**2 Properties of Lipid Aggregates** The molecular shapes of membrane lipids cause them to aggregate in aqueous solution as bilayers. These form closed vesicles known as liposomes that are useful model membranes and drug delivery systems. Bilayers are essentially impermeable to polar molecules, except for water. Likewise, the flip-flop of a lipid in a bilayer is an extremely rare event. In contrast, bilayers above their transition temperatures behave as two-dimensional fluids in which the individual lipid molecules freely diffuse in the bilayer plane. Cholesterol decreases membrane fluidity and broadens the temperature range of its order–disorder transition by interfering with the orderly packing of the lipids' fatty acid side chains.

**3 Biological Membranes** Biological membranes contain a high proportion of proteins. Integral proteins, for example, bacteriorhodopsin, the photosynthetic reaction center, porins, and fatty acid amide hydrolase, have nonpolar surface regions that hydrophobically associate with the bilayer core. Peripheral proteins, for example, cytochrome *c*, bind to integral proteins on the membrane surface or to phospholipid head groups via polar interactions. Specific integral proteins are invariably associated with a particular side of the membrane or, if they are transmembrane proteins, have only one orientation. Lipid-linked proteins contain covalently attached isoprenoid, fatty acyl, and/or glycosylphosphatidylinositol (GPI) groups that serve to anchor these proteins to membranes and to mediate protein–protein interactions. According to the fluid mosaic model of membrane structure, integral proteins resemble icebergs floating on a two-dimensional lipid sea. These proteins, as observed by the freeze-fracture and freeze-etch techniques, are randomly distributed in the membrane. Certain lipids and/or proteins may form specific aggregates on one leaflet of a membrane.

The erythrocyte cytoskeleton is responsible for the shape, flexibility, and fluidity of the red cell. Spectrin, the major constituent of the cytoskeleton, is a wormlike ( $\alpha\beta$ )<sub>2</sub> heterotetramer that is cross-linked by actin oligomers and band 4.1 protein. The resulting protein meshwork is anchored to the

membrane by the association of spectrin with ankyrin, which, in turn, binds to band 3 protein, a transmembrane protein that forms an anion channel.

The erythrocyte surface bears the various blood group antigens. The antigens of the ABO system differ in the sugar at a nonreducing end. The ABO blood group substances occur in the plasma membranes of many cells and in the secretions of many individuals.

Gap junctions are hexagonal transmembrane protein tubes that link adjoining cells. The gap junction's central channel, which closes at high intracellular levels of  $\text{Ca}^{2+}$ , allows small molecules and ions but not macromolecules to pass between cells. The connexin subunits of a gap junction's two face-to-face hexameric connexons each contain four transmembrane helices.

Bacterial channel-forming toxins such as  $\alpha$ -hemolysin form oligomers on the outer surface of a target cell's plasma membrane. These insert themselves into the membrane to form pores through which small molecules and ions leak, thereby killing the cell.

**4 Membrane Assembly and Protein Targeting** New membranes are generated by the expansion of old ones. Lipids are synthesized by membrane-bound enzymes and are deposited on one side of the membrane. They migrate to the other side by flip-flops that are catalyzed by membrane-bound flippases and phospholipid translocases. In eukaryotes, lipids are transported between different membranes by lipid vesicles or by phospholipid-exchange proteins.

In the secretory pathway, transmembrane proteins and proteins destined for secretion are ribosomally synthesized with an N-terminal signal sequence. A signal peptide is bound by an RNA-containing signal recognition particle (SRP), which then arrests polypeptide synthesis. The SRP-ribosome complex binds to the SRP receptor (SR) in complex with the translocon on the endoplasmic reticulum (ER) membrane and, on GTP hydrolysis by both the SRP and SR, resumes polypeptide synthesis. As a protein destined for secretion passes through the translocon into the ER lumen, its signal peptide is removed by an ER-resident signal peptidase, its folding is facilitated through interactions with ER-resident chaperone proteins such as BiP, and its post-translational processing, mainly signal peptide excision and glycosylation, is initiated. Integral proteins, whose transmembrane (TM) segments each contain signal-anchor sequences, also enter the translocon, which laterally installs these TM segments into the ER membrane. The orientation of TM helices in membranes usually obeys the positive-inside rule. Some proteins are wholly synthesized in the cytoplasm before being translocated into the ER.

Proteins are transferred between the ER, the Golgi apparatus (where further post-translational processing takes place), and their final destinations via membranous vesicles that are coated with clathrin, COPI, or COPII. Clathrin-coated vesicles also participate in endocytosis. Polyhedral clathrin cages are formed by triskelions, which are trimers of heavy chains, each of which binds a light chain. Clathrin-coated vesicle formation is primed by the action of ARNO, a guanine nucleotide exchange factor (GEF) that induces the small GTPase ARF1 to exchange its bound GDP for GTP and then insert its myristoyl group into the membrane. ARF1 · GTP then recruits adapter proteins such as AP1 and

AP2, which simultaneously bind clathrin heavy chains and TM proteins that are cargo proteins or are receptors for soluble cargo proteins inside the vesicle. The formation of the clathrin cage drives vesicle budding, but its actual release from its parent membrane requires the action of the GTPase dynamin. Shortly after its release, the vesicle uncoats in a process mediated by the chaperone protein Hsc70. COPI- and COPII-coated vesicles undergo similar processes, although they do not require a dynamin-like protein to bud off from their parent membranes. The Sec13/31 components of COPII-coated vesicles form cuboctahedral cages. The receptors in coated vesicles bind their target cargo proteins through specific signals such as the mannose-6-phosphate group that directs proteins to the lysosome or the C-terminal KDEL sequence that retrieves normally ER-resident proteins from the Golgi to the ER.

The fusion of a vesicle with its target membrane is initiated when a Rab protein, a small GTPase, induces the loose tethering of the two membranes. The vesicle is then more firmly anchored (docked) to the membrane through interactions between cognate R-SNAREs on the vesicle and Q-SNAREs on the target membrane. In neurons, synaptic vesicles dock with the presynaptic membrane through the association of the R-SNARE synaptobrevin (VAMP) with the Q-SNAREs syntaxin and SNAP-25 to form a 4-helix bundle. These neuronal SNAREs are specifically cleaved by tetanus and botulinum neurotoxins. The bilayer fusion step probably occurs as a result of the mechanical stresses generated by the formation of the several SNARE complexes at the fusion site. The neuronal SM protein nSec1 binds to syntaxin with high affinity so as to prevent the formation of the SNARE complex. A Rab protein and/or its effectors apparently induce nSec1 to release syntaxin and thereby permit the formation of the SNARE complex. After vesicle fusion, the SNARE complex must be dissociated in order to be recycled. This occurs through the auspices of the ATP-driven molecular chaperone NSF, which binds to the SNARE complex through the intermediacy of a SNAP protein.

Nuclear-encoded mitochondrial proteins are synthesized by cytosolic ribosomes and enter the mitochondrion post-translationally. A protein can only pass through a membrane in its unfolded form and hence must first be unfolded by ATP-driven molecular chaperones such as Hsp70 and MSF. A matrix-directed protein is passed through the mitochondrial outer membrane via the TOM complex, which recognizes the protein's amphipathic and positively charged N-terminal signal sequence. The N-terminal presequence then crosses the intermembrane space to encounter the TIM23 complex, which translocates it through the inner membrane into the matrix. This latter process is driven both by the mitochondrial membrane potential, which electrophoretically draws the positively charged presequence into the matrix, and by the ATP-driven chaperone mtHsp70, which binds to Tim44 in the matrix and pulls the unfolded protein into the matrix via a Brownian ratchet mechanism. MPP then excises the N-terminal signal sequence from the protein, which subsequently folds to its native state as facilitated by a battery of resident chaperones including mtHsp70 and Hsp60/Hsp10. Metabolite carrier proteins, which lack N-terminal presequences but have internal targeting sequences, also enter the intermembrane space via the TOM complex. However, they are then escorted by the

Tim9–Tim10 complex to the TIM22 complex, which laterally inserts them into the inner mitochondrial membrane. Many TM proteins that occupy the inner mitochondrial membrane are inserted there from the matrix by the Oxa1 protein, an indirect pathway that is a relic of the mitochondrion's descent from a gram-negative bacterium. Likewise, proteins that form  $\beta$  barrels are translocated by the TOM complex into the intermembrane space, from which they are inserted into the outer membrane by the SAM complex.

**5 Lipoproteins** Lipids are transported in the circulation by plasma lipoproteins. These are essentially droplets of triacylglycerols and cholesteryl esters coated with a monolayer of phospholipids, cholesterol, and apolipoproteins. The amphiphilic apolipoprotein helices float on the lipoprotein surface in hydrophobic contact with its lipid interior. Chylomicrons and VLDL function to respectively transport triacylglycerols and cholesterol from the intestines and the liver to the tissues. HDL transports mainly cholesterol from

the tissues to the liver, the only organ capable of disposing of significant quantities of cholesterol. The triacylglycerols of chylomicrons and VLDL are degraded by lipoprotein lipase that lines the capillaries. LDL, the cholesterol-containing degradation product of VLDL, binds to cell-surface LDL receptors (LDLRs) and is taken into cells by receptor-mediated endocytosis. The presence of excess intracellular cholesterol inhibits the synthesis of both LDLR and cholesterol. A major cause of atherosclerosis is an excess of plasma LDL, a phenomenon that is particularly evident in individuals with familial hypercholesterolemia, who lack functional LDLRs. The excess LDL becomes oxidized and is taken up by the macrophages that inhabit atherosclerotic plaques via their scavenger receptors. Atherosclerosis, a multifactorial disease, is also correlated with a low concentration of HDL, which functions as a cholesterol scavenger. The apoE2 and apoE4 variants of apoE are implicated in cardiovascular disease, whereas apoE4 is also implicated in Alzheimer's disease.

## PROBLEMS

1. Explain the difference in melting points between *trans*-oleic acid (44.5°C) and *cis*-oleic acid (13.4°C).
2. Why do animals that live in cold climates generally have more polyunsaturated fatty acid residues in their fats than do animals that live in warm climates?
- \*3. How many different isomers of phosphatidylserine, triacylglycerol, and cardiolipin can be made from four types of fatty acids?
4. Estimate the thickness of the surface layer formed by Benjamin Franklin's teaspoon of oil on Clapham pond (1 teaspoon = 5 mL and 1 acre = 4047 m<sup>2</sup>).
5. “Hard water” contains a relatively high concentration of Ca<sup>2+</sup>. Explain why soap is ineffective for washing in hard water.
6. Explain why pure hydrocarbons do not form monolayers on water.
7. Soap bubbles are inside-out bilayers; that is, the polar head groups of the amphiphiles, together with some water, are in apposition, whereas their hydrophobic tails extend into the air. Explain the physical basis of this phenomenon.
8. Describe the action of detergents in extracting integral proteins from membranes. How do they keep these proteins from precipitating? Why do mild detergents such as Triton X-100 bind only to proteins that form lipid complexes?
- \*9. Is the transmembrane portion of glycophorin A (Fig. 12-21)  $\alpha$  helical (use the Chou and Fasman rules; Section 9-3Aa)?
10. The symmetries of oligomeric integral proteins are constrained by the requirement that their subunits must all have the same orientation with respect to the plane of the membrane. What symmetries can these proteins have? Explain. (Protein symmetry is discussed in Section 8-5B.)
11. (a) How many residues must an  $\alpha$  helix contain in order to span the 30-Å-thick hydrocarbon core of a lipid bilayer? (b) How many residues in a  $\beta$  sheet are required to span this bilayer core if it is inclined by 30° with respect to the normal to the membrane

plane? (c) Why do most transmembrane  $\alpha$  helices and  $\beta$  strands have more than these minimum numbers?

**12.** Explain why antibodies against type A blood group antigens are inhibited by *N*-acetylgalactosamine, whereas anti-B antibodies are inhibited by galactose.

**13.** (a) Individuals with a certain one of the ABO blood types are said to be “universal donors,” whereas those with another type are said to be “universal recipients.” What are these blood types? Explain. (b) Antibodies are contained in blood plasma, which is blood with its red and white cells removed. Indicate the various compatibilities of blood plasma from an individual with one ABO blood type with an individual with a different ABO blood type. (c) Considering the answers to Parts a and b, why is it possible that there can be a universal donor and a universal recipient for a transfusion of whole blood?

**14.** Anti-H antibodies are not normally found in human blood. They may, however, be elicited in animals by the injection of human blood. How would such antibodies be expected to react with tissues from individuals with type A, type B, and type O blood groups?

**15.** *Thermus aquaticus* is a thermophilic bacterium that grows between the temperatures of 50 and 80°C. Although the signal peptide binding groove of its Ffh M domain is lined with hydrophobic groups, only three of them are Met side chains. In contrast, the binding grooves of mesophilic organisms (those that live at normal temperatures) are lined with numerous Met side chains (11 in *E. coli*). In addition, one wall of the binding groove is disordered in the X-ray structure of the *E. coli* M domain but ordered in that of *T. aquaticus* (both proteins were crystallized at room temperature). Suggest a reason for these evolutionary adaptations in *T. aquaticus*.

**16.** Influenza virus neuraminidase (Section 33-4Bd) is a type II protein in which three Arg residues are located just before the N-terminal end of its signal-anchor sequence. What is the likely effect of mutating all of these Arg residues to Glu?

**\*17.** In a genetically distinct form of familial hypercholesterolemia, LDL binds to the cell surface but fails to be internalized by endocytosis. Electron microscopy reveals that each mutant cell has its normal complement of coated pits but that ferritin-conjugated LDL does not bind to them. Rather, the bound LDL is uniformly distributed about the noncoated regions of the cell surfaces. Apparently the binding properties of the mutant LDL receptors are normal but they are in the wrong place. What do these data suggest about how LDL receptor is assembled into coated pits?

**18.** Table 12-6 indicates that the densities of lipoproteins increase as their particle diameters decrease. Explain.

**19.** Certain types of animal viruses form by budding out from a cell surface much like coated pits bud into the cytoplasm during endocytosis to form coated vesicles. In both cases, the membranous vesicles form on a polyhedral protein scaffolding. Sketch the budding of an animal virus and indicate the location of its membrane relative to its protein shell.

**20.** Why aren't chylomicrons taken up by LDL receptors?

**21. Wolman's disease** is a rapidly fatal homozygous defect characterized by a severe deficiency in **cholesteryl ester hydrolase**, the enzyme that catalyzes the hydrolysis of intracellularly located cholesteryl esters. Describe the microscopic appearance of the cells of victims of Wolman's disease.

Bovine pancreatic  
ribonuclease S in  
complex with a  
nonhydrolyzable  
substrate analog, the

phosphonate UpcA.

## PART III

# MECHANISMS OF ENZYME ACTION

*This page intentionally left blank*

# Introduction to Enzymes

## CHAPTER 13

- 1 **Historical Perspective**
- 2 **Substrate Specificity**
  - A. Stereospecificity
  - B. Geometric Specificity
- 3 **Coenzymes**
- 4 **Control of Enzymatic Activity**
- 5 **A Primer of Enzyme Nomenclature**

The enormous variety of biochemical reactions that comprise life are nearly all mediated by a series of remarkable biological catalysts known as **enzymes**. Although enzymes are subject to the same laws of nature that govern the behavior of other substances, they differ from ordinary chemical catalysts in several important respects:

**1. Higher reaction rates:** The rates of enzymatically catalyzed reactions are typically factors of  $10^6$  to  $10^{12}$  greater than those of the corresponding uncatalyzed reactions and are at least several orders of magnitude greater than those of the corresponding chemically catalyzed reactions.

**2. Milder reaction conditions:** Enzymatically catalyzed reactions occur under relatively mild conditions: temperatures below  $100^\circ\text{C}$ , atmospheric pressure, and nearly neutral pH's. In contrast, efficient chemical catalysis often requires elevated temperatures and pressures as well as extremes of pH.

**3. Greater reaction specificity:** Enzymes have a vastly greater degree of specificity with respect to the identities of both their **substrates** (reactants) and their products than do chemical catalysts; that is, enzymatic reactions rarely have side products. For example, in the enzymatic synthesis of proteins on ribosomes (Section 32-3), polypeptides consisting of well over 1000 amino acid residues are made all but error free. Yet, in the chemical synthesis of polypeptides, side reactions and incomplete reactions presently limit the lengths of polypeptides that can be accurately produced in reasonable yields to  $\sim 200$  residues (Section 7-5B).

**4. Capacity for control:** The catalytic activities of many enzymes vary in response to the concentrations of substances other than their substrates and products. The mechanisms of these control processes include allosteric control, covalent modification of enzymes, and variation of the amounts of enzymes synthesized.

Consideration of these remarkable catalytic properties of enzymes leads to one of the central questions of biochemistry: *How do enzymes work?* We address this issue in this part of the text.

In this chapter, following a historical review, we commence our study of enzymes with a discussion of two clear instances of enzyme action: one that illustrates how enzyme specificity is manifested, and a second that exemplifies the control of enzyme activity. These are by no means exhaustive treatments but are intended to highlight these all-important aspects of enzyme mechanism. We shall encounter numerous other examples of these phenomena in our study of metabolism (Chapters 16–28). These two expositions are interspersed with a consideration of the roles of enzymatic cofactors. The chapter ends with a short synopsis of enzyme nomenclature. In Chapter 14 we take up the formalism of enzyme kinetics because the study of the rates of enzymatically catalyzed reactions provides indispensable mechanistic information. Finally, Chapter 15 is a general discussion of the catalytic mechanisms employed by enzymes, followed by an examination of the mechanisms of several specific enzymes.

### 1 HISTORICAL PERSPECTIVE

The early history of **enzymology**, the study of enzymes, is largely that of biochemistry itself; these disciplines evolved together from nineteenth century investigations of fermentation and digestion. Research on fermentation is widely considered to have begun in 1810 with Joseph Gay-Lussac's determination that ethanol and  $\text{CO}_2$  are the principal products of sugar decomposition by yeast. In 1835, Jacob Berzelius, in the first general theory of chemical catalysis, pointed out that an extract of malt known as **diastase** (now known to contain the enzyme  **$\alpha$ -amylase**; Section 11-2Db) catalyzes the hydrolysis of starch more efficiently than does sulfuric acid. Yet, despite the ability of mineral acids to mimic the effect of diastase, it was the inability to reproduce most other biochemical reactions in the laboratory that led Louis Pasteur, in the mid-nineteenth century, to propose that the processes of fermentation could only occur in living cells. Thus, as was common in his era, Pasteur assumed that living systems were endowed with a "vital force" that permitted them to evade the laws of nature governing inanimate matter. Others, however, notably Justus von Liebig, argued that biological processes are caused by

the action of chemical substances that were then known as “ferments.” Indeed, the name “enzyme” (Greek: *en*, in + *zyme*, yeast) was coined in 1878 by Wilhelm Friedrich Kühne in an effort to emphasize that there is something *in* yeast, as opposed to the yeast itself, that catalyzes the reactions of fermentation. Nevertheless, it was not until 1897 that Eduard Buchner obtained a cell-free yeast extract that could carry out the synthesis of ethanol from glucose (**alcoholic fermentation**; Section 17-3B).

Emil Fischer’s discovery, in 1894, that glycolytic enzymes can distinguish between stereoisomeric sugars led to the formulation of his **lock-and-key hypothesis**: *The specificity of an enzyme (the lock) for its substrate (the key) arises from their geometrically complementary shapes.* Yet the chemical composition of enzymes was not firmly established until well into the twentieth century. In 1926, James Sumner, who crystallized the first enzyme, jack bean **urease**, which catalyzes the hydrolysis of urea to  $\text{NH}_3$  and  $\text{CO}_2$ , demonstrated that these crystals consist of protein. Since Sumner’s preparations were somewhat impure, however, the protein nature of enzymes was not generally accepted until the mid-1930s, when John Northrop and Moses Kunitz showed that there is a direct correlation between the enzymatic activities of crystalline pepsin, trypsin, and chymotrypsin and the amounts of protein present. Enzymological experience since then has amply demonstrated that enzymes are proteins (although it has more recently been shown that RNA can also have catalytic properties; Section 31-4Ae).

Although the subject of enzymology has a long history, most of our understanding of the nature and functions of enzymes is a product of the last 60 years. Only with the advent of modern techniques for separation and analysis (Chapter 6) has the isolation and characterization of an enzyme become less than a monumental task. It was not until 1963 that the first amino acid sequence of an enzyme, that of **bovine pancreatic ribonuclease A** (Section 15-1Ab), was reported in its entirety, and not until 1965 that the first X-ray structure of an enzyme, that of hen egg white **lysozyme** (Section 15-2A), was elucidated. In the years since then, tens of thousands of enzymes have been purified and characterized to at least some extent, and the pace of this endeavor is rapidly accelerating.

## 2 SUBSTRATE SPECIFICITY

*The noncovalent forces through which substrates and other molecules bind to enzymes are similar in character to the forces that dictate the conformations of the proteins themselves (Section 8-4): Both involve van der Waals, electrostatic, hydrogen bonding, and hydrophobic interactions.* In general, a substrate-binding site consists of an indentation or cleft on the surface of an enzyme molecule that is complementary in shape to the substrate (geometric complementarity). Moreover, the amino acid residues that form the binding site are arranged to interact specifically with the substrate in an attractive manner (electronic complementarity; Fig. 13-1). Molecules that differ in shape or functional group distribution from the substrate cannot productively bind to the

**Figure 13-1** An enzyme–substrate complex illustrating both the geometric and the physical complementarity between enzymes and substrates. Hydrophobic groups are represented by an h in a brown circle, and dashed lines represent hydrogen bonds.

enzyme; that is, they cannot form enzyme–substrate complexes that lead to the formation of products. The substrate-binding site may, in accordance with the lock-and-key hypothesis, exist in the absence of bound substrate or it may, as suggested by the induced-fit hypothesis (Section 10-4C), form about the substrate as it binds to the enzyme. *X-ray studies indicate that the substrate-binding sites of most enzymes are largely preformed but that most of them exhibit at least some degree of induced fit on binding substrate.*

### A. Stereospecificity

*Enzymes are highly specific both in binding chiral substrates and in catalyzing their reactions.* This **stereospecificity** arises because enzymes, by virtue of their inherent chirality (proteins consist of only L-amino acids), form asymmetric active sites. For example, trypsin readily hydrolyzes polypeptides composed of L-amino acids but not those consisting of D-amino acids. Likewise, the enzymes involved with glucose metabolism (Section 17-2) are specific for D-glucose residues.

*Enzymes are absolutely stereospecific in the reactions they catalyze.* This was strikingly demonstrated for the case of **yeast alcohol dehydrogenase (YADH)** by Frank Westheimer and Birgit Vennesland. Alcohol dehydrogenase catalyzes the interconversion of ethanol and acetaldehyde according to the reaction

**Figure 13-2** The structures and reaction of nicotinamide adenine dinucleotide (NAD<sup>+</sup>) and nicotinamide adenine dinucleotide phosphate (NADP<sup>+</sup>). Their reduced forms are NADH and NADPH. These substances, which are collectively referred to as the **nicotinamide coenzymes** or **pyridine nucleotides** (nicotinamide is a pyridine derivative), function, as is indicated in later chapters, as intracellular carriers of reducing equivalents (electrons). Note that only the nicotinamide ring is changed in the reaction. Reduction formally involves the transfer of two hydrogen atoms (H·), although the actual reduction may occur via a different mechanism.

X = H    **Nicotinamide adenine dinucleotide (NAD<sup>+</sup>)**  
 X = PO<sub>3</sub><sup>2-</sup>    **Nicotinamide adenine dinucleotide phosphate (NADP<sup>+</sup>)**

The structures of NAD<sup>+</sup> and NADH are presented in Fig. 13-2. Ethanol, it will be recalled, is a prochiral molecule (see Section 4-2Ca for a discussion of prochirality):

Ethanol's two methylene H atoms may be distinguished if the molecule is held in some sort of asymmetric jig (Fig. 13-3). The substrate-binding sites of enzymes are, of course, just such jigs because they immobilize the reacting groups of the substrate on the enzyme surface.

Westheimer and Vennesland elucidated the stereospecific nature of the YADH reaction through the following series of experiments:

1. If the YADH reaction is carried out with deuterated ethanol, the product NADH is deuterated:

Note that the nicotinamide ring of NAD<sup>+</sup> is also prochiral.

2. On isolating this NADD and using it in the reverse reaction to reduce normal acetaldehyde, the deuterium is

**Figure 13-3** Prochiral differentiation. The specific attachment of a prochiral center to an enzyme binding site permits the enzyme to differentiate between prochiral groups. Note: If it were possible, the binding of the prochiral molecule's mirror image to the same three sites from the underside of the binding site as pictured here would still result in H<sub>pro-R</sub> pointing toward a different position.

quantitatively transferred from the NADH to the acetaldehyde to form the product ethanol:

3. If the enantiomer of the foregoing  $\text{CH}_3\text{CHDOH}$  is made as follows:

none of the deuterium is transferred from the product ethanol to  $\text{NAD}^+$  in the reverse reaction.

4. If, however, this ethanol is converted to its tosylate and then inverted by  $\text{S}_{\text{N}}2$  hydrolysis to yield the enantiomeric ethanol,

***p*-Toluenesulfonyl chloride (tosyl chloride)**

the deuterium is again quantitatively transferred to  $\text{NAD}^+$  in the YADH reaction.

The foregoing observations, in addition to showing that there is direct hydrogen transfer in the YADH reaction (Experiments 1 and 2), indicate that the enzyme distinguishes between the *pro-S* and *pro-R* hydrogens of ethanol as well as the *si* and *re* faces of the nicotinamide ring of  $\text{NAD}^+$  (Experiments 2–4). It was later demonstrated, by stereospecific syntheses, that YADH transfers the *pro-R* hydrogen of ethanol to the *re* face of the nicotinamide ring of  $\text{NAD}^+$  as is drawn in the preceding diagrams.

*The stereospecificity of YADH is by no means unusual. As we consider biochemical reactions we shall find that nearly all enzymes that participate in chiral reactions are absolutely stereospecific.*

**a. Stereospecificity in the NADH-Dependent Dehydrogenases May Have Functional Significance**

In our exploration of metabolism, we shall encounter numerous species of NADH-dependent dehydrogenases that function to reduce (or oxidize) a great variety of substrates. These various dehydrogenases are more or less equally distributed between those transferring the *pro-R* (*re*-side) and the *pro-S* (*si*-side) hydrogens at C4 of NADH (also known as A-side and B-side transfers).

Yet, despite the fact that *si*- and *re*-side hydrogen transfers to or from the nicotinamide ring yield chemically identical products, a particular specificity of transfer is rigidly maintained within classes of dehydrogenases catalyzing similar reactions in different organisms. Indeed, dehydrogenases that catalyze reactions whose equilibrium constants with their natural substrates in the direction of reduction are  $<10^{-12} M$  almost always transfer the nicotinamide's *pro-R* hydrogen, whereas those with equilibrium constants  $>10^{-10} M$  generally transfer the *pro-S* hydrogen. Why has evolution so assiduously maintained this stereospecificity? Is it simply the result of a historical accident or does it serve some physiological function?

The NADH hydrogen transferred in a given enzymatic reaction is almost certainly that on the side of the nicotinamide ring facing the substrate. It was therefore widely assumed that the stereospecificity in any given class of dehydrogenases simply arose through a random choice made early in evolutionary history. Once made, this choice became “locked in,” because flipping a nicotinamide ring about its glycosidic bond in NADH would result, it was presumed, in its carboxamide group obstructing catalytically essential residues on the enzyme.

In an effort to shed light on this matter, Steven Benner mutated YADH in a manner that the X-ray structure of the closely similar enzyme horse **liver alcohol dehydrogenase (LADH)** suggests permits the *si* face of nicotinamide to bind to the enzyme without interfering with catalysis. The resulting mutant enzyme (Leu 182  $\rightarrow$  Ala) makes one stereochemical “mistake” every 850,000 turnovers versus one mistake every 7 billion turnovers for wild-type (unmutated) YADH. This 8000-fold decrease in stereospecificity indicates that at least some of the side chains responsible for YADH's stereospecificity are not essential for catalysis and hence strengthens the argument that stereospecificity in the dehydrogenases has functional significance.

**B. Geometric Specificity**

The stereospecificity of enzymes is not particularly surprising in light of the complementarity of an enzymatic binding site for its substrate. A substrate of the wrong chirality will

not fit into an enzymatic binding site for much the same reasons that you cannot fit your right hand into your left glove. *In addition to their stereospecificity, however, most enzymes are quite selective about the identities of the chemical groups on their substrates.* Indeed, such **geometric specificity** is a more stringent requirement than is stereospecificity. After all, your left glove will more or less fit left hands that have somewhat different sizes and shapes than your own.

*Enzymes vary considerably in their degree of geometric specificity.* A few enzymes are absolutely specific for only one compound. Most enzymes, however, catalyze the reactions of a small range of related compounds. For example, YADH catalyzes the oxidation of small primary and secondary alcohols to their corresponding aldehydes or ketones but none so efficiently as that of ethanol. Even methanol and isopropanol, which differ from ethanol only by the deletion or addition of a CH<sub>2</sub> group, are oxidized by YADH at rates that are, respectively, 25-fold and 2.5-fold slower than that for ethanol. Similarly, NADP<sup>+</sup>, which differs from NAD<sup>+</sup> only by the addition of a phosphoryl group at the 2' position of its adenosine ribose group (Fig. 13-2), does not bind to YADH. On the other hand, there are many enzymes that bind NADP<sup>+</sup> but not NAD<sup>+</sup>.

Some enzymes, particularly digestive enzymes, are so permissive in their ranges of acceptable substrates that their geometric specificities are more accurately described as preferences. Carboxypeptidase A, for example, catalyzes the hydrolysis of C-terminal peptide bonds to all residues except Arg, Lys, and Pro if the preceding residue is not Pro (Table 7-1). However, the rate of this enzymatic reaction varies with the identities of the residues in the vicinity of the C-terminus of the polypeptide (see Fig. 7-5). Some enzymes are not even very specific in the type of reaction they catalyze. Thus chymotrypsin, in addition to its ability to mediate peptide bond hydrolysis, also catalyzes ester bond hydrolysis.

Moreover, the acyl group acceptor in the chymotrypsin reaction need not be water; amino acids, alcohols, or ammonia can also act in this capacity. You should realize, however, that such permissiveness is much more the exception than the rule. Indeed, most intracellular enzymes function *in vivo* (in the cell) to catalyze a particular reaction on a specific substrate.

### 3 COENZYMES

Enzymes catalyze a wide variety of chemical reactions. Their functional groups can readily participate in acid–base reactions, form certain types of transient covalent

bonds, and take part in charge–charge interactions (Section 15-1). They are, however, less suitable for catalyzing oxidation–reduction reactions and many types of group-transfer processes. Although enzymes catalyze such reactions, they mainly do so in association with small molecule **cofactors**, which essentially act as the enzymes' "chemical teeth."

Cofactors may be metal ions, such as the Zn<sup>2+</sup> required for the catalytic activity of carboxypeptidase A, or organic molecules known as **coenzymes**, such as the NAD<sup>+</sup> in YADH (Section 13-2A). Some cofactors, for instance NAD<sup>+</sup>, are but transiently associated with a given enzyme molecule, so that, in effect, they function as cosubstrates. Other cofactors, known as **prosthetic groups**, are essentially permanently associated with their protein, often by covalent bonds. For example, the heme prosthetic group of hemoglobin is tightly bound to its protein through extensive hydrophobic and hydrogen bonding interactions together with a covalent bond between the heme Fe<sup>2+</sup> ion and His F8 (Sections 10-1A and 10-2B).

Coenzymes are chemically changed by the enzymatic reactions in which they participate. Thus, in order to complete the catalytic cycle, the coenzyme must be returned to its original state. For prosthetic groups, this can occur only in a separate phase of the enzymatic reaction sequence. For transiently bound coenzymes, such as NAD<sup>+</sup>, however, the regeneration reaction may be catalyzed by a different enzyme.

A catalytically active enzyme–cofactor complex is called a **holoenzyme** (Greek: *holos*, whole). The enzymatically inactive protein resulting from the removal of a holoenzyme's cofactor is referred to as an **apoenzyme** (Greek: *apo*, away); that is,

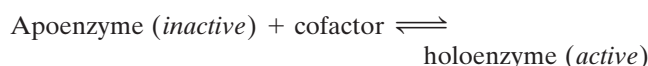

Table 13-1 lists the most common coenzymes together with the types of reactions in which they participate. We shall

**Table 13-1** The Common Coenzymes

Coenzyme	Reaction Mediated	Section Discussed
Biotin	Carboxylation	23-1A
Cobalamin (B <sub>12</sub> ) coenzymes	Alkylation	25-2E
Coenzyme A	Acyl transfer	21-2A
Flavin coenzymes	Oxidation– reduction	16-2C
Lipoic acid	Acyl transfer	21-2A
Nicotinamide coenzymes	Oxidation– reduction	13-2A
Pyridoxal phosphate	Amino group transfer	26-1A
Tetrahydrofolate	One-carbon group transfer	26-4D
Thiamine pyrophosphate	Aldehyde transfer	17-3B

**Figure 13-4** Structures of nicotinamide and nicotinic acid.

These vitamins form the redox-active components of the nicotinamide coenzymes  $\text{NAD}^+$  and  $\text{NADP}^+$  (compare with Fig. 13-2).

describe the structures of these substances and their reaction mechanisms in the appropriate sections of the textbook.

#### a. Many Vitamins Are Coenzyme Precursors

Many organisms are unable to synthesize certain portions of essential cofactors and therefore these substances must be present in the organism's diet; thus they are **vitamins**. In fact, many coenzymes were discovered as growth factors for microorganisms or substances that cure nutritional deficiency diseases in humans and animals. For example, the  $\text{NAD}^+$  component **nicotinamide** (alternatively known as **niacinamide**) or its carboxylic acid analog **nicotinic acid (niacin)** (Fig. 13-4), relieves the dietary deficiency disease in humans known as **pellagra**. Pellagra, which is characterized by diarrhea, dermatitis, and dementia, was endemic in the rural southern United States in the early twentieth century. Most animals, including humans, can synthesize nicotinamide from the amino acid tryptophan (Section 28-5A). The corn-rich diet that was prevalent in the rural South, however, contained little available nicotinamide or tryptophan from which to synthesize it. [Corn actually contains significant quantities of nicotinamide but in a form that requires treatment with base before it can be intestinally absorbed. The Mexican Indians, who are thought to have domesticated the corn plant, customarily soak corn meal in lime water—dilute  $\text{Ca}(\text{OH})_2$  solution—before using it to make their staple food, tortillas.]

**Table 13-2** Vitamins That Are Coenzyme Precursors

Vitamin	Coenzyme	Human Deficiency Disease
Biotin	Biocytin	<i>a</i>
Cobalamin ( $\text{B}_{12}$ )	Cobalamin ( $\text{B}_{12}$ ) coenzymes	Pernicious anemia
Folic acid	Tetrahydrofolate	Megaloblastic anemia
Nicotinamide	Nicotinamide coenzymes	Pellagra
Pantothenate	Coenzyme A	<i>a</i>
Pyridoxine ( $\text{B}_6$ )	Pyridoxal phosphate	<i>a</i>
Riboflavin ( $\text{B}_2$ )	Flavin coenzymes	<i>a</i>
Thiamine ( $\text{B}_1$ )	Thiamine pyrophosphate	Beriberi

<sup>a</sup>No specific name; deficiency in humans is rare or unobserved.

The vitamins in the human diet that are coenzyme precursors are all **water-soluble vitamins** (Table 13-2). In contrast, the **lipid-soluble vitamins**, such as **vitamins A and D**, are not components of coenzymes, although they are also required in trace amounts in the diets of many higher animals. The distant ancestors of humans probably had the ability to synthesize the various vitamins, as do many modern plants and microorganisms. Yet, since vitamins are normally available in the diets of higher animals, which all eat other organisms, or are synthesized by the bacteria that normally inhabit their digestive systems, it is believed that the then superfluous cellular machinery to synthesize them was lost through evolution.

## 4 CONTROL OF ENZYMATIC ACTIVITY

An organism must be able to control the catalytic activities of its component enzymes so that it can coordinate its numerous metabolic processes, respond to changes in its environment, and grow and differentiate, all in an orderly manner. There are two ways that this may occur:

**1. Control of enzyme availability:** *The amount of a given enzyme in a cell depends on both its rate of synthesis and its rate of degradation.* Each of these rates is directly controlled by the cell. For example, *E. coli* grown in the absence of the disaccharide lactose (Fig. 11-13) lack the enzymes to metabolize this sugar. Within minutes of their exposure to lactose, however, these bacteria commence synthesizing the enzymes required to utilize this nutrient (Section 31-1Aa). Similarly, the various tissues of a higher organism contain different sets of enzymes, although most of its cells contain identical genetic information. How cells achieve this control of enzyme synthesis is a major subject of Part V of this textbook. The degradation of proteins is discussed in Section 32-6.

**2. Control of enzyme activity:** *An enzyme's catalytic activity may be directly controlled through conformational or structural alterations.* The rate of an enzymatically catalyzed reaction is directly proportional to the concentration of its enzyme–substrate complex, which, in turn, varies with the enzyme and substrate concentrations and with the enzyme's substrate-binding affinity (Section 14-2A). The catalytic activity of an enzyme can therefore be controlled through the variation of its substrate-binding affinity. Recall that Sections 10-1 and 10-4 detail how hemoglobin's oxygen affinity is allosterically controlled by the binding of ligands such as  $\text{O}_2$ ,  $\text{CO}_2$ ,  $\text{H}^+$ , and BPG. These homotropic and heterotropic effects (ligand binding that, respectively, alters the binding affinity of the same or different ligands) result in cooperative (sigmoidal)  $\text{O}_2$ -binding curves such as those of Figs. 10-6 and 10-8. *An enzyme's substrate-binding affinity may likewise vary with the binding of small molecule effectors, thereby changing the enzyme's catalytic activity.* In this section we consider the allosteric control of enzymatic activity by examining one particular example: **aspartate transcarbamoylase (ATCase)** from *E. coli*. (The activities of many enzymes are similarly controlled through

**Figure 13-5** The rate of the reaction catalyzed by ATCase as a function of aspartate concentration. The rates were measured in the absence of allosteric effectors, in the presence of 0.4 mM CTP (inhibition), and in the presence of 2.0 mM ATP (activation). [After Kantrowitz, E.R., Pastra-Landis, S.C., and Lipscomb, W.N., *Trends Biochem. Sci.* 5, 125 (1980).] See the Animated Figures

their reversible covalent modification, usually by the phosphorylation of a Ser residue. We study this form of enzymatic control in Section 18-3.)

#### a. The Feedback Inhibition of ATCase Controls Pyrimidine Biosynthesis

Aspartate transcarbamoylase catalyzes the formation of *N*-carbamoylaspartate from carbamoyl phosphate and aspartate:

Arthur Pardee demonstrated that this reaction is the first step unique to the biosynthesis of pyrimidines (Section 28-2A), major components of nucleic acids.

The allosteric behavior of *E. coli* ATCase was investigated by John Gerhart and Howard Schachman, who demonstrated that this enzyme exhibits positive homotropic cooperative binding of both its substrates, namely, aspartate and carbamoyl phosphate. Moreover, ATCase is

heterotropically inhibited by **cytidine triphosphate (CTP)**, a pyrimidine nucleotide, and is heterotropically activated by **adenosine triphosphate (ATP)**, a purine nucleotide. CTP therefore decreases the enzyme's catalytic rate, whereas ATP increases it (Fig. 13-5).

CTP, a product of the pyrimidine biosynthesis pathway (Fig. 13-6), is a nucleic acid precursor (Section 5-4). Consequently, when rapid nucleic acid biosynthesis has depleted a cell's CTP pool, this effector dissociates from ATCase through mass action, thereby deinhibiting the enzyme and increasing the rate of CTP synthesis. Conversely, if the rate of CTP synthesis outstrips its rate of uptake, the resulting excess CTP inhibits ATCase, which, in turn, reduces the rate of CTP synthesis. *This is an example of feedback inhibition, a common mode of metabolic control in which the concentration of a biosynthetic pathway product controls the activity of an enzyme near the beginning of that pathway.*

The metabolic significance of the ATP activation of ATCase is that it tends to coordinate the rates of synthesis of purine and pyrimidine nucleotides for nucleic acid biosynthesis. For instance, if the ATP and CTP concentrations are out of balance with ATP in excess, ATCase is activated to synthesize pyrimidines until balance is achieved. (Note: The ATP concentration in cells is normally greater than the CTP concentration because ATP is in greater demand. Hence the ATP concentration required to activate ATCase is higher than the CTP concentration required to inhibit it by an equal amount.) Conversely, if CTP is in excess, the resulting CTP inhibition of ATCase permits purine biosynthesis to attain this balance.

**Figure 13-6** Schematic representation of the pyrimidine biosynthesis pathway. CTP, the end product of the pathway, inhibits ATCase, which catalyzes the pathway's first step.

### b. Allosteric Changes Alter ATCase's Substrate-Binding Sites

*E. coli* ATCase (309 kD) has the subunit composition  $c_6r_6$ , where  $c$  and  $r$  represent its catalytic and regulatory subunits (311 and 153 residues). The X-ray structure of ATCase (Fig. 13-7), determined by William Lipscomb, reveals that the catalytic subunits are arranged as two sets of trimers ( $c_3$ ) in complex with three sets of regulatory dimers ( $r_2$ ) to form a molecule with the rotational symmetry of a trigonal prism ( $D_3$  symmetry; Section 8-5B). Each regulatory dimer joins two catalytic subunits in different  $c_3$  trimers.

Dissociated catalytic trimers retain their catalytic activity, exhibit a noncooperative (hyperbolic) substrate saturation curve, have a maximum catalytic rate higher than that of intact enzyme, and are unaffected by the presence of either ATP or CTP. The isolated regulatory dimers bind these allosteric effectors but are devoid of enzymatic activity.

Evidently, the regulatory subunits allosterically reduce the activity of the catalytic subunits in the intact enzyme.

As allosteric theory predicts (Section 10-4), the activator ATP preferentially binds to ATCase's active (R or high substrate affinity) state, whereas the inhibitor CTP preferentially binds to the enzyme's inactive (T or low substrate affinity) state. Similarly, the unreactive bisubstrate analog ***N*-(phosphonacetyl)-L-aspartate (PALA)**

binds tightly to R-state but not to T-state ATCase (the use of unreactive substrate analogs is common in the study of enzyme mechanisms because they form stable complexes

**Figure 13-7** X-ray structure of ATCase from *E. coli*. The T-state enzyme in complex with CTP is viewed (a) along the protein's molecular 3-fold axis of symmetry and (b) along a molecular 2-fold axis of symmetry perpendicular to the view in Part a. The polypeptide chains are drawn in worm form embedded in their transparent molecular surface. The regulatory dimers (yellow) join the upper catalytic trimer (red) to the lower catalytic trimer (blue). CTP is drawn in space-filling form colored according to atom type (C green, O red, N blue, and P orange). (c) The R-state enzyme in complex with PALA viewed as in Part b. PALA is drawn in space-filling form. Note how the rotation of the regulatory dimers in the T  $\rightarrow$  R transition causes the catalytic trimers to move apart along the 3-fold axis. [Based on X-ray structures by William Lipscomb, Harvard University, PDBids 5AT1 and 8ATC.]  See Kinemage Exercise 11-1

**Figure 13-8** Comparison of the polypeptide backbones of the ATCase catalytic subunit in the T state (orange) and the R state (blue). The subunit consists of two domains, with the one on the left containing the carbamoyl phosphate binding site and that on the right forming the aspartic acid binding site. The T  $\rightarrow$  R

transition brings the two domains together such that their two bound substrates can react to form product. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.] X-ray structures by William Lipscomb, Harvard University.]

that are amenable to structural study rather than rapidly reacting to form products as do true substrates).

The X-ray structures of the T-state ATCase–CTP complex and the R-state ATCase–PALA complex reveal that the T  $\rightarrow$  R transition maintains the protein's  $D_3$  symmetry. The comparison of these two structures (Fig. 13-7) indicates that in the T  $\rightarrow$  R transition, the enzyme's catalytic trimers separate along the molecular 3-fold axis by  $\sim 11$  Å and reorient about this axis relative to each other by  $12^\circ$  such that these trimers assume a more nearly eclipsed configuration than is seen in Fig. 13-7a. In addition, the regulatory dimers rotate clockwise by  $15^\circ$  about their 2-fold axes and separate by  $\sim 4$  Å along the 3-fold axis. Such large quaternary shifts are reminiscent of those in hemoglobin (Section 10-2B).

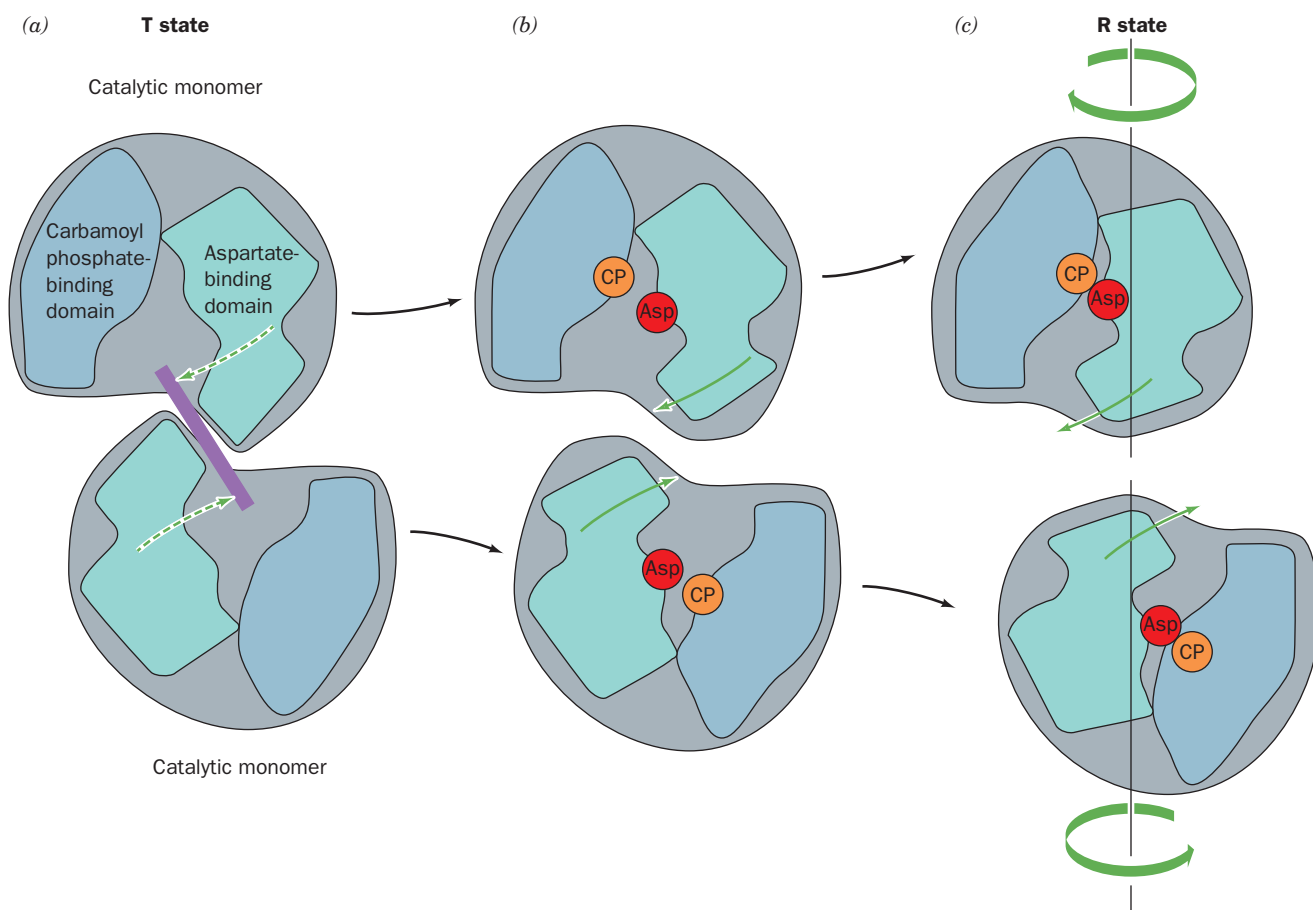

ATCase's substrates, carbamoyl phosphate and aspartate, each bind to a separate domain of the catalytic subunit (Fig. 13-8). The binding of PALA to the enzyme, which presumably mimics the binding of both substrates, induces active site closure in a manner that would bring them together so as to promote their reaction. The resulting atomic shifts, up to 8 Å for some residues (Fig. 13-8), trigger ATCase's T  $\rightarrow$  R quaternary shift. Indeed, *ATCases's tertiary and quaternary shifts are so tightly coupled through extensive*

*intersubunit contacts (see below) that they cannot occur independently* (Fig. 13-9). The binding of substrate to one catalytic subunit therefore increases the substrate-binding affinity and catalytic activity of the other catalytic subunits and hence accounts for the enzyme's positively cooperative substrate binding, much as occurs in hemoglobin (Section 10-2C). Thus, low levels of PALA actually activate ATCase by promoting its T  $\rightarrow$  R transition: ATCase has such high affinity for this unreactive bisubstrate analog that the binding of one molecule of PALA converts all six of its catalytic subunits to the R state. Evidently, *ATCase closely follows the symmetry model of allosterism* (Section 10-4B).

### c. The Structural Basis of Allosterism in ATCase

What are the interactions that stabilize the T and R states of ATCase and why must their interconversion be concerted? The region of the protein that undergoes the most profound conformational rearrangement with the T  $\rightarrow$  R transition is a flexible loop composed of residues 230 to 250 in the catalytic (*c*) subunit, the so-called 240s loop [the symmetry-related red and blue loops that lie side by side in the T state (center of Fig. 13-7b) but are vertically apposed in the R state (center of Fig. 13-7c)]. In the T state, each 240s loop forms two intersubunit hydrogen bonds

**Figure 13-9** Schematic diagram indicating the tertiary and quaternary conformational changes in two vertically interacting catalytic ATCase subunits. (a) In the absence of bound substrate the protein is held in the T state because the motions that bring together the two domains of each subunit (dashed arrows) are prevented by steric interference (purple bar) between the contacting aspartate binding domains. (b) The binding of carbamoyl phosphate (CP) followed by aspartic acid (Asp) to

their respective binding sites causes the subunits to move apart and rotate with respect to each other so as to permit the T  $\rightarrow$  R transition. (c) In the R state, the two domains of each subunit come together so as to promote the reaction of their bound substrates to form products. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.] See Kinemage Exercises 11-1 and 11-2

with the vertically opposite *c* subunit (Fig. 13-7b), together with an intrasubunit hydrogen bond. Domain closure as a consequence of substrate binding (Figs. 13-8 and 13-9) ruptures these hydrogen bonds and replaces them, in the R state, with new intrachain hydrogen bonds. The consequent reorientation of the 240s loop is thought to be largely responsible for the quaternary shift to the R state (see below). Since the Glu 239 carboxyl group is the acceptor in all of the above T-state interchain and R-state intrachain hydrogen bonds, this hypothesis is corroborated by the observation that the mutation of Glu 239 to Gln converts ATCase to an enzyme that is devoid of both homotropic and heterotropic effects and that has a quaternary structure midway between those of the R and T states.

What is the structural basis for heterotropic effects in ATCase? Both the inhibitor CTP and the activator ATP bind to the same site on the outer edge of the regulatory (*r*) subunit, about 60 Å away from the nearest catalytic site. CTP binds preferentially to the T state, increasing its stabil-

ity, while ATP binds preferentially to the R state, increasing its stability. The binding of these effectors to their less favored states also has structural consequences. When CTP binds to R-state ATCase, it reorients several residues at the nucleotide binding site, which induces a contraction in the length of the regulatory dimer ( $r_2$ ). This distortion, through the interactions of residues at the *r-c* interface, causes the catalytic trimers ( $c_3$ ) to come together by 0.5 Å (become more T-like, that is, less active, which presumably destabilizes the R state). This, in turn, reorients key residues in the enzyme's active sites, thereby decreasing the enzyme's catalytic activity. ATP has essentially opposite effects when binding to the T-state enzyme: It causes the catalytic trimers to move apart by 0.4 Å (become more R-like, that is, more active, which presumably destabilizes the T state), thereby reorienting key residues in the enzyme's active sites so as to increase the enzyme's catalytic activity. The binding of CTP to T-state ATCase does not further compress the catalytic trimers but, nevertheless, perturbs active

site residues in a way that further stabilizes the T state. Although the X-ray structure of ATP complexed to R-state ATCase has not yet been reported, it is expected that ATP binding perturbs the R state in a manner analogous but opposite to the binding of CTP to T-state ATCase.

#### d. Allosteric Transitions in Other Enzymes Resemble Those of Hemoglobin and ATCase

Allosteric enzymes are widely distributed in nature and tend to occupy key regulatory positions in metabolic pathways. Three such enzymes, in addition to hemoglobin and ATCase, have had their X-ray structures determined in both their R and T states: **phosphofructokinase** (Sections 17-2C and 17-4F), **fructose-1,6-bisphosphatase** (Section 23-1Ah), and **glycogen phosphorylase** (Section 18-1A). In all five proteins, quaternary changes, through which binding and catalytic effects are communicated among active sites, are concerted and preserve the symmetry of the protein. This is because each of these proteins has two sets of alternative contacts, which are stabilized largely by hydrogen bonds that mostly involve side chains of opposite charge. In all five proteins, the quaternary shifts are primarily rotations of subunits relative to one another with only small translations. Secondary structures are largely preserved in T → R transitions, which is probably important for mechanically transmitting heterotropic effects over the tens of Ångströms necessary in these proteins. The ubiquity of these structural features among allosteric proteins of known structures suggests that the control mechanisms of other allosteric enzymes, by and large, follow this model.

## 5 A PRIMER OF ENZYME NOMENCLATURE

Enzymes, as we have seen throughout the text so far, are commonly named by appending the suffix *-ase* to the name of the enzyme's substrate or to a phrase describing the enzyme's catalytic action. Thus urease catalyzes the hydrolysis of urea and alcohol dehydrogenase catalyzes the oxidation of alcohols to their corresponding aldehydes. Since there were at first no systematic rules for naming enzymes, this practice occasionally resulted in two different names being used for the same enzyme or, conversely, in the same name being used for two different enzymes. Moreover, many enzymes, such as catalase, which mediates the dismutation of H<sub>2</sub>O<sub>2</sub> to H<sub>2</sub>O and O<sub>2</sub>, were given names that provide no clue as to their function; even such atrocities as "old yellow enzyme" had crept into use. In an effort to eliminate this confusion and to provide rules for rationally naming the rapidly growing number of newly discovered

**Table 13-3 Enzyme Classification According to Reaction Type**

Classification	Type of Reaction Catalyzed
1. Oxidoreductases	Oxidation–reduction reactions
2. Transferases	Transfer of functional groups
3. Hydrolases	Hydrolysis reactions
4. Lyases	Group elimination to form double bonds
5. Isomerases	Isomerization
6. Ligases	Bond formation coupled with ATP hydrolysis

enzymes, a scheme for the systematic functional classification and nomenclature of enzymes was adopted by the International Union of Biochemistry and Molecular Biology (IUBMB).

*Enzymes are classified and named according to the nature of the chemical reactions they catalyze.* There are six major classes of reactions that enzymes catalyze (Table 13-3), as well as subclasses and sub-subclasses within these classes. Each enzyme is assigned two names and a four-number classification. Its **accepted** or **recommended name** is convenient for everyday use and is often an enzyme's previously used name. Its **systematic name** is used when ambiguity must be minimized; it is the name of its substrate(s) followed by a word ending in *-ase* specifying the type of reaction the enzyme catalyzes according to its major group classification. For example, the Enzyme Nomenclature Database (available from <http://www.brenda-enzymes.info/> and from <http://www.chem.qmul.ac.uk/iubmb/enzyme/>) indicates that the enzyme whose alternative name is lysozyme (Section 11-3Ba) has the systematic name peptidoglycan *N*-acetylmuramoylhydrolase and the Classification Number EC 3.2.1.17. Here "EC" stands for *Enzyme Commission*, the first number (3) indicates the enzyme's major class (hydrolases; Table 13-3), the second number (2) denotes its subclass (glycosylases), the third number (1) designates its sub-subclass (enzymes hydrolyzing *O*- and *S*-glycosyl compounds), and the fourth number (17) is the enzyme's arbitrarily assigned serial number in its sub-subclass. As another example, the enzyme with the recommended name alcohol dehydrogenase has the systematic name alcohol:NAD<sup>+</sup> oxidoreductase and the classification number EC 1.1.1.1. In this text, as in general biochemical terminology, we shall most often use the recommended names of enzymes but when ambiguity must be minimized, we shall refer to an enzyme's systematic name.

## CHAPTER SUMMARY

**2 Substrate Specificity** Enzymes specifically bind their substrates through geometrically and physically complementary interactions. This permits enzymes to be absolutely stereospecific, both in binding substrates and in catalyzing reactions. Enzymes vary in the more stringent requirement of geometric specificity. Some are highly specific for the identity of their substrates, whereas others can bind a wide range of substrates and catalyze a variety of related types of reactions.

**3 Coenzymes** Enzymatic reactions involving oxidation–reduction reactions and many types of group-transfer processes are mediated by coenzymes. Many vitamins are coenzyme precursors.

**4 Control of Enzyme Activity** Enzymatic activity may be regulated by the allosteric alteration of substrate-binding affinity. For example, the rate of the reaction catalyzed by *E. coli*

ATCase is subject to positive homotropic control by substrates, heterotropic inhibition by CTP, and heterotropic activation by ATP. ATCase has the subunit composition  $c_6r_6$ . Its isolated catalytic trimers are catalytically active but not subject to allosteric control. The regulatory dimers bind ATP and CTP. Substrate binding induces a tertiary conformational shift in the catalytic subunits, which increases the subunit's substrate-binding affinity and catalytic efficiency. This tertiary shift is strongly coupled to ATCase's large quaternary T  $\rightarrow$  R conformational shift, thereby accounting for the enzyme's allosteric properties. Other allosteric enzymes appear to operate in a similar manner.

**5 A Primer of Enzyme Nomenclature** Enzymes are classified according to their recommended name, their systematic name, and their EC classification number, which is indicative of the type of reaction catalyzed by the enzyme.

*Kinetics is the study of the rates at which chemical reactions occur. A major purpose of such a study is to gain an understanding of a reaction mechanism, that is, a detailed description of the various steps in a reaction process and the sequence with which they occur. Thermodynamics, as we saw in Chapter 3, tells us whether a given process can occur spontaneously but provides little indication as to the nature or even the existence of its component steps. In contrast, the rate of a reaction and how this rate changes in response to different conditions is intimately related to the path followed by the reaction and is therefore indicative of its reaction mechanism.*

In this chapter, we take up the study of **enzyme kinetics**, a subject that is of enormous practical importance in biochemistry because:

1. It is through kinetic studies that the binding affinities of substrates and inhibitors to an enzyme can be determined and that the maximum catalytic rate of an enzyme can be established.

2. By observing how the rate of an enzymatic reaction varies with the reaction conditions and combining this information with that obtained from chemical and structural studies of the enzyme, the enzyme's catalytic mechanism may be elucidated.

3. Most enzymes, as we shall see in later chapters, function as members of metabolic pathways. The study of the kinetics of an enzymatic reaction leads to an understanding of that enzyme's role in an overall metabolic process.

4. Under the proper conditions, the rate of an enzymatically catalyzed reaction is proportional to the amount of the enzyme present, and therefore most enzyme assays (measurements of the amount of enzyme present) are based on kinetic studies of the enzyme. Measurements of enzymatically catalyzed reaction rates are therefore among the most commonly employed procedures in biochemical and clinical analyses.

We begin our consideration of enzyme kinetics by reviewing chemical kinetics because enzyme kinetics is based on this formalism. Following that, we derive the basic equations of enzyme kinetics, describe the effects of inhibitors on enzymes, and consider how the rates of enzymatic reactions vary with pH. We end by outlining the kinetics of complex enzymatic reactions.

Kinetics is, by and large, a mathematical subject. Although the derivations of kinetic equations are occasionally rather detailed, the level of mathematical skills it requires should not challenge anyone who has studied elementary calculus. Nevertheless, to prevent mathematical detail from obscuring the underlying enzymological principles, the derivations of all but the most important kinetic equations have been collected in the appendix to this chapter. Those who wish to cultivate a deeper understanding of enzyme kinetics are urged to consult this appendix.

## 1 CHEMICAL KINETICS

Enzyme kinetics is a branch of chemical kinetics and, as such, shares much of the same formalism. In this section we

shall therefore review the principles of chemical kinetics so that, in later sections, we can apply them to enzymatically catalyzed reactions.

### A. Elementary Reactions

A reaction of overall stoichiometry

may actually occur through a sequence of **elementary reactions** (simple molecular processes) such as

Here A represents reactants, P products, and  $I_1$  and  $I_2$  symbolize **intermediates** in the reaction. *The characterization of the elementary reactions comprising an overall reaction process constitutes its mechanistic description.*

#### a. Rate Equations

At constant temperature, elementary reaction rates vary with reactant concentration in a simple manner. Consider the general elementary reaction:

*The rate of this process is proportional to the frequency with which the reacting molecules simultaneously come together, that is, to the products of the concentrations of the reactants.* This is expressed by the following **rate equation**

$$\text{Rate} = k[A]^a[B]^b \cdots [Z]^z \quad [14.1]$$

where  $k$  is a proportionality constant known as a **rate constant**. The **order** of a reaction is defined as  $(a + b + \cdots + z)$ , the sum of the exponents in the rate equation. *For an elementary reaction, the order corresponds to the **molecularity** of the reaction, the number of molecules that must simultaneously collide in the elementary reaction.* Thus the elementary reaction  $A \rightarrow P$  is an example of a **first-order** or **unimolecular** reaction, whereas the elementary reactions  $2A \rightarrow P$  and  $A + B \rightarrow P$  are examples of **second-order** or **bimolecular** reactions. Unimolecular and bimolecular reactions are common. **Termolecular** reactions are unusual and fourth- and higher order elementary reactions are unknown. This is because the simultaneous collision of three molecules is a rare event; that of four or more molecules essentially never occurs.

### B. Rates of Reactions

We can experimentally determine the order of a reaction by measuring  $[A]$  or  $[P]$  as a function of time; that is,

$$v = -\frac{d[A]}{dt} = \frac{d[P]}{dt} \quad [14.2]$$

where  $v$  is the instantaneous rate or **velocity** of the reaction. For the first-order reaction  $A \rightarrow P$ :

$$v = -\frac{d[A]}{dt} = k[A] \quad [14.3a]$$

For second-order reactions such as  $2A \rightarrow P$ :

$$v = -\frac{d[A]}{dt} = k[A]^2 \quad [14.3b]$$

whereas for  $A + B \rightarrow P$ , a second-order reaction that is first order in  $[A]$  and first order in  $[B]$ ,

$$v = -\frac{d[A]}{dt} = -\frac{d[B]}{dt} = k[A][B] \quad [14.3c]$$

The rate constants of first- and second-order reactions must have different units. In terms of units,  $v$  in Eq. [14.3a] is expressed as  $M \cdot s^{-1} = kM$ . Therefore,  $k$  must have units of reciprocal seconds ( $s^{-1}$ ) in order for Eq. [14.3a] to balance. Similarly, for second-order reactions,  $M \cdot s^{-1} = kM^2$ , so that  $k$  has the units  $M^{-1} s^{-1}$ .

The order of a specific reaction can be determined by measuring the reactant or product concentrations as a function of time and comparing the fit of these data to equations describing this behavior for reactions of various orders. To do this we must first derive these equations.

#### a. First-Order Rate Equation

The equation for  $[A]$  as a function of time for a first-order reaction,  $A \rightarrow P$ , is obtained by rearranging Eq. [14.3a]

$$\frac{d[A]}{[A]} \equiv d \ln [A] = -k dt$$

and integrating it from  $[A]_0$ , the initial concentration of A, to  $[A]$ , the concentration of A at time  $t$ :

$$\int_{[A]_0}^{[A]} d \ln [A] = -k \int_0^t dt$$

This results in

$$\ln [A] = \ln [A]_0 - kt \quad [14.4a]$$

or, by taking the antilogs of both sides,

$$[A] = [A]_0 e^{-kt} \quad [14.4b]$$

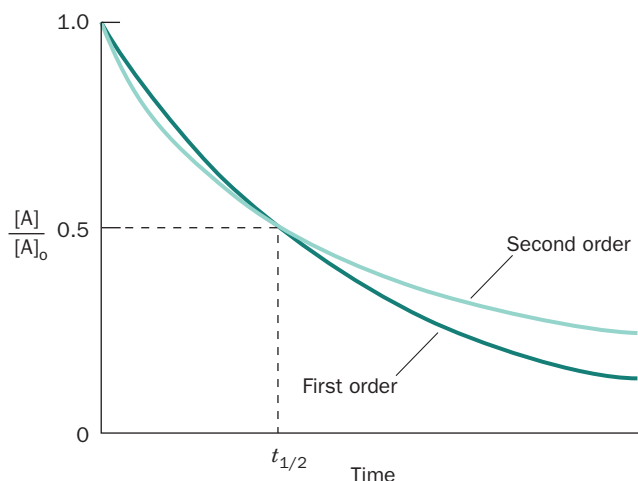

Equation [14.4a] is a linear equation in terms of the

**Figure 14-1** Plot of  $\ln[A]$  versus time for a first-order reaction. This illustrates the graphical determination of the rate constant  $k$  using Eq. [14.4a].

variables  $\ln[A]$  and  $t$  as is diagrammed in Fig. 14-1. Therefore, if a reaction is first order, a plot of  $\ln[A]$  versus  $t$  will yield a straight line whose slope is  $-k$ , the negative of the first-order rate constant, and whose intercept on the  $\ln[A]$  axis is  $\ln[A]_0$ .

Substances that are inherently unstable, such as radioactive nuclei, decompose through first-order reactions (first-order processes are not just confined to chemical reactions). One of the hallmarks of a first-order reaction is that *the time for half of the reactant initially present to decompose, its half-time or half-life,  $t_{1/2}$ , is a constant and hence independent of the initial concentration of the reactant.* This is easily demonstrated by substituting the relationship  $[A] = [A]_0/2$  when  $t = t_{1/2}$  into Eq. [14.4a] and rearranging:

**Figure 14-2** Comparison of the progress curves for first- and second-order reactions that have the same value of  $t_{1/2}$ . [After Tinoco, I., Jr., Sauer, K., and Wang, J.C., *Physical Chemistry. Principles and Applications in Biological Sciences* (2nd ed.), p. 291, Prentice-Hall (1985).]

$$\ln\left(\frac{[A]_0/2}{[A]_0}\right) = -kt_{1/2}$$

Thus

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{k} \quad [14.5]$$

In order to appreciate the course of a first-order reaction, let us consider the decomposition of  $^{32}\text{P}$ , a radioactive isotope that is widely used in biochemical research. It has a half-life of 14 days. Thus, after 2 weeks, one-half of the  $^{32}\text{P}$  initially present in a given sample will have decomposed; after another 2 weeks, one-half of the remainder, or three-quarters of the original sample, will have decomposed; etc. The long-term storage of waste  $^{32}\text{P}$  therefore presents little problem, since after 1 year (26 half-lives), only 1 part in  $2^{26} = 67$  million of the original sample will remain. How much will remain after 2 years? In contrast,  $^{14}\text{C}$ , another commonly employed radioactive tracer, has a half-life of 5715 years. Only a small fraction of a given quantity of  $^{14}\text{C}$  will decompose over the course of a human lifetime.

### b. Second-Order Rate Equation for One Reactant

In a second-order reaction with one type of reactant,  $2A \rightarrow P$ , the variation of  $[A]$  with time is quite different from that in a first-order reaction. Rearranging Eq. [14.3b] and integrating it over the same limits used for the first-order reaction yields

$$\int_{[A]_0}^{[A]} \frac{d[A]}{[A]^2} = k \int_0^t dt$$

so that

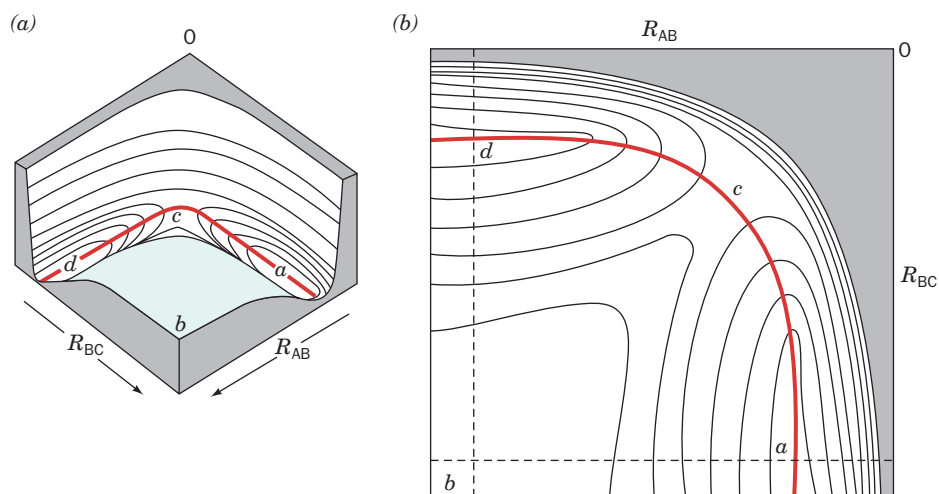

$$\frac{1}{[A]} = \frac{1}{[A]_0} + kt \quad [14.6]$$

Equation [14.6] is a linear equation in terms of the variables  $1/[A]$  and  $t$ . Consequently, Eqs. [14.4a] and [14.6] may be used to distinguish a first-order from a second-order reaction by plotting  $\ln[A]$  versus  $t$  and  $1/[A]$  versus  $t$  and observing which, if any, of these plots is a straight line.

Figure 14-2 compares the different shapes of the progress curves describing the disappearance of  $A$  in first- and second-order reactions having the same half-times. Note that before the first half-time, the second-order progress curve descends more steeply than the first-order curve, but after this time the first-order progress curve is the more rapidly decreasing of the two. The half-time for a second-order reaction is expressed  $t_{1/2} = 1/(k[A]_0)$  and therefore, in contrast to a first-order reaction, is dependent on the initial reactant concentration.

### C. Transition State Theory

The goal of kinetic theory is to describe reaction rates in terms of the physical properties of the reacting molecules. A theoretical framework for doing so, which explicitly considers the structures of the reacting molecules and how they collide, was developed in the 1930s, principally by Henry Eyring. This view of reaction processes, known as **transition state theory** or **absolute rate theory**, is the foundation of much of modern kinetics and has provided an

**Figure 14-3** Potential energy of the colinear  $\text{H} + \text{H}_2$  system as a function of its internuclear distances,  $R_{\text{AB}}$  and  $R_{\text{BC}}$ . The reaction is represented as (a) a perspective drawing and (b) the corresponding contour diagram. The points  $a$  and  $d$  are approaching potential energy minima,  $b$  is approaching a maximum, and  $c$  is a saddle point. [After Frost, A.A. and Pearson, R.G., *Kinetics and Mechanism* (2nd ed.), p. 80, Wiley (1961).]

extraordinarily productive framework for understanding how enzymes catalyze reactions.

### a. The Transition State

Consider a bimolecular elementary reaction involving three atoms A, B, and C:

Clearly atom C must approach the diatomic molecule A—B so that, at some point in the reaction, a high-energy (unstable) complex represented as  $\text{A}\cdots\text{B}\cdots\text{C}$  exists in which the A—B covalent bond is in the process of breaking while the B—C bond is in the process of forming.

Let us consider the simplest example of this reaction: that of a hydrogen atom with diatomic hydrogen ( $\text{H}_2$ ) to yield a new  $\text{H}_2$  molecule and a different hydrogen atom:

The potential energy of this triatomic system as a function of the relative positions of its component atoms is plotted in Fig. 14-3. Its shape is of two long and deep valleys parallel to the coordinate axes with sheer walls rising toward the axes and less steep ones rising toward a plateau where both coordinates are large (the region of point  $b$ ). The two val-

leys are joined by a pass or saddle near the origin of the diagram (point  $c$ ). The minimum energy configuration is that of an  $\text{H}_2$  molecule and an isolated atom, that is, with one coordinate large and the other at the  $\text{H}_2$  covalent bond distance [near points  $a$  (the reactants) and  $d$  (the products)]. During a collision, the reactants generally approach one another with little deviation from the minimum energy reaction pathway (line  $a-c-d$ ) because other trajectories would require much greater energy. As the atom and molecule come together, they increasingly repel one another (have increasing potential energy) and therefore usually fly apart. *If, however, the system has sufficient kinetic energy to continue its coalescence, it will cause the covalent bond of the  $\text{H}_2$  molecule to weaken until ultimately, if the system reaches the saddle point (point  $c$ ), there is an equal probability that either the reaction will occur or that the system will decompose back to its reactants.* Therefore, at this saddle point, the system is said to be at its **transition state** and hence to be an **activated complex**. Moreover, since the concentration of the activated complex is small, *the decomposition of the activated complex is postulated to be the rate-determining process of this reaction.*

*The minimum free energy pathway of a reaction is known as its **reaction coordinate**.* Figure 14-4a, which is

**Figure 14-4** Transition state diagrams. (a) For the  $\text{H} + \text{H}_2$  reaction. This is a section taken along the  $a-c-d$  line in

Fig. 14-3. (b) For a spontaneous reaction, that is, one in which the free energy decreases.

called a **transition state diagram** or a **reaction coordinate diagram**, shows the free energy of the H + H<sub>2</sub> system along the reaction coordinate (line *a—c—d* in Fig. 14-3). It can be seen that the transition state is the point of highest free energy on the reaction coordinate. If the atoms in the triatomic system are of different types, as is diagrammed in Fig. 14-4*b*, the transition state diagram is no longer symmetrical because there is a free energy difference between reactants and products.

### b. Thermodynamics of the Transition State

The realization that the attainment of the transition state is the central requirement in any reaction process led to a detailed understanding of reaction mechanisms. For example, consider a bimolecular reaction that proceeds along the following pathway:

where X<sup>‡</sup> represents the activated complex. Therefore, considering the preceding discussion,

$$\frac{d[P]}{dt} = k[A][B] = k'[X^\ddagger] \quad [14.7]$$

where *k* is the ordinary rate constant of the elementary reaction and *k'* is the rate constant for the decomposition of X<sup>‡</sup> to products.

In contrast to stable molecules, such as A and P, which occur at energy minima, the activated complex occurs at an energy maximum and is therefore only metastable (like a ball balanced on a pin). Transition state theory nevertheless assumes that X<sup>‡</sup> is in rapid equilibrium with the reactants; that is,

$$K^\ddagger = \frac{X^\ddagger}{[A][B]} \quad [14.8]$$

where *K*<sup>‡</sup> is an equilibrium constant. *This central assumption of transition state theory permits the powerful formalism of thermodynamics to be applied to the theory of reaction rates.*

If *K*<sup>‡</sup> is an equilibrium constant it can be expressed as

$$-RT \ln K^\ddagger = \Delta G^\ddagger \quad [14.9]$$

where Δ*G*<sup>‡</sup> is the Gibbs free energy of the activated complex less that of the reactants (Fig. 14-4*b*), *T* is the absolute temperature, and *R* (= 8.3145 J · K<sup>-1</sup> mol<sup>-1</sup>) is the gas constant (this relationship between equilibrium constants and free energy is derived in Section 3-4A). Then combining Eqs. [14.7] through [14.9] yields

$$\frac{d[P]}{dt} = k' e^{-\Delta G^\ddagger/RT} [A][B] \quad [14.10]$$

This equation indicates that the rate of a reaction depends not only on the concentrations of its reactants but also decreases exponentially with Δ*G*<sup>‡</sup>. *Thus, the larger the difference between the free energy of the transition state and that of the reactants, that is, the less stable the transition state, the slower the reaction proceeds.*

In order to continue, we must now evaluate *k'*, the rate constant for passage of the activated complex over the maximum in the transition state diagram (sometimes referred to as the **activation barrier** or the **kinetic barrier** of the reaction). This transition state model permits us to do so (although the following derivation is by no means rigorous). The activated complex is held together by a bond that is associated with the reaction coordinate and that is assumed to be so weak that it flies apart during its first vibrational excursion. Therefore, *k'* is expressed

$$k' = \kappa \nu \quad [14.11]$$

where *ν* is the vibrational frequency of the bond that breaks as the activated complex decomposes to products and *κ*, the **transmission coefficient**, is the probability that the breakdown of the activated complex, X<sup>‡</sup>, will be in the direction of product formation rather than back to reactants. For most spontaneous reactions in solution, *κ* is between 0.5 and 1.0; for the colinear H + H<sub>2</sub> reaction, we saw that it is 0.5.

We have nearly finished our job of evaluating *k'*. All that remains is to determine the value of *ν*. Planck's law states that

$$\nu = \varepsilon/h \quad [14.12]$$

where, in this case, *ε* is the average energy of the vibration that leads to the decomposition of X<sup>‡</sup>, and *h* (= 6.6261 × 10<sup>-34</sup> J · s) is Planck's constant. Statistical mechanics tells us that at temperature *T*, the classical energy of an oscillator is

$$\varepsilon = k_B T \quad [14.13]$$

where *k<sub>B</sub>* (= 1.3807 × 10<sup>-23</sup> J · K<sup>-1</sup>) is a constant of nature known as the **Boltzmann constant** and *k<sub>B</sub>T* is essentially the available thermal energy. Combining Eqs. [14.11] through [14.13]

$$k' = \frac{\kappa k_B T}{h} \quad [14.14]$$

Then assuming, as is done for most reactions, that *κ* = 1 (*κ* can rarely be calculated with any confidence), the combination of Eqs. [14.7] and [14.10] with [14.14] yields the expression for the rate constant *k* of our elementary reaction:

$$k = \frac{k_B T}{h} e^{-\Delta G^\ddagger/RT} \quad [14.15]$$

This equation indicates that *the rate of reaction decreases as its free energy of activation, Δ*G*<sup>‡</sup>, increases.* Conversely, as the temperature rises, so that there is increased thermal energy available to drive the reacting complex over the activation barrier, the reaction speeds up. (Of course, enzymes, being proteins, are subject to thermal denaturation, so that the rate of an enzymatically catalyzed reaction falls precipitously with increasing temperature once the enzyme's denaturation temperature has been surpassed.) Keep in mind, however, that transition state theory is an ideal model; real systems behave in a more complicated, although qualitatively similar, manner.

**Figure 14-5** Transition state diagram for the two-step overall reaction  $A \rightarrow I \rightarrow P$ . For  $k_1 < k_2$  (green curve), the first step is rate determining, whereas if  $k_1 > k_2$  (red curve), the second step is rate determining.

