = 1.013 bar = 14.696 psi  
 1 bar = 100 kPa = 0.987 atm = 750.1 torr  
 1 torr = 1 mm Hg

Temperature: K = °C + 273  
 °C = (5/9)(°F - 32)

Volume: 1 L = 1 × 10<sup>-3</sup> m<sup>3</sup> = 1000 cm<sup>3</sup>

**PHYSICAL CONSTANTS**

| Name                      | Symbol   | SI Units                                          | cgs Units                             |
|---------------------------|----------|---------------------------------------------------|---------------------------------------|

**SOME PREFIXES USED IN THE INTERNATIONAL SYSTEM OF UNITS**

|                   |       |   |
|-------------------|-------|---|
| 10 <sup>9</sup>   | giga  | G |
| 10 <sup>6</sup>   | mega  | M |
| 10 <sup>3</sup>   | kilo  | k |
| 10 <sup>-1</sup>  | deci  | d |
| 10 <sup>-2</sup>  | centi | c |
| 10 <sup>-3</sup>  | milli | m |
| 10 <sup>-6</sup>  | micro | μ |
| 10 <sup>-9</sup>  | nano  | n |
| 10 <sup>-12</sup> | pico  | p |
| 10 <sup>-15</sup> | femto | f |

**CONVERSION FACTORS**

Energy: 1 joule = 10<sup>7</sup> ergs = 0.239 cal  
 1 cal = 4.184 joule

Length: 1 nm = 10 Å = 1 × 10<sup>-7</sup> cm = 1 × 10<sup>-9</sup> m

Mass: 1 kg = 1000 g = 2.2 lb  
 1 lb = 453.6 g

Pressure: 1 atm = 760 torr = 1.013 bar = 14.696 psi  
 1 bar = 100 kPa = 0.987 atm = 750.1 torr  
 1 torr = 1 mm Hg

Temperature: K = °C + 273  
 °C = (5/9)(°F - 32)

Volume: 1 L = 1 × 10<sup>-3</sup> m<sup>3</sup> = 1000 cm<sup>3</sup>

**PHYSICAL CONSTANTS**

| Name                      | Symbol   | SI Units                                          | cgs Units                             |
|---------------------------|----------|---------------------------------------------------|---------------------------------------|
| Avogadro's number         | <i>N</i> | 6.022137 × 10 <sup>23</sup> /mol                  | 6.022137 × 10 <sup>23</sup> /mol      |
| Boltzmann constant        | <i>k</i> | 1.38066 × 10 <sup>-23</sup> J/K                   | 1.38066 × 10 <sup>-16</sup> erg/K     |
| Curie                     | Ci       | 3.7 × 10 <sup>10</sup> d/s                        | 3.7 × 10 <sup>10</sup> d/s            |
| Electron charge           | <i>e</i> | 1.602177 × 10 <sup>-19</sup> coulomb <sup>b</sup> | 4.80321 × 10 <sup>-10</sup> esu       |
| Faraday constant          | <i>F</i> | 96485 J/V · mol                                   | 9.6485 × 10 <sup>11</sup> erg/V · mol |
| Gas constant <sup>a</sup> | <i>R</i> | 8.31451 J/K · mol                                 | 8.31451 × 10 <sup>7</sup> erg/K · mol |
| Light speed (vacuum)      | <i>c</i> | 2.99792 × 10 <sup>8</sup> m/s                     | 2.99792 × 10 <sup>10</sup> cm/s       |
| Planck's constant         | <i>h</i> | 6.626075 × 10 <sup>-34</sup> J · s                | 6.626075 × 10 <sup>-27</sup> erg · s  |

<sup>a</sup>Other values of *R*: 1.9872 cal/K · mol = 0.082 L · atm/K · mol

<sup>b</sup>1 coulomb = 1 J/V

**USEFUL EQUATIONS**

|                                                        |                                                                                      |
|--------------------------------------------------------|--------------------------------------------------------------------------------------|
| Henderson–Hasselbalch equation                         | pH = pK <sub>a</sub> + log([A <sup>-</sup> ]/[HA])                                   |
| Michaelis–Menten equation                              | v = V <sub>max</sub> [S]/(K <sub>M</sub> + [S])                                      |
| Free energy change under non-standard-state conditions | ΔG = ΔG° + RT ln([C][D]/[A][B])                                                      |
| Free energy change and standard reduction potential    | ΔG°' = -nFΔE° <sub>0</sub>                                                           |
| Reduction potentials in a redox reaction               | ΔE° <sub>0</sub> = E° <sub>0</sub> (acceptor) - E° <sub>0</sub> (donor)              |
| Proton motive force                                    | Δp = ΔΨ - 2.3RT ΔpH/F                                                                |
| Passive diffusion of a charged species                 | ΔG = G <sub>2</sub> - G <sub>1</sub> = RT ln(C <sub>2</sub> /C <sub>1</sub> ) + ZFΔΨ |

| ER            | endoplasmic reticulum                                | J                 | joule                                                     |