### c. Multistep Reactions Have Rate-Determining Steps

Since chemical reactions commonly consist of several elementary reaction steps, let us consider how transition state theory treats such reactions. For a multistep reaction such as

where I is an intermediate of the reaction, there is an activated complex for each elementary reaction step; the shape of the transition state diagram for such a reaction reflects the relative rates of the elementary reactions involved. For this reaction, if the first reaction step is slower than the second reaction step ( $k_1 < k_2$ ), then the activation barrier of the first step must be higher than that of the second step, and conversely if the second reaction step is the slower (Fig. 14-5). Since the rate of formation of product P can only be as fast as the slowest elementary reaction, *if one reaction step of an overall reaction is much slower than the other, the slow step acts as a “bottleneck” and is therefore said to be the rate-determining step of the reaction.*

### d. Catalysis Reduces $\Delta G^\ddagger$

Biochemistry is, of course, mainly concerned with enzyme-catalyzed reactions. *Catalysts act by lowering the activation barrier for the reaction being catalyzed* (Fig. 14-6). If a catalyst lowers the activation barrier of a reaction by  $\Delta\Delta G_{\text{cat}}^\ddagger$  then, according to Eq. [14.15], the rate of the reaction is enhanced by the factor  $e^{\Delta\Delta G_{\text{cat}}^\ddagger/RT}$ . Thus, a 10-fold rate enhancement requires that  $\Delta\Delta G_{\text{cat}}^\ddagger = 5.71 \text{ kJ} \cdot \text{mol}^{-1}$ , less than half the energy of a typical hydrogen bond; a millionfold rate acceleration occurs when  $\Delta\Delta G_{\text{cat}}^\ddagger = 34.25 \text{ kJ} \cdot \text{mol}^{-1}$ , a small fraction of the energy of most covalent bonds. The rate enhancement is therefore a sensitive function of  $\Delta\Delta G_{\text{cat}}^\ddagger$ .

Note that the kinetic barrier is lowered by the same amount for both the forward and the reverse reactions

**Figure 14-6** The effect of a catalyst on the transition state diagram of a reaction. Here  $\Delta\Delta G_{\text{cat}}^\ddagger = \Delta G_{\text{uncat}}^\ddagger - \Delta G_{\text{cat}}^\ddagger$ .

(Fig. 14-6). Consequently, a catalyst equally accelerates the forward and the reverse reactions so that the equilibrium constant for the reaction remains unchanged. The chemical mechanisms through which enzymes lower the activation barriers of reactions are the subject of Section 15-1. There we shall see that the most potent such mechanism often involves the enzymatic binding of the transition state of the catalyzed reaction in preference to the substrate.

## 2 ENZYME KINETICS

 **See Guided Exploration 12: Michaelis–Menten kinetics, Lineweaver–Burk plots, and enzyme inhibition** The chemical reactions of life are mediated by enzymes. These remarkable catalysts, as we saw in Chapter 13, are individually highly specific for particular reactions. Yet collectively they are extremely versatile in that the many thousand enzymes now known carry out such diverse reactions as hydrolysis, polymerization, functional group transfer, oxidation–reduction, dehydration, and isomerization, to mention only the most common classes of enzymatically mediated reactions. Enzymes are not passive surfaces on which reactions take place but, rather, are complex molecular machines that operate through a great diversity of mechanisms. For instance, some enzymes act on only a single substrate molecule; others act on two or more different substrate molecules whose order of binding may or may not be obligatory. Some enzymes form covalently bound intermediate complexes with their substrates; others do not.

*Kinetic measurements of enzymatically catalyzed reactions are among the most powerful techniques for elucidating the catalytic mechanisms of enzymes.* The remainder of this chapter is therefore largely concerned with the development of the kinetic tools that are most useful in the determination of enzymatic mechanisms. We begin, in this section, with a presentation of the basic theory of enzyme kinetics.

### A. The Michaelis–Menten Equation

The study of enzyme kinetics began in 1902 when Adrian Brown reported an investigation of the rate of hydrolysis of sucrose as catalyzed by the yeast enzyme **invertase** (now known as  **$\beta$ -fructofuranosidase**):

Brown demonstrated that when the sucrose concentration is much higher than that of the enzyme, the reaction rate becomes independent of the sucrose concentration; that is, the rate is **zero order** with respect to sucrose. He therefore proposed that the overall reaction is composed of two elementary reactions in which the substrate forms a complex with the enzyme that subsequently decomposes to products and enzyme:

Here E, S, ES, and P symbolize the enzyme, substrate, **enzyme–substrate complex**, and products, respectively (for enzymes composed of multiple identical subunits, E refers to active sites rather than enzyme molecules). According to this model, *when the substrate concentration becomes high enough to entirely convert the enzyme to the ES form, the second step of the reaction becomes rate limiting and the overall reaction rate becomes insensitive to further increases in substrate concentration.*

The general expression for the **velocity** (rate) of this reaction is

$$v = \frac{d[\text{P}]}{dt} = k_2[\text{ES}] \quad [14.16]$$

The overall rate of production of ES is the difference between the rates of the elementary reactions leading to its appearance and those resulting in its disappearance:

$$\frac{d[\text{ES}]}{dt} = k_1[\text{E}][\text{S}] - k_{-1}[\text{ES}] - k_2[\text{ES}] \quad [14.17]$$

This equation cannot be explicitly integrated, however, without simplifying assumptions. Two possibilities are

**1. Assumption of equilibrium:** In 1913, Leonor Michaelis and Maud Menten, building on earlier work by Victor Henri, assumed that  $k_{-1} \gg k_2$ , so that the first step of the reaction achieves equilibrium.

$$K_S = \frac{k_{-1}}{k_1} = \frac{[\text{E}][\text{S}]}{[\text{ES}]} \quad [14.18]$$

Here  $K_S$  is the dissociation constant of the first step in the enzymatic reaction. With this assumption, Eq. [14.17] can be integrated. Although this assumption is not often correct, in recognition of the importance of this pioneering work, the noncovalently bound enzyme–substrate complex ES is known as the **Michaelis complex**.

**2. Assumption of steady state:** Figure 14-7 illustrates the progress curves of the various participants in the preceding reaction model under the physiologically common

**Figure 14-7** Progress curves for the components of a simple Michaelis–Menten reaction. Note that with the exception of the transient phase of the reaction, which occurs before the shaded block, the slopes of the progress curves for [E] and [ES] are essentially zero so long as  $[\text{S}] \gg [\text{E}]_T$  (within the shaded block). [After Segel, I.H., *Enzyme Kinetics*, p. 27, Wiley (1975).]  See the Animated Figures

condition that substrate is in great excess over enzyme. With the exception of the initial stage of the reaction, the so-called **transient phase**, which is usually over within milliseconds of mixing the enzyme and substrate, [ES] remains approximately constant until the substrate is nearly exhausted. Hence, the rate of synthesis of ES must equal its rate of consumption over most of the course of the reaction; that is, [ES] maintains a **steady state**. One can therefore assume with a reasonable degree of accuracy that [ES] is constant; that is,

$$\frac{d[\text{ES}]}{dt} = 0 \quad [14.19]$$

This so-called **steady-state assumption** was first proposed in 1925 by George E. Briggs and John B.S. Haldane.

In order to be of use, kinetic expressions for overall reactions must be formulated in terms of experimentally measurable quantities. The quantities [ES] and [E] are not, in general, directly measurable but the total enzyme concentration

$$[\text{E}]_T = [\text{E}] + [\text{ES}] \quad [14.20]$$

is usually readily determined. The rate equation for our enzymatic reaction is then derived as follows. Combining Eq. [14.17] with the steady-state assumption, Eq. [14.19], and the conservation condition, Eq. [14.20], yields

$$k_1([\text{E}]_T - [\text{ES}])[S] = (k_{-1} + k_2)[\text{ES}]$$

which on rearrangement becomes

$$[\text{ES}](k_{-1} + k_2 + k_1[\text{S}]) = k_1[\text{E}]_{\text{T}}[\text{S}]$$

Dividing both sides by  $k_1$  and solving for  $[\text{ES}]$ ,

$$[\text{ES}] = \frac{[\text{E}]_{\text{T}}[\text{S}]}{K_M + [\text{S}]}$$

where  $K_M$ , which is known as the **Michaelis constant**, is defined

$$K_M = \frac{k_{-1} + k_2}{k_1} \quad [14.21]$$

The meaning of this important constant is discussed below.

The **initial velocity** of the reaction from Eq. [14.16] can then be expressed in terms of the experimentally measurable quantities  $[\text{E}]_{\text{T}}$  and  $[\text{S}]$ :

$$v_o = \left( \frac{d[\text{P}]}{dt} \right)_{t=t_s} = k_2[\text{ES}] = \frac{k_2[\text{E}]_{\text{T}}[\text{S}]}{K_M + [\text{S}]} \quad [14.22]$$

where  $t_s$  is the time when the steady state is first achieved (usually milliseconds after  $t = 0$ ). The use of the initial velocity (operationally taken as the velocity measured before more than  $\sim 10\%$  of the substrate has been converted to product) rather than just the velocity minimizes such complicating factors as the effects of reversible reactions, inhibition of the enzyme by product, and progressive inactivation of the enzyme.

The **maximal velocity** of a reaction,  $V_{\text{max}}$ , occurs at high substrate concentrations when the enzyme is **saturated**, that is, when it is entirely in the ES form:

$$V_{\text{max}} = k_2[\text{E}]_{\text{T}} \quad [14.23]$$

Therefore, combining Eqs. [14.22] and [14.23], we obtain

$$v_o = \frac{V_{\text{max}}[\text{S}]}{K_M + [\text{S}]} \quad [14.24]$$

This expression, the **Michaelis–Menten equation**, is the basic equation of enzyme kinetics. It describes a rectangular hyperbola such as is plotted in Fig. 14-8 (although this curve is rotated by  $45^\circ$  and translated to the origin with respect to the examples of hyperbolas seen in most elementary

**Figure 14-8** Plot of the initial velocity  $v_o$  of a simple Michaelis–Menten reaction versus the substrate concentration  $[\text{S}]$ . Points are plotted in  $0.5\text{-}K_M$  intervals of substrate concentration between  $0.5 K_M$  and  $5 K_M$ .  See the Animated Figures

algebra texts). The saturation function for oxygen binding to myoglobin, Eq. [10.4], has the same functional form.

#### a. Significance of the Michaelis Constant

The Michaelis constant,  $K_M$ , has a simple operational definition. At the substrate concentration where  $[\text{S}] = K_M$ , Eq. [14.24] yields  $v_o = V_{\text{max}}/2$  so that  $K_M$  is the substrate concentration at which the reaction velocity is half-maximal. Therefore, if an enzyme has a small value of  $K_M$ , it achieves maximal catalytic efficiency at low substrate concentrations.

The magnitude of  $K_M$  varies widely with the identity of the enzyme and the nature of the substrate (Table 14-1). It is also a function of temperature and pH (see Section 14-4). The Michaelis constant (Eq. [14.21]) can be expressed as

$$K_M = \frac{k_{-1}}{k_1} + \frac{k_2}{k_1} = K_S + \frac{k_2}{k_1} \quad [14.25]$$

Since  $K_S$  is the dissociation constant of the Michaelis complex, as  $K_S$  decreases, the enzyme's affinity for substrate

**Table 14-1** Values of  $K_M$ ,  $k_{\text{cat}}$ , and  $k_{\text{cat}}/K_M$  for Some Enzymes and Substrates

Enzyme	Substrate	$K_M$ (M)	$k_{\text{cat}}$ ( $\text{s}^{-1}$ )	$k_{\text{cat}}/K_M$ ( $\text{M}^{-1} \cdot \text{s}^{-1}$ )
Acetylcholinesterase	Acetylcholine	$9.5 \times 10^{-5}$	$1.4 \times 10^4$	$1.5 \times 10^8$
Carbonic anhydrase	$\text{CO}_2$	$1.2 \times 10^{-2}$	$1.0 \times 10^6$	$8.3 \times 10^7$
	$\text{HCO}_3^-$	$2.6 \times 10^{-2}$	$4.0 \times 10^5$	$1.5 \times 10^7$
Catalase	$\text{H}_2\text{O}_2$	$2.5 \times 10^{-2}$	$1.0 \times 10^7$	$4.0 \times 10^8$
Chymotrypsin	<i>N</i> -Acetylglycine ethyl ester	$4.4 \times 10^{-1}$	$5.1 \times 10^{-2}$	$1.2 \times 10^{-1}$
	<i>N</i> -Acetylvaline ethyl ester	$8.8 \times 10^{-2}$	$1.7 \times 10^{-1}$	1.9
	<i>N</i> -Acetyltyrosine ethyl ester	$6.6 \times 10^{-4}$	$1.9 \times 10^2$	$2.9 \times 10^5$
Fumarase	Fumarate	$5.0 \times 10^{-6}$	$8.0 \times 10^2$	$1.6 \times 10^8$
	Malate	$2.5 \times 10^{-5}$	$9.0 \times 10^2$	$3.6 \times 10^7$
Superoxide dismutase	Superoxide ion ( $\text{O}_2^-$ )	$3.6 \times 10^{-4}$	$1.0 \times 10^6$	$2.8 \times 10^9$
Urease	Urea	$2.5 \times 10^{-2}$	$1.0 \times 10^4$	$4.0 \times 10^5$

increases.  $K_M$  is therefore also a measure of the affinity of the enzyme for its substrate providing  $k_2/k_{-1}$  is small compared with  $K_S$ , that is,  $k_2 < k_{-1}$ .

### B. Analysis of Kinetic Data

There are several methods for determining the values of the parameters of the Michaelis–Menten equation. At very high values of  $[S]$ , the initial velocity  $v_o$  asymptotically approaches  $V_{\max}$ . In practice, however, it is very difficult to assess  $V_{\max}$  accurately from direct plots of  $v_o$  versus  $[S]$  such as Fig. 14-8. Even at such high substrate concentrations as  $[S] = 10 K_M$ , Eq. [14.24] indicates that  $v_o$  is only 91% of  $V_{\max}$ , so that the extrapolated value of the asymptote will almost certainly be underestimated.

A better method for determining the values of  $V_{\max}$  and  $K_M$ , which was formulated by Hans Lineweaver and Dean Burk, uses the reciprocal of Eq. [14.24]:

$$\frac{1}{v_o} = \left( \frac{K_M}{V_{\max}} \right) \frac{1}{[S]} + \frac{1}{V_{\max}} \quad [14.26]$$

This is a linear equation in  $1/v_o$  and  $1/[S]$ . If these quantities are plotted, in the so-called **Lineweaver–Burk** or **double-reciprocal plot**, the slope of the line is  $K_M/V_{\max}$ , the  $1/v_o$  intercept is  $1/V_{\max}$ , and the extrapolated  $1/[S]$  intercept is  $-1/K_M$  (Fig. 14-9). A disadvantage of this plot is that most experimental measurements involve relatively high  $[S]$  and are therefore crowded onto the left side of the graph. Furthermore, for small values of  $[S]$ , small errors in  $v_o$  lead to large errors in  $1/v_o$  and hence to large errors in  $K_M$  and  $V_{\max}$ .

Several other types of plots, each with its advantages and disadvantages, have been formulated for the determination of  $V_{\max}$  and  $K_M$  from kinetic data. With the advent of conveniently available computers, however, kinetic data

**Figure 14-9** A double-reciprocal (Lineweaver–Burk) plot. Error bars are  $\pm 0.05 V_{\max}$ . The indicated points are the same as those in Fig. 14-8. Note the large effect of small errors at small  $[S]$  (large  $1/[S]$ ) and the crowding together of points at large  $[S]$ .

 See the Animated Figures

are commonly analyzed by mathematically sophisticated statistical treatments. Nevertheless, Lineweaver–Burk plots are valuable for the visual presentation of kinetic data as well as being useful in the analysis of kinetic data from enzymes requiring more than one substrate (Section 14-5C).

#### a. $k_{\text{cat}}/K_M$ Is a Measure of Catalytic Efficiency

An enzyme's kinetic parameters provide a measure of its catalytic efficiency. We may define the catalytic constant of an enzyme as

$$k_{\text{cat}} = \frac{V_{\max}}{[E]_T} \quad [14.27]$$

This quantity is also known as the **turnover number** of an enzyme because it is the number of reaction processes (turnovers) that each active site catalyzes per unit time. The turnover numbers for a selection of enzymes are given in Table 14-1. Note that these quantities vary by over eight orders of magnitude depending on the identity of the enzyme as well as that of its substrate. Equation [14.23] indicates that for the Michaelis–Menten model,  $k_{\text{cat}} = k_2$ . For enzymes with more complicated mechanisms,  $k_{\text{cat}}$  may be a function of several rate constants.

When  $[S] \ll K_M$ , very little ES is formed. Consequently,  $[E] \approx [E]_T$ , so that Eq. [14.22] reduces to a second-order rate equation:

$$v_o \approx \left( \frac{k_2}{K_M} \right) [E]_T [S] \approx \left( \frac{k_{\text{cat}}}{K_M} \right) [E] [S] \quad [14.28]$$

$k_{\text{cat}}/K_M$  is the apparent second-order rate constant of the enzymatic reaction; the rate of the reaction varies directly with how often enzyme and substrate encounter one another in solution. The quantity  $k_{\text{cat}}/K_M$  is therefore a measure of an enzyme's catalytic efficiency.

#### b. Some Enzymes Have Attained Catalytic Perfection

Is there an upper limit on enzymatic catalytic efficiency? From Eq. [14.21] we find

$$\frac{k_{\text{cat}}}{K_M} = \frac{k_2}{K_M} = \frac{k_1 k_2}{k_{-1} + k_2} \quad [14.29]$$

This ratio is maximal when  $k_2 \gg k_{-1}$ , that is, when the formation of product from the Michaelis complex, ES, is fast compared to its decomposition back to substrate and enzyme. Then  $k_{\text{cat}}/K_M = k_1$ , the second-order rate constant for the formation of ES. The term  $k_1$ , of course, can be no greater than the frequency with which enzyme and substrate molecules collide with each other in solution. This **diffusion-controlled limit** is in the range of  $10^8$  to  $10^9 M^{-1} \cdot s^{-1}$ . Thus, enzymes with such values of  $k_{\text{cat}}/K_M$  must catalyze a reaction almost every time they encounter a substrate molecule. Table 14-1 indicates that several enzymes, namely, catalase, superoxide dismutase, fumarase, acetylcholinesterase, and possibly carbonic anhydrase, have achieved this state of virtual catalytic perfection.

**Figure 14-10** Cross section through the active site of human superoxide dismutase (SOD). The enzyme binds both a  $\text{Cu}^{2+}$  and a  $\text{Zn}^{2+}$  ion (orange and cyan spheres). SOD's molecular surface is represented by a dot surface that is colored according to its electrostatic charge, with red most negative, yellow negative, green neutral, cyan positive, and blue most positive. The electrostatic field vectors are represented by similarly colored arrows. Note how this electrostatic field would draw the negatively charged superoxide ion into its binding site, which is located between the  $\text{Cu}^{2+}$  ion and Arg 143. [Courtesy of Elizabeth Getzoff, The Scripps Research Institute, La Jolla, California.]

Since the active site of an enzyme generally occupies only a small fraction of its total surface area, how can any enzyme catalyze a reaction every time it encounters a substrate molecule? In the case of **superoxide dismutase (SOD)**, it appears that the arrangement of charged groups on the enzyme's surface serves to electrostatically guide the charged substrate to the enzyme's active site (Fig. 14-10). [SOD, which is present in nearly all cells, functions to inactivate the highly reactive and therefore destructive **superoxide radical**  $\text{O}_2^{\cdot-}$  by catalyzing the reaction  $2 \text{O}_2^{\cdot-} + 2\text{H}^+ \rightarrow \text{H}_2\text{O}_2 + \text{O}_2$ ; Section 22-4Ch]. Other enzymes, including **acetylcholinesterase** (Section 20-5C), have similar mechanisms to funnel polar substrates to their active sites.

### C. Reversible Reactions

The Michaelis–Menten model implicitly assumes that enzymatic reverse reactions may be neglected. Yet many enzymatic reactions are highly reversible (have a small free energy of reaction) and therefore have products that back react to form substrates at a significant rate. In this section we therefore relax the Michaelis–Menten restriction of no back reaction and, by doing so, discover some interesting and important kinetic principles.

#### a. The One-Intermediate Model

Modification of the Michaelis–Menten model to incorporate a back reaction yields the following reaction scheme:

(Here ES might just as well be called EP because this model does not specify the nature of the intermediate complex.) The equation describing the kinetic behavior of this model, which is derived in Appendix A of this chapter, is expressed

$$v = \frac{\frac{V_{\max}^f [\text{S}]}{K_M^S} - \frac{V_{\max}^r [\text{P}]}{K_M^P}}{1 + \frac{[\text{S}]}{K_M^S} + \frac{[\text{P}]}{K_M^P}} \quad [14.30]$$

where

$$\begin{aligned} V_{\max}^f &= k_2 [\text{E}]_{\text{T}} & V_{\max}^r &= k_{-1} [\text{E}]_{\text{T}} \\ K_M^S &= \frac{k_{-1} + k_2}{k_1} & K_M^P &= \frac{k_{-1} + k_2}{k_{-2}} \end{aligned}$$

and

$$[\text{E}]_{\text{T}} = [\text{E}] + [\text{ES}]$$

This is essentially a Michaelis–Menten equation that works backwards as well as forwards. Indeed, at  $[\text{P}] = 0$ , that is, when  $v = v_0$ , this equation becomes the Michaelis–Menten equation.

#### b. The Haldane Relationship

At equilibrium (which occurs after the reaction has run its course),  $v = 0$ , so Eq. [14.30], which holds at equilibrium as well as at steady state, can be solved to yield

$$K_{\text{eq}} = \frac{[\text{P}]_{\text{eq}}}{[\text{S}]_{\text{eq}}} = \frac{V_{\max}^f K_M^P}{V_{\max}^r K_M^S} \quad [14.31]$$

where  $[\text{P}]_{\text{eq}}$  and  $[\text{S}]_{\text{eq}}$  are the concentrations of P and S at equilibrium. This so-called **Haldane relationship** demonstrates that *the kinetic parameters of a reversible enzymatically catalyzed reaction are not independent of one another. Rather, they are related by the equilibrium constant for the overall reaction, which, of course, is independent of the presence of the enzyme.*

#### c. Kinetic Data Cannot Unambiguously Establish a Reaction Mechanism

An enzyme that forms a reversible complex with its substrate should likewise form one with its product; that is, it should have a mechanism such as

The equation describing the kinetic behavior of this two-intermediate model, whose derivation is analogous to that described in Appendix A for the one-intermediate model,

has a form identical to that of Eq. [14.30]. However, its parameters  $V_{\max}^f$ ,  $V_{\max}^r$ ,  $K_M^S$ , and  $K_M^P$  are defined in terms of the six kinetic constants of the two-intermediate model rather than the four of the one-intermediate model. In fact, the steady-state rate equations for reversible reactions with three or more intermediates also have this same form but with yet different definitions of the four parameters.

The values of  $V_{\max}^f$ ,  $V_{\max}^r$ ,  $K_M^S$ , and  $K_M^P$  in Eq. [14.30] can be determined by suitable manipulations of the initial substrate and product concentrations under steady-state conditions. This, however, will not yield the values of the rate constants for our two-intermediate model because there are six such constants and only four equations describing their relationships. Moreover, steady-state kinetic measurements are incapable of distinguishing the number of intermediates in a reversible enzymatic reaction because the form of Eq. [14.30] does not change with the number of intermediates.

The functional identities of the equations describing these reaction schemes may be understood in terms of an analogy between our  $n$ -intermediate reversible reaction model and a “black box” containing a system of water pipes with one inlet and one drain:

At steady state, that is, after the pipes have filled with water, one can measure the relationship between input pressure and output flow. However, such measurements yield no information concerning the detailed construction of the plumbing connecting the inlet to the drain. This would require additional observations such as opening the black box and tracing the pipes. *Likewise, steady-state kinetic measurements can provide a phenomenological description of enzymatic behavior, but the nature of the intermediates remains indeterminate. Rather, these intermediates must be detected and characterized by independent means such as by spectroscopic analysis.*

The foregoing discussion brings to light a central principle of kinetic analysis: *The steady-state kinetic analysis of a reaction cannot unambiguously establish its mechanism.* This is because no matter how simple, elegant, or rational a mechanism one postulates that fully accounts for kinetic data, there are an infinite number of alternative mechanisms, perhaps complicated, awkward, and seemingly irrational, that can account for these kinetic data equally well. Usually it is the simpler and more elegant mechanism that turns out to be correct, but this is not always the case. *If*

*however, kinetic data are not compatible with a given mechanism, then the mechanism must be rejected.* Therefore, although kinetics cannot be used to establish a mechanism unambiguously without confirming data, such as the physical demonstration of an intermediate's existence, the steady-state kinetic analysis of a reaction is of great value because it can be used to eliminate proposed mechanisms.

### 3 INHIBITION

Many substances alter the activity of an enzyme by combining with it in a way that influences the binding of substrate and/or its turnover number. Substances that reduce an enzyme's activity in this way are known as **inhibitors**.

Many inhibitors are substances that structurally resemble their enzyme's substrate but either do not react or react very slowly compared to substrate. Such inhibitors are commonly used to probe the chemical and conformational nature of a substrate-binding site as part of an effort to elucidate the enzyme's catalytic mechanism. In addition, many enzyme inhibitors are effective chemotherapeutic agents, since an “unnatural” substrate analog can block the action of a specific enzyme. For example, **methotrexate** (also called **amethopterin**) chemically resembles **dihydrofolate**. Methotrexate binds tightly to the enzyme **dihydrofolate reductase**, thereby preventing it from carrying out its normal function, the reduction of dihydrofolate to **tetrahydrofolate**, an essential cofactor in the biosynthesis of the DNA precursor dTMP (Section 28-3Bd):

Rapidly dividing cells, such as cancer cells, which are actively engaged in DNA synthesis, are far more susceptible to methotrexate than are slower growing cells such as those of most normal mammalian tissues. Hence, methotrexate, when administered in proper dosage, kills cancer cells without fatally poisoning the host.

There are various mechanisms through which enzyme inhibitors can act. In this section, we discuss several of the simplest such mechanisms and their effects on the kinetic behavior of enzymes that follow the Michaelis–Menten model.

### A. Competitive Inhibition

A substance that competes directly with a normal substrate for an enzymatic binding site is known as a **competitive inhibitor**. Such an inhibitor usually resembles the substrate to the extent that it specifically binds to the active site but differs from it so as to be unreactive. Thus methotrexate is a competitive inhibitor of dihydrofolate reductase. Similarly, **succinate dehydrogenase**, a citric acid cycle enzyme that functions to convert **succinate** to **fumarate** (Section 21-3F), is competitively inhibited by **malonate**, which structurally resembles succinate but cannot be dehydrogenated:

The effectiveness of malonate in competitively inhibiting succinate dehydrogenase strongly suggests that the enzyme's substrate-binding site is designed to bind both of

the substrate's carboxylate groups, presumably through the influence of two appropriately placed positively charged residues.

The general model for competitive inhibition is given by the following reaction scheme:

Here it is assumed that I, the inhibitor, binds reversibly to the enzyme and is in rapid equilibrium with it so that

$$K_I = \frac{[E][I]}{[EI]} \quad [14.32]$$

and EI, the enzyme–inhibitor complex, is catalytically inactive. A *competitive inhibitor therefore acts by reducing the concentration of free enzyme available for substrate binding*.

Our goal, as before, is to express  $v_o$  in terms of measurable quantities, in this case  $[E]_T$ ,  $[S]$ , and  $[I]$ . We begin, as in the derivation of the Michaelis–Menten equation, with the expression for the conservation condition, which must now take into account the existence of EI.

$$[E]_T = [E] + [EI] + [ES] \quad [14.33]$$

The enzyme concentration can be expressed in terms of  $[ES]$  by rearranging Eq. [14.17] under the steady-state condition:

$$[E] = \frac{K_M[ES]}{[S]} \quad [14.34]$$

That of the enzyme–inhibitor complex is found by rearranging Eq. [14.32] and substituting Eq. [14.34] into it:

$$[EI] = \frac{[E][I]}{K_I} = \frac{K_M[ES][I]}{[S]K_I} \quad [14.35]$$

Substituting the latter two results into Eq. [14.33] yields

$$[E]_T = [ES] \left\{ \frac{K_M}{[S]} \left( 1 + \frac{[I]}{K_I} \right) + 1 \right\}$$

which can be solved for  $[ES]$  by rearranging it to

$$[ES] = \frac{[E]_T[S]}{K_M \left( 1 + \frac{[I]}{K_I} \right) + [S]}$$

so that, according to Eq. [14.22], the initial velocity is expressed

$$v_o = k_2[ES] = \frac{k_2[E]_T[S]}{K_M \left( 1 + \frac{[I]}{K_I} \right) + [S]} \quad [14.36]$$

Then defining

$$\alpha = \left(1 + \frac{[I]}{K_I}\right) \quad [14.37]$$

and  $V_{\max} = k_2[E]_T$  as in Eq. [14.23],

$$v_o = \frac{V_{\max}[S]}{\alpha K_M + [S]} \quad [14.38]$$

This is the Michaelis–Menten equation with  $K_M$  modulated by  $\alpha$ , a function of the inhibitor concentration (which, according to Eq. [14.37], must always be  $\geq 1$ ). The value of  $[S]$  at  $v_o = V_{\max}/2$  is therefore  $\alpha K_M$ .

Figure 14-11 shows the hyperbolic plot of Eq. [14.38] for various values of  $\alpha$ . Note that as  $[S] \rightarrow \infty$ ,  $v_o \rightarrow V_{\max}$  for any value of  $\alpha$ . The larger the value of  $\alpha$ , however, the greater  $[S]$  must be to approach  $V_{\max}$ . Thus, the inhibitor does not affect the turnover number of the enzyme. Rather, the presence of I has the effect of making  $[S]$  appear more dilute than it actually is, or alternatively, making  $K_M$  appear larger than it really is. Conversely, increasing  $[S]$  shifts the substrate-binding equilibrium toward ES. Hence, there is true competition between I and S for the enzyme's substrate-binding site; their binding is mutually exclusive.

Recasting Eq. [14.38] in the double-reciprocal form yields

$$\frac{1}{v_o} = \left(\frac{\alpha K_M}{V_{\max}}\right) \frac{1}{[S]} + \frac{1}{V_{\max}} \quad [14.39]$$

A plot of this equation is linear and has a slope of  $\alpha K_M/V_{\max}$ , a  $1/[S]$  intercept of  $-1/\alpha K_M$ , and a  $1/v_o$  intercept of  $1/V_{\max}$  (Fig. 14-12). *The double-reciprocal plots for a competitive inhibitor at various concentrations of I intersect at  $1/V_{\max}$  on the  $1/v_o$  axis; this is diagnostic for competitive inhibition as compared with other types of inhibition (Sections 14-3B and 14-3C).*

**Figure 14-11** Competitive inhibition. Plot of the initial velocity  $v_o$  of a simple Michaelis–Menten reaction versus the substrate concentration  $[S]$  in the presence of different concentrations of a competitive inhibitor.

By determining the values of  $\alpha$  at different inhibitor concentrations, the value of  $K_I$  can be found from Eq. [14.37]. In this way, competitive inhibitors can be used to probe the structural nature of an active site. For example, to ascertain the importance of the various segments of an ATP molecule

for binding to the active site of an ATP-requiring enzyme, one might determine the  $K_I$ , say, for ADP, AMP (adenosine monophosphate), ribose, triphosphate ion, etc. Since many of these ATP components are catalytically inactive, inhibition studies are the most convenient means of monitoring their binding to the enzyme.

If the inhibitor binds irreversibly to the enzyme, the inhibitor is classified as an **inactivator**, as is any agent that somehow inactivates the enzyme. Inactivators truly reduce the effective level of  $[E]_T$  at all values of  $[S]$ . Reagents that modify specific amino acid residues can act in this manner.

**Figure 14-12** Lineweaver–Burk plot of the competitively inhibited Michaelis–Menten enzyme described by Fig. 14-11. Note that all lines intersect on the  $1/v_o$  axis at  $1/V_{\max}$ .  See the Animated Figures

### B. Uncompetitive Inhibition

In **uncompetitive inhibition**, the inhibitor binds directly to the enzyme–substrate complex but not to the free enzyme:

The inhibitor-binding step, which has the dissociation constant

$$K'_1 = \frac{[\text{ES}][\text{I}]}{[\text{ESI}]} \quad [14.40]$$

is assumed to be at equilibrium. The binding of the uncompetitive inhibitor, which need not resemble the substrate, is envisioned to cause structural distortion of the active site, thereby rendering the enzyme catalytically inactive. (If the inhibitor binds to enzyme alone, it does so without affecting its affinity for substrate.)

The Michaelis–Menten equation for uncompetitive inhibition, which is derived in Appendix B of this chapter, is

$$v_o = \frac{V_{\max}[\text{S}]}{K_M + \alpha'[\text{S}]} \quad [14.41]$$

where

$$\alpha' = 1 + \frac{[\text{I}]}{K'_1} \quad [14.42]$$

Inspection of this equation indicates that *at high values of [S],  $v_o$  asymptotically approaches  $V_{\max}/\alpha'$ , so that, in contrast to competitive inhibition, the effects of uncompetitive inhibition on  $V_{\max}$  are not reversed by increasing the substrate concentration.* However, at low substrate concentrations, that is, when  $[\text{S}] \ll K_M$ , the effect of an uncompetitive inhibitor becomes negligible, again the opposite behavior of a competitive inhibitor.

When cast in the double-reciprocal form, Eq. [14.41] becomes

$$\frac{1}{v_o} = \left( \frac{K_M}{V_{\max}} \right) \frac{1}{[\text{S}]} + \frac{\alpha'}{V_{\max}} \quad [14.43]$$

The Lineweaver–Burk plot for uncompetitive inhibition is linear with slope  $K_M/V_{\max}$ , as in the uninhibited reaction, and with  $1/v_o$  and  $1/[\text{S}]$  intercepts of  $\alpha'/V_{\max}$  and  $-\alpha'/K_M$ , respectively. A series of Lineweaver–Burk plots at various uncompetitive inhibitor concentrations consists of a family of parallel lines (Fig. 14-13). This is diagnostic for uncompetitive inhibition.

Uncompetitive inhibition requires that the inhibitor affect the catalytic function of the enzyme but not its substrate binding. For single-substrate enzymes it is difficult to conceive of how this could happen with the

**Figure 14-13** Lineweaver–Burk plot of a simple Michaelis–Menten enzyme in the presence of uncompetitive inhibitor. Note that all lines have identical slopes of  $K_M/V_{\max}$ .

 See the Animated Figures

exception of small inhibitors such as protons (see Section 14-4) or metal ions. As we discuss in Section 14-5C, however, uncompetitive inhibition is important for multisubstrate enzymes.

### C. Mixed Inhibition

If both the enzyme and the enzyme–substrate complex bind inhibitor, the following model results:

Both of the inhibitor-binding steps are assumed to be at equilibrium but with different dissociation constants:

$$K_1 = \frac{[\text{E}][\text{I}]}{[\text{EI}]} \quad \text{and} \quad K'_1 = \frac{[\text{ES}][\text{I}]}{[\text{ESI}]} \quad [14.44]$$

This phenomenon is alternatively known as **mixed inhibition** or **noncompetitive inhibition**. Presumably a mixed inhibitor binds to enzyme sites that participate in both substrate binding and catalysis.

The Michaelis–Menten equation for mixed inhibition, which is derived in Appendix C of this chapter, is

$$v_o = \frac{V_{\max}[\text{S}]}{\alpha K_M + \alpha'[\text{S}]} \quad [14.45]$$

where  $\alpha$  and  $\alpha'$  are defined in Eqs. [14.37] and [14.42], respectively. It can be seen from Eq. [14.45] that the name “mixed inhibition” arises from the fact that the denominator has the factor  $\alpha$  multiplying  $K_M$  as in competitive inhibition (Eq. [14.38]) and the factor  $\alpha'$  multiplying  $[\text{S}]$  as in uncompetitive inhibition (Eq. [14.41]). Mixed inhibitors

**Figure 14-14** Lineweaver–Burk plot of a simple Michaelis–Menten enzyme in the presence of a mixed inhibitor. Note that the lines all intersect to the left of the  $1/v_0$  axis. The coordinates of this intersection point are given in brackets. When  $K_I = K'_I$ ,  $\alpha = \alpha'$  and the lines intersect on the  $1/[S]$  axis at  $-1/K_M$ . See the Animated Figures

are therefore effective at both high and low substrate concentrations.

The Lineweaver–Burk equation for mixed inhibition is

$$\frac{1}{v_0} = \left( \frac{\alpha K_M}{V_{\max}} \right) \frac{1}{[S]} + \frac{\alpha'}{V_{\max}} \quad [14.46]$$

The plot of this equation consists of lines that have slope  $\alpha K_M/V_{\max}$  with a  $1/v_0$  intercept of  $\alpha'/V_{\max}$  and a  $1/[S]$  intercept of  $-\alpha'/\alpha K_M$  (Fig. 14-14). Algebraic manipulation of Eq. [14.46] for different values of  $[I]$  reveals that this equation describes a family of lines that intersect to the left of the  $1/v_0$  axis (Fig. 14-14). For the special case in which  $K_I = K'_I$  ( $\alpha = \alpha'$ ), the intersection is, in addition, on the  $1/[S]$  axis, a situation which, in an ambiguity of nomenclature, is sometimes described as noncompetitive inhibition.

Table 14-2 provides a summary of the preceding results concerning the inhibition of simple Michaelis–Menten

enzymes. The quantities  $K_M^{\text{app}}$  and  $V_{\max}^{\text{app}}$  are the “apparent” values of  $K_M$  and  $V_{\max}$  that would actually be observed in the presence of inhibitor for the Michaelis–Menten equation describing the inhibited enzymes.

## 4 EFFECTS OF pH

Enzymes, being proteins, have properties that are quite pH sensitive. Most proteins, in fact, are active only within a narrow pH range, typically 5 to 9. This is a result of the effects of pH on a combination of factors: (1) the binding of substrate to enzyme, (2) the catalytic activity of the enzyme, (3) the ionization of substrate, and (4) the variation of protein structure (usually significant only at extremes of pH).

### a. pH Dependence of Simple Michaelis–Menten Enzymes

The initial rates for many enzymatic reactions exhibit bell-shaped curves as a function of pH (e.g., Fig. 14-15). These curves reflect the ionizations of certain amino acid residues that must be in a specific ionization state for enzyme activity. The following model can account for such pH effects.

In this expansion of the simple one substrate–no back reaction mechanism, it is assumed that only EH and ESH are catalytically active.

The Michaelis–Menten equation for this model, which is derived in Appendix D, is

$$v_0 = \frac{V'_{\max} [S]}{K'_M + [S]} \quad [14.47]$$

**Table 14-2** Effects of Inhibitors on the Parameters of the Michaelis–Menten Equation<sup>a</sup>

Type of Inhibition	$V_{\max}^{\text{app}}$	$K_M^{\text{app}}$
None	$V_{\max}$	$K_M$
Competitive	$V_{\max}$	$\alpha K_M$
Uncompetitive	$V_{\max}/\alpha'$	$K_M/\alpha'$
Mixed	$V_{\max}/\alpha'$	$\alpha K_M/\alpha'$

<sup>a</sup> $\alpha = 1 + \frac{[I]}{K_I}$  and  $\alpha' = 1 + \frac{[I]}{K'_I}$ .

**Figure 14-15** Effect of pH on the initial rate of the reaction catalyzed by the enzyme fumarase. [After Tanford, C., *Physical Chemistry of Macromolecules*, p. 647, Wiley (1961).]

Here the apparent Michaelis–Menten parameters are defined

$$V'_{\max} = V_{\max}/f_2 \quad \text{and} \quad K'_M = K_M(f_1/f_2)$$

where

$$f_1 = \frac{[\text{H}^+]}{K_{E1}} + 1 + \frac{K_{E2}}{[\text{H}^+]}$$

$$f_2 = \frac{[\text{H}^+]}{K_{ES1}} + 1 + \frac{K_{ES2}}{[\text{H}^+]}$$

and  $V_{\max}$  and  $K_M$  refer to the active forms of the enzyme, EH and ESH. Note that at any given pH, Eq. [14.47] behaves as a simple Michaelis–Menten equation, but because of the pH dependence of  $f_1$  and  $f_2$ ,  $v_o$  varies with pH in a bell-shaped manner (e.g., Fig. 14-15).

### b. Evaluation of Ionization Constants

The ionization constants of enzymes that obey Eq. [14.47] can be evaluated by the analysis of the curves of  $\log V'_{\max}$  versus pH, which provides values of  $K_{ES1}$  and  $K_{ES2}$  (Fig. 14-16a), and of  $\log(V'_{\max}/K'_M)$  versus pH, which yields  $K_{E1}$  and  $K_{E2}$  (Fig. 14-16b). This, of course, entails the determination of the enzyme's Michaelis–Menten parameters at each of a series of different pH's.

The measured  $pK$ 's often provide valuable clues as to the identities of the amino acid residues essential for enzymatic activity. For example, a measured  $pK$  of  $\sim 4$  suggests that an Asp or Glu residue is essential to the enzyme. Similarly,  $pK$ 's of  $\sim 6$  or  $\sim 10$  suggest the participation of a His or a Lys residue, respectively. However, a given acid–base group may vary by as much as several pH units from its expected value as a consequence of the electrostatic influence of nearby charged groups, as well as of the prox-

**Figure 14-16** The pH dependence of (a)  $\log V'_{\max}$  and (b)  $\log(V'_{\max}/K'_M)$ . The light blue lines indicate how the values of the molecular ionization constants can be determined by graphical extrapolation.

imity of regions of low polarity. For example, the carboxylate group of a Glu residue forming a salt bridge with a Lys residue is stabilized by the nearby positive charge and therefore has a lower  $pK$  than it would otherwise have; that is, it is more difficult to protonate. Conversely, a carboxylate group immersed in a region of low polarity is less acidic than normal because it attracts protons more strongly than if it were in a region of higher polarity. The identification of a kinetically characterized  $pK$  with a particular amino acid residue must therefore be verified by other types of measurements such as the use of group-specific reagents to inactivate a putative essential residue.

## 5 BISUBSTRATE REACTIONS

We have heretofore been concerned with reactions involving enzymes that require only a single substrate. Yet enzymatic reactions involving two substrates and yielding two products

account for  $\sim 60\%$  of known biochemical reactions. Almost all of these so-called **bisubstrate reactions** are either **transferase** reactions in which the enzyme catalyzes the transfer of a specific functional group, X, from one of the substrates to the other:

or oxidation–reduction reactions in which reducing equivalents are transferred between the two substrates. For example, the hydrolysis of a peptide bond by trypsin (Section 7-1Da) is the transfer of the peptide carbonyl group from

In it, a functional group X of the first substrate A (= P—X) is displaced from the substrate by the enzyme E to yield the first product P and a stable enzyme form F (= E—X) in which X is tightly (often covalently) bound to the enzyme (Ping). In the second stage of the reaction, X is displaced from the enzyme by the second substrate B to yield the second product Q (= B—X), thereby regenerating the original form of the enzyme, E (Pong). Such reactions are therefore also known as **double-displacement reactions**. Note that in Ping Pong Bi Bi reactions, the substrates A and B do not encounter one another on the surface of the enzyme. Many enzymes, including chymotrypsin (Section 15-3), transaminases (Section 26-1A), and some flavoenzymes, react with Ping Pong mechanisms.

### B. Rate Equations

Steady-state kinetic measurements can be used to distinguish among the foregoing bisubstrate mechanisms. In order to do so, one must first derive their rate equations. This can be done in much the same manner as for single-substrate enzymes, that is, solving a set of simultaneous linear equations consisting of an equation expressing the steady-state condition for each kinetically distinct enzyme complex plus one equation representing the conservation condition for the enzyme. This, of course, is a more complex undertaking for bisubstrate enzymes than it is for single-substrate enzymes.

The rate equations for the above described bisubstrate mechanisms in the absence of products are given below in double-reciprocal form.

#### a. Ordered Bi Bi

$$\frac{1}{v_o} = \frac{1}{V_{\max}} + \frac{K_M^A}{V_{\max}[A]} + \frac{K_M^B}{V_{\max}[B]} + \frac{K_S^A K_M^B}{V_{\max}[A][B]} \quad [14.48]$$

#### b. Rapid Equilibrium Random Bi Bi

The rate equation for the general Random Bi Bi reaction is quite complicated. However, in the special case that both substrates are in rapid and independent equilibrium with the enzyme, that is, when the EAB—EPQ interconversion is rate determining, the initial rate equation reduces to the

following relatively simple form. This mechanism is known as the **Rapid Equilibrium Random Bi Bi** mechanism:

$$\frac{1}{v_o} = \frac{1}{V_{\max}} + \frac{K_S^A K_M^B}{V_{\max} K_S^B [A]} + \frac{K_M^B}{V_{\max} [B]} + \frac{K_S^A K_M^B}{V_{\max} [A][B]} \quad [14.49]$$

#### c. Ping Pong Bi Bi

$$\frac{1}{v_o} = \frac{K_M^A}{V_{\max} [A]} + \frac{K_M^B}{V_{\max} [B]} + \frac{1}{V_{\max}} \quad [14.50]$$

#### d. Physical Significance of the Bisubstrate Kinetic Parameters

The kinetic parameters in the equations describing bisubstrate reactions have meanings similar to those for single-substrate reactions.  $V_{\max}$  is the maximal velocity of the enzyme obtained when both A and B are present at saturating concentrations,  $K_M^A$  and  $K_M^B$  are the respective concentrations of A and B necessary to achieve  $\frac{1}{2}V_{\max}$  in the presence of a saturating concentration of the other, and  $K_S^A$  and  $K_S^B$  are the respective dissociation constants of A and B from the enzyme, E.

### C. Differentiating Bisubstrate Mechanisms

One can discriminate between Ping Pong and Sequential mechanisms from their contrasting properties in linear plots such as those of the Lineweaver–Burk type.

#### a. Diagnostic Plot for Ping Pong Bi Bi Reactions

A plot of  $1/v_o$  versus  $1/[A]$  at constant  $[B]$  for Eq. [14.50] yields a straight line of slope  $K_M^A/V_{\max}$  and an intercept on the  $1/v_o$  axis equal to the last two terms in Eq. [14.50]. Since the slope is independent of  $[B]$ , such plots for different values of  $[B]$  yield a family of parallel lines (Fig. 14-18). A plot of  $1/v_o$  versus  $1/[B]$  for different values of  $[A]$  likewise yields a family of parallel lines. Such parallel lines are diagnostic for a Ping Pong mechanism.

#### b. Diagnostic Plot for Sequential Bi Bi Reactions

The equations representing the Ordered Bi Bi mechanism (Eq. [14.48]) and the Rapid Equilibrium Random Bi Bi

**Figure 14-18** Double-reciprocal plots for an enzymatic reaction with a Ping Pong Bi Bi mechanism. (a) Plots of  $1/v_o$

versus  $1/[A]$  at various constant concentrations of B. (b) Plots of  $1/v_o$  versus  $1/[B]$  at various constant concentrations of A.

**Figure 14-19** Double-reciprocal plots of an enzymatic reaction with a Sequential Bi Bi mechanism. (a) Plots of  $1/v_o$  versus  $1/[A]$  at various constant concentrations of B. (b) Plots of  $1/v_o$  versus  $1/[B]$  at various constant concentrations of A. The corresponding

plots for Rapid Equilibrium Random Bi Bi reactions have identical appearances; their lines all intersect to the left of the  $1/v_o$  axis.

Bi mechanism (Eq. [14.49]) have identical functional dependence on  $[A]$  and  $[B]$ .

Equation [14.48] can be rearranged to

$$\frac{1}{v_o} = \frac{K_M^A}{V_{\max}} \left( 1 + \frac{K_S^A K_M^B}{K_M^A [B]} \right) \frac{1}{[A]} + \frac{1}{V_{\max}} \left( 1 + \frac{K_M^B}{[B]} \right) \quad [14.51]$$

Thus plotting  $1/v_o$  versus  $1/[A]$  for constant  $[B]$  yields a linear plot with a slope equal to the coefficient of  $1/[A]$  and an intercept on the  $1/v_o$  axis equal to the second term of Eq. [14.51] (Fig. 14-19a). Alternatively, Eq. [14.48] can be rearranged to

$$\frac{1}{v_o} = \frac{K_M^B}{V_{\max}} \left( 1 + \frac{K_S^A}{[A]} \right) \frac{1}{[B]} + \frac{1}{V_{\max}} \left( 1 + \frac{K_M^A}{[A]} \right) \quad [14.52]$$

which yields a linear plot of  $1/v_o$  versus  $1/[B]$  for constant  $[A]$  with a slope equal to the coefficient of  $1/[B]$  and an intercept on the  $1/v_o$  axis equal to the second term of Eq. [14.52] (Fig. 14-19b). *The characteristic feature of these plots, which is indicative of a Sequential mechanism, is that the lines intersect to the left of the  $1/v_o$  axis.*

### c. Differentiating Random and Ordered Sequential Mechanisms

The Ordered Bi Bi mechanism may be experimentally distinguished from the Random Bi Bi mechanism through **product inhibition studies**. If only one product of the reaction, P or Q, is added to the reaction mixture, the reverse reaction still cannot occur. Nevertheless, by binding to the enzyme, this product will inhibit the forward reaction. For

an Ordered Bi Bi reaction, Q (= B—X, the second product to be released) directly competes with A (= P—X, the leading substrate) for binding to E and hence is a competitive inhibitor of A when  $[B]$  is fixed (the presence of X in Q = B—X interferes with the binding of A = P—X). However, since B combines with EA, not E, Q is a mixed inhibitor of B when  $[A]$  is fixed (Q interferes with both the binding of B to enzyme and with the catalysis of the reaction). Similarly, P, which combines only with EQ, is a mixed inhibitor of A when  $[B]$  is held constant and of B when  $[A]$  is held constant. In contrast, in a Rapid Equilibrium Bi Bi reaction, since both products as well as both substrates can combine directly with E, both P and Q are competitive inhibitors of A when  $[B]$  is constant and of B when  $[A]$  is constant. These product inhibition patterns are summarized in Table 14-3.

### D. Isotope Exchange

Mechanistic conclusions based on kinetic analyses alone are fraught with uncertainties and are easily confounded by inaccurate experimental data. A particular mechanism for an enzyme is therefore greatly corroborated if the mechanism can be shown to conform to experimental criteria other than kinetic analysis.

*Sequential (single-displacement) and Ping Pong (double-displacement) bisubstrate mechanisms may be differentiated through the use of isotope exchange studies.* Double-displacement reactions are capable of exchanging an isotope from the first product P back to the first substrate A in

**Table 14-3** Patterns of Product Inhibition for Sequential Bisubstrate Mechanisms

Mechanism	Product Inhibitor	[A] Variable	[B] Variable
Ordered Bi Bi	P	Mixed	Mixed
	Q	Competitive	Mixed
Rapid Equilibrium Random Bi Bi	P	Competitive	Competitive
	Q	Competitive	Competitive

the absence of the second substrate. Consider an overall Ping Pong reaction catalyzed by the bisubstrate enzyme E

in which, as usual,  $A = P-X$ ,  $Q = B-X$ , and X is the group that is transferred from one substrate to the other in the course of the reaction. Only the first step of the reaction can take place in the absence of B. If a small amount of isotopically labeled P, denoted  $P^*$ , is added to this reaction mixture then, in the reverse reaction,  $P^*-X$  will form:

that is, isotopic exchange will occur.

In contrast, let us consider the first step of a Sequential reaction. Here a noncovalent enzyme-substrate complex forms:

Addition of  $P^*$  cannot result in an exchange reaction because no covalent bonds are broken in the formation of  $E \cdot P-X$ ; that is, there is no P released from the enzyme to exchange with  $P^*$ . The demonstration of isotopic exchange for a bisubstrate enzyme is therefore convincing evidence favoring a Ping Pong mechanism.

#### a. Isotope Exchange in Sucrose Phosphorylase and Maltose Phosphorylase

The enzymes **sucrose phosphorylase** and **maltose phosphorylase** provide two clear-cut examples of how enzymatically catalyzed isotopic exchange reactions are used to differentiate kinetic mechanisms. Sucrose phosphorylase catalyzes the overall reaction

If the enzyme is incubated with sucrose and isotopically labeled fructose in the absence of phosphate, it is observed that the label passes into the sucrose:

For the reverse reaction, if the enzyme is incubated with glucose-1-phosphate and  $^{32}\text{P}$ -labeled phosphate, this label exchanges into the glucose-1-phosphate:

These observations indicate that a tight glucosyl-enzyme complex is formed with the release of fructose, thereby establishing that the sucrose phosphorylase reaction occurs via a Ping Pong mechanism. This finding has been conclusively corroborated by the isolation and characterization of the glucosyl-enzyme complex.

The enzyme **maltose phosphorylase** catalyzes a similar overall reaction:

In contrast to sucrose phosphorylase, however, it does not catalyze isotopic exchange between glucose-1-phosphate and  $^{32}\text{P}$ phosphate or between maltose and  $^{14}\text{C}$ glucose. Likewise, a glucosyl-enzyme complex has not been detected. This evidence is consistent with maltose phosphorylase having a sequential mechanism.

## APPENDIX Derivations of Michaelis-Menten Equation Variants

### A. The Michaelis-Menten Equation for Reversible Reactions—Equation [14.30]

The conservation condition for the reversible reaction with one intermediate (Section 14-2Ca) is

$$[E]_{\text{T}} = [E] + [ES] \quad [14.A1]$$

The steady-state condition (as well as the equilibrium condition) is

$$\frac{d[ES]}{dt} = k_1[E][S] + k_{-2}[E][P] - (k_{-1} + k_2)[ES] = 0 \quad [14.A2]$$

so that

$$[E] = \left( \frac{k_{-1} + k_2}{k_1[S] + k_{-2}[P]} \right) [ES] \quad [14.A3]$$

Substituting this result into Eq. [14.A1] yields

$$[E]_{\text{T}} = \left( \frac{k_{-1} + k_2}{k_1[S] + k_{-2}[P]} + 1 \right) [ES] \quad [14.A4]$$

The velocity of the reaction is expressed

$$v = -\frac{d[S]}{dt} = k_1[E][S] - k_{-1}[ES] \quad [14.A5]$$

which can be combined with Eq. [14.A3] to give

$$v = \left( \frac{k_1[S](k_{-1} + k_2)}{k_1[S] + k_{-2}[P]} - k_{-1} \right) [ES] \quad [14.A6]$$

which, in turn, is combined with Eq. [14.A4] to yield

$$v = \left( \frac{k_1 k_2 [S] - k_{-1} k_{-2} [P]}{k_{-1} + k_2 + k_1 [S] + k_{-2} [P]} \right) [E]_T \quad [14.A7]$$

Dividing the numerator and denominator of this equation by  $(k_{-1} + k_2)$  results in

$$v = \left( \frac{k_2 \left( \frac{k_1}{k_{-1} + k_2} \right) [S] - k_{-1} \left( \frac{k_{-2}}{k_{-1} + k_2} \right) [P]}{1 + \left( \frac{k_1}{k_{-1} + k_2} \right) [S] + \left( \frac{k_{-2}}{k_{-1} + k_2} \right) [P]} \right) [E]_T \quad [14.A8]$$

Then, if we define the following parameters analogously with the constants of the Michaelis–Menten equation (Eqs. [14.23] and [14.21]),

$$\begin{aligned} V_{\max}^f &= k_2 [E]_T & V_{\max}^r &= k_{-1} [E]_T \\ K_M^S &= \frac{k_{-1} + k_2}{k_1} & K_M^P &= \frac{k_{-1} + k_2}{k_{-2}} \end{aligned}$$

we obtain the Michaelis–Menten equation for a reversible one-intermediate reaction:

$$v = \frac{V_{\max}^f [S] - V_{\max}^r [P]}{1 + \frac{[S]}{K_M^S} + \frac{[P]}{K_M^P}} \quad [14.30]$$

### B. Michaelis–Menten Equation for Uncompetitive Inhibition–Equation [14.41]

For uncompetitive inhibition (Section 14-3B), the inhibitor binds to the Michaelis complex with dissociation constant

$$K'_1 = \frac{[ES][I]}{[ESI]} \quad [14.A9]$$

The conservation condition is

$$[E]_T = [E] + [ES] + [ESI] \quad [14.A10]$$

Substituting in Eqs. [14.34] and [14.A9] yields

$$[E]_T = [ES] \left( \frac{K_M}{[S]} + 1 + \frac{[I]}{K'_1} \right) \quad [14.A11]$$

Defining  $\alpha'$  analogously to Eq. [14.37] as

$$\alpha' = 1 + \frac{[I]}{K'_1} \quad [14.A12]$$

and  $v_o$  and  $V_{\max}$  as in Eqs. [14.22] and [14.23], respectively,

$$v_o = k_2 [ES] = \frac{V_{\max}}{\frac{K_M}{[S]} + \alpha'} \quad [14.A13]$$

which on rearrangement yields the Michaelis–Menten equation for uncompetitive inhibition:

$$v_o = \frac{V_{\max} [S]}{K_M + \alpha' [S]} \quad [14.41]$$

### C. The Michaelis–Menten Equation for Mixed Inhibition–Equation [14.45]

In mixed inhibition (Section 14-3C), the inhibitor-binding steps have different dissociation constants:

$$K_1 = \frac{[E][I]}{[EI]} \quad \text{and} \quad K'_1 = \frac{[ES][I]}{[ESI]} \quad [14.A14]$$

(Here, for the sake of mathematical simplicity, we are making the thermodynamically unsupportable assumption that EI does not react with S to form ESI. Inclusion of this reaction requires a more complex derivation than that given here but leads to results that are substantially the same.) The conservation condition for this reaction scheme is

$$[E]_T = [E] + [EI] + [ES] + [ESI] \quad [14.A15]$$

so that substituting in Eqs. [14.A14]

$$[E]_T = [E] \left( 1 + \frac{[I]}{K_1} \right) + [ES] \left( 1 + \frac{[I]}{K'_1} \right) \quad [14.A16]$$

Defining  $\alpha$  and  $\alpha'$  as in Eqs. [14.37] and [14.A12], respectively, Eq. [14.A16] becomes

$$[E]_T = [E] \alpha + [ES] \alpha' \quad [14.A17]$$

Then substituting in Eq. [14.34]

$$[E]_T = [ES] \left( \frac{\alpha K_M}{[S]} + \alpha' \right) \quad [14.A18]$$

Defining  $v_o$  and  $V_{\max}$  as in Eqs. [14.22] and [14.23] results in the Michaelis–Menten equation for mixed inhibition:

$$v_o = \frac{V_{\max} [S]}{\alpha K_M + \alpha' [S]} \quad [14.45]$$

### D. The Michaelis–Menten Equation for Ionizable Enzymes–Equation [14.47]

In the model presented in Section 14-4a to account for the effect of pH on enzymes, the dissociation constants for the ionizations are

$$\begin{aligned} K_{E2} &= \frac{[H^+][E^-]}{[EH]} & K_{ES2} &= \frac{[H^+][ES^-]}{[ESH]} \\ K_{E1} &= \frac{[H^+][EH]}{[EH_2^+]} & K_{ES1} &= \frac{[H^+][ESH]}{[ESH_2^+]} \end{aligned} \quad [14.A19]$$

Protonation and deprotonation are among the fastest known reactions, so that, with the exception of the few enzymes with extremely high turnover numbers, it can be reasonably assumed that all acid–base reactions are at

equilibrium. The conservation condition is

$$[E]_T = [EH]_T + [ESH]_T \quad [14.A20]$$

where  $[E]_T$  is the total enzyme present in any form,

$$\begin{aligned} [EH]_T &= [EH_2^+] + [EH] + [E^-] \\ &= [EH] \left( \frac{[H^+]}{K_{E1}} + 1 + \frac{K_{E2}}{[H^+]} \right) \\ &= [EH]f_1 \end{aligned} \quad [14.A21]$$

and

$$\begin{aligned} [ESH]_T &= [ESH_2^+] + [ESH] + [ES^-] \\ &= [ESH] \left( \frac{[H^+]}{K_{ES1}} + 1 + \frac{K_{ES2}}{[H^+]} \right) \\ &= [ESH]f_2 \end{aligned} \quad [14.A22]$$

Then making the steady-state assumption

$$\frac{d[ESH]}{dt} = k_1[EH][S] - (k_{-1} + k_2)[ESH] = 0 \quad [14.A23]$$

and solving for  $[EH]$

$$[EH] = \frac{(k_{-1} + k_2)[ESH]}{k_1[S]} = \frac{K_M[ESH]}{[S]} \quad [14.A24]$$

Therefore, from Eq. [14.A21],

$$[EH]_T = \frac{K_M[ESH]f_1}{[S]} \quad [14.A25]$$

which, together with Eqs. [14.A20] and [14.A22], yields

$$[E]_T = [ESH] \left( \frac{K_M f_1}{[S]} + f_2 \right) \quad [14.A26]$$

As in the simple Michaelis–Menten derivation, the initial rate is

$$v_o = k_2[ESH] = \frac{k_2[E]_T}{\left( \frac{K_M f_1}{[S]} \right) + f_2} = \frac{(k_2/f_2)[E]_T[S]}{K_M(f_1/f_2) + [S]} \quad [14.A27]$$

Then defining the “apparent” values of  $K_M$  and  $V_{\max} = k_2[E]_T$  at a given pH:

$$K'_M = K_M(f_1/f_2) \quad [14.A28]$$

and

$$V'_{\max} = V_{\max}/f_2 \quad [14.A29]$$

the Michaelis–Menten equation modified to account for pH effects is

$$v_o = \frac{V'_{\max}[S]}{K'_M + [S]} \quad [14.47]$$

## CHAPTER SUMMARY

**1 Chemical Kinetics** Complicated reaction processes occur through a series of elementary reaction steps defined as having a molecularity equal to the number of molecules that simultaneously collide to form products. The order of a reaction can be determined from the characteristic functional form of its progress curve. Transition state theory postulates that the rate of a reaction depends on the free energy of formation of its activated complex. This complex, which occurs at the free energy maximum of the reaction coordinate, is poised between reactants and products and is therefore also known as the transition state. Transition state theory explains that catalysis results from the reduction of the free energy difference between the reactants and the transition state.

**2 Enzyme Kinetics** In the simplest enzymatic mechanism, the enzyme and substrate reversibly combine to form an enzyme–substrate complex known as the Michaelis complex, which may irreversibly decompose to form product and the regenerated enzyme. The rate of product formation is expressed by the Michaelis–Menten equation, which is derived under the assumption that the concentration of the Michaelis complex is constant, that is, at a steady state. The Michaelis–Menten equation, which has the functional form of a rectangular hyperbola, has two parameters:  $V_{\max}$ , the maximal rate of the reaction, which occurs when the substrate concentration is saturating, and  $K_M$ , the Michaelis constant, which has the value of the substrate concentration at the half-maximal reaction rate.

These parameters may be graphically determined using the Lineweaver–Burk plot. Physically more realistic models of enzyme mechanisms than the Michaelis–Menten model assume the enzymatic reaction to be reversible and to have one or more intermediates. The functional form of the equations describing the reaction rates for these models is independent of their number of intermediates, so that the models cannot be differentiated using only steady-state kinetic measurements.

**3 Inhibition** Enzymes may be inhibited by competitive inhibitors, which compete with the substrate for the enzymatic binding site. The effect of a competitive inhibitor may be reversed by increasing the substrate concentration. An uncompetitive inhibitor inactivates a Michaelis complex on binding to it. The maximal rate of an uncompetitively inhibited enzyme is a function of inhibitor concentration, and therefore the effect of an uncompetitive inhibitor cannot be reversed by increasing substrate concentration. In mixed inhibition, the inhibitor binds to both the enzyme and the enzyme–substrate complex to form a complex that is catalytically inactive. The rate equation describing this situation has characteristics of both competitive and uncompetitive reactions.

**4 Effects of pH** The rate of an enzymatic reaction is a function of hydrogen ion concentration. At any pH, the rate of a simple enzymatic reaction can be described by the Michaelis–Menten equation. However, its parameters  $V_{\max}$  and  $K_M$  vary with pH. By the evaluation of kinetic rate curves

as a function of pH, the  $pK$ 's of an enzyme's ionizable binding and catalytic groups can be determined, which may help identify these groups.

**5 Bisubstrate Reactions** The majority of enzymatic reactions are bisubstrate reactions in which two substrates react to form two products. Bisubstrate reactions may have Ordered or Random Sequential mechanisms or Ping Pong Bi Bi mechanisms, among others. The initial rate equations for any of these

mechanisms involve five parameters, which are analogous to either Michaelis–Menten equation parameters or equilibrium constants. The various bisubstrate mechanisms may be experimentally differentiated according to the forms of their double-reciprocal plots and from the nature of their product inhibition patterns. Isotope exchange reactions provide an additional, nonkinetic method of differentiating bisubstrate mechanisms.

## PROBLEMS

1. The hydrolysis of sucrose:

takes the following time course.

Time (min)	[Sucrose] (M)
0	0.5011
30	0.4511
60	0.4038
90	0.3626
130	0.3148
180	0.2674

Determine the first-order rate constant and the half-life of the reaction. Why does this bimolecular reaction follow a first-order rate law? How long will it take to hydrolyze 99% of the sucrose initially present? How long will it take if the amount of sucrose initially present is twice that given in the table?

2. By what factor will a reaction at 25°C be accelerated if a catalyst reduces the free energy of its activated complex by 1 kJ · mol<sup>-1</sup>; by 10 kJ · mol<sup>-1</sup>?

3. For a Michaelis–Menten reaction,  $k_1 = 5 \times 10^7 \text{ M}^{-1} \cdot \text{s}^{-1}$ ,  $k_{-1} = 2 \times 10^4 \text{ s}^{-1}$ , and  $k_2 = 4 \times 10^2 \text{ s}^{-1}$ . Calculate  $K_S$  and  $K_M$  for this reaction. Does substrate binding achieve equilibrium or the steady state?

\*4. The following table indicates the rates at which a substrate reacts as catalyzed by an enzyme that follows the Michaelis–Menten mechanism: (1) in the absence of inhibitor; (2) and (3) in the presence of 10 mM concentration, respectively, of either of two inhibitors. Assume  $[E]_T$  is the same for all reactions.

[S] (mM)	(1) $v_o$ ( $\mu\text{M} \cdot \text{s}^{-1}$ )	(2) $v_o$ ( $\mu\text{M} \cdot \text{s}^{-1}$ )	(3) $v_o$ ( $\mu\text{M} \cdot \text{s}^{-1}$ )
1	2.5	1.17	0.77
2	4.0	2.10	1.25
5	6.3	4.00	2.00
10	7.6	5.7	2.50
20	9.0	7.2	2.86

(a) Determine  $K_M$  and  $V_{\text{max}}$  for the enzyme. For each inhibitor determine the type of inhibition and  $K_I$  and/or  $K_I'$ . What additional information would be required to calculate the turnover number

of the enzyme? (b) For  $[S] = 5 \text{ mM}$ , what fraction of the enzyme molecules have a bound substrate in the absence of inhibitor, in the presence of  $10 \text{ mM}$  inhibitor of type (2), and in the presence of  $10 \text{ mM}$  inhibitor of type (3)?

**\*5.** Ethanol in the body is oxidized to acetaldehyde ( $\text{CH}_3\text{CHO}$ ) by liver alcohol dehydrogenase (LADH). Other alcohols are also oxidized by LADH. For example, methanol, which is mildly intoxicating, is oxidized by LADH to the quite toxic product formaldehyde ( $\text{CH}_2\text{O}$ ). The toxic effects of ingesting methanol (a component of many commercial solvents) can be reduced by administering ethanol. The ethanol acts as a competitive inhibitor of the methanol by displacing it from LADH. This provides sufficient time for the methanol to be harmlessly excreted by the kidneys. If an individual has ingested  $100 \text{ mL}$  of methanol (a lethal dose), how much  $100 \text{ proof}$  whiskey (50% ethanol by volume) must he imbibe to reduce the activity of his LADH toward methanol to 5% of its original value? The adult human body contains  $\sim 40 \text{ L}$  of aqueous fluids throughout which ingested alcohols are rapidly and uniformly mixed. The densities of ethanol and methanol are both  $0.79 \text{ g} \cdot \text{cm}^{-3}$ . Assume the  $K_M$  values of LADH for ethanol and methanol to be  $1.0 \times 10^{-3} \text{ M}$  and  $1.0 \times 10^{-2} \text{ M}$ , respectively, and that  $K_I = K_M$  for ethanol.

**6.** The  $K_M$  of a Michaelis–Menten enzyme for a substrate is  $1.0 \times 10^{-4} \text{ M}$ . At a substrate concentration of  $0.2 \text{ M}$ ,  $v_o = 43 \mu\text{M} \cdot \text{min}^{-1}$  for a certain enzyme concentration. However, with a substrate concentration of  $0.02 \text{ M}$ ,  $v_o$  has the same value. (a) Using numerical calculations, show that this observation is accurate. (b) What is the best range of  $[S]$  for measuring  $K_M$ ?

**7.** Why are uncompetitive and mixed inhibitors generally considered to be more effective *in vivo* than competitive inhibitors?

**8.** Explain why an exact fit to a kinetic model of the experimental parameters describing a reaction does not prove that the reaction follows the model.

**9.** An enzyme that follows the model for pH effects presented in Section 14-4a has  $\text{p}K_{\text{ES1}} = 4$  and  $\text{p}K_{\text{ES2}} = 8$ . What is the pH at which  $V'_{\text{max}}$  is a maximum for this enzyme? What fraction of  $V_{\text{max}}$  does  $V'_{\text{max}}$  achieve at this pH?

**10.** Derive the initial rate equation for a Rapid Equilibrium Random Bi Bi reaction. Assume the equilibrium constants  $K_S^A$  and

$K_S^B$  for binding A and B to the enzyme are independent of whether the other substrate is bound (an assumption that constrains  $K_M^B = K_S^B$  in Eq. [14.49]).

**\*11.** Consider the following variation of a Ping Pong Bi Bi mechanism.

Assume that the substrate-binding reactions are in rapid equilibrium,

$$K_S^A = \frac{[\text{E}][\text{A}]}{[\text{EA}]} \quad \text{and} \quad K_S^B = \frac{[\text{F}][\text{B}]}{[\text{FB}]}$$

that both  $[\text{A}] \gg [\text{E}]_T$  and  $[\text{B}] \gg [\text{E}]_T$ , that neither product release reaction is reversible, and that the steady-state approximation is valid. (a) Derive an expression for  $v_o$  in terms of  $K_S^A$ ,  $K_S^B$ ,  $k_2$ , and  $k_4$ . (b) Indicate the form of the double-reciprocal plots for  $1/v_o$  versus  $1/[\text{A}]$  for various values of  $[\text{B}]$ . (c) Indicate the form of the double-reciprocal plots for  $1/v_o$  versus  $1/[\text{B}]$  for various values of  $[\text{A}]$ .

**12.** Creatine kinase catalyzes the reaction

which functions to regenerate ATP in muscle. Rabbit muscle creatine kinase exhibits the following kinetic behavior. In the absence of both products, plots of  $1/v_o$  versus  $1/[\text{MgADP}^-]$  at different fixed concentrations of phosphocreatine yield lines that intersect to the left of the  $1/v_o$  axis. Similarly, plots of  $1/v_o$  versus  $1/[\text{phosphocreatine}]$  in the absence of product at different fixed concentrations of  $\text{MgADP}^-$  yield lines that intersect to the left of the  $1/v_o$  axis. In the absence of one of the reaction products,  $\text{MgATP}^{2-}$  or creatine, plots of  $1/v_o$  versus  $1/[\text{MgADP}^-]$  at different concentrations of the other product intersect on the  $1/v_o$  axis. The same is true of the plots of  $1/v_o$  versus  $1/[\text{phosphocreatine}]$ . Indicate a kinetic mechanism that is consistent with this information.

- C. HIV Protease and Its Inhibitors

Enzymes, as we have seen, cause rate enhancements that are orders of magnitude greater than those of the best chemical catalysts. Yet they operate under mild conditions and are highly specific as to the identities of both their substrates and their products. These catalytic properties are so remarkable that many nineteenth century scientists concluded that enzymes have characteristics that are not shared by substances of nonliving origin. To this day, there are few enzymes for which we understand in more than cursory detail how they achieve their enormous rate accelerations. Nevertheless, it is now abundantly clear that the catalytic mechanisms employed by enzymes are identical to those used by chemical catalysts. Enzymes are simply better designed.

In this chapter we consider the nature of enzymatic catalysis. We begin by discussing the underlying principles of chemical catalysis as elucidated through the study of organic reaction mechanisms. We then embark on a detailed examination of the catalytic mechanisms of several of the best characterized enzymes: **lysozyme** and the **serine proteases**. Their study should lead to an appreciation of the intricacies of these remarkably efficient catalysts as well as of the experimental methods used to elucidate their proper-

ties. We end with a discussion of how drugs are discovered and tested, a process that depends heavily on the principles of enzymology since many drug targets are enzymes. In doing so, we consider how therapeutically effective inhibitors of **HIV-1 protease** were discovered.

## 1 CATALYTIC MECHANISMS

*Catalysis is a process that increases the rate at which a reaction approaches equilibrium.* Since, as we discussed in Section 14-1Cb, the rate of a reaction is a function of its free energy of activation ( $\Delta G^\ddagger$ ), a catalyst acts by lowering the height of this kinetic barrier; that is, a catalyst stabilizes the transition state with respect to the uncatalyzed reaction. There is, in most cases, nothing unique about enzymatic mechanisms of catalysis in comparison to nonenzymatic mechanisms. *What apparently make enzymes such powerful catalysts are two related properties: their specificity of substrate binding combined with their optimal arrangement of catalytic groups.* An enzyme's arrangement of binding and catalytic groups is, of course, the product of eons of evolution: Nature has had ample opportunity to fine-tune the performances of most enzymes.

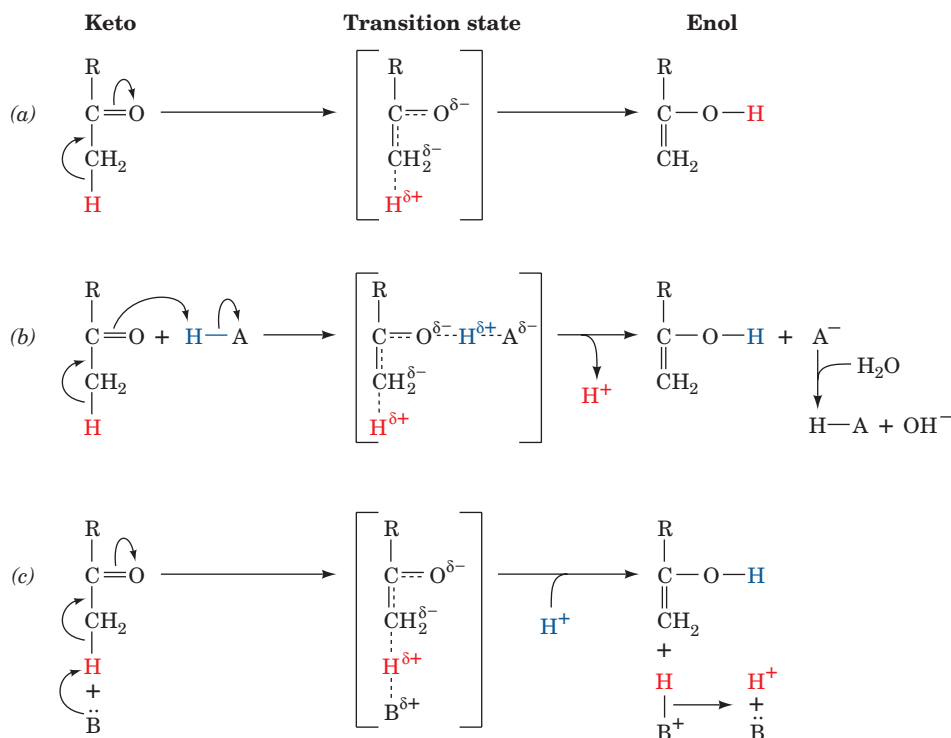

The types of catalytic mechanisms that enzymes employ have been classified as:

1. Acid–base catalysis.
2. Covalent catalysis.
3. Metal ion catalysis.
4. Electrostatic catalysis.
5. Proximity and orientation effects.
6. Preferential binding of the transition state complex.

In this section, we examine these various phenomena. In doing so we shall frequently refer to the organic model compounds that have been used to characterize these catalytic mechanisms.

### A. Acid–Base Catalysis

*General acid catalysis is a process in which partial proton transfer from a Brønsted acid (a species that can donate protons; Section 2-2A) lowers the free energy of a reaction's transition state.* For example, an uncatalyzed keto–enol tautomerization reaction occurs quite slowly as a result of

**Figure 15-1** Mechanisms of keto–enol tautomerization. (a) Uncatalyzed, (b) general acid catalyzed, and (c) general base catalyzed.

the high energy of its carbanionlike transition state (Fig. 15-1a). Proton donation to the oxygen atom (Fig. 15-1b), however, reduces the carbanion character of the transition state, thereby catalyzing the reaction. A reaction may also be stimulated by **general base catalysis** if its rate is increased by partial proton abstraction by a Brønsted base (a species that can combine with a proton; Fig. 15-1c). Some reactions may be simultaneously subject to both processes: a **concerted general acid–base catalyzed reaction**.

#### a. Mutarotation Is Catalyzed by Acids and by Bases

The mutarotation of glucose provides an instructive example of acid–base catalysis. Recall that a glucose molecule can assume either of two anomeric cyclic forms through the intermediacy of its linear form (Section 11-1B):

In aqueous solvents, the initial rate of mutarotation of  $\alpha\text{-D-glucose}$ , as monitored by polarimetry (Section 4-2A), is observed to follow the relationship:

$$v = -\frac{d[\alpha\text{-D-glucose}]}{dt} = k_{\text{obs}}[\alpha\text{-D-glucose}] \quad [15.1]$$

where  $k_{\text{obs}}$  is the reaction's apparent first-order rate constant. The mutarotation rate increases with the concentrations of general acids and general bases; they are thought to catalyze mutarotation according to the mechanism:

This model is consistent with the observation that in aprotic solvents such as benzene, **2,3,4,6-O-tetramethyl- $\alpha$ -D-glucose** (a less polar benzene-soluble analog)

**2,3,4,6-O-Tetramethyl- $\alpha$ -D-glucose**

does not undergo mutarotation. Yet, the reaction is catalyzed by the addition of phenol, a weak benzene-soluble acid, together with pyridine, a weak benzene-soluble base, according to the rate equation:

$$v = k[\text{phenol}][\text{pyridine}][\text{tetramethyl-}\alpha\text{-D-glucose}] \quad [15.2]$$

Moreover, in the presence of  **$\alpha$ -pyridone**, whose acid and base groups can rapidly interconvert between two tautomeric forms and are situated so that they can simultaneously catalyze mutarotation,

the reaction follows the rate law

$$v = k'[\alpha\text{-pyridone}][\text{tetramethyl-}\alpha\text{-D-glucose}] \quad [15.3]$$

where  $k' = 7000M \times k$ . This increased rate constant indicates that  $\alpha$ -pyridone does, in fact, catalyze mutarotation in a concerted fashion since  $1M$   $\alpha$ -pyridone has the same catalytic effect as impossibly high concentrations of phenol and pyridine (e.g.,  $70M$  phenol and  $100M$  pyridine).

Many types of biochemically significant reactions are susceptible to acid and/or base catalysis. These include the hydrolysis of peptides and esters, the reactions of phosphate groups, tautomerizations, and additions to carbonyl groups. The side chains of the amino acid residues Asp, Glu, His, Cys, Tyr, and Lys have  $pK$ 's in or near the physiological pH range (Table 4-1), which we shall see permits them to act in the enzymatic capacity of general acid and/or base catalysts in analogy with known organic mechanisms. Indeed, the ability of enzymes to arrange several catalytic groups about their substrates makes concerted acid-base catalysis a common enzymatic mechanism.

### b. The RNase A Reaction Incorporates General Acid-Base Catalysis

**Bovine pancreatic ribonuclease A (RNase A)** provides an illuminating example of enzymatically mediated general acid-base catalysis. This digestive enzyme functions to

hydrolyze RNA to its component nucleotides. The isolation of **2',3'-cyclic nucleotides** from RNase A digests of RNA indicates that the enzyme mediates the following reaction sequence:

The RNase A reaction exhibits a pH rate profile that peaks near pH 6 (Fig. 15-2). Analysis of this curve (Section 14-4b), together with chemical derivatization and X-ray studies, indicates that RNase A has two essential His residues, His 12 and His 119, which act in a concerted manner as general acid and base catalysts (the structure of RNase A is sketched in Fig. 9-2). Evidently, the RNase A reaction is a two-step process (Fig. 15-3):

1. His 12, acting as a general base, abstracts a proton from an RNA 2'-OH group, thereby promoting its nucleophilic

**Figure 15-2** The pH dependence of  $V_{\max}/K'_M$  in the RNase A-catalyzed hydrolysis of cytidine-2',3'-cyclic phosphate.  $V_{\max}/K'_M$  is in units of  $M^{-1} \cdot s^{-1}$ . Analysis of this curve (Section 14-4b) suggests the catalytic participation of groups with  $pK$ 's of 5.4 and 6.4. [After del Rosario, E.J. and Hammes, G.G., *Biochemistry* **8**, 1887 (1969).]

**Figure 15-3** The bovine pancreatic RNase A-catalyzed hydrolysis of RNA is a two-step process with the intermediate formation of a 2',3'-cyclic nucleotide.

attack on the adjacent phosphorus atom while His 119, acting as a general acid, promotes bond scission by protonating the leaving group.

2. The 2',3'-cyclic intermediate is hydrolyzed through what is essentially the reverse of the first step in which water replaces the leaving group. Thus His 12 acts as a general acid and His 119 as a general base to yield the hydrolyzed RNA and the enzyme in its original state.

## B. Covalent Catalysis

Covalent catalysis involves rate acceleration through the transient formation of a catalyst–substrate covalent bond. The decarboxylation of **acetoacetate**, as chemically catalyzed by primary amines, is an example of such a process (Fig. 15-4). In the first stage of this reaction, the amine nucleophilically attacks the carbonyl group of acetoacetate to form a **Schiff base** (imine bond).

The protonated nitrogen atom of the covalent intermediate then acts as an electron sink (Fig. 15-4, bottom) so as to reduce the otherwise high-energy enolate character of the transition state. The formation and decomposition of the Schiff base occur quite rapidly, so that these steps are not rate determining in this reaction sequence.

### a. Covalent Catalysis Has Both Nucleophilic and Electrophilic Stages

As the preceding example indicates, covalent catalysis may be conceptually decomposed into three stages:

**Figure 15-4** The decarboxylation of acetoacetate. The uncatalyzed reaction mechanism is shown at the top and the reaction mechanism as catalyzed by primary amines is shown at the bottom.

1. The nucleophilic reaction between the catalyst and the substrate to form a covalent bond.

2. The withdrawal of electrons from the reaction center by the now electrophilic catalyst.

3. The elimination of the catalyst, a reaction that is essentially the reverse of stage 1.

Reaction mechanisms are somewhat arbitrarily classified as occurring with either **nucleophilic catalysis** or **electrophilic catalysis** depending on which of these effects provides the greater driving force for the reaction, that is, which catalyzes its rate-determining step. The primary amine–catalyzed decarboxylation of acetoacetate is clearly an electrophilically catalyzed reaction since its nucleophilic phase, Schiff base formation, is not its rate-determining step. In other covalently catalyzed reactions, however, the nucleophilic phase may be rate determining.

The nucleophilicity of a substance is closely related to its basicity. Indeed, the mechanism of nucleophilic catalysis resembles that of general base catalysis except that, instead of abstracting a proton from the substrate, the catalyst nucleophilically attacks it so as to form a covalent bond. Consequently, if covalent bond formation is the rate-determining step of a covalently catalyzed reaction, the reaction rate tends to increase with the covalent catalyst's basicity ( $pK$ ).

An important aspect of covalent catalysis is that the more stable the covalent bond formed, the less readily it will decompose in the final steps of a reaction. A good covalent catalyst must therefore combine the seemingly contradictory properties of high nucleophilicity and the ability to form a good leaving group, that is, to easily reverse the bond formation step. Groups with high polarizabilities (highly mobile electrons), such as imidazole and thiol functions, have these properties and hence make good covalent catalysts.

### b. Certain Amino Acid Side Chains and Coenzymes Can Serve as Covalent Catalysts

Enzymes commonly employ covalent catalytic mechanisms as is indicated by the large variety of covalently linked enzyme–substrate reaction intermediates that have been isolated. For example, the enzymatic decarboxylation of acetoacetate proceeds, much as described above, through Schiff base formation with an enzyme Lys residue’s  $\epsilon$ -amino group. The covalent intermediate, in this case, has been isolated through  $\text{NaBH}_4$  reduction of its imine bond to an amine, thereby irreversibly inhibiting the enzyme. Other enzyme functional groups that participate in covalent catalysis include the imidazole moiety of His, the thiol group of Cys, the carboxyl function of Asp, and the hydroxyl group of Ser. In addition, several coenzymes, most notably **thiamine pyrophosphate** (Section 17-3Ba) and **pyridoxal phosphate** (Section 26-1Aa), function in association with their apoenzymes mainly as covalent catalysts.

### c. Metal Ion Catalysis

Nearly one-third of all known enzymes require the presence of metal ions for catalytic activity. There are two classes of metal ion–requiring enzymes that are distinguished by the strengths of their ion–protein interactions:

1. **Metalloenzymes** contain tightly bound metal ions, most commonly transition metal ions such as  $\text{Fe}^{2+}$ ,  $\text{Fe}^{3+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Mn}^{2+}$ , or  $\text{Co}^{3+}$ .

2. **Metal-activated enzymes** loosely bind metal ions from solution, usually the alkali and alkaline earth metal ions  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$ , or  $\text{Ca}^{2+}$ .

Metal ions participate in the catalytic process in three major ways:

1. By binding to substrates so as to orient them properly for reaction.
2. By mediating oxidation–reduction reactions through reversible changes in the metal ion’s oxidation state.
3. By electrostatically stabilizing or shielding negative charges.

In this section we shall be mainly concerned with the third aspect of metal ion catalysis. The other forms of enzyme-mediated metal ion catalysis are considered in later chapters in conjunction with discussions of specific enzyme mechanisms.

#### a. Metal Ions Promote Catalysis through Charge Stabilization

In many metal ion–catalyzed reactions, the metal ion acts in much the same way as a proton to neutralize negative charge, that is, it acts as a Lewis acid. Yet *metal ions are often much more effective catalysts than protons because metal ions can be present in high concentrations at neutral pH’s and can have charges greater than +1*. Metal ions have therefore been dubbed “superacids.”

The decarboxylation of **dimethyloxaloacetate**, as catalyzed by metal ions such as  $\text{Cu}^{2+}$  and  $\text{Ni}^{2+}$ , is a nonenzymatic example of catalysis by a metal ion:

Here the metal ion ( $\text{M}^{n+}$ ), which is chelated by the dimethyloxaloacetate, electrostatically stabilizes the developing enolate ion of the transition state. This mechanism is supported by the observation that acetoacetate, which cannot form such a chelate, is not subject to metal ion–catalyzed decarboxylation. Most enzymes that decarboxylate oxaloacetate require a metal ion for activity.

#### b. Metal Ions Promote Nucleophilic Catalysis via Water Ionization

A metal ion’s charge makes its bound water molecules more acidic than free  $\text{H}_2\text{O}$  and therefore a source of  $\text{OH}^-$  ions even below neutral pH’s. For example, the water molecule of  $(\text{NH}_3)_5\text{Co}^{3+}(\text{H}_2\text{O})$  ionizes according to the reaction:

with a  $\text{p}K$  of 6.6, which is  $\sim 9$  pH units below the  $\text{p}K$  of free  $\text{H}_2\text{O}$ . The resulting metal ion–bound hydroxyl group is a potent nucleophile.

An instructive example of this phenomenon occurs in the catalytic mechanism of **carbonic anhydrase** (Section 10-1C), a widely occurring enzyme that catalyzes the reaction:

Carbonic anhydrase contains an essential  $\text{Zn}^{2+}$  ion that lies at the bottom of an  $\sim 15\text{-\AA}$ -deep active site cleft (Fig. 8-41), where it is tetrahedrally coordinated by three evolutionarily invariant His side chains and an O atom of either an

(a)

(b)

**Figure 15-5** X-ray structures of human carbonic anhydrase.

(a) Its active site in complex with bicarbonate ion. The polypeptide is shown in ribbon form (gold) with its side chains shown in stick form colored according to atom type (C green, N blue, and O red). The protein-bound  $\text{Zn}^{2+}$  ion (cyan sphere) is tetrahedrally liganded (gray bonds) by three invariant His side chains and the  $\text{HCO}_3^-$  ion, which is shown in ball-and-stick form. The  $\text{HCO}_3^-$  ion also interacts with the protein via van der Waals contacts (dot surface colored according to atom type) and a hydrogen bonded network (dashed gray lines) involving Thr 199 and Glu 106. [Based on an X-ray structure by K.K. Kannan, Bhabha Atomic Research Center, Bombay, India. PDBid 1HCB.]

(b) The active site showing the proton shuttle through which His 64, acting as a general base, abstracts a proton from the  $\text{Zn}^{2+}$ -bound  $\text{H}_2\text{O}$  to form an  $\text{OH}^-$  ion. The polypeptide backbone is shown in ribbon form (cyan), and its side chains and several bound solvent molecules are shown in ball-and-stick form with C black, N blue, and O red. The proton shuttle consists of two water molecules that form a hydrogen bonded network (dotted white lines) that bridges the  $\text{Zn}^{2+}$ -bound  $\text{OH}^-$  ion and His 64 in its “in” conformation. On protonation, His 64 swings to the “out” conformation. [Courtesy of David Christianson, University of Pennsylvania.]  See Interactive Exercise 3

$\text{HCO}_3^-$  ion (Fig. 15-5a) or a water molecule (Fig. 15-5b). The enzyme has the following catalytic mechanism:

1. We begin with a water molecule bound to the protein in the  $\text{Zn}^{2+}$  ion's fourth liganding position (Fig. 15-5b). This  $\text{Zn}^{2+}$ -polarized  $\text{H}_2\text{O}$  ionizes in a process facilitated through general base catalysis by His 64 in its “in” conformation. Although His 64 is too far away from the  $\text{Zn}^{2+}$ -bound water to directly abstract its proton, these entities are linked by two intervening water molecules to form a hydrogen bonded network that is thought to act as a proton shuttle.

2. The resulting  $\text{Zn}^{2+}$ -bound  $\text{OH}^-$  ion nucleophilically attacks the nearby enzymatically bound  $\text{CO}_2$ , thereby converting it to  $\text{HCO}_3^-$ .

In doing so, the  $\text{Zn}^{2+}$ -bound  $\text{OH}^-$  group donates a hydrogen bond to Thr 199, which in turn donates a hydrogen bond to Glu 106 (Fig. 15-5a). These interactions orient the  $\text{OH}^-$  group with the optimal geometry (see below) for nucleophilic attack on the substrate  $\text{CO}_2$ .

3. The catalytic site is regenerated by the exchange of the  $\text{Zn}^{2+}$ -bound  $\text{HCO}_3^-$  reaction product for  $\text{H}_2\text{O}$  together

with the deprotonation of His 64. In the latter process, His 64 swings to its “out” conformation (Fig. 15-5b), which may facilitate proton transfer to the bulk solvent.

### C. Metal Ions Promote Reactions through Charge Shielding

Another important enzymatic function of metal ions is **charge shielding**. For example, the actual substrates of **kinases** (phosphoryl-transfer enzymes utilizing ATP) are  $\text{Mg}^{2+}$ -ATP complexes such as

rather than just ATP. Here, the  $\text{Mg}^{2+}$  ion's role, in addition to its orienting effect, is to shield electrostatically the negative charges of the phosphate groups. Otherwise, these charges would tend to repel the electron pairs of attacking nucleophiles, especially those with anionic character.

### D. Electrostatic Catalysis

The binding of substrate generally excludes water from an enzyme's active site. The local dielectric constant of the active site therefore resembles that in an organic solvent, where electrostatic interactions are much stronger than they are in aqueous solutions (Section 8-4A). The charge distribution in a medium of low dielectric constant can greatly influence chemical reactivity. Thus, as we have seen, the  $\text{p}K$ 's of amino acid side chains in proteins may vary by several units from their nominal values (Table 4-1) because of the proximity of charged groups.

Although experimental evidence and theoretical analyses on the subject are still sparse, there are mounting indications that the charge distributions about the active sites of enzymes are arranged so as to stabilize the transition states of the catalyzed reactions. Such a mode of rate enhancement, which resembles the form of metal ion catalysis discussed above, is termed **electrostatic catalysis**. Moreover, in several enzymes, these charge distributions apparently serve to guide polar substrates toward their binding sites so that the rates of these enzymatic reactions are greater than their apparent diffusion-controlled limits (Section 14-2Bb).

### E. Catalysis through Proximity and Orientation Effects

Although enzymes employ catalytic mechanisms that resemble those of organic model reactions, they are far more catalytically efficient than these models. Such efficiency must arise from the specific physical conditions at enzyme catalytic sites that promote the corresponding chemical reactions. The most obvious effects are **proximity** and **orientation**: Reactants must come together with the proper spatial relationship for a reaction to occur. For example, in the

bimolecular reaction of imidazole with *p*-nitrophenylacetate,

the progress of the reaction is conveniently monitored by the appearance of the intensely yellow ***p*-nitrophenolate ion**:

$$\frac{d[p\text{-NO}_2\phi\text{O}^-]}{dt} = k_1[\text{imidazole}][p\text{-NO}_2\phi\text{Ac}] = k_1'[p\text{-NO}_2\phi\text{Ac}] \quad [15.4]$$

where  $\phi$  = phenyl. Here  $k_1'$ , the pseudo-first-order rate constant, is  $0.0018 \text{ s}^{-1}$  when  $[\text{imidazole}] = 1M$ . However, for the intramolecular reaction

the first-order rate constant  $k_2 = 0.043 \text{ s}^{-1}$ ; that is,  $k_2 = 24 k_1'$ . Thus, when the  $1M$  imidazole catalyst is covalently attached to the reactant, it is 24-fold more effective than when it is free in solution; that is, the imidazole group in the intramolecular reaction behaves as if its concentration is  $24M$ . This rate enhancement has contributions from both proximity and orientation.

#### a. Proximity Alone Contributes Relatively Little to Catalysis

Let us make a rough calculation as to how the rate of a reaction is affected purely by the proximity of its reacting groups. Following Daniel Koshland's treatment, we shall make several reasonable assumptions:

1. Reactant species, that is, functional groups, are about the size of water molecules.
2. Each reactant species in solution has 12 nearest-neighbor molecules, as do packed spheres of identical size.

3. Chemical reactions occur only between reactants that are in contact.

4. The reactant concentration in solution is low enough so that the probability of any reactant species being in simultaneous contact with more than one other reactant molecule is negligible.

Then the reaction:

obeys the second-order rate equation

$$v = \frac{d[A-B]}{dt} = k_1[A][B] = k_2[A, B]_{pairs} \quad [15.5]$$

where  $[A, B]_{pairs}$  is the concentration of contacting molecules of A and B. The value of this quantity is

$$[A, B]_{pairs} = \frac{12[A][B]}{55.5M} \quad [15.6]$$

since there are 12 ways that A can be in contact with B, and  $[A]/55.5M$  is the fraction of sites occupied by A in water solution ( $[H_2O] = 55.5M$  in dilute aqueous solutions) and hence the probability that a molecule of B will be next to one of A. Combining Eqs. [15.5] and [15.6] yields

$$v = k_1 \left( \frac{55.5}{12} \right) [A, B]_{pairs} = 4.6k_1 [A, B]_{pairs} \quad [15.7]$$

Thus, in the absence of other effects, this model predicts that for the intramolecular reaction,

**Figure 15-6** The geometry of an  $S_N2$  reaction. The attacking nucleophile,  $Y^-$ , must approach the tetrahedrally coordinated and hence  $sp^3$ -hybridized C atom along the direction opposite that of its bond to the leaving group, X, a process called **backside attack**. In the transition state of the reaction, the C atom becomes trigonal bipyramidally coordinated and hence  $sp^2$ - $p$  hybridized, with the  $p$  orbital (blue) forming partial bonds to X and Y. The three  $sp^2$  orbitals form bonds to the C atom's three

$k_2 = 4.6k_1$ , which is a rather small rate enhancement. Factors that will increase this value other than proximity alone clearly must be considered.

#### b. Properly Orienting Reactants and Arresting Their Relative Motions Can Result in Large Catalytic Rate Enhancements

The foregoing theory is, of course, quite simple. For example, it does not take into account the relative orientations of the reacting molecules. Yet molecules are not equally reactive in all directions as Koshland's simple theory assumes. Rather, *they react most readily only if they have the proper relative orientation*. For example, in an  $S_N2$  (bimolecular nucleophilic substitution) reaction, the incoming nucleophile optimally attacks its target C atom along the direction opposite to that of the bond to the leaving group (Fig. 15-6). The approaches of reacting atoms along a trajectory that deviates by as little as  $10^\circ$  from this optimum direction can reduce the reaction rate by as much as a factor of  $\sim 100$ . In a related phenomenon, a molecule may be maximally reactive only when it assumes a conformation that aligns its various orbitals in a way that minimizes the electronic energy of its transition state, an effect termed **stereoelectronic assistance** or **stereoelectronic control**.

Another effect that we have neglected in our treatment of proximity is that of motions of the reacting groups with respect to one another. Yet, in the transition state complex, the reacting groups have little relative motion. In fact, as Thomas Bruice demonstrated, the rates of intramolecular reactions are greatly increased by arresting a molecule's internal motions in a way that increases the mole fraction of the reacting groups that are in a conformation which can

other substituents (R, R', and R''), which have shifted their positions into the plane perpendicular to the X—C—Y axis (curved arrows). Any deviation from this optimal geometry would increase the free energy of the transition state,  $\Delta G^\ddagger$ , and hence reduce the rate of the reaction (Eq. [14.15]). The transition state then decomposes to products in which the R, R', and R'' have inverted their positions about the C atom, which has rehybridized to  $sp^3$ , and  $X^-$  has been released.

enter the transition state (Table 15-1). Similarly, when an enzyme brings two molecules together in a bimolecular reaction, as William Jencks pointed out, not only does it increase their proximity, but it freezes out their relative translational and rotational motions (decreases their entropy), thereby enhancing their reactivity. Theoretical studies by Bruice indicate that much of this rate enhancement can arise from the enzymatic binding of substrates in a conformation that readily enters the transition state.

*Enzymes, as we shall see in Sections 16-2 and 16-3, bind substrates in a manner that both aligns and immobilizes them so as to optimize their reactivities. The free energy required to do so is derived from the specific binding free energy of substrate to enzyme.*

### F. Catalysis by Preferential Transition State Binding

The rate enhancements effected by enzymes are often greater than can be reasonably accounted for by the catalytic mechanisms so far discussed. However, we have not yet considered one of the most important mechanisms of enzymatic catalysis: *the binding of the transition state to an enzyme with greater affinity than the corresponding substrates or products.* When taken together with the previously described catalytic mechanisms, preferential transition state binding rationalizes the observed rates of enzymatic reactions.

The original concept of transition state binding proposed that enzymes mechanically strained their substrates toward the transition state geometry through binding sites into which undistorted substrates did not properly fit. This so-called **rack mechanism** (in analogy with the medieval torture device) was based on the extensive evidence for the role of strain in promoting organic reactions. For example, the rate of the reaction,

is 315 times faster when R is CH<sub>3</sub> rather than when it is H because of the greater steric repulsions between the CH<sub>3</sub> groups and the reacting groups. Similarly, ring opening reactions are considerably more facile for strained rings such as cyclopropane than for unstrained rings such as cyclohexane. In either process, *the strained reactant more closely resembles the transition state of the reaction than does the corresponding unstrained reactant.* Thus, as was first suggested by Linus Pauling and further amplified by Richard Wolfenden and Gustav Lienhard, *interactions that preferentially bind the transition state increase its concentration and therefore proportionally increase the reaction rate.*

Let us quantitate this statement by considering the kinetic consequences of preferentially binding the transition state of an enzymatically catalyzed reaction involving a single substrate. The substrate S may react to form product P

**Table 15-1** Relative Rates of Anhydride Formation for Esters Possessing Different Degrees of Motional Freedom in the Reaction:

Reactants <sup>a</sup>	Relative Rate Constant
$\text{R}_1\text{-C}(=\text{O})\text{-O-C}_6\text{H}_4\text{-Br}$ + $\text{R}_2\text{-C}(=\text{O})\text{-O}^-$	1.0
	$\sim 1 \times 10^3$
	$\sim 2.3 \times 10^5$
	$\sim 8 \times 10^7$

either spontaneously or through enzymatic catalysis:

The relationships between the various states of these two reaction pathways are indicated in the following scheme:

where

$$K_R = \frac{[\text{ES}]}{[\text{E}][\text{S}]} \quad K_T = \frac{[\text{ES}^\ddagger]}{[\text{E}][\text{S}^\ddagger]}$$

$$K_N^* = \frac{[\text{E}][\text{S}^\ddagger]}{[\text{E}][\text{S}]} \quad K_E^* = \frac{[\text{ES}^\ddagger]}{[\text{ES}]}$$

are all association constants. Consequently,

$$\frac{K_T}{K_R} = \frac{[\text{S}][\text{ES}^\ddagger]}{[\text{S}^\ddagger][\text{ES}]} = \frac{K_E^*}{K_N^*} \quad [15.8]$$

According to transition state theory, Eqs. [14.7] and [14.14], the rate of the uncatalyzed reaction can be expressed

$$v_N = k_N[\text{S}] = \left(\frac{\kappa k_B T}{h}\right)[\text{S}^\ddagger] = \left(\frac{\kappa k_B T}{h}\right)K_N^*[\text{S}] \quad [15.9]$$

Similarly, the rate of the enzymatically catalyzed reaction is

$$v_E = k_E[ES] = \left(\frac{\kappa k_B T}{h}\right)[ES^\ddagger] = \left(\frac{\kappa k_B T}{h}\right)K_E^\ddagger[ES] \quad [15.10]$$

Therefore, combining Eqs. [15.8] to [15.10],

$$\frac{k_E}{k_N} = \frac{K_E^\ddagger}{K_N^\ddagger} = \frac{K_T}{K_R} \quad [15.11]$$

This equation indicates that *the more tightly an enzyme binds its reaction's transition state ( $K_T$ ) relative to the substrate ( $K_R$ ), the greater the rate of the catalyzed reaction ( $k_E$ ) relative to that of the uncatalyzed reaction ( $k_N$ ); that is, catalysis results from the preferential binding and therefore the stabilization of the transition state ( $S^\ddagger$ ) relative to that of the substrate ( $S$ ) (Fig. 15-7).*

According to Eq. [14.15], the ratio of the rates of the catalyzed versus the uncatalyzed reaction is expressed

$$\frac{k_E}{k_N} = \exp[(\Delta G_N^\ddagger - \Delta G_E^\ddagger)/RT] \quad [15.12]$$

A rate enhancement factor of  $10^6$  therefore requires that an enzyme bind its transition state complex with  $10^6$ -fold higher affinity than its substrate, which corresponds to a  $34.2 \text{ kJ} \cdot \text{mol}^{-1}$  stabilization at  $25^\circ\text{C}$ . This is roughly the free energy of two hydrogen bonds. Consequently, *the enzymatic binding of a transition state ( $ES^\ddagger$ ) by two hydrogen bonds that cannot form in the Michaelis complex ( $ES$ ) should result in a rate enhancement of  $\sim 10^6$  based on this effect alone.*

It is commonly observed that the specificity of an enzyme is manifested by its turnover number ( $k_{\text{cat}}$ ) rather than by its substrate-binding affinity. In other words, an enzyme binds poor substrates, which have a low reaction rate, as well as or even better than good ones, which have a high reaction rate. Such enzymes apparently use a good substrate's intrinsic binding energy to stabilize the corresponding transition state; that is, *a good substrate does not necessarily bind to its enzyme with high affinity, but does so on activation to the transition state.*

**Figure 15-7** Reaction coordinate diagrams for a hypothetical enzymatically catalyzed reaction involving a single substrate (blue) and the corresponding uncatalyzed reaction (red).

See the Animated Figures

### a. Transition State Analogs Are Potent Competitive Inhibitors

If an enzyme preferentially binds its transition state, then it can be expected that **transition state analogs**, stable molecules that resemble  $S^\ddagger$  or one of its components, are potent competitive inhibitors of the enzyme. For example, the reaction catalyzed by **proline racemase** from *Clostridium sticklandii* is thought to occur via a planar transition state:

Proline racemase is competitively inhibited by the planar analogs of proline, **pyrrole-2-carboxylate** and  **$\Delta$ -1-pyrroline-2-carboxylate**,

both of which bind to the enzyme with 160-fold greater affinity than does proline. These compounds are therefore thought to be analogs of the transition state in the proline racemase reaction. In contrast, **tetrahydrofuran-2-carboxylate**,

**Tetrahydrofuran-2-carboxylate**

which more closely resembles the tetrahedral structure of proline, is not nearly as good an inhibitor as these compounds. A 160-fold increase in binding affinity corresponds, according to Eq. [15.12], to a  $12.6 \text{ kJ} \cdot \text{mol}^{-1}$  increase in the free energy of binding. This quantity presumably reflects the additional binding affinity that proline racemase has for proline's planar transition state over that of the undistorted molecule.

Hundreds of transition state analogs for various enzymatic reactions have been reported. Some are naturally occurring antibiotics. Others were designed to investigate the mechanisms of particular enzymes and/or to act as specific enzymatic inhibitors for therapeutic or agricultural use. Indeed, as we discuss in Section 15-4C, *the theory that enzymes bind transition states with higher affinity than substrates has led to a rational basis for drug design based on the understanding of specific enzyme reaction mechanisms.*

**Figure 15-8** The alternating NAG–NAM polysaccharide component of bacterial cell walls. The position of the lysozyme cleavage site is shown.

## 2 LYSOZYME

In the following two sections, we shall investigate the catalytic mechanisms of several well-characterized enzymes. In doing so, we shall see how enzymes apply the catalytic principles described in Section 15-1. You should note that *the great catalytic efficiency of enzymes arises from their simultaneous use of several of these catalytic mechanisms.*

**Lysozyme** is an enzyme that destroys bacterial cell walls. It does so, as we saw in Section 11-3Ba, by hydrolyzing the  $\beta(1 \rightarrow 4)$  glycosidic linkages from **N-acetylmuramic acid (NAM)** to **N-acetylglucosamine (NAG)** in the alternating NAM–NAG polysaccharide component of cell wall peptidoglycans (Fig. 15-8). It likewise hydrolyzes  $\beta(1 \rightarrow 4)$ -linked poly(NAG) (chitin), a cell wall component of most fungi. Lysozyme occurs widely in the cells and secretions of vertebrates, where it may function as a bactericidal agent. However, the observation that few pathogenic bacteria are susceptible to lysozyme alone has prompted the suggestion that this enzyme mainly helps dispose of bacteria after they have been killed by other means.

Hen egg white (HEW) lysozyme is the most widely studied species of lysozyme and is one of the mechanistically best understood enzymes. It is a rather small (14.7 kD) and readily available protein (an egg contains  $\sim 5$  g of it), whose single polypeptide chain consists of 129 amino acid residues and is internally cross-linked by four disulfide bonds (Fig. 15-9). HEW lysozyme catalyzes the hydrolysis of its substrate at a rate that is  $\sim 10^8$ -fold greater than that of the uncatalyzed reaction.

### A. Enzyme Structure

The elucidation of an enzyme's mechanism of action requires a knowledge of the structure of its enzyme–substrate complex. This is because, even if the active site residues have been identified through chemical, physical, and genetic means, their three-dimensional arrangements relative to the substrate as well as to each other must be known for an understanding of how the enzyme works. However, an enzyme binds its good substrates only transiently before it catalyzes a reaction and releases the products. Consequently, *most of our knowledge of enzyme–substrate complexes derives from X-ray studies of enzymes in complex with inhibitors or poor substrates that remain stably bound*

to the enzyme for the several hours that are usually required to measure a protein crystal's X-ray diffraction intensities (although techniques for measuring X-ray intensities in less than 1 s have been developed). The large solvent-filled channels that occupy much of the volume of most protein crystals (Section 8-3Aa) often permit the formation of enzyme–inhibitor complexes by the diffusion of inhibitor molecules into crystals of the native protein.

The X-ray structure of HEW lysozyme, which was elucidated by David Phillips in 1965, was the second structure of a protein and the first of an enzyme to be determined at

**Figure 15-9** Primary structure of HEW lysozyme. The amino acid residues that line the substrate-binding pocket are shown in dark purple.

high resolution. The protein molecule is roughly ellipsoidal in shape with dimensions  $30 \times 30 \times 45 \text{ \AA}$  (Fig. 15-10). Its most striking feature is a prominent cleft, the substrate-binding site, that traverses one face of the molecule. The polypeptide chain contains five helical segments as well as a three-stranded antiparallel  $\beta$  sheet that comprises much of one wall of the binding cleft. As expected, most of the nonpolar side chains are in the interior of the molecule, out of contact with the aqueous solvent.

#### a. The Nature of the Binding Site

NAG oligosaccharides of less than five residues are but very slowly hydrolyzed by HEW lysozyme (Table 15-2), although these substrate analogs bind to the enzyme's active site and are thus its competitive inhibitors. The X-ray structure of the  $(\text{NAG})_3$ -lysozyme complex reveals that  $(\text{NAG})_3$  is bound at substrate subsites A, B, and C in Fig. 15-10. This inhibitor associates with the enzyme through strong hydrogen

bonding interactions, some of which involve the acetamido groups of residues A and C, as well as through close-fitting hydrophobic contacts. In an example of induced-fit ligand binding (Section 10-4C), there is a slight ( $\sim 1 \text{ \AA}$ ) closure of lysozyme's binding cleft on binding  $(\text{NAG})_3$ .

#### b. Lysozyme's Catalytic Site Was Identified through Model Building

$(\text{NAG})_3$  takes several weeks to hydrolyze under the influence of lysozyme. It was therefore assumed that the complex revealed by X-ray analysis is unproductive; that is, the enzyme's catalytic site occurs at neither the A—B nor the B—C glycosidic bonds. [Presumably, the rare occasions when  $(\text{NAG})_3$  is hydrolyzed occur when it binds productively at the catalytic site.]

In order to locate lysozyme's catalytic site, Phillips used model building to investigate how a larger substrate could bind to the enzyme. Lysozyme's active site cleft is long enough to

**Figure 15-10** X-ray structure of HEW lysozyme in complex with  $(\text{NAG})_6$ . The protein is represented by its transparent molecular surface with its polypeptide chain in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The  $(\text{NAG})_6$ , which is drawn in stick form with its sugar residues designated A, at its nonreducing end, through F, at its reducing end, binds in a deep cleft in the enzyme surface. Rings A, B, and C (colored according to atom type with C green, N blue, and O red) are observed in the X-ray structure of the

complex of  $(\text{NAG})_3$  with lysozyme; the positions of rings D, E, and F (C cyan, N blue, O red) were inferred by model building. The side chains of lysozyme's active site residues, Glu 35 and Asp 52, which are drawn in space-filling form (C yellow, O red), catalyze the hydrolysis of the glycosidic bond between rings D and E. [Based on an X-ray structure by David Phillips, Oxford University. PDBid 1HEW.]  See **Interactive Exercise 6** and **Kinemage Exercise 9**.

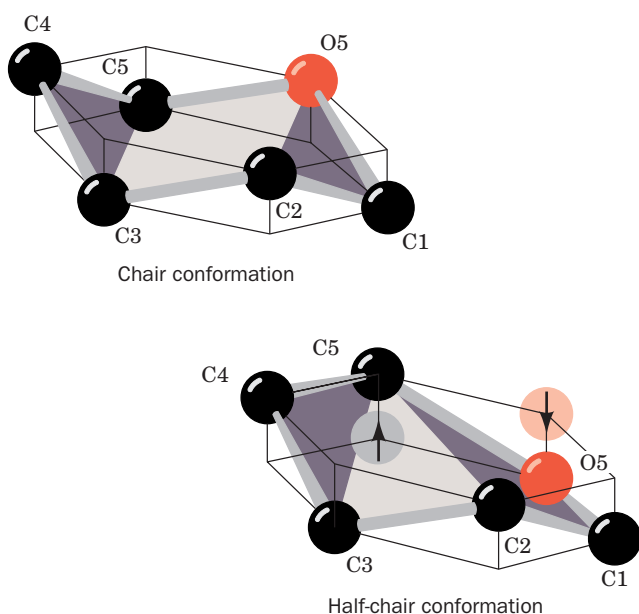

**Table 15-2** Rates of HEW Lysozyme-Catalyzed Hydrolysis of Selected Oligosaccharide Substrate Analogs

Compound	$k_{\text{cat}}$ ( $\text{s}^{-1}$ )
(NAG) <sub>2</sub>	$2.5 \times 10^{-8}$
(NAG) <sub>3</sub>	$8.3 \times 10^{-6}$
(NAG) <sub>4</sub>	$6.6 \times 10^{-5}$
(NAG) <sub>5</sub>	0.033
(NAG) <sub>6</sub>	0.25

accommodate (NAG)<sub>6</sub>, which the enzyme rapidly hydrolyzes (Table 15-2). However, the fourth NAG residue (the D-ring in Fig. 15-10) appeared unable to bind to the enzyme because its C6 and O6 atoms too closely contact Glu 35, Trp 108, and the acetamido group of the C-ring. This steric interference could be relieved by distorting the glucose ring from its normal chair conformation to that of a half-chair (Fig. 15-11). This distortion, which renders atoms C1, C2, C5, and O5 of residue D coplanar, moves the —C6H<sub>2</sub>OH group from its normal equatorial position to an axial position where it makes no close contacts and can hydrogen bond to the backbone carbonyl group of Gln 57 and the amido group of Val 109 (Fig. 15-12). Continuing the model building, Phillips found that the E- and F-rings apparently bind to the enzyme without distortion and with a number of favorable hydrogen bonding and van der Waals contacts.

We are almost in a position to identify lysozyme's catalytic site. In the enzyme's natural substrate, every second

**Figure 15-11** Chair and half-chair conformations. Hexose rings normally assume the chair conformation. It is postulated, however, that binding by lysozyme distorts the D-ring into the half-chair conformation such that atoms C1, C2, C5, and O5 are coplanar. See the Animated Figures

**Figure 15-12** Interactions of lysozyme with its substrate. The view is into the binding cleft with the heavier edges of the rings facing the outside of the enzyme and the lighter ones against the bottom of the cleft. [Illustration, Irving Geis. residue is an NAM. Model building, however, indicated that its lactyl side chain cannot be accommodated in the binding subsites of either residues C or E. Hence, the NAM residues must bind to the enzyme in subsites B, D, and F.

The observation that lysozyme hydrolyzes  $\beta(1 \rightarrow 4)$  linkages from NAM to NAG indicates that bond cleavage occurs either between rings B and C or rings D and E. Since  $(\text{NAG})_3$  is stably bound to but not cleaved by the enzyme while spanning subsites B and C, the probable cleavage site is between rings D and E. This conclusion is supported by John Rupley's observation that lysozyme nearly quantitatively hydrolyzes  $(\text{NAG})_6$  between the second and third residues from its reducing terminus (the end with a free  $\text{C1-OH}$ ), just as is expected if the enzyme has six saccharide-binding subsites and cleaves its bound substrate between rings D and E.

The bond that lysozyme cleaves was identified by carrying out the lysozyme-catalyzed hydrolysis of  $(\text{NAG})_3$  in  $\text{H}_2^{18}\text{O}$ . The resulting product had  $^{18}\text{O}$  bonded to the C1 atom of its newly liberated reducing terminus, thereby demonstrating that bond cleavage occurs between C1 and the bridge oxygen O1:

Thus, lysozyme catalyzes the hydrolysis of the  $\text{C1-O1}$  bond of a bound substrate's D residue. Moreover, *this reaction occurs with retention of configuration, so that the D-ring product remains the  $\beta$  anomer.*

## B. Catalytic Mechanism

It remains to identify lysozyme's catalytic groups. The reaction catalyzed by lysozyme, the hydrolysis of a glycoside, is the conversion of an acetal to a hemiacetal. Nonenzymatic acetal hydrolysis is an acid-catalyzed reaction that involves the protonation of a reactant oxygen atom followed by cleavage of its  $\text{C-O}$  bond (Fig. 15-13). This results in the formation of a resonance-stabilized carbocation that is called an **oxonium ion**. To attain maximum orbital overlap, and thus resonance stabilization, the oxonium ion's R and R' groups must be coplanar with its C, O, and H atoms (stereoelectronic assistance). The oxonium ion then adds water to yield the hemiacetal and regenerate the acid catalyst. In searching for catalytic groups on an enzyme that mediates acetal hydrolysis, we should therefore seek a

**Figure 15-13** Mechanism of the nonenzymatic acid-catalyzed hydrolysis of an acetal to a hemiacetal. The reaction involves the protonation of one of the acetal's oxygen atoms followed by cleavage of its  $\text{C-O}$  bond to form an alcohol ( $\text{R}''\text{OH}$ ) and a resonance-stabilized carbocation (oxonium ion). The addition of water to the oxonium ion forms the hemiacetal and regenerates the  $\text{H}^+$  catalyst. Note that the oxonium ion's C, O, H, R, and R' atoms all lie in the same plane.

potential acid catalyst and possibly a group that could further stabilize an oxonium ion intermediate.

### a. Glu 35 and Asp 52 Are Lysozyme's Catalytic Residues

The only functional groups in the immediate vicinity of lysozyme's reaction center that have the required catalytic properties are the side chains of Glu 35 and Asp 52, residues that are invariant in the family of lysozymes of which HEW lysozyme is the prototype. These side chains, which are disposed to either side of the  $\beta(1 \rightarrow 4)$  glycosidic linkage to be cleaved (Fig. 15-10), have markedly different environments. Asp 52 is surrounded by several conserved polar residues with which it forms a complex hydrogen bonded network. Asp 52 is therefore predicted to have a normal  $\text{pK}$ ; that is, it should be unprotonated and hence negatively charged throughout the 3 to 8 pH range in which lysozyme is catalytically active. In contrast, *the carboxyl group of Glu 35 is nestled in a predominantly nonpolar pocket, where, as we discussed in Section 15-1D, it is likely to remain protonated at unusually high pH's for carboxyl groups.* Indeed, neutron diffraction studies, which provide similar information to X-ray diffraction studies but also reveal the positions of hydrogen atoms, indicate that Glu 35 is protonated at physiological pH. The closest approaches in the X-ray structures between the carboxyl O atoms of both Asp 52 and Glu 35 and the  $\text{C1-O1}$  bond of NAG D-ring are  $\sim 3 \text{ \AA}$ , which makes them the prime candidates for electrostatic and acid catalysts, respectively.

### b. The Lysozyme Catalytic Mechanism Proceeds via a Covalent Intermediate

Lysozyme's catalytic mechanism was largely formulated by Phillips based on the foregoing information. However,

as we shall see, further investigations have required that important changes be made to the original version of this mechanism. The presently accepted mechanism occurs as follows (Fig. 15-14):

**Figure 15-14** The lysozyme reaction mechanism. Glu 35 acts as an acid catalyst, and Asp 52 acts as a covalent catalyst. Only the substrate D- and E-rings are shown. R represents the *N*-acetyl group at C2, and R' represents the  $\text{CH}_3\text{CHCOO}^-$  group at C3. The resonance-stabilized oxonium ion transition state

requires that C1, C2, C5, and O5 be coplanar (orange shading) creating a half-chair conformation. Step 5 includes the participation of an oxonium ion transition state that is not shown.  See Kinemage Exercise 9

1. Lysozyme attaches to a bacterial cell wall by binding to a hexasaccharide unit. In the process, the D-ring is distorted toward the half-chair conformation in response to the unfavorable contacts that its  $\text{—C6H}_2\text{OH}$  group would otherwise make with the protein.

2. Glu 35 transfers its proton to the O1 atom linking the D- and E-rings, the only polar group in its vicinity, thereby cleaving the C1—O1 bond (general acid catalysis). This step converts the D-ring to a planar resonance-stabilized oxonium ion transition state, whose formation is facilitated by the strain distorting it to the half-chair conformation (catalysis by the preferential binding of the transition state). The positively charged oxonium ion is stabilized by the presence of the nearby negatively charged Asp 52 carboxylate group (electrostatic catalysis). The E-ring product is released.

3. The Asp 52 carboxylate group nucleophilically attacks the now electron-poor C1 of the D ring to form a covalent **glycosyl-enzyme intermediate** (covalent catalysis).

4. Water replaces the E-ring product in the active site.

5. Hydrolysis of the covalent bond with the assistance of Glu 35 (general base catalysis), which involves another oxonium ion transition state, regenerates the active site groups. The enzyme then releases the D-ring product, completing the catalytic cycle.

The double-displacement mechanism diagrammed in Fig. 15-14 (in which the Asp 52 carboxylate group displaces O1 from C1 of the D-ring and is, in turn, displaced by water) allows the incoming water molecule to attach to the same face of the D-ring as the E-ring it replaces. Consequently, the configuration of the D-ring is retained. A single-displacement reaction, in which water directly displaces O1, would invert the configuration at C1 of the D-ring between the substrate and product, a result that is not observed.

### C. Testing the Catalytic Mechanism

The forgoing mechanism is the product of over 40 years of enzymatic research. It differs in important ways from the mechanism Phillips originally proposed based on his structural studies of lysozyme and a knowledge of the mechanism of nonenzymatic acetal hydrolysis. In the remainder of this section, we discuss the highlights of these enzymatic studies to illustrate how scientific models evolve.

#### a. Confirming the Identities of Lysozyme's Catalytic Residues

The identities of lysozyme's catalytically important groups have been experimentally verified through site-directed mutagenesis (Section 5-5Gc) and the use of group-specific reagents:

**Glu 35.** The mutagenesis of Glu 35 to Gln yields a protein with no detectable catalytic activity (<0.1% of wild type), although it has only a  $\sim 1.5$ -fold decrease in substrate affinity. *Glu 35 must therefore be essential for lysozyme's catalytic activity.*

**Asp 52.** The mutagenesis of Asp 52 to Asn, which has a polarity comparable to that of Asp but lacks its negative

charge, yields an enzyme with no more than 5% of wild-type lysozyme's catalytic activity even though this mutation causes an  $\sim 2$ -fold increase in the enzyme's affinity for substrate. *Asp 52 is therefore important for enzymatic activity.*

**Noninvolvement of Other Amino Acid Residues.** Lysozyme's other carboxyl groups besides Glu 35 and Asp 52 do not participate in the catalytic process, as was demonstrated by reacting lysozyme with carboxyl-specific reagents in the presence of substrate. This treatment yields an almost fully active enzyme in which all carboxyl groups but Glu 35 and Asp 52 are derivatized. Other group-specific reagents that modify, for instance, His, Lys, Met, or Tyr residues but induce no major protein structure disruptions, cause little change in lysozyme's catalytic efficiency.

#### b. Role of Strain

Many of the mechanistic investigations of lysozyme have had the elusive goal of establishing the catalytic role of strain. Not all of these studies, as we shall see, supported the Phillips mechanism, thereby stimulating a series of investigations that eventually settled this issue.

*Measurements of the binding equilibria of various oligosaccharides to lysozyme indicate that all saccharide residues except that binding to the D subsite contribute energetically toward the binding of substrate to lysozyme; binding NAM in the D subsite requires a free energy input of  $12.1 \text{ kJ} \cdot \text{mol}^{-1}$  (Table 15-3). The Phillips mechanism explains this observation as being indicative of the energy penalty of straining the D-ring from its preferred chair conformation toward the half-chair form.*

As we discussed in Section 15-1Fa, an enzyme that catalyzes a reaction by the preferential binding of its transition state has a greater binding affinity for an inhibitor that has the transition state geometry (a transition state analog) than it does for its substrate. The  $\delta$ -lactone analog of  $(\text{NAG})_4$  (Fig. 15-15) is presumably a transition state analog of lysozyme since *this compound's lactone ring has the half-chair conformation that geometrically resembles the proposed oxonium ion transition state of the substrate's D-ring*. X-ray studies indicate, in accordance with prediction, that this inhibitor binds to lysozyme's A—B—C—D subsites such that the lactone ring occupies the D subsite in a half-chairlike conformation.

**Table 15-3** Binding Free Energies of HEW Lysozyme Subsites

Site	Bound Saccharide	Binding Free Energy ( $\text{kJ} \cdot \text{mol}^{-1}$ )
A	NAG	-7.5
B	NAM	-12.3
C	NAG	-23.8
<b>D</b>	<b>NAM</b>	<b>+12.1</b>
E	NAG	-7.1
F	NAM	-7.1

Source: Chipman, D.M. and Sharon, N., *Science* **165**, 459 (1969).

**Figure 15-15** Transition state analog inhibition of lysozyme. The  $\delta$ -lactone analog of (NAG)<sub>4</sub> (left) resembles the transition state of the lysozyme reaction (right). Note that atoms C1, C2, C5, and O5 in each structure are coplanar (as indicated by orange shading), consistent with the half-chair conformation of the hexose ring.

Despite the foregoing, *the role of substrate distortion in lysozyme catalysis had been questioned*. Theoretical studies by Michael Levitt and Arieh Warshel on substrate binding by lysozyme suggested that the protein is too flexible to mechanically distort the D-ring of a bound substrate. Rather, these calculations implied that transition state stabilization occurs through the displacement by substrate of several tightly bound water molecules from the D subsite. The resulting desolvation of the Asp 52 carboxylate group would significantly enhance its capacity to electrostatically stabilize the transition state oxonium ion. This study therefore concluded that “electrostatic strain” rather than steric strain is the more important factor in stabilizing lysozyme’s transition state.

In an effort to obtain further experimental information bearing on the Phillips strain mechanism, Nathan Sharon and David Chipman determined the D subsite-binding affinities of several saccharides by comparing the lysozyme-binding affinities of various substrate analogs. The NAG lactone inhibitor binds to the D subsite with 9.2 kJ · mol<sup>-1</sup> greater affinity than does NAG. This quantity corresponds, according to Eq. [14.15], to no more than an ~40-fold rate enhancement of the lysozyme reaction as a result of strain (recall that the difference in binding energy between a transition state analog and a substrate is indicative of the enzyme’s rate enhancement arising from the preferential binding of the transition state complex). Such an enhancement is hardly a major portion of lysozyme’s ~10<sup>8</sup>-fold rate enhancement (accounting for only ~20% of the reaction’s  $\Delta\Delta G_{\text{cat}}^\ddagger$ ; Section 14-1Cd). Moreover, an *N*-acetylxylosamine (XylNac) residue,

which lacks the sterically hindered —C6H<sub>2</sub>OH group of NAM and NAG, has only marginally greater binding affinity for the D subsite (−3.8 kJ · mol<sup>-1</sup>) than does NAG (−2.5 kJ · mol<sup>-1</sup>). Yet recall that the Phillips mechanism postulates that it is the unfavorable contacts made by this —C6H<sub>2</sub>OH group that promotes D-ring distortion. Nevertheless, lysozyme does not hydrolyze saccharides with XylNac in the D subsite.

The apparent inconsistencies among the foregoing experimental observations were largely rationalized by Michael James’ highly accurate (1.5-Å resolution) X-ray crystal structure determination of lysozyme in complex with NAM–NAG–NAM. This trisaccharide binds, as expected, to the B, C, and D subsites of lysozyme. *The NAM in the D subsite, in agreement with the Phillips mechanism, is distorted to the half-chair conformation with its —C6H<sub>2</sub>OH group in a nearly axial position due to steric clashes that would otherwise occur with the acetamido group of the C subsite NAG* (although, contrary to the original Phillips mechanism, Glu 35 and Trp 108 are too far away from the —C6H<sub>2</sub>OH group to contribute to this distortion). This strained conformation is stabilized by a strong hydrogen bond between the D-ring O6 and the backbone NH of Val 109 (Fig. 15-12; transition state stabilization). Indeed, the mutation of Val 109 to Pro, which lacks the NH group to make such a hydrogen bond, inactivates the enzyme. Lysozyme’s lack of hydrolytic activity when XylNac occupies its D subsite is likewise explained by the absence of this hydrogen bond and the consequent lesser stability of the XylNac ring’s half-chair transition state.

The unexpectedly small free energy differences in binding NAG, NAG lactone, and XylNac to the D subsite are explained by the observation that undistorted NAG and XylNac can be modeled into the D subsite as it occurs in the X-ray structure of the lysozyme · NAM–NAG–NAM complex. NAM’s bulky lactyl side chain prevents it from binding to the D subsite in this manner.

### c. Evidence for a Covalent Intermediate

The original Phillips mechanism proposed that the lysozyme reaction proceeds via the direct attack of a water molecule on C1 of the half-chair-distorted D-ring so as to directly displace the E-ring (a single-displacement reaction) and therefore did not involve the intermediate formation of a covalent bond (much like the mechanism diagrammed in Fig. 15-14 but skipping Step 3). This was based on Phillip’s observation that the distance between C1 of the D-ring and a carboxyl O of Asp 52 (which participates in a network of hydrogen bonds that appear to hold this side chain in place) are too long to form a covalent bond (minimally 2.3 Å in the NAM–NAG–NAM complex without significantly disrupting the protein structure vs ~1.4 Å for a C—O single bond). The fact that the lysozyme reaction proceeds with retention of configuration was attributed to the shielding of the reaction intermediate by the enzyme, thereby preventing a water molecule from approaching the bond being cleaved from its back side as normally occurs in a single-displacement reaction. This aspect of the original Phillips mechanism was widely accepted for

over 35 years because no enzyme–substrate covalent bond had been detected in any of the numerous experimental studies of hen egg white (HEW) lysozyme.

Despite the foregoing, all other  $\beta$ -glycosidases of known structure that cleave glycosidic linkages with net retention of configuration at the anomeric carbon (as does HEW lysozyme) have been shown to do so via a covalent glycosyl–enzyme intermediate. The active sites of these so-called **retaining  $\beta$ -glycosidases** structurally resemble that of HEW lysozyme. Moreover, there is no direct evidence indicative of the existence of a long-lived oxonium ion at the active site of any retaining  $\beta$ -glycosidase, including HEW lysozyme (the lifetime of a glucosyl oxonium ion in water is  $\sim 10^{-12}$  s, a time only slightly larger than that of a bond vibration). Consequently, there had been a growing suspicion that the HEW lysozyme reaction also proceeds via a covalent intermediate, one between the D-ring's anomeric carbon (C1) and the side chain carboxyl group of Asp 52 to form an ester linkage (as generated by Step 3 in Fig. 15-14). This intermediate presumably reacts with  $H_2O$  in what is essentially the reverse of the reaction leading to its formation, thereby yielding the reaction's second product (Steps 4 and 5 of Fig. 15-14). In this double-displacement mechanism, the oxonium ion is proposed to be the transition state on the way to forming the covalent intermediate, rather than being an intermediate itself as it was in the original Phillips mechanism.

If, in fact, HEW lysozyme follows the mechanism in Fig. 15-14, the reason that its covalent intermediate had not been observed is that its rate of breakdown must be much faster than its rate of formation. Hence, if this intermediate is to be experimentally observed, its rate of formation must be made significantly greater than its rate of breakdown. To do so, Stephen Withers capitalized on three phenomena. First, if, as postulated, the reaction goes through an oxonium ion transition state, all steps involving its formation should be slowed by the electron withdrawing effects of substituting F (the most electronegative element) at C2 of the D-ring. Second, mutating Glu 35 to Gln (E35Q) removes the general acid–base that catalyzes the reaction, further slowing all steps involving the oxonium ion transition state. Third, substituting an additional F atom at C1 of the D-ring accelerates the formation of the intermediate because this F is a good leaving group. Making all three of these changes should increase the rate of formation of the proposed covalent intermediate relative to its breakdown and hence should result in its accumulation. Withers therefore incubated E35Q HEW lysozyme with NAG- $\beta(1 \rightarrow 4)$ -2-deoxy-2-fluoro- $\beta$ -D-glucopyranosyl fluoride (**NAG2FGlcF**):

Electrospray ionization mass spectrometry (ESI-MS; Sec-

tion 7-11) of this reaction mixture revealed a sharp peak at 14,683 D, consistent with the formation of the proposed covalent intermediate, but no significant peak at or near the 14,314-D molecular mass of the mutant enzyme alone.

The X-ray structure of this covalent complex unambiguously reveals the expected  $\sim 1.4$ -Å-long covalent bond between C1 of the D-ring NAG and a side chain carboxyl O of Asp 52 (Fig. 15-16). This D-ring NAG adopts an undistorted chair conformation, thus indicating that it is a reaction intermediate rather than an approximation of the transition state. The superposition of this covalent complex with that of the above described complex of NAM–NAG–NAM with wild-type HEW lysozyme reveals how this covalent bond forms (Fig. 15-16). The shortening of the 3.2-Å distance between the D-ring NAG C1 and the Asp 52 O in the NAM–NAG–NAM

**Figure 15-16 The HEW lysozyme covalent intermediate.** The substrate C- and D-rings and Asp 52 are shown in the superposition of the X-ray structures of the covalent complex formed by reacting E35Q lysozyme with NAG2FGlcF (C green, N blue, O red, and F magenta) and the noncovalent complex of wild-type lysozyme with NAM–NAG–NAM (C yellow, N blue, and O red). Note that the covalent bond between Asp 52 and C1 of the D-ring forms when the D-ring in the noncovalent complex relaxes from its distorted half-chair conformation to an undistorted chair conformation and that the side chain of Asp 52 undergoes an  $\sim 45^\circ$  rotation about its  $C_\alpha$ – $C_\beta$  bond. [Based on X-ray structures by David Vocadlo and Stephen Withers, University of British Columbia, Vancouver, Canada; and Michael James, University of Alberta, Edmonton, Canada. PDBids 1H6M and 9LYZ.]

complex to  $\sim 1.4$  Å in the covalent complex is almost entirely a consequence of the relaxation of the D-ring from the half-chair to the chair conformation combined with an  $\sim 45^\circ$  rotation of the Asp 52 side chain about its  $C_\alpha-C_\beta$  bond; the positions of the D-ring O4 and O6 atoms are essentially unchanged. Hence, over 35 years after its formulation, it was shown that *the Phillips mechanism must be altered to take into account the transient formation of this covalent glycosyl-enzyme ester intermediate (covalent catalysis)*. Keep in mind, however, that in order to form this covalent linkage, the D-ring must pass through an oxonium-like transition state, which requires it to transiently assume the half-chair conformation.

### 3 SERINE PROTEASES

Our next example of enzymatic mechanisms is a diverse group of proteolytic enzymes known as the **serine proteases** (Table 15-4). These enzymes are so named because they have a common catalytic mechanism characterized by the possession of a peculiarly reactive Ser residue that is essential for their enzymatic activity. The serine proteases are the most thoroughly understood family of enzymes as a result of their extensive examination over a nearly 60-year period by kinetic, chemical, physical, and genetic techniques. In this section, we mainly study the best characterized serine proteases, **chymotrypsin**, **trypsin**, and **elastase**. We also consider how these three enzymes, which are synthesized in inactive forms, are physiologically activated.

#### A. Kinetics and Catalytic Groups

Chymotrypsin, trypsin, and elastase are digestive enzymes that are synthesized by the pancreatic acinar cells (Fig. 1-10c) and secreted, via the pancreatic duct, into the duodenum (the small intestine's upper loop). All of these enzymes

catalyze the hydrolysis of peptide (amide) bonds but with different specificities for the side chains flanking the scissile (to be cleaved) peptide bond (recall that chymotrypsin is specific for a bulky hydrophobic residue preceding the scissile peptide bond, trypsin is specific for a positively charged residue, and elastase is specific for a small neutral residue; Table 7-2). Together, they form a potent digestive team.

#### a. Ester Hydrolysis as a Kinetic Model

That chymotrypsin can act as an esterase as well as a protease is not particularly surprising because the chemical mechanisms of ester and amide hydrolysis are almost identical. The study of chymotrypsin's esterase activity has led to important insights concerning this enzyme's catalytic mechanism. Kinetic measurements by Brian Hartley of the chymotrypsin-catalyzed hydrolysis of *p*-nitrophenylacetate

indicated that the reaction occurs in two phases (Fig. 15-17):

1. The “burst phase,” in which the highly colored *p*-nitrophenolate ion is rapidly formed in amounts stoichiometric with the quantity of active enzyme present.
2. The “steady-state phase,” in which *p*-nitrophenolate is generated at a reduced but constant rate that is independent of substrate concentration.

**Table 15-4** A Selection of Serine Proteases

Enzyme	Source	Function
Trypsin	Pancreas	Digestion of proteins
Chymotrypsin	Pancreas	Digestion of proteins
Elastase	Pancreas	Digestion of proteins
Thrombin	Vertebrate serum	Blood clotting
Plasmin	Vertebrate serum	Dissolution of blood clots
Kallikrein	Blood and tissues	Control of blood flow
Complement C1	Serum	Cell lysis in the immune response
Acrosomal protease	Sperm acrosome	Penetration of ovum
Lysosomal protease	Animal cells	Cell protein turnover
Cocoonase	Moth larvae	Dissolution of cocoon after metamorphosis
$\alpha$ -Lytic protease	<i>Lysobacter enzymogenes</i>	Possibly digestion
Proteases A and B	<i>Streptomyces griseus</i>	Possibly digestion
Subtilisin	<i>Bacillus subtilis</i>	Possibly digestion

Source: Stroud, R.M., *Sci. Am.* **231**(1), 86 (1974).

**Figure 15-17** Time course of *p*-nitrophenylacetate hydrolysis as catalyzed by two different concentrations of chymotrypsin.

The enzyme rapidly binds substrate and releases the first product, *p*-nitrophenolate ion, but the second product, acetate ion, is released more slowly. Consequently, the rate of *p*-nitrophenolate generation begins rapidly (burst phase) but

slows as acyl-enzyme complex accumulates until the rate of *p*-nitrophenolate generation approaches that of acetate release (steady state). The extrapolation of the steady state curve to zero time (*dashed lines*) indicates the initial concentration of active enzyme. [After Hartley, B.S. and Kilby, B.A., *Biochem. J.* **56**, 294 (1954).]

These observations have been interpreted in terms of a two-stage reaction sequence in which the enzyme (**1**) rapidly reacts with the *p*-nitrophenylacetate to release *p*-nitrophenolate ion forming a covalent acyl-enzyme intermediate that (**2**) is slowly hydrolyzed to release acetate:

Chymotrypsin evidently follows a Ping Pong Bi Bi mechanism (Section 14-5A). Chymotrypsin-catalyzed amide hydrolysis has been shown to follow a reaction pathway similar to that of ester hydrolysis but with the first step of the reaction, enzyme acylation, being rate determining rather than the deacylation step.

#### b. Identification of the Catalytic Residues

Chymotrypsin's catalytically important groups were identified by chemical labeling studies. These are described below.

**Ser 195.** A diagnostic test for the presence of the active Ser of serine proteases is its reaction with **diisopropylphosphorofluoridate (DIPF)**:

which irreversibly inactivates the enzyme. Other Ser residues, including those on the same protein, do not react with DIPF. *DIPF reacts only with Ser 195 of chymotrypsin, thereby demonstrating that this residue is the enzyme's active Ser.*

The use of DIPF as an enzyme inactivating agent came about through the discovery that organophosphorus compounds such as DIPF are potent nerve poisons. The neurotoxicity of DIPF arises from its ability to inactivate **acetylcholinesterase**, a serine esterase that catalyzes the hydrolysis of **acetylcholine**:

Acetylcholine is a **neurotransmitter**: It transmits nerve impulses across the **synapses** (junctions) between certain types of nerve cells (Sections 12-4Da and 20-5Cb). The inactivation of acetylcholinesterase prevents the otherwise rapid hydrolysis of the acetylcholine released by a nerve impulse and thereby interferes with the regular sequence of nerve impulses. DIPF is of such great toxicity to humans that it has been used militarily as a nerve gas. Related compounds, such as **parathion** and **malathion**,

**Parathion**

**Malathion**

are useful insecticides because they are far more toxic to insects than to mammals.

**His 57.** A second catalytically important residue was discovered through **affinity labeling**. In this technique, a substrate analog bearing a reactive group specifically binds at the enzyme's active site, where it reacts to form a stable covalent bond with a nearby susceptible group (these reactive substrate analogs have therefore been described as the "Trojan horses" of biochemistry). The affinity labeled groups can subsequently be identified by peptide mapping (Section 7-1J). Chymotrypsin specifically binds **tosyl-L-phenylalanine chloromethyl ketone (TPCK)**,

**Figure 15-18** Reaction of TPCK with chymotrypsin to alkylate His 57.

because of its resemblance to a Phe residue (one of chymotrypsin's preferred residues; Table 7-2). Active site-bound TPCK's chloromethyl ketone group is a strong alkylating agent; it reacts with His 57 (Fig. 15-18), thereby inactivating the enzyme. The TPCK reaction is inhibited by  **$\beta$ -phenylpropionate**,

**$\beta$ -Phenylpropionate**

a competitive inhibitor of chymotrypsin that presumably competes with TPCK for its enzymatic binding site. Moreover, the TPCK reaction does not occur in 8M urea, a denaturing reagent, or with DIP-chymotrypsin, in which the active site is blocked. These observations establish that *His 57 is an essential active site residue of chymotrypsin*.

## B. X-Ray Structures

Bovine chymotrypsin, bovine trypsin, and porcine elastase are strikingly homologous: The primary structures of these ~240-residue monomeric enzymes are ~40% identical and their internal sequences are even more alike (in comparison, the  $\alpha$  and  $\beta$  chains of human hemoglobin have a 44% sequence identity). Furthermore, *all of these enzymes have an active Ser and a catalytically essential His as well as similar kinetic mechanisms*. It therefore came as no surprise when their X-ray structures all proved to be closely related.

To most conveniently compare the structures of these three digestive enzymes, they have been assigned the same amino acid residue numbering scheme. Bovine chymotrypsin is synthesized as an inactive 245-residue precursor named **chymotrypsinogen** that is proteolytically converted to chymotrypsin (Section 15-3Ea). In what follows, the numbering of the amino acid residues in chymotrypsin, trypsin, and elastase will be that of the corresponding residues in bovine chymotrypsinogen.

The X-ray structure of bovine chymotrypsin was elucidated in 1967 by David Blow. This was followed by the

**Figure 15-19** X-ray structure of bovine trypsin in covalent complex with its inhibitor leupeptin. The protein, viewed looking into its upper  $\beta$  barrel, is represented by its transparent molecular surface with its polypeptide chain in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*), but with loop L1 (residues 185–188) blue-green, loop L2 (residues 221–225) violet, and Tyr 172 and Gly 216 purple. The side chains of the catalytic triad (Ser 195, His 57, and Asp 102) and Asp 189 are drawn in ball-and-stick form

colored according to atom type (C green, N blue, O red) with hydrogen bonds represented by dashed black lines. **Leupeptin** (acetyl-Leu-Leu-Arg in which the terminal carboxyl group is replaced by  $-\text{CHO}$ ) is drawn in stick form (C cyan, N blue, O red) with its Arg side chain occupying the enzyme's specificity pocket (*magenta mesh*). [Based on an X-ray structure by Daniel Koshland, Jr., University of California at Berkeley. PDBid 2AGL.]  See Kinemage Exercise 10-1

**Figure 15-20** The active site residues of trypsin. Residues are drawn in ball-and-stick form with C green, N blue, and O red and viewed similarly to Fig. 15-19. The catalytic triad consists of Ser

195, His 57, and Asp 102. [Based on an X-ray structure by Daniel Koshland, Jr., University of California at Berkeley. PDBid 2AGL.]

determination of the structures of bovine trypsin (Fig. 15-19) by Robert Stroud and Richard Dickerson, and porcine elastase by David Shotton and Herman Watson. Each of these proteins is folded into two structurally similar domains, each of which have extensive regions of antiparallel  $\beta$  sheets arranged in a 6-stranded  $\beta$  barrel, but contain little helix. The catalytically essential His 57 and Ser 195 are located in a cleft between the  $\beta$  barrels, as is the invariant (in all serine proteases) Asp 102, which is buried in a solvent-inaccessible pocket. These three residues form a hydrogen bonded constellation referred to as the **catalytic triad** (Figs. 15-19 and 15-20).

#### a. The Structural Basis of Substrate Specificity Can Be Quite Complex

The X-ray structures of the above three enzymes suggest the basis for their differing substrate specificities (Fig. 15-21):

1. In chymotrypsin, the bulky aromatic side chain of the preferred Phe, Trp, or Tyr residue (Table 7-2) that con-

tributes the carbonyl group of the scissile peptide fits snugly into a slitlike hydrophobic pocket, the specificity pocket, that is located near the catalytic groups (Fig. 15-19).

**Figure 15-21** Specificity pockets of three serine proteases. The side chains of key residues that determine the size and nature of the specificity pocket are shown along with a representative substrate for each enzyme. Chymotrypsin prefers to cleave peptide bonds following large hydrophobic side chains; trypsin prefers Lys or Arg; and elastase prefers Ala, Gly, or Val. [After a drawing in Branden, C. and Tooze, J., *Introduction to Protein Structure* (2nd ed.), Garland Publishing, p. 213 (1999).]

2. In trypsin, the residue corresponding to chymotrypsin Ser 189, which lies at the back of the specificity pocket, is the anionic residue Asp (Fig. 15-19). The cationic side chains of trypsin's preferred residues, Arg or Lys, can therefore form ion pairs with this Asp residue. The rest of chymotrypsin's specificity pocket is preserved in trypsin so that it can accommodate the bulky side chains of Arg and Lys.

3. Elastase is so named because it rapidly hydrolyzes the otherwise nearly indigestible Ala, Gly, and Val-rich protein **elastin** (a connective tissue protein with rubber-like elastic properties). Elastase's specificity pocket is largely occluded by the side chains of a Val and a Thr residue that replace two Gly's lining this pocket in both chymotrypsin and trypsin. Consequently elastase, whose specificity pocket is better described as a depression, specifically cleaves peptide bonds after small neutral residues, particularly Ala. In contrast, chymotrypsin and trypsin hydrolyze such peptide bonds extremely slowly because these small substrates cannot be sufficiently immobilized on the enzyme surface for efficient catalysis to occur (Section 15-1E).

Thus, for example, trypsin catalyzes the hydrolysis of peptidyl amide substrates with an Arg or Lys residue preceding the scissile bond with an efficiency, as measured by  $k_{\text{cat}}/K_M$  (Section 14-2Ba), that is  $10^6$ -fold greater than that for the corresponding Phe-containing substrates. Conversely, chymotrypsin catalyzes the hydrolysis of substrates after Phe, Trp, and Tyr residues  $10^4$ -fold more efficiently than after the corresponding Lys-containing substrates.

Despite the foregoing, the mutagenic change in trypsin of Asp 189  $\rightarrow$  Ser (D189S) by William Rutter did not switch its specificity to that of chymotrypsin but instead yielded a poor, nonspecific protease. Moreover, even replacing the other three residues in trypsin's specificity pocket that differ from those in chymotrypsin, with those of chymotrypsin, fails to yield a significantly improved enzyme. However, trypsin is converted to a reasonably active chymotrypsin-like enzyme when, in addition to the foregoing changes (collectively designated S1), both of its two surface loops that connect the walls of the specificity pocket (Fig. 15-19), L1 (residues 185–188) and L2 (residues 221–225), are replaced by those of chymotrypsin (termed Tr  $\rightarrow$  Ch[S1 + L1 + L2]). Although this mutant enzyme still has a low substrate-binding affinity,  $K_S$ , the additional mutation Y172W in a third surface loop yields an enzyme (Tr  $\rightarrow$  Ch[S1 + L1 + L2 + Y172W]) that has 15% of chymotrypsin's catalytic efficiency. Curiously, these loops, whose sequences are largely conserved in each enzyme, are not structural components of either the specificity pocket or the extended substrate binding site in chymotrypsin or in trypsin (Fig. 15-19).

Careful comparisons, by Charles Craik and Robert Fletterick, of the X-ray structures of chymotrypsin and trypsin with those of the closely similar Tr  $\rightarrow$  Ch[S1 + L1 + L2] and Tr  $\rightarrow$  Ch[S1 + L1 + L2 + Y172W] in complex with a Phe-containing chloromethyl ketone inhibitor reveal the

structural basis of substrate specificity in trypsin and chymotrypsin. Efficient catalysis in the serine proteases requires that the enzyme's active site be structurally intact and that the substrate's scissile bond be properly positioned relative to the catalytic triad and other components of the active site (see below). The above mutagenic changes do not affect the structure of the catalytic triad or those portions of the active site that bind the substrate's leaving group (that segment on the C-terminal side of the scissile bond). However, the main chain conformation of the conserved Gly 216 (which forms two hydrogen bonds to the backbone of the third residue before the substrate's scissile bond in an antiparallel  $\beta$  pleated sheet-like arrangement) differs in trypsin and chymotrypsin and adopts a chymotrypsin-like structure in both hybrid proteins. Evidently, if Gly 216 adopts a trypsin-like conformation, the scissile bond in Phe-containing substrates is mis-oriented for efficient catalysis. Thus, despite the fact that Gly 216 is conserved in trypsin and chymotrypsin, the differing structures of loop L2 in the two enzymes maintain it in distinct conformations.

Loop L1, which interacts with L2 in both trypsin and chymotrypsin, is largely disordered in the X-ray structure of Tr  $\rightarrow$  Ch[S1 + L1 + L2]. Modeling a trypsin-like L1 into Tr  $\rightarrow$  Ch[S1 + L1 + L2] results in severe steric clashes with the chymotrypsin-like L2. Thus, the requirement of a chymotrypsin-like L1 for the efficient catalysis by Tr  $\rightarrow$  Ch[S1 + L1 + L2] appears to arise from the need to permit L2 to adopt a chymotrypsin-like conformation.

The side chain of Tyr 172 extends toward the base of the specificity pocket. The improvement in substrate binding affinity of Tr  $\rightarrow$  Ch[S1 + L1 + L2 + Y172W] over Tr  $\rightarrow$  Ch[S1 + L1 + L2] arises from structural rearrangements in this region of the enzyme caused by the increased bulk and different hydrogen bonding requirements of Trp versus Tyr. These changes appear to improve both the structural stability of residues forming the specificity pocket and their specificity for chymotrypsin-like substrates. These results therefore highlight an important caveat for genetic engineers: *Enzymes are so exquisitely tailored to their functions that they often respond to mutagenic tinkering in unexpected ways.*

## b. Evolutionary Relationships Among Serine Proteases

We have seen that sequence and structural homologies among proteins reveal their evolutionary relationships (Sections 7-3 and 9-6). *The great similarities among chymotrypsin, trypsin, and elastase indicate that these proteins evolved through gene duplications of an ancestral serine protease followed by the divergent evolution of the resulting enzymes (Section 7-3C).*

Several serine proteases from various sources provide further insights into the evolutionary relationships among the serine proteases. ***Streptomyces griseus* protease A (SGPA)** is a bacterial serine protease of chymotryptic specificity that exhibits extensive structural similarity, although only  $\sim 20\%$  sequence identity, with the pancreatic

serine proteases. The primordial trypsin gene evidently arose before the divergence of prokaryotes and eukaryotes.

There are three known serine proteases whose primary and tertiary structures bear no discernible relationship to each other or to chymotrypsin but which, nevertheless, contain catalytic triads at their active sites whose structures closely resemble that of chymotrypsin:

1. **Subtilisin**, an endopeptidase that was originally isolated from *Bacillus subtilis*.
2. Wheat germ **serine carboxypeptidase II**, an exopeptidase whose structure is surprisingly similar to that of carboxypeptidase A (Fig. 8-19a) even though the latter protease has an entirely different catalytic mechanism from that of the serine proteases (see Problem 3).
3. *E. coli* **ClpP**, which functions in the degradation of cellular proteins (Section 32-6B).

Since the orders of the corresponding active site residues in the amino acid sequences of the four types of serine proteases are quite different (Fig. 15-22), it seems highly improbable that they could have evolved from a common ancestor serine protease. These proteins apparently constitute a remarkable example of **convergent evolution**: Nature seems to have independently discovered the same catalytic mechanism at least four times. (In addition, **human cytomegalovirus protease**, an essential protein for virus replication that bears no resemblance to the above

proteases, has active site Ser and His residues whose relative positions are similar to those in other serine proteases but lacks an active site Asp residue; it appears to have a catalytic dyad.)

### C. Catalytic Mechanism

 **See Guided Exploration 12: The catalytic mechanism of serine proteases** The extensive active site homologies among the various serine proteases indicate that they all have the same catalytic mechanism. On the basis of considerable chemical and structural data gathered in many laboratories, the following catalytic mechanism has been formulated for the serine proteases, here given in terms of chymotrypsin (Fig. 15-23):

1. After chymotrypsin has bound substrate to form the Michaelis complex, *Ser 195*, in the reaction's rate-determining step, nucleophilically attacks the scissile peptide's carbonyl group to form a complex known as the **tetraedral intermediate** (covalent catalysis). X-ray studies indicate that Ser 195 is ideally positioned to carry out this nucleophilic attack (proximity and orientation effects). The imidazole ring of His 57 takes up the liberated proton, thereby forming an imidazolium ion (general base catalysis). This process is aided by the polarizing effect of the unsolvated carboxylate ion of Asp 102, which is hydrogen bonded to His 57 (electrostatic catalysis; see Section 15-3Dd). Indeed, the mutagenic replacement of trypsin's Asp

**Figure 15-22** Relative positions of the active site residues in subtilisin, chymotrypsin, serine carboxypeptidase II, and ClpP protease. The peptide backbones of Ser 214, Trp 215, and Gly 216 in chymotrypsin, and their counterparts in subtilisin, participate

in substrate-binding interactions. [After Robertus, J.D., Alden, R.A., Birktoft, J.J., Kraut, J., Powers, J.C., and Wilcox, P.E., *Biochemistry* **11**, 2449 (1972).]  **See Kinemage Exercise 10-2**

**Figure 15-23 Catalytic mechanism of the serine proteases.** The reaction involves (1) the nucleophilic attack of the active site Ser on the carbonyl carbon atom of the scissile peptide bond to form the tetrahedral intermediate; (2) the decomposition of the tetrahedral intermediate to the acyl-enzyme intermediate

through general acid catalysis by the active site Asp-polarized His, followed by loss of the amine product and its replacement by a water molecule; (3) the reversal of Step 2 to form a second tetrahedral intermediate; and (4) the reversal of Step 1 to yield the reaction's carboxyl product and the active enzyme.

102 by Asn leaves the enzyme's  $K_M$  substantially unchanged at neutral pH but reduces its  $k_{cat}$  to  $\sim 0.05\%$  of its wild-type value. Neutron diffraction studies have

demonstrated that Asp 102 remains a carboxylate ion rather than abstracting a proton from the imidazolium ion to form an uncharged carboxylic acid group. The tetrahedral

intermediate has a well-defined, although transient, existence. We shall see that *much of chymotrypsin's catalytic power derives from its preferential binding of the transition state leading to this intermediate (transition state binding catalysis)*.

**2.** The tetrahedral intermediate decomposes to the **acyl-enzyme intermediate** under the driving force of proton donation from N3 of His 57 (general acid catalysis). The amine leaving group ( $R'NH_2$ , the new N-terminal portion of the cleaved polypeptide chain) is released from the enzyme and replaced by water from the solvent.

**3 & 4.** The acyl-enzyme intermediate (which, in the absence of enzyme, would be a stable compound) is rapidly deacylated by what is essentially the reverse of the previous steps followed by the release of the resulting carboxylate product (the new C-terminal portion of the cleaved polypeptide chain), thereby regenerating the active enzyme. In this process, water is the attacking nucleophile and Ser 195 is the leaving group.

#### D. Testing the Catalytic Mechanism

The formulation of the foregoing model for catalysis by serine proteases has prompted numerous investigations of its validity. In this section we discuss several of the most revealing of these studies.

##### a. The Tetrahedral Intermediate Is Mimicked in a Complex of Trypsin with Trypsin Inhibitor

Convincing structural evidence for the existence of the tetrahedral intermediate was provided by Robert Huber in an X-ray study of the complex between the 58-residue protein **bovine pancreatic trypsin inhibitor (BPTI)** and trypsin. BPTI binds to and inactivates trypsin, thereby preventing any trypsin that is prematurely activated in the pancreas from digesting that organ (Section 15-3E). BPTI binds to the active site region of trypsin across a tightly packed interface that is cross-linked by a complex network of hydrogen bonds. This complex's  $10^{13} M^{-1}$  association constant, among the largest of any known protein-protein interaction, emphasizes BPTI's physiological importance.

The portion of BPTI in contact with the trypsin active site resembles bound substrate. The side chain of BPTI Lys 15I (here "I" differentiates BPTI residues from trypsin residues) occupies the trypsin specificity pocket (Fig. 15-24a) and the peptide bond between Lys 15I and Ala 16I is positioned as if it were the scissile peptide bond (Fig. 15-24b). What is most remarkable about this structure is that *its active site complex assumes a conformation well along the reaction coordinate toward the tetrahedral intermediate*: The side chain oxygen of trypsin Ser 195, the active Ser, is in closer-than-van der Waals contact ( $2.6 \text{ \AA}$ ) with the pyramidally distorted carbonyl carbon of BPTI's "scissile" peptide. Despite this close contact, the proteolytic reaction cannot proceed past this point along the reaction coordinate because of the rigidity of the active site complex and because it is so tightly sealed that the leaving group cannot leave and water cannot enter the reaction site.