COMMON ABBREVIATIONS USED BY BIOCHEMISTS (CONTINUED)

|                  |                                                     |                  |                                                   |
|------------------|-----------------------------------------------------|------------------|---------------------------------------------------|
| k                | kilo ( $10^3$ )                                     | PLP              | pyridoxal-5-phosphate                             |
| $k_{\text{cat}}$ | turnover number                                     | Pol              | polymerase                                        |
| $K_M$            | Michaelis constant                                  | $\text{PP}_i$    | pyrophosphate ion ( $\text{P}_2\text{O}_7^{4-}$ ) |
| kb               | kilobase                                            | PQ               | plastoquinone                                     |
| kDa              | kilodalton                                          | Pro              | proline                                           |
| L                | liter                                               | PRPP             | 5-phosphoribosyl-1-pyrophosphate                  |
| LDH              | lactate dehydrogenase                               | PS               | phosphatidylserine                                |
| LDL              | low-density lipoprotein                             | PTH              | parathyroid hormone                               |
| Leu              | leucine                                             | $\text{QH}_2$    | reduced coenzyme Q (ubiquinol)                    |
| Lys              | lysine                                              | R                | gas constant                                      |
| M                | molar (mol/L)                                       | rpm              | revolutions per minute                            |
| m                | milli ( $10^{-3}$ )                                 | RER              | rough endoplasmic reticulum                       |
| Man              | mannose                                             | RF               | release factor                                    |
| Mb               | myoglobin                                           | R5P              | ribose-5-phosphate                                |
| Met              | methionine                                          | RFLP             | restriction fragment length polymorphism          |
| mL               | milliliter                                          | RNA              | ribonucleic acid                                  |
| mm               | millimeter                                          | rRNA             | ribosomal RNA                                     |
| mM               | millimolar (mmol/L)                                 | RuBP             | ribulose-1,5-bisphosphate                         |
| mmol             | millimole                                           | S                | Svedberg unit                                     |
| $\mu$            | micro ( $10^{-6}$ )                                 | S                | sedimentation coefficient                         |
| $\mu\text{m}$    | micrometer                                          | s                | second                                            |
| $\mu\text{M}$    | micromolar ( $\mu\text{mol/L}$ )                    | SDS              | sodium dodecylsulfate                             |
| $\mu\text{mol}$  | micromole                                           | Ser              | serine                                            |
| mol              | mole                                                | snRNA            | small nuclear RNA                                 |
| mRNA             | messenger RNA                                       | snRNP            | small nuclear ribonucleoprotein                   |
| mV               | millivolt                                           | SRP              | signal recognition particle                       |
| N                | Avogadro's number                                   | T                | absolute temperature                              |
| n                | nano ( $10^{-9}$ )                                  | TCA              | tricarboxylic acid cycle                          |
| $\text{NAD}^+$   | nicotinamide adenine dinucleotide                   | THF              | tetrahydrofolate                                  |
| NADH             | reduced nicotinamide adenine dinucleotide           | Thr              | threonine                                         |
| $\text{NADP}^+$  | nicotinamide adenine dinucleotide phosphate         | 3PG              | 3-phosphoglycerate                                |
| NADPH            | reduced nicotinamide adenine dinucleotide phosphate | TMV              | tobacco mosaic virus                              |
| nm               | nanometer                                           | TPP              | thiamine pyrophosphate                            |
| NMR              | nuclear magnetic resonance                          | tRNA             | transfer RNA                                      |
| p                | pico ( $10^{-12}$ )                                 | Trp              | tryptophan                                        |
| $\text{P}_i$     | inorganic phosphate ( $\text{HPO}_4^{2-}$ )         | 2PG              | 2-phosphoglycerate                                |
| PAGE             | polyacrylamide gel electrophoresis                  | Tyr              | tyrosine                                          |
| PBG              | porphobilinogen                                     | UDP              | uridine diphosphate                               |
| PC               | phosphatidylcholine                                 | UDPG             | UDP-glucose                                       |
| PCR              | polymerase chain reaction                           | UMP              | uridine monophosphate                             |
| PE               | phosphatidylethanolamine                            | UTP              | uridine triphosphate                              |
| PEP              | phosphoenolpyruvate                                 | UV               | ultraviolet                                       |
| PG               | prostaglandin                                       | V                | volt                                              |
| Phe              | phenylalanine                                       | $V_{\text{max}}$ | maximal velocity                                  |
| PI               | phosphatidyl-inositol                               | Val              | valine                                            |
| PK               | pyruvate kinase                                     | VLDL             | very low-density lipoprotein                      |
| PKU              | phenylketonuria                                     | XMP              | xanthosine monophosphate                          |
|                  |                                                     | YAC              | yeast artificial chromosome                       |
|                  |                                                     | yr               | year                                              |