(a)

(b)

**Figure 15-24 Trypsin-BPTI complex.** (a) The X-ray structure shown as a cutaway surface drawing indicating how trypsin (red) binds BPTI (green). The green protrusion extending into the red cavity near the center of the figure represents the Lys 15I side chain occupying trypsin's specificity pocket. Note the close complementary fit of these two proteins. [Courtesy of Michael Connolly, New York University.] (b) Trypsin Ser 195, the active Ser, is in closer-than-van der Waals contact with the carbonyl carbon of BPTI's scissile peptide, which is pyramidally distorted toward Ser 195. The normal proteolytic reaction is apparently arrested somewhere along the reaction coordinate between the Michaelis complex and the tetrahedral intermediate.

Protease inhibitors are common in nature, where they have protective and regulatory functions. For example, certain plants release protease inhibitors in response to insect bites, thereby causing the offending insect to starve by inactivating its digestive enzymes. Protease inhibitors constitute  $\sim 10\%$  of the nearly 200 proteins of blood serum. For instance,  **$\alpha_1$ -proteinase inhibitor**, which is secreted by the liver, inhibits **leukocyte elastase** (leukocytes are a type of white blood cell; the action of leukocyte elastase is thought to be part of the inflammatory process). Pathological variants of  $\alpha_1$ -proteinase inhibitor with reduced activity are associated with **pulmonary emphysema**, a degenerative disease of the lungs resulting from the hydrolysis of its elastic fibers. Smokers also suffer from reduced activity of their  $\alpha_1$ -proteinase inhibitor because of the oxidation of its active site Met residue. Full activity of this inhibitor is not regained until several hours after smoking.

### b. Serine Proteases Preferentially Bind the Transition State

Detailed comparisons of the X-ray structures of several serine protease–inhibitor complexes have revealed a further structural basis for catalysis in these enzymes (Fig. 15-25):

1. The conformational distortion that occurs with the formation of the tetrahedral intermediate causes the carbonyl oxygen of the scissile peptide to move deeper into the active site so as to occupy a previously unoccupied position, the **oxyanion hole**.

2. There it forms two hydrogen bonds with the enzyme that cannot form when the carbonyl group is in its normal trigonal conformation. These two enzymatic hydrogen bond donors were first noted by Joseph Kraut to occupy corresponding positions in chymotrypsin and subtilisin. He proposed the existence of the oxyanion hole based on the premise that convergent evolution had made the active sites of these unrelated enzymes functionally identical.

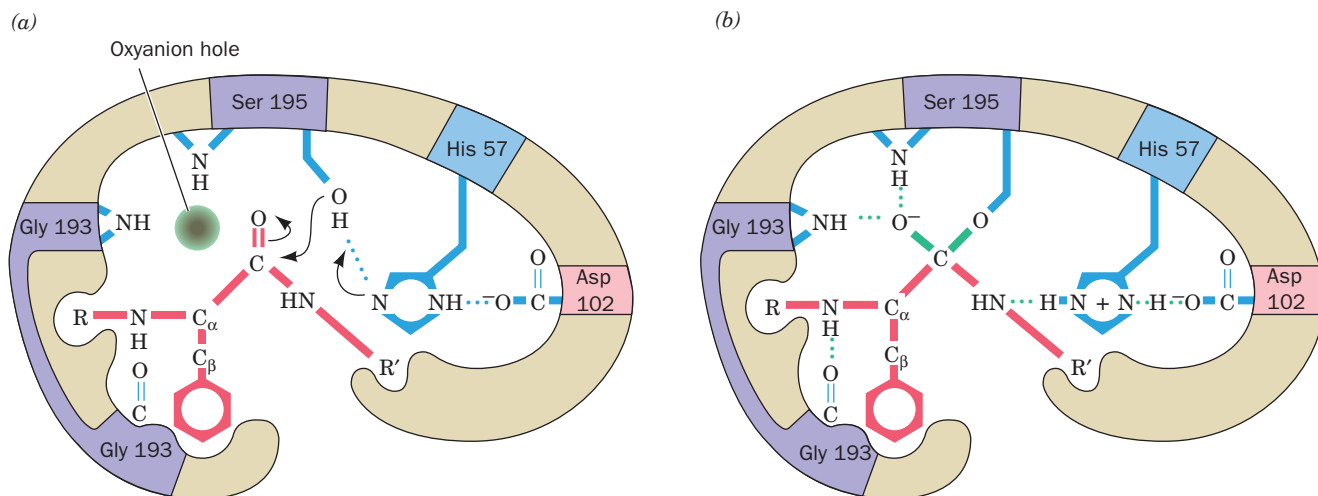

3. The tetrahedral distortion, moreover, permits the formation of an otherwise unsatisfied hydrogen bond between the enzyme and the backbone NH group of the residue preceding the scissile peptide. Consequently, *the enzyme binds the tetrahedral intermediate in preference to either the Michaelis complex or the acyl–enzyme intermediate*.

It is this phenomenon that is responsible for much of the catalytic efficiency of serine proteases (see below). In fact, the reason that DIPF is such an effective inhibitor of serine proteases is because its tetrahedral phosphate group makes this compound a transition state analog of the enzyme.

### c. The Tetrahedral Intermediate and the Water Molecule Attacking the Acyl–Enzyme Intermediate Have Been Directly Observed

Most enzymatic reactions turn over far too rapidly for their intermediate states to be studied by X-ray or NMR techniques. Consequently, much of our structural knowledge of these intermediate states derives from the study of enzyme–inhibitor complexes or complexes of substrates with inactivated enzymes. Yet the structural relevance of these complexes is subject to doubt precisely because they are catalytically unproductive.

In an effort to rectify this situation for serine proteases, Janos Hajdu and Christopher Schofield searched for peptide–protease complexes that are stable at a pH at which the protease is inactive but that could be rendered active by changing the pH. To do so, they screened libraries of peptides for their ability to bind to porcine pancreatic elastase at pH 3.5 (at which His 57 is protonated and hence unable to act as a general base) through the use of ESI-MS (Section 7-1I). They thereby discovered that YPFVEPI, a heptapeptide segment of the human milk protein  $\beta$ -casein that is named **BCM7**, forms a complex with elastase, whose mass is consistent with the formation of an ester linkage between BCM7 and the enzyme. In the presence of  $^{18}\text{OH}_2$  at pH 7.5 (where elastase is active), the  $^{18}\text{O}$  label was incorporated into both BCM7 and the elastase–BCM7 complex, thereby demonstrating that the reaction of BCM7 with elastase is reversible at this pH. Fragmentation studies by fast atom bombardment–tandem mass spectrometry (FAB–MS/MS; Section 7-1I) further revealed that BCM7 that had been incubated with elastase in the presence of  $^{18}\text{OH}_2$  at pH 7.5 incorporated the  $^{18}\text{O}$  label into only its C-terminal Ile residue.

**Figure 15-25** Transition state stabilization in the serine proteases. (a) In the Michaelis complex, the trigonal carbonyl carbon of the scissile peptide is conformationally constrained from binding in the oxyanion hole (*upper left*). (b) In the tetrahedral intermediate, the now charged carbonyl oxygen of the scissile peptide (the oxyanion) has entered the oxyanion hole, thereby hydrogen bonding to the backbone NH groups of

Gly 193 and Ser 195. The consequent conformational distortion permits the NH group of the residue preceding the scissile peptide bond to form an otherwise unsatisfied hydrogen bond to Gly 193. Serine proteases therefore preferentially bind the tetrahedral intermediate. [After Robertus, J.D., Kraut, J., Alden, R.A., and Birktoft, J.J., *Biochemistry* **11**, 4302 (1972).] **See Kinemage Exercise 10-3**

The X-ray structure of the BCM7–elastase complex at pH 5 (Fig. 15-26a) revealed that BCM7's C-terminal carboxyl group, in fact, forms an ester linkage with elastase's Ser 195 side chain hydroxyl group to form the expected acyl–enzyme intermediate. Moreover, this X-ray structure reveals the presence of a bound water molecule that appears poised to nucleophilically attack the ester linkage (the distance from this water molecule to BCM7's C-terminal C atom is 3.1 Å and the line between them is nearly perpendicular to the plane of the acyl group). His 57, which is hydrogen bonded to this water molecule, is properly positioned to abstract one of its protons, thereby activating it for the nucleophilic attack (general base catalysis). The carbonyl O atom of the acyl group occupies the enzyme's oxyanion hole such that it is hydrogen bonded to the main chain N atoms of both Ser 195 and Gly 193. This is in agreement with spectroscopic measurements indicating that the acyl–enzyme intermediate's carbonyl group is, in fact, hydrogen bonded to the oxyanion hole. It was initially assumed that the oxyanion hole acts only to stabilize the tetrahedral oxyanion transition state that resides near the tetrahedral intermediate on the catalytic reaction coordinate. However, it now appears that the oxyanion hole also functions to polarize the carbonyl group of the acyl–enzyme intermediate toward an oxyanion (electrostatic catalysis).

(a)

**Figure 15-26** X-ray structures of porcine pancreatic elastase in complex with the heptapeptide BCM7 (YPFVEPI). The residues of elastase are specified by the three-letter code and those of BCM7 are specified by the one-letter code. (a) The complex at pH 5. The enzyme's active site residues and the heptapeptide (whose N-terminal three residues are disordered) are shown in ball-and-stick form with elastase C green, BCM7 C cyan, N blue, O red, S yellow, and the bond between the Ser 195 O atom and the C-terminal C atom of BCM7 lavender. The enzyme-bound water molecule, which appears poised to nucleophilically attack the acyl–enzyme's carbonyl C atom, is represented by an orange sphere. The dashed gray lines represent the catalytically

The catalytic reaction was initiated in crystals of the BCM7–elastase complex by transferring them to a buffer at pH 9. After soaking in this buffer for 1 min, the crystals were rapidly frozen in liquid N<sub>2</sub> (–196°C), thereby arresting the enzymatic reaction (recall that the catalytically essential collective motions of proteins cease at such low temperatures; Section 9-4a). The X-ray structure of such a frozen crystal (Fig. 15-26b) revealed that the above acyl–enzyme intermediate had converted to the tetrahedral intermediate, whose oxyanion, as expected, remained hydrogen bonded to the N atoms of Ser 195 and Gly 193. Comparison of this crystal structure with that of the acyl–enzyme intermediate reveals that the enzyme's active site residues do not significantly change their positions in the conversion from the acyl–enzyme intermediate to the tetrahedral intermediate. However, the peptide substrate must do so out of steric necessity when the trigonal planar acyl group converts to the tetrahedral oxyanion (compare Figs. 15-26a and 15-26b). In response, several enzyme residues that contact the peptide but which are distant from the active site also shift their positions (not shown in Fig. 15-26).

#### d. The Role of the Catalytic Triad: Low-Barrier Hydrogen Bonds

The earlier literature postulated that the Asp 102-polarized His 57 side chain directly abstracts a proton

(b)

important hydrogen bonds and the dotted gray line indicates the trajectory that the bound water molecule presumably follows in nucleophilically attacking the acyl group's carbonyl C atom. (b) The complex after being brought to pH 9 for 1 min and then rapidly frozen in liquid nitrogen. The various groups in the structure are represented and colored as in Part a. Note that the water molecule in Part a has become a hydroxyl substituent (orange) to the carbonyl C atom, thereby yielding the tetrahedral intermediate. [Based on X-ray structures by Christopher Schofield and Janos Hajdu, University of Oxford, U.K. PDBids (a) 1HAX and (b) 1HAZ.]

from Ser 195, thereby converting its weakly nucleophilic  $-\text{CH}_2\text{OH}$  group to a highly nucleophilic alkoxide ion,  $-\text{CH}_2\text{O}^-$ :

In the process, the anionic charge of Asp 102 was thought to be transferred, via a tautomeric shift of His 57, to Ser 195. The catalytic triad was therefore originally named the **charge relay system**. It is now realized, however, that such a mechanism is implausible because an alkoxide ion ( $pK \geq 15$ ) has far greater proton affinity than does His 57 ( $pK \approx 7$ , as measured by NMR techniques). How, then, can Asp 102 nucleophilically activate Ser 195?

A possible solution to this conundrum has been pointed out by W.W. Cleland and Maurice Kreevoy and, independently, by John Gerlt and Paul Gassman. Proton transfers between hydrogen bonded groups ( $\text{D}-\text{H}\cdots\text{A}$ ) only occur at physiologically reasonable rates when the  $pK$  of the proton donor is no more than 2 or 3 pH units greater than that of the protonated form of the proton acceptor (the height of the kinetic barrier,  $\Delta G^\ddagger$ , for the protonation of an acceptor by a more basic donor increases with the difference between the  $pK$ 's of the donor and acceptor). However, when the  $pK$ 's of the hydrogen bonding donor (D) and acceptor (A) groups are nearly equal, the distinction between them breaks down: *The hydrogen atom becomes more or less equally shared between them* ( $\text{D}\cdots\text{H}\cdots\text{A}$ ). Such **low-barrier hydrogen bonds (LBHBs)** are unusually short and strong (they are also known as **short, strong hydrogen bonds**): They have, as studies of model compounds in the gas phase indicate, association free energies as high as  $-40$  to  $-80$

$\text{kJ}\cdot\text{mol}^{-1}$  versus the  $-12$  to  $-30$   $\text{kJ}\cdot\text{mol}^{-1}$  for normal hydrogen bonds (the energy of the normally covalent  $\text{D}-\text{H}$  bond is subsumed into the low-barrier hydrogen bonding system) and a  $\text{D}\cdots\text{H}$  length of  $<2.55$  Å for  $\text{O}-\text{H}\cdots\text{O}$  and  $<2.65$  Å for  $\text{N}-\text{H}\cdots\text{O}$  versus 2.8 to 3.1 Å for normal hydrogen bonds.

LBHBs are unlikely to exist in dilute aqueous solution because water molecules, which are excellent hydrogen bonding donors and acceptors, effectively compete with  $\text{D}-\text{H}$  and  $\text{A}$  for hydrogen bonding sites. However, LBHBs may exist in nonaqueous solution and in the active sites of enzymes that exclude bulk solvent water. If so, an effective enzymatic "strategy" would be to convert a weak hydrogen bond in the Michaelis complex to a strong hydrogen bond in the transition state, thereby facilitating proton transfer while applying the difference in the free energy between the normal and low-barrier hydrogen bonds to preferentially binding the transition state. In fact, as Perry Frey has shown, the NMR spectrum of the proton linking His 57 to Asp 102 in chymotrypsin (which exhibits a particularly large downfield chemical shift indicative of deshielding) is consistent with the formation of an LBHB in the transition state (Fig. 15-25b; the  $pK$ 's of protonated His 57 and Asp 102 are nearly equal in the anhydrous environment of the active site complex). This presumably promotes proton transfer from Ser 195 to His 57 as in the charge relay mechanism. Moreover, an ultrahigh (0.78 Å) resolution X-ray structure of *Bacillus lentus* subtilisin by Richard Bott reveals that the hydrogen bond between His 64 and Asp 32 of its catalytic triad has an unusually short  $\text{N}\cdots\text{O}$  distance of  $2.62 \pm 0.01$  Å and that its H atom is nearly centered between the N and O atoms (note that this highly accurate protein X-ray structure is one of the very few in which H atoms are observed and in which short  $\text{D}\cdots\text{A}$  distances are confidently measured).

Although several studies, such as the foregoing, have revealed the existence of unusually short hydrogen bonds in enzyme active sites, it is far more difficult to demonstrate experimentally that they are unusually strong, as LBHBs are predicted to be. In fact, several studies of the strengths of unusually short hydrogen bonds in organic model compounds in nonaqueous solutions suggest that these hydrogen bonds are not unusually strong. Consequently, a lively debate has ensued as to the catalytic significance of LBHBs. Yet if enzymes do not form LBHBs, it remains to be explained how, in numerous widely accepted enzymatic mechanisms that we shall encounter, the conjugate base of an acidic group can abstract a proton from a far more basic group.

#### e. Much of a Serine Protease's Catalytic Activity Arises from Preferential Transition State Binding

Despite the foregoing, blocking the action of the catalytic triad through the specific methylation of His 57 by treating chymotrypsin with **methyl-*p*-nitrobenzene sulfonate**

yields an enzyme that is a reasonably good catalyst: It enhances the rate of proteolysis by as much as a factor of  $2 \times 10^6$  over the uncatalyzed reaction, whereas the native enzyme has a rate enhancement factor of  $\sim 10^{10}$ . Similarly, the mutation of Ser 195, His 57, or even all three residues of the catalytic triad yields enzymes that enhance proteolysis rates by  $\sim 5 \times 10^4$ -fold over that of the uncatalyzed reaction. Evidently, the catalytic triad provides a nucleophile and is an alternate source and sink of protons (general acid–base catalysis). However, *a large portion of chymotrypsin's rate enhancement must be attributed to its preferential binding of the catalyzed reaction's transition state.*

#### f. Enzymes Have Free Energy Landscapes That Facilitate Catalysis

How does an enzyme-catalyzed reaction reach its transition state? Recall that, under physiological conditions, proteins are highly dynamic entities with structural fluctuations having periods ranging from  $\sim 10^{-15}$  s for bond vibrations to 1 s or more for triggered conformational changes (Section 9-4). The turnover times for enzymatic reactions,  $1/k_{\text{cat}}$ , are mostly in the range 1  $\mu\text{s}$  to 1 s (Table 14-1), but yet the lifetime of a transition state is only around that of a bond vibration (Section 14-1Cb). Thus, even for a reaction with a turnover time as little as 1  $\mu\text{s}$ , every atom in the enzyme–substrate complex undergoes approximately  $10^{-6}/10^{-15} = 10^9$  vibrational excursions between turnovers. Apparently, *the transition state is an arrangement of substrate and catalytic groups that occurs extremely rarely through the fluctuations of its component atoms.*

Proteins, as we have seen, are designed by evolution to fold to their native states via a series of conformational adjustments that follow funnel-shaped free energy landscapes (Section 9-1Ch). A variety of structural, mutational, and theoretical studies indicate that *enzyme–sub-*

*strate complexes are similarly evolutionarily designed to structurally rearrange themselves through a progression of conformational changes that lead to the formation of the transition state.* This explains, for example, why the mutation of a residue far from the active site of an enzyme that does not appear to have a structurally important role, may nevertheless significantly reduce the rate of the reaction that the enzyme catalyzes. Such a mutation perturbs extended hydrogen bonding networks and long range electrostatic interactions in a way that alters the entire enzyme's spectrum of thermal motions. This changes the enzyme's free energy landscape so as to reduce the probability that it will achieve the transition state in a given time period.

#### E. Zymogens

Most proteolytic enzymes are biosynthesized as somewhat larger inactive precursors known as **zymogens** (enzyme precursors, in general, are known as **proenzymes**). In the case of digestive enzymes, the reason for this is clear: If these enzymes were synthesized in their active forms, they would digest the tissues that synthesized them. Indeed, **acute pancreatitis**, a painful and sometimes fatal condition that can be precipitated by pancreatic trauma, is characterized by the premature activation of the digestive enzymes synthesized by this gland.

##### a. Serine Proteases Are Autocatalytically Activated

Trypsin, chymotrypsin, and elastase are activated according to the following pathways:

**Trypsin.** The activation of **trypsinogen**, the zymogen of trypsin, occurs as a two-stage process when trypsinogen enters the duodenum from the pancreas. **Enteropeptidase**, a single-pass transmembrane serine protease that is located in the duodenal mucosa, specifically hydrolyzes trypsinogen's Lys 15—Ile 16 peptide bond, thereby excising its N-terminal hexapeptide (Fig. 15-27). This yields the active enzyme, which has Ile 16 at its N-terminus. Since this

**Figure 15-27** Activation of trypsinogen to form trypsin.

Proteolytic excision of the N-terminal hexapeptide is catalyzed by either enteropeptidase or trypsin. The chymotrypsinogen residue numbering is used here; that is, Val 10 is actually trypsinogen's N-terminus and Ile 16 is trypsin's N-terminus.

**Figure 15-28** Activation of chymotrypsinogen by proteolytic cleavage. Both  $\pi$ - and  $\alpha$ -chymotrypsin are enzymatically active.  See Kinemage Exercise 10-4

activating cleavage occurs at a trypsin-sensitive site (recall that trypsin cleaves after Arg and Lys residues), the small amount of trypsin produced by enteropeptidase also catalyzes trypsinogen activation, generating more trypsin, etc.; that is, trypsinogen activation is autocatalytic.

**Chymotrypsin.** Chymotrypsinogen is activated by the specific tryptic cleavage of its Arg 15—Ile 16 peptide bond to form  $\pi$ -chymotrypsin (Fig. 15-28).  $\pi$ -Chymotrypsin subsequently undergoes autolysis (self-digestion) to specifically excise two dipeptides, Ser 14—Arg 15 and Thr 147—Asn 148, thereby yielding the equally active enzyme  $\alpha$ -chymotrypsin (heretofore and hereafter referred to as chymotrypsin). The biochemical significance of this latter process, if any, is unknown.

**Elastase. Proelastase,** the zymogen of elastase, is activated similarly to trypsinogen by a single tryptic cleavage that excises a short N-terminal polypeptide.

#### b. Biochemical “Strategies” That Prevent Premature Zymogen Activation

Trypsin activates pancreatic **procarboxypeptidases A and B** and **prophospholipase A<sub>2</sub>** (the action of phospholipase A<sub>2</sub> is outlined in Section 25-1) as well as the pancreatic serine proteases. Premature trypsin activation can consequently trigger a series of events that lead to pancreatic self-digestion. Nature has therefore evolved an elaborate defense against such inappropriate trypsin activation. We have already seen (Section 15-3Da) that pancreatic trypsin inhibitor binds essentially irreversibly to any trypsin formed in the pancreas so as to inactivate it. Furthermore, the trypsin-catalyzed activation of trypsinogen (Fig. 15-27) occurs quite slowly, presumably because the unusually

large negative charge of its highly evolutionarily conserved N-terminal hexapeptide repels the Asp at the back of trypsin’s specificity pocket (Fig. 15-21). Finally, pancreatic zymogens are stored in intracellular vesicles called **zymogen granules** whose membranous walls are thought to be resistant to enzymatic degradation.

#### c. Zymogens Have Distorted Active Sites

Since the zymogens of trypsin, chymotrypsin, and elastase have all their catalytic residues, why aren’t they enzymatically active? Comparisons of the X-ray structures of trypsinogen with that of trypsin and of chymotrypsinogen with that of chymotrypsin show that on activation, the newly liberated N-terminal Ile 16 residue moves from the surface of the protein to an internal position, where its free cationic amino group forms an ion pair with the invariant anionic Asp 194 (Fig. 15-20). Aside from this change, however, the structures of these zymogens closely resemble those of their corresponding active enzymes. Surprisingly, this resemblance includes their catalytic triads, an observation which led to the discovery that these zymogens are actually catalytically active, albeit at a very low level. Careful comparisons of the corresponding enzyme and zymogen structures revealed the reason for this low activity: *The zymogens’ specificity pockets and oxyanion holes are improperly formed such that, for example, the amide NH of chymotrypsinogen’s Gly 193 points in the wrong direction to form a hydrogen bond with the tetrahedral intermediate (see Fig. 15-25).* Hence, the zymogens’ very low enzymatic activity arises from their reduced ability to bind substrate productively and to stabilize the tetrahedral intermediate. These observations provide further structural evidence favoring the role of preferred transition state binding in the catalytic mechanism of serine proteases.

## 4 DRUG DESIGN

The improvements in medical care over the past several decades are, in large measure, attributable to the development of a huge variety of drugs, which have eliminated or greatly relieved numerous human ailments. Such medications include antibiotics (which have enormously reduced the impact of infectious diseases), anti-inflammatory agents (which reduce the effects of inflammatory diseases such as arthritis), analgesics and anesthetics (which make modern surgical techniques possible), agents that reduce the incidence and severity of cardiovascular disease and stroke, antidepressants, antipsychotics, agents that inhibit stomach acid secretion (which prevent stomach ulcers and heartburn), agents to combat allergies and asthma, immunosuppressants (which make organ transplants possible), agents used for cancer chemotherapy, and a great variety of other substances.

Early human cultures almost certainly recognized both the beneficial and toxic effects of indigenous plant and animal products and used many of them as “medications.” Unfortunately, most of these substances were useless or even harmful. Although there were sporadic attempts over the 2500 years preceding the modern era to formulate rational systems of drug discovery, they had little success because they were based mainly on unfounded theories and superstition (e.g., the doctrine of signatures stated that if a plant resembles a particular body part, it must be designed by nature to influence that body part) rather than observation and experiment. Consequently, at the beginning of the 20th century, only three known drugs, apart from folk medicines, were effective in treating specific diseases: (1) **Digitalis**, a heart stimulant extracted from the foxglove plant (Section 20-3Af), was used to treat various heart conditions; (2) **quinine** (Section 26-4Ak), obtained from the bark and roots of the *Cinchona* tree, was used to treat malaria; and (3) mercury was used to treat syphilis (a cure that was often worse than the disease). It was not until several decades later that the rise of the scientific method coupled to the rapidly increasing knowledge of physiology, biochemistry, and chemistry led to effective methods of drug discovery. In fact, the vast majority of drugs in use today were discovered and developed in the past four decades.

In this section we discuss the elements of drug discovery and **pharmacology** (Greek: *pharmakon*, drug; the science of drugs, including their composition, uses, and effects). The section ends with a consideration of one of the major successes of modern drug discovery methods, HIV protease inhibitors.

### A. Techniques of Drug Discovery

Most drugs act by modifying the function of a particular **receptor** in the body or in an invading pathogen. In most cases, the receptor is a protein to which the drug specifically binds. It may be an enzyme, a transmembrane channel that transports a specific substance into or out of a cell (Chapter 20), and/or a protein that participates in an inter- or intracellular signaling pathway (Chapter 19). In all of these cases, a substance that in binding to a receptor modulates its

function is known as an **agonist**, whereas a substance that binds to a receptor without affecting its function but blocks the binding of agonists is called an **antagonist**. The biochemical and physiological effects of a drug and its mechanism of action are referred to as its **pharmacodynamics**.

#### a. Drug Discovery Is a Complex Procedure

How are new drugs discovered? Nearly all drugs that have been in use for over 15 years were discovered by screening large numbers of synthetic compounds and natural products for the desired effect. Drug candidates that are natural products are usually discovered by the fractionation of the organisms in which they occur, which are often plants used in folk remedies of the conditions of interest. Humans having the condition whose treatment is being sought cannot be used as “guinea pigs” in this initial screening process, and even guinea pigs or other laboratory animals such as mice or dogs (if they can be made to be suitable models of the condition under consideration) are too expensive to use on the many thousands of compounds that are usually tested. Thus, *in vitro* **screens** are initially used, such as the degree of binding of a drug candidate to an enzyme that is implicated in a disease of interest, toxicity toward the target bacteria in the search for a new antibiotic, or effects on a line of cultured mammalian cells. However, as the number of drug candidates is winnowed down, more sensitive screens such as testing in animals are employed.

A drug candidate that exhibits a desired effect is called a **lead compound** (or, colloquially, a lead; pronounced leed). A good lead compound binds to its target receptor with a dissociation constant,  $K_D < 1 \mu M$ . Such a high affinity is necessary to minimize a drug’s less specific binding to other macromolecules in the body and to ensure that only low doses of the drug need be taken. For enzyme inhibitors, the dissociation constant is the inhibitor’s  $K_I$  or  $K_I'$  (Section 14-3). Other common measures of the effect of a drug are the **IC<sub>50</sub>**, the inhibitor concentration at which an enzyme exhibits 50% of its maximal activity; the **ED<sub>50</sub>**, the effective dose of a drug required to produce a therapeutic effect in 50% of a test sample; the **TD<sub>50</sub>**, the mean toxic dose required to produce a particular toxic effect in animals; and the **LD<sub>50</sub>**, the mean lethal dose required to kill 50% of a test sample.

For an inhibitor of an enzyme that follows Michaelis–Menten kinetics, the  $IC_{50}$  is determined by measuring the ratio  $v_I/v_o$  for several values of  $[I]$  at constant  $[S]$ , where  $v_I$  is the initial velocity of the enzyme when the inhibitor concentration is  $[I]$ . By dividing Eq. [14.24] by Eq. [14.38] with  $\alpha$  defined according to Eq. [14.37], we see that

$$\frac{v_I}{v_o} = \frac{K_M + [S]}{K_M\alpha + [S]} = \frac{K_M + [S]}{K_M\left(1 + \frac{[I]}{K_I}\right) + [S]} \quad [15.13]$$

When  $v_I/v_o = 0.5$  (50% inhibition),

$$[I] = [IC_{50}] = K_I\left(1 + \frac{[S]}{K_M}\right) \quad [15.14]$$

Consequently, if the measurements of  $v_I/v_o$  are made with  $[S] \ll K_M$ , then  $[IC_{50}] = K_I$ .

The ratio  $TD_{50}/ED_{50}$  is defined as a drug's **therapeutic index**, the ratio of the dose of the drug that produces toxicity to that which produces the desired effect. It is, of course, preferable that a drug have a high therapeutic index, but this is not always possible.

#### b. Cathepsin K Is a Drug Target for Osteoporosis

The development of genomic sequencing techniques (Section 7-2B) and hence the characterization of tens of thousands of previously unknown genes is providing an enormous number of potential drug targets. For example, **osteoporosis** (Greek: *osteon*, bone + *poros*, porous), a condition that afflicts mostly postmenopausal women, is characterized by the progressive loss of bone mass leading to a greatly increased frequency of bone fracture, most often of the hip, spine, and wrist. Bones consist of a protein matrix that is >90% type I collagen (Section 8-2B), in which spindle- or plate-shaped crystals of **hydroxyapatite**,  $Ca_5(PO_4)_3OH$ , are embedded. Bones are by no means static structures. They undergo continuous remodeling through the countervailing action of two types of bone cells: **osteoblasts** (Greek: *blast*, germ cell), which synthesize bone's protein matrix in which its mineral component is laid down; and **osteoclasts** (Greek: *clast*, broken), which solubilize mineralized bone matrix through the secretion of proteolytic enzymes into an extracellular bone resorption pit, which is maintained at pH 4.5. The acidic solution dissolves the bone's mineral component, thereby exposing its protein matrix to proteolytic degradation. Osteoporosis arises when bone resorption outstrips bone formation.

In the search for a drug target for osteoporosis, a cDNA library (Sections 5-5E and 5-5Fa) was prepared from an **osteoclastoma** (a cancer derived from osteoclasts; normally osteoclasts are very rare cells). Around 4% of these cDNAs encode a heretofore unknown protease, which was named **cathepsin K** (cathepsins are proteases that occur in the lysosome). Further studies, both at the cDNA and protein levels, indicated that cathepsin K is only expressed at high levels in osteoclasts. Microscopic examination of osteoclasts that had been stained with antibodies directed against cathepsin K revealed that this enzyme is localized at the contact site between osteoclasts and the bone resorption pit. Subsequently, it was shown that mutations in the gene encoding cathepsin K are the cause of **pseudosyndactylism**, a rare hereditary disease which is characterized by hardened and fragile bones, short stature, skull deformities, and osteoclasts that demineralize bone normally but do not degrade its protein matrix. Evidently, cathepsin K functions to degrade the protein matrix of bone and hence is an attractive drug target for the treatment of osteoporosis. Indeed, several cathepsin K inhibitors are in clinical trials (Section 15-4Bb).

#### c. SARs and QSARs Are Useful Tools for Drug Discovery

A lead compound is used as a point of departure to design more efficacious compounds. Experience has shown that even minor modifications to a drug candidate can result in major changes in its pharmacological properties. Thus, one might place methyl, chloro, hydroxyl, or benzyl groups at various places on a lead compound in an effort to improve

its pharmacodynamics. For most drugs in use today, 5 to 10 thousand related compounds were typically synthesized in generating the medicinally useful drug. These were not random procedures but were guided by experience as medicinal chemists tested various derivatives of a lead compound: For those compounds that had improved efficacy, derivatives were made and tested; etc. This process has been systematized through the use of **structure–activity relationships (SARs)**: the determination, via synthesis and screening, of which groups on a lead compound are important for its drug function and which are not. For example, if a phenyl group on a lead compound interacts hydrophobically with a flat region of its receptor, then hydrogenating the phenyl ring to form a nonplanar cyclohexane ring will yield a compound with reduced affinity for the receptor.

A logical extension of the SAR concept is to quantify it, that is, to determine a **quantitative structure–activity relationship (QSAR)**. This idea is based on the premise that there is a relatively simple mathematical relationship between the biological activity of a drug and its physicochemical properties. For instance, if the hydrophobicity of a drug is important for its biological activity, then changing the substituents on the drug so as to alter its hydrophobicity will affect its activity. A measure of the substance's hydrophobicity is its **partition coefficient,  $P$** , between the two immiscible solvents, octanol and water, at equilibrium:

$$P = \frac{\text{concentration of drug in octanol}}{\text{concentration of drug in water}} \quad [15.15]$$

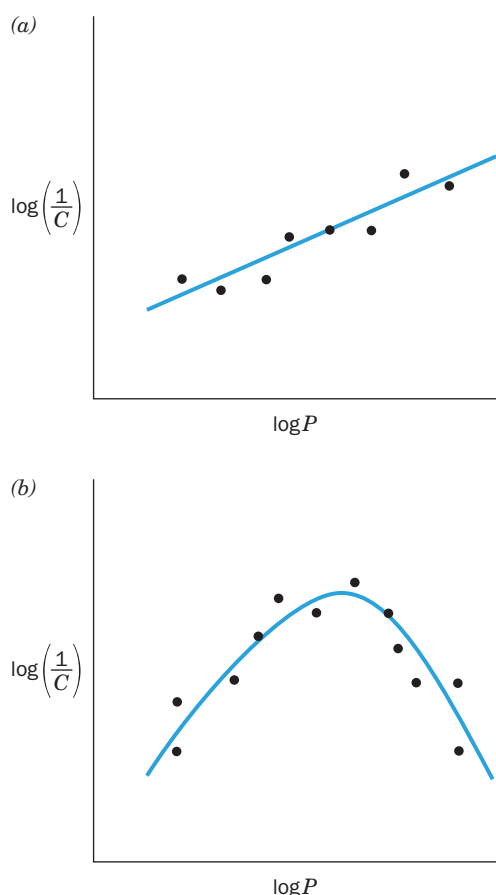

Biological activity may be expressed as  $1/C$ , where  $C$  is the drug concentration required to achieve a specified level of biological function (e.g.,  $IC_{50}$ ). Then a plot of  $\log 1/C$  versus  $\log P$  (the use of logarithms keeps the plot on a manageable scale) for a series of derivatives of the lead compound having a relatively small range of  $\log P$  values often indicates a linear relationship (Fig. 15-29a), which can therefore be expressed:

$$\log\left(\frac{1}{C}\right) = k_1 \log P + k_2 \quad [15.16]$$

Here  $k_1$  and  $k_2$  are constants, whose optimum values in this QSAR can be determined by computerized curve-fitting methods. For compounds with a larger range of  $\log P$  values, it is likely that a plot of  $\log 1/C$  versus  $\log P$  will have a maximum value (Fig. 15-29b) and hence be better described by a quadratic equation:

$$\log\left(\frac{1}{C}\right) = k_1(\log P)^2 + k_2 \log P + k_3 \quad [15.17]$$

Of course, the biological activities of few substances depend only on their hydrophobicities. A QSAR can therefore simultaneously take into account several physicochemical properties of substituents such as their  $pK$  values, van der Waals radii, hydrogen bonding energy, and conformation. The values of the constants for each of the terms in a QSAR is indicative of the contribution of that term to the drug's activity. The use of QSARs to optimize the biological activity of a lead compound has proven to be a valuable tool in drug discovery.

**Figure 15-29** Hypothetical QSAR plots of  $\log(1/C)$  versus  $\log P$  for a series of related compounds. (a) A plot that is best described by a linear equation. (b) A plot that is best described by a quadratic equation.

#### d. Structure-Based Drug Design

Since the mid 1980s, dramatic advances in the speed and precision with which a macromolecular structure can be determined by X-ray crystallography and NMR (Section 8-3A) have enabled **structure-based drug design**, a process that greatly reduces the number of compounds that need be synthesized in a drug discovery program. As its name implies, structure-based drug design (also called **rational drug design**) uses the structure of a receptor in complex with a drug candidate to guide the development of more efficacious compounds. Such a structure will reveal, for example, the positions of the hydrogen bonding donors and acceptors in a receptor binding site as well as cavities in the binding site into which substituents might be placed on a drug candidate to increase its binding affinity for the receptor. These direct visualization techniques are usually supplemented with molecular modeling tools such as the computation of the minimum energy conformation of a

proposed derivative, quantum mechanical calculations that determine its charge distribution and hence how it would interact electrostatically with the receptor, and docking simulations in which an inhibitor candidate is computationally modeled into the binding site on the receptor to assess potential interactions. Structure-based drug design is an iterative process: The structure of the receptor in complex with a compound with improved properties is determined in an effort to further improve its properties.

#### e. Combinatorial Chemistry, Fragment-Based Lead Discovery, and High-Throughput Screening

As structure-based methods were developed, it appeared that they would become the dominant mode of drug discovery. However, the advent of **combinatorial chemistry** techniques to rapidly and inexpensively synthesize large numbers of related compounds combined with the development of robotic **high-throughput screening** techniques has caused the drug discovery “pendulum” to again swing toward the “make-many-compounds-and-see-what-they-do” approach. A familiar example of combinatorial chemistry is the parallel synthesis of the large number of different oligonucleotides on a DNA microarray (Section 7-6B). If a lead compound can similarly be synthesized in a stepwise manner from several smaller modules, then the substituents on each of these modules can be varied in parallel to produce a library of related compounds (e.g., Fig. 15-30).

A variety of synthetic techniques have been developed that permit the combinatorial synthesis of thousands of related compounds in a single procedure. Thus, whereas investigations into the importance of a hydrophobic group at a particular position in a lead compound might previously have prompted the individual syntheses of only the ethyl, propyl, and benzyl derivatives of the compound, the use of combinatorial synthesis would permit the generation of perhaps 100 different groups at that position. This would far more effectively map out the potential range of the substituent and possibly identify an unexpectedly active analog. Interestingly, QSAR and computational techniques have been combined in the development of “virtual combinatorial chemistry,” a procedure in which libraries of compounds are computationally “synthesized” and “analyzed” to predict their efficacy, thereby again reducing the number of compounds that must actually be synthesized in order to generate an effective drug.

The relatively recently developed approach to drug discovery known as **fragment-based lead discovery (FBLD)** has shown encouraging signs of success. In this method, rather than screening large numbers of potential lead compounds for substances that bind with high affinity to a drug target, only a relatively small number of simple compounds are screened for their ability to bind to the drug target with low affinity. Substances that do so, which likely bind to only a small portion of the drug target’s surface area, are then

**Figure 15-30** The combinatorial synthesis of arylidene diamides. If ten different variants of each R group are used in the synthesis, then 1000 different derivatives will be synthesized.

“grown” by adding chemical groups and/or linking several such fragments together. Thus, FBLD discovers a lead compound one piece at a time rather than all at once.

## B. Introduction to Pharmacology

The *in vitro* development of an effective drug candidate is only the first step in the drug development process. *Besides causing the desired response in its isolated target receptor, a useful drug must be delivered in sufficiently high concentration to this receptor where it resides in the human body without causing unacceptable side effects.*

### a. Pharmacokinetics Is a Multifaceted Phenomenon

The most convenient form of drug administration is orally (by mouth). In order to reach its target receptor, a drug administered in this way must surmount a series of formidable barriers: (1) It must be chemically stable in the highly acidic (pH 1) environment of the stomach and must not be degraded by the digestive enzymes in the gastrointestinal tract; (2) it must be absorbed from the gastrointestinal tract into the bloodstream, that is, it must pass through several cell membranes; (3) it must not bind too tightly to other substances in the body (e.g., lipophilic substances tend to be absorbed by certain plasma proteins and by fat tissue; anions may be bound by plasma proteins, mainly **albumin**; and cations may be bound by nucleic acids); (4) it must survive derivatization by the battery of enzymes, mainly in the liver, that function to detoxify **xenobiotics** (foreign compounds), as discussed below (note that the intestinal blood flow drains directly into the liver via the portal vein, so that the liver processes all orally ingested substances before they reach the rest of the body); (5) it must avoid rapid excretion by the kidneys; (6) it must pass from the capillaries to its target tissue; (7) if it is targeted to the brain, it must cross the **blood–brain barrier**, which blocks the passage of most polar substances; and (8) if it is targeted to an intracellular receptor, it must pass through the plasma membrane and, possibly, other intracellular membranes. The ways in which a drug interacts with these various barriers is known as its **pharmacokinetics**. Thus, the **bioavailability** of a drug (the extent to which it reaches its site of action, which is usually taken to be the systemic circulation) depends on both the dose given and its pharmacokinetics. Of course, barriers (1) and (2) can be circumvented by injecting the drug [e.g., some forms of penicillin (Fig. 11-28) must be injected because their functionally essential  $\beta$ -lactam rings are highly susceptible to acid hydrolysis], but this mode of drug delivery is undesirable for long-term use.

Since the pharmacokinetics of a drug candidate is as important to its efficacy as is its pharmacodynamics, both must be optimized in producing a medicinally useful drug. The following empirically based rules, formulated by Christopher Lipinski and known as **Lipinski’s “rule of five,”** state that an orally administered compound is likely to exhibit poor absorption or permeation if:

1. Its molecular mass is greater than 500 D.
2. It has more than 5 hydrogen bond donors (expressed as the sum of its OH and NH groups).

3. It has more than 10 hydrogen bond acceptors (expressed as the sum of its N and O atoms).

4. Its value of  $\log P$  is greater than 5.

Drug candidates that disobey Rule 1 are likely to have low solubilities and to only pass through cell membranes with difficulty; those that disobey Rules 2 and/or 3 are likely to be too polar to pass through cell membranes; and those that disobey Rule 4 are likely to be poorly soluble in aqueous solution and hence unable to gain access to membrane surfaces. Thus, *the most effective drugs are usually a compromise; they are neither too lipophilic nor too hydrophilic.* In addition, their  $pK$  values are usually in the range 6 to 8 so that they can readily assume both their ionized and unionized forms at physiological pH’s. This permits them to cross cell membranes in their unionized form and to bind to their receptor in their ionized form. However, since the concentration of a drug at its receptor depends, as we saw, on many different factors, the pharmacokinetics of a drug candidate may be greatly affected by even small chemical changes. QSARs and other computational tools have been developed to predict these effects but they are, as yet, rather crude.

### b. Toxicity and Adverse Reactions Eliminate Most Drug Candidates

The final criteria that a drug candidate must meet are that its use be safe and efficacious in humans. Tests for these properties are initially carried out in animals, but since humans and animals often react quite differently to a particular drug, the drug must ultimately be tested in humans through **clinical trials**. In the United States, clinical trials are monitored by the Food and Drug Administration (FDA) and have three increasingly detailed (and expensive) phases:

**Phase I.** This phase is primarily designed to test the safety of a drug candidate but is also used to determine its dosage range and the optimal dosage method (e.g., orally vs injection) and frequency. It is usually carried out on a small number (20–100) of normal, healthy volunteers, but in the case of a drug candidate known to be highly toxic (e.g., a cancer chemotherapeutic agent), it is carried out on volunteer patients with the target disease.

**Phase II.** This phase mainly tests the efficacy of the drug against the target disease in 100 to 500 volunteer patients but also refines the dosage range and checks for side effects. The effects of the drug candidate are usually assessed via **single blind tests**, procedures in which the patient is unaware of whether he/she has received the drug or a control substance. Usually the control substance is a **placebo** (an inert substance with the same physical appearance, taste, etc., as the drug being tested) but, in the case of a life-threatening disease, it is an ethical necessity that the control substance be the best available treatment against the disease.

**Phase III.** This phase monitors adverse reactions from long-term use as well as confirming efficacy in 1000 to 5000 patients. It pits the drug candidate against control substances through the statistical analysis of carefully designed **double blind tests**, procedures in which neither the patients nor the clinical investigators evaluating the patients’ responses to the drug know whether a given patient has received the

drug or a control substance. This is done to minimize bias in the subjective judgments the investigators must make.

Currently, only about 5 drug candidates in 5000 that enter preclinical trials reach clinical trials. Of these, only one, on average, is ultimately approved for clinical use, with ~40% of drug candidates passing Phase I trials and ~50% of those passing Phase II trials (most drug candidates that enter Phase III trials are successful). In recent years, the preclinical portion of a drug discovery process has averaged ~3 years to complete, whereas successful clinical trials have usually required an additional 7 to 10 years. These successive stages of the drug discovery process are increasingly expensive, so that to successfully bring a drug to market costs, on average, around \$300 million.

The most time-consuming and expensive aspect of a drug development program is identifying a drug candidate's rare adverse reactions. Nevertheless, it is not an uncommon experience for a drug to be brought to market only to be withdrawn some months or years later when it is found to have caused unanticipated life-threatening side effects in as few as 1 in 10,000 individuals (the search for new applications of an approved drug and its postmarketing surveillance are known as its Phase IV clinical trials). For example, in 1997, the FDA withdrew its approval of the drug **fenfluramine (fen)**,

which it had approved in 1973 for use as an appetite suppressant in short-term (a few weeks) weight loss programs. Fenfluramine had become widely prescribed, often for extended periods, together with another appetite suppressant, **phentermine (phen; approved in 1959)**, a combination known as **fen-phen** (although the FDA had not approved of the use of the two drugs in combination, once it approves a drug for any purpose, a physician may prescribe it for any other purpose, a practice known as off-label use). The withdrawal of fenfluramine was prompted by over 100 reports of heart valve damage in individuals (mostly women) who had taken fen-phen for an average of 12 months (phentermine was not withdrawn because the evidence indicated that fenfluramine was the responsible agent). This rare side effect had not been observed in the clinical trials of fenfluramine, in part because, being an extremely unusual type of drug reaction, it had not been screened for.

More recently (2004), the widely prescribed analgesic **Vioxx** was withdrawn from use due to its previously undetected cardiac side effects, although the closely related analgesic **Celebrex** remains available (Section 25-7Bb).

### c. The Cytochromes P450 Metabolize Most Drugs

Why is it that a drug that is well tolerated by the majority of patients can pose such a danger to others? *Differences in reactions to drugs arise from genetic differences*

*among individuals as well as differences in their disease states, other drugs they are taking, age, sex, and environmental factors.* The **cytochromes P450**, which function in large part to detoxify xenobiotics and participate in the metabolic clearance of the majority of drugs in use, provide instructive examples of these phenomena.

The cytochromes P450 constitute a superfamily of heme-containing enzymes that occur in nearly all living organisms, from bacteria to mammals [their name arises from the characteristic 450-nm peak in their absorption spectra when reacted in their Fe(II) state with CO]. The human genome encodes 57 **isozymes** (catalytically and structurally similar but genetically distinct enzymes from the same organism; also called **isoforms**) of cytochromes P450, about one-third of which occur only in the liver (P450 isozymes are named by the letters "CYP" followed by a number designating its family, an uppercase letter designating its subfamily, and often another number; e.g., CYP2D6). These **monooxygenases** (Fig. 15-31), which in animals are embedded in the endoplasmic reticulum membrane, catalyze reactions of the sort

The electrons ( $e^-$ ) are supplied by NADPH, which passes them to cytochrome P450's heme prosthetic group via the intermediacy of the enzyme **NADPH-P450 reductase**. Here RH represents a wide variety of usually lipophilic compounds for which the different cytochromes P450 are specific. They include polycyclic aromatic hydrocarbons [PAHs, frequently carcinogenic (cancer-causing) compounds that are present in tobacco smoke, broiled meats, and other pyrolysis products], polycyclic biphenyls (PCBs,

**Figure 15-31** X-ray structure of the human cytochrome P450 CYP2C9 in complex with the blood clotting inhibitor warfarin. A cutaway diagram of the enzyme's active site region drawn with its surface purple and with its polypeptide backbone in ribbon form colored in rainbow order from N-terminus (blue) to C-terminus (red). The heme (seen edgewise), the Cys side chain that axially ligands the heme Fe atom, and the warfarin (**coumadin**; Fig. 35-12) are shown in ball-and-stick form with C gray, N blue, O red, S yellow, and Fe orange. [Courtesy of Astex Therapeutics, Limited. PDBid 1OG5.]

which were widely used in electrical insulators and as plasticizers and are also carcinogenic), steroids (in whose syntheses cytochromes P450 participate; Sections 25-6A and 25-6C), and many different types of drugs. The xenobiotics are thereby converted to a more water-soluble form, which aids in their excretion by the kidneys. Moreover, the newly generated hydroxyl groups are often enzymatically conjugated (covalently linked) to polar substances such as glucuronic acid (Section 11-1Cb), glycine, sulfate, and acetate, which further enhances aqueous solubility. The many types of cytochromes P450 in animals, which have different substrate specificities (although these specificities tend to be broad and hence often overlap), are thought to have arisen in response to the numerous toxins which plants produce, presumably to discourage animals from eating them (other P450s function to catalyze specific biosynthetic reactions).

**Drug-drug interactions** are often mediated by cytochromes P450. For example, if drug A is metabolized by or otherwise inhibits a cytochrome P450 isozyme that metabolizes drug B, then coadministering drugs A and B will cause the bioavailability of drug B to increase above the value it would have had if it alone had been administered. This phenomenon is of particular concern if drug B has a low therapeutic index. Conversely, if, as is often the case, drug A induces the increased expression of the cytochrome P450 isozyme that metabolizes it and drug B, then co-administering drugs A and B may reduce drug B's bioavailability, a

phenomenon that was first noted when certain antibiotics caused oral contraceptives to lose their efficacy. Moreover, if drug B is metabolized to a toxic product, its increased rate of reaction may result in an adverse reaction. Environmental pollutants such as PAHs or PCBs are also known to induce the expression of specific cytochrome P450 isozymes and thereby alter the rates at which certain drugs are metabolized. Finally, some of these same effects may occur in patients with liver disease, as well as arising from age-based, gender-based, and individual differences in liver physiology.

Although the cytochromes P450 presumably evolved to detoxify and/or help eliminate harmful substances, in several cases they have been shown to participate in converting relatively innocuous compounds to toxic agents. For example, **acetaminophen** (Fig. 15-32), a widely used analgesic and antipyretic (fever reducer), is quite safe when taken in therapeutic doses (1.2 g/day for an adult) but in large doses (>10 g) is highly toxic. This is because, in therapeutic amounts, 95% of the acetaminophen present is enzymatically glucuronidated or sulfated at its —OH group to the corresponding conjugates, which are readily excreted. The remaining 5% is converted, through the action of a cytochrome P450 (CYP2E1), to **acetimidoquinone** (Fig. 15-32), which is then conjugated with **glutathione**, a tripeptide with an unusual  $\gamma$ -amide bond that participates in a wide variety of metabolic processes (Section 26-4C). However, when acetaminophen is taken in large amounts, the glucuronida-

**Figure 15-32** The metabolic reactions of acetaminophen that convert it to its conjugate with glutathione.

tion and sulfation pathways become saturated and hence the cytochrome P450-mediated pathway becomes increasingly important. If hepatic (liver) glutathione is depleted faster than it can be replaced, acetimidoquinone, a reactive compound, instead conjugates with the sulfhydryl groups of cellular proteins, resulting in often fatal hepatotoxicity.

Many of the cytochromes P450 in humans are unusually **polymorphic**, that is, there are several common alleles (variants) of the genes encoding these enzymes. Alleles that cause diminished, enhanced, and qualitatively altered rates of drug metabolism have been characterized for many of the cytochromes P450. The distributions of these various alleles differ markedly among ethnic groups and hence probably arose to permit each group to cope with the toxins in its particular diet.

Polymorphism in a given cytochrome P450 results in differences between individuals in the rates at which they metabolize certain drugs. For instance, in cases that a cytochrome P450 variant has absent or diminished activity, otherwise standard doses of a drug that the enzyme normally metabolizes may cause the bioavailability of the drug to reach toxic levels. Conversely, if a particular P450 enzyme has enhanced activity (usually because the gene encoding it has been duplicated one or more times), higher than normal doses of a drug that the enzyme metabolizes would have to be administered to obtain the required therapeutic effect. However, if the drug is metabolized to a toxic product, this may result in an adverse reaction. Several known P450 variants have altered substrate specificities and hence produce unusual metabolites, which also may cause harmful side effects.

Experience has amply demonstrated that *there is no such thing as a drug that is entirely free of adverse reactions*. However, as the enzymes and their variants that participate in drug metabolism are characterized and rapid and

inexpensive genotyping methods are developed, it may become possible to tailor drug treatment to an individual's genetic makeup rather than to the population as a whole. This rapidly developing area of study is known as **pharmacogenomics** (or, more colloquially, as “personalized genomics” or “personalized medicine”).

### C. HIV Protease and Its Inhibitors

**Acquired immunodeficiency syndrome (AIDS)**, the only major epidemic attributable to a previously unknown pathogen to appear in the 20th century (it was first described in 1981), is caused by **human immunodeficiency virus type 1 (HIV-1)**; the closely related **HIV-2**, which we shall not explicitly discuss here, also causes AIDS and has a similar response to drugs). HIV-1, which was discovered in 1983 by Françoise Barré-Sinoussi, Luc Montagnier, and Robert Gallo, is a **retrovirus**, a family of viruses that were independently characterized in 1970 by David Baltimore and Howard Temin. The retroviral genome is a single-stranded RNA that reproduces inside its host cell by transcribing the RNA to double-stranded DNA in a process mediated by the virally encoded enzyme **reverse transcriptase** (Section 30-4C). The DNA is then inserted into the host cell's chromosomal DNA by a viral enzyme named **integrase** and is passively replicated along with the cell's DNA. However, under activating conditions (which for HIV-1 often is an infection by another pathogen), the retroviral DNA is transcribed, the proteins it encodes are expressed and inserted in or anchored to the host cell plasma membrane, and new **virions** (virus particles) are produced by the budding out of a viral protein-laden segment of plasma membrane so as to enclose viral RNA (Fig. 15-33).

HIV-1 is targeted to and specifically replicates within **helper T cells**, essential components of the immune system

**Figure 15-33** The assembly, budding, and maturation of HIV-1. SU is the surface glycoprotein gp120 and TM is the transmembrane protein gp41. [After Turner, B.G. and Summers, M.F., *J. Mol. Biol.* **285**, 4 (1999).]

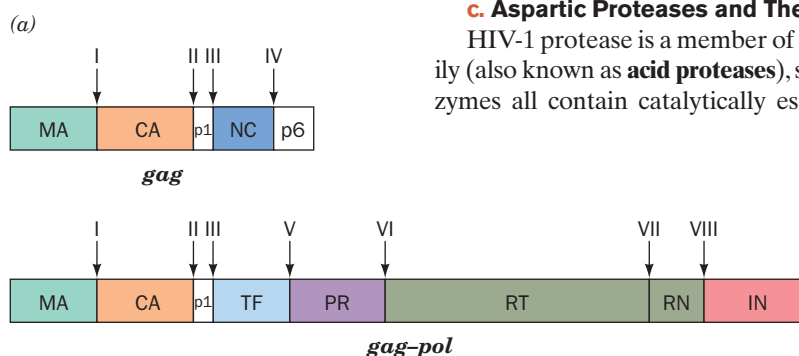

(Section 35-2Aa). Unlike most types of retroviruses, HIV-1 eventually kills the cells producing it. Although the helper *T* cells within which HIV-1 are actively replicating are often destroyed by the immune system, those within which the HIV-1 is latent (its DNA is not being transcribed) are not detected by the immune system and hence provide a reservoir of HIV-1 (other types of cells also harbor HIV-1). Consequently, over a several year period after the initial infection (during most of which the host exhibits no obvious symptoms), the host's immune system is steadily depleted until it has deteriorated to the point that the host regularly falls victim to and is eventually killed by opportunistic pathogens that individuals with normally functioning immune systems can readily withstand. It is this latter stage of an HIV infection that is called AIDS. In the absence of effective therapy, AIDS is almost invariably fatal. Through the year 2008, nearly 30 million people had died of AIDS and an estimated 35 million others, largely in sub-Saharan Africa, were HIV-positive, numbers that are increasing at the rate of  $\sim 3$  million per year. As a consequence of this global catastrophe, HIV has been characterized and effective countermeasures against it have been devised faster than for any other pathogen in history.

#### a. Reverse Transcriptase Inhibitors Are Only Partially Effective

The first drug to be approved by the FDA (in 1987) to fight AIDS was **3'-azido-3'-deoxythymidine (AZT; zidovudine)**,

**3'-Azido-3'-deoxythymidine (AZT; zidovudine)**

**Figure 15-34 HIV-1 polyproteins.** (a) The organization of the HIV-1 gag and gag-pol polyproteins. The symbols used are MA, matrix protein; CA, capsid protein; NC, nucleocapsid protein; TF, transmembrane protein; PR, protease; RT, reverse transcriptase; RN, ribonuclease; and IN, integrase. (b) The sequences flanking the HIV-1 protease cleavage sites (red bonds) indicated in Part a.

which had first been synthesized in 1964 as a possible anti-cancer agent (it was ineffective). AZT is a nucleoside analog that, on enzymatic conversion to its triphosphate in the cell (the plasma membrane is impermeable to nucleoside triphosphates), inhibits HIV-1 reverse transcriptase, as do the several other drugs (Section 30-4Ca) that the FDA had approved to treat AIDS prior to 1996. Unfortunately, these agents only slow the progression of an HIV infection but do not stop it. This is in part because they are toxic, mainly to the bone marrow cells that are blood cell precursors, and hence cannot be taken in large doses. More important, however, is that reverse transcriptase, unlike most other DNA polymerases (Section 30-2A), cannot correct its mistakes and hence frequently generates mutations (about one per  $10^4$  bp and, since the viral genome consists of  $\sim 10^4$  bp, each viral genome bears, on average, one new mutation). Consequently, *under the selective pressure of an anti-HIV drug such as AZT, the drug's target receptor rapidly evolves to a drug-resistant form.*

#### b. HIV-1 Polyproteins Are Cleaved by HIV-1 Protease

HIV-1, as do other retroviruses, synthesizes its proteins in the form of **polyproteins**, which each consist of several tandemly linked proteins (Fig. 15-34). HIV-1 encodes two polyproteins, **gag** (55 kD) and **gag-pol** (160 kD), which are both anchored to the plasma membrane via N-terminal myristoylation (Section 12-3Bb). These polyproteins are then cleaved to their component proteins through the action of **HIV-1 protease**, but only after this enzyme has excised itself from gag-pol. This process occurs only after the virion has budded off from the host cell and results in a large structural reorganization of the virion (Fig. 15-33). The virion is thereby converted from its noninfectious immature form to its pathogenic mature form. If HIV-1 protease is inactivated, either mutagenically or by an inhibitor, the virion remains noninfectious. Hence HIV-1 protease is an opportune drug target.

#### c. Aspartic Proteases and Their Catalytic Mechanism

HIV-1 protease is a member of the **aspartic protease** family (also known as **acid proteases**), so called because these enzymes all contain catalytically essential Asp residues that

**Figure 15-35 Renin participation in blood pressure regulation.**

Renin proteolytically cleaves the 13-residue polypeptide **angiotensinogen** to the 10-residue polypeptide **angiotensin I**. This latter peptide is then cleaved by **angiotensin converting enzyme (ACE)** to the 8-residue polypeptide **angiotensin II**, which, on binding to its receptor, induces vasoconstriction and retention of  $\text{Na}^+$  and water by the kidneys, resulting in increased blood pressure. Consequently several inhibitors of renin and of ACE have been developed for the control of **hypertension** (high blood pressure).

occur in the signature sequence Asp–Thr/Ser–Gly. Humans have several known aspartic proteases including **pepsin**, a digestive enzyme secreted by the stomach (its specificity is indicated in Table 7-2) that functions at pH 1 and which was the first enzyme to be recognized (named in 1836 by Theodor Schwann); **chymosin** (formerly **rennin**), a stomach enzyme, occurring mainly in infants, that specifically cleaves a Phe–Met peptide bond in the milk protein  **$\kappa$ -casein**, thereby causing milk to curdle, making it easier to digest

(a)

**Figure 15-36 X-ray structure of porcine pepsin.** (a) Ribbon diagram in which the N-terminal domain (residues 1–172) is gold, the C-terminal domain (residues 173–326) is cyan, the side chains of the active site Asp residues are shown in ball-and-stick form with C green and O red, and the water molecule that is bound by these Asp side chains is represented by a red sphere. The protein is viewed with the pseudo-2-fold axis relating core

(calf stomach chymosin has been used for millennia to make cheese); **cathepsins D and E**, lysosomal proteases that function to degrade cellular proteins; **renin**, which participates in the regulation of blood pressure and electrolyte balance (Fig. 15-35); and  **$\beta$ -secretase** (also known as **memapsin 2**), a transmembrane protein common in brain that participates in cleaving  $\text{A}\beta$  precursor protein to yield amyloid- $\beta$  protein ( $\text{A}\beta$ ), which is implicated in Alzheimer's disease (Section 9-5B). In addition, many fungi secrete aspartic proteases, presumably to aid them in invading the tissues they colonize.

Eukaryotic aspartic proteases are  $\sim 330$ -residue monomeric proteins. The X-ray structure of pepsin (Fig. 15-36a), which closely resembles those of other eukaryotic aspartic proteases, reveals that this croissant-shaped protein consists of two homologous domains that are related by approximate 2-fold symmetry (although only about 25 residues in the core  $\beta$  sheets of each domain are closely related by this symmetry). Each domain contains a catalytically essential Asp in an analogous position. The X-ray structures of enzyme–inhibitor complexes of various aspartate proteases indicate that substrates bind in a prominent cleft between the two domains that could accommodate an  $\sim 8$ -residue polypeptide segment in an extended  $\beta$  sheet-like conformation. The active site Asp residues are located at the base of this cleft (Fig. 15-36a).

What is the catalytic mechanism of eukaryotic aspartic proteases? Proteolytic enzymes, in general, have three essential catalytic components:

1. A nucleophile to attack the carbonyl C atom of the scissile peptide to form a tetrahedral intermediate (Ser 195 serves this function in trypsin; Fig. 15-23).
2. An electrophile to stabilize the negative charge that develops on the carbonyl O atom of the tetrahedral intermediate (the H bonding donors lining the oxyanion hole, Gly 193 and Ser 195, do so in trypsin; Fig. 15-25).

(b)

portions of the two domains tipped from vertical toward the viewer. (b) Enlarged view of the active site Asp residues and their bound water molecule indicating the lengths (in  $\text{\AA}$ ) of possible hydrogen bonds (*thin gray bonds*). The X-ray structures of other aspartic proteases exhibit similar interatomic distances. [Based on an X-ray structure by Anita Sielecki and Michael James, University of Alberta, Edmonton, Canada. PDBid 4PEP.]

3. A proton donor so as to make the amide N atom of the scissile peptide a good leaving group (the imidazolium group of His 57 in trypsin; Fig. 15-23).

Pepsin's pH rate profile (Section 14-4) suggests that it has two ionizable essential residues, one with  $pK \approx 1.1$  and the other with  $pK \approx 4.7$ , which are almost certainly the carboxyl groups of its essential Asp residues. At the pH of the stomach, the Asp residue with  $pK 4.7$  is protonated and that with  $pK 1.1$  is partially ionized. This suggests that the ionized carboxyl group acts as a nucleophile to form the putative tetrahedral intermediate. However, no covalent intermediate between an aspartic protease and its substrate has ever been detected.

The two active site Asp residues in eukaryotic aspartic proteases are in close proximity and both appear to form hydrogen bonds to a bridging water molecule that is present in several X-ray structures of eukaryotic aspartic proteases (Fig. 15-36*b*). This, together with a variety of enzymological and kinetic data, led Thomas Meeke to propose the following catalytic mechanism for aspartic proteases (Fig. 15-37):

**Figure 15-37 Catalytic mechanism of aspartic proteases. (1)** The nucleophilic attack of the enzyme-activated water molecule (red) on the carbonyl carbon atom of the scissile peptide bond (green) to form the tetrahedral intermediate. This reaction step is promoted by general base catalysis by the Asp on the right and general acid catalysis by the Asp on the left (blue). **(2)** The decomposition of the tetrahedral intermediate to form products via general acid catalysis by the Asp on the right and general base catalysis by the Asp on the left.

1. An active site Asp carboxylate group, acting as a general base, activates the bound water molecule, the so-called lytic water, to nucleophilically attack the scissile peptide's carbonyl C as an  $\text{OH}^-$  ion. Proton donation (general acid catalysis) by the second, previously uncharged active site Asp stabilizes the oxyanion that would otherwise form in the resulting tetrahedral intermediate.

2. The N atom of the scissile peptide is protonated by the first Asp (general acid catalysis) resulting, through charge rearrangement and proton transfer to the second Asp (general base catalysis), in amide bond scission.

Aspartic proteases are inhibited by compounds with tetrahedral carbon atoms at a position mimicking a scissile peptide bond (see below). This strongly suggests that these

**Figure 15-38 X-ray structure of HIV-1 protease.** (a) Uncomplexed and (b) in complex with its inhibitor saquinavir (structural formula in Fig. 15-41). In each structure, the homodimeric protein is viewed with its 2-fold axis of symmetry vertical and is shown as a ribbon diagram with one subunit gold and the other cyan. The side chains of the active site Asp residues, Asp 25 and Asp 25', as well as the saquinavir in Part b, are shown in ball-and-stick form with C green, N blue, and O red. Note how the  $\beta$  hairpin "flaps" at the top of the uncomplexed enzyme have folded down over the inhibitor in the saquinavir complex. Compare these structures with that of the similarly viewed pepsin in Fig. 15-36*a*. [Part a based on an X-ray structure by Tom Blundell, Birkbeck College, London, U.K., and Part b based on an X-ray structure by Robert Crowther, Hoffmann-LaRoche Ltd., Nutley, New Jersey. PDBids (a) 3PHV and (b) 1HXB.] See Interactive Exercise 7

enzymes preferentially bind their transition states (transition state stabilization), thereby enhancing catalysis.

#### d. HIV-1 Protease Inhibitors Are Effective Anti-AIDS Agents

HIV-1 protease differs from eukaryotic aspartic proteases in that it is a homodimer of 99-residue subunits. Nevertheless, its X-ray structure (Fig. 15-38a), determined independently in 1989 by Alexander Wlodawer, by Manuel Navia and Paula Fitzgerald, and by Tom Blundell, closely resembles those of eukaryotic aspartic proteases. Thus, HIV-1 protease has the enzymatically unusual property that its single active site is formed by two identical symmetrically arranged subunits. Quite possibly HIV-1 protease resembles the putative primordial aspartic protease that, through gene duplication, evolved to form the eukaryotic enzymes (although HIV-1 protease is well suited to the limited amount of genetic information that a virus can carry).

Once the structure of HIV-1 protease became available, intensive efforts were mounted in numerous laboratories to find therapeutically effective inhibitors of this enzyme. In this process, nearly 300 X-ray structures and several

NMR structures have been reported of HIV-1 protease, its mutants, and the proteases of other retroviruses, both alone and in their complexes with a great variety of inhibitors. Hence, HIV-1 protease is perhaps the most exhaustively structurally studied protein.

Comparison of the X-ray structure of HIV-1 protease alone (Fig. 15-38a) with that of its complexes with polypeptide-like inhibitors (e.g., Fig. 15-38b) reveals that, on binding an inhibitor, the  $\beta$  hairpin “flaps” covering the “top” of the substrate-binding cleft swing down by as much as 7 Å to enclose the inhibitor. Such an inhibitor binds to the 2-fold symmetric enzyme in a 2-fold pseudosymmetric extended conformation such that the inhibitor interacts with the enzyme much like a strand in a  $\beta$  sheet (Fig. 15-39). On the “floor” of the binding cleft, each signature sequence (Asp 25–Thr 26–Gly 27) is located in a loop that is stabilized by a network of hydrogen bonds similar to that observed in eukaryotic aspartic proteases. The inhibitor interacts with the enzyme via a hydrogen bond to the active site residue Asp 25. However, contrary to the case for eukaryotic aspartic proteases (Fig. 15-36b), no X-ray structure of an HIV-1 protease contains a water molecule within

**Figure 15-39** Arrangement of hydrogen bonds between HIV-1 protease and a modeled substrate. In the nomenclature used here, polypeptide residues in one subunit are assigned primed numbers to differentiate them from the residues of the other subunit; substrate residues on the N-terminal side of the scissile peptide bond are designated P<sub>1</sub>, P<sub>2</sub>, P<sub>3</sub>, ... , counting toward the

N-terminus; substrate residues on its C-terminal side are designated P<sub>1</sub>', P<sub>2</sub>', P<sub>3</sub>', ... , counting toward the C-terminus; and the symbols S<sub>1</sub>, S<sub>2</sub>, S<sub>3</sub>, ... , and S<sub>1</sub>', S<sub>2</sub>', S<sub>3</sub>', ... , designate the enzyme's corresponding residue-binding subsites. The scissile peptide bond is marked by arrows. [After Wlodawer, A. and Vondrasek, J., *Annu. Rev. Biophys. Biomol. Struct.* **27**, 257 (1998).]

hydrogen bonding distance of Asp 25 or Asp 25'. On the flap side of the binding cleft, the inhibitor interacts with Gly 48 and Gly 48' and with a water molecule that is not the attacking nucleophile but which mediates the contacts between the flaps and the inhibitor backbone.

Although HIV-1 protease specifically cleaves the gag and gag-pol polyproteins at a total of 8 sites (Fig. 15-34b), these sites appear to have little in common except that their immediately flanking residues are nonpolar and mostly bulky. Indeed, binding studies indicate that HIV-1 protease's specificity arises from the cumulative effects of the interactions between the enzyme and the amino acids in positions P<sub>4</sub> through P<sub>4</sub>'. However, three of the peptides cleaved by HIV-1 have either the sequence Phe-Pro or Tyr-Pro, which are sequences that human aspartic proteases do not cleave. Hence, HIV-1 protease inhibitors containing groups that resemble either of these dipeptides would be unlikely to inhibit essential human aspartic proteases.

An effective HIV-1 protease inhibitor should resemble a substrate with its scissile peptide replaced by a group that the

**Figure 15-40** Comparison of a normal peptide bond (top) to a selection of groups (red) that are isosteres (stereochemical analogs) of the tetrahedral intermediate in reactions catalyzed by aspartic proteases.

enzyme cannot cleave. Such a group should, preferably, enhance the enzyme's affinity for the inhibitor. Mimics of the tetrahedral intermediate (Fig. 15-37), that is, transition state analogs, are likely to do so. Consequently, a variety of such groups (Fig. 15-40) have been investigated in efforts to synthesize therapeutically effective inhibitors of HIV-1 protease.

Although HIV-1 protease has high *in vitro* affinity for its polypeptide-based inhibitors, these substances have poor oral bioavailability (they are degraded by digestive

**Figure 15-41** Some HIV-1 protease inhibitors that are in clinical use. Note that in addition to its generic (chemical) name, each drug has a proprietary trade name, here in parentheses, under which it is marketed.

proteases) and pharmacokinetics (they do not readily pass through cell membranes.). Consequently, therapeutically effective HIV-1 protease inhibitors must be **peptidomimetics** (peptide mimics), substances that sterically and perhaps physically, but not chemically, resemble polypeptides. The use of peptidomimetics also permits conformational constraints to be imposed on a drug candidate that would not be present in the corresponding polypeptide.

The FDA has approved ten HIV-1 protease inhibitors (Fig. 15-41), the first of which, **saquinavir**, was sanctioned in late 1995. These peptidomimetics have  $IC_{50}$ 's against HIV in culture ranging from 2 to 60 nM but have little or no activity against human aspartic proteases ( $K_1$ 's  $> 10 \mu M$ ). They are the first drugs to clearly prolong the lives of AIDS victims. Their development, in each case, was a complex iterative process that required the design, synthesis, and evaluation of numerous related compounds. In several cases, these investigations capitalized on the wealth of experience gained in developing peptidomimetic inhibitors of the aspartic protease renin and in the resulting stockpiles of these compounds.

All the FDA-approved HIV-1 protease inhibitors initially cause a rapid and profound decline in a patient's plasma HIV load, which is often paralleled by immune system recovery. However, as we saw with reverse transcriptase inhibitors, mutant forms of the protease that are resistant to the inhibitor being used arise, usually within 4 to 12 weeks. Moreover, such a mutant protease is likely to be resistant to other HIV-1 protease inhibitors, because all of the HIV-1 protease inhibitors are targeted to the same binding site. This has led to the use of combination therapies in which an HIV-1 protease inhibitor is administered together with one, or more often, two inhibitors of other viral processes (inhibitors of reverse transcriptase, integrase, and viral entry into host cells). This is because any virus that gains resistance to one drug in a regimen will be suppressed

by the other drug(s) in that regimen. In addition, the HIV-1 protease inhibitor **ritonavir** has been shown to be a potent inhibitor of the cytochrome P450 isoforms (CYP3A4,5,7) that metabolize other protease inhibitors and hence is usually prescribed in low dosage as an adjunct to another protease inhibitor to improve the latter's pharmacokinetics.

The plasma virus levels in many patients who were placed on combination therapy rapidly became undetectable and have remained so for several years. This, however, does not constitute a cure: If drug therapy is interrupted, the virus will reappear in the plasma because certain tissues in the body harbor latent viruses that are unaffected by and/or inaccessible to drug therapy. Thus, the presently available anti-HIV medications must be taken for a lifetime.

Current anti-HIV therapies are by no means ideal. To maximize their oral bioavailability, some of the different drugs must be taken well before or after a meal but others must be taken with a meal. To minimize the probability of resistant forms of HIV arising, the bioavailability of each drug must be maintained at a certain minimum level and hence each drug must be taken on a rigid schedule. Moreover, these drugs have significant side effects, mainly fatigue, nausea, diarrhea, tingling and numbness with ritonavir, and kidney stones with **indinavir**. Consequently, numerous AIDS patients fail to take their medications properly, which greatly increases the likelihood that they will develop resistance to these drugs and infect others with drug-resistant viruses. Finally, HIV-1 protease inhibitors, being complex molecules, are difficult to synthesize and therefore are relatively expensive, so that in the developing countries in which AIDS is most prevalent, governments and most individuals cannot afford to purchase these drugs, even if they were to be supplied at cost. It is therefore important that anti-HIV therapies be developed that are easy for patients to comply with, are inexpensive, and ideally, will totally eliminate an HIV infection.

## CHAPTER SUMMARY

**1 Catalytic Mechanisms** Most enzymatic mechanisms of catalysis have ample precedent in organic catalytic reactions. Acid- and base-catalyzed reactions occur, respectively, through the donation or abstraction of a proton to or from a reactant so as to stabilize the reaction's transition state complex. Enzymes often employ ionizable amino acid side chains as general acid-base catalysts. Covalent catalysis involves nucleophilic attack of the catalyst on the substrate to transiently form a covalent bond followed by the electrophilic stabilization of a developing negative charge in the reaction's transition state. Various protein side chains as well as certain coenzymes can act as covalent catalysts. Metal ions, which are common enzymatic components, catalyze reactions by stabilizing developing negative charges in a manner resembling general acid catalysis. Metal ion-bound water molecules are potent sources of  $OH^-$  ions at neutral pH's. Metal ions also facilitate enzymatic reactions through the charge shielding of

bound substrates. The arrangement of charged groups about an enzymatic active site of low dielectric constant in a manner that stabilizes the transition state complex results in the electrostatic catalysis of the enzymatic reaction. Enzymes catalyze reactions by bringing their substrates into close proximity in reactive orientations. The enzymatic binding of the substrates in a bimolecular reaction arrests their relative motions resulting in a rate enhancement. The preferential enzymatic binding of the transition state of a catalyzed reaction over the substrate is an important rate enhancement mechanism. Transition state analogs are potent competitive inhibitors because they bind to the enzyme more tightly than does the corresponding substrate.

**2 Lysozyme** Lysozyme catalyzes the hydrolysis of  $\beta(1 \rightarrow 4)$ -linked poly(NAG-NAM), the bacterial cell wall polysaccharide, as well as that of poly(NAG). Lysozyme binds a hexasaccharide so as to distort its D-ring toward the

half-chair conformation of the planar oxonium ion transition state. This is followed by cleavage of the C1—O1 bond between the D- and E-rings as promoted by proton donation from Glu 35. The resulting oxonium ion transition state is electrostatically stabilized by the nearby carboxyl group of Asp 52, which then forms a covalent bond with C1. The E-ring leaving group is subsequently replaced by water, which in what is essentially a reversal of the previous reaction sequence, attacks C1 yielding the reaction's second product and regenerating the enzyme. The roles of Glu 35 and Asp 52 in lysozyme catalysis have been verified through mutagenesis studies. Structural and binding studies indicate that strain is of major catalytic importance in the lysozyme mechanism. Mass spectrometry and X-ray studies have shown that the lysozyme reaction proceeds via a covalent glycosyl-enzyme intermediate involving Asp 52 rather than by the noncovalently bound oxonium ion intermediate postulated by the original Phillips mechanism.

**3 Serine Proteases** Serine proteases constitute a widespread class of proteolytic enzymes that are characterized by the possession of a reactive Ser residue. The pancreatic synthesized digestive enzymes trypsin, chymotrypsin, and elastase are sequentially and structurally related but have different side chain specificities for their substrates. All have the same catalytic triad, Asp 102, His 57, and Ser 195, at their active sites. The differing side chain specificities of trypsin and chymotrypsin depend in a complex way on the structures of the loops that connect the walls of the specificity pocket, as well as on the charge of the side chain at the base of the specificity pocket. Subtilisin, serine carboxypeptidase II, and ClpP are unrelated serine proteases that have essentially the same active site geometry as do the pancreatic enzymes.

Catalysis in serine proteases is initiated by the nucleophilic attack of the active Ser on the carbonyl carbon atom of the scissile peptide to form the tetrahedral intermediate, a process that may be facilitated by the formation of a low-barrier hydrogen bond between Asp 102 and His 57. The tetrahedral intermediate, which is stabilized by its preferential binding to the enzyme's active site, then decomposes to the acyl-enzyme intermediate under the impetus of proton donation from the Asp 102-polarized His 57. After the replacement of the leaving group by solvent H<sub>2</sub>O, the catalytic process is reversed to yield the second product and the regenerated enzyme. The active Ser is not unusually reactive but is ideally situated to nucleophilically attack the activated scissile peptide. The X-ray structure of the trypsin-BPTI complex indicates the existence of the tetrahedral intermediate, whereas X-ray structures of a complex of elastase with the heptapeptide BCM7 have visualized both the acyl-enzyme intermediate and the tetrahedral intermediate. Enzyme-substrate complexes have free energy landscapes that facilitate the formation of the transition state.

The pancreatic serine proteases are synthesized as zymogens to prevent pancreatic self-digestion. Trypsinogen is activated by a single proteolytic cleavage by enteropeptidase. The resulting trypsin similarly activates trypsinogen as well as chymotrypsinogen, proelastase, and other pancreatic digestive enzymes. Trypsinogen's catalytic triad is structurally intact. The

zymogen's low catalytic activity arises from a distortion of its specificity pocket and oxyanion hole, so that it is unable to productively bind substrate or preferentially bind the catalytic reaction's transition state.

**4 Drug Design** Drugs act by binding to and thereby modifying the functions of receptors. Many promising drug candidates, which are known as lead compounds, have been found by methods in which a large number of compounds are tested for drug efficacy in an assay that is a suitable surrogate of the disease/condition under consideration. Lead compounds are then chemically manipulated in the search for compounds with improved drug efficacy. Structure-activity relationships (SARs) and quantitative structure-activity relationships (QSARs) are useful tools in this endeavor. Structure-based drug design uses the X-ray and NMR structures of drug candidates in complex with their target proteins, together with a variety of molecular modeling tools, to guide the search for improved drug candidates. However, the advent of combinatorial chemistry, fragment-based lead discovery, and high-throughput screening procedures has extended the "make-many-compounds-and-see-what-they-do" approaches to drug discovery.

In order to reach their target receptors, drugs must have favorable pharmacokinetics, that is, they must readily traverse numerous physical barriers in the body, avoid chemical transformation by enzymes, and not be excreted too rapidly. Most useful drugs are neither too lipophilic nor too hydrophilic so that they can both gain access to the necessary membranes and pass through them. Drug toxicity, dosage, efficacy, and the nature of rare adverse reactions are determined through extensive and carefully designed clinical trials. Most drugs are metabolically cleared through oxidative hydroxylation by one of the numerous cytochrome P450 isozymes. This permits the hydroxylated drugs to be enzymatically conjugated to polar groups such as glucuronic acid and glycine, which increases their rates of excretion by the kidneys. Drug-drug interactions are frequently mediated by cytochromes P450. Polymorphisms among cytochromes P450 are often responsible for the variations among individuals in their response to a given drug, including adverse reactions.

The formulation of HIV-1 protease inhibitors to control HIV infections is one of the major triumphs of modern drug discovery methods. HIV are retroviruses that attack specific immune system cells and thereby degrade the immune system over a period of several years to the point that it is no longer able defend against opportunistic infections. HIV-1 protease functions to cleave the polyproteins in immature HIV-1 virions that have budded out from a host cell, thus generating the mature, infectious form. HIV-1 protease is an aspartic protease that, as do eukaryotic aspartic proteases such as pepsin, uses its two active site Asp residues to activate its bound lytic water molecule as the nucleophile that attacks and thereby cleaves specific peptide bonds in the substrate polyprotein. All of the FDA-approved peptidomimetic inhibitors of HIV-1 protease cause a rapid and profound decrease in plasma HIV levels, although they do not entirely eliminate the virus. They are used in combination with inhibitors of other viral processes to minimize the ability of the rapidly mutating HIV to evolve drug-resistant forms.

## BIOINFORMATICS EXERCISES

Bioinformatics Exercises are available at [www.wiley.com/college/voet](http://www.wiley.com/college/voet).

## Chapter 12

**Enzyme Inhibitors and Rational Drug Design.**

- 1. Dihydrofolate Reductase.** Examine the structure of an enzyme with an inhibitor bound to it.
- 2. HIV Protease.** Compare the structures of complexes containing HIV protease and an inhibitor.
- 3. Pharmacogenomics and Single Nucleotide Polymorphisms.** Use online databases to find information on cytochrome P450 polymorphisms.

## PROBLEMS

**1.** Explain why  $\gamma$ -pyridone is not nearly as effective a catalyst for glucose mutarotation as is  $\alpha$ -pyridone. What about  $\beta$ -pyridone?

**2.** RNA is rapidly hydrolyzed in alkaline solution to yield a mixture of nucleotides whose phosphate groups are bonded to either the 2' or the 3' positions of the ribose residues. DNA, which lacks RNA's 2' OH groups, is resistant to alkaline degradation. Explain.

**3.** Carboxypeptidase A, a  $\text{Zn}^{2+}$ -containing enzyme, hydrolyzes the C-terminal peptide bonds of polypeptides (Fig 8-19a). In the enzyme-substrate complex, the  $\text{Zn}^{2+}$  ion is coordinated to three enzyme side chains, the carbonyl oxygen of the scissile peptide bond, and a water molecule. A plausible model for the enzyme's reaction mechanism that is consistent with X-ray and enzymological data is diagrammed in Fig. 15-42. What are the roles of the  $\text{Zn}^{2+}$  ion and Glu 270 in this mechanism?

**4.** In the following lactonization reaction,

the relative reaction rate when  $\text{R} = \text{CH}_3$  is  $3.4 \times 10^{11}$  times that when  $\text{R} = \text{H}$ . Explain.

**\*5.** Derive the analog of Eq. [15.11] for an enzyme that catalyzes the reaction:

Assume the enzyme must bind A before it can bind B:

**6.** Explain, in thermodynamic terms, why an "enzyme" that stabilizes its Michaelis complex as much as its transition state does not catalyze a reaction.

**7.** Suggest a transition state analog for proline racemase that differs from those discussed in the text. Justify your suggestion.

**8.** Wolfenden has stated that it is meaningless to distinguish between the "binding sites" and the "catalytic sites" of enzymes. Explain.

**9.** Explain why oxalate ( $^-\text{OOC}\text{COO}^-$ ) is an inhibitor of oxaloacetate decarboxylase.

**10.** In light of the information given in this chapter, why are enzymes such large molecules? Why are active sites almost always

**Michaelis complex**

↓ attack of water

**Tetrahedral intermediate**

↓ scissile bond scission

**Enzyme-product complex**

**Figure 15-42** Mechanism of carboxypeptidase A.

located in clefts or depressions in enzymes rather than on protrusions?

**11.** Predict the effects on lysozyme catalysis of changing Phe 34, Ser 36, and Trp 108 to Arg, assuming that this change does not significantly alter the structure of the protein.

**\*12.** The incubation of  $(\text{NAG})_4$  with lysozyme results in the slow formation of  $(\text{NAG})_6$  and  $(\text{NAG})_2$ . Propose a mechanism for this reaction. What aspect of the lysozyme mechanism is supported by this reaction?

**13.** How would the lysozyme binding affinity of the following  $\beta(1 \rightarrow 4)$ -linked tetrasaccharide compare with that of  $\text{NAG-NAM-NAG-NAM}$ ? Explain.

**14.** A major difficulty in investigating the properties of the pancreatic serine proteases is that these enzymes, being proteins themselves, are self-digesting. This problem is less severe, however, for solutions of chymotrypsin than it is for solutions of trypsin or elastase. Explain.

**15.** The comparison of the active site geometries of chymotrypsin and subtilisin under the assumption that their similarities have catalytic significance has led to greater mechanistic understanding of both these enzymes. Discuss the validity of this strategy.

**16. Benzamidine** ( $K_1 = 1.8 \times 10^{-5} M$ ) and **leupeptin** ( $K_1 = 1.8 \times 10^{-7} M$ ; Fig. 15-19)

are both specific competitive inhibitors of trypsin. Explain their mechanisms of inhibition. Design leupeptin analogs that inhibit chymotrypsin and elastase.

**17.** Trigonal boronic acid derivatives have a high tendency to form tetrahedral adducts. **2-Phenylethyl boronic acid**

**2-Phenylethyl boronic acid**

is an inhibitor of subtilisin and chymotrypsin. Indicate the structure of these enzyme-inhibitor complexes.

**18.** Tofu (bean curd), a high-protein soybean product that is widely consumed in China and Japan, is prepared in such a way as to remove the trypsin inhibitor present in soybeans. Explain the reason(s) for this treatment.

**19.** Explain why mutating all three residues of trypsin's catalytic triad has essentially no greater effect on the enzyme's catalytic rate enhancement than mutating only Ser 195.

**20.** Explain why chymotrypsin is not self-activating as is trypsin.

**21.** Does Lipinski's "rule of five" predict that a hexapeptide would be a therapeutically effective drug? Explain.

**22.** The preferred antidote for acetaminophen overdose is *N*-acetylcysteine. Explain why the administration of this substance, which must occur within 8 to 16 hours of the overdose, is an effective treatment.

**23.** Why would the activation of HIV-1 protease before the virus buds from its host cell be disadvantageous to the virus? Explain.

Schematic diagram of the major pathways of energy metabolism.

# METABOLISM

*This page intentionally left blank*

# Introduction to Metabolism

## CHAPTER 16

### 1 Metabolic Pathways

### 2 Organic Reaction Mechanisms

- A. Chemical Logic
- B. Group-Transfer Reactions
- C. Oxidations and Reductions
- D. Eliminations, Isomerizations, and Rearrangements
- E. Reactions That Make and Break Carbon–Carbon Bonds

### 3 Experimental Approaches to the Study of Metabolism

- A. Metabolic Inhibitors, Growth Studies, and Biochemical Genetics
- B. Isotopes in Biochemistry
- C. Isolated Organs, Cells, and Subcellular Organelles
- D. Systems Biology

### 4 Thermodynamics of Phosphate Compounds

- A. Phosphoryl-Transfer Reactions
- B. Rationalizing the “Energy” in “High-Energy” Compounds
- C. The Role of ATP

### 5 Oxidation–Reduction Reactions

- A. The Nernst Equation
- B. Measurements of Redox Potentials
- C. Concentration Cells

### 6 Thermodynamics of Life

- A. Living Systems Cannot Be at Equilibrium
- B. Nonequilibrium Thermodynamics and the Steady State
- C. Thermodynamics of Metabolic Control

*Living organisms are not at equilibrium.* Rather, they require a continuous influx of free energy to maintain order in a universe bent on maximizing disorder. **Metabolism** is the overall process through which living systems acquire and utilize the free energy they need to carry out their various functions. *They do so by coupling the exergonic reactions of nutrient oxidation to the endergonic processes required to maintain the living state* such as the performance of mechanical work, the active transport of molecules against concentration gradients, and the biosynthesis of complex molecules. How do living things acquire this necessary free energy? And what is the nature of the energy coupling process?

**Phototrophs** (plants and certain bacteria; Section 1-1A) acquire free energy from the sun through **photosynthesis**, a process in which light energy powers the endergonic reaction of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  to form carbohydrates and  $\text{O}_2$  (Chapter 24). **Chemotrophs** obtain their free energy by oxidizing organic compounds (carbohydrates, lipids, proteins)

obtained from other organisms, ultimately phototrophs. *This free energy is most often coupled to endergonic reactions through the intermediate synthesis of “high-energy” phosphate compounds such as **adenosine triphosphate (ATP)** (Section 16-4).* In addition to being completely oxidized, nutrients are broken down in a series of metabolic reactions to common intermediates that are used as precursors in the synthesis of other biological molecules.

A remarkable property of living systems is that, despite the complexity of their internal processes, they maintain a steady state. This is strikingly demonstrated by the observation that, over a 40-year time span, a normal human adult consumes literally tons of nutrients and imbibes over 20,000 L of water, but does so without significant weight change. This steady state is maintained by a sophisticated set of metabolic regulatory systems. In this introductory chapter to metabolism, we outline the general characteristics of metabolic pathways, study the main types of chemical reactions that comprise these pathways, and consider the experimental techniques that have been most useful in their elucidation. We then discuss the free energy changes associated with reactions of phosphate compounds and oxidation–reduction reactions. Finally we consider the thermodynamic nature of biological processes, that is, what properties of life are responsible for its self-sustaining character.

## 1 METABOLIC PATHWAYS

*Metabolic pathways are series of consecutive enzymatic reactions that produce specific products.* Their reactants, intermediates, and products are referred to as **metabolites**. Since an organism utilizes many metabolites, it has many metabolic pathways. Figure 16-1 shows a metabolic map for a typical cell with many of its interconnected pathways. Each reaction on the map is catalyzed by a distinct enzyme, of which there are ~4000 known. At first glance, this network seems hopelessly complex. Yet, by focusing on its major areas in the following chapters, for example, the main pathways of glucose oxidation (the shaded areas of Fig. 16-1), we shall become familiar with its most important avenues and their interrelationships. Maps of metabolic pathways in a more readable form can be found on the Web at <http://www.expasy.org/cgi-bin/search-biochem-index>, <http://www.iubmb-nicholson.org/>, and <http://www.genome.ad.jp/kegg/metabolism.html>.

**Figure 16-1** Map of the major metabolic pathways in a typical cell. The main pathways of glucose metabolism are shaded. [Designed by Donald Nicholson. Published by BDH Ltd., Poole 2, Dorset, England.]

The reaction pathways that comprise metabolism are often divided into two categories:

**1. Catabolism**, or degradation, in which nutrients and cell constituents are broken down exergonically to salvage their components and/or to generate free energy.

**2. Anabolism**, or biosynthesis, in which biomolecules are synthesized from simpler components.

The free energy released by catabolic processes is conserved through the synthesis of ATP from ADP and phosphate or through the reduction of the coenzyme  $\text{NADP}^+$  to NADPH (Fig. 13-2). ATP and NADPH are the major free energy sources for anabolic pathways (Fig. 16-2).

A striking characteristic of degradative metabolism is that it converts large numbers of diverse substances (carbohydrates, lipids, and proteins) to common intermediates. These intermediates are then further metabolized in a central oxidative pathway that terminates in a few end products. Figure 16-3 outlines the breakdown of various foodstuffs, first to their monomeric units, and then to the common intermediate, **acetyl-coenzyme A (acetyl-CoA)** (Fig. 21-2).

Biosynthesis carries out the opposite process. *Relatively few metabolites, mainly pyruvate, acetyl-CoA, and the citric acid cycle intermediates, serve as starting materials for a host of varied biosynthetic products.* In the next several chapters we discuss many degradative and biosynthetic pathways in detail. For now, let us consider some general characteristics of these processes.

Five principal characteristics of metabolic pathways stem from their function of generating products for use by the cell:

**1. Metabolic pathways are irreversible.** A highly exergonic reaction (having a large negative free energy change) is irreversible; that is, it goes to completion. If such a reaction is part of a multistep pathway, it confers directionality on the pathway; that is, it makes the entire pathway irreversible.

**2. Catabolic and anabolic pathways must differ.** If two metabolites are metabolically interconvertible, the pathway

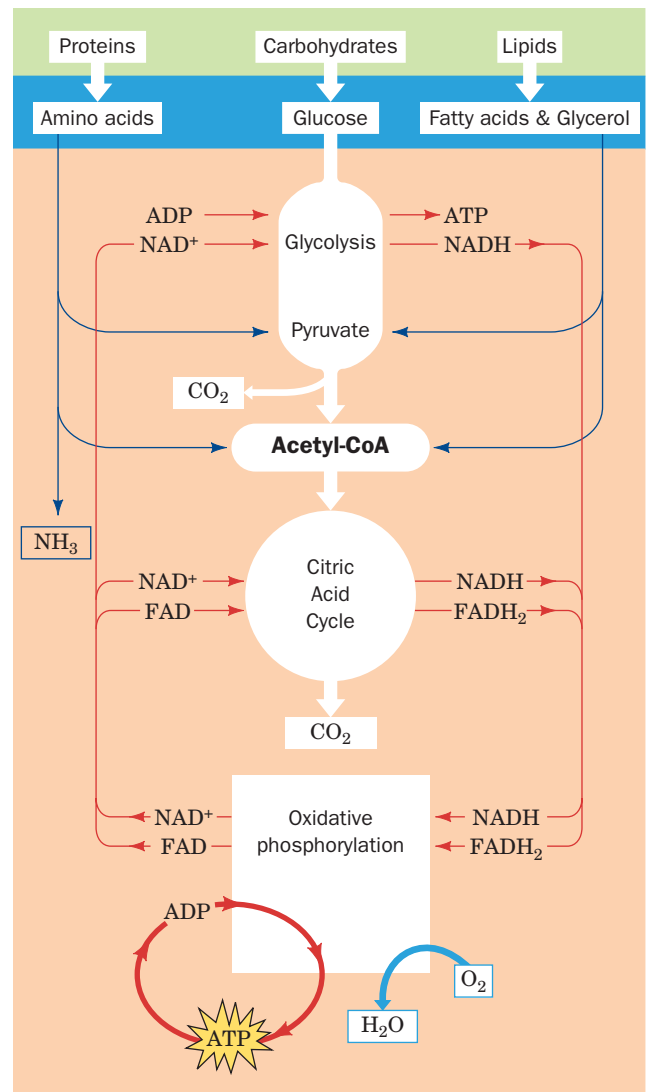

from the first to the second must differ from the pathway from the second back to the first:

This is because if metabolite 1 is converted to metabolite 2 by an exergonic process, the conversion of metabolite 2 to metabolite 1 requires that free energy be supplied in order to bring this otherwise endergonic process “back up the hill.” Consequently, the two pathways must differ in at least

**Figure 16-2** ATP and NADPH are the sources of free energy for biosynthetic reactions. They are generated through the degradation of complex metabolites.

**Figure 16-3** Overview of catabolism. Complex metabolites such as carbohydrates, proteins, and lipids are degraded first to their monomeric units, chiefly glucose, amino acids, fatty acids, and glycerol, and then to the common intermediate, acetyl-coenzyme A (acetyl-CoA). The acetyl group is then oxidized to  $\text{CO}_2$  via the citric acid cycle with the concomitant reduction of  $\text{NAD}^+$  and FAD. Reoxidation of these latter coenzymes by  $\text{O}_2$  via the electron-transport chain and oxidative phosphorylation yields  $\text{H}_2\text{O}$  and ATP.

one of their reaction steps. *The existence of independent interconversion routes, as we shall see, is an important property of metabolic pathways because it allows independent control of the two processes.* If metabolite 2 is required by the cell, it is necessary to “turn off” the pathway from 2 to 1 while “turning on” the pathway from 1 to 2. Such independent control would be impossible without different pathways.

### 3. Every metabolic pathway has a first committed step.

Although metabolic pathways are irreversible, most of their component reactions function close to equilibrium. Early in each pathway, however, there is an irreversible (exergonic) reaction that “commits” the intermediate it produces to continue down the pathway.

### 4. All metabolic pathways are regulated.

Metabolic pathways are regulated by laws of supply and demand. In order to exert control on the flux of metabolites through a metabolic pathway, it is necessary to regulate its rate-limiting step. The first committed step, being irreversible, functions too slowly to permit its substrates and products to equilibrate (if the reaction were at equilibrium, it would not be irreversible). Since most of the other reactions in a pathway function close to equilibrium, the first committed step is often one of its rate-limiting steps. Most metabolic pathways are therefore controlled by regulating the enzymes that catalyze their first committed step(s). This is an efficient way to exert control because it prevents the unnecessary synthesis of metabolites further along the pathway when they are not required. Specific aspects of such flux control are discussed in Section 17-4C.

### 5. Metabolic pathways in eukaryotic cells occur in specific cellular locations.

The compartmentation of the eukaryotic cell allows different metabolic pathways to operate in different locations, as is listed in Table 16-1 (these organelles are described in Section 1-2A). For example, ATP is mainly generated in the mitochondrion but much of it is utilized in the cytoplasm. The synthesis of metabolites in specific membrane-bounded subcellular compartments makes their transport between these compartments a vital component of eukaryotic metabolism. Biological membranes are selectively permeable to metabolites because of

the presence in membranes of specific transport proteins. The transport protein that facilitates the passage of ATP through the mitochondrial membrane is discussed in Section 20-4C, along with the characteristics of membrane transport processes in general. The synthesis and utilization of acetyl-CoA are also compartmentalized. This metabolic intermediate is utilized in the cytosolic synthesis of fatty acids but is synthesized in mitochondria. Yet there is no transport protein for acetyl-CoA in the mitochondrial membrane. How cells solve this fundamental problem is discussed in Section 25-4D. In multicellular organisms, compartmentation is carried a step further to the level of tissues and organs. The mammalian liver, for example, is largely responsible for the synthesis of glucose from noncarbohydrate precursors (**gluconeogenesis**; Section 23-1) so as to maintain a relatively constant level of glucose in the circulation, whereas adipose tissue is specialized for the storage and mobilization of triacylglycerols. The metabolic interdependence of the various organs is the subject of Chapter 27.

## 2 ORGANIC REACTION MECHANISMS

Almost all of the reactions that occur in metabolic pathways are enzymatically catalyzed organic reactions. Section 15-1 details the various mechanisms enzymes have at their disposal for catalyzing reactions: acid–base catalysis, covalent catalysis, metal ion catalysis, electrostatic catalysis, proximity and orientation effects, and transition state binding. Few enzymes alter the chemical mechanisms of these reactions, so *much can be learned about enzymatic mechanisms from the study of nonenzymatic model reactions.* We therefore begin our study of metabolic reactions by outlining the types of reactions we shall encounter and the mechanisms by which they have been observed to proceed in nonenzymatic systems.

Christopher Walsh has classified biochemical reactions into four categories: (1) **group-transfer reactions**; (2) **oxidations and reductions**; (3) **eliminations, isomerizations, and rearrangements**; and (4) **reactions that make or break carbon–carbon bonds**. Much is known about the mechanisms of

**Table 16-1** Metabolic Functions of Eukaryotic Organelles

Organelle	Function
Mitochondrion	Citric acid cycle, electron transport and oxidative phosphorylation, fatty acid oxidation, amino acid breakdown
Cytosol	Glycolysis, pentose phosphate pathway, fatty acid biosynthesis, many reactions of gluconeogenesis
Lysosomes	Enzymatic digestion of cell components and ingested matter
Nucleus	DNA replication and transcription, RNA processing
Golgi apparatus	Post-translational processing of membrane and secretory proteins; formation of plasma membrane and secretory vesicles
Rough endoplasmic reticulum	Synthesis of membrane-bound and secretory proteins
Smooth endoplasmic reticulum	Lipid and steroid biosynthesis
Peroxisomes (glyoxisomes in plants)	Oxidative reactions catalyzed by amino acid oxidases and catalase; glyoxylate cycle reactions in plants

these reactions and about the enzymes that catalyze them. The discussions in the next several chapters focus on these mechanisms as they apply to specific metabolic interconversions. In this section we outline the four reaction categories and discuss how our knowledge of their reaction mechanisms derives from the study of model organic reactions. We begin by briefly reviewing the chemical logic used in analyzing these reactions.

### A. Chemical Logic

A covalent bond consists of an electron pair shared between two atoms. In breaking such a bond, the electron pair can either remain with one of the atoms (**heterolytic bond cleavage**) or separate such that one electron accompanies each of the atoms (**homolytic bond cleavage**) (Fig. 16-4). Homolytic bond cleavage, which usually produces unstable radicals, occurs mostly in oxidation–reduction reactions. Heterolytic C–H bond cleavage involves either carbanion and proton ( $\text{H}^+$ ) formation or carbocation (carbonium ion) and hydride ion ( $\text{H}^-$ ) formation. Since hydride ions are highly reactive species and carbon atoms are slightly more electronegative than hydrogen atoms, bond cleavage in which the electron pair remains with the carbon atom is the predominant mode of C–H bond breaking in biochemical systems. Hydride ion abstraction occurs only if the hydride is transferred directly to an acceptor such as  $\text{NAD}^+$  or  $\text{NADP}^+$ .

Compounds participating in reactions involving heterolytic bond cleavage and bond formation are categorized into two broad classes: electron rich and electron deficient. Electron-rich compounds, which are called **nucleophiles** (nucleus lovers), are negatively charged or contain unshared electron pairs that easily form covalent bonds with electron-deficient centers. Biologically important nucleophilic groups include amino, hydroxyl, imidazole, and sulfhydryl functions (Fig. 16-5a). The nucleophilic forms of these groups are also their basic forms. Indeed, nucleophilicity and basicity are closely related properties (Sec-

#### Homolytic:

#### Heterolytic:

**Figure 16-4** Modes of C–H bond breaking. Homolytic cleavage yields radicals, whereas heterolytic cleavage yields either (i) a carbanion and a proton or (ii) a carbocation and a hydride ion.

tion 15-1Ba): A compound acts as a base when it forms a covalent bond with  $\text{H}^+$ , whereas it acts as a nucleophile when it forms a covalent bond with an electron-deficient center other than  $\text{H}^+$ , usually an electron-deficient carbon atom:

Electron-deficient compounds are called **electrophiles** (electron lovers). They may be positively charged, contain an unfilled valence electron shell, or contain an electronegative atom. The most common electrophiles in biochemical

#### (a) Nucleophiles

**Figure 16-5** Biologically important nucleophilic and electrophilic groups. (a) Nucleophiles are the conjugate bases of weak acids such as the hydroxyl, sulfhydryl, amino, and

#### (b) Electrophiles

imidazole groups. (b) Electrophiles contain an electron-deficient atom (red).

systems are  $H^+$ , metal ions, the carbon atoms of carbonyl groups, and cationic imines (Fig. 16-5b).

Reactions are best understood if the electron pair rearrangements involved in going from reactants to products can be traced. In illustrating these rearrangements we shall use the **curved arrow convention** in which the movement of an electron pair is symbolized by a curved arrow emanating from the electron pair and pointing to the electron-deficient center attracting the electron pair. For example, imine formation, a biochemically important reaction between an amine and an aldehyde or ketone, is represented:

In the first reaction step, the amine's unshared electron pair adds to the electron-deficient carbonyl carbon atom while one electron pair from its  $C=O$  double bond transfers to the oxygen atom. In the second step, the unshared electron pair on the nitrogen atom adds to the electron-deficient carbon atom with the elimination of water. *At all times, the rules of chemical reason prevail:* For example, there are never five bonds to a carbon atom or two bonds to a hydrogen atom.

## B. Group-Transfer Reactions

The group transfers that occur in biochemical systems involve the transfer of an electrophilic group from one nucleophile to another:

They could equally well be called nucleophilic substitution reactions. The most commonly transferred groups in biochemical reactions are acyl groups, phosphoryl groups, and glycosyl groups (Fig. 16-6):

**Figure 16-6** Types of metabolic group-transfer reactions.

(a) Acyl group transfer involves addition of a nucleophile ( $Y$ ) to the electrophilic carbon atom of an acyl compound to form a tetrahedral intermediate. The original acyl carrier ( $X$ ) is then expelled to form a new acyl compound. (b) Phosphoryl group transfer involves the in-line (with the leaving group) addition of a nucleophile ( $Y$ ) to the electrophilic phosphorus atom of a tetrahedral phosphoryl group. This yields a trigonal bipyramidal intermediate whose apical positions are occupied by the leaving group ( $X$ ) and the attacking group ( $Y$ ). Elimination of the leaving

group to complete the transfer reaction results in the phosphoryl group's inversion of configuration. (c) Glycosyl group transfer involves the substitution of one nucleophilic group for another at C1 of a sugar ring. This reaction usually occurs via a double displacement mechanism in which the elimination of the original glycosyl carrier ( $X$ ) is accompanied by the intermediate formation of a resonance-stabilized carbocation (oxonium ion) followed by the addition of the adding nucleophile ( $Y$ ). The reaction also may occur via a single displacement mechanism in which  $Y$  directly displaces  $X$  with inversion of configuration.

**1. Acyl group transfer** from one nucleophile to another almost invariably involves the addition of a nucleophile to the acyl carbonyl carbon atom so as to form a tetrahedral intermediate (Fig. 16-6a). Peptide bond hydrolysis, as catalyzed, for example, by chymotrypsin (Section 15-3C), is a familiar example of such a reaction.

**2. Phosphoryl group transfer** proceeds via the in-line addition of a nucleophile to a phosphoryl phosphorus atom to yield a trigonal bipyramidal intermediate whose apexes are occupied by the adding and leaving groups (Fig. 16-6b). The overall reaction results in the tetrahedral phosphoryl group's inversion of configuration. Indeed, chiral phosphoryl compounds have been shown to undergo just such an inversion. For example, Jeremy Knowles has synthesized ATP made chiral at its  $\gamma$ -phosphoryl group by isotopic substitution and demonstrated that this group is inverted on its transfer to glucose in the reaction catalyzed by **hexokinase** (Fig. 16-7).

**3. Glycosyl group transfer** involves the substitution of one nucleophilic group for another at C1 of a sugar ring (Fig. 16-6c). This is the central carbon atom of an acetal. Chemical models of acetal reactions generally proceed via acid-catalyzed cleavage of the first bond to form a

**Figure 16-7** The phosphoryl-transfer reaction catalyzed by **hexokinase**. During its transfer to the 6-OH group of glucose, the  $\gamma$ -phosphoryl group of ATP made chiral by isotopic substitution undergoes inversion of configuration via a trigonal bipyramidal intermediate.

resonance-stabilized carbocation at C1 (an oxonium ion). The lysozyme-catalyzed hydrolysis of bacterial cell wall polysaccharides (Section 15-2Bb) is such a reaction.

### C. Oxidations and Reductions

Oxidation–reduction (redox) reactions involve the loss or gain of electrons. The thermodynamics of these reactions is discussed in Section 16-5. Many of the redox reactions that occur in metabolic pathways involve C–H bond cleavage with the ultimate loss of two bonding electrons by the carbon atom. These electrons are transferred to an electron acceptor such as  $\text{NAD}^+$  (Fig. 13-2). Whether these reactions involve homolytic or heterolytic bond cleavage has not always been rigorously established. In most instances heterolytic cleavage is assumed when radical species are not observed. It is useful, however, to visualize redox C–H bond cleavage reactions as hydride transfers as diagrammed below for the oxidation of an alcohol by  $\text{NAD}^+$ :

For aerobic organisms, the terminal acceptor for the electron pairs removed from metabolites by their oxidation is molecular oxygen ( $\text{O}_2$ ). Recall that this molecule is a ground state diradical species whose unpaired electrons have parallel spins. The rules of electron pairing (the Pauli exclusion principle) therefore dictate that  $\text{O}_2$  can only accept unpaired electrons; that is, electrons must be transferred to  $\text{O}_2$  one at a time (in contrast to redox processes in which electrons are transferred in pairs). Electrons that are removed from metabolites as pairs must therefore be passed to  $\text{O}_2$  via the electron-transport chain one at a time. This is accomplished through the use of conjugated coenzymes that have stable radical oxidation states and can therefore undergo both  $1e^-$  and  $2e^-$  redox reactions. One such coenzyme is **flavin adenine dinucleotide (FAD)**;

**Figure 16-8** The molecular formula and reactions of the coenzyme flavin adenine dinucleotide (FAD). The term “flavin” is synonymous with the isoalloxazine system. The D-ribose residue is derived from the alcohol of the sugar D-ribose. The FAD may be half-reduced to the stable radical FADH• or fully reduced to FADH<sub>2</sub> (*boxes*). Consequently, different FAD-containing enzymes cycle between different oxidation states of FAD. FAD is usually tightly bound to its enzymes, so that this coenzyme is normally a prosthetic group rather than a

cosubstrate as is, for example, NAD<sup>+</sup>. Consequently, although humans and other higher animals are unable to synthesize the isoalloxazine component of flavins and hence must obtain it in their diets [for example, in the form of **riboflavin (vitamin B<sub>2</sub>)**], riboflavin deficiency is quite rare in humans. The symptoms of riboflavin deficiency, which are associated with general malnutrition or bizarre diets, include an inflamed tongue, lesions in the corners of the mouth, and dermatitis.

Fig. 16-8). **Flavins** (substances that contain the **isoalloxazine** ring) can undergo two sequential one-electron transfers or a simultaneous two-electron transfer that bypasses the semiquinone state.

#### D. Eliminations, Isomerizations, and Rearrangements

##### a. Elimination Reactions Form Carbon–Carbon Double Bonds

**Elimination reactions** result in the formation of a double bond between two previously single-bonded saturated centers. The substances eliminated may be H<sub>2</sub>O, NH<sub>3</sub>, an alcohol (ROH), or a primary amine (RNH<sub>2</sub>). The dehydration of an alcohol, for example, is an elimination reaction:

Bond breaking and bond making in this reaction may proceed via one of three mechanisms (Fig. 16-9a): (1) concerted; (2) stepwise with the C–O bond breaking first to form a carbocation; or (3) stepwise with the C–H bond breaking first to form a carbanion.

Enzymes catalyze dehydration reactions by either of two simple mechanisms: (1) protonation of the OH group by an acidic group (acid catalysis) or (2) abstraction of the proton by a basic group (base catalysis). Moreover, in a stepwise reaction, the charged intermediate may be stabilized

**Figure 16-9** Possible elimination reaction mechanisms using dehydration as an example. Reactions may be (a) either concerted, stepwise via a carbocation intermediate, or stepwise via a carbanion intermediate; and may occur with (b) either trans (anti) or cis (syn) stereochemistry.

by an oppositely charged active site group (electrostatic catalysis). The glycolytic enzyme **enolase** (Section 17-2I) and the citric acid cycle enzyme **fumarase** (Section 21-3G) catalyze such dehydration reactions.

Elimination reactions may take one of two possible stereochemical courses (Fig. 16-9b): (1) trans (anti) eliminations, the most prevalent biochemical mechanism, and (2) cis (syn) eliminations, which are biochemically less common.

### b. Biochemical Isomerizations Involve Intramolecular Hydrogen Atom Shifts

Biochemical **isomerization reactions** involve the intramolecular shift of a hydrogen atom so as to change the location of a double bond. In such a process, a proton is removed from one carbon atom and added to another. The metabolically most prevalent isomerization reaction is the **aldose–ketose interconversion**, a base-catalyzed reaction that occurs via **enediolate anion** intermediates (Fig. 16-10). The glycolytic enzyme **phosphoglucose isomerase** catalyzes such a reaction (Section 17-2B).

**Racemization** is an isomerization reaction in which a hydrogen atom shifts its stereochemical position at a molecule's

**Figure 16-10** Mechanism of aldose–ketose isomerization. The reaction occurs with acid–base catalysis and proceeds via *cis*-enediolate intermediates.

only chiral center so as to invert that chiral center (e.g., the racemization of proline by proline racemase; Section 15-1Fa). Such an isomerization is called an **epimerization** in a molecule with more than one chiral center.

### c. Rearrangements Produce Altered Carbon Skeletons

**Rearrangement reactions** break and reform C–C bonds so as to rearrange a molecule's carbon skeleton. There are few such metabolic reactions. One is the conversion of **L-methylmalonyl-CoA** to **succinyl-CoA** by **methylmalonyl-CoA mutase**, an enzyme whose prosthetic group is a **vitamin B<sub>12</sub>** derivative:

This reaction is involved in the oxidation of fatty acids with an odd number of carbon atoms (Section 25-2Ec) and several amino acids (Section 26-3Ec).

### E. Reactions That Make and Break Carbon–Carbon Bonds

Reactions that make and break carbon–carbon bonds form the basis of both degradative and biosynthetic metabolism. The breakdown of glucose to CO<sub>2</sub> involves five such cleavages, whereas its synthesis involves the reverse process. Such reactions, considered from the synthetic direction, involve addition of a nucleophilic carbanion to an electrophilic carbon atom. The most common electrophilic

carbon atoms in such reactions are the  $sp^2$ -hybridized carbonyl carbon atoms of aldehydes, ketones, esters, and  $\text{CO}_2$ :

Stabilized carbanions must be generated to add to these electrophilic centers. Three examples are the **aldol condensation** (catalyzed, e.g., by **aldolase**; Section 17-2D), **Claisen ester condensation** (**citrate synthase**; Section 21-3A), and the decarboxylation of  $\beta$ -keto acids (**isocitrate dehy-**

**drogenase**, Section 21-3C; and **fatty acid synthase**, Section 25-4C). In nonenzymatic systems, both the aldol condensation and Claisen ester condensation involve the base-catalyzed generation of a carbanion  $\alpha$  to a carbonyl group (Fig. 16-11*a,b*). The carbonyl group is electron withdrawing and thereby provides resonance stabilization by forming an enolate (Fig. 16-12*a*). The enolate may be further stabilized by neutralizing its negative charge. Enzymes do so through hydrogen bonding or protonation (Fig. 16-12*b*), conversion of the carbonyl group to a protonated Schiff base (covalent catalysis; Fig. 16-12*c*), or by its coordination

**Figure 16-11** Examples of C—C bond formation and cleavage reactions. (a) Aldol condensation, (b) Claisen ester condensation, and (c) decarboxylation of a  $\beta$ -keto acid. All three

types of reactions involve generation of a resonance-stabilized carbanion followed by addition of this carbanion to an electrophilic center.

**Figure 16-12** Stabilization of carbanions. (a) Carbanions adjacent to carbonyl groups are stabilized by the formation of enolates. (b) Carbanions adjacent to carbonyl groups hydrogen bonded to general acids are stabilized electrostatically or by charge neutralization. (c) Carbanions adjacent to protonated imines (Schiff bases) are stabilized by the formation of enamines. (d) Metal ions stabilize carbanions adjacent to carbonyl groups by the electrostatic stabilization of the enolate.

to a metal ion (metal ion catalysis; Fig. 16-12d). The decarboxylation of a  $\beta$ -keto acid does not require base catalysis for the generation of the resonance-stabilized carbanion; the highly exergonic formation of  $\text{CO}_2$  provides its driving force (Fig. 16-11c).

### 3 EXPERIMENTAL APPROACHES TO THE STUDY OF METABOLISM

A metabolic pathway can be understood at several levels:

1. In terms of the sequence of reactions by which a specific nutrient is converted to end products, and the energetics of these conversions.

2. In terms of the mechanisms by which each intermediate is converted to its successor. Such an analysis requires the isolation and characterization of the specific enzymes that catalyze each reaction.

3. In terms of the control mechanisms that regulate the flow of metabolites through the pathway. An exquisitely

complex network of regulatory processes renders metabolic pathways remarkably sensitive to the needs of the organism; the output of a pathway is generally only as great as required.

As you might well imagine, the elucidation of a metabolic pathway on all of these levels is a complex process, involving contributions from a variety of disciplines. Most of the techniques used to do so involve somehow perturbing the system and observing the perturbation's effect on growth or on the production of metabolic intermediates. One such technique is the use of metabolic inhibitors that block metabolic pathways at specific enzymatic steps. Another is the study of genetic abnormalities that interrupt specific metabolic pathways. Techniques have also been developed for the dissection of organisms into their component organs, tissues, cells, and subcellular organelles, and for the purification and identification of metabolites as well as the enzymes that catalyze their interconversions. The use of isotopic tracers to follow the paths of specific atoms and molecules through the metabolic maze has become routine. Techniques utilizing NMR technology are able to trace metabolites noninvasively as they react *in vivo*. This section outlines the use of these various techniques.

#### A. Metabolic Inhibitors, Growth Studies, and Biochemical Genetics

##### a. Pathway Intermediates Accumulate in the Presence of Metabolic Inhibitors

The first metabolic pathway to be completely traced was the conversion of glucose to ethanol in yeast by a process known as **glycolysis** (Section 17-1A). In the course of these studies, certain substances, called **metabolic inhibitors**, were found to block the pathway at specific points, thereby causing preceding intermediates to build up. For instance, iodoacetate causes yeast extracts to accumulate fructose-1,6-bisphosphate, whereas fluoride causes the buildup of two phosphate esters, 3-phosphoglycerate and 2-phosphoglycerate. The isolation and characterization of these intermediates was vital to the elucidation of the glycolytic pathway: Chemical intuition combined with this information led to the prediction of the pathway's intervening steps. Each of the proposed reactions was eventually shown to occur *in vitro* as catalyzed by a purified enzyme.

##### b. Genetic Defects Also Cause Metabolic Intermediates to Accumulate

Archibald Garrod's realization, in the early 1900s, that human genetic diseases are the consequence of deficiencies in specific enzymes (Section 1-4Cd) also contributed to the elucidation of metabolic pathways. For example, on the ingestion of either phenylalanine or tyrosine, individuals with the largely harmless inherited condition known as **alcaptonuria**, but not normal subjects, excrete **homogentisic acid** in their urine (Section 26-3Hd). This is because the liver of alcaptonurics lacks an enzyme that catalyzes the breakdown of homogentisic acid. Another genetic disease, **phenylketonuria** (Section 26-3Hd), results in the accumulation of

**phenylpyruvate** in the urine (and which, if untreated, causes severe mental retardation in infants). Ingested phenylalanine and phenylpyruvate appear as phenylpyruvate in the urine of affected subjects, whereas tyrosine is metabolized normally. The effects of these two abnormalities suggested the pathway for phenylalanine metabolism diagrammed in Fig. 16-13. However, the supposition that phenylpyruvate but not tyrosine occurs on the normal pathway of phenylalanine metabolism because phenylpyruvate accumulates in the urine of phenylketonurics has proved incorrect. This indicates the pitfalls of relying solely on metabolic blocks and the consequent buildup of intermediates as indicators of a metabolic pathway. In this case, phenylpyruvate formation was later shown to arise from a normally minor pathway that becomes significant only when the phenylalanine concentration is abnormally high, as it is in phenylketonurics.

### c. Metabolic Blocks Can Be Generated by Genetic Manipulation

Early metabolic studies led to the astounding discovery that *the basic metabolic pathways in most organisms are essentially identical*. This metabolic uniformity has greatly facilitated the study of metabolic reactions. A mutation that inactivates or deletes an enzyme in a pathway of interest can be readily generated in rapidly reproducing microorganisms through the use of **mutagens** (chemical agents that induce genetic changes; Section 32-1A), X-rays, or genetic engineering techniques (Section 5-5). Desired mutants are identified by their requirement of the pathway's end product for growth. For example, George Beadle and Edward Tatum proposed a pathway of arginine biosynthesis in the mold *Neurospora crassa* based on their analysis of three arginine-requiring **auxotrophic mutants** (mutants requiring a specific nutrient for growth), which were isolated after X-irradiation (Fig. 16-14). This landmark study also conclusively demonstrated that enzymes are specified by genes (Section 1-4Cd).

### d. Genetic Manipulations of Higher Organisms Provide Metabolic Insights

**Transgenic organisms** (Section 5-5H) constitute valuable resources for the study of metabolism. *They can be used to both create metabolic blocks and to express genes in tissues where they are not normally present*. For example, **creatine kinase** catalyzes the formation of **phosphocreatine** (Section 16-4Cd), a substance that functions to generate ATP rapidly when it is in short supply. This enzyme is normally present in many tissues, including brain and muscle, but not in liver. The introduction of the gene encoding creatine kinase into the liver of a mouse causes the liver to synthesize phosphocreatine when the mouse is fed creatine, as demonstrated by localized *in vivo* NMR techniques (Fig. 16-15; NMR is discussed below). The presence of

**Figure 16-13** Pathway for phenylalanine degradation.

It was originally hypothesized that phenylpyruvate was a pathway intermediate based on the observation that phenylketonurics excrete ingested phenylalanine and phenylpyruvate as phenylpyruvate. Further studies, however, demonstrated that phenylpyruvate is not a homogentisate precursor; rather, phenylpyruvate production is significant only when the phenylalanine concentration is abnormally high. Instead, tyrosine is the normal product of phenylalanine degradation.

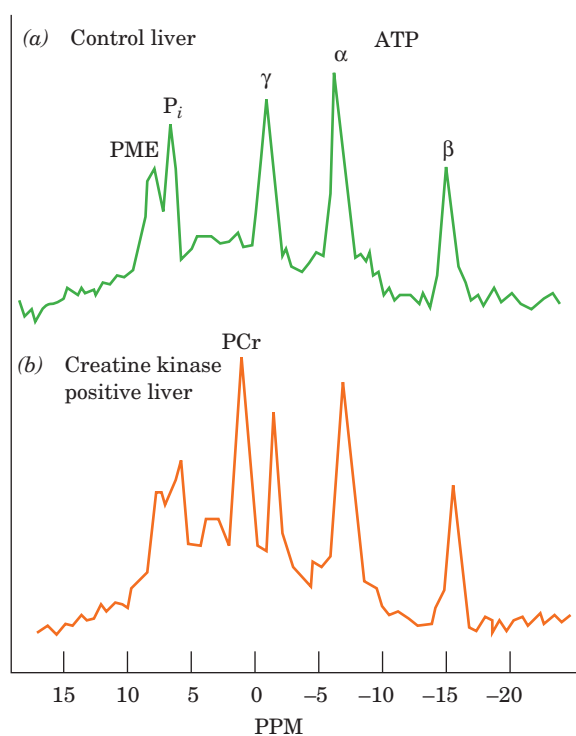

**Figure 16-14** Pathway of arginine biosynthesis indicating the positions of genetic blocks. All of these mutants grow in the presence of arginine, but mutant 1 also grows in the presence of the (nonstandard)  $\alpha$ -amino acids **citrulline** or **ornithine** and mutant 2 grows in the presence of citrulline. This is because in

mutant 1, an enzyme leading to the production of ornithine is absent but enzymes farther along the pathway are normal. In mutant 2, the enzyme catalyzing citrulline production is defective, whereas in mutant 3 an enzyme involved in the conversion of citrulline to arginine is lacking.

phosphocreatine in a transgenic mouse liver protects the animal against the sharp drop in [ATP] ordinarily caused by fructose overload (Section 17-5Aa). This genetic manip-

ulation technique is being used to study mechanisms of metabolic control *in vivo*.

Metabolic pathways are regulated both by controlling the activities of regulatory enzymes (Sections 17-4 and 18-3) and by controlling their concentrations at the level of gene expression (Sections 31-3, 32-4, and 34-3). The important question of how hormones and diet control metabolic processes at the level of gene expression is being addressed through the use of transgenic animals. **Reporter genes** (genes whose products are easily detected; Section 5-5Gd) are placed under the influence of **promoters** (genetic elements that regulate transcriptional initiation; Section 5-4Aa) that control the expression of specific regulatory enzymes, and the resulting composite gene is expressed in animals. The transgenic animals can then be treated with specific hormones and/or diets and the production of the reporter gene product measured. For instance, in an investigation by Richard Hanson, the promoter for the enzyme **phosphoenolpyruvate carboxykinase (PEPCK)** was attached to the structural gene encoding **growth hormone (GH)**. PEPCK, an important regulatory enzyme in **gluconeogenesis** (the synthesis of glucose from noncarbohydrate precursors; Section 23-1), is normally present in liver and kidneys but not in blood. GH, however, is secreted into the blood and its presence there can be readily quantitated by an ELISA (Section 6-1Da). Mice transgenic for PEPCK/GH were fed either a high-carbohydrate/low-protein diet or a high-protein/low-carbohydrate diet, which are known to decrease and increase PEPCK activity, respectively. GH in high concentrations was detected only in the serum of PEPCK/GH mice on a high-protein diet, thereby indicating that the GH was synthesized under the same dietary control as that of the PEPCK expressed by the normal gene. Thus, the activity of PEPCK in PEPCK/GH mice can be continuously monitored, albeit indirectly, through serum GH assays (the direct measurement of PEPCK in mouse liver or kidney requires the sacrifice of the animal and hence can be done only once). Such use of reporter genes has proved to be of great value in the study of the genetic control of metabolism.

**Figure 16-15** The expression of creatine kinase in transgenic mouse liver as demonstrated by localized *in vivo*  $^{31}\text{P}$  NMR.

(a) The spectrum of a normal mouse liver after the mouse had been fed a diet supplemented with 2% creatine. The peaks corresponding to inorganic phosphate ( $P_i$ ), the  $\alpha$ ,  $\beta$ , and  $\gamma$  phosphoryl groups of ATP, and phosphomonoesters (PME) are labeled. (b) The spectrum of the liver of a mouse transgenic for creatine kinase that had been fed a diet supplemented with 2% creatine. The phosphocreatine peak is labeled PCr. [After Koretsky, A.P., Brosnan, M.J., Chen, L., Chen, J., and Van Dyke, T.A., *Proc. Natl. Acad. Sci.* **87**, 3114 (1990)].

Modern techniques also make it possible to insert a mutation that inactivates or deletes an enzyme or control protein in a pathway of interest in higher organisms such as mice (**knock-out mice**; Section 5-5H). Knockout mice have proved useful for studying metabolic control mechanisms. For example, PEPCK activity is thought to be controlled exclusively by increasing or decreasing its availability. Diet affects its production, as we have seen. However, this demand-based control is superimposed on the developmental regulation of PEPCK production. The enzyme is not produced at all in early embryos and only appears near birth, when gluconeogenesis is required to supply the glucose that had been previously available *in utero*. One of the proteins thought to be responsible for the developmental regulation of PEPCK production is **CCAAT/enhancer-binding protein  $\alpha$  (C/EBP $\alpha$ )**, a **transcription factor** (Section 5-4Aa; transcriptional regulation in eukaryotes is discussed in Section 34-3B). Newborn mice homozygous for the targeted deletion of the *clebpa* gene (*clebpa* knockout mice) do not produce C/EBP $\alpha$  and therefore do not produce PEPCK. Consequently, their livers cannot synthesize the glucose necessary to maintain adequate blood glucose levels once they are disconnected from the maternal circulation. Indeed, these mice become so hypoglycemic that they die within 8 hours of birth. Clearly C/EBP $\alpha$  has an important role in the developmental regulation of PEPCK.

## B. Isotopes in Biochemistry

The specific labeling of metabolites such that their interconversions can be traced is an indispensable technique for elucidating metabolic pathways. Franz Knoop formulated this technique in 1904 to study fatty acid oxidation. He fed dogs fatty acids chemically labeled with phenyl groups and isolated the phenyl-substituted end products from their urine. From the differences in these products when the phenyl-substituted starting material contained odd and even numbers of carbon atoms he deduced that fatty acids are degraded in C<sub>2</sub> units (Section 25-2).

### a. Isotopes Specifically Label Molecules without Altering Their Chemical Properties

Chemical labeling has the disadvantage that the chemical properties of labeled metabolites differ from those of normal metabolites. This problem is eliminated by labeling molecules of interest with **isotopes** (atoms with the same number of protons but a different number of neutrons in their nuclei). Recall that the chemical properties of an element are a consequence of its electron configuration which, in turn, is determined by its atomic number, not its atomic mass. The metabolic fate of a specific atom in a metabolite can therefore be elucidated by isotopically labeling that position and following its progress through the metabolic pathway of interest. The advent of isotopic labeling and tracing techniques in the 1940s therefore revolutionized the study of metabolism. (**Isotope effects**, which are changes in reaction rates arising from the mass differences between isotopes, are in most instances negligible. Where they are significant, most noticeably between hydrogen and its isotopes deuterium and tritium, they have been used to gain insight into enzymatic reaction mechanisms.)

### b. NMR Can Be Used to Study Metabolism in Whole Animals

Nuclear magnetic resonance (NMR) detects specific isotopes due to their characteristic nuclear spins. Among the isotopes that NMR can detect are <sup>1</sup>H, <sup>13</sup>C, and <sup>31</sup>P. Since the NMR spectrum of a particular nucleus varies with its immediate environment, it is possible to identify the peaks corresponding to specific atoms even in relatively complex mixtures.

The development of magnets large enough to accommodate animals and humans, and to localize spectra to specific organs, has made it possible to study metabolic pathways noninvasively by NMR techniques. Thus, <sup>31</sup>P NMR can be used to study energy metabolism in muscle by monitoring the levels of ATP, ADP, inorganic phosphate, and phosphocreatine (Figure 16-15). Indeed, a <sup>31</sup>P NMR system has been patented to measure the muscular metabolic efficiency and maximum power of race horses while they are walking or running on a motor-driven treadmill in order to identify promising animals and to evaluate the efficacy of their training and nutritional programs.

Isotopically labeling specific atoms of metabolites with <sup>13</sup>C (which is only 1.10% naturally abundant) permits the metabolic progress of the labeled atoms to be followed by <sup>13</sup>C NMR. Figure 16-16 shows *in vivo* <sup>13</sup>C NMR spectra of a rat liver before and after an injection of D-[1-<sup>13</sup>C]glucose. The <sup>13</sup>C can be seen entering the liver and then being converted to glycogen (the storage form of glucose; Chapter 18). <sup>1</sup>H NMR techniques are being used to determine the *in vivo* levels of a variety of metabolites in tissues such as brain and muscle.

### c. The Detection of Radioactive Isotopes

All elements have isotopes. For example, the atomic mass of naturally occurring Cl is 35.45 D because, at least on Earth, it is a mixture of 55% <sup>35</sup>Cl and 45% <sup>36</sup>Cl (other isotopes of Cl are present in only trace amounts). Stable isotopes are generally identified and quantitated by mass spectrometry or NMR techniques. Many isotopes, however, are unstable; they undergo **radioactive decay**, a process that involves the emission from the radioactive nuclei of subatomic particles such as helium nuclei ( **$\alpha$  particles**), electrons ( **$\beta$  particles**), and/or photons ( **$\gamma$  radiation**). Radioactive nuclei emit radiation with characteristic energies. For example, <sup>3</sup>H, <sup>14</sup>C, and <sup>32</sup>P all emit  $\beta$  particles but with respective energies of 0.018, 0.155, and 1.71 MeV. The radiation from <sup>32</sup>P is therefore highly penetrating, whereas that from <sup>3</sup>H and <sup>14</sup>C is not. (<sup>3</sup>H and <sup>14</sup>C, as all radioactive isotopes, must, nevertheless, be handled with great caution because they can cause genetic damage on ingestion.)

Radiation can be detected by a variety of techniques. Those most commonly used in biochemical investigations are **proportional counting** (known in its simplest form as **Geiger counting**), **liquid scintillation counting**, and **autoradiography**. Proportional counters electronically detect the ionizations in a gas caused by the passage of radiation. Moreover, they can also discriminate between particles of different energies and thus simultaneously determine the amounts of two or more different isotopes present.

Although proportional counters are quite simple to use, the radiation from two of the most widely used isotopes in

**Figure 16-16** The conversion of  $[1-^{13}\text{C}]$ glucose to glycogen as observed by localized *in vivo*  $^{13}\text{C}$  NMR. (a) The natural abundance  $^{13}\text{C}$  NMR spectrum of the liver of a live rat. Note the resonance corresponding to C1 of glycogen. (b) The  $^{13}\text{C}$  NMR spectrum of the liver of the same rat  $\sim 5$  min after it was intravenously injected with 100 mg of  $[1-^{13}\text{C}]$ glucose (90% enriched). The resonances of the C1 atom of both the  $\alpha$  and  $\beta$  anomers of glucose are clearly distinguishable from each other and from the resonance of the C1 atom of glycogen. (c) The  $^{13}\text{C}$  NMR spectrum of the liver of the same rat  $\sim 30$  min after the  $[1-^{13}\text{C}]$ glucose injection. The C1 resonances of both the  $\alpha$  and  $\beta$  glucose anomers are much reduced while the C1 resonance of glycogen has increased. [After Reo, N.V., Siegfried, B.A., and Acherman, J.J.H., *J. Biol. Chem.* **259**, 13665 (1984)].

biochemical analysis,  $^3\text{H}$  and  $^{14}\text{C}$ , have insufficient penetrating power to enter a proportional counter's detection chamber with reasonable efficiency. This limitation is circumvented through liquid scintillation counting. In this

**Table 16-2** Some Trace Isotopes of Biochemical Importance

Stable Isotopes		
Nucleus	Natural Abundance (%)	
$^2\text{H}$	0.012	
$^{13}\text{C}$	1.07	
$^{15}\text{N}$	0.36	
$^{18}\text{O}$	0.20	
Radioactive Isotopes		
Nucleus	Radiation Type	Half-Life
$^3\text{H}$	$\beta$	12.31 years
$^{14}\text{C}$	$\beta$	5715 years
$^{22}\text{Na}$	$\beta^+$ , $\gamma$	2.60 years
$^{32}\text{P}$	$\beta$	14.28 days
$^{35}\text{S}$	$\beta$	87.2 days
$^{45}\text{Ca}$	$\beta$	162.7 days
$^{60}\text{Co}$	$\beta$ , $\gamma$	5.271 years
$^{125}\text{I}$	$\gamma$	59.4 days
$^{131}\text{I}$	$\beta$ , $\gamma$	8.02 days

technique, a radioactive sample is dissolved or suspended in a solution containing fluorescent substances that emit a pulse of light when struck by radiation. The light is detected electronically so that the number of light pulses can be counted. The emitting nucleus can also be identified because the intensity of a light pulse is proportional to the radiation energy (the number of fluorescent molecules excited by a radioactive particle is proportional to the particle's energy).

In autoradiography, radiation is detected by its blackening of photographic film. The radioactive sample is laid on, or in some cases mixed with, the photographic emulsion and, after sufficient exposure time (from minutes to months), the film is developed. Autoradiography is widely used to locate radioactive substances in polyacrylamide gels (e.g., Fig. 6-27). Position-sensitive radiation counters (electronic film) are similarly employed.

#### d. Radioactive Isotopes Have Characteristic Half-Lives

Radioactive decay is a random process whose rate for a given isotope depends only on the number of radioactive atoms present. It is therefore a simple first-order process whose half-life,  $t_{1/2}$ , is a function only of the rate constant,  $k$ , for the decay process (Section 14-1Ba):

$$t_{1/2} = \frac{\ln 2}{k} = \frac{0.693}{k} \quad [14.5]$$

Because  $k$  is different for each radioactive isotope, each has a characteristic half-life. The properties of some isotopes in common biochemical use are listed in Table 16-2.

**Figure 16-17** The metabolic origin of the nitrogen atoms in heme. Only [ $^{15}\text{N}$ ]glycine, of many  $^{15}\text{N}$ -labeled metabolites, is an  $^{15}\text{N}$ -labeled heme precursor.

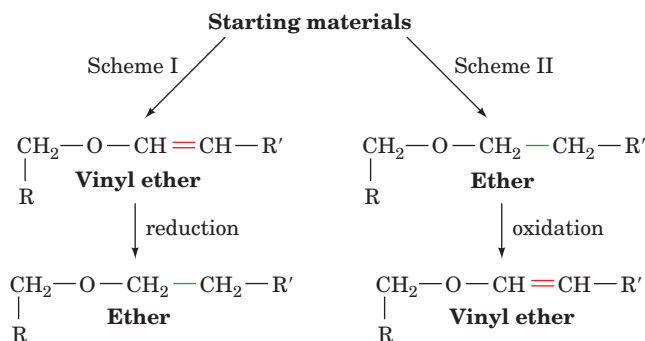

### e. Isotopes Are Indispensable for Establishing the Metabolic Origins of Complex Metabolites and Precursor-Product Relationships

The metabolic origins of complex molecules such as heme, cholesterol, and phospholipids may be determined by administering isotopically labeled starting materials to animals and isolating the resulting products. One of the early advances in metabolic understanding resulting from the use of isotopic tracers was the demonstration, by David Shemin and David Rittenberg in 1945, that the nitrogen atoms of heme are derived from glycine rather than from ammonia, glutamic acid, proline, or leucine (Section 26-4Aa). They showed this by feeding rats these  $^{15}\text{N}$ -labeled nutrients, isolating the heme in their blood, and analyzing it for  $^{15}\text{N}$  content. Only when the rats were fed [ $^{15}\text{N}$ ]glycine did the heme contain  $^{15}\text{N}$  (Fig. 16-17). This technique was also used to demonstrate that all of cholesterol's carbon atoms are derived from acetyl-CoA (Section 25-6A).

Isotopic tracers are also useful in establishing the order of appearance of metabolic intermediates, their so-called **precursor-product relationships**. An example of such an analysis concerns the biosynthesis of the complex phospholipids called **plasmalogens** and **alkylacylglycerophospholipids** (Section 25-8Ab). Alkylacylglycerophospholipids are ethers, whereas the closely related plasmalogens are vinyl ethers. Their similar structures brings up the interesting

question of their biosynthetic relationship: Which is the precursor and which is the product? Two possible modes of synthesis can be envisioned (Fig. 16-18):

**I.** The starting material is converted to the vinyl ether (plasmalogen), which is then reduced to yield the ether (alkylacylglycerophospholipid). Accordingly, the vinyl ether would be the precursor and the ether the product.

**Figure 16-18** Two possible pathways for the biosynthesis of ether- and vinyl ether-containing phospholipids. **(I)** The vinyl ether is the precursor and the ether is the product. **(II)** The ether is the precursor and the vinyl ether is the product.

**II.** The ether is formed first and then oxidized to yield the vinyl ether. The ether would then be the precursor and the vinyl ether the product.

*Precursor–product relationships can be most easily sorted out through the use of radioactive tracers.* A pulse of the labeled starting material is administered to an organism and the specific radioactivities of the resulting metabolic products are followed with time (Fig. 16-19):

(here the \* represents the radioactive label). Metabolic pathways, as we shall see in Section 16-6Ba, normally operate in a steady state; that is, the throughput of metabolites in each of its reaction steps is equal. Moreover, the rates of most metabolic reactions are first order for a given substrate. Making these assumptions, we note that the rate of change of B's radioactivity,  $[\text{B}^*]$ , is equal to the rate of passage of label from  $\text{A}^*$  to  $\text{B}^*$  less the rate of passage of label from  $\text{B}^*$  to the pathway's next product:

$$\frac{d[\text{B}^*]}{dt} = k[\text{A}^*] - k[\text{B}^*] = k([\text{A}^*] - [\text{B}^*]) \quad [16.1]$$

where  $k$  is the pseudo-first-order rate constant for both the conversion of A to B and the conversion of B to its product, and  $t$  is time. Inspection of this equation indicates the criteria that must be met to establish that A is the precursor of B (Fig. 16-19):

**1.** Before the radioactivity of the product  $[\text{B}^*]$  is maximal,  $d[\text{B}^*]/dt > 0$ , so  $[\text{A}^*] > [\text{B}^*]$ ; that is, *while the radioactivity of a product is rising, it should be less than that of its precursor.*

**2.** When  $[\text{B}^*]$  is maximal,  $d[\text{B}^*]/dt = 0$ , so  $[\text{A}^*] = [\text{B}^*]$ ; that is, *when the radioactivity of a product is at its peak, it should be equal to that of its precursor.* This result also implies that *the radioactivity of a product peaks after that of its precursor.*

**Figure 16-19** The flow of a pulse of radioactivity from precursor to product. At point 1, product radioactivity ( $\text{B}^*$ , purple) is increasing and is less than that of its precursor ( $\text{A}^*$ , orange); at point 2, product radioactivity is maximal and is equal to that of its precursor; and at point 3, product radioactivity is decreasing and is greater than that of its precursor.

**3.** After  $[\text{B}^*]$  begins to decrease,  $d[\text{B}^*]/dt < 0$ , so  $[\text{A}^*] < [\text{B}^*]$ ; that is, *after the radioactivity of a product has peaked, it should remain greater than that of its precursor.*

Such a determination of the precursor–product relationship between alkylacylglycerophospholipid and plasmalogen, using  $^{14}\text{C}$ -labeled starting materials, indicated that the ether is the precursor and the vinyl ether is the product (Fig. 16-18, Scheme II).

### C. Isolated Organs, Cells, and Subcellular Organelles

In addition to understanding the chemistry and catalytic events that occur at each step of a metabolic pathway, it is important to learn where a given pathway occurs within an organism. Early workers studied metabolism in whole animals. For example, the role of the pancreas in diabetes was established by Frederick Banting and Charles Best in 1921 by surgically removing that organ from dogs and observing that these animals then developed the disease.

The metabolic products produced by a particular organ can be studied by **organ perfusion** or in **tissue slices**. In organ perfusion, a specific organ is surgically removed from an animal and the organ's arteries and veins are connected to an artificial circulatory system. The composition of the material entering the organ can thereby be controlled and its metabolic products monitored. Metabolic processes can be similarly studied in slices of tissue thin enough to be nourished by free diffusion in an appropriate nutrient solution. Otto Warburg pioneered the tissue slice technique in the early twentieth century through his studies of respiration, in which he used a manometer to measure the changes in gas volume above tissue slices as a consequence of their  $\text{O}_2$  consumption.

A given organ or tissue generally contains several cell types. **Cell sorters** are devices that can separate cells according to type once they have been treated with the enzymes trypsin and collagenase to destroy the intercellular matrix that binds them into a tissue. This technique allows further localization of metabolic function. A single cell type may also be grown in **tissue culture** for study. Although culturing cells often results in their loss of differentiated function, techniques have been developed for maintaining several cell types that still express their original characteristics.

As discussed in Section 16-1, metabolic pathways in eukaryotes are compartmentalized in various subcellular organelles (Table 16-1). For example, oxidative phosphorylation occurs in the mitochondrion, whereas glycolysis and fatty acid biosynthesis occur in the cytosol. Such observations are made by breaking cells open and fractionating their components by differential centrifugation (Section 6-1B), possibly followed by zonal ultracentrifugation through a sucrose density gradient or by equilibrium density gradient ultracentrifugation in a  $\text{CsCl}$  density gradient, which, respectively, separate particles according to their size and density (Section 6-5B). The cell fractions are then analyzed for biochemical function.

## D. Systems Biology

Metabolism has traditionally been studied by hypothesis-based research: isolating individual enzymes and metabolites and assembling them into metabolic pathways as guided by experimentally testable hypotheses. This is a reductionist approach: the explanation of the workings of a system in terms of its component parts. A different, so-called integrative approach, **systems biology**, has recently emerged with the advent of complete genome sequences, the development of rapid and sensitive techniques for analyzing large numbers of gene transcripts, proteins, and metabolites all at once, and the development of new computational and mathematical tools. Systems biology is discovery-based: collecting and integrating enormous amounts of data in searchable databases so that the properties and dynamics of entire biological networks can be analyzed. As a result, our understanding of the path from genotype to phenotype has expanded. In addition to the central dogma of molecular biology (Section 5-4), that a single gene composed of DNA is transcribed to mRNA, which is translated to a single protein that influences metabolism, we are increasingly taking into account the genome, transcriptome, proteome, and **metabolome** (the complete set of a cell's metabolites) and their interrelationships (Fig. 16-20). The term **bibliome** (Greek: *biblion*, book) has even been coined to denote the systematic incorporation of pre-existing information about reaction mechanisms and metabolic pathways. In the following paragraphs we discuss some of these emerging technologies and new fields of study.

### a. Transcriptomics

The overall metabolic capabilities of an organism are encoded by its genome (its entire complement of genes). In principle, it should be possible to reconstruct a cell's metabolic activities from its genomic sequence. However, at present, this can be done only in a general sense. For example, the 4.0-Mb genome of *Vibrio cholerae*, the bacterium that causes cholera, contains a large repertoire of genes encoding transport proteins and enzymes for catabolizing a

wide range of nutrients. This is consistent with the complicated lifestyle of *V. cholerae*, which can live on its own, in association with zooplankton, or in the human gastrointestinal tract (where it causes cholera; Section 19-2Cd). However, a simple catalog of an organism's genes does not reveal how these genes function. Thus, some genes are expressed continuously at high levels, whereas others are expressed rarely, for example, only when the organism encounters a particular metabolite.

Creating an accurate picture of gene expression is the goal of **transcriptomics**, the study of a cell's transcriptome (its entire complement of mRNAs). Identifying and quantifying all the transcripts from a single cell type reveals which genes are active. Cells transcribe thousands of genes at once so this study requires the use of DNA microarray technology (Section 7-6B). For example, Fig. 7-39 shows a DNA microarray that indicates the differences in gene expression between yeast grown in the presence and absence of glucose.

Differences in the expression of particular genes have been correlated with many developmental processes or growth patterns. For example, DNA microarrays have been used to profile the patterns of gene expression in tumor cells because different types of tumors express different types and amounts of proteins (Section 34-3B). This information is useful in choosing how best to treat a cancer.

### b. Proteomics

The correlation between the amount of a particular mRNA and the amount of its protein product is imperfect. This is because the various mRNAs and their corresponding proteins are synthesized and degraded at different rates. Furthermore, many proteins are post-translationally modified, sometimes in several different ways (e.g., by phosphorylation or glycosylation). Consequently, the number of unique proteins in a cell exceeds the number of unique mRNAs.

A more reliable way than transcriptomics to assess gene expression is to examine a cell's proteome, the complete set of proteins that the cell synthesizes. This **proteomics**

**Figure 16-20** The relationship between genotype and phenotype. The path from genetic information (genotype) to metabolic function (phenotype) has several steps. Portions of the genome are transcribed to produce the transcriptome, which

directs the synthesis of the proteome, whose various activities are responsible for synthesizing and degrading the components of the metabolome.

approach requires that the proteins first be separated, usually by two-dimensional (2D) gel electrophoresis (Section 6-4D). Individual proteins are then identified by using tandem mass spectrometry to obtain amino acid sequence information (Section 7-11a) and correlating it with protein sequence databases. All the proteins that are contained in a cell or tissue under a given set of conditions can thereby be catalogued.

One can compare all the proteins synthesized by a cell under two different sets of conditions by using different isotopically labeled reagents that are either contained in the growth medium (e.g., deuterated amino acids) or that are reacted with the cell extract. One technique for labeling cellular proteins uses **isotope-coded affinity tags (ICATs)**, which are analogous to the differently fluorescing dyes that are used to label cDNAs.

An ICAT contains three functional elements: an iodoacetyl group to react with Cys residues, a linker that

contains either 8 hydrogen (light) or 8 deuterium (heavy) atoms, and **biotin**, a coenzyme (Section 23-1Ab) that is used as a biotechnology tool because of its extremely tight binding to the protein **avidin** ( $K = 10^{-15} M$ ; Fig. 16-21a). Avidin is immobilized on a chromatographic resin so that the ICAT-labeled peptides can be isolated by biotin/avidin affinity chromatography (Section 6-3C).

The ICAT procedure is illustrated in Fig. 16-21b. Two protein mixtures representing two different growth conditions are treated with light (d0) or heavy (d8) versions of the ICAT reagent. The labeled protein mixtures are combined and digested with trypsin to form Cys-containing labeled peptides, which are then isolated by biotin/avidin affinity chromatography. Individual peptides are separated by liquid chromatography and detected by mass spectrometry (LC/MS). The ratio of the intensities of the light and heavy peptide signals indicates the relative peptide abundance in the two samples. Tandem mass spectrometry

**Figure 16-21 The isotope-coded affinity tag (ICAT) method for quantitative proteome analysis.** (a) An example of an ICAT reagent that contains an iodoacetyl reactive group, a linker, and a biotin residue. X denotes the position of hydrogen (d0) or deuterium (d8). (b) The ICAT strategy for differential labeling of proteins expressed by cells under two different sets of conditions. (1) Proteins from states A and B are respectively treated with the light (d0) and heavy (d8) forms of the ICAT reagent. (2) The labeled protein mixtures are combined. (3) The labeled proteins are digested with trypsin to form Cys-containing labeled peptides. These peptides are then purified by biotin/avidin

affinity chromatography. The purified peptides are analyzed by mass spectrometry in two ways: (4) Liquid chromatography followed by mass spectrometry (LC/MS) is used to quantitate the peptides. The ratio of the signal intensities from the corresponding light and heavy peptides indicates the relative peptide abundance in the two mixtures. (5) Tandem mass spectrometry (MS/MS) is used to determine the amino acid sequence of each peptide and to thereby identify the protein from which it is derived by comparing the peptide's sequence to those in a database of all known proteins.

(MS/MS) is then used to sequence each peptide and determine its identity. This method was used to identify many of the yeast proteins whose mRNA concentrations increased or decreased when glucose was absent from the growth medium (Fig. 7-39). A hope for the future is that samples from diseased and normal subjects can be compared in this manner to find previously undetected disease markers that would allow early diagnosis of various diseases.

### c. Metabolomics

In order to describe a cell's functional state (its phenotype) we need, in addition to the cell's genome, transcriptome, and proteome, a quantitative description of all of the metabolites it contains under a given set of conditions, its metabolome. However, a cell or tissue contains thousands of metabolites with greatly varying properties, so that identifying and quantifying all these substances is a daunting task, requiring many different analytical tools. Consequently, this huge undertaking is often subdivided. For example, **lipidomics** is the subdiscipline of **metabolomics** aimed at identifying and characterizing all lipids in a cell under a particular set of conditions, including how these lipids influence membrane structure, cell signaling, gene expression, cell-cell interactions, etc., whereas **glycomics** similarly identifies and characterizes all the carbohydrates in a cell.

A recently constructed model of the human metabolome—based on 1496 protein-encoding genes, 2004 proteins, 2766 metabolites, and 3311 metabolic and transport reactions—has been used to simulate 288 known metabolic functions in a variety of cell and tissue types. This *in silico* (computerized) model is expected to provide a framework for future advances in human systems biology.

## 4 THERMODYNAMICS OF PHOSPHATE COMPOUNDS

The endergonic processes that maintain the living state are driven by the exergonic reactions of nutrient oxidation. This coupling is most often mediated through the syntheses of a few types of “high-energy” intermediates whose exergonic consumption drives endergonic processes. These intermediates therefore form a sort of universal free energy “currency” through which free energy-producing reactions “pay for” the free energy-consuming processes in biological systems.

**Adenosine triphosphate (ATP; Fig. 16-22)**, which occurs in all known life-forms, is the “high-energy” intermediate that constitutes the most common cellular energy currency. Its central role in energy metabolism was first recognized in 1941 by Fritz Lipmann and Herman Kalckar. ATP consists of an **adenosine** moiety to which three **phosphoryl groups** ( $-\text{PO}_3^{2-}$ ) are sequentially linked via a **phosphoester bond** followed by two **phosphoanhydride bonds**. **Adenosine diphosphate (ADP)** and **5'-adenosine monophosphate (AMP)** are similarly constituted but with only two and one phosphoryl units, respectively.

In this section we consider the nature of phosphoryl-transfer reactions, discuss why some of them are so exergonic, and outline how the cell consumes and regenerates ATP.

## A. Phosphoryl-Transfer Reactions

*Phosphoryl-transfer reactions,*

are of enormous metabolic significance. Some of the most important reactions of this type involve the synthesis and hydrolysis of ATP:

where  $\text{P}_i$  and  $\text{PP}_i$ , respectively, represent **orthophosphate** ( $\text{PO}_4^{3-}$ ) and **pyrophosphate** ( $\text{P}_2\text{O}_7^{4-}$ ) in any of their ionization states. These highly exergonic reactions are coupled to numerous endergonic biochemical processes so as to drive them to completion. Conversely, ATP is regenerated by coupling its formation to a more highly exergonic metabolic process (the thermodynamics of coupled reactions is discussed in Section 3-4C).

To illustrate these concepts, let us consider two examples of phosphoryl-transfer reactions. The initial step in the metabolism of glucose is its conversion to glucose-6-phosphate (Section 17-2A). Yet the direct reaction of glucose and  $\text{P}_i$  is thermodynamically unfavorable (Fig. 16-23a). In biological systems, however, this reaction is coupled to the exergonic hydrolysis of ATP, so the overall reaction is thermodynamically favorable. ATP can be similarly regenerated by coupling its synthesis from ADP and  $\text{P}_i$  to the even more exergonic hydrolysis of **phosphoenolpyruvate** (Fig. 16-23b; Section 17-2J).

The bioenergetic utility of phosphoryl-transfer reactions stems from their kinetic stability to hydrolysis combined with their capacity to transmit relatively large amounts of free energy. The  $\Delta G^\circ$  values of hydrolysis of several phosphorylated compounds of biochemical importance are tabulated in Table 16-3. The negatives of these values are often referred to as **phosphate group-transfer potentials**; they

**Figure 16-22** The structure of ATP indicating its relationship to ADP, AMP, and adenosine. The phosphoryl groups, starting with that on AMP, are referred to as the  $\alpha$ ,  $\beta$ , and  $\gamma$  phosphates. Note the difference between phosphoester and phosphoanhydride bonds.

**Figure 16-23 Some overall coupled reactions involving ATP.** (a) The phosphorylation of glucose to form glucose-6-phosphate and ADP. (b) The phosphorylation of ADP by phosphoenolpyruvate to form ATP and pyruvate. Each reaction

has been conceptually decomposed into a direct phosphorylation step (half-reaction 1) and a step in which ATP is hydrolyzed (half-reaction 2). Both half-reactions proceed in the direction in which the overall reaction is exergonic ( $\Delta G < 0$ ).

are a measure of the tendency of phosphorylated compounds to transfer their phosphoryl groups to water. Note that ATP has an intermediate phosphate group-transfer potential. Under standard conditions, the compounds above ATP in Table 16-3 can spontaneously transfer a phosphoryl group to ADP to form ATP, which can, in turn,

spontaneously transfer a phosphoryl group to the hydrolysis products (ROH form) of the compounds below it.

**Table 16-3 Standard Free Energies of Phosphate Hydrolysis of Some Compounds of Biological Interest**

Compound	$\Delta G^{\circ'} \text{ (kJ} \cdot \text{mol}^{-1}\text{)}$
Phosphoenolpyruvate	-61.9
1,3-Bisphosphoglycerate	-49.4
<b>ATP (<math>\rightarrow</math> AMP + PP<sub>i</sub>)</b>	<b>-45.6</b>
Acetyl phosphate	-43.1
Phosphocreatine	-43.1
<b>ATP (<math>\rightarrow</math> ADP + P<sub>i</sub>)</b>	<b>-30.5</b>
Glucose-1-phosphate	-20.9
PP <sub>i</sub>	-19.2
Fructose-6-phosphate	-13.8
Glucose-6-phosphate	-13.8
Glycerol-3-phosphate	-9.2

#### a. $\Delta G$ of ATP Hydrolysis Varies with pH, Divalent Metal Ion Concentration, and Ionic Strength

The  $\Delta G$  of a reaction varies with the total concentrations of its reactants and products and thus with their ionic states (Eq. [3.15]). The  $\Delta G$ 's of hydrolysis of phosphorylated compounds are therefore highly dependent on pH, divalent metal ion concentration (divalent metal ions such as  $\text{Mg}^{2+}$  have high phosphate-binding affinities), and ionic strength. Reasonable estimates of the intracellular values of these quantities as well as of [ATP], [ADP], and [ $P_i$ ] (which are generally on the order of millimolar) indicate that ATP hydrolysis under physiological conditions has  $\Delta G \approx -50 \text{ kJ} \cdot \text{mol}^{-1}$  rather than the  $-30.5 \text{ kJ} \cdot \text{mol}^{-1}$  of its  $\Delta G^{\circ'}$ . Nevertheless, for the sake of consistency in comparing reactions, we shall usually refer to the latter value.

The above situation for ATP is not unique. It is important to keep in mind that *within a given cell, the concentrations of most substances vary both with location and time. Indeed, the concentrations of many ions, coenzymes, and metabolites commonly vary by several orders of magnitude across membranous organelle boundaries.* Unfortunately, it is usually quite difficult to obtain an accurate measurement of the concentration of any particular chemical species in a specific cellular compartment. The  $\Delta G$ 's for most *in vivo* reactions are therefore little more than estimates.

## B. Rationalizing the “Energy” in “High-Energy” Compounds

Bonds whose hydrolysis proceeds with large negative values of  $\Delta G^\circ$  (customarily more negative than  $-25 \text{ kJ} \cdot \text{mol}^{-1}$ ) are often referred to as “**high-energy**” bonds or “**energy-rich**” bonds and are frequently symbolized by the squiggle ( $\sim$ ). Thus ATP may be represented as  $\text{AR}-\text{P}\sim\text{P}\sim\text{P}$ , where A, R, and P symbolize adenylyl, ribosyl, and phosphoryl groups, respectively. Yet, the phosphoester bond joining the adenylyl group of ATP to its  $\alpha$ -phosphoryl group appears to be not greatly different in electronic character from the so-called “high-energy” bonds bridging its  $\beta$  and  $\gamma$  phosphoryl groups. In fact, none of these bonds have any unusual properties, so the term “high-energy” bond is somewhat of a misnomer. (In any case, it should not be confused with the term “bond energy,” which is defined as the energy required to break, not hydrolyze, a covalent bond.) Why then, should the phosphoryl-transfer reactions of ATP be so exergonic? The answer comes from the comparison of the stabilities of the reactants and products of these reactions.

Several different factors appear to be responsible for the “high-energy” character of phosphoanhydride bonds such as those in ATP (Fig. 16-24):

**1.** The resonance stabilization of a phosphoanhydride bond is less than that of its hydrolysis products. This is because a phosphoanhydride’s two strongly electron-withdrawing phosphoryl groups must compete for the lone pair of electrons of its bridging oxygen atom, whereas this competition is absent in the hydrolysis products. In other words, the electronic requirements of the phosphoryl groups are less satisfied in a phosphoanhydride than in its hydrolysis products.

**2.** Of perhaps greater importance is the destabilizing effect of the electrostatic repulsions between the charged groups of a phosphoanhydride in comparison to that of its hydrolysis products. In the physiological pH range, ATP has three to four negative charges whose mutual electrostatic repulsions are partially relieved by ATP hydrolysis.

**3.** Another destabilizing influence, which is difficult to assess, is the smaller solvation energy of a phosphoanhydride in comparison to that of its hydrolysis products. Some estimates

**Figure 16-24** Resonance and electrostatic stabilization in a phosphoanhydride and its hydrolysis products. The competing resonances (curved arrows from the central O) and charge–charge repulsions (zigzag line) between the phosphoryl groups of a phosphoanhydride decrease its stability relative to its hydrolysis products.

suggest that this factor provides the dominant thermodynamic driving force for the hydrolysis of phosphoanhydrides.

A further property of ATP that suits it to its role as an energy intermediate stems from the relative kinetic stability of phosphoanhydride bonds to hydrolysis. Most types of anhydrides are rapidly hydrolyzed in aqueous solution. Phosphoanhydride bonds, however, have unusually large free energies of activation. Consequently, ATP is reasonably stable under physiological conditions but is readily hydrolyzed in enzymatically mediated reactions.

### a. Other “High-Energy” Compounds

The compounds in Table 16-3 with phosphate group-transfer potentials significantly greater than that of ATP have additional destabilizing influences:

**1. Acyl phosphates.** The hydrolysis of **acyl phosphates** (mixed phosphoric–carboxylic anhydrides), such as **acetyl phosphate** and **1,3-bisphosphoglycerate**,

is driven by the same competing resonance and differential solvation influences that function in the hydrolysis of phosphoanhydrides. Apparently these effects are more pronounced for acyl phosphates than for phosphoanhydrides.

**2. Enol phosphates.** The high phosphate group-transfer potential of an **enol phosphate**, such as phosphoenolpyruvate (Fig. 16-23b), derives from its **enol** hydrolysis product being less stable than its **keto** tautomer. Consider the hydrolysis reaction of an enol phosphate as occurring in two steps (Fig. 16-25). The hydrolysis step is subject to the driving forces discussed above. *It is therefore the highly exergonic enol–keto conversion that provides phosphoenolpyruvate with the added thermodynamic impetus to phosphorylate ADP to form ATP.*

**3. Phosphoguanidines.** The high phosphate group-transfer potentials of **phosphoguanidines**, such as **phosphocreatine** and **phosphoarginine**, largely result from the competing resonances in their **guanidino** group, which are even more pronounced than they are in the phosphate group of phosphoanhydrides (Fig. 16-26). Consequently, phosphocreatine can phosphorylate ADP (see Section 16-4Cd).

Compounds such as **glucose-6-phosphate** or **glycerol-3-phosphate**,

$\alpha$ -D-Glucose-6-phosphate

L-Glycerol-3-phosphate

**Figure 16-25 Hydrolysis of phosphoenolpyruvate.** The reaction is broken down into two steps, hydrolysis and tautomerization.

which are below ATP in Table 16-3, have no significantly different resonance stabilization or charge separation in comparison with their hydrolysis products. Their free energies of hydrolysis are therefore much less than those of the preceding “high-energy” compounds.

### C. The Role of ATP

As Table 16-3 indicates, *in the thermodynamic hierarchy of phosphoryl-transfer agents, ATP occupies the middle rank.* This enables ATP to serve as an energy conduit between “high-energy” phosphate donors and “low-energy” phosphate acceptors (Fig. 16-27). Let us examine the general biochemical scheme of how this occurs.

**Figure 16-26** Competing resonances in phosphoguanidines.

In general, the highly exergonic phosphoryl-transfer reactions of nutrient degradation are coupled to the formation of ATP from ADP and  $\text{P}_i$  through the auspices of various enzymes known as **kinases**, enzymes that catalyze the transfer of phosphoryl groups between ATP and other molecules. Consider the two reactions in Fig. 16-23b. If carried out independently, these reactions would not influence each other. In the cell, however, the enzyme **pyruvate**

**Figure 16-27** The flow of phosphoryl groups from “high-energy” phosphate donors, via the ATP–ADP system, to “low-energy” phosphate acceptors.

**Figure 16-28** The phosphorylation of fructose-6-phosphate by ATP to form fructose-1,6-bisphosphate and ADP.

**kinase** couples the two reactions by catalyzing the transfer of the phosphoryl group of phosphoenolpyruvate directly to ADP to result in an overall exergonic reaction (Section 17-2J).

#### a. Consumption of ATP

In its role as the universal energy currency of living systems, ATP is consumed in a variety of ways:

**1. Early stages of nutrient breakdown.** The exergonic hydrolysis of ATP to ADP may be enzymatically coupled to an endergonic phosphorylation reaction to form “low-energy” phosphate compounds. We have seen one example of this in the hexokinase-catalyzed formation of glucose-6-phosphate (Fig. 16-23a). Another example is the **phosphofructokinase**-catalyzed phosphorylation of **fructose-6-phosphate** to form **fructose-1,6-bisphosphate** (Fig. 16-28). Both of these reactions occur in the first stage of glycolysis (Section 17-2).

**2. Interconversion of nucleoside triphosphates.** Many biosynthetic processes, such as the synthesis of proteins and nucleic acids, require nucleoside triphosphates other than ATP. These include the ribonucleoside triphosphates CTP, GTP, and UTP, which, together with ATP, are utilized, for example, in the biosynthesis of RNA (Section 31-2) and the deoxyribonucleoside triphosphate DNA precursors dATP, dCTP, dGTP, and dTTP (Section 5-4C). All these **nucleoside triphosphates (NTPs)** are synthesized from ATP and the corresponding **nucleoside diphosphate (NDP)** in reactions catalyzed by the nonspecific enzyme **nucleoside diphosphate kinase**:

The  $\Delta G^{\circ'}$  values for these reactions are nearly zero, as might be expected from the structural similarities among the NTPs. These reactions are driven by the depletion of the NTPs through their exergonic hydrolysis in the biosynthetic reactions in which they participate (Section 3-4C).

**3. Physiological processes.** The hydrolysis of ATP to ADP and  $\text{P}_i$  energizes many essential endergonic physiological processes such as chaperone-assisted protein folding (Section 9-2C), muscle contraction (Section 35-3B), and the transport of molecules and ions against concentration gradients (Section 20-3). In general, these processes result from conformational changes in proteins (enzymes) that occur in response to their binding of ATP. This is followed by the exergonic hydrolysis of ATP and release of

ADP and  $\text{P}_i$ , thereby causing these processes to be unidirectional (irreversible).

**4. Additional phosphoanhydride cleavage in highly endergonic reactions.** Although many reactions involving ATP yield ADP and  $\text{P}_i$  (**orthophosphate cleavage**), others yield AMP and  $\text{PP}_i$  (**pyrophosphate cleavage**). In these latter cases, the  $\text{PP}_i$  is rapidly hydrolyzed to  $2\text{P}_i$  by **inorganic pyrophosphatase** ( $\Delta G^{\circ'} = -19.2 \text{ kJ} \cdot \text{mol}^{-1}$ ) so that the *pyrophosphate cleavage of ATP ultimately results in the hydrolysis of two “high-energy” phosphoanhydride bonds*. The attachment of amino acids to tRNA molecules for protein synthesis is an example of this phenomenon (Fig. 16-29 and Section 32-2C). The two steps of the reaction involving the amino acid are readily reversible because the free energies of hydrolysis of the bonds formed are comparable to that of ATP hydrolysis. The overall reaction is driven to completion by the hydrolysis of  $\text{PP}_i$ , which is essentially irreversible. Nucleic acid biosynthesis from the appropriate NTPs also releases  $\text{PP}_i$  (Sections 30-1A and 31-2). The free energy changes of these vital reactions are around zero, so the subsequent hydrolysis of  $\text{PP}_i$  is essential to drive the synthesis of nucleic acids.

#### b. Formation of ATP

To complete its intermediary metabolic function, ATP must be replenished. This is accomplished through three types of processes:

**1. Substrate-level phosphorylation.** ATP may be formed, as is indicated in Fig. 16-23b, from phosphoenolpyruvate by direct transfer of a phosphoryl group from a “high-energy” compound to ADP. Such reactions, which are referred to as **substrate-level phosphorylations**, most commonly occur in the early stages of carbohydrate metabolism (Section 17-2).

**2. Oxidative phosphorylation and photophosphorylation.** Both oxidative metabolism and photosynthesis act to generate a proton ( $\text{H}^+$ ) concentration gradient across a membrane (Sections 22-3 and 24-2D). Discharge of this gradient is enzymatically coupled to the formation of ATP from ADP and  $\text{P}_i$  (the reverse of ATP hydrolysis). In oxidative metabolism, this process is called **oxidative phosphorylation**, whereas in photosynthesis it is termed **photophosphorylation**. Most of the ATP produced by respiring and photosynthesizing organisms is generated in this manner.

**3. Adenylate kinase reaction.** The AMP resulting from pyrophosphate cleavage reactions of ATP is converted to

**Figure 16-29** Pyrophosphate cleavage in the synthesis of an aminoacyl-tRNA. Here the squiggle (~) represents a “high-energy” bond. In the first reaction step, the amino acid is **adenylated** by ATP. In the second step, a tRNA molecule

displaces the AMP moiety to form an aminoacyl-tRNA. The exergonic hydrolysis of pyrophosphate ( $\Delta G^{\circ} = -19.2 \text{ kJ} \cdot \text{mol}^{-1}$ ) drives the reaction forward.

ADP in a reaction catalyzed by the enzyme **adenylate kinase** (Section 17-4Fe):

The ADP is subsequently converted to ATP through substrate-level phosphorylation, oxidative phosphorylation, or photophosphorylation.

### c. Rate of ATP Turnover

The cellular role of ATP is that of a free energy transmitter rather than a free energy reservoir. The amount of ATP in a cell is typically only enough to supply its free energy needs for a minute or two. Hence, ATP is continually being hydrolyzed and regenerated. Indeed,  $^{32}\text{P}$ -labeling experiments indicate that the metabolic half-life of an ATP molecule varies from seconds to minutes depending on the cell type and its metabolic activity. For instance, brain cells have only a few seconds' supply of ATP (which, in part, accounts for the rapid deterioration of brain tissue by oxygen deprivation). An average person at rest consumes and regenerates ATP at a rate of  $\sim 3 \text{ mol} (1.5 \text{ kg}) \cdot \text{h}^{-1}$  and as much as an order of magnitude faster during strenuous activity.

### d. Phosphocreatine Provides a “High-Energy” Reservoir for ATP Formation

Muscle and nerve cells, which have a high ATP turnover (a maximally exerting muscle has only a fraction of a second's ATP supply), have a free energy reservoir that functions to regenerate ATP rapidly. In vertebrates, phosphocreatine (Fig. 16-26) functions in this capacity. It is synthesized by the reversible phosphorylation of creatine by ATP as catalyzed by **creatine kinase**:

Note that this reaction is endergonic under standard conditions. However, the intracellular concentrations of its reactants and products (typically  $4 \text{ mM}$  ATP and  $0.013 \text{ mM}$

ADP) are such that it operates close to equilibrium ( $\Delta G \approx 0$ ). Accordingly, when the cell is in a resting state, so that  $[\text{ATP}]$  is relatively high, the reaction proceeds with net synthesis of phosphocreatine, whereas at times of high metabolic activity, when  $[\text{ATP}]$  is low, the equilibrium shifts so as to yield net synthesis of ATP. *Phosphocreatine thereby acts as an ATP “buffer” in cells that contain creatine kinase.* A resting vertebrate skeletal muscle normally has sufficient phosphocreatine to supply its free energy needs for several minutes (but for only a few seconds at maximum exertion). In the muscles of some invertebrates, such as lobsters, phosphoarginine performs the same function. These phosphoguanidines are collectively named **phosphagens**.

## 5 OXIDATION–REDUCTION REACTIONS

**Oxidation–reduction reactions**, processes involving the transfer of electrons, are of immense biochemical significance; living things derive most of their free energy from them. In photosynthesis (Chapter 24),  $\text{CO}_2$  is **reduced** (gains electrons) and  $\text{H}_2\text{O}$  is **oxidized** (loses electrons) to yield carbohydrates and  $\text{O}_2$  in an otherwise endergonic process that is powered by light energy. In aerobic metabolism, which is carried out by all eukaryotes and many prokaryotes, the overall photosynthetic reaction is essentially reversed so as to harvest the free energy of oxidation of carbohydrates and other organic compounds in the form of ATP (Chapter 22). Anaerobic metabolism generates ATP, although in lower yields, through intramolecular oxidation–reductions of various organic molecules, for example, glycolysis (Chapter 17). In certain anaerobic bacteria, ATP is generated through the use of non- $\text{O}_2$  oxidizing agents such as sulfate or nitrate. In this section we outline the thermodynamics of oxidation–reduction reactions in order to understand the quantitative aspects of these crucial biological processes.

### A. The Nernst Equation

Oxidation–reduction reactions (also known as **redox** or **oxidoreduction reactions**) resemble other types of chemical reactions in that they involve group transfer. For instance, hydrolysis transfers a functional group to water. In oxidation–reduction reactions, the “groups” transferred are electrons, which are passed from an **electron donor (reductant or reducing agent)** to an **electron acceptor (oxidant or oxidizing agent)**. For example, in the reaction

$\text{Cu}^+$ , the reductant, is oxidized to  $\text{Cu}^{2+}$  while  $\text{Fe}^{3+}$ , the oxidant, is reduced to  $\text{Fe}^{2+}$ .

Redox reactions may be divided into two **half-reactions** or **redox couples**, such as

whose sum is the above whole reaction. These half-reactions occur during oxidative metabolism in the vital mitochondrial electron transfer mediated by **cytochrome c oxidase** (Section 22-2C5). Note that for electrons to be transferred, both half-reactions must occur simultaneously. In fact, the electrons are the two half-reactions' common intermediate.

#### a. Electrochemical Cells

A half-reaction consists of an electron donor and its conjugate electron acceptor; in the oxidation half-reaction shown above,  $\text{Cu}^+$  is the electron donor and  $\text{Cu}^{2+}$  is its conjugate electron acceptor. Together these constitute a **conjugate redox pair** analogous to the conjugate acid–base pair ( $\text{HA}$  and  $\text{A}^-$ ) of a Brønsted acid (Section 2-2A). An important difference between redox pairs and acid–base pairs, however, is that *the two half-reactions of a redox reaction, each consisting of a conjugate redox pair, may be physically separated so as to form an electrochemical cell* (Fig. 16-30). In such a device, each half-reaction takes place in its separate **half-cell**, and electrons are passed between half-cells as an electric current in the wire connecting their two electrodes. A salt bridge is necessary to complete the electrical circuit by providing a conduit for ions to migrate in the maintenance of electrical neutrality.

The free energy of an oxidation–reduction reaction is particularly easy to determine through a simple measurement of the voltage difference between its two half-cells. Consider the general redox reaction:

in which  $n$  electrons per mole of reactants are transferred from reductant ( $\text{B}_{\text{red}}$ ) to oxidant ( $\text{A}_{\text{ox}}^{n+}$ ). The free energy of this reaction is expressed, according to Eq. [3.15], as

$$\Delta G = \Delta G^\circ + RT \ln \left( \frac{[\text{A}_{\text{red}}][\text{B}_{\text{ox}}^{n+}]}{[\text{A}_{\text{ox}}^{n+}][\text{B}_{\text{red}}]} \right) \quad [16.2]$$

Equation [3.12] indicates that, under reversible conditions,

$$\Delta G = -w' = -w_{\text{el}} \quad [16.3]$$

where  $w'$ , the non-pressure–volume work, is, in this case,  $w_{\text{el}}$ , the electrical work required to transfer the  $n$  moles of electrons through the electric potential difference  $\Delta \mathcal{E}$ . This, according to the laws of electrostatics, is

$$w_{\text{el}} = n\mathcal{F} \Delta \mathcal{E} \quad [16.4]$$

where  $\mathcal{F}$ , the **faraday**, is the electrical charge of 1 mol of electrons ( $1 \mathcal{F} = 96,485 \text{ C} \cdot \text{mol}^{-1} = 96,485 \text{ J} \cdot \text{V}^{-1} \cdot \text{mol}^{-1}$ , where C and V are the symbols for coulomb and volt). Thus, substituting Eq. [16.4] into Eq. [16.3],

$$\Delta G = -n\mathcal{F} \Delta \mathcal{E} \quad [16.5]$$

Combining Eqs. [16.2] and [16.5], and making the analogous substitution for  $\Delta G^\circ$ , yields the **Nernst equation**:

$$\Delta \mathcal{E} = \Delta \mathcal{E}^\circ - \frac{RT}{n\mathcal{F}} \ln \left( \frac{[\text{A}_{\text{red}}][\text{B}_{\text{ox}}^{n+}]}{[\text{A}_{\text{ox}}^{n+}][\text{B}_{\text{red}}]} \right) \quad [16.6]$$

which was originally formulated in 1881 by Walther Nernst. Here  $\Delta \mathcal{E}$ , the **electromotive force (emf)** or **redox potential**, may be described as the “electron pressure” that the electrochemical cell exerts. The quantity  $\Delta \mathcal{E}^\circ$ , the redox potential when all components are in their standard states, is called the **standard redox potential**. If these standard states refer to biochemical standard states (Section 3-4Ba), then  $\Delta \mathcal{E}^\circ$  is replaced by  $\Delta \mathcal{E}^{\circ'}$ . Note that a positive  $\Delta \mathcal{E}$  in Eq. [16.5] results in a negative  $\Delta G$ ; in other words, *a positive  $\Delta \mathcal{E}$  is indicative of a spontaneous reaction, one that can do work*.

### B. Measurements of Redox Potentials

The free energy change of a redox reaction may be determined, as Eq. [16.5] indicates, by simply measuring its redox potential with a voltmeter (Fig. 16-30). Consequently, voltage measurements are commonly employed to characterize the sequence of reactions comprising a metabolic

**Figure 16-30** Example of an electrochemical cell. The half-cell undergoing oxidation (here  $\text{Cu}^+ \rightarrow \text{Cu}^{2+} + e^-$ ) passes the liberated electrons through the wire to the half-cell undergoing reduction (here  $e^- + \text{Fe}^{3+} \rightarrow \text{Fe}^{2+}$ ). Electroneutrality in the two half-cells is maintained by the transfer of ions through the electrolyte-containing salt bridge.

electron-transport pathway (such as mediates, e.g., oxidative metabolism; Chapter 22).

Any redox reaction can be divided into its component half-reactions:

where, by convention, both half-reactions are written as reductions. These half-reactions can be assigned **reduction potentials**,  $\mathcal{E}_A$  and  $\mathcal{E}_B$ , in accordance with the Nernst equation:

$$\mathcal{E}_A = \mathcal{E}_A^\circ - \frac{RT}{n\mathcal{F}} \ln\left(\frac{[A_{\text{red}}]}{[A_{\text{ox}}^{n+}]}\right) \quad [16.7a]$$

$$\mathcal{E}_B = \mathcal{E}_B^\circ - \frac{RT}{n\mathcal{F}} \ln\left(\frac{[B_{\text{red}}]}{[B_{\text{ox}}^{n+}]}\right) \quad [16.7b]$$

For the redox reaction of any two half-reactions:

$$\Delta\mathcal{E}^\circ = \mathcal{E}_{(e^- \text{-acceptor})}^\circ - \mathcal{E}_{(e^- \text{-donor})}^\circ \quad [16.8]$$

Thus, when the reaction proceeds with A as the electron acceptor and B as the electron donor,  $\Delta\mathcal{E}^\circ = \mathcal{E}_A^\circ - \mathcal{E}_B^\circ$  and similarly for  $\Delta\mathcal{E}$ .

Reduction potentials, like free energies, must be defined with respect to some arbitrary standard. By convention, standard reduction potentials are defined with respect to the standard hydrogen half-reaction

in which  $\text{H}^+$  at pH 0, 25°C, and 1 atm is in equilibrium with  $\text{H}_2(\text{g})$  that is in contact with a Pt electrode. This half-cell is arbitrarily assigned a standard reduction potential of  $\mathcal{E}^\circ = 0\text{ V}$  ( $1\text{ V} = 1\text{ J} \cdot \text{C}^{-1}$ ). For the biochemical convention, we likewise define the standard (pH = 0) hydrogen half-reaction as having  $\mathcal{E}' = 0$  so that the hydrogen half-cell at the biochemical standard state (pH = 7) has  $\mathcal{E}' = -0.421\text{ V}$  (Table 16-4). When  $\Delta\mathcal{E}$  is positive,  $\Delta G$  is negative (Eq. [16.5]), indicating a spontaneous process. In combining two half-reactions under standard conditions, the direction of spontaneity therefore involves the reduction of the redox couple with the more positive standard reduction potential. In other words, *the more positive the standard reduction potential, the greater the tendency for the redox couple's oxidized form to accept electrons and thus become reduced.*

**Table 16-4** Standard Reduction Potentials of Some Biochemically Important Half-Reactions

Half-Reaction	$\mathcal{E}'$ (V)
$\frac{1}{2}\text{O}_2 + 2\text{H}^+ + 2e^- \rightleftharpoons \text{H}_2\text{O}$	0.815
$\text{NO}_3^- + 2\text{H}^+ + 2e^- \rightleftharpoons \text{NO}_2^- + \text{H}_2\text{O}$	0.42
Cytochrome $a_3(\text{Fe}^{3+}) + e^- \rightleftharpoons$ cytochrome $a_3(\text{Fe}^{2+})$	0.385
$\text{O}_2(\text{g}) + 2\text{H}^+ + 2e^- \rightleftharpoons \text{H}_2\text{O}_2$	0.295
Cytochrome $a(\text{Fe}^{3+}) + e^- \rightleftharpoons$ cytochrome $a(\text{Fe}^{2+})$	0.29
Cytochrome $c(\text{Fe}^{3+}) + e^- \rightleftharpoons$ cytochrome $c(\text{Fe}^{2+})$	0.235
Cytochrome $c_1(\text{Fe}^{3+}) + e^- \rightleftharpoons$ cytochrome $c_1(\text{Fe}^{2+})$	0.22
Cytochrome $b(\text{Fe}^{3+}) + e^- \rightleftharpoons$ cytochrome $b(\text{Fe}^{2+})$ (mitochondrial)	0.077
Ubiquinone + $2\text{H}^+ + 2e^- \rightleftharpoons$ ubiquinol	0.045
Fumarate <sup>-</sup> + $2\text{H}^+ + 2e^- \rightleftharpoons$ succinate <sup>-</sup>	0.031
$\text{FAD} + 2\text{H}^+ + 2e^- \rightleftharpoons \text{FADH}_2$ (in flavoproteins)	-0.040

### a. Biochemical Half-Reactions Are Physiologically Significant

The biochemical standard reduction potentials ( $\mathcal{E}^{\circ}$ ) of some biochemically important half-reactions are listed in Table 16-4. The oxidized form of a redox couple with a large positive standard reduction potential has a high affinity for electrons and is a strong electron acceptor (oxidizing agent), whereas its conjugate reductant is a weak electron donor (reducing agent). For example,  $O_2$  is the strongest oxidizing agent in Table 16-4, whereas  $H_2O$ , which tightly holds its electrons, is the table's weakest reducing agent. The converse is true of half-reactions with large negative standard reduction potentials. Since electrons spontaneously flow from low to high reduction potentials, they are transferred, under standard conditions, from the reduced products in any half-reaction in Table 16-4 to the oxidized reactants of any half-reaction above it (although this may not occur at a measurable rate in the absence of a suitable enzyme). Thus, in biological systems, the approximate lower limit for a standard reduction potential is  $-0.421\text{ V}$  because reductants with a lesser value of  $\mathcal{E}^{\circ}$  would reduce protons to  $H_2$ . However, reducing centers in proteins that are protected from water may have lower potentials. Note that the  $Fe^{3+}$  ions of the various cytochromes tabulated in Table 16-4 have significantly different redox potentials. This indicates that *the protein components of redox enzymes play active roles in electron-transfer reactions by modulating the redox potentials of their bound redox-active centers.*

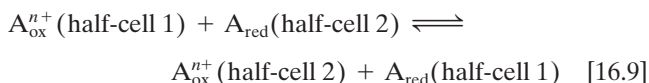

Electron-transfer reactions are of great biological importance. For example, in the mitochondrial electron-transport chain (Section 22-2), the primary source of ATP in eukaryotes, electrons are passed from NADH (Fig. 13-2) along a series of electron acceptors of increasing reduction potential (many of which are listed in Table 16-4) to  $O_2$ . ATP is generated from ADP and  $P_i$  by coupling its synthesis to this free energy cascade. *NADH thereby functions as an energy-rich electron-transfer coenzyme.* In fact, the oxidation of one NADH to  $NAD^+$  supplies sufficient free energy to generate 2.5 ATPs (Section 22-2Bb). The  $NAD^+/NADH$  redox couple functions as the electron acceptor in many exergonic metabolite oxidations. In serving as the electron donor in ATP synthesis, it fulfills its cyclic role as a free energy conduit in a manner analogous to ATP. The metabolic roles of redox coenzymes are further discussed in succeeding chapters.

### C. Concentration Cells

*A concentration gradient has a lower entropy (greater order) than the corresponding uniformly mixed solution and therefore requires the input of free energy for its formation. Consequently, discharge of a concentration gradient is an exergonic process that may be harnessed to drive an endergonic reaction.* For example, discharge of a proton concentration gradient (generated by the reactions of the electron-transport chain) across the inner mitochondrial membrane drives the enzymatic synthesis of ATP from ADP and  $P_i$  (Section 22-3). Likewise, nerve impulses,

which require electrical energy, are transmitted through the discharge of  $[Na^+]$  and  $[K^+]$  gradients that nerve cells generate across their cell membranes (Section 20-5B). Quantitation of the free energy contained in a concentration gradient is accomplished by use of the concepts of electrochemical cells.

The reduction potential and free energy of a half-cell vary with the concentrations of its reactants. An electrochemical cell may therefore be constructed from two half-cells that contain the same chemical species but at different concentrations. The overall reaction for such an electrochemical cell may be represented

and, according to the Nernst equation, since  $\Delta\mathcal{E}^{\circ} = 0$  when the same reaction occurs in both cells,

$$\Delta\mathcal{E} = \frac{RT}{n\mathcal{F}} \ln \left( \frac{[A_{\text{ox}}^{n+}(\text{half-cell 2})][A_{\text{red}}(\text{half-cell 1})]}{[A_{\text{ox}}^{n+}(\text{half-cell 1})][A_{\text{red}}(\text{half-cell 2})]} \right)$$

Such **concentration cells** are capable of generating electrical work until they reach equilibrium. This occurs when the concentration ratios in the half-cells become equal ( $K_{\text{eq}} = 1$ ). The reaction constitutes a sort of mixing of the two half-cells; the free energy generated is a reflection of the entropy of this mixing. The thermodynamics of concentration gradients as they apply to membrane transport is discussed in Section 20-1.

## 6 THERMODYNAMICS OF LIFE

One of the last refuges of **vitalism**, the doctrine that biological processes are not bound by the physical laws that govern inanimate objects, was the belief that living things can somehow evade the laws of thermodynamics. This view was partially refuted by elaborate calorimetric measurements on living animals that are entirely consistent with the energy conservation predictions of the first law of thermodynamics. However, the experimental verification of the second law of thermodynamics in living systems is more difficult. It has not been possible to measure the entropy of living matter because the heat,  $q_p$ , of a reaction at a constant  $T$  and  $P$  is only equal to  $T\Delta S$  if the reaction is carried out reversibly (Eq. [3.8]). Obviously, the dismantling of a living organism to its component molecules for such a measurement would invariably result in its irreversible death. Consequently, the present experimentally verified state of knowledge is that the entropy of living matter is less than that of the products to which it decays.

In this section we consider the special aspects of the thermodynamics of living systems. Knowledge of these matters, which is by no means complete, has enhanced our understanding of how metabolic pathways are regulated, how cells respond to stimuli, and how organisms grow and change with time.

### A. Living Systems Cannot Be at Equilibrium

**Classical or equilibrium thermodynamics** (Chapter 3) applies largely to reversible processes in closed systems. The fate of any isolated system, as we discussed in Section 3-4A, is that it must inevitably reach equilibrium. For example, if its reactants are in excess, the forward reaction will proceed faster than the reverse reaction until equilibrium is attained ( $\Delta G = 0$ ). In contrast, open systems may remain in a nonequilibrium state as long as they are able to acquire free energy from their surroundings in the form of reactants, heat, or work. While classical thermodynamics provides invaluable information concerning open systems by indicating whether a given process can occur spontaneously, further thermodynamic analysis of open systems requires the application of the more recently elucidated principles of **nonequilibrium or irreversible thermodynamics**. In contrast to classical thermodynamics, this theory explicitly takes time into account.

*Living organisms are open systems and therefore can never be at equilibrium.* As indicated above, they continuously ingest high-enthalpy, low-entropy nutrients, which they convert to low-enthalpy, high-entropy waste products. The free energy resulting from this process is used to do work and to produce the high degree of organization characteristic of life. If this process is interrupted, the organism ultimately reaches equilibrium, which for living things is synonymous with death. For example, one theory of aging holds that senescence results from the random but inevitable accumulation in cells of genetic defects that interfere with and ultimately disrupt the proper functioning of living processes. [The theory does not, however, explain how single-celled organisms or the germ cells of multicellular organisms (sperm and ova), which are in effect immortal, are able to escape this so-called **error catastrophe**.]

Living systems must maintain a nonequilibrium state for several reasons:

1. Only a nonequilibrium process can perform useful work.
2. The intricate regulatory functions characteristic of life require a nonequilibrium state because a process at equilibrium cannot be controlled (similarly, a ship that is dead in the water will not respond to its rudder).
3. The complex cellular and molecular systems that conduct biological processes can be maintained only in the nonequilibrium state. Living systems are inherently unstable because they are degraded by the very biochemical reactions to which they give rise. Their regeneration, which must occur almost simultaneously with their degradation, requires the continuous influx of free energy. For example, the ATP-generating consumption of glucose (Section 17-2), as has been previously mentioned, occurs with the initial consumption of ATP through its reactions with glucose to form glucose-6-phosphate and with fructose-6-phosphate to form fructose-1,6-bisphosphate. Consequently, if metabolism is suspended long enough to exhaust the available ATP supply, glucose metabolism cannot be resumed. Life therefore differs in a fundamental way from a complex

machine such as a computer. Both require a throughput of free energy to be active. However, the function of the machine is based on a static structure, so that the machine can be repeatedly switched on and off. Life, in contrast, is based on a self-destructing but self-renewing process, which once interrupted, cannot be reinitiated.

### B. Nonequilibrium Thermodynamics and the Steady State

In a nonequilibrium process, something (such as matter, electrical charge, or heat) must flow, that is, change its spatial distribution. In classical mechanics, the acceleration of mass occurs in response to force. *Similarly, flow in a thermodynamic system occurs in response to a thermodynamic force (driving force), which results from the system's nonequilibrium state.* For example, the flow of matter in diffusion is motivated by the thermodynamic force of a concentration gradient; the migration of electrical charge (electric current) occurs in response to a gradient in an electric field (a voltage difference); the transport of heat results from a temperature gradient; and a chemical reaction results from a difference in chemical potential. Such flows are said to be **conjugate** to their thermodynamic force.

A thermodynamic force may also promote a **nonconjugate flow** under the proper conditions. For example, a gradient in the concentration of matter can give rise to an electric current (a concentration cell), heat (such as occurs on mixing H<sub>2</sub>O and HCl), or a chemical reaction (the mitochondrial production of ATP through the dissipation of a proton gradient). Similarly, a gradient in electrical potential can motivate a flow of matter (electrophoresis), heat (resistive heating), or a chemical reaction (the charging of a battery). When a thermodynamic force stimulates a nonconjugate flow, the process is called **energy transduction**.

#### a. Living Things Maintain the Steady State

*Living systems are, for the most part, characterized by being in a steady state.* By this it is meant that all flows in the system are constant, so that the system does not change with time. Some environmental steady-state processes are schematically illustrated in Fig. 16-31. Ilya Prigogine, a pioneer in the development of irreversible thermodynamics, has shown that a steady-state system produces the maximum amount of useful work for a given energy expenditure under the prevailing conditions. *The steady state of an open system is therefore its state of maximum thermodynamic efficiency.* Furthermore, in analogy with Le Châtelier's principle (Section 3-4A), slight perturbations from the steady state give rise to changes in flows that counteract these perturbations so as to return the system to the steady state. *The steady state of an open system is therefore analogous to the equilibrium state of an isolated system; both are stable states.*

In the following chapters we shall see that many biological regulatory mechanisms function to maintain a steady state. For example, the flow of reaction intermediates through a metabolic pathway is often inhibited by an excess of final product and stimulated by an excess of starting material through the allosteric regulation of its key enzymes (Section 13-4).

**Figure 16-31** Two examples of open systems in a steady state.

(a) A constant flow of water in the river occurs under the influence of the force of gravity. The water level in the reservoir is maintained by rain, the major source of which is the evaporation of seawater. Hence the entire cycle is ultimately powered by the sun. (b) The steady state of the biosphere is

similarly maintained by the sun. Plants harness the sun's radiant energy to synthesize carbohydrates from  $\text{CO}_2$  and  $\text{H}_2\text{O}$ . The eventual metabolism of the carbohydrates by the plants or by the animals that eat them results in the release of their stored free energy and the return of the  $\text{CO}_2$  and  $\text{H}_2\text{O}$  to the environment to complete the cycle.

Living things have apparently evolved so as to take maximum thermodynamic advantage of their environments.

### C. Thermodynamics of Metabolic Control

#### a. Enzymes Selectively Catalyze Required Reactions

*Biological reactions are highly specific; only reactions that lie on metabolic pathways take place at significant rates despite the many other thermodynamically favorable reactions*

*that are also possible.* As an example, let us consider the reactions of ATP, glucose, and water. Two thermodynamically favorable reactions that ATP can undergo are phosphoryl transfer to form ADP and glucose-6-phosphate, and hydrolysis to form ADP and  $\text{P}_i$  (Fig. 16-23a). The free energy profiles of these reactions are diagrammed in Fig. 16-32. ATP hydrolysis is thermodynamically favored over the phosphoryl transfer to glucose. However, their relative rates are determined by their free energies of activation to their transition

**Figure 16-32** Reaction coordinate diagrams. These are (1) the reaction of ATP and water (purple curve), and the reaction of ATP and glucose (2) in the presence (orange curve) and (3) in the absence (yellow curve) of an appropriate enzyme. Although

the hydrolysis of ATP is a more exergonic reaction than the phosphorylation of glucose ( $\Delta G_1$  is more negative than  $\Delta G_2$ ), the latter reaction is predominant in the presence of a suitable enzyme because it is kinetically favored ( $\Delta G_2^\ddagger < \Delta G_1^\ddagger$ ).

states ( $\Delta G^\ddagger$  values; Section 14-1Cb) and the relative concentrations of glucose and water. The larger  $\Delta G^\ddagger$ , the slower the reaction. In the absence of enzymes,  $\Delta G^\ddagger$  for the phosphoryl-transfer reaction is greater than that for hydrolysis, so the hydrolysis reaction predominates (although neither reaction occurs at a biologically significant rate).

The free energy barriers of both of the nonenzymatic reactions are far higher than that of the enzyme-catalyzed phosphoryl transfer to glucose. Hence enzymatic formation of glucose-6-phosphate is kinetically favored over the nonenzymatic hydrolysis of ATP. *It is the role of an enzyme, in this case hexokinase, to selectively reduce the free energy of activation of a chemically coupled reaction so that it approaches equilibrium faster than the more thermodynamically favored uncoupled reaction.*

#### b. Many Enzymatic Reactions Are Near Equilibrium

Although metabolism as a whole is a nonequilibrium process, many of its component reactions function close to equilibrium. The reaction of ATP and creatine to form phosphocreatine (Section 16-4Cd) is an example of such a reaction. The ratio  $[\text{creatine}]/[\text{phosphocreatine}]$  depends on  $[\text{ATP}]$  because creatine kinase, the enzyme catalyzing this reaction, has sufficient activity to equilibrate the reaction rapidly. The net rate of such an equilibrium reaction is effectively controlled by varying the concentrations of its reactants and/or products.

#### c. Pathway Throughput Is Regulated by Controlling Enzymes Operating Far from Equilibrium

Other biological reactions function far from equilibrium. For example, the phosphofructokinase reaction (Fig. 16-28)

has an equilibrium constant of  $K'_{\text{eq}} = 300$  but under physiological conditions in rat heart muscle has the mass action ratio  $[\text{fructose-1,6-bisphosphate}][\text{ADP}]/[\text{fructose-6-phosphate}][\text{ATP}] = 0.03$ , which corresponds to  $\Delta G = -25.7 \text{ kJ} \cdot \text{mol}^{-1}$  (Eq. [3.15]). This situation arises from a buildup of reactants because there is insufficient phosphofructokinase activity to equilibrate the reaction. Changes in substrate concentrations therefore have relatively little effect on the rate of the phosphofructokinase reaction; the enzyme is close to saturation. Only changes in the activity of the enzyme, through allosteric interactions, for example, can significantly alter this rate. An enzyme such as phosphofructokinase is therefore analogous to a dam on a river. Substrate **flux** (rate of flow) is controlled by varying its activity (allosterically or by other means), much as a dam controls the flow of a river below the dam by varying the opening of its floodgates (when the water levels on the two sides of the dam are different, that is, when they are not at equilibrium).

Understanding of how reactant flux in a metabolic pathway is controlled requires knowledge of which reactions are functioning near equilibrium and which are far from it. Most enzymes in a metabolic pathway operate near equilibrium and therefore have net rates that are sensitive only to their substrate concentrations. However, as we shall see in the following chapters (particularly in Section 17-4), *certain enzymes, which are strategically located in a metabolic pathway, operate far from equilibrium. These enzymes, which are targets for metabolic regulation by allosteric interactions and other mechanisms, are responsible for the maintenance of a stable steady-state flux of metabolites through the pathway.* This situation, as we have seen, maximizes the pathway's thermodynamic efficiency.

## CHAPTER SUMMARY

**1 Metabolic Pathways** Metabolic pathways are series of consecutive enzymatically catalyzed reactions that produce specific products for use by an organism. The free energy released by degradation (catabolism) is, through the intermediacy of ATP and NADPH, used to drive the endergonic processes of biosynthesis (anabolism). Carbohydrates, lipids, and proteins are all converted to the common intermediate acetyl-CoA, whose acetyl group is then converted to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  through the action of the citric acid cycle and oxidative phosphorylation. A relatively few metabolites serve as starting materials for a host of biosynthetic products. Metabolic pathways have five principal characteristics: (1) Metabolic pathways are irreversible; (2) if two metabolites are interconvertible, the synthetic route from the first to the second must differ from the route from the second to the first; (3) every metabolic pathway has an exergonic first committed step; (4) all metabolic pathways are regulated, usually at the first committed step; and (5) metabolic pathways in eukaryotes occur in specific subcellular compartments.

**2 Organic Reaction Mechanisms** Almost all metabolic reactions fall into four categories: (1) group-transfer reactions; (2) oxidation–reduction reactions; (3) eliminations, isomerizations, and rearrangements; and (4) reactions that make or break

carbon–carbon bonds. Most of these reactions involve heterolytic bond cleavage or formation occurring through the addition of nucleophiles to electrophilic carbon atoms. Group-transfer reactions therefore involve transfer of an electrophilic group from one nucleophile to another. The main electrophilic groups transferred are acyl groups, phosphoryl groups, and glycosyl groups. The most common nucleophiles are amino, hydroxyl, imidazole, and sulfhydryl groups. Electrophiles participating in metabolic reactions are protons, metal ions, carbonyl carbon atoms, and cationic imines. Oxidation–reduction reactions involve loss or gain of electrons. Oxidation at carbon usually involves C–H bond cleavage, with the ultimate loss by C of the two bonding electrons through their transfer to an electron acceptor such as  $\text{NAD}^+$ . The terminal electron acceptor in aerobes is  $\text{O}_2$ . Elimination reactions are those in which a C=C double bond is created from two saturated carbon centers with the loss of  $\text{H}_2\text{O}$ ,  $\text{NH}_3$ ,  $\text{ROH}$ , or  $\text{RNH}_2$ . Dehydration reactions are the most common eliminations. Isomerizations involve shifts of double bonds within molecules. Rearrangements are biochemically uncommon reactions in which intramolecular C–C bonds are broken and reformed to produce new carbon skeletons. Reactions that make and break C–C bonds form the basis of both degradative and biosynthetic

metabolism. In the synthetic direction, these reactions involve addition of a nucleophilic carbanion to an electrophilic carbon atom. The most common electrophilic carbon atom is the carbonyl carbon, whereas carbanions are usually generated by removal of a proton from a carbon atom adjacent to a carbonyl group or by decarboxylation of a  $\beta$ -keto acid.

### 3 Experimental Approaches to the Study of Metabolism

Experimental approaches employed in elucidating metabolic pathways include the use of metabolic inhibitors, growth studies, and biochemical genetics. Metabolic inhibitors block pathways at specific enzymatic steps. Identification of the resulting intermediates indicates the course of the pathway. Mutations, which occur naturally in genetic diseases or can be induced by mutagens, X-rays, or genetic engineering, may also result in the absence or inactivity of an enzyme. Modern genetic techniques make it possible to express foreign genes in higher organisms (transgenic animals) or inactivate (knock out) a gene and study the effects of these changes on metabolism. When isotopic labels are incorporated into metabolites and allowed to enter a metabolic system, their paths may be traced from the distribution of label in the intermediates. NMR is a noninvasive technique that may be used to detect and study metabolites *in vivo*. Studies on isolated organs, tissue slices, cells, and subcellular organelles have contributed enormously to our knowledge of the localization of metabolic pathways. Systems biology endeavors to quantitatively describe the properties and dynamics of biological networks as a whole through the integration of genomic, transcriptomic, proteomic, and metabolomic information.

### 4 Thermodynamics of Phosphate Compounds

Free energy is supplied to endergonic metabolic processes by the ATP produced via exergonic metabolic processes. ATP's  $-30.5 \text{ kJ} \cdot \text{mol}^{-1} \Delta G^\circ$  of hydrolysis is intermediate between those of "high-energy" metabolites such as phosphoenolpyruvate and "low-energy" metabolites such as glucose-6-phosphate. The "high-energy" phosphoryl groups are enzymatically transferred to ADP, and the resulting ATP, in a separate reaction, phosphorylates "low-energy" compounds. ATP may also un-

dergo pyrophosphate cleavage to yield  $\text{PP}_i$ , whose subsequent hydrolysis adds further thermodynamic impetus to the reaction. ATP is present in too short a supply to act as an energy reservoir. This function, in vertebrate nerve and muscle cells, is carried out by phosphocreatine, which under low-ATP conditions readily transfers its phosphoryl group to ADP to form ATP.

### 5 Oxidation–Reduction Reactions

The half-reactions of redox reactions may be physically separated to form two electrochemical half-cells. The redox potential for the reduction of A by B,

in which  $n$  electrons are transferred, is given by the Nernst equation

$$\Delta \mathcal{E} = \Delta \mathcal{E}^\circ - \frac{RT}{n\mathcal{F}} \ln \left( \frac{[\text{A}_{\text{red}}][\text{B}_{\text{ox}}^{n+}]}{[\text{A}_{\text{ox}}^{n+}][\text{B}_{\text{red}}]} \right)$$

The redox potential of such a reaction is related to the reduction potentials of its component half-reactions,  $\mathcal{E}_A$  and  $\mathcal{E}_B$ , by

$$\Delta \mathcal{E} = \mathcal{E}_A - \mathcal{E}_B$$

If  $\mathcal{E}_A > \mathcal{E}_B$ , then  $\text{A}_{\text{ox}}^{n+}$  has a greater electron affinity than does  $\text{B}_{\text{ox}}^{n+}$ . The reduction potential scale is defined by arbitrarily setting the reduction potential of the standard hydrogen half-cell to zero. Redox reactions are of great metabolic importance. For example, the oxidation of NADH yields 2.5 ATPs through the mediation of the electron-transport chain.

### 6 Thermodynamics of Life

Living organisms are open systems and therefore cannot be at equilibrium. They must continuously dissipate free energy in order to carry out their various functions and preserve their highly ordered structures. The study of nonequilibrium thermodynamics has indicated that the steady state, which living processes maintain, is the state of maximum efficiency under the constraints governing open systems. Control mechanisms that regulate biological processes preserve the steady state by regulating the activities of enzymes that are strategically located in metabolic pathways.

## PROBLEMS

1. Glycolysis (glucose breakdown) has the overall stoichiometry:

whereas that of gluconeogenesis (glucose synthesis) is

What is the overall stoichiometry of the glycolytic breakdown of 1 mol of glucose followed by its gluconeogenic synthesis? Explain why it is necessary that the pathways of these two processes be independently controlled and why they must differ by at least one reaction.

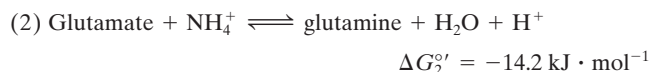

2. It has been postulated that a trigonal bipyramidal pentavalent phosphorus intermediate can undergo a vibrational deformation process known as **pseudorotation** in which its apical ligands exchange with two of its equatorial ligands via a tetragonal pyramidal transition state:

In a nucleophilic substitution reaction, would two cycles of pseudorotation, so as to place the leaving group (X) in an apical position and the attacking group (Y) in an equatorial position, lead to retention or inversion of configuration on the departure of the leaving group?

3. One **Curie (Ci)** of radioactivity is defined as  $3.70 \times 10^{10}$  disintegrations per second, the number that occurs in 1 g of pure  $^{226}\text{Ra}$ . A sample of  $^{14}\text{CO}_2$  has a specific radioactivity of  $5 \mu\text{Ci} \cdot \mu\text{mol}^{-1}$ . What percentage of its C atoms are  $^{14}\text{C}$ ?

4. In the hydrolysis of ATP to ADP and  $\text{P}_i$ , the equilibrium concentration of ATP is too small to be measured accurately. A better way of determining  $K'_{\text{eq}}$ , and hence  $\Delta G^{\circ'}$  of this reaction, is to break it up into two steps whose values of  $\Delta G^{\circ'}$  can be accurately determined. This has been done using the following pair of reactions (the first being catalyzed by **glutamine synthetase**):

What is the  $\Delta G^{\circ'}$  of ATP hydrolysis according to these data?

\*5. Consider the reaction catalyzed by hexokinase:

A mixture containing 40 mM ATP and 20 mM glucose was incubated with hexokinase at pH 7 and 25°C. Calculate the equilibrium concentrations of the reactants and products (see Table 16-3).

6. In aerobic metabolism, glucose is completely oxidized in the reaction

with the coupled generation of 32 ATP molecules from 32 ADP and 32  $\text{P}_i$ . Assuming the  $\Delta G$  for the hydrolysis of ATP to ADP and

$P_i$  under intracellular conditions is  $-50 \text{ kJ} \cdot \text{mol}^{-1}$  and that for the combustion of glucose is  $-2823.2 \text{ kJ} \cdot \text{mol}^{-1}$ , what is the efficiency of the glucose oxidation reaction in terms of the free energy sequestered in the form of ATP?

**7.** Typical intracellular concentrations of ATP, ADP, and  $P_i$  in muscles are 5.0, 0.5, and 1.0 mM, respectively. At 25°C and pH 7: (a) What is the free energy of hydrolysis of ATP at these concentrations? (b) Calculate the equilibrium concentration ratio of phosphocreatine to creatine in the creatine kinase reaction:

if ATP and ADP have the above concentrations. (c) What concentration ratio of ATP to ADP would be required under the foregoing conditions to yield an equilibrium concentration ratio of phosphocreatine to creatine of 1? Assuming the concentration of  $P_i$  remained 1.0 mM, what would the free energy of hydrolysis of ATP be under these latter conditions?

**\*8.** Assuming the intracellular concentrations of ATP, ADP, and  $P_i$  are those given in Problem 7: (a) Calculate the concentration of AMP at pH 7 and 25°C under the condition that the adenylate kinase reaction:

is at equilibrium. (b) Calculate the equilibrium concentration of AMP when the free energy of hydrolysis of ATP to ADP and  $P_i$  is  $-55 \text{ kJ} \cdot \text{mol}^{-1}$ . Assume  $[P_i]$  and  $([\text{ATP}] + [\text{ADP}])$  remain constant.

**9.** Using the data in Table 16-4, list the following substances in order of their decreasing oxidizing power: (a) fumarate<sup>-</sup>, (b) cystine, (c) O<sub>2</sub>, (d) NADP<sup>+</sup>, (e) cytochrome *c* (Fe<sup>3+</sup>), and (f) lipoic acid.

**10.** Calculate the equilibrium concentrations of reactants and products for the reaction:

when the initial concentrations of acetoacetate<sup>-</sup> and NADH are 0.01 and 0.005M, respectively, and β-hydroxybutyrate<sup>-</sup> and NAD<sup>+</sup> are initially absent. Assume the reaction takes place at 25°C and pH 7.

**11.** In anaerobic bacteria, the final metabolic electron acceptor is some molecule other than O<sub>2</sub>. A major requirement for any redox pair utilized as a metabolic free energy source is that it provides sufficient free energy to generate ATP from ADP and  $P_i$ . Indicate which of the following redox pairs are sufficiently exergonic to enable a properly equipped bacterium to utilize them as a major energy source. Assume that redox reactions forming ATP require two electrons and that  $\Delta\mathcal{G} = \Delta\mathcal{G}'$ .

- (a) Ethanol + NO<sub>3</sub><sup>-</sup>      (c) H<sub>2</sub> + S  
(b) Fumarate<sup>-</sup> + SO<sub>3</sub><sup>2-</sup>      (d) Acetaldehyde + acetaldehyde

**12.** Calculate  $\Delta G'^{\circ}$  for the following pairs of half-reactions at pH 7 and 25°C. Write a balanced equation for the overall reaction and indicate the direction in which it occurs spontaneously under standard conditions.

- (a) (H<sup>+</sup>/½H<sub>2</sub>) and (½O<sub>2</sub> + 2H<sup>+</sup>/H<sub>2</sub>O)  
(b) (Pyruvate<sup>-</sup> + 2H<sup>+</sup>/lactate<sup>-</sup>) and (NAD<sup>+</sup> + H<sup>+</sup>/NADH)

**\*13.** The chemiosmotic hypothesis (Section 22-3A) postulates that ATP is generated in the two-electron reaction:

which is driven by a metabolically generated pH gradient in the mitochondria. What is the magnitude of the pH gradient required for net synthesis of ATP at 25°C and pH 7, if the steady-state concentrations of ATP, ADP, and  $P_i$  are 0.01, 10, and 10 mM, respectively?

**14.** Gastric juice is 0.15M HCl. The blood plasma, which is the source of this H<sup>+</sup> and Cl<sup>-</sup>, is 0.10M in Cl<sup>-</sup> and has a pH of 7.4. Calculate the free energy necessary to produce the HCl in 0.1 L of gastric juice at 37°C.

- F. Regulation of Glycolysis in Muscle

### 5 Metabolism of Hexoses Other than Glucose

- A. Fructose
- B. Galactose
- C. Mannose

At this point we commence our discussions of specific metabolic pathways by considering **glycolysis** (Greek: *glykos*, sweet; *lysis*, loosening), the pathway by which **glucose** is converted via **fructose-1,6-bisphosphate** to **pyruvate** with the generation of 2 mol of ATP per mole of glucose. This sequence of 10 enzymatic reactions, which is probably the most completely understood biochemical pathway, plays a key role in energy metabolism by providing a significant portion of the energy utilized by most organisms and by preparing glucose, as well as other carbohydrates, for oxidative degradation.

In our study of glycolysis, and indeed of all of metabolism, we shall attempt to understand the pathway on four levels:

1. The chemical interconversion steps, that is, the sequence of reactions by which glucose is converted to the pathway’s end products.
2. The mechanism of the enzymatic conversion of each pathway intermediate to its successor.
3. The energetics of the conversions.
4. The mechanisms controlling the **flux** (rate of flow) of metabolites through the pathway.

The flux of metabolites through a pathway is remarkably sensitive to the needs of the organism for the products of the pathway. Through an exquisitely complex network of control mechanisms, flux through a pathway is only as great as required.

## 1 THE GLYCOLYTIC PATHWAY

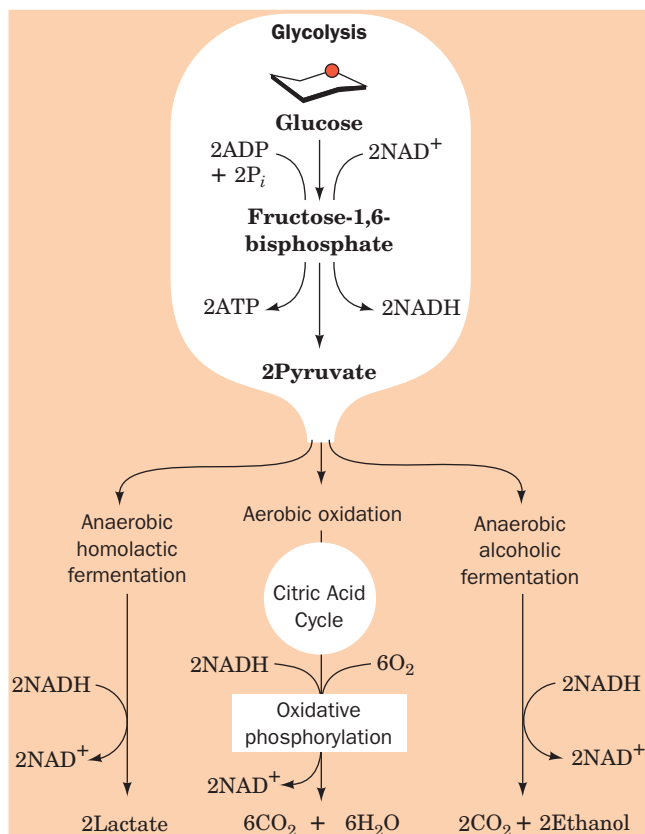

An overview of glucose metabolism is diagrammed in Fig. 17-1. *Under aerobic conditions, the pyruvate formed by glycolysis is further oxidized by the citric acid cycle (Chapter 21) and oxidative phosphorylation (Chapter 22) to CO<sub>2</sub> and water. Under anaerobic conditions, however, the pyruvate is instead converted to a reduced end product, which is **lactate** in muscle (**homolactic fermentation**; a fermentation is an anaerobic biological reaction process) and ethanol + CO<sub>2</sub> in yeast (**alcoholic fermentation**).*

### A. Historical Perspective

The fermentation of glucose to ethanol and CO<sub>2</sub> by yeast (Fig. 17-2) has been a useful process since before the dawn of recorded history. Winemaking and bread baking both exploit this process. Yet the scientific investigation of the mechanism of glycolysis began only in the latter half of the nineteenth century.

In the years 1854 to 1864, Louis Pasteur established that fermentation is caused by microorganisms. It was not until 1897, however, that Eduard Buchner demonstrated that cell-free yeast extracts can also carry out this process.

**Figure 17-1 Glycolysis.** Glycolysis converts glucose to pyruvate while generating two ATPs. Under anaerobic conditions, alcoholic fermentation of pyruvate occurs in yeast, whereas homolactic fermentation occurs in muscle. Under aerobic conditions, pyruvate is oxidized to  $\text{H}_2\text{O}$  and  $\text{CO}_2$  via the citric acid cycle (Chapter 21) and oxidative phosphorylation (Chapter 22).

This discovery refuted the then widely held belief that fermentation, and every other biological process, was mediated by some “vital force” inherent in living matter, and thereby brought glycolysis within the province of chemistry. This was a major step in the development of biochemistry as a science. Although, in principle, the use of cell-free extracts enabled a systematic “dissection” of the reactions involved in the pathway, the complete elucidation of the glycolytic pathway was still a long-range project because analytical techniques for the isolation and identification of intermediates and enzymes had to be developed concurrently.

In the years 1905 to 1910, Arthur Harden and William Young made two important discoveries:

1. Inorganic phosphate is required for fermentation and is incorporated into fructose-1,6-bisphosphate, an intermediate in the process.

2. A cell-free yeast extract can be separated, by dialysis, into two fractions that are both required for fermentation: A nondialyzable heat-labile fraction they named **zymase**; and a dialyzable, heat-stable fraction they called

**Figure 17-2 Electron micrograph of yeast cells.** [Biophoto Associates/Photo Researchers, Inc.]

**cozymase.** It was shown later by others that zymase is a mixture of enzymes and that cozymase is a mixture of co-factors: coenzymes such as  $\text{NAD}^+$ , ATP, and ADP, as well as metal ions.

In their efforts to identify pathway intermediates, the early investigators of glycolysis developed a general technique of metabolic investigation that is in use today: *Reagents are found that inhibit the production of pathway products, thereby causing the buildup of metabolites that can then be identified as pathway intermediates.* Over years of investigation that attempted to identify glycolytic intermediates, various reagents were found that inhibit the production of ethanol from glucose in yeast extracts. The use of different inhibitors results in the accumulation of different intermediates. For example, the addition of iodoacetate to fermenting yeast extracts causes the buildup of fructose-1,6-bisphosphate, whereas addition of fluoride ion induces the accumulation of **3-phosphoglycerate** and **2-phosphoglycerate**:

**3-Phosphoglycerate**

**2-Phosphoglycerate**

The mechanisms by which these inhibitors act are discussed in Sections 17-2Da and 17-2I, respectively.

One remarkable finding of these studies was that the same intermediates and enzyme activities could be isolated not only from yeast, but from a great variety of other organisms. With few exceptions (see Problem 11 in this chapter), *living things all metabolize glucose by identical pathways. In spite of their enormous diversity, they share a common biochemistry.*

By 1940, the efforts of many investigators had come to fruition with the elucidation of the complete pathway of glycolysis. The work of three of these individuals, Gustav Embden, Otto Meyerhof, and Jacob Parnas, has been commemorated in that glycolysis is alternatively known as the **Embden–Meyerhof–Parnas pathway**. Other major contributors to the elucidation of this pathway were Carl and Gerty Cori, Carl Neuberg, Robert Robison, and Otto Warburg.

## B. Pathway Overview

Before beginning our detailed discussion of the enzymes of glycolysis, let us first take a moment to survey the overall pathway as it fits in with animal metabolism as a whole. Glucose usually arises in the blood as a result of the breakdown of higher polysaccharides (Sections 11-2B, 11-2Db, and 18-1) or from its synthesis from noncarbohydrate sources (**gluconeogenesis**; Section 23-1). The fate of nonglucose hexoses is discussed in Section 17-5. Glucose enters most cells by specific carriers that transport it from the exterior of the cell into the cytosol (Section 20-2E). *The enzymes of glycolysis are located in the cytosol, where they are only loosely associated, if at all, with cell structures such as membranes.* However, there is considerable circumstantial evidence that successive enzymes in the glycolytic pathway loosely associate, presumably to facilitate the efficient transfer of intermediates between enzymes. Such associations of functionally related enzymes have been referred to as **metabolons**. Nevertheless, no actual complexes of glycolytic enzymes have yet been isolated.

*Glycolysis converts glucose to two C<sub>3</sub> units (pyruvate) of lower free energy in a process that harnesses the released free energy to synthesize ATP from ADP and P<sub>i</sub>.* This process requires a pathway of chemically coupled phosphoryl-transfer reactions (Sections 16-4 and 16-6). Thus the chemical strategy of glycolysis is

1. Add phosphoryl groups to the glucose.
2. Chemically convert phosphorylated intermediates into compounds with high phosphate group-transfer potentials.
3. Chemically couple the subsequent hydrolysis of reactive substances to ATP synthesis.

The 10 enzyme-catalyzed reactions of glycolysis are diagrammed in Fig. 17-3. Note that ATP is used early in the pathway to synthesize phosphoryl compounds (Reactions

1 and 3) but is later resynthesized (Reactions 7 and 10). Glycolysis may therefore be considered to occur in two stages:

**Stage I** (Reactions 1–5): A preparatory stage in which the hexose glucose is phosphorylated and cleaved to yield two molecules of the triose **glyceraldehyde-3-phosphate**. This process utilizes two ATPs in a kind of energy investment.

**Stage II** (Reactions 6–10): The two molecules of glyceraldehyde-3-phosphate are converted to pyruvate, with concomitant generation of four ATPs. Glycolysis therefore has a net profit of two ATPs per glucose: Stage I consumes two ATPs; Stage II produces four ATPs.

The overall reaction is

### a. The Oxidizing Power of NAD<sup>+</sup> Must Be Recycled

NAD<sup>+</sup> is the primary oxidizing agent of glycolysis. The NADH produced by this process (Fig. 17-3, Reaction 6) must be continually reoxidized to keep the pathway supplied with NAD<sup>+</sup>. There are three common ways that this occurs (Fig. 17-1, *bottom*):

1. Under anaerobic conditions in muscle, NAD<sup>+</sup> is regenerated when NADH reduces pyruvate to lactate (homolactic fermentation; Section 17-3A).
2. Under anaerobic conditions in yeast, pyruvate is decarboxylated to yield CO<sub>2</sub> and acetaldehyde and the latter is reduced by NADH to yield NAD<sup>+</sup> and ethanol (alcoholic fermentation; Section 17-3B).
3. Under aerobic conditions, the mitochondrial oxidation of each NADH to NAD<sup>+</sup> yields 2.5 ATPs (Section 22-2A).

Thus, in aerobic glycolysis, NADH may be thought of as a “high-energy” compound, whereas in anaerobic glycolysis its free energy of oxidation is dissipated as heat.

## 2 THE REACTIONS OF GLYCOLYSIS

 **See Guided Exploration 14: Glycolysis overview** In this section we examine the reactions of glycolysis more closely, describing the properties of the individual enzymes and their mechanisms. In Section 17-3 we consider the anaerobic fate of pyruvate. Finally, in Section 17-4 we consider the thermodynamics of the entire process and address the problem of how the flux of metabolites through the pathway is controlled. As we study the individual glycolytic enzymes we shall encounter many organic reaction mechanisms (Section 16-2). Indeed, the study of organic reaction mechanisms has been invaluable in understanding the mechanisms by which enzymes catalyze reactions.

**Figure 17-3 Degradation of glucose via the glycolytic pathway.** Glycolysis may be considered to occur in two stages. Stage I (Reactions 1–5): Glucose is phosphorylated and cleaved to form two molecules of the triose glyceraldehyde-3-phosphate. This requires the expenditure of two ATPs in an “energy investment”

(Reactions 1 and 3). Stage II (Reactions 6–10): The two molecules of glyceraldehyde-3-phosphate are converted to pyruvate with the concomitant generation of four ATPs (Reactions 7 and 10).  See the Animated Figures

Note that the X-ray structure of each of the 10 glycolytic enzymes has been reported. All of these enzymes are either homodimers or homotetramers with  $D_2$  symmetry (Section 8-5B), whose subunits consist mainly of  $\alpha/\beta$  domains (Section 8-3Bi).

### A. Hexokinase: First ATP Utilization

Reaction 1 of glycolysis is the transfer of a phosphoryl group from ATP to glucose to form **glucose-6-phosphate (G6P)** in a reaction catalyzed by **hexokinase (HK)**:

A **kinase** is an enzyme that transfers phosphoryl groups between ATP and a metabolite (Section 16-4C). The metabolite that serves as the phosphoryl group acceptor for a specific kinase is identified in the prefix of the kinase name. HK is a relatively nonspecific enzyme contained in all cells that catalyzes the phosphorylation of hexoses such as D-glucose, D-mannose, and D-fructose. Liver cells also contain **glucokinase**, which catalyzes the same reaction but which is primarily involved in the maintenance of blood glucose levels (Section 18-3Fa). The second substrate for HK, as with other kinases, is an  $Mg^{2+}$ -ATP complex. In fact, uncomplexed ATP is a potent competitive inhibitor of HK. In what follows, we shall rarely refer to this  $Mg^{2+}$  requirement, but keep in mind that it is essential for kinase enzymatic activity (other divalent metal ions such as  $Mn^{2+}$  often satisfy the metal ion requirements of kinases *in vitro*, but  $Mg^{2+}$  is the normal physiological species).

#### a. Kinetics and Mechanism of the Hexokinase Reaction

Hexokinase has a Random Bi Bi mechanism in which the enzyme forms a ternary complex with glucose and  $Mg^{2+}$ -ATP before the reaction occurs. The  $Mg^{2+}$ , by complexing with the phosphate oxygen atoms, is thought to shield their negative charges, making the phosphorus atom

**Figure 17-4** The nucleophilic attack of the C6—OH group of glucose on the  $\gamma$  phosphate of an  $Mg^{2+}$ -ATP complex. The position of the  $Mg^{2+}$  ion is shown as an example; its actual position(s) has not been conclusively established. In any case, the  $Mg^{2+}$  functions to shield the negatively charged groups of ATP and thereby facilitates the nucleophilic attack.

more accessible for the nucleophilic attack of the C6—OH group of glucose (Fig. 17-4).

An important mechanistic question is why does HK catalyze the transfer of a phosphoryl group from ATP to glucose to yield G6P, but not to water to yield ADP +  $P_i$  (ATP hydrolysis)? Water is certainly small enough to fit into the phosphoryl acceptor group's enzymatic binding site. Furthermore, phosphoryl transfer from ATP to water is more exergonic than it is to glucose (Table 16-3), particularly since  $[H_2O] = 55.5 M$  and  $[glucose] = 5$  to  $10$  mM *in vivo*. Yet HK catalyzes phosphoryl transfer to glucose 40,000 times faster than it does to water.

The answer was provided by Thomas Steitz via X-ray structural studies of yeast HK. Comparison of the X-ray structures of HK and the glucose-HK complex indicates that *glucose induces a large conformational change in HK* (Fig. 17-5). The two lobes that form its active site cleft swing together by up to  $11.5$  Å so as to engulf the glucose in a manner that suggests the closing of jaws. *This movement places the ATP in close proximity to the —C6H<sub>2</sub>OH group of glucose and excludes water from the active site (catalysis by proximity effects; Section 15-1E)*. If the catalytic and reacting groups were in the proper position for reaction while the enzyme was in the open position (Fig. 17-5a), ATP hydrolysis would almost certainly be the dominant reaction. This conclusion is confirmed by the observation that **xylose**, which differs from glucose only by the lack of the —C6H<sub>2</sub>OH group,

greatly enhances the rate of ATP hydrolysis by HK (presumably xylose induces the activating conformational change while water occupies the binding site of the missing

**Figure 17-5** Conformational changes in yeast hexokinase on binding glucose. The enzyme is represented by its transparent molecular surface with its embedded ribbon diagram colored with its large domain purple and its small domain yellow. (a) Free hexokinase. (b) Hexokinase in complex with glucose drawn in space-filling form with C green and O red. Note the prominent bilobal appearance of the free enzyme. In the enzyme–substrate complex these lobes have swung together by a 17° rotation to engulf the substrate. [Based on an X-ray structure by Igor Polikarpov, Instituto de Física em São Carlos, Brazil. PDBids 1IG8 and 3B8A.]  See Interactive Exercise 8

hydroxymethyl group). Clearly, *this substrate-induced conformational change in HK is responsible for the enzyme's specificity*. In addition, the active site polarity is reduced by exclusion of water, thereby expediting the nucleophilic reaction process. Other kinases have the same deeply clefted structure as HK (e.g., Section 17-2G) and undergo conformational changes on binding their substrates. This suggests

that all kinases have similar mechanisms for maintaining specificity.

### B. Phosphoglucose Isomerase

Reaction 2 of glycolysis is the conversion of G6P to **fructose-6-phosphate (F6P)** by **phosphoglucose isomerase (PGI)**; also called **glucose-6-phosphate isomerase**. This is the isomerization of an aldose to a ketose:

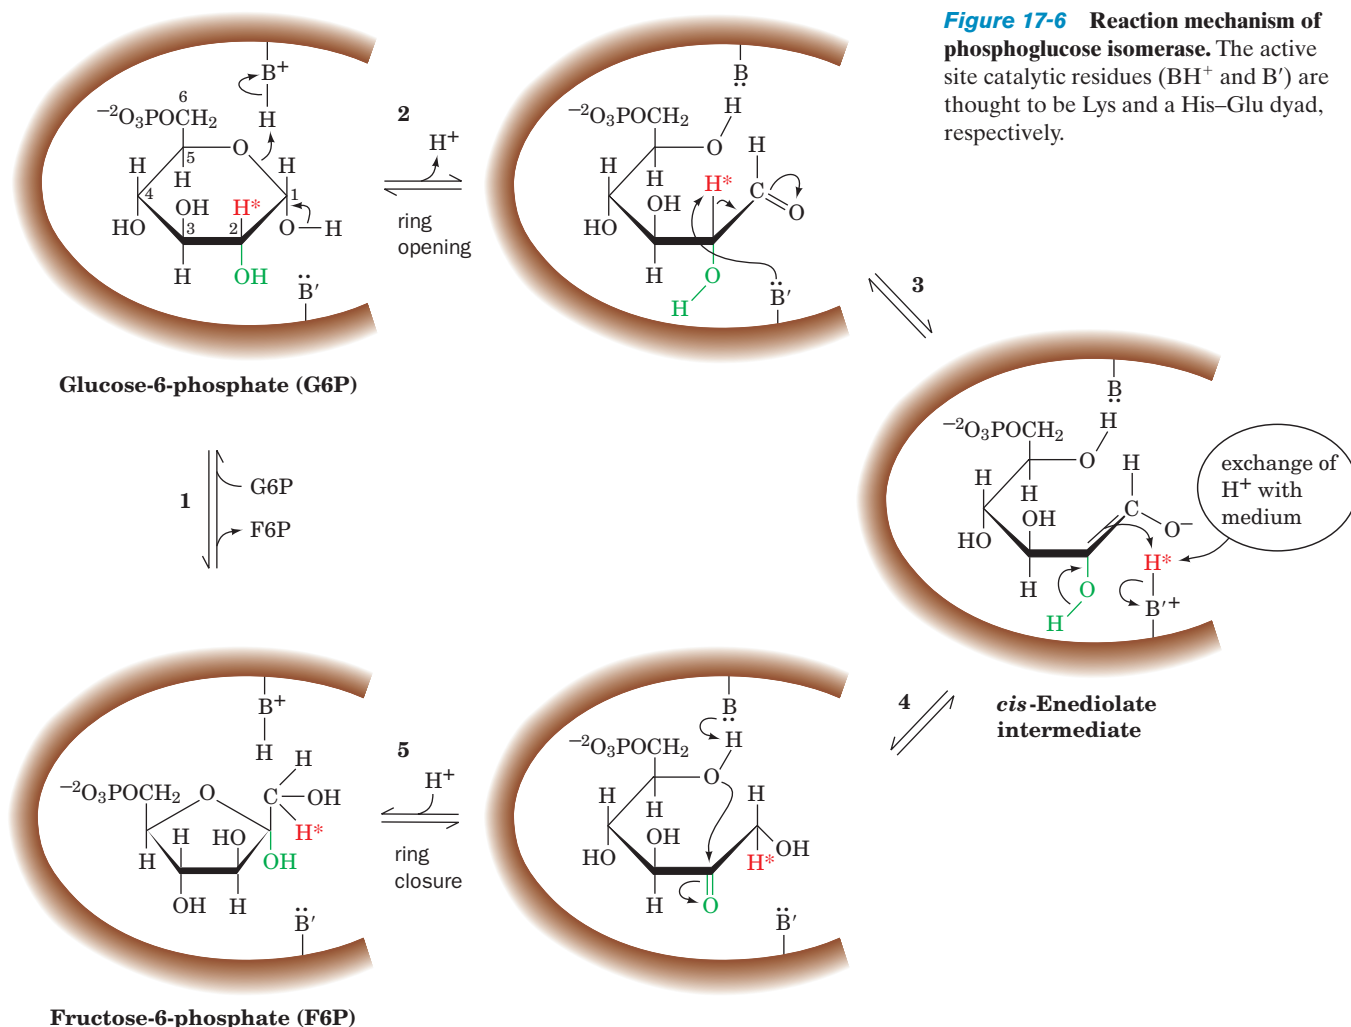

Since G6P and F6P both exist predominantly in their cyclic forms (Fig. 11-4 shows these structures for the unphosphorylated sugars), the reaction requires ring opening, followed by isomerization, and subsequent ring closure. The determination of the enzyme's pH dependence led to a hypothesis for amino acid side chain participation in the catalytic mechanism. The catalytic rate exhibits a bell-shaped pH dependence curve with characteristic  $pK$ 's of 6.7 and 9.3, which suggests the catalytic participation of both a His and a Lys (Section 14-4). Indeed, comparison of the amino acid sequences of PGI from several different organisms reveals that both a His and Lys are conserved. However, a Glu residue is also conserved, and as we have seen for lysozyme (Section 15-2Ba), Glu can have an unusually high  $pK$  under certain conditions. In fact, the X-ray structure of PGI reveals that Glu 216 and His 388 form a hydrogen bonded catalytic dyad (resembling the interaction of the Asp and His residues in the catalytic triad of serine proteases; Fig. 15-20), which facilitates the action of His 388 as an acid–base catalyst.

A proposed reaction mechanism for the PGI reaction involves general acid–base catalysis by the enzyme (Fig. 17-6):

**Step 1** Substrate binding.

**Step 2** An acid, presumably the Lys  $\epsilon$ -amino group, catalyzes ring opening.

**Step 3** A base, presumably the imidazole portion of the His–Glu dyad, abstracts the acidic proton from C2 to form

a *cis*-enediolate intermediate (this proton is acidic because it is  $\alpha$  to a carbonyl group).

**Step 4** The proton is replaced on C1 in an overall proton transfer. Protons abstracted by bases are labile and exchange rapidly with solvent protons. Nevertheless, Irwin Rose confirmed this step by demonstrating that [2-<sup>3</sup>H]G6P is occasionally converted to [1-<sup>3</sup>H]F6P by intramolecular proton transfer before the <sup>3</sup>H has had a chance to exchange with the medium.

**Step 5** Ring closure to form the product, which is subsequently released to yield free enzyme, thereby completing the catalytic cycle.

*PGI*, like most enzymes, catalyzes reactions with nearly absolute stereospecificity. To appreciate this, let us compare the proposed enzymatic reaction mechanism with that in the nonenzymatic base-catalyzed isomerization of glucose, fructose, and mannose (Fig. 17-7). Glucose and mannose are epimers of one another because they differ only with

**Figure 17-7** Base-catalyzed isomerization of glucose, mannose, and fructose. In the absence of enzyme, this reaction is nonstereospecific.

respect to their configuration at one chiral center, C2 (Section 11-1A). In the enediolate intermediate, as well as in the linear form of fructose, C2 lacks chirality. Therefore, in nonenzymatic systems, base-catalyzed isomerization of glucose also results in racemization of C2 with the production of mannose. In the presence of PGI, however,  $^1\text{H}$  NMR measurements indicate that the rate of the isomerization reaction is several orders of magnitude greater than that of the epimerization reaction. Evidently, PGI shields the face of the enediolate to which  $\text{H}^+$  must be added to form mannose-6-phosphate.

### C. Phosphofructokinase: Second ATP Utilization

In Reaction 3 of glycolysis, **phosphofructokinase (PFK)** phosphorylates F6P to yield fructose-1,6-bisphosphate [FBP or **F1,6P**; previously known as **fructose-1,6-diphosphate (FDP)**]:

This reaction is similar to the hexokinase reaction (Reaction 1 in Fig. 17-3; Section 17-2A). PFK catalyzes the nucleophilic attack by the C1—OH group of F6P on the electrophilic  $\gamma$ -phosphorus atom of the  $\text{Mg}^{2+}$ -ATP complex.

**Figure 17-8** Mechanism for base-catalyzed aldol cleavage. Aldol condensation occurs by the reverse mechanism.

*PFK plays a central role in the control of glycolysis because it catalyzes one of the pathway's rate-determining reactions.* In many organisms the activity of PFK is enhanced allosterically by several substances, including AMP, and inhibited allosterically by several other substances, including ATP and citrate. The control of PFK is exquisitely complex; the mechanism by which it regulates the glycolytic pathway is examined in Section 17-4F.

### D. Aldolase

**Aldolase** catalyzes Reaction 4 of glycolysis, the cleavage of FBP to form the two trioses **glyceraldehyde-3-phosphate (GAP)** and **dihydroxyacetone phosphate (DHAP)**:

This reaction is an **aldol cleavage (retro aldol condensation)** whose nonenzymatic base-catalyzed mechanism is shown in Fig. 17-8. Note that aldol cleavage between C3 and C4 of FBP requires a carbonyl at C2 and a hydroxyl at C4. Hence, the “logic” of Reaction 2 in the glycolytic pathway, the isomerization of G6P to F6P, is clear. Aldol cleavage of G6P would have resulted in products of unequal carbon chain length, while aldol cleavage of FBP results in two

interconvertible C3 compounds that can therefore enter a common degradative pathway. The enolate intermediate in the aldol cleavage reaction is stabilized by resonance, as shown, as a result of the electron-withdrawing character of the carbonyl oxygen atom.

Note that at this point in the pathway the atom numbering system changes. Atoms 1, 2, and 3 of glucose become atoms 3, 2, and 1 of DHAP, thus reversing order. Atoms 4, 5, and 6 become atoms 1, 2, and 3 of GAP (Fig. 17-3).

#### a. There Are Two Mechanistic Classes of Aldolases

Aldol cleavage is catalyzed by stabilizing its enolate intermediate through increased electron delocalization. There are two types of aldolases that are classified according to the chemistry they employ to stabilize the enolate. In Class I aldolases, which occur in animals and plants, the reaction occurs as follows (Fig. 17-9):

**Step 1** Substrate binding.

**Step 2** Reaction of the FBP carbonyl group with the  $\epsilon$ -amino group of the active site Lys 229 to form an iminium cation, that is, a protonated Schiff base.

**Step 3** C3—O4 bond cleavage resulting in enamine formation and the release of GAP. The iminium ion, as we saw in Section 16-2E, is a better electron-withdrawing group than is the oxygen atom of the precursor carbonyl group. Thus, catalysis occurs because the enamine intermediate (Fig. 17-9, Step 3) is more stable than the corresponding enolate intermediate of the base-catalyzed aldol cleavage reaction (Fig. 17-8, Step 2).

**Step 4** Protonation of the enamine to an iminium cation.

**Step 5** Hydrolysis of this iminium cation to release DHAP, with regeneration of the free enzyme.

Proof for the formation of the Schiff base in Step 2 was provided by “trapping”  $^{14}\text{C}$ -labeled DHAP on the enzyme by reacting it with  $\text{NaBH}_4$ , which reduces imines to amines:

The radioactive product was hydrolyzed and identified as ***N*<sup>6</sup>- $\beta$ -glyceryl lysine**.

Cys and His residues were initially thought to act as the acid and base catalysts that facilitate the proton transfers in the aldolase reaction because the appropriate group-specific reagents inactivate the enzyme by reacting with these residues. For example, the reaction of a specific Cys residue of aldolase with iodoacetic acid inactivates the enzyme and results in the buildup of the FBP observed in the early glycolysis inhibition studies (Section 17-1A). However, site-directed mutagenesis to Ala of the Cys residue thought to be involved in the catalytic activity results in no loss of enzymatic function. Modification of this Cys residue apparently prevents the conformational changes required for productive substrate binding.

An early X-ray structure of aldolase suggested that a Tyr side chain was positioned to act as the active site acid–base catalyst and that the His was instead necessary for the maintenance of the Tyr’s catalytically active orientation. A re-examination of the X-ray data caused yet another modification of the mechanism. The Tyr originally seen at the active site has changed position in this new analysis, so that it is out of reach of the active site. Asp 33 and Lys 229 now appear to be acting as acid–base catalysts. These residues are evolutionarily conserved and their mutagenesis eliminates enzyme activity. This is an excellent example of the caution that must be exercised in the interpretation of chemical modification and structural data, and the power of site-directed mutagenesis in the study of enzyme mechanisms (although see Section 15-3Ba).

Class II aldolases, which occur in fungi, algae, and some bacteria, do not form a Schiff base with the substrate. Rather, a divalent cation, usually  $\text{Zn}^{2+}$  or  $\text{Fe}^{2+}$ , polarizes the carbonyl oxygen of the substrate to stabilize the enolate intermediate of the reaction (Fig. 16-12d):

Are the two classes of aldolases related? Although both classes exhibit the Uni Bi kinetics implicit in their mechanisms, they exhibit only  $\sim 15\%$  sequence identity, which places them in the lower end of the twilight zone for establishing homology (Section 7-4Ba). Nevertheless, their X-ray structures reveal that they have the same fold, the  $\alpha/\beta$  barrel. The evolution of this particularly common fold is discussed in Section 8-3Bh.

#### b. Why Two Classes of Aldolase?

Since glycolysis presumably arose very early in evolutionary history, the existence of two classes of aldolase is unexpected. It had originally been postulated that, since Class I aldolases occur in higher organisms, Class II aldolases must be the more primitive enzyme form, that is, less metabolically capable than are the Class I enzymes. However, the discovery that some organisms simultaneously express both classes of aldolase suggests that both enzyme classes are evolutionarily ancient and equally

**Figure 17-9** Enzymatic mechanism of Class I aldolase. The reaction involves (1) substrate binding; (2) Schiff base formation between the enzyme's active site Lys residue and FBP; (3) aldol cleavage to form an enamine intermediate of the enzyme and

DHAP with release of GAP (shown with its *re* face up); (4) tautomerization and protonation to the iminium form of the Schiff base; and (5) hydrolysis of the Schiff base with release of DHAP.  See the Animated Figures.

adept at carrying out their metabolic functions. Thus, the expression of both classes of aldolase in some organisms probably represents an ancient metabolic redundancy that evolution has eliminated in most contemporary organisms. Whatever the reason for the occurrence of two classes of aldolase, the fact that Class II aldolases do not occur in mammals makes them an attractive target in the development of antibacterial drugs.

### c. Aldolase Is Stereospecific

The aldolase reaction provides another example of the extraordinary stereospecificity of enzymes. In the nonenzymatic aldol condensation to form hexose-1,6-bisphosphate from DHAP and GAP, there are four possible products depending on whether the *pro-R* or *pro-S* hydrogen at C3 of DHAP is removed and whether the resulting carbanion attacks GAP on its *re* or its *si* face:

In the enzymatic aldol condensation (Fig. 17-9 in reverse), carbanion formation from the enzyme–DHAP iminium ion (Fig. 17-9, Step 4 in reverse) occurs with removal of only the *pro-S* hydrogen. Attack of this carbanion occurs only on the *si* face of the enzyme-bound GAP carbonyl group, so that only FBP is formed (Fig. 17-9, Step 3 in reverse).

### E. Triose Phosphate Isomerase

Only one of the products of the aldol cleavage reaction, GAP, continues along the glycolytic pathway (Fig. 17-3). However, DHAP and GAP are ketose–aldose isomers just as are F6P and G6P. Interconversion of GAP and DHAP therefore probably occurs via an enediol or enediolate intermediate in analogy with the phosphoglucose isomerase reaction (Fig. 17-6). **Triose phosphate isomerase (TIM** or

**TPI**; Figs. 8-19b and 8-52) catalyzes this process in Reaction 5 of glycolysis, the final reaction of Stage I:

Support for this reaction scheme comes from the use of the transition state analogs **phosphoglycohydroxamate** and **2-phosphoglycolate**, stable compounds whose geometric structures resemble that of the proposed enediol or enediolate intermediate:

Since enzymes catalyze reactions by binding the transition state complex more tightly than the substrate (Section 15-1F), phosphoglycohydroxamate and 2-phosphoglycolate should bind more tightly to TIM than does substrate. In fact, phosphoglycohydroxamate and 2-phosphoglycolate bind 155- and 100-fold more tightly to TIM than do either GAP or DHAP.

#### a. Glu 165 Functions as a General Base

The pH dependence of the TIM reaction is a bell-shaped curve with  $pK$ 's of 6.5 and 9.5. The similarity of these  $pK$ 's to the corresponding quantities of the phosphoglucose isomerase reaction suggests the participation of both an acid and a base in the TIM reaction as well. However, pH studies alone, as we have seen, are difficult to

interpret in terms of specific amino acid residues since the active site environment may alter the  $pK$  of an acidic or basic group.

Affinity labeling reagents have been employed in an effort to identify the base at the active site of TIM. Both **bromohydroxyacetone phosphate** and **glycidol phosphate**

**Bromohydroxyacetone phosphate**

**Glycidol phosphate**

inactivate TIM by forming esters of Glu 165, whose carboxylate group, X-ray studies indicate, is ideally situated to abstract the C2 proton from the substrate (general base catalysis). In fact, the mutagenic replacement of Glu 165 by Asp, which X-ray studies show withdraws the carboxylate group only  $\sim 1$  Å farther away from the substrate than its position in the wild-type enzyme, reduces TIM's catalytic power  $\sim 1000$ -fold. Note that Glu 165's  $pK$  is drastically altered from the 4.1 value of the free amino acid to the observed 6.5 value. This provides yet another striking example of the effect of environment on the properties of amino acid side chains.

### b. The TIM Reaction Probably Occurs via Concerted General Acid–Base Catalysis Involving Low-Barrier Hydrogen Bonds

The X-ray structure of yeast TIM in complex with phosphoglycohydroxamate indicates that His 95 is hydrogen bonded to and hence is properly positioned to protonate the carbonyl oxygen atom of GAP (general acid catalysis):

However, NMR studies indicate that His 95 is in its neutral imidazole form rather than its protonated imidazolium form. How can an imidazole N3—H group, which has a highly basic  $pK$  of  $\sim 14$ , protonate a carbonyl oxygen atom

that, when protonated, has a very acidic  $pK$  of  $<0$ ? Likewise, how can the Glu 165 carboxylate group ( $pK$  6.5) abstract the C2 proton from GAP ( $pK \sim 17$ )? A plausible answer is that these proton shifts are facilitated by the formation of low-barrier hydrogen bonds (LBHBs). These unusually strong associations ( $-40$  to  $-80$   $\text{kJ} \cdot \text{mol}^{-1}$  vs  $-12$  to  $-30$   $\text{kJ} \cdot \text{mol}^{-1}$  for normal hydrogen bonds), as we have seen in the case of the serine protease catalytic triad (Section 15-3Dd), form when the  $pK$ 's of the hydrogen bonding donor and acceptor groups are nearly equal. They can be important contributors to rate enhancement if they form only in the transition state of an enzymatically catalyzed reaction.

In converting GAP to the enediol (or enediolate) intermediate (Fig. 17-10, *left*), the  $pK$  of the protonated form of its carbonyl oxygen, which becomes a hydroxyl group, increases to  $\sim 14$ , which closely matches that of neutral His 95. The resulting LBHB between this hydroxyl group and His 95 permits the neutral imidazole side chain to protonate the oxygen atom. Likewise, as the carbonyl oxygen is protonated, the  $pK$  of the C2—H proton decreases to  $\sim 7$ , close to the  $pK$  of the Glu 165 carboxylate. It therefore appears that the reaction occurs via simultaneous proton abstraction by Glu 165 and protonation by His 95 (concerted general acid–base catalysis). The LBHBs postulated to form in the transition state, but not in the Michaelis complex, between Glu 165 and C2—H and between His 95 and the carbonyl oxygen atom are thought to provide some of the transition state stabilization necessary to catalyze the reaction. The positively charged side chain of Lys 12, which is probably responsible for the 9.5  $pK$  observed in TIM's pH rate profile, is thought to electrostatically stabilize the negatively charged transition state. The conversion of the enediol(ate) intermediate to DHAP is likewise facilitated by the formation of transition state LBHBs (Fig. 17-10, *right*). In fact, in the high resolution ( $1.2$  Å) X-ray structure of TIM in complex with DHAP, determined by Ann McDermott and Liang Tong, the hydrogen bond between His 95 and O2 of DHAP has an unusually short distance of  $2.6$  Å. In addition, a carboxylate oxygen atom of Glu 165 forms extraordinarily close contacts of  $\sim 3.0$  Å with both C1 and C2 of DHAP.

### c. A Flexible Loop Both Preferentially Binds and Protects the Enediol Intermediate

The comparison of the X-ray structure of the TIM · phosphoglycohydroxamate complex with that of TIM alone reveals that a 10-residue loop, which is closed over the active site in the enzyme–substrate complex, is flipped up in the unoccupied active site like a hinged lid, a movement that involves main chain shifts of  $>7$  Å (Fig. 17-11). A four-residue segment of this loop makes a hydrogen bond with the phosphate group of the substrate. Mutagenic excision of these four residues neither significantly distorts the protein nor greatly impairs substrate binding. The catalytic power of the mutant enzyme is, nevertheless, reduced  $10^5$ -fold and it only weakly binds phosphoglycohydroxamate. Evidently, the closed loop preferentially stabilizes the enzymatic reaction's enediol-like transition state.

**Figure 17-10** Proposed enzymatic mechanism of the TIM reaction. The reaction proceeds via the concerted abstraction of the C2—H proton of GAP by the carboxylate group of Glu 165 and the protonation of the GAP carbonyl oxygen atom by the imidazole group of His 95. The  $pK$ 's of the corresponding donor and acceptor groups participating in each proton transfer process become nearly equal in the transition state and hence are

proposed to form low-barrier hydrogen bonds (red dashed lines), which act to stabilize the transition state. The resulting enediol (or possibly the electrostatically stabilized enediolate) intermediate then reacts in a similar fashion with the carboxyl group of Glu 165 protonating C1, while the deprotonated N3 atom of His 95 abstracts the proton on the 2-hydroxyl group to yield DHAP.

**Figure 17-11** Ribbon diagram of yeast TIM in complex with its transition state analog 2-phosphoglycolate. A single 248-residue subunit of this homodimeric enzyme is viewed roughly along the axis of its  $\alpha/\beta$  barrel. The enzyme's flexible loop, residues 168 through 177, is cyan and the side chains of Lys 12, His 95, and Glu 165 are purple, magenta, and red, respectively. The 2-phosphoglycolate is shown in space-filling form colored according to atom type (C green, O red, P yellow). [Based on an X-ray structure by Gregory Petsko, Brandeis University. PDBID 2YPI.]  See Interactive Exercise 2 and Kinemage Exercises 12-1 and 12-2

**Figure 17-12** The spontaneous decomposition of the enediol intermediate in the TIM reaction to form methylglyoxal through the elimination of a phosphate group. (a)

This reaction can occur only when the C—O bond to the phosphate group lies in a plane that is nearly perpendicular to that of the enediol so as to permit the formation of a double bond in the intermediate enol product. (b) When the C—O bond to the phosphate group lies in a plane that is nearly parallel to that of the enediol, the *p* orbitals on the resulting intermediate product would be perpendicular to each other and hence lack the overlap necessary to form a  $\pi$  bond, that is, a double bond. The resulting unsatisfied bonding capacity greatly increases the energy of the reaction intermediate and hence makes the reaction highly unfavorable.

The closed loop conformation in the TIM reaction provides a striking example of the stereoelectronic control that enzymes can exert on a reaction (Section 15-1Eb). In solution, the enediol intermediate readily breaks down with the elimination of the phosphate at C3 to form the toxic compound **methylglyoxal** (Fig. 17-12a). On the enzyme's surface, however, this reaction is prevented because the phosphate group is held by the flexible loop in the plane of the enediol, a position that disfavors phosphate elimination. In order for this elimination to occur, the C—O bond to the phosphate group must lie, as shown in Fig. 17-12a, in the plane perpendicular to that of the enediol. This is because, if the phosphate group were to be eliminated while this C—O bond was in the plane of the enediol as diagrammed in Fig. 17-12b, the  $\text{CH}_2$  group of the resulting enol product would be twisted  $90^\circ$  out of the plane of the rest of the molecule. Such a conformation is energetically prohibitive because it prevents the formation of the enol's double bond by eliminating the overlap between its component *p* orbitals. In the mutant enzyme lacking the flexible loop, the enediol is able to escape:  $\sim 85\%$  of the enediol intermediate is released into solution, where it rapidly decomposes to methylglyoxal and  $P_i$ . Thus, flexible loop closure also ensures that substrate is efficiently transformed to product.

On the basis of the foregoing X-ray structures, it had been widely assumed that the binding of substrate to TIM is **ligand-gated**, that is, it induces loop closure. Yet, if this were the case, the reversibility of the TIM reaction and the chemical resemblance of its reactant and product (GAP and DHAP) make it difficult to rationalize how product could be released. However, NMR measurements by John Williams and McDermott reveal that, in fact, loop motion still occurs when TIM is binding either glycerol-3-phosphate (a substrate analog) or 2-phosphoglycolate (a transition state analog) and is sufficiently fast (on a time scale of 100  $\mu\text{s}$ ) to account for the catalytic reaction rate (a turnover

time of 230  $\mu\text{s}$ ). This is a clear example of how complementary information supplied by X-ray and NMR methods has yielded important insights into an enzymatic mechanism that neither technique alone could have provided.

#### d. TIM Is a Perfect Enzyme

TIM, as Jeremy Knowles demonstrated, has achieved catalytic perfection in that the rate of bimolecular reaction between enzyme and substrate is diffusion controlled; that is, product formation occurs as rapidly as enzyme and substrate can collide in solution, so that any increase in TIM's catalytic efficiency would not increase the reaction rate (Section 14-2Bb). Because of the high interconversion efficiency of GAP and DHAP, these two metabolites are maintained in equilibrium:  $K = [\text{GAP}]/[\text{DHAP}] = 4.73 \times 10^{-2}$ ; that is,  $[\text{DHAP}] \gg [\text{GAP}]$  at equilibrium. However, as GAP is utilized in the succeeding reaction of the glycolytic pathway, more DHAP is converted to GAP, so that these compounds maintain their equilibrium ratio. One common pathway therefore accounts for the metabolism of both products of the aldolase reaction.

Let us now take stock of where we are in our travels down the glycolytic pathway. At this stage, the glucose, which has been transformed into two GAPs, has completed the preparatory stage of glycolysis. This process has required the expenditure of two ATPs. However, this investment has resulted in the conversion of one glucose to two  $\text{C}_3$  units, each of which has a phosphoryl group that, with a little chemical artistry, can be converted to a "high-energy" compound (Section 16-4Ba) whose free energy of hydrolysis can be coupled to ATP synthesis. *This energy investment is doubly repaid in the final stage of glycolysis in which the two phosphorylated  $\text{C}_3$  units are transformed to two pyruvates with the coupled synthesis of four ATPs per glucose.*

### F. Glyceraldehyde-3-Phosphate Dehydrogenase: First "High-Energy" Intermediate Formation

Reaction 6 of glycolysis involves the oxidation and phosphorylation of GAP by  $\text{NAD}^+$  and  $\text{P}_i$  as catalyzed by **glyceraldehyde-3-phosphate dehydrogenase (GAPDH)**; Figs. 8-45 and 8-53b):

This is the first instance of the chemical artistry alluded to above. *In this reaction, aldehyde oxidation, an exergonic reaction, drives the synthesis of the acyl phosphate **1,3-bisphosphoglycerate (1,3-BPG)**; previously called **1,3-diphosphoglycerate**.* Recall that acyl phosphates are compounds with high phosphate group-transfer potential (Section 16-4Ba).

#### a. Mechanistic Studies

Several key enzymological experiments have contributed to the elucidation of the GAPDH reaction mechanism (Fig. 17-13):

**1.** GAPDH is inactivated by alkylation with stoichiometric amounts of iodoacetate. The presence of **carboxymethylcysteine** in the hydrolysate of the resulting alkylated enzyme (Fig. 17-13a) suggests that GAPDH has an active site Cys sulfhydryl group.

**2.** GAPDH quantitatively transfers  $^3\text{H}$  from C1 of GAP to  $\text{NAD}^+$  (Fig. 17-13b), thereby establishing that this reaction occurs via direct hydride transfer.

**3.** GAPDH catalyzes exchange of  $^{32}\text{P}$  between  $^{32}\text{P}\text{P}_i$  and the product analog **acetyl phosphate** (Fig. 17-13c). Such isotope exchange reactions are indicative of an acyl-enzyme intermediate (Section 14-5D).

**Figure 17-13** Some reactions employed in elucidating the enzymatic mechanism of GAPDH. (a) The reaction of iodoacetate with an active site Cys residue. (b) Quantitative

tritium transfer from substrate to  $\text{NAD}^+$ . (c) The enzyme-catalyzed exchange of  $^{32}\text{P}$  from phosphate to acetyl phosphate.

**Figure 17-14** Enzymatic mechanism of glyceraldehyde-3-phosphate dehydrogenase. (1) GAP binds to the enzyme; (2) the active site sulfhydryl group forms a thiohemiacetal with the substrate; (3)  $\text{NAD}^+$  oxidizes the thiohemiacetal to a thioester; (4) the newly formed NADH is replaced on the enzyme by  $\text{NAD}^+$ ; and (5)  $\text{P}_i$  attacks the thioester, forming the acyl phosphate product, 1,3-BPG, and regenerating the active enzyme.

See the Animated Figures

David Trentham has proposed a mechanism for GAPDH based on this information and the results of kinetic studies (Fig. 17-14):

**Step 1** GAP binds to the enzyme.

**Step 2** The essential sulfhydryl group, acting as a nucleophile, attacks the aldehyde to form a **thiohemiacetal**.

**Step 3** The thiohemiacetal undergoes oxidation to an **acyl thioester** by direct transfer of a hydride to  $\text{NAD}^+$ . This intermediate, which has been isolated, has a high group-transfer potential. *The energy of aldehyde oxidation has not been dissipated but has been conserved through the synthesis of the thioester and the reduction of  $\text{NAD}^+$  to NADH.*

**Step 4** Another molecule of  $\text{NAD}^+$  replaces NADH.

**Step 5** The thioester intermediate undergoes nucleophilic attack by  $\text{P}_i$  to regenerate free enzyme and form 1,3-BPG. This “high-energy” mixed anhydride generates ATP from ADP in the next reaction of glycolysis.

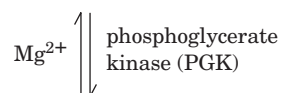

### G. Phosphoglycerate Kinase: First ATP Generation

Reaction 7 of the glycolytic pathway results in the first formation of ATP together with **3-phosphoglycerate (3PG)** in

a reaction catalyzed by **phosphoglycerate kinase (PGK)**:

#### 1,3-Bisphosphoglycerate (1,3-BPG)

#### 3-Phosphoglycerate (3PG)

(Note: The name “kinase” is given to any enzyme that transfers a phosphoryl group between ATP and a metabolite. Nothing is implied as to the exergonic direction of transfer.)

(a)

**Figure 17-15 X-ray structures of phosphoglycerate kinase (PGK).** (a) The yeast enzyme in complex with 3PG and  $\text{Mg}^{2+}$ -ATP. (b) The *T. maritima* enzyme in complex with 3PG and  $\text{Mg}^{2+}$ -AMPPNP. In both structures, the enzyme is represented by its transparent molecular surface with its embedded ribbon diagram colored with its N-terminal domain yellow and its C-terminal domain purple. The  $\text{Mg}^{2+}$ -ATP,  $\text{Mg}^{2+}$ -AMPPNP, and 3PG are drawn in space-filling form

(b)

colored according to atom type (ATP and AMPPNP C green, 3PG C cyan, N blue, O red, P orange, and  $\text{Mg}^{2+}$  pale green). Note the similar overall appearance of PGK and hexokinase (Fig. 17-5), although these proteins unrelated. [Based on X-ray structures by Herman Watson, University of Bristol, U.K.; and Günter Auerbach and Robert Huber, Max-Planck-Institut für Biochemie, Martinsreid, Germany. PDBids 3PGK and 1VPE.]

The X-ray structure of yeast PGK in complex with  $\text{Mg}^{2+}$ -ATP and 3PG, its enzyme-product complex, was determined by Herman Watson (Fig. 17-15a). Note its conspicuously bilobal appearance and the close approach between the ATP's  $\gamma$ -phosphate group and one of the 3PG's

**Figure 17-16 Mechanism of the PGK reaction.**

carboxylate oxygen atoms. The 3PG and the  $\text{Mg}$ -ATP are respectively bound to PGK's N- and C-terminal domains.

The X-ray structure of PGK from the thermophile *Thermotoga maritima* in complex with 3PG and the nonhydrolyzable ATP analog **AMPPNP** (ATP with the O atom bridging its  $\beta$  and  $\gamma$  phosphate groups replaced by an NH group) reveals that its two domains have swung together relative to those in the 50% identical yeast PGK (Fig. 17-15b). This forms the catalytic site and permits the substrates to react in a water-free environment, much as occurs with hexokinase (Section 17-2Aa).

Figure 17-16 indicates a reaction mechanism for PGK that is consistent with its observed sequential kinetics. The terminal phosphoryl oxygen of ADP nucleophilically attacks the C1 phosphorus atom of 1,3-BPG to form the reaction product.

The energetics of the overall GAPDH-PGK reaction pair are

Although the GAPDH reaction is endergonic, the strongly exergonic nature of the transfer of a phosphoryl group from 1,3-BPG to ADP makes the overall synthesis of NADH and ATP from GAP,  $P_i$ ,  $NAD^+$ , and ADP favorable.

### H. Phosphoglycerate Mutase

In Reaction 8 of glycolysis, 3PG is converted to **2-phosphoglycerate (2PG)** by **phosphoglycerate mutase (PGM)**:

A **mutase** catalyzes the transfer of a functional group from one position to another on a molecule. This reaction is a necessary preparation for the next reaction in glycolysis, which generates a “high-energy” phosphoryl compound for use in ATP synthesis.

**Figure 17-17** The active site region of yeast phosphoglycerate mutase (dephospho form). The substrate, 3PG, which is drawn in ball-and-stick form with C green, O red, and P orange, binds to an ionic pocket whose side chains are drawn in stick form with C green, N blue, and O red. His 8 is phosphorylated in the active enzyme. [Based on an X-ray structure by Jennifer Littlechild, University of Exeter, U.K. PDBid 1QHF.]

#### a. Reaction Mechanism of PGM

At first sight, the reaction catalyzed by PGM appears to be a simple intramolecular phosphoryl transfer. This is not the case, however. *The active enzyme has a phosphoryl group at its active site, which it transfers to the substrate to form a bisphospho intermediate. This intermediate then rephosphorylates the enzyme to form the product and regenerate the active phosphoenzyme.* The following experimental data permitted the elucidation of PGM’s enzymatic mechanism:

##### 1. Catalytic amounts of **2,3-bisphosphoglycerate (2,3-BPG)**; previously known as **2,3-diphosphoglycerate**)

**2,3-Bisphosphoglycerate (2,3-BPG)**

are required for enzymatic activity; that is, 2,3-BPG acts as a reaction primer.

**2.** Incubation of the enzyme with catalytic amounts of  $^{32}\text{P}$ -labeled 2,3-BPG yields a  $^{32}\text{P}$ -labeled enzyme. Zelda Rose demonstrated that this was a result of the phosphorylation of a His residue:

**Phospho-His residue**

**3.** The enzyme’s X-ray structure shows His at the active site (Fig. 17-17). In the active enzyme, His 8 is phosphorylated.

These data are consistent with a mechanism in which the active enzyme contains a phospho-His residue at the active site (Fig. 17-18):

**Step 1** 3PG binds to the phosphoenzyme in which His 8 is phosphorylated.

**Step 2** This phosphoryl group is transferred to the substrate, resulting in an intermediate 2,3-BPG · enzyme complex.

**Steps 3 and 4** The complex decomposes to form the product 2PG with regeneration of the phosphoenzyme.

*The phosphoryl group on 3PG therefore ends up on the C2 of the next 3PG to undergo reaction.*

**Figure 17-18** Proposed reaction mechanism for phosphoglycerate mutase. The active form of the enzyme contains a phospho-His residue at the active site. (1) Formation of an enzyme-substrate complex; (2) transfer of the enzyme-bound phosphoryl group to the substrate; (3) rephosphorylation

of the enzyme by the other phosphoryl group of the substrate; and (4) release of product regenerating the active phosphoenzyme. (5) Occasionally, 2,3-BPG dissociates from the enzyme, leaving it in an inactive, dephospho form that must be rephosphorylated by the reverse reaction.

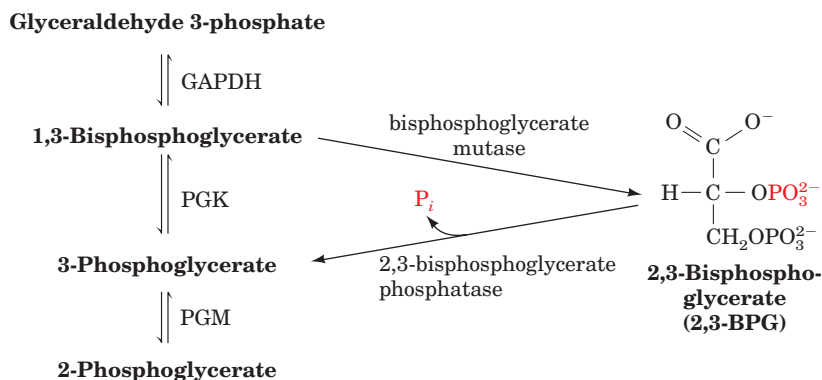

Occasionally, 2,3-BPG dissociates from the enzyme (Fig. 17-18; Step 5), leaving it in an inactive form. Trace amounts of 2,3-BPG must therefore always be available to regenerate the active phosphoenzyme by the reverse reaction.

#### b. Glycolysis Influences Oxygen Transport

2,3-BPG specifically binds to deoxyhemoglobin and thereby alters the oxygen affinity of hemoglobin (Section 10-1D). The concentration of 2,3-BPG in erythrocytes is

much higher ( $\sim 5$  mM) than the trace amounts required for its use as a primer of PGM. Erythrocytes synthesize and degrade 2,3-BPG by a detour from the glycolytic pathway, diagrammed in Fig. 17-19. **Bisphosphoglycerate mutase** catalyzes the transfer of a phosphoryl group from C1 to C2 of 1,3-BPG. The resulting 2,3-BPG is hydrolyzed to 3PG by **2,3-bisphosphoglycerate phosphatase**. The rate of glycolysis affects the oxygen affinity of hemoglobin through the mediation of 2,3-BPG. Consequently, inherited defects of

**Figure 17-19** The pathway for the synthesis and degradation of 2,3-BPG in erythrocytes is a detour from the glycolytic pathway.

glycolysis in erythrocytes alter the capacity of the blood to transport oxygen (Fig. 17-20). For example, the concentration of glycolytic intermediates in hexokinase-deficient erythrocytes is less than normal because hexokinase catalyzes the first reaction of glycolysis. This results in a diminished 2,3-BPG concentration and therefore in increased hemoglobin oxygen affinity. Conversely, pyruvate kinase deficiency decreases hemoglobin oxygen affinity through the increase of 2,3-BPG resulting from the blockade of the last reaction in glycolysis. Thus, although erythrocytes, which lack nuclei and other organelles, have but a minimal metabolism, this metabolism is physiologically significant.

### I. Enolase: Second "High-Energy" Intermediate Formation

In Reaction 9 of glycolysis, 2PG is dehydrated to **phosphoenolpyruvate (PEP)** in a reaction catalyzed by **enolase**:

The enzyme forms a complex with a divalent cation such as  $\text{Mg}^{2+}$  before the substrate is bound. A second divalent metal ion then binds to the enzyme. As is mentioned in Section 17-1A, fluoride ion inhibits glycolysis, resulting in the accumulation of 2PG and 3PG. It does so by strongly inhibiting enolase in the presence of  $\text{P}_i$ .  $\text{F}^-$  and  $\text{P}_i$  form a tightly bound complex with the  $\text{Mg}^{2+}$  at the enzyme's active site, blocking substrate binding and thereby inactivating the enzyme. Enolase's substrate, 2PG, therefore builds up and, as it does so, is equilibrated with 3PG by PGM.

#### a. Catalytic Mechanism of Enolase

The dehydration (elimination of  $\text{H}_2\text{O}$ ) catalyzed by enolase might occur in one of three ways (Fig. 16-9a): (1) The  $-\text{OH}$  group at C3 can leave first, generating a carbocation

**Figure 17-20** The oxygen-saturation curves of hemoglobin in normal erythrocytes (red curve) and in those from patients with hexokinase deficiency (green) and with pyruvate kinase deficiency (purple). [After Delivoria-Papadopoulos, M., Oski, F.A., and Gottlieb, A.J., *Science* **165**, 601 (1969).]

at C3; (2) the C2 proton can leave first, generating a carbanion at C2; or (3) the reaction can be concerted. Isotope exchange studies by Paul Boyer demonstrated that the C2 proton of 2PG exchanges with solvent 12 times faster than the rate of PEP formation. However, the C3 oxygen exchanges with solvent at a rate roughly equivalent with the overall reaction rate. This suggests the following mechanism (Fig. 17-21):

**Step 1** Rapid carbanion formation at C2 facilitated by a general base on the enzyme. The abstracted proton can readily exchange with the solvent, accounting for its observed rapid exchange rate.

**Step 2** Rate-limiting elimination of the  $-\text{OH}$  group at C3. This is consistent with the slow rate of exchange of this hydroxyl group with solvent.

The enolase reaction (Fig. 17-21) is of mechanistic interest because it involves the abstraction of the decidedly nonacidic proton at C2 ( $pK > 30$ ), followed by the elimination of an  $\text{OH}^-$  ion, which is a poor leaving group. The X-ray structure of yeast enolase in complex with two  $\text{Mg}^{2+}$  ions and an equilibrium mixture of 2PG and PEP (enolase's substrate and product), determined by George Reed and Ivan Rayment, reveals that enolase binds 2PG in an intricate complex that involves both  $\text{Mg}^{2+}$  ions. Mutagenic and enzymological studies indicate that the reaction involves the Lys 345 side chain functioning as a general base

**Figure 17-21** Proposed reaction mechanism of enolase. **(1)** Rapid formation of a carbanion by removal of a proton at C2 by Lys 345 acting as a general base; this proton can rapidly exchange with the solvent. **(2)** Slow elimination of  $\text{H}_2\text{O}$  to form phosphoenolpyruvate with general acid catalysis by Glu 211; the C3 oxygen of the substrate can exchange with solvent only as rapidly as this step occurs.

and the Glu 211 side chain functioning as a general acid. Lys 396 and the two  $\text{Mg}^{2+}$  ions are thought to stabilize the increased negative charge that develops on the carboxylate ion in the delocalized carbanion intermediate.

#### J. Pyruvate Kinase: Second ATP Generation

In Reaction 10 of glycolysis, its final reaction, **pyruvate kinase (PK)** couples the free energy of PEP hydrolysis to the synthesis of ATP to form pyruvate:

**Figure 17-22** Mechanism of the reaction catalyzed by pyruvate kinase. (1) Nucleophilic attack of an ADP  $\beta$ -phosphoryl oxygen atom on the phosphorus atom of PEP to form ATP and

enolpyruvate; and (2) tautomerization of enolpyruvate to pyruvate.

### a. Catalytic Mechanism of PK

The PK reaction, which requires the participation of both monovalent ( $\text{K}^+$ ) and divalent ( $\text{Mg}^{2+}$ ) cations, occurs as follows (Fig. 17-22):

**Step 1** A  $\beta$ -phosphoryl oxygen of ADP nucleophilically attacks the PEP phosphorus atom, thereby displacing enolpyruvate and forming ATP. This reaction conserves the free energy of PEP hydrolysis.

**Step 2** Enolpyruvate converts to pyruvate. This enol–keto tautomerization is sufficiently exergonic to drive the coupled endergonic synthesis of ATP (Section 16-4Ba).

We can now see the “logic” of the enolase reaction. The standard free energy of hydrolysis of 2PG ( $\Delta G^{\circ'}$ ) is only  $-17.6 \text{ kJ}\cdot\text{mol}^{-1}$ , which is insufficient to drive ATP synthesis ( $\Delta G^{\circ'} = 30.5 \text{ kJ}\cdot\text{mol}^{-1}$  for ATP synthesis from ADP and  $\text{P}_i$ ). The dehydration of 2PG results in the formation of a “high-energy” compound capable of such synthesis [the standard free energy of hydrolysis of PEP is  $-61.9 \text{ kJ}\cdot\text{mol}^{-1}$  (Fig. 16-25)]. In other words, PEP is a “high-energy” compound, 2PG is not.

## 3 FERMENTATION: THE ANAEROBIC FATE OF PYRUVATE

For glycolysis to continue,  $\text{NAD}^+$ , which cells have in limited quantities, must be recycled after its reduction to NADH by GAPDH (Fig. 17-3; Reaction 6). In the presence of oxygen, the reducing equivalents of NADH are passed into the mitochondria for reoxidation (Chapter 22). Under anaerobic conditions, on the other hand, the  $\text{NAD}^+$  is replenished by the reduction of pyruvate in an extension of the glycolytic pathway. Two processes for the anaerobic replenishment of  $\text{NAD}^+$  are homolactic and alcoholic fermentation, which occur in muscle and yeast, respectively.

### A. Homolactic Fermentation

In muscle, particularly during vigorous activity when the demand for ATP is high and oxygen has been depleted, **lactate dehydrogenase (LDH)** catalyzes the oxidation of

NADH by pyruvate to yield  $\text{NAD}^+$  and **lactate**. This reaction is often classified as Reaction 11 of glycolysis:

LDH, as do other  $\text{NAD}^+$ -requiring enzymes, catalyzes its reaction with absolute stereospecificity: The *pro-R* (A-side) hydrogen at C4 of NADH is stereospecifically transferred to the *re* face of pyruvate at C2 to form L- (or S-) lactate. This regenerates  $\text{NAD}^+$  for participation in the GAPDH reaction. The hydride transfer to pyruvate is from the same face of the nicotinamide ring as that to acetaldehyde in the alcohol dehydrogenase reaction (Section 13-2A) but from the opposite (*si*) face of the nicotinamide ring as that to GAP in the GAPDH reaction (Section 17-2F).

Mammals have two different types of LDH subunits, the M type and the H type, which together form five tetrameric isozymes:  $\text{M}_4$ ,  $\text{M}_3\text{H}$ ,  $\text{M}_2\text{H}_2$ ,  $\text{MH}_3$ , and  $\text{H}_4$ . Although these hybrid forms occur in most tissues, the H-type subunit predominates in aerobic tissues such as heart muscle, while the M-type subunit predominates in tissues that are subject to anaerobic conditions such as skeletal muscle and liver.  $\text{H}_4$

**Figure 17-23** The active site region of porcine  $H_4$  LDH in complex with *S-lac-NAD*<sup>+</sup>, a covalent adduct of lactate and  $NAD^+$ . The adduct is shown in ball-and-stick form with C green, N blue, O red, and P yellow, except for the covalent bond between the methylene substituent to lactate atom C3 and nicotinamide atom C5, which is light green. The three LDH side chains that form hydrogen bonds (white lines) with the pyruvate residue are shown in stick form with C magenta and N blue. [Based on an X-ray structure by Michael Rossmann, Purdue University. PDBid 5LDH.]

LDH has a low  $K_M$  for pyruvate and is allosterically inhibited by high levels of this metabolite, whereas the  $M_4$  isozyme has a higher  $K_M$  for pyruvate and is not inhibited by it. The other isozymes have intermediate properties that vary with the ratio of their two types of subunits. It has therefore been proposed, although not without disagreement, that H-type LDH is better adapted to function in the oxidation of lactate to pyruvate, whereas M-type LDH is more suited to catalyze the reverse reaction.

The X-ray structure of porcine  $H_4$  LDH in complex with *S-lac-NAD*<sup>+</sup> (a bisubstrate analog in which atom C3 of lactate is covalently linked to nicotinamide atom C5 of  $NAD^+$  via a  $CH_2$  group) was determined by Michael Rossmann (Fig. 17-23; he also determined the X-ray structure of dogfish  $M_4$  LDH shown in Fig. 8-54a). Lactate atom O2, its hydroxyl oxygen, is hydrogen bonded to the side chains of both Arg 109 and His 195, whereas the lactate carboxyl group at C1 is doubly hydrogen bonded to the side chain of Arg 171. On the basis of this structure and extensive enzymological evidence, Rossmann proposed the following mechanism for pyruvate reduction by LDH (Fig. 17-24): *The pro-R hydride is transferred from C4 of NADH's nicotinamide ring to C2 of pyruvate with the concomitant transfer of a proton from the imidazolium moiety of His 195*

**Figure 17-24** Reaction mechanism of lactate dehydrogenase.

The reaction involves direct hydride transfer from  $NADH$  to pyruvate's carbonyl carbon atom accompanied by proton donation from the imidazolium group of His 195 to the pyruvate carbonyl oxygen atom. The latter process is facilitated by the positive charge on the nearby side chain of Arg 109.

to pyruvate O2, thereby yielding  $NAD^+$  and lactate. The proton transfer is facilitated by repulsive interactions with the closely associated positively charged side chain of Arg 109. These interactions also serve to properly orient the pyruvate, as does the salt bridge that the pyruvate carboxyl group forms with the side chain of Arg 171.

The overall process of anaerobic glycolysis in muscle can be represented:

*Much of the lactate, the end product of anaerobic glycolysis, is exported from the muscle cell via the blood to the liver, where it is reconverted to glucose (Section 23-1C).*

Contrary to the widely held belief, it is not lactate buildup in the muscle *per se* that causes muscle fatigue and soreness but the accumulation of glycolytically generated acid (muscles can maintain their workload in the presence of high lactate concentrations if the pH is kept constant; but see Section 27-2B). Indeed, it is well known among hunters that the meat of an animal that has run to exhaustion before being killed has a sour taste. This is a result of lactic acid buildup in the muscles.

## B. Alcoholic Fermentation

Under anaerobic conditions in yeast,  $\text{NAD}^+$  is regenerated in a manner that has been of importance to mankind for thousands of years: the conversion of pyruvate to ethanol and  $\text{CO}_2$ . Ethanol is, of course, the active ingredient of wine and spirits;  $\text{CO}_2$  so produced leavens bread. From the point of view of the yeast, however, alcoholic fermentation has a practical benefit that homolactic fermentation cannot supply: Yeast employ ethanol as a kind of antibiotic to eliminate competing organisms. This is because yeast can grow in ethanol concentrations  $>12\%$  ( $2.5M$ ), whereas few other organisms can survive in  $>5\%$  ethanol (recall that ethanol is a widely used antiseptic).

### a. TPP Is an Essential Cofactor of Pyruvate Decarboxylase

Yeast produces ethanol and  $\text{CO}_2$  via two consecutive reactions (Fig. 17-25). The first reaction is the decarboxylation of pyruvate to form acetaldehyde and  $\text{CO}_2$  as catalyzed by **pyruvate decarboxylase (PDC;** an enzyme not present in animals). PDC contains the coenzyme **thiamine pyrophosphate [TPP;** Fig. 17-26; also called **thiamin diphosphate (ThDP)**], which it binds tightly but noncovalently. The coenzyme is employed because decarboxylation of an  $\alpha$ -keto acid such as pyruvate requires the buildup of negative charge on the carbonyl carbon atom in the transition state, an unstable situation:

This transition state may be stabilized by delocalization of the developing negative charge into a suitable “electron sink.” The amino acid residues of proteins function poorly in this capacity but TPP does so easily.

The “business” end of TPP is the **thiazolium ring** (Fig. 17-26). Its  $\text{C}2\text{—H}$  group is relatively acidic because of the adjacent positively charged quaternary nitrogen atom, which electrostatically stabilizes the carbanion formed on dissociation of the proton. This dipolar carbanion (or **ylid**) is the active form of the coenzyme. The mechanism of PDC catalysis is as follows (Fig. 17-27):

**Step 1** Nucleophilic attack by the ylid form of TPP on the carbonyl carbon of pyruvate to form a covalent adduct.

**Step 2** Departure of  $\text{CO}_2$  to generate a resonance-stabilized carbanion adduct in which the thiazolium ring of the coenzyme acts as an electron sink.

**Step 3** Protonation of the carbanion.

**Step 4** Elimination of the TPP ylid to form acetaldehyde and regenerate the active enzyme.

This mechanism has been corroborated by the isolation of the **hydroxyethylthiamine pyrophosphate** intermediate (Fig. 17-27).

The X-ray structure of PDC in complex with TPP (Fig. 17-28), which was determined by William Furey and Martin Sax, has suggested a role for TPP’s aminopyrimidine ring in the formation of the active ylid. Ylid formation requires a base to remove the  $\text{C}2$  proton. Yet PDC has no basic side chain that is properly positioned to do so. The amino group of the enzyme-bound TPP’s aminopyrimidine ring is suitably positioned to accept this proton; however, its  $\text{p}K$  is too low to do so efficiently and one of its protons sterically

**Figure 17-25** The two reactions of alcoholic fermentation. (1) Decarboxylation of pyruvate to form acetaldehyde is followed by (2) reduction of the acetaldehyde to ethanol by  $\text{NADH}$ .

resonance-stabilized carbanion; (3) protonation of the carbanion; and (4) elimination of the TPP ylid and release of product.

**Figure 17-28** A portion of the X-ray structure of pyruvate decarboxylase from *Saccharomyces uvarum* (brewer's yeast) in complex with its TPP cofactor. The enzyme's identical 563-residue subunits form a tightly associated dimer, two of which associate loosely to form a tetramer. The TPP and the side chain of Glu 51 are shown in stick form with C green, N blue, O red, S yellow, and P gold. The TPP binds in a cavity situated between the dimer's two subunits (cyan and magenta), where it hydrogen bonds to Glu 51. [Based on an X-ray structure by William Furey and Martin Sax, Veterans Administration Medical Center and University of Pittsburgh, Pittsburgh, Pennsylvania. PDBid 1PYD.]  See Interactive Exercise 9

clashes with the C2 proton. It is therefore proposed that the aminopyrimidine is converted to its imino tautomeric form on the enzyme's surface in a reaction involving proton donation by Glu 51 (Fig. 17-29). The imine, in turn, accepts a proton from C2, thereby forming the ylid, with tautomerization back to the amino form. The participation of N1' and the 4'-amino group of the aminopyrimidine is supported by experiments showing that TPP analogs missing either of these functionalities are catalytically inactive. H/D exchange experiments followed by  $^1\text{H}$  NMR analysis of the exchange products indicate that when TPP is bound to PDC in complex with the substrate analog **pyruvamide** ( $\text{CH}_3\text{—CO—CO—NH}_2$ ), its rate of exchange to form the active species (ylid) is much greater ( $>6 \times 10^2 \text{ s}^{-1}$ ) than the enzyme's catalytic rate ( $k_{\text{cat}} = 10 \text{ s}^{-1}$ ). Moreover, the mutation of PDC's Glu 51 to Gln reduces the rate of H/D exchange to  $1.7 \text{ s}^{-1}$ , thereby supporting Glu 51's postulated function of donating a proton to N1' of TPP's aminopyrimidine ring.

#### b. Beriberi Is a Thiamine Deficiency Disease

The ability of TPP's thiazolium ring to add to carbonyl groups and act as an "electron sink" makes it the coenzyme most utilized in  $\alpha$ -keto acid decarboxylations. TPP is also

**Figure 17-29** The formation of the active ylid form of TPP in the pyruvate decarboxylase reaction. This reaction requires the participation of TPP's aminopyrimidine ring together with general acid catalysis by Glu 51. The predominant form of the cofactor on the enzyme is the imine, but the rate of formation of the active ylid is fast relative to the enzyme's catalytic rate.

involved in decarboxylation reactions that we shall encounter in other metabolic pathways. Consequently, thiamine (**vitamin B<sub>1</sub>**), which is neither synthesized nor stored in significant amounts by the tissues of most vertebrates, is required in their diets. Its deficiency in humans results in an ultimately fatal condition known as **beriberi** (Sinhalese for weakness) that is characterized by neurological disturbances causing pain, paralysis and atrophy (wasting) of the limbs, and/or cardiac failure resulting in edema (the accumulation of fluid in tissues and body cavities). Beriberi was particularly prevalent in the late nineteenth and early twentieth centuries in the rice-consuming areas of Asia after the introduction of steam-powered milling machines that polished the rice

grains to remove their coarse but thiamine-containing outer layers (the previously used milling procedures were less efficient and hence left sufficient thiamine on the grains). Parboiling rice before milling, a process common in India, causes the rice kernels to absorb nutrients from their outer layers, thereby decreasing the incidence of beriberi. Once thiamine deficiency was recognized as the cause of beriberi, enrichment procedures were instituted so that today it has ceased to be a problem except in areas undergoing famine. However, beriberi occasionally develops in chronic alcoholics due to their penchant for drinking but not eating.

### c. Reduction of Acetaldehyde and Regeneration of NAD<sup>+</sup>

The acetaldehyde formed by the decarboxylation of pyruvate is reduced to ethanol by NADH in a reaction catalyzed by **alcohol dehydrogenase (ADH)**. Each subunit of the tetrameric yeast ADH (YADH) binds one NADH and one Zn<sup>2+</sup> ion. The Zn<sup>2+</sup> ion functions to polarize the carbonyl group of acetaldehyde (Fig. 17-30), so as to stabilize the developing negative charge in the transition state of the reaction (the role of metal ions in enzymes is discussed in Section 15-1C). This facilitates the transfer of NADH's *pro-R* hydrogen (the same atom that LDH transfers) to acetaldehyde's *re* face, forming ethanol with the transferred hydrogen in the *pro-R* position (Section 13-2A).

Both homolactic and alcoholic fermentation have the same function: the anaerobic regeneration of NAD<sup>+</sup> for continued glycolysis. Their main difference is in their metabolic products.

Mammalian liver ADH (**LADH**) functions to metabolize the alcohols anaerobically produced by intestinal flora as well as those from external sources (the direction of the ADH reaction varies with the relative concentrations of

**Figure 17-30** The reaction mechanism of alcohol dehydrogenase involves direct hydride transfer of the *pro-R* hydrogen of NADH to the *re* face of acetaldehyde.

ethanol and acetaldehyde). Each subunit of this dimeric enzyme binds one  $\text{NAD}^+$  and two  $\text{Zn}^{2+}$  ions, although only one of these ions participates directly in catalysis. There is significant amino acid sequence similarity between YADH and LADH, so it is quite likely that both enzymes have the same general mechanism.

### C. Energetics of Fermentation

Thermodynamics permits us to dissect the process of fermentation into its component parts and to account for the free energy changes that occur. This enables us to calculate the efficiency with which the free energy of degradation of glucose is utilized in the synthesis of ATP. The overall reaction of homolactic fermentation is

( $\Delta G^{\circ'}$  is calculated from the data in Table 3-4 using Eqs. [3.19] and [3.21] adapted for  $2\text{H}^+$  ions.) For alcoholic fermentation, the overall reaction is

Each of these reactions is coupled to the net formation of two ATPs, which requires  $\Delta G^{\circ'} = +61 \text{ kJ} \cdot \text{mol}^{-1}$  of glucose consumed (Table 16-3). Dividing the  $\Delta G^{\circ'}$  of ATP formation by that of lactate formation indicates that homolactic fermentation is 31% “efficient”; that is, 31% of the free energy released by this process under standard biochemical conditions is sequestered in the form of ATP. The rest is dissipated as heat, thereby making the process irreversible. Likewise, alcoholic fermentation is 26% efficient under biochemical standard state conditions. Actually, *under physiological conditions, where the concentrations of reactants and products differ from those of the standard state, these reactions have free energy efficiencies of >50%*.

#### a. Glycolysis Is Used for Rapid ATP Production

Anaerobic fermentation utilizes glucose in a profligate manner compared to oxidative phosphorylation: Fermentation results in the production of 2 ATPs per glucose, whereas oxidative phosphorylation yields 32 ATPs per glucose (Chapter 22). This accounts for Pasteur’s observation that yeast consumes far more sugar when growing anaerobically than when growing aerobically (the **Pasteur effect**; Section 22-4C). However, *the rate of ATP production by anaerobic glycolysis can be up to 100 times faster than that of oxidative phosphorylation. Consequently, when tissues such as muscle are rapidly consuming ATP, they regenerate it almost entirely by anaerobic glycolysis.* (Homolactic fermentation does not really “waste” glucose since the lactate so produced is aerobically reconverted to glucose by the liver; Section 23-1C).

Skeletal muscles consist of both **slow-twitch** (Type I) and **fast-twitch** (Type II) fibers. Fast-twitch fibers, so called because they predominate in muscles capable of short bursts of rapid activity, are nearly devoid of mitochondria, so that they must obtain nearly all of their ATP through anaerobic

glycolysis, for which they have a particularly large capacity. Muscles designed to contract slowly and steadily, in contrast, are enriched in slow-twitch fibers that are rich in mitochondria and obtain most of their ATP through oxidative phosphorylation. (Fast- and slow-twitch fibers were originally known as white and red fibers, respectively, because otherwise pale colored muscle tissue, when enriched with mitochondria, takes on the red color characteristic of their heme-containing cytochromes. However, fiber color has been shown to be an imperfect indicator of muscle physiology.)

In a familiar example, the flight muscles of migratory birds such as ducks and geese, which need a continuous energy supply, are rich in slow-twitch fibers and therefore such birds have dark breast meat. In contrast, the flight muscles of less ambitious fliers, such as chickens and turkeys, which are used only for short bursts (often to escape danger), consist mainly of fast-twitch fibers that form white meat. In humans, the muscles of sprinters are relatively rich in fast-twitch fibers, whereas distance runners have a greater proportion of slow-twitch fibers (although their muscles have the same color). World class distance runners have a remarkably high capacity to generate ATP aerobically. This was demonstrated by the noninvasive  $^{31}\text{P}$  NMR monitoring of the ATP,  $\text{P}_i$ , phosphocreatine, and pH levels in their exercising but untrained forearm muscles. These observations suggest that the muscles of these athletes are better endowed genetically for endurance exercise than those of “normal” individuals.

## 4 METABOLIC REGULATION AND CONTROL

Living organisms, as we saw in Section 16-6, are thermodynamically open systems that tend to maintain a steady state rather than reaching equilibrium (death for living things). Thus the **flux** (rate of flow) of intermediates through a metabolic pathway is constant; that is, the rates of synthesis and breakdown of each pathway intermediate maintain it at a constant concentration. Such a state, it will be recalled, is one of maximum thermodynamic efficiency (Section 16-6Ba). *Regulation of the steady state (homeostasis) must be maintained in the face of changes in flux through the pathway in response to changes in demand.*

The terms metabolic control and metabolic regulation are often used interchangeably. However, for our purposes we shall give them different definitions: **Metabolic regulation** is the process by which the steady-state flow of metabolites through a pathway is maintained, whereas **metabolic control** is the influence exerted on the enzymes of a pathway in response to an external signal in order to alter the flux of metabolites.

### A. Homeostasis and Metabolic Control

There are two reasons why metabolic flow must be controlled:

- I. To provide products at the rate they are needed, that is, to balance supply with demand.

**II.** To maintain the steady-state concentrations of the intermediates in a pathway within a narrow range (homeostasis).

Organisms maintain homeostasis for several reasons:

1. In an open system, such as metabolism, the steady state is the state of maximum thermodynamic efficiency (Section 16-6Ba).
2. Many intermediates participate in more than one pathway, so that changing their concentrations may disturb a delicate balance.
3. The rate at which a pathway can respond to a control signal slows if large changes in intermediate concentrations are involved.
4. Large changes in intermediate concentrations may have deleterious effects on cellular osmotic properties.

The concentrations of intermediates and the level of metabolic flux at which a pathway is maintained vary with the needs of the organism through a highly responsive system of precise controls. Such pathways are analogous to rivers that have been dammed to provide a means of generating electricity. Although water is continually flowing in and out of the lake formed by the dam, a relatively constant water level is maintained. The rate of water outflow from the lake is precisely controlled at the dam and is varied in response to the need for electrical power. In this section, we examine the mechanisms by which metabolic pathways in general, and the glycolytic pathway in particular, are controlled in response to biological energy needs.

## B. Metabolic Flux

Since a metabolic pathway is a series of enzyme-catalyzed reactions, it is easiest to describe the flux of metabolites through the pathway by considering its reaction steps individually. The flux of metabolites,  $J$ , through each reaction step is the rate of the forward reaction,  $v_f$ , less that of the reverse reaction,  $v_r$ :

$$J = v_f - v_r \quad [17.1]$$

At equilibrium, by definition, there is no flux ( $J = 0$ ), although  $v_f$  and  $v_r$  may be quite large. At the other extreme, in reactions that are far from equilibrium,  $v_f \gg v_r$ , so that the flux is essentially equal to the rate of the forward reaction,  $J \approx v_f$ . *The flux throughout a steady-state pathway is constant and is set (generated) by the pathway's rate-determining step (or steps). Consequently, control of flux through a metabolic pathway requires: (1) that the flux through this flux-generating step vary in response to the organism's metabolic requirements and (2) that this change in flux be communicated throughout the pathway to maintain a steady state.*

The classic description of metabolic control and regulation is that every metabolic pathway has a rate-limiting step and is regulated by controlling the rate of this pivotal

enzyme. These so-called regulatory enzymes are almost invariably allosteric enzymes subject to feedback inhibition (Section 13-4) and are often also controlled by covalent modification (which we discuss in Section 18-3).

Several questions arise. Are these regulatory enzymes really rate limiting for the pathway? Is there really only one step in the pathway that is rate limiting, or might there be a number of enzymes contributing to the regulation of the pathway? Does controlling these enzymes really control the flux of metabolites through the pathway or is the function of feedback inhibition really to maintain a steady state? These are complicated questions with complicated answers.

## C. Metabolic Control Analysis

While it has been common practice to assume that every metabolic pathway has a rate-limiting step, experiments suggest that the situation becomes more complex when these pathways are combined in a living organism. Hence, it is important to develop methods to quantitatively analyze metabolic systems in order to establish mechanisms of control and regulation. **Metabolic control analysis**, developed by Henrik Kacser and Jim Burns and independently by Reinhart Heinrich and Tom Rapoport, provides a framework for considering these problems. It is a way of quantitatively describing the behavior of metabolic systems in response to various perturbations.

### a. The Flux Control Coefficient Measures the Sensitivity of the Flux to the Change in Enzyme Concentration

Metabolic control analysis makes no *a priori* assumption that only one step is rate limiting. Instead, it defines a **flux control coefficient**,  $C^J$  (where  $J$  is an index, not an exponent), to measure the sensitivity of flux to a change in enzyme concentration. The flux control coefficient is defined as the fractional change in flux,  $J$ , with respect to the fractional change in enzyme concentration,  $[E]$ :

$$C^J = \frac{\partial J/J}{\partial [E]/[E]} = \frac{\partial \ln J}{\partial \ln [E]} \approx \frac{\Delta J/J}{\Delta [E]/[E]} \quad [17.2]$$

(recall that  $\partial x/x = \partial \ln x$ ).

The flux control coefficient is the analog of the kinetic order of a reaction. If a reaction is first order in substrate concentration,  $[S]$ , then doubling  $[S]$  doubles the rate of the reaction, whereas if the reaction is zero order in  $[S]$  (e.g., in a saturated enzymatic reaction), then the reaction rate is insensitive to the value of  $[S]$ . Similarly, if the flux control coefficient of an enzyme is 1, then doubling the concentration of the enzyme,  $[E]$ , doubles the flux through the pathway and if it is zero, the flux is insensitive to the value of  $[E]$ . Of course, the flux control coefficient may have some intermediate value between 0 and 1. For example, if a 10% increase in the enzyme concentration increases the flux by only 7.5%, the flux control coefficient would be  $0.075/0.10 = 0.75$ .

The flux through a metabolic system is generally controlled by more than one enzyme. Consequently, the flux

Dividing Eq. [17.3] by  $J$ , multiplying the right side by  $v_f/v_f$ , and substituting in Eq. [17.1] yields

$$\frac{\Delta J}{J} = \frac{\Delta v_f}{v_f} \frac{v_f}{J} = \frac{\Delta v_f}{v_f} \frac{v_f}{(v_f - v_r)} \quad [17.4]$$

which relates  $\Delta J/J$ , the fractional change in flux through the rate-determining step(s), to  $\Delta v_f/v_f$ , the fractional change in  $v_f$ , the forward rate of the next reaction in the pathway.

In Section 14-2A, we discussed the relationship between substrate concentration and the rate of an enzymatic reaction as expressed by the Michaelis–Menten equation:

$$v_f = \frac{V_{\max}^f [A]}{K_M + [A]} \quad [14.24]$$

In the simplest and physiologically most common situation,  $[A] \ll K_M$ , so that

$$v_f = \frac{V_{\max}^f [A]}{K_M} \quad [17.5]$$

and

$$\Delta v_f = \frac{V_{\max}^f \Delta [A]}{K_M} \quad [17.6]$$

Hence,

$$\frac{\Delta v_f}{v_f} = \frac{\Delta [A]}{[A]} \quad [17.7]$$

that is, the fractional change in forward reaction rate is equal to the fractional change in substrate concentration. Then, by substituting Eq. [17.7] into Eq. [17.4], we find that

$$\frac{\Delta J}{J} = \frac{\Delta [A]}{[A]} \frac{v_f}{(v_f - v_r)} \quad [17.8]$$

This equation relates the fractional change in flux through a metabolic pathway's rate-determining step(s) to the fractional change in substrate concentration necessary to communicate that change to the following reaction steps. *The quantity  $v_f/(v_f - v_r)$  is a measure of the sensitivity of a reaction's fractional change in flux to its fractional change in substrate concentration.* This quantity is also a measure of the reversibility of the reaction, that is, how close it is to equilibrium:

**1.** In an irreversible reaction,  $v_r$  approaches 0 (relative to  $v_f$ ) and therefore  $v_f/(v_f - v_r)$  approaches 1. The reaction therefore requires a nearly equal fractional increase in its substrate concentration in order to respond to a fractional increase in flux.

**2.** As a reaction approaches equilibrium,  $v_r$  approaches  $v_f$  and hence  $v_f/(v_f - v_r)$  approaches infinity. The reaction's response to a fractional increase in flux therefore requires a much smaller fractional increase in its substrate concentration.

Consequently, *the ability of a reaction to communicate a change in flux increases as the reaction approaches equilib-*

*rium.* A series of sequential reactions that are all near equilibrium therefore have the same flux and maintain concentrations of intermediates in a steady state (homeostasis).

#### d. The Elasticity Coefficient Measures the Sensitivity of an Enzymatic Reaction to the Change in Substrate Concentration

The ratio  $v_f/(v_f - v_r)$ , which measures the sensitivity of an enzymatic reaction rate to the change in substrate concentration, is called, in metabolic control analysis, the **elasticity coefficient**,  $\varepsilon$ . It is the fractional change in the net rate of an enzyme reaction,  $v$ , with respect to the fractional change in the substrate concentration,  $[A]$ :

$$\varepsilon = \frac{\partial v/v}{\partial [A]/[A]} = \frac{\partial \ln v}{\partial \ln [A]} \approx \frac{v_f}{v_f - v_r} \quad [17.9]$$

(When studying an individual enzymatic reaction, so that the fractional change in the net rate through the reaction,  $\Delta v/v$ , corresponds to the fractional change in the flux,  $\Delta J/J$ , and  $[A] \ll K_M$ , this equation is simply a rearrangement of Eq. [17.8].) The value of the elasticity coefficient depends on the kinetic characteristics of the enzyme and how close to equilibrium the enzyme is functioning. As mentioned above, if an enzyme is functioning far from equilibrium ( $v_f \gg v_r$ ), changing the substrate concentration will have a small effect on the net rate of the enzyme reaction ( $\varepsilon$  will be close to 1). However, if the enzyme is functioning very close to equilibrium so that both the forward and reverse reaction rates are much faster than the overall net rate,  $\varepsilon$  approaches infinity and it takes only a tiny change in substrate concentration to adjust to a new flux. Such large elasticity coefficients are therefore associated with maintaining homeostasis.

#### D. Supply–Demand Analysis

Early studies on control of metabolic pathways focused on individual pathways, ignoring their overall physiological functions. Control was always assumed to reside within the pathway. However, often when enzymes thought to be “rate controlling” in an individual pathway were overproduced in living organisms using genetic engineering techniques, increases in enzyme concentrations of as much as 10-fold had no effect on the flux through the specific pathway studied. The flux control coefficients of the overproduced enzymes were near zero in the *in vivo* system; they were already present in metabolic excess. The flux must somehow have been controlled from outside of the pathway. This is because, as we now realize, it is impossible to separate a pathway from the process(es) that utilizes the product(s) of that pathway (i.e., the living organisms must have reduced the activities of these enzymes in keeping with their metabolic requirements, that is, they maintained homeostasis).

*Degradation pathways are inextricably linked to the biosynthetic pathways that utilize their products* (Fig. 16-2). This is a **supply–demand process** and both supply and

demand are involved in the two metabolic control challenges: flux control and homeostasis. Jan-Hendrik Hofmeyr and Athel Cornish-Bowden have used metabolic control analysis to explore such a system, lumping all of the reactions of the supply pathway(s) together into one block and all of the reactions of the demand pathway(s) into a second block.

Here X is the intermediate that is produced by the supply block for use by the demand block. For the supply block, X is a product and a feedback inhibitor, so that as the concentration of X increases, the rate of flow through the supply block decreases. For the demand block, X is a substrate, so that as the concentration of X increases, the rate of flow through the demand block increases until it becomes saturated. When the flux through the supply block is equal to the flux through the demand block, the concentration of X is in a steady state, the point at which its rate of production is equal to its rate of utilization. This rate defines the actual flux through the supply–demand system and the steady-state concentration of X.

#### a. The Steady-State Concentration of Intermediates Responds to Changes in Supply and/or Demand

The response of the steady-state concentration of the intermediate, X, to any small change in the rate of the supply or demand block depends entirely on the elasticity coefficients of the two blocks at the steady state. Imagine that the activity of the demand block increases. This would result in a decrease of [X] and a concomitant increase in the flux through the supply block as feedback inhibition is decreased. The shift would continue until the rates through the supply and demand blocks equalize, shifting the system to a new steady state with a lower [X] and higher overall flux. Alternatively, if the activity of the supply block increases, producing a higher value of [X], the demand block would respond by increasing its rate to re-establish a new steady state at this higher [X]. *The higher the elasticity coefficient of the responding block, the smaller the change that [X] must make in order to re-establish a steady state.*

The question remains, where is the control? Is it in the supply block or in the demand block? The answer is that it is in the block for which the elasticity coefficient is lowest. Since it is the change in [X] that causes the readjustment of the steady state and the change in flux, the block for which the largest change in [X] is produced for a given change in rate is the controlling block. The change in flux for a given change in the rate in a particular block is its flux control coefficient, so the *control lies in the block that has the highest flux control coefficient and the lowest elasticity coefficient*. For example, if the supply block has a very high elasticity coefficient and the demand block has a very low elasticity coefficient, increased demand need cause very little decrease in [X] to result in a change in supply rate to reach a

new steady state. However, because of the low elasticity coefficient of the demand block, there will have to be a much larger increase in [X] due to an increase in supply to cause the rate of the demand block to increase enough to reach a new steady state. Consequently, increasing the activity of the demand block would have a much larger effect on the flux than increasing the activity of the supply block. Thus, for this case, the flux is much more sensitive to changes in demand than to changes in supply, that is, the flux control coefficient of the demand block is much greater than that of the supply block.

There is a reciprocal relationship between the flux control coefficient and the elasticity coefficient. The larger the flux control coefficient, the lower the elasticity coefficient, and vice versa. The ratio of the elasticity coefficients of the supply and demand blocks determines the distribution of flux control between supply and demand. *When the ratio of the supply elasticity coefficient to the demand elasticity coefficient is greater than 1, as in our example, flux control lies in the demand portion of the pathway, and vice versa.*

#### b. The Elasticity Coefficient Describes the Regulation of Steady-State Intermediate Concentrations

In addition to controlling flux through the supply–demand system, the steady-state concentrations of the intermediates are also regulated. We have seen that the larger the elasticity coefficient of a given block, the smaller the change in [X] that is needed to re-establish a steady state and change the flux. Keeping the change in [X] as small as possible while changing the flux and maintaining a steady state is very important. *The larger the elasticity coefficient, the more sensitive the regulation of homeostasis.*

Flux control requires a high flux control coefficient, which requires a low elasticity coefficient. Regulation of homeostasis requires a high elasticity coefficient, which requires a low flux control coefficient. A large difference in the elasticity coefficients of the supply and demand blocks therefore leads to the exclusive control of flux by one or the other of the blocks. *The functions of flux and concentration control are mutually exclusive. If the demand block controls the flux, the function of the supply block is to regulate homeostasis.*

#### c. Feedback Inhibition Is Required for Homeostasis, Not Flux Control

When the demand block is exerting flux control, an increase in demand results in a decrease in the concentration of X, thereby decreasing feedback inhibition of the supply block. Feedback inhibition might therefore appear to be an essential part of the control process. In fact, this is not the case. Feedback inhibition is not part of the control system but part of the homeostasis system. It determines the range of [X] at which there is a steady state. In the absence of feedback inhibition, the supply block will be insensitive to [X] for most of that concentration range but will become sensitive to [X] near equilibrium, where the demand block could then control the flux. However, this would require

such high concentrations of X and the other metabolites in the supply pathway as to be osmotically dangerous. Feedback inhibition maintains homeostasis at physiologically reasonable metabolite concentrations.

## E. Mechanisms of Flux Control

### a. Flux through a Pathway Is Controlled at Its Rate-Determining Step(s)

The metabolic flux through an entire pathway is determined by controlling its rate-determining step(s), which by definition is much slower than the following reaction step(s). The product(s) of the rate-determining step(s) is therefore removed before it can equilibrate with the reactant, so that the rate-determining step(s) functions far from equilibrium and has a large negative free energy change. In an analogous manner, the flow of a river can only be controlled at a dam, which creates a difference in water levels between its upstream and downstream sides; this is a situation that also has a large negative free energy change, in this case resulting from the hydrostatic pressure head. Yet, as we have just seen, the elasticity coefficient,  $\epsilon$ , of a nonequilibrium reaction ( $v_f \gg v_r$ ) is close to 1; that is, its substrate concentration must double (in the absence of other controlling effects) in order to double the reaction flux rate (Eq. [17.8]). However, some pathway fluxes vary by factors that are much greater than can be explained by changes in substrate concentrations. For example, glycolytic fluxes are known to vary by factors of 100 or more, whereas variations of substrate concentrations over such a large range are unknown. Consequently, although changes in substrate concentration can communicate a change in flux at the rate-determining step(s) to the other (near equilibrium;  $v_f \approx v_r$ ) reaction steps of the pathway, there must be other mechanisms that control the flux of the rate-determining step(s).

The flux through a rate-determining step(s) of a pathway may be altered by several mechanisms:

**1. Allosteric control:** Many enzymes are allosterically controlled (Section 13-4) by effectors that are often substrates, products, or coenzymes in the pathway but not necessarily of the enzyme in question (feedback regulation). One such enzyme is PFK, an important glycolytic regulatory enzyme (Section 17-4Fb).

**2. Covalent modification (enzymatic interconversion):** Many enzymes that regulate pathway fluxes have specific sites that may be enzymatically phosphorylated and dephosphorylated at specific Ser, Thr, and/or Tyr residues or covalently modified in some other way. Such enzymatic modification processes, which are themselves subject to control, greatly alter the activities of the modified enzymes. This flux control mechanism is discussed in Section 18-3.

**3. Substrate cycles:** If  $v_f$  and  $v_r$  in Eq. [17.8] represent the rates of two opposing nonequilibrium reactions that are catalyzed by different enzymes,  $v_f$  and  $v_r$  may be independently varied. The flux through such a substrate cycle,

as we shall see in the next section, is more sensitive to the concentrations of allosteric effectors than is the flux through a single unopposed nonequilibrium reaction.

**4. Genetic control:** Enzyme concentrations, and hence enzyme activities, may be altered by protein synthesis in response to metabolic needs. Genetic control of enzyme concentrations is a major concern of Part V of this textbook.

Mechanisms 1 to 3 can respond rapidly (within seconds or minutes) to external stimuli and are therefore classified as “short-term” control mechanisms. Mechanism 4 responds more slowly to changing conditions (within hours or days in higher organisms) and is therefore referred to as a “long-term” control mechanism.

## F. Regulation of Glycolysis in Muscle

Elucidation of the flux regulation mechanisms of a given pathway involves the determination of the pathway’s regulatory enzymes involved in the rate-determining steps together with the identification of the modulators of these enzymes and their mechanism(s) of modulation. A hypothesis may then be formulated that can be tested *in vivo*. A common procedure for establishing regulatory mechanisms involves three steps.

**1.** Identification of the rate-determining step(s) of the pathway. One way to do so is to measure the *in vivo*  $\Delta G$ ’s of all the reactions in the pathway to determine how close to equilibrium they function. Those that operate far from equilibrium are potential control points; the enzymes catalyzing them may be regulated by one or more of the mechanisms listed above. Another way of establishing the rate-determining step(s) of a pathway is to measure the effect of a known inhibitor on a specific reaction step and on the flux through the pathway as a whole. The ratio of the fractional change in the activity of the inhibited enzyme to the fractional change in the total flux (the flux control coefficient) will vary between 0 and 1. The closer the ratio is to 1, the more involved that enzyme is in the regulation of the total flux through the pathway.

**2.** *In vitro* identification of allosteric modifiers of the enzymes catalyzing the rate-determining reactions. The mechanisms by which these compounds act are determined from their effects on the enzyme’s kinetics. From this information, a model of the allosteric mechanisms for regulating the pathway may be formulated.

**3.** Measurement of the *in vivo* levels of the proposed regulators under various conditions to establish whether these concentration changes are consistent with the proposed regulation mechanism.

### a. Free Energy Changes in the Reactions of Glycolysis

Let us examine the thermodynamics of glycolysis with an eye toward understanding its regulatory mechanisms. This must be done separately for each type of tissue in question because glycolysis is regulated in different tissues

**Table 17-1**  $\Delta G^{\circ}$  and  $\Delta G$  of the Reactions of Glycolysis in Heart Muscle<sup>a</sup>

Reaction	Enzyme	$\Delta G^{\circ}$ (kJ · mol <sup>-1</sup> )	$\Delta G$ (kJ · mol <sup>-1</sup> )
1	HK	-20.9	-27.2
2	PGI	+2.2	-1.4

in different ways. We shall confine ourselves to muscle tissue. First we establish the pathway's possible regulation points through the identification of its nonequilibrium reactions. Table 17-1 lists the standard free energy change ( $\Delta G^{\circ}$ ) and the actual physiological free energy change ( $\Delta G$ ) associated with each reaction in the pathway. It is important to realize that the free energy changes associated with the reactions under standard conditions may differ dramatically from those in effect under physiological conditions. For example, the  $\Delta G^{\circ}$  for aldolase is +22.8 kJ · mol<sup>-1</sup>, whereas under physiological conditions in heart muscle it is close to zero, indicating that the *in vivo* activity of aldolase is sufficient to equilibrate its substrates and products. The same is true of the GAPDH + PGK reaction series. Nevertheless, in a steady-state pathway, all the reactions must have  $\Delta G < 0$ . This is because if  $\Delta G > 0$  for any reaction, its flux would be in the reverse direction.

*In the glycolytic pathway, only three reactions, those catalyzed by hexokinase (HK), phosphofructokinase (PFK), and pyruvate kinase (PK), function with large negative free energy changes in heart muscle under physiological conditions* (Table 17-1). These nonequilibrium reactions of glycolysis are the candidates for the flux-control points. The other glycolytic reactions function near equilibrium: Their forward and reverse rates are much faster than the actual flux through the pathway (although their forward rates must be at least slightly greater than their reverse rates). Consequently, these near-equilibrium reactions are very sensitive to changes in the concentration of pathway intermediates (they have high elasticity coefficients) and

thereby rapidly communicate any changes in flux generated at the rate-determining step(s) throughout the rest of the pathway, ensuring the maintenance of a steady state (homeostasis).

#### **b. Phosphofructokinase Is a Major Target for Regulating the Flux of Glycolysis in Muscle**

*In vitro* kinetic studies of HK, PFK, and PK indicate that each is controlled by a variety of compounds, some of which are listed in Table 17-2. Yet, when the G6P source for glycolysis is glycogen, rather than glucose, as is often the case in skeletal muscle (Section 18-1), the hexokinase reaction is not required. *PFK, an elaborately controlled enzyme functioning far from equilibrium, evidently is the major target for regulating glycolysis in muscle under most conditions.*

PFK (Fig. 17-32a) is a tetrameric enzyme with two conformational states, R and T, that are in equilibrium. ATP is both a substrate and an allosteric inhibitor of PFK. Each subunit has two binding sites for ATP, a substrate site and an inhibitor site. The substrate site binds ATP equally well in either conformation, but the inhibitor site binds ATP almost exclusively in the T state. The other substrate of PFK, F6P, preferentially binds to the R state. Consequently, at high concentrations, ATP acts as a heterotropic allosteric inhibitor of PFK by binding to the T state, thereby shifting the  $T \rightleftharpoons R$  equilibrium in favor of the T state and thus decreasing PFK's affinity for F6P (this is similar to the action of 2,3-BPG in decreasing the affinity of hemoglobin for O<sub>2</sub>; Section 10-2F). In graphical terms, at high concentrations of

**Table 17-2** Some Effectors of the Nonequilibrium Enzymes of Glycolysis

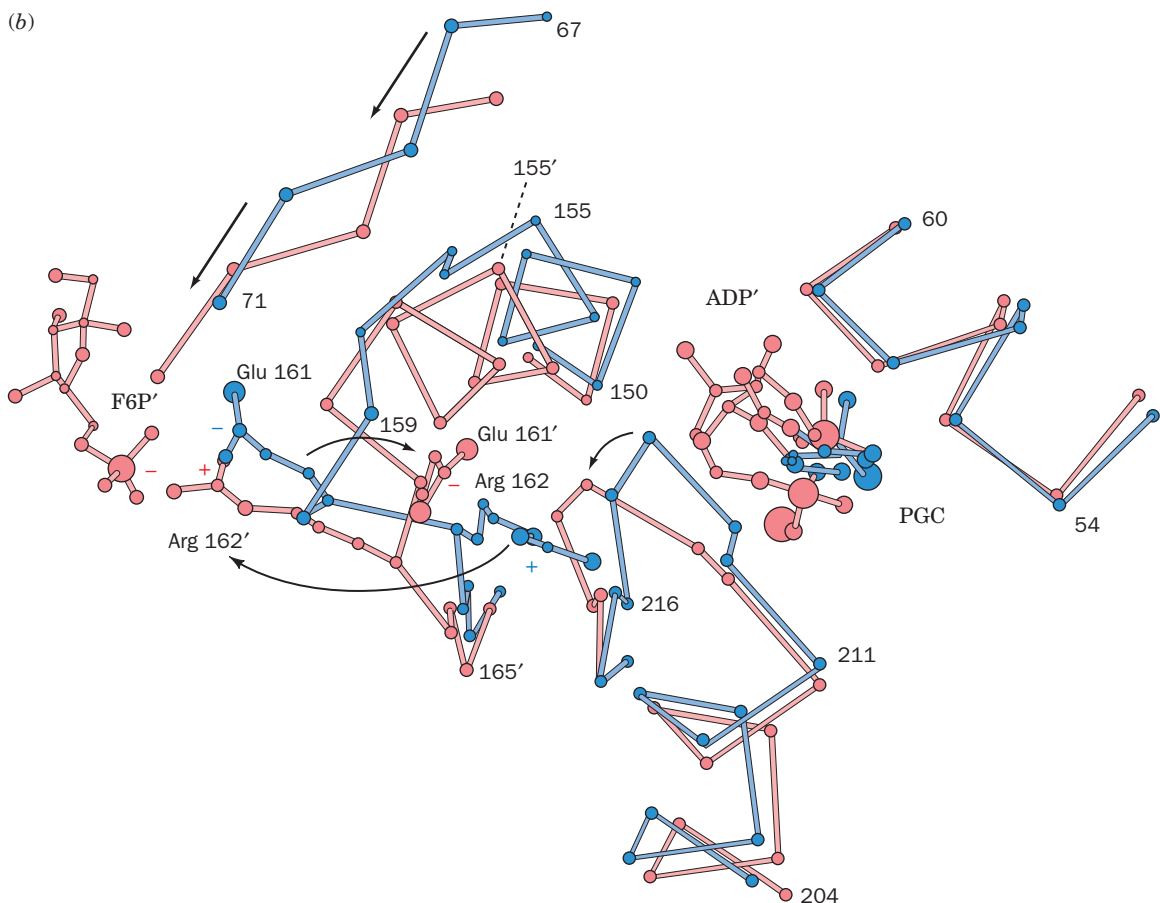

Enzyme	Inhibitors	Activators <sup>a</sup>
HK	G6P	—
PFK	ATP, citrate, PEP	ADP, AMP, cAMP, FBP, F2,6P, F6P, NH <sub>4</sub> <sup>+</sup> , P <sub>i</sub>
PK (muscle)	ATP	AMP, PEP, FBP

<sup>a</sup>The activators for PFK are better described as deinhibitors of ATP because they reverse the effect of inhibitory concentrations of ATP.

**Figure 17-32 X-ray structure of PFK.** (a) Two subunits of the tetrameric enzyme are shown in ribbon form (the other two subunits, which have been omitted for clarity, are related to those shown by a 2-fold rotation about a vertical axis). Each subunit binds its products, F6P (near the center of each subunit) and  $Mg^{2+}$ -ADP (lower right and upper left), together with its activator  $Mg^{2+}$ -ADP (upper right and lower left, in the rear), all in space-filling form with atoms colored according to type (ADP C green, F6P C cyan, N blue, O red, P orange, and Mg purple). Note the close proximity of the product ADP's  $\beta$ -phosphate group to the phosphoryl group at F6P's 1-position, the group that PFK transfers from ATP to F6P. [Based on an X-ray structure by Phillip Evans, Cambridge University, U.K. PDBid 1PFK.] (b) A superposition of those segments of the T-state (blue) and R-state (red) enzymes that undergo a large conformational rearrangement on the T  $\rightarrow$  R allosteric transition (indicated by the arrows). Residues of the R-state structure are marked by a prime. Also shown are bound ligands: the nonphysiological inhibitor 2-phosphoglycolate (PGC; a PEP analog) for the T state, and the cooperative substrate F6P and the activator ADP for the R state. [After Schirmer, T. and Evans, P.R., *Nature* **343**, 142 (1990). PDBids 4PFK and 6PFK.]  See Kinemage Exercises 13-1 and 13-2

ATP, the hyperbolic (noncooperative) curve of PFK activity versus  $[F6P]$  is converted to the sigmoidal (cooperative) curve characteristic of allosteric enzymes (Fig. 17-33; cooperative and noncooperative processes are discussed in

Section 10-1Ba). For example, when  $[F6P] = 0.5 \text{ mM}$  (the dashed line in Fig. 17-33), the enzyme is nearly maximally active, but in the presence of  $1 \text{ mM}$  ATP, the activity drops to 15% of its original level (a nearly 7-fold decrease).

**Figure 17-33 PFK activity versus F6P concentration.** The various conditions are: blue, no inhibitors (low, noninhibitory [ATP]); green, 1 mM ATP (inhibitory); and red, 1 mM ATP + 0.1 mM AMP. [After data from Mansour, T.E. and Ahlfors, C.E., *J. Biol. Chem.* **243**, 2523–2533 (1968).]  See the Animated Figures.

[Actually, the most potent allosteric effector of PFK is **fructose-2,6-bisphosphate (F2,6P)**. We discuss the role of F2,6P in regulating PFK activity when we study the mechanism by which the liver maintains blood glucose concentrations (Section 18-3Fc).]

### c. Structural Basis for PFK's Allosteric Change in F6P Affinity

The X-ray structures of PFK from several organisms have been determined for both the R and the T states by Phillip Evans. The R state of PFK is homotropically stabilized by the binding of its substrate fructose-6-phosphate (F6P). In the R state of *Bacillus stearothermophilus* PFK, the side chain of Arg 162 forms a salt bridge with the phosphoryl group of an F6P bound in an active site of another subunit (Fig. 17-32b). However, Arg 162 is located at the end of a helical turn that unwinds on transition to the T state. The positively charged side chain of Arg 162 thereby swings away and is replaced by the negatively charged side chain of Glu 161. As a consequence, the doubly negative phosphoryl group of F6P has a greatly diminished affinity for the T-state enzyme. The unwinding of this helical turn, which is obligatory for the R → T transition, is prevented by the binding of the activator ADP to its effector site on PFK in the R state, and facilitated by the binding of ATP to this effector site in the T state. Evidently, the same conformational shift is responsible for both the homotropic and the heterotropic allosteric effects in PFK.

### d. AMP Overcomes the ATP Inhibition of PFK

Direct allosteric control of PFK by ATP may superficially appear to be the means by which glycolytic flux is regulated. After all, when [ATP] is high as a result of low metabolic demand, PFK is inhibited and flux through the pathway is low; conversely, when [ATP] is low, flux through

the pathway is high and ATP is synthesized to replenish the pool. Consideration of the physiological variation in ATP concentration, however, indicates that the situation may be more complex. The metabolic flux through glycolysis may vary by 100-fold or more, depending on the metabolic demand for ATP. However, measurements of [ATP] *in vivo* at various levels of metabolic activity indicate that [ATP] varies <10% between rest and vigorous exertion. Yet *there is no known allosteric mechanism that can account for a 100-fold change in flux of a nonequilibrium reaction with only 10% change in effector concentration.* Thus, some other mechanism, or mechanisms, must be responsible for controlling glycolytic flux.

The inhibition of PFK by ATP is relieved by AMP. This results from AMP's preferential binding to the R state of PFK. If a PFK solution containing 1 mM ATP and 0.5 mM F6P is brought to 0.1 mM in AMP, the activity of PFK rises from 10 to 50% of its maximal activity, a 5-fold increase (Fig. 17-33).

[ATP] decreases by only 10% in going from a resting state to one of vigorous activity because it is buffered by the action of two enzymes: creatine kinase (Section 16-4Cd) and, of particular importance to this discussion, **adenylate kinase (AK; also known as myokinase)**. Adenylate kinase catalyzes the reaction

which rapidly equilibrates the ADP resulting from ATP hydrolysis in muscle contraction with ATP and AMP.

In muscle, [ATP] is ~50 times [AMP] and ~10 times [ADP], so that, *as a result of the adenylate kinase reaction, a 10% decrease in [ATP] will cause over a 4-fold increase in [AMP]* (see Problem 12 in this chapter). Consequently, a metabolic signal consisting of a decrease in [ATP] too small to relieve PFK inhibition is amplified significantly by the adenylate kinase reaction, which increases [AMP] by an amount sufficient to produce a much larger increase in PFK activity.

### e. Adenylate Kinase's Internal Motions Act as an Energetic Counterweight to Balance Substrate Binding

Adenylate kinase, like other kinases, must be specific to prevent undesirable phosphoryl-transfer reactions such as hydrolysis. However, once the reaction has occurred, the tightly bound products must be rapidly released to maintain the enzyme's catalytic efficiency. With kinases such as hexokinase and phosphoglycerate kinase, this process is accomplished by the closing of "jaws" on the bound substrates that open when product is formed (Figs. 17-5 and 17-15), a process that is presumably driven by the exergonic free energy change of the reaction the enzyme catalyzes. However, since the AK reaction is energetically neutral (it replaces one phosphodiester bond with another), AK specificity is accomplished by a somewhat different means. Comparison of the X-ray structures, determined

**Figure 17-34** Conformational changes in *E. coli* adenylate kinase (AK) on binding substrate. (a) The unliganded enzyme. (b) The enzyme with the bound substrate analog  $\text{Ap}_5\text{A}$ . The  $\text{Ap}_5\text{A}$  is drawn in stick form colored according to atom type (C green, N blue, O red, and P yellow). The protein's cyan and blue domains undergo extensive conformational changes on

ligand binding, whereas the remainder of the protein (magenta), whose orientation is the same in Parts a and b, largely maintains its conformation. Compare these structures to that of porcine AK (Fig. 8-54b). [Based on X-ray structures by Georg Schulz, Institut für Organische Chemie und Biochemie, Freiburg, Germany. PDBids (a) 4AKE and (b) 1AKE.]

by Georg Schulz, of unliganded AK with AK in complex with the inhibitory bisubstrate analog  $\text{Ap}_5\text{A}$  (two ADPs connected by a fifth phosphate) indicates that two  $\sim 30$ -residue domains of AK close over the  $\text{Ap}_5\text{A}$ , thereby tightly binding it and excluding water (Fig. 17-34). This comparison also suggests how AK avoids falling into the energy well of tight-binding substrates and products. On binding substrate, a portion of the protein remote from the active site increases its chain mobility and thereby “absorbs” some of the free energy of substrate binding (recall that an X-ray structure determination reveals atomic mobilities as well as positions; Section 9-4). This region “resolidifies” on product release. This mechanism, Schulz has hypothesized, acts as an “energetic counterweight” that permits facile product release and hence maintains a high reaction rate.

#### f. Substrate Cycling Can Increase Flux Sensitivity

Even though a mechanism exists for amplifying the effect of a small change in  $[\text{ATP}]$  by producing a larger change in  $[\text{AMP}]$ , a 4-fold increase in  $[\text{AMP}]$  would allosterically increase the activity of PFK by only  $\sim 10$ -fold, an amount insufficient to account for the observed 100-fold

increase in glycolytic flux. Small changes in effector concentration (and therefore  $v_f$ ) can only cause relatively large changes in the flux through a reaction ( $v_f - v_r$ ) if the reaction is functioning close to equilibrium. The reason for this high sensitivity is that for such reactions, the term  $v_f/(v_f - v_r)$  in Eq. [17.8] (the elasticity coefficient) is large, that is, the reverse reaction contributes significantly to the value of the net flux. This is not the case for the PFK reaction.

Such equilibrium-like conditions may be imposed on a nonequilibrium reaction if a second enzyme catalyzes the regeneration of substrate from product in a thermodynamically favorable manner. Then  $v_r$  is no longer negligible compared to  $v_f$ . This situation requires that the forward process (formation of FBP from F6P) and reverse process (breakdown of FBP to F6P) be accomplished by different reactions since the laws of thermodynamics would otherwise be violated. In the following paragraphs, we discuss the nature of such substrate cycles.

Under physiological conditions, the reaction catalyzed by PFK:

is highly exergonic ( $\Delta G = -25.9 \text{ kJ} \cdot \text{mol}^{-1}$ , Table 17-1). Consequently, the back reaction has a negligible rate compared to the forward reaction. **Fructose-1,6-bisphosphatase (FBPase)**, however, which is present in many mammalian tissues (and which is an essential enzyme in gluconeogenesis; Section 23-1), catalyzes the exergonic hydrolysis of FBP ( $\Delta G = -8.6 \text{ kJ} \cdot \text{mol}^{-1}$ ):

Note that the combined reactions catalyzed by PFK and FBPase result in net ATP hydrolysis:

Such a set of opposing reactions is known as a substrate cycle because it cycles a substrate to an intermediate and back again. When this set of reactions was discovered, it was referred to as a **futile cycle** since its net result seemed to be the useless consumption of ATP. In fact, when it was found that the PFK activators AMP and F2,6P allosterically inhibit FBPase, it was suggested that only one of these enzymes was functional in a cell under any given set of conditions. It was subsequently demonstrated, however, that both enzymes often function simultaneously at significant rates.

### g. Substrate Cycling Can Account for Glycolytic Flux Variation

Eric Newsholme proposed that substrate cycles are not at all “futile” but, rather, have a regulatory function. The *in vivo* activities of enzymes and concentrations of metabolites are extremely difficult to measure, so that their values are rarely known accurately. However, let us make the physiologically reasonable assumption that a 4-fold increase in [AMP], resulting from the adenylate kinase reaction, causes PFK activity ( $v_f$ ) to increase from 10 to 90% of its maximum and FBPase activity ( $v_r$ ) to decrease from 90 to 10% of its maximum. The maximum activity of muscle PFK is known from *in vitro* studies to be ~10-fold greater than that of muscle FBPase. Hence, if we assign full activity of PFK to be 100 arbitrary units, then full activity of FBPase is 10 such units. The flux through the PFK reaction in glycolysis under conditions of low [AMP] is

$$J_{\text{low}} = v_f(\text{low}) - v_r(\text{low}) = 10 - 9 = 1$$

where  $v_f$  is catalyzed by PFK and  $v_r$  by FBPase. The flux under conditions of high [AMP] is

$$J_{\text{high}} = v_f(\text{high}) - v_r(\text{high}) = 90 - 1 = 89$$

Substrate cycling could therefore amplify the effect of changes in [AMP] on the net rate of phosphorylation of F6P. Without the substrate cycle, a 4-fold increase in [AMP] increases the net flux by about 9-fold, whereas with the cycle the same increase in [AMP] causes a  $J_{\text{high}}/J_{\text{low}} =$

$89/1 \approx 90$ -fold increase in net flux. Consequently, under the above assumptions, a 10% change in [ATP] could stimulate a 90-fold change in flux through the glycolytic pathway by a combination of the adenylate kinase reaction and substrate cycles.

### h. Physiological Impact of Substrate Cycling

Substrate cycling, if it has a regulatory function, does not increase the maximum flux through a pathway. On the contrary, it functions to decrease its minimum flux. In a sense, the substrate is put into a “holding pattern.” In the case described above, the cycling of substrate is the energetic “price” that a muscle must pay to be able to change rapidly from a resting state, in which substrate cycling is maximal, to one of sustained high activity. However, the rate of substrate cycling may itself be under hormonal or nervous control so as to increase the sensitivity of the metabolic system under conditions when high activity (fight or flight) is anticipated (we address the involvement of hormones in metabolic regulation in Sections 18-3E and 18-3F).

In some tissues, substrate cycles function to produce heat. For example, many insects require a thoracic temperature of 30°C to be able to fly. Yet bumblebees are capable of flight at ambient temperatures as low as 10°C. Bumblebee flight muscle FBPase has a maximal activity similar to that of its PFK (10-fold greater than our example for mammalian muscle); furthermore, unlike all other known muscle FBPases, it is not inhibited by AMP. This permits the FBPase and PFK of bumblebee flight muscle to be highly active simultaneously so as to generate heat. Since the maximal rate of FBP cycling possible in bumblebee flight muscle generates only 10 to 15% of the required heat, however, other mechanisms of thermogenesis must also be operative. Nevertheless, FBP cycling is probably significant because, unlike bumblebees, honeybees, which have no FBPase activity in their flight muscles, cannot fly when the temperature is low.

### i. Substrate Cycling, Thermogenesis, and Obesity

Many animals, including adult humans, generate some of their body heat, particularly when it is cold, through substrate cycling in muscle and liver, one mechanism of a process known as **nonshivering thermogenesis** (the muscle contractions of shivering or any other movement also produce heat; another mechanism of nonshivering thermogenesis is described in Section 22-3Da). Substrate cycling is stimulated by thyroid hormones (which stimulate metabolism in most tissues; Section 19-1D), as is indicated, for example, by the observation that rats lacking a functioning thyroid gland do not survive at 5°C. Chronically obese individuals tend to have lower than normal metabolic rates, which is probably due, in part, to a reduced rate of nonshivering thermogenesis. Such individuals therefore tend to be cold sensitive. Indeed, whereas normal individuals increase their rate of thyroid hormone activation on exposure to cold, genetically obese animals and obese humans fail to do so.

### j. The Overexpression of PFK Does Not Increase the Rate of Glycolysis

PFK has long been thought to be the controlling enzyme of glycolysis. It was therefore expected that increasing the level of expression of PFK in yeast cells via genetic engineering techniques would increase the rate of glycolysis independent of the demand for glycolytic products. It has been amply demonstrated, however, that this is not the case. Although PFK is a major regulatory enzyme of glycolysis, its catalytic activity *in vivo* is controlled by the concentrations of the effectors that reflect the needs of the demand blocks that utilize its products.

Metabolic control analysis, in addition to helping us recognize that control can be shared by several enzymes in a pathway, has also alerted us to the difference between control and regulation. *Although PFK has a major role in regulating the flux through glycolysis, it is controlled, in vivo, by factors outside the pathway.* An increase in the *in vivo* concentration of PFK will therefore not increase the flux through the pathway because these controlling factors adjust the catalytic activity of PFK only to meet the needs of the cell.

## 5 METABOLISM OF HEXOSES OTHER THAN GLUCOSE

While glucose is the primary end product of the digestion of starch and glycogen (Section 11-2D), three other hexoses are also prominent digestion products: **Fructose**, obtained from fruits and from the hydrolysis of sucrose (table sugar); **galactose**, obtained from the hydrolysis of lactose (milk sugar); and **mannose**, obtained from the digestion of polysaccharides and glycoproteins. After digestion, these monosaccharides enter the bloodstream, which carries them to various tissues. *The metabolism of fructose, galactose, and mannose proceeds by their conversion to glycolytic intermediates, from which point they are broken down in a manner identical to glucose.*

### A. Fructose

Fructose is a major fuel source in diets that contain large amounts of sucrose (a disaccharide of fructose and glucose; Fig. 11-13). There are two pathways for the metabolism of fructose; one occurs in muscle and the other occurs in liver. This dichotomy results from the different enzymes present in these various tissues.

Fructose metabolism in muscle differs little from that of glucose. Hexokinase (Section 17-2A), which converts glucose to G6P on entry into muscle cells, also phosphorylates fructose, yielding F6P (Fig. 17-35, *left*). The entry of fructose into glycolysis therefore involves only one reaction step.

Liver contains little hexokinase; rather, it contains glucokinase, which phosphorylates only glucose (Section 17-2A). Fructose metabolism in liver must therefore differ from that in muscle. In fact, liver converts fructose to glycolytic

intermediates through a pathway that involves seven enzymes (Fig. 17-35, *right*):

1. **Fructokinase** catalyzes the phosphorylation of fructose by ATP at C1 to form **fructose-1-phosphate**. *Neither hexokinase nor phosphofructokinase can phosphorylate fructose-1-phosphate at C6 to form the glycolytic intermediate fructose-1,6-bisphosphate.*

2. Class I aldolase (Section 17-2Da) has several isoenzyme forms. Muscle contains Type A aldolase, which is specific for fructose-1,6-bisphosphate. Liver, however, contains Type B aldolase, which also utilizes fructose-1-phosphate as a substrate (Type B aldolase is also called **fructose-1-phosphate aldolase**). In liver, fructose-1-phosphate therefore undergoes an aldol cleavage (Section 17-2D):

3. Direct phosphorylation of glyceraldehyde by ATP through the action of **glyceraldehyde kinase** forms the glycolytic intermediate glyceraldehyde-3-phosphate.

- 4-7. Alternatively, glyceraldehyde is converted to the glycolytic intermediate dihydroxyacetone phosphate by reduction to glycerol by NADH as catalyzed by alcohol dehydrogenase (Reaction 4), phosphorylation to glycerol-3-phosphate by ATP through the action of **glycerol kinase** (Reaction 5), and reoxidation by NAD<sup>+</sup> to dihydroxyacetone phosphate as mediated by glycerol phosphate dehydrogenase (Reaction 6). The DHAP is then converted to GAP by triose phosphate isomerase (Reaction 7).

As this complex series of reactions suggests, the liver has an enormous repertory of enzymes. This is because the liver is involved in the breakdown of a great variety of metabolites. Efficiency in metabolic processing dictates that many of these substances be converted to glycolytic intermediates. The liver, in fact, contains many of the enzymes necessary to do so.

#### a. Excessive Fructose Depletes Liver P<sub>i</sub>

At one time, fructose was thought to have advantages over glucose for intravenous feeding. The liver, however, encounters metabolic problems when the blood concentration of this sugar is too high (higher than can be attained by simply eating fructose-containing foods). When the fructose concentration is high, fructose-1-phosphate may be produced faster than Type B aldolase can cleave it. Intravenous feeding of large amounts of fructose may therefore result in high enough fructose-1-phosphate accumulation to severely deplete the liver's store of P<sub>i</sub>. Under these conditions, [ATP] drops, thereby activating glycolysis and lactate production. The lactate concentration in the blood and the consequent low pH under such conditions can reach life-threatening levels.

**Fructose intolerance**, a genetic disease in which ingestion of fructose causes the same fructose-1-phosphate accumulation as with its intravenous feeding, results from a deficiency of Type B aldolase. This condition appears to be

**Figure 17-35 Metabolism of fructose.** In muscle (left), the conversion of fructose to the glycolytic intermediate F6P involves only one enzyme, hexokinase. In liver (right), seven enzymes participate in the conversion of fructose to glycolytic

intermediates: (1) fructokinase, (2) fructose-1-phosphate aldolase, (3) glyceraldehyde kinase, (4) alcohol dehydrogenase, (5) glycerol kinase, (6) glycerol phosphate dehydrogenase, and (7) triose phosphate isomerase.

self-limiting: Individuals with fructose intolerance rapidly develop a strong distaste for anything sweet.

### B. Galactose

Galactose comprises half of the milk sugar lactose and is thus a major fuel constituent of dairy products. Galactose and glucose are epimers that differ only in their configuration about C4:

The enzymes of glycolysis are specific; they do not recognize the galactose configuration. An epimerization reaction must therefore be carried out before galactose enters the glycolytic pathway. This reaction takes place after the conversion of galactose to its uridine diphosphate derivative. The role of UDP-sugars and other nucleotidyl-sugars is discussed in more detail in Sections 18-2 and 23-3. The entire pathway converting galactose to a glycolytic intermediate, which was elucidated by Luis Leloir and is therefore known as the **Leloir pathway**, involves four reactions (Fig. 17-36):

1. Galactose is phosphorylated at C1 by ATP in a reaction catalyzed by **galactokinase**.

2. **Galactose-1-phosphate uridylyltransferase** transfers UDP-glucose's uridylyl group to galactose-1-phosphate to yield **glucose-1-phosphate (G1P)** and **UDP-galactose** by the reversible cleavage of UDP-glucose's pyrophosphoryl bond.

**Figure 17-36 Metabolism of galactose.** Four enzymes participate in the conversion of galactose to the glycolytic intermediate G6P: **(1)** galactokinase, **(2)** galactose-1-phosphate

uridylyltransferase, **(3)** UDP-galactose-4-epimerase, and **(4)** phosphoglucomutase.

**3. UDP-galactose-4-epimerase** converts UDP-galactose to UDP-glucose. This enzyme has an associated NAD<sup>+</sup>, which suggests that the reaction involves the sequential oxidation and reduction of the hexose C4 atom:

**4.** G1P is converted to the glycolytic intermediate G6P by the action of **phosphoglucomutase** (Section 18-1B).

### a. Galactosemia

**Galactosemia** is a genetic disease characterized by the inability to convert galactose to glucose. Its symptoms include failure to thrive, mental retardation, and in some instances death from liver damage. Most cases of galactosemia involve a mutation in the enzyme catalyzing Reaction 2 of the interconversion, galactose-1-phosphate uridylyltransferase. This reaction is a double displacement in which an enzyme His side chain first nucleophilically attacks the  $\alpha$ -phosphoryl group of UDP-glucose, displacing G1P and forming a uridylyl-His intermediate:

Galactose-1-phosphate then displaces the uridylyl group from the enzyme's His to form UDP-galactose:

A Gln residue forms hydrogen bonds to the uridylyl group's phosphoryl oxygens to stabilize the intermediate uridylyl-His. Mutation of this Gln to Arg inactivates the enzyme. Formation of UDP-galactose from galactose-1-phosphate

**Figure 17-37 Metabolism of mannose.** Two enzymes are required to convert mannose to the glycolytic intermediate F6P: (1) hexokinase and (2) phosphomannose isomerase.

is thus prevented, leading to a buildup of toxic metabolic by-products. For example, the increased galactose concentration in the blood results in a higher galactose concentration in the lens of the eye where this sugar is reduced to **galactitol**.

The presence of this sugar alcohol in the lens eventually causes cataract formation (clouding of the lens).

Galactosemia is treated by a galactose-free diet. Except for the mental retardation, this reverses all symptoms of the disease. The galactosyl units that are essential for the synthesis of glycoproteins (Section 11-3C) and glycolipids (Section 12-1D) may be synthesized from glucose by a reversal of the epimerase reaction. These syntheses therefore do not require dietary galactose.

### C. Mannose

Mannose, a common component of glycoproteins (Section 11-3C), and glucose are C2 epimers:

Mannose enters the glycolytic pathway after its conversion to F6P via a two-reaction pathway (Fig. 17-37):

1. Hexokinase (Section 17-2A) converts mannose to mannose-6-phosphate.
2. **Phosphomannose isomerase** then converts this aldose to the ketose F6P. The mechanism of the phosphomannose isomerase reaction resembles that catalyzed by phosphoglucose isomerase (Section 17-2B); it involves an enediolate intermediate.

## CHAPTER SUMMARY

**1 The Glycolytic Pathway** Glycolysis is the metabolic pathway by which most life-forms degrade glucose to two molecules of pyruvate with the concomitant net generation of two ATPs. The overall reaction:

occurs in 10 enzymatically catalyzed reactions.

**2 The Reactions of Glycolysis** In the preparatory stage of glycolysis, which encompasses its first five reactions, glucose reacts with two ATPs, in an “energy investment,” to form fructose-1,6-bisphosphate, which is subsequently converted to two molecules of glyceraldehyde-3-phosphate. In the second stage of glycolysis, the “payoff” stage, which comprises its last five reactions, glyceraldehyde-3-phosphate reacts with  $\text{NAD}^+$  and  $\text{P}_i$  to form the “high-energy” compound 1,3-bisphosphoglycerate. This compound reacts in the last four reactions of

the pathway with two ADPs to form pyruvate and two ATPs per molecule. The mechanisms of the 10 glycolytic enzymes have been elucidated through chemical and kinetic measurements combined with X-ray structural studies. The glycolytic enzymes exhibit stereospecificity in the reactions that they catalyze. In at least two kinases, phosphoryl transfer from substrate to water is prevented by substrate-induced conformational changes that form the active site and exclude water from it.

**3 Fermentation: The Anaerobic Fate of Pyruvate** The  $\text{NAD}^+$  consumed in the formation of 1,3-BPG must be regenerated if glycolysis is to continue. In the presence of  $\text{O}_2$ ,  $\text{NAD}^+$  is regenerated by oxidative phosphorylation in the mitochondria. Under anaerobic conditions in muscle, pyruvate is reduced by NADH, yielding lactate and  $\text{NAD}^+$  in a reaction catalyzed by lactate dehydrogenase. In many muscles, particularly during strenuous activity, the process of homolactic fermentation is a major free energy source. In anaerobic yeast,  $\text{NAD}^+$  is regenerated by alcoholic fermentation in two reactions. First pyruvate is

decarboxylated to acetaldehyde by pyruvate decarboxylase, an enzyme that requires thiamine pyrophosphate as a cofactor. The acetaldehyde is then reduced by NADH to form ethanol and NAD<sup>+</sup> in a reaction catalyzed by alcohol dehydrogenase.

**4 Metabolic Regulation and Control** Metabolic regulation is the process by which the steady-state flow of metabolites through a pathway is maintained. Metabolic control is the force exerted on the enzymes of the pathway in response to an external signal in order to increase or decrease the flow while maintaining the steady state to the extent possible. Homeostasis is the regulation of the steady state. Metabolic flow must be controlled to balance supply with demand and also to maintain homeostasis. It is possible for more than one enzyme to be rate-limiting in a metabolic pathway. Metabolic control analysis provides a framework for the study of metabolic systems *in vivo* that share control among more than one enzyme, and it quantitatively describes flux control and homeostasis. The flux control coefficient measures the sensitivity of the flux to a change in enzyme concentration. The elasticity coefficient measures the sensitivity of an enzymatic rate to the change in substrate concentration. Both supply and demand are involved in flux control and homeostasis. The response of the steady-state concentration of intermediates to changes in the supply or demand blocks depends entirely on the elasticity coefficients of the two blocks at the steady state. When the supply elasticity coefficient is greater than the demand elasticity coefficient, flux control lies in the demand portion of the pathway, and vice versa. Homeostasis control depends on large elasticity coefficients, whereas flux control requires a low elasticity coefficient and a high flux control coefficient. If the demand block controls the flux, the function of the supply block is to control homeostasis. Feedback

inhibition determines the range of concentration of intermediates at which there is a steady state. It maintains homeostasis at physiologically reasonable metabolite concentrations, sometimes far from their equilibrium values.

The flux through a reaction that is close to equilibrium is very sensitive to changes in substrate concentration. Hence, the steady-state flux through a metabolic pathway can only be regulated by a nonequilibrium reaction. Nonequilibrium reactions are controlled by allosteric interactions, substrate cycles, covalent modification, and genetic (long-term) control mechanisms. In muscle glycolysis, phosphofructokinase (PFK) catalyzes one of the flux-generating steps. Although PFK is inhibited by high concentrations of one of its substrates, ATP, the 10% variation of [ATP] over the range of metabolic activity has insufficient influence on PFK activity to account for the observed 100-fold range in glycolytic flux. [AMP] has a 4-fold variation in response to the 10% variation of [ATP] through the action of adenylate kinase. Although AMP relieves the ATP inhibition of PFK, its concentration variation is also insufficient to account for the observed glycolytic flux range. However, the product of the PFK reaction, fructose-1,6-bisphosphate, is hydrolyzed to F6P by FBPase, which is inhibited by AMP. The substrate cycle catalyzed by these two enzymes confers, at least in principle, the necessary sensitivity of the glycolytic flux to variations in [AMP]. Substrate cycling is an important source of nonshivering thermogenesis.

**5 Metabolism of Hexoses Other than Glucose** Digestion of carbohydrates yields glucose as the primary product. Other prominent products are fructose, galactose, and mannose. These monosaccharides are metabolized through their conversion to glycolytic intermediates.

## PROBLEMS

1. Write out the reactions of the glycolytic pathway from glucose to lactate using structural formulas for all intermediates. Learn the names of these intermediates and the enzymes that catalyze the reactions.

2.  $\Delta G^{\circ}$  for the aldolase reaction is  $+22.8 \text{ kJ} \cdot \text{mol}^{-1}$ . In the cell, at  $37^{\circ}\text{C}$ , the mass action ratio  $[\text{DHAP}]/[\text{GAP}] = 5.5$ . Calculate the equilibrium ratio of  $[\text{FBP}]/[\text{GAP}]$  when  $[\text{GAP}]$  is (a)  $2 \times 10^{-5} \text{ M}$  and (b)  $10^{-3} \text{ M}$ .

3. The pH dependence of the rate of the triose phosphate isomerase (TIM) reaction has characteristic  $\text{pK}$ 's of 6.5 and 9.5. His 95, a catalytically essential residue, has been shown to have a  $\text{pK}$  of 4.5. Why doesn't the pH rate curve indicate the existence of this  $\text{pK}$ ?

4. Arsenate ( $\text{AsO}_4^{3-}$ ), a structural analog of phosphate, can act as a substrate for any reaction in which phosphate is a substrate. Arsenate esters, unlike phosphate esters, are kinetically as well as thermodynamically unstable and hydrolyze almost instantaneously. Write a balanced overall equation for conversion of glucose to pyruvate in the presence of ATP, ADP,  $\text{NAD}^+$ , and either (a) phosphate or (b) arsenate. (c) Why is arsenate a poison?

5. When glucose is degraded anaerobically via glycolysis there is no overall oxidation or reduction of the substrate. The fermentation reaction is therefore said to be "balanced." The free energy required for ATP formation is nevertheless obtained from favorable electron-transfer reactions. Which metabolic intermediate is the electron donor and which is the electron acceptor when glucose is degraded by a balanced glycolytic fermentation: (a) in muscle and (b) in yeast?

6. In which carbon atoms of pyruvate would radioactivity be found if glucose metabolized by the glycolytic pathway were labeled with  $^{14}\text{C}$  at: (a) C1 and (b) C4? (Note: Assume that triose phosphate isomerase is able to equilibrate dihydroxyacetone phosphate and glyceraldehyde-3-phosphate.)

\*7. The following reaction is catalyzed by an enzyme very similar to Class I aldolases:

Write a plausible mechanism for this reaction using curved arrows to indicate the electron flow.

8. The half-reactions involved in the LDH reaction and their standard reduction potentials are

Calculate  $\Delta G$  for the reaction at the biochemical standard state under the following conditions:

- $[\text{lactate}]/[\text{pyruvate}] = 1$ ;  $[\text{NAD}^+]/[\text{NADH}] = 1$
- $[\text{lactate}]/[\text{pyruvate}] = 160$ ;  $[\text{NAD}^+]/[\text{NADH}] = 160$
- $[\text{lactate}]/[\text{pyruvate}] = 1000$ ;  $[\text{NAD}^+]/[\text{NADH}] = 1000$
- Under what conditions will the reaction spontaneously favor NADH oxidation?
- In order for the free energy change of the glyceraldehyde-3-phosphate dehydrogenase reaction to favor glycolysis, the  $[\text{NAD}^+]/[\text{NADH}]$  ratio must be maintained close to  $10^3$ . Under anaerobic conditions in mammalian muscle, lactate dehydrogenase performs this function. How high can the  $[\text{lactate}]/[\text{pyruvate}]$  ratio become in muscle cells before the LDH-catalyzed reaction ceases to be favorable in the direction of  $\text{NAD}^+$  production while maintaining the foregoing  $[\text{NAD}^+]/[\text{NADH}]$  ratio constant?

9. Although it is not the primary flux-control point for glycolysis, pyruvate kinase is subject to allosteric regulation. (a) What is the metabolic importance of regulating flux through the pyruvate kinase reaction? (b) What is the advantage of activating pyruvate kinase with fructose-1,6-bisphosphate?

\*10. Based on the involvement of thiamine pyrophosphate (TPP) in the pyruvate decarboxylase reaction, which of the following reactions, if any, might be expected to utilize TPP as a cofactor?

Write hypothetical mechanisms for each reaction showing where TPP is involved or why it is unnecessary.

11. The glycolytic pathway for glucose breakdown is almost universal. Some bacteria, however, utilize an alternate route called the **Entner-Doudoroff pathway** (Fig. 17-38). Like the glycolytic pathway in yeast, the final product is ethanol. (a) Write balanced equations for the conversion of glucose to ethanol and  $\text{CO}_2$  via the Entner-Doudoroff pathway and the yeast alcoholic fermentation. (b) Infer from your stoichiometries why the glycolytic pathway rather than the Entner-Doudoroff pathway is almost universal.

**Figure 17-38** Entner–Doudoroff pathway for glucose breakdown.

**\*12.** The hydrolysis of ATP to ADP in the cell results in a concomitant change in [AMP] as mediated by adenylate kinase. (a) Assuming that  $[\text{ATP}] \gg [\text{AMP}]$  and that the total adenine nucleotide concentration in the cell,  $A_T = [\text{AMP}] + [\text{ADP}] + [\text{ATP}]$ ,

is constant, derive an expression for [AMP] in terms of [ATP] and  $A_T$ . (b) Assuming an initial  $[\text{ATP}]/[\text{ADP}]$  of 10 and  $A_T = 5 \text{ mM}$ , calculate the ratio of the final to initial values of [AMP] on a 10% decrease of [ATP].

### 4 Glycogen Storage Diseases

*Everything should be made as simple as possible, but not simpler.*

Albert Einstein

Glucose, a major metabolic fuel source, is degraded via glycolysis to produce ATP (Chapter 17). Higher organisms protect themselves from potential fuel shortage by polymerizing excess glucose for storage as high molecular mass glucans (glucose polysaccharides) that may be readily mobilized in times of metabolic need. In plants, this glucose storage substance is starch, a mixture of the  $\alpha(1 \rightarrow 4)$ -linked glucan  $\alpha$ -amylose (Fig. 11-18) and amylopectin, which differs from  $\alpha$ -amylose by the presence of  $\alpha(1 \rightarrow 6)$  branches every 24 to 30 residues (Fig. 11-19). In animals, the storage glucan is **glycogen** (Fig. 18-1), which differs from amylopectin only in that its branches occur every 8 to 14 residues. Glycogen occurs in 100- to 400-Å-diameter cytoplasmic granules (Figs. 11-20 and 18-1c), which contain up to 120,000 glucose units. They are especially prominent in the cells that make the greatest use of glycogen, muscle (maximally 1–2% glycogen by weight) and liver cells (maximally 10% glycogen by weight, an ~12-h energy supply for the body). Glycogen granules also contain the enzymes

that catalyze glycogen synthesis and degradation as well as some of the enzymes that regulate these processes.

As we shall see in this chapter, glycogen's glucose units are mobilized by their sequential removal from the glucan chains' nonreducing ends (ends lacking a C1—OH group). *Glycogen's highly branched structure is therefore physiologically significant: It permits glycogen's rapid degradation through the simultaneous release of the glucose units at the end of every branch.*

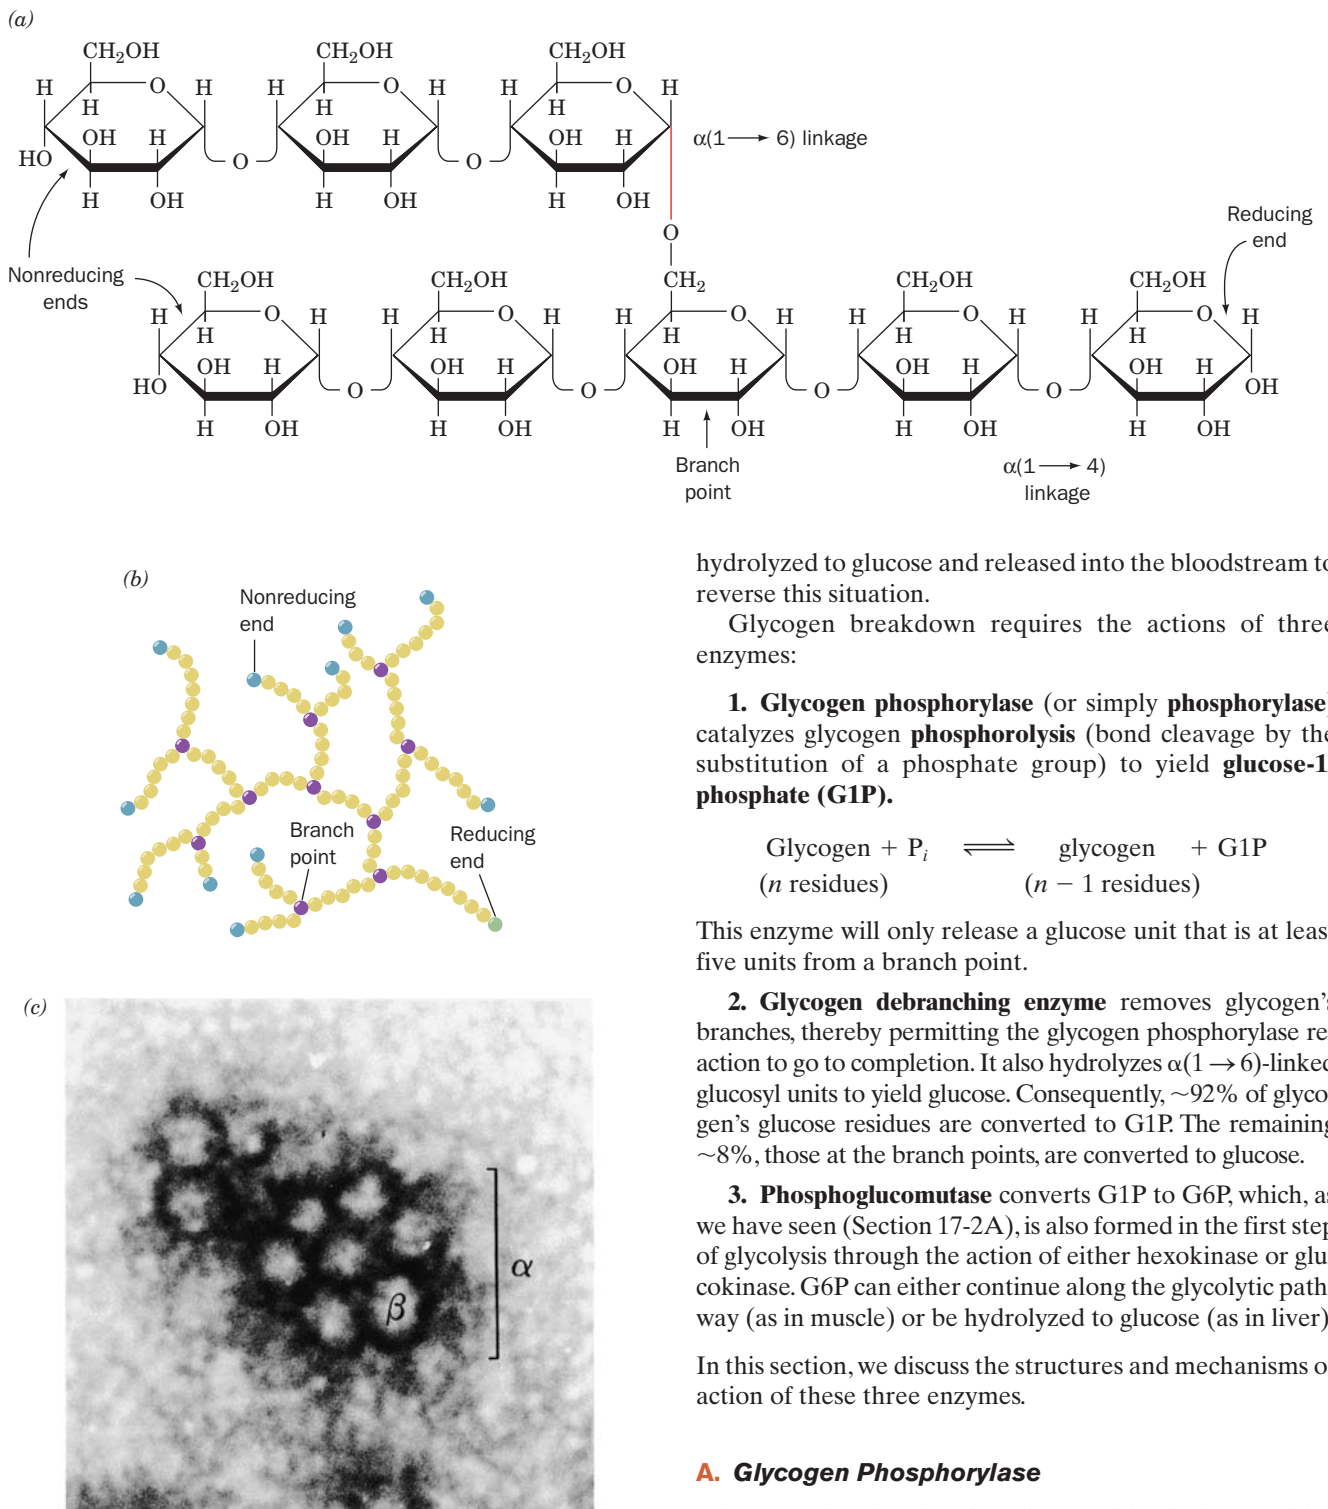

Why does the body go to such metabolic effort to use glycogen for energy storage when fat, which is far more abundant in the body, seemingly serves the same purpose? The answer is threefold:

1. Muscles cannot mobilize fat as rapidly as they can glycogen.
2. The fatty acid residues of fat cannot be metabolized anaerobically (Section 25-2).
3. Animals cannot convert fatty acids to glucose (Section 23-1), so fat metabolism alone cannot adequately maintain essential blood glucose levels (Section 18-3F).

As with all metabolic processes, there are several levels on which glycogen metabolism may be understood. We shall examine this process in order to understand the pathway's thermodynamics and the reaction mechanisms of its individual steps but will emphasize the mechanisms by which glycogen synthesis and breakdown rates are controlled. We began our consideration of metabolic control mechanisms in Section 17-4 with a discussion of the role of allosteric interactions and substrate cycles in the regulation of glycolysis. Glycogen metabolism's more complex control systems provide us with examples of several additional control processes: covalent modification of enzymes and enzyme cascades. In addition, we shall consider glycogen metabolism as a model for the role of hormones in the overall regulatory process. We end the chapter by discussing the consequences of genetic defects in various enzymes of glycogen metabolism.

### 1 GLYCOGEN BREAKDOWN

Liver and muscle are the two major storage tissues for glycogen. In muscle, the need for ATP results in the conversion of glycogen to glucose-6-phosphate (G6P) for entry into glycolysis. In liver, low blood glucose concentration triggers glycogen breakdown to G6P, which in this case is

**Figure 18-1 Structure of glycogen.** (a) Molecular formula. In the actual molecule the chains are much longer than shown. (b) Schematic diagram illustrating its branched structure. Branch points in the actual molecule are separated by 8 to 14 glucosyl units. Note that the molecule, no matter how big, has but one reducing end. (c) Electron micrograph of a glycogen granule from rat skeletal muscle. Each granule ( $\alpha$ ) consists of several spherical glycogen molecules ( $\beta$ ) and its associated proteins. [From Calder, P.C., *Int. J. Biochem.* **23**, 1339 (1991). Copyright Elsevier Science. Used with permission.]

hydrolyzed to glucose and released into the bloodstream to reverse this situation.

Glycogen breakdown requires the actions of three enzymes:

**1. Glycogen phosphorylase** (or simply **phosphorylase**) catalyzes glycogen **phosphorolysis** (bond cleavage by the substitution of a phosphate group) to yield **glucose-1-phosphate (G1P)**.

This enzyme will only release a glucose unit that is at least five units from a branch point.

**2. Glycogen debranching enzyme** removes glycogen's branches, thereby permitting the glycogen phosphorylase reaction to go to completion. It also hydrolyzes  $\alpha(1 \rightarrow 6)$ -linked glucosyl units to yield glucose. Consequently,  $\sim 92\%$  of glycogen's glucose residues are converted to G1P. The remaining  $\sim 8\%$ , those at the branch points, are converted to glucose.

**3. Phosphoglucomutase** converts G1P to G6P, which, as we have seen (Section 17-2A), is also formed in the first step of glycolysis through the action of either hexokinase or glucokinase. G6P can either continue along the glycolytic pathway (as in muscle) or be hydrolyzed to glucose (as in liver).

In this section, we discuss the structures and mechanisms of action of these three enzymes.

### A. Glycogen Phosphorylase

Glycogen phosphorylase is a dimer of identical 842-residue (97-kD) subunits that catalyzes the controlling step in glycogen breakdown. It is regulated both by allosteric interactions and by covalent modification. *The enzyme-catalyzed modification/demodification process yields two forms of phosphorylase: phosphorylase a, which has a phosphoryl group esterified to Ser 14 in each of its subunits, and phosphorylase b, which lacks these phosphoryl groups. Phosphorylase's allosteric inhibitors, ATP, G6P, and glucose, and its allosteric activator, AMP (to name only the enzyme's most prominent*

effectors), interact differently with the phospho- and dephosphoenzymes, resulting in an extremely sensitive control process. We study this control process in Section 18-3C.

### a. Structural Domains and Binding Sites

The high-resolution X-ray structures of phosphorylase *a* and phosphorylase *b* were determined by Robert Fletterick and Louise Johnson, respectively. The structure of phosphorylase *b*, despite its lack of a Ser-linked phosphate, is very similar to that of phosphorylase *a* (Fig. 18-2). Both structures have two domains, an N-terminal domain (residues 1–484; among the largest known domains), and a C-terminal domain (residues 485–842). The N-terminal domain is

**Figure 18-2** X-ray structure of rabbit muscle glycogen phosphorylase *a*. The homodimeric enzyme is drawn in ribbon form and viewed along its 2-fold axis. Each subunit consists of an N-terminal domain, which is subdivided into an interface subdomain (residues 1–315) and a glycogen-binding subdomain (residues 316–484), and a C-terminal domain (residues 485–842). The enzyme's several ligands are drawn in stick form colored according to type with N blue, O red, P orange, and C atoms as indicated. The active site is marked by a bound glucose molecule (C yellow). Pyridoxal phosphate (PLP) is covalently linked to the side chain of Lys 678 in the C-terminal domain (C magenta). In addition, the enzyme binds its allosteric effector AMP (C cyan) and **maltose** (C green), an  $\alpha(1 \rightarrow 4)$ -linked glucose heptamer, which is bound in the enzyme's glycogen storage site. Ser 14-P, the phosphoryl group on Ser 14, is drawn in space-filling form. [X-ray structure coordinates courtesy of Stephen Sprang, University of Texas Southwest Medical Center.]  See

**Kinemage Exercise 14-1**

further divided into an interface subdomain (residues 1–315), which includes the covalent modification site (Ser 14), the allosteric effector site, and all the intersubunit contacts in the dimer; and a glycogen-binding subdomain (residues 316–484), which contains the “glycogen storage site” (see below). The catalytic site is located at the center of the subunit where these two subdomains come together with the C-terminal domain. In Section 18-3 we discuss the allosteric behavior of glycogen phosphorylase and the conformational differences between phosphorylases *a* and *b*.

Glycogen forms a left-handed helix with 6.5 glucose residues per turn, similar to  $\alpha$ -amylose (Fig. 11-18*b*). An  $\sim 30$ -Å-long crevice on the surface of the phosphorylase monomer that has the same radius of curvature as glycogen connects the glycogen storage site, which binds glycogen, to the active site, which phosphorylates it. *Since this crevice can accommodate four or five sugar residues in a chain but is too narrow to admit branched oligosaccharides, it provides a clear physical rationale for the inability of phosphorylase to cleave glycosyl residues closer than five units from a branch point.* Presumably the glycogen storage site increases the catalytic efficiency of phosphorylase by permitting it to phosphorylate many glucose residues on the same glycogen particle without having to dissociate and reassociate completely between catalytic cycles.

### b. Pyridoxal Phosphate Is an Essential Cofactor for Phosphorylase

Phosphorylase contains **pyridoxal-5'-phosphate (PLP)**

**Pyridoxal-5'-phosphate (PLP)**

**PLP covalently bound to phosphorylase via a Schiff base to Lys 679**

and requires it for activity. This vitamin B<sub>6</sub> derivative is covalently linked to phosphorylase via a Schiff base to Lys 679. PLP is similarly linked to a variety of enzymes involved in amino acid metabolism, where it is an essential cofactor in transamination reactions (Section 26-1Aa). The

**Figure 18-3** The reaction mechanism of glycogen

**phosphorylase.** Here PL is an enzyme-bound pyridoxal group and  $BH^+$  is a positively charged amino acid side chain, probably that of Lys 568, necessary for the maintenance of PLP electrical neutrality. **(1)** Formation of an  $E \cdot P_i \cdot$  glycogen ternary complex. **(2)** Formation of a shielded oxonium ion intermediate from the  $\alpha$ -linked terminal glucosyl residue involving acid catalysis by  $P_i$  as facilitated by proton transfer from PLP. The oxonium ion has the half-chair conformation. **(3)** Reaction of  $P_i$  with the oxonium ion with overall retention of configuration about C1 to form  $\alpha$ -D-glucose-1-phosphate. The glycogen, which has one less residue than before, cycles back to Step 1.

an intriguing example of nature's opportunism in using the same cofactor to perform different chemistries.

Extensive studies on phosphorylase using PLP analogs in which various parts of this molecule are missing or modified indicate that only its phosphate group participates in the catalytic process. Indeed, the X-ray structures of phosphorylase reveal that only PLP's phosphate group is near this enzyme's active site. This phosphoryl group most probably functions as an acid-base catalyst.

### c. Kinetics and Reaction Mechanism

The phosphorylase reaction results in the cleavage of the C1—O1 bond from a nonreducing terminal glucosyl unit of glycogen, yielding G1P. This reaction proceeds with retention of configuration, which suggests that the phosphorylase occurs via a double displacement mechanism (two sequential nucleophilic substitutions, each occurring with inversion of configuration; Fig. 16-6c) involving a covalent glucosyl-enzyme intermediate. Yet, phosphorylase exhibits Rapid Equilibrium Random Bi Bi kinetics (Section 14-5), not Ping Pong kinetics, as would be expected for a double displacement mechanism. Furthermore, all attempts to establish the existence of the putative covalent intermediate have been unsuccessful.

An alternative mechanism (Fig. 18-3), which is compatible with the available kinetic, chemical, and structural data, commences with the formation of a ternary enzyme  $\cdot P_i \cdot$  glycogen complex, followed by the generation of an intermediate shielded oxonium ion similar to the transition state in the lysozyme reaction (which also involves

mechanism of PLP participation in the phosphorylase reaction must differ from that in these other enzymes because, for example, reduction of the Schiff base with  $NaBH_4$  ( $-HC=N- \rightarrow -H_2C-NH-$ ) has no effect on the activity of phosphorylase, whereas it inactivates the PLP-requiring enzymes of amino acid metabolism. This is

glycosidic bond cleavage in a polysaccharide; Section 15-2B). *Bond cleavage, with its consequent oxonium ion formation, is assisted by protonation of the glycosidic oxygen by the  $P_i$  substrate (acid catalysis)*. Phosphorylase has no protein nucleophilic or carboxylate groups in the vicinity of the scissile glycosidic bond and hence would be unable to form a covalent intermediate as does lysozyme. However, since the PLP phosphoryl group is within hydrogen bonding distance of the  $P_i$ , it appears that bond cleavage is facilitated by the simultaneous protonation of the reacting  $P_i$  by the PLP phosphoryl group in a kind of proton relay. The resulting oxonium ion (Fig. 18-3) is stabilized through its formation of an ion pair with the anionic  $P_i$  (electrostatic catalysis), which subsequently collapses to yield product, G1P, in a reaction step that is facilitated by the abstraction of a proton from  $P_i$  by the PLP phosphoryl group (base catalysis).

Support for the oxonium ion mechanism comes from the observation that **1,5-gluconolactone**

**1,5-Gluconolactone**

is a potent inhibitor of phosphorylase. 1,5-Gluconolactone has the same half-chair conformation as the proposed oxonium ion, suggesting that it is a transition state analog that mimics the oxonium ion at the active site of phosphorylase (Section 15-1F).

### B. Phosphoglucomutase

Phosphorylase converts the glucosyl units of glycogen to G1P, which, in turn, is converted by phosphoglucomutase to G6P either for entry into glycolysis in muscle or hydroly-

ysis to glucose in liver. The X-ray structure of rabbit muscle phosphoglucomutase indicates that the active site of this 561-residue monomeric enzyme is largely buried at the bottom of a particularly deep crevice in the protein. The phosphoglucomutase reaction is similar to that catalyzed by phosphoglycerate mutase (Section 17-2Ha). A phosphoryl group is transferred from the active phosphoenzyme to G6P, forming **glucose 1,6-bisphosphate (G1,6P)**, which then rephosphorylates the enzyme to yield G1P (Fig. 18-4). An important difference between this enzyme and phosphoglycerate mutase is that the phosphoryl group in phosphoglucomutase is covalently bound to a Ser hydroxyl group rather than to a His imidazole nitrogen.

G1,6P occasionally dissociates from phosphoglucomutase, resulting in the inactivation of this enzyme. The presence of small amounts of G1,6P is therefore necessary to keep phosphoglucomutase fully active. This intermediate is provided by **phosphoglucokinase**, which catalyzes the phosphorylation of the C6—OH group of G1P by ATP.

### C. Glycogen Debranching Enzyme

Glycogen debranching enzyme, an ~1540-residue monomer, acts as an  $\alpha(1 \rightarrow 4)$  transglycosylase (glycosyl transferase) by transferring an  $\alpha(1 \rightarrow 4)$ -linked trisaccharide unit from a “limit branch” of glycogen to the nonreducing end of another branch (Fig. 18-5). This reaction forms a new  $\alpha(1 \rightarrow 4)$  linkage with three more units available for phosphorylase-catalyzed phosphorolysis. The  $\alpha(1 \rightarrow 6)$  bond linking the remaining glycosyl residue in the branch to the main chain is hydrolyzed (not phosphorylated) by the same debranching enzyme to yield glucose and debranched glycogen. Thus *debranching enzyme has different active sites for the transferase reaction and the  $\alpha(1 \rightarrow 6)$ -glucosidase reaction*. The presence of two independent catalytic activities on the same enzyme no doubt improves the efficiency of the debranching process.

**Figure 18-4** The mechanism of action of phosphoglucomutase. (1) The OH group at C1 of G6P attacks the phosphoenzyme to form a dephosphoenzyme—G1,6P intermediate. (2) The Ser—OH

group on the dephosphoenzyme attacks the phosphoryl group at C6 to regenerate the phosphoenzyme with the formation of G1P.

**Figure 18-5** Reactions catalyzed by debranching enzyme. The enzyme transfers the terminal three  $\alpha(1 \rightarrow 4)$ -linked glucose residues from a “limit branch” of glycogen to the nonreducing end of another branch. The  $\alpha(1 \rightarrow 6)$  bond of the residue

remaining at the branch point is hydrolyzed by further action of debranching enzyme to yield free glucose. The newly elongated branch is subject to degradation by glycogen phosphorylase.

The maximal rate of the glycogen phosphorylase reaction is much greater than that of the glycogen debranching reaction. Consequently, the outermost branches of glycogen, which comprise nearly half of its residues, are degraded in muscle in a few seconds under conditions of high metabolic demand. Glycogen degradation beyond this point requires debranching and hence occurs more slowly. This, in part, accounts for the fact that a muscle can sustain its maximum exertion for only a few seconds.

#### **D. Thermodynamics of Glycogen Metabolism: The Need for Separate Pathways of Synthesis and Breakdown**

The  $\Delta G^{\circ}$  ( $\Delta G$  under standard biochemical conditions) for the phosphorylase reaction is  $+3.1 \text{ kJ} \cdot \text{mol}^{-1}$ , so, as Eq. [3.15] indicates, this reaction is at equilibrium ( $\Delta G = 0$ ) at  $25^{\circ}\text{C}$  when  $[\text{P}_i]/[\text{G1P}] = 3.5$ . In the cell, however, this concentration ratio varies between 30 and 100, which places  $\Delta G$  in the range  $-5$  to  $-8 \text{ kJ} \cdot \text{mol}^{-1}$ ; that is, *under physiological conditions, glycogen breakdown is exergonic*. The synthesis of glycogen from G1P under physio-

logical conditions is therefore thermodynamically unfavorable without free energy input. Consequently, *glycogen biosynthesis and breakdown must occur by separate pathways*. Thus we encounter a recurrent metabolic strategy: *Biosynthetic and degradative pathways of metabolism are almost always different (Section 16-1)*. There are two important reasons for this. The first, as we have seen, is that both pathways may be required under similar *in vivo* metabolite concentrations. This situation is thermodynamically impossible if one pathway is just the reverse of the other. The second reason is equally important: Reactions catalyzed by different enzymes can be independently regulated, which permits very fine flux control. We have seen this principle in operation in the glycolytic conversion of fructose-6-phosphate (F6P) to fructose-1,6-bisphosphate (F1,6P) by phosphofructokinase (PFK; Section 17-4F). The reverse process in that case (hydrolysis of F1,6P) is catalyzed by fructose bisphosphatase (FBPase). Independent control of those two enzymes provides precise regulation of glycolytic flux.

Glycogen metabolism, like glycolysis, is exquisitely regulated by the independent control of its synthetic and

degradative pathways. In the next section we examine the pathway of glycogen synthesis and, in Section 18-3, we explore the regulatory process.

## 2 GLYCOGEN SYNTHESIS

Although the thermodynamic arguments presented in Section 18-1D demonstrate that glycogen synthesis and breakdown must occur by separate pathways, it was not thermodynamic arguments that led to the general acceptance of this idea. Rather, it was the elucidation of the cause of **McArdle's disease**, a rare inherited glycogen storage disease that results in painful muscle cramps on strenuous exertion (Section 18-4). The muscle tissue from individuals with McArdle's disease exhibits no glycogen phosphorylase activity and is therefore incapable of glycogen breakdown. Their muscles, nevertheless, contain moderately high quantities of normal glycogen. Clearly, there must be separate pathways for glycogen synthesis and breakdown.

Since the direct conversion of G1P to glycogen and  $P_i$  is thermodynamically unfavorable (positive  $\Delta G$ ) under all physiological  $P_i$  concentrations, glycogen biosynthesis requires an additional exergonic step. This is accomplished, as Luis Leloir discovered in 1957, by combining G1P with uridine triphosphate (UTP) to form **uridine diphosphate glucose (UDP-glucose or UDPG)**:

**Uridine diphosphate glucose (UDPG)**

**Figure 18-6** Reaction catalyzed by **UDP-glucose pyrophosphorylase**. The reaction is a phosphoanhydride exchange in which the phosphoryl oxygen of G1P attacks the  $\alpha$  phosphorus atom of UTP to form UDPG and release  $PP_i$ . The  $PP_i$  is rapidly hydrolyzed by inorganic pyrophosphatase.

UDPG's "high-energy" status permits it to spontaneously donate glucosyl units to the growing glycogen chain.

The enzymes catalyzing the three steps involved in the glycogen synthesis pathway are **UDP-glucose pyrophosphorylase**, **glycogen synthase**, and **glycogen branching enzyme**. In this section, we examine the reactions catalyzed by these enzymes. Discussion of how these enzymes are controlled is reserved for Section 18-3.

### A. UDP-Glucose Pyrophosphorylase

UDP-glucose pyrophosphorylase catalyzes the reaction of UTP and G1P (Fig. 18-6). In this reaction, the phosphoryl oxygen of G1P attacks the  $\alpha$  phosphorus atom of UTP to form UDPG and release  $PP_i$ . The  $\Delta G^{\circ'}$  of this phosphoanhydride exchange is, as expected, nearly zero. However, the  $PP_i$  formed is hydrolyzed in an exergonic reaction by the omnipresent enzyme inorganic pyrophosphatase. The overall reaction for the formation of UDPG is therefore also exergonic:

*The cleavage of a nucleoside triphosphate to form  $PP_i$  is a common biosynthetic strategy. The free energy of  $PP_i$  hydrolysis can then be utilized together with the free energy of nucleoside triphosphate hydrolysis to drive an otherwise endergonic reaction to completion (Section 16-4Ca).*

## B. Glycogen Synthase

In the next step of glycogen synthesis, the glucosyl unit of UDPG is transferred to the C4—OH group on one of glycogen's nonreducing ends to form an  $\alpha(1 \rightarrow 4)$ -glycosidic bond (Fig. 18-7). The glycogen synthase reaction, like those of glycogen phosphorylase and lysozyme, is thought to involve a glucosyl oxonium ion intermediate or transition state since it is also inhibited by 1,5-gluconolactone, an analog that mimics the oxonium ion's half-chair geometry.

The  $\Delta G^\circ$  for the glycogen synthase reaction is  $-13.4 \text{ kJ} \cdot \text{mol}^{-1}$ , making the overall reaction spontaneous under the same conditions that glycogen breakdown by glycogen phosphorylase is also spontaneous. The rates of both reactions may then be independently controlled. There is, however, an energetic price for doing so. In this case, for each molecule of *GIP* that is converted to glycogen and then regenerated, one molecule of *UTP* is hydrolyzed to *UDP* and *P<sub>i</sub>*. The cyclic synthesis and breakdown of glycogen is therefore not a perpetual motion "machine" but, rather, is an "engine" that is powered by *UTP* hydrolysis. The *UTP* is replenished through a phosphate-transfer reaction mediated by **nucleoside diphosphate kinase** (Section 28-1Ba):

so that *UTP* hydrolysis is energetically equivalent to *ATP*

hydrolysis. This reaction occurs via a Ping Pong mechanism in which an active site His residue is transiently phosphorylated at its *N*<sub>δ</sub> position much as occurs in the phosphoglycerate mutase reaction of glycolysis (Section 17-2Ha).

Mammals express two ~70% identical isoforms of glycogen synthase, one mainly in muscle, and the other in liver, much as is the case with glycogen phosphorylase. Plants and bacteria express **starch/glycogen synthases** but these employ **ADP-glucose** as glucose donors rather than **UDP-glucose** and exhibit very little sequence similarity to animal glycogen synthases.

### a. Glycogenin Initiates Glycogen Synthesis

Glycogen synthase cannot simply link together two glucose residues; it can only extend an already existing  $\alpha(1 \rightarrow 4)$ -linked glucan chain. How, then, is glycogen synthesis initiated? The answer is that the first step in glycogen synthesis is the self-catalyzed attachment of a glucose residue to the Tyr 194 OH group of a 332-residue homodimeric protein named **glycogenin**. Glycogenin, which was discovered by William Whelan, further extends the glucan chain by up to ~9 additional **UDP-glucose**-supplied residues, forming a "primer" for the initiation of glycogen synthesis. Only at this point does glycogen synthase commence glycogen synthesis, which it initiates on the "primer" while tightly complexed to glycogenin. However, these proteins dissociate after the growing glycogen

**Figure 18-7** Reaction catalyzed by glycogen synthase. The reaction involves a glucosyl oxonium ion intermediate.

granule has reached some minimum size. Analysis of glycogen granules for glycogenin and glycogen synthase shows that they are present in a 1:1 ratio. Evidently, each glycogen molecule (Fig. 18-1c) is associated with one molecule each of glycogenin and glycogen synthase.

The X-ray structure of rabbit muscle glycogenin in complex with UDPG (Fig. 18-8), determined by Thomas Hurley and Peter Roach, reveals that the enzyme's N-terminal portion consists of a Rossmann-like fold (Section 8-3Bi) that is common to the nucleotide-binding domains of most glycosyltransferases. The OH group of its Tyr 194 is 21 and 16 Å distant from C1 of the UDPG's glucosyl group on the same and on the opposite subunit. Moreover, the glycosyltransferase reaction occurs with retention of configuration about the glucosyl C1 atom. This suggests that the glucosyl group is first transferred to an intermediate nucleophile and then transferred to Tyr 194 or to a glucose group that is linked to Tyr 194 (a double displacement reaction). Site-directed mutagenesis has identified Asp 162 as the probable nucleophile, whereas Asp 159 appears to have a role in binding and activating the acceptor molecule. Evidently, glycogenin undergoes large conformational changes during

**Figure 18-8** X-ray structure of rabbit muscle glycogenin. The upper subunit of this homodimeric enzyme is colored in rainbow order from its N-terminus (blue) to its C-terminus (red) and the lower subunit is pale green. UDPG is drawn in ball-and-stick form with C green, N blue, O red, and P orange. The side chains of Tyr 194, to which the glucose residue at glycogen's reducing end is linked, and Asp 159 and Asp 162, are drawn in stick form with C cyan and O red.  $Mn^{2+}$  ions, which are thought to electrostatically stabilize the leaving group, UDP, are represented by lavender spheres. Residues 262 to 332, which are implicated in binding glycogen synthase, are not visible in the X-ray structure and hence disordered. [Based on an X-ray structure by Thomas Hurley and Peter Roach, Indiana University School of Medicine. PDBid 1LL2.]

its catalytic cycle, although the nature of these changes is unknown. Indeed, it is unclear whether a given subunit transfers glucosyl groups to itself or to the opposite subunit.

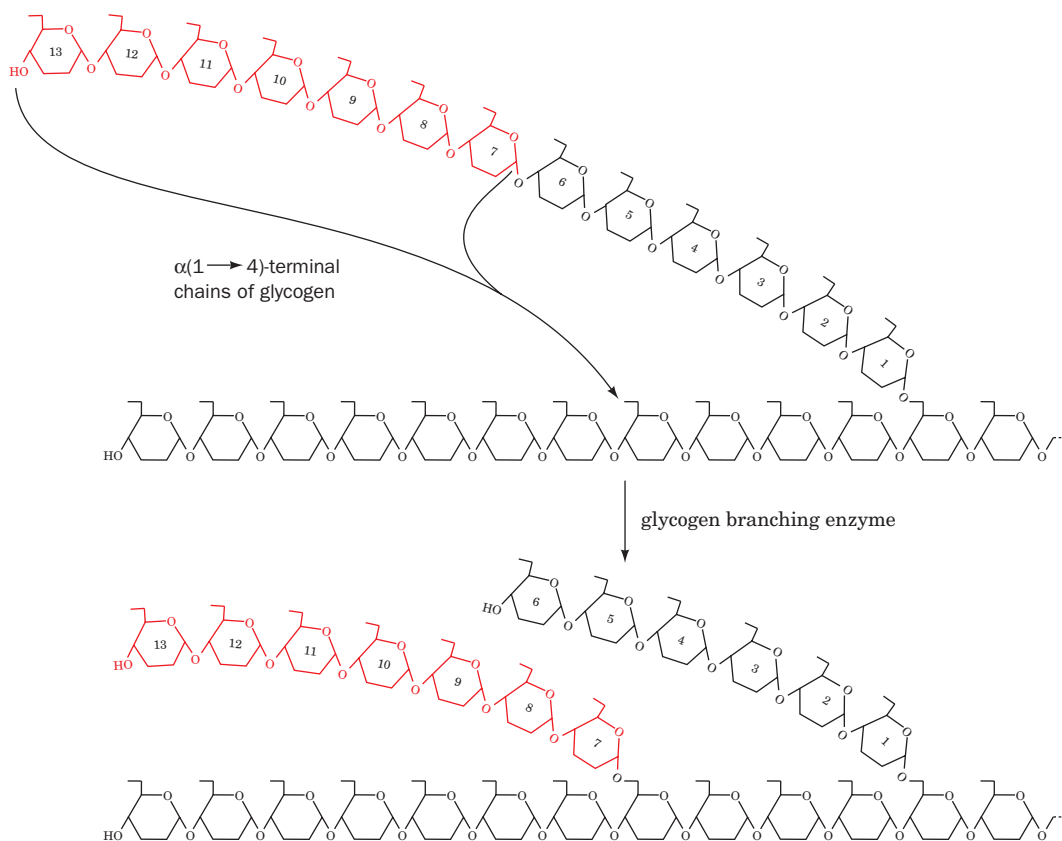

### C. Glycogen Branching Enzyme

Glycogen synthase catalyzes only  $\alpha(1 \rightarrow 4)$ -linkage formation to yield  $\alpha$ -amylose. Branching to form glycogen is accomplished by an  $\sim 700$ -residue monomeric enzyme, **amylo-(1,4  $\rightarrow$  1,6)-transglycosylase (glycogen branching enzyme)**, which is distinct from glycogen debranching enzyme. Branches are created by the transfer of terminal chain segments consisting of  $\sim 7$  glucosyl residues to the C6—OH groups of glucose residues on the same or another glycogen chain (Fig. 18-9). Each transferred segment must come from a chain of at least 11 residues, and the new branch point must be at least 4 residues away from other branch points.

Debranching (Section 18-1C) involves breaking and reforming  $\alpha(1 \rightarrow 4)$ -glycosidic bonds and only the hydrolysis of  $\alpha(1 \rightarrow 6)$ -glycosidic bonds; branching, on the other hand, involves breaking  $\alpha(1 \rightarrow 4)$ -glycosidic bonds and reforming  $\alpha(1 \rightarrow 6)$  linkages. The need to hydrolyze glycogen's  $\alpha(1 \rightarrow 6)$ -glycosidic bonds rather than to convert them to  $\alpha(1 \rightarrow 4)$  linkages is explained by the energetics of these reactions. The free energy of hydrolysis of an  $\alpha(1 \rightarrow 4)$ -glycosidic bond is  $-15.5 \text{ kJ} \cdot \text{mol}^{-1}$ , whereas that of an  $\alpha(1 \rightarrow 6)$ -glycosidic bond is only  $-7.1 \text{ kJ} \cdot \text{mol}^{-1}$ . Consequently, the hydrolysis of an  $\alpha(1 \rightarrow 4)$ -glycosidic bond drives the synthesis of an  $\alpha(1 \rightarrow 6)$ -glycosidic bond, but the reverse reaction is endergonic.

#### a. Glycogen Particles Are Fabricated to Optimize Glucose Mobilization

The biological function of glycogen is to maximize the density of stored glucose units consistent with the need to rapidly mobilize it under conditions of high metabolic demand. To do so, three related parameters must be optimized: the number of tiers of branches in a glycogen molecule, the number of branches per tier, and the average chain length per tier. For a glycogen molecule with a fixed

**Figure 18-9 The branching of glycogen.** Branches are formed by transferring a 7-residue terminal segment from an  $\alpha(1 \rightarrow 4)$ -linked glucan chain to the C6—OH group of a glucose residue on the same or another chain.

number of residues, the number of outer branches from which glucose can be mobilized before debranching is required decreases as the average chain length increases (recall that debranching is a slower process than phosphorylation). However, molecules with longer chains have a greater number of glucose residues that can be phosphorylated between branch points. Since the density of outermost branches is sterically limited, the maximum size of a glycogen molecule decreases as the average number of branches per tier increases. Mature glycogen particles from a variety of animals have  $\sim 12$  tiers of branches, with  $\sim 2$  branches per tier and branch lengths averaging  $\sim 13$  residues. Mathematical analysis suggests that these values are close to optimal for mobilizing the greatest amount of glucose in the shortest possible time.

### 3 CONTROL OF GLYCOGEN METABOLISM

We have just seen that both glycogen synthesis and breakdown are exergonic under the same physiological conditions. If both pathways operate simultaneously, however,

all that is achieved is wasteful hydrolysis of UTP. This situation is similar to that of the phosphofructokinase–fructose bisphosphatase substrate cycle (Section 17-4Ff). Glycogen phosphorylase and glycogen synthase therefore must be under stringent control such that glycogen is either synthesized or utilized according to cellular needs. The astonishing mechanism of this control is our next topic of discussion. It involves not only allosteric control and substrate cycles but enzyme-catalyzed covalent modification of both glycogen synthase and glycogen phosphorylase. The covalent modification reactions are themselves ultimately under hormonal control through an enzymatic cascade.

#### A. Direct Allosteric Control of Glycogen Phosphorylase and Glycogen Synthase

As we saw in Section 17-4B, the net flux of reactants,  $J$ , through a step in a metabolic pathway is the difference between the forward and reverse reaction velocities,  $v_f$  and  $v_r$ . The fractional variation in the flux through any step in a pathway with a change in substrate concentration approaches infinity as that reaction step approaches equilibrium ( $v_f \approx v_r$ ; Eq. [17.4]). The flux through a near-equilibrium reaction

**Figure 18-10** The control of glycogen phosphorylase activity. The enzyme may assume the enzymatically inactive T conformation (*above*) or the catalytically active R form (*below*). The conformation of phosphorylase *b* is allosterically controlled by effectors such as AMP, ATP, and G6P and is mostly in the T state under physiological conditions. In contrast, the modified form of the enzyme, phosphorylase *a*, is largely unresponsive to

these effectors and is mostly in the R state unless there is a high level of glucose. Under usual physiological conditions, the enzymatic activity of glycogen phosphorylase is essentially determined by its rates of modification and demodification. Note that only the T form enzyme is subject to phosphorylation and dephosphorylation, so effector binding influences the rates of these modification/demodification events.

is therefore all but uncontrollable. As we have seen for the case of PFK and FBPase, however, *precise flux control of a pathway is possible when an enzyme functioning far from equilibrium is opposed by a separately controlled enzyme. Then,  $v_f$  and  $v_r$  vary independently. In fact, under these circumstances, even the flux direction is controllable if  $v_r$  can be made larger than  $v_f$ .* Exactly this situation occurs in glycogen metabolism through the opposition of the glycogen phosphorylase and glycogen synthase reactions. The rates of both of these reactions are under allosteric control by effectors that include ATP, G6P, and AMP. In muscle, glycogen phosphorylase is activated by AMP and inhibited by ATP and G6P (Fig. 18-10, *left*). Glycogen synthase, on the other hand, is activated by G6P. When there is high demand for ATP (low [ATP], low [G6P], and high [AMP]), glycogen phosphorylase is stimulated and glycogen synthase is inhibited, so flux through this pathway favors glycogen breakdown. When [ATP] and [G6P] are high, the reverse is true and glycogen synthesis is favored.

The structural differences between the active (R) and inactive (T) conformations of glycogen phosphorylase (Figs. 18-11*a* and 18-11*b*) can be understood in terms of the symmetry model of allosterism (Section 10-4B). The T-state enzyme has a buried active site and hence a low affinity for its substrates, whereas the R-state enzyme has an accessible catalytic site and a high-affinity phosphate binding site.

AMP promotes phosphorylase's T (*inactive*)  $\rightarrow$  R (*active*) conformational shift by binding to the R state of the enzyme at its allosteric effector site (Fig. 18-10, *left*). In doing so, AMP's adenine, ribose, and phosphate groups bind to separate segments of the polypeptide chain so as to link the active site, the subunit interface, and the N-terminal region (Fig. 18-11*c*), the latter having undergone a large conformational shift (36 Å for Ser 14) from its position in the T-state enzyme (Figs. 18-11*a* and 18-11*b*). AMP binding also causes glycogen phosphorylase's tower helices (Figs. 18-2 and 18-11) to tilt and pull apart so as to achieve a more favorable packing. These tertiary movements trigger a concerted T  $\rightarrow$  R transition, which largely consists of an  $\sim 10^\circ$  relative rotation of the two subunits about an axis at the subunit interface that is perpendicular to the dimer's 2-fold axis of symmetry. The enzyme's 2-fold symmetry is thereby preserved in accordance with the symmetry model of allosterism (Section 10-4B). The movement of the tower helices also displaces and disorders a loop (the 280s loop, residues 282–286), which covers the T-state active site so as to prevent substrate access. It also causes the Arg 569 side chain, which is located in the active site near the PLP phosphoryl group and the  $P_i$ -binding site, to rotate in a way that increases the enzyme's binding affinity for its anionic  $P_i$  substrate (Figs. 18-11*a* and 18-11*b*).

Curiously, ATP also binds to the allosteric effector site, but in the T state, so that it inhibits rather than promotes

**Figure 18-11 Conformational changes in glycogen phosphorylase.** Ribbon diagrams of one subunit of the dimeric enzyme glycogen phosphorylase *b* (a) in the T state in the absence of allosteric effectors and (b) in the R state with bound AMP. The view is of the lower (orange) subunit in Fig. 18-2 rotated by  $\sim 45^\circ$  about a horizontal axis. The tower helix is blue; the N-terminal helix is cyan; the N-terminal residues that change conformation on AMP binding are red; and residues 281 to 288, the 280s loop, which in the R state are mostly disordered and hence not seen, are green. Of the groups that are shown in space-filling representation, the side chain of Ser 14, the phosphorylation site, and AMP, which binds only to the R state enzyme, have C green, N blue, O red, and P orange; the side chain of Arg 569, which reorients in the T  $\rightarrow$  R transition so as to interact with the substrate phosphate, has C cyan and N blue; and sulfate ions bound near Ser 14 and at the active site of the R state enzyme, which mimic the sterically similar phosphate ions, have O red and S orange. The PLP at the active site is drawn in stick form with C magenta, N blue, O red, and P orange. [Based on X-ray structures by Louise Johnson, Oxford University, U.K. PDBids 8GPB and 7GPB.] (c) The portion of the glycogen phosphorylase *a* dimer in the vicinity of the dimer interface showing the position of the Ser 14 phosphate group, the AMP bound in the allosteric effector site, and the active site-bound glucose molecule. The view is along the molecular 2-fold axis and hence is similar to that in Fig. 18-2. Residues 5 to 80 and 265 to 310 are, respectively, cyan and blue in one subunit and pink and magenta in the other. The AMP and glucose are shown in space-filling representation with C green, N dark blue, O red, and P orange. The Ser 14 phosphate group is also shown in space-filling representation with O dark red and P yellow. [X-ray structure coordinates courtesy of Stephen Sprang, University of Texas Southwest Medical Center.]  See Kinemage Exercises 14-2 and 14-3

the T  $\rightarrow$  R conformational shift. This is because, as structural analysis indicates, the  $\beta$  and  $\gamma$  phosphate groups of ATP bind to the enzyme such that its ribose and  $\alpha$  phosphate

groups are displaced relative to those of AMP, thus destabilizing the R state. The inhibitory action of ATP on phosphorylase is therefore simply understood: It competes with

AMP for binding to phosphorylase and, in doing so, prevents the relative motions of the three polypeptide segments required for phosphorylase activation.

The above allosteric interactions are superimposed on an even more sophisticated control system involving covalent modifications (phosphorylation/dephosphorylation) of glycogen phosphorylase and glycogen synthase. These modifications alter the structures of the enzymes so as to change their responses to allosteric regulators. We shall therefore discuss the general concept of covalent modification and how it increases the sensitivity of a metabolic system to effector concentration changes. We subsequently consider the functions of such modifications in glycogen metabolism. Only then will we be in a position to take up the detailed consideration of allosteric control in glycogen metabolism.

### B. Covalent Modification of Enzymes by Cyclic Cascades: Effector "Signal" Amplification

Glycogen synthase and glycogen phosphorylase can each be enzymatically interconverted between two forms with different kinetic and allosteric properties through a complex series of reactions known as a **cyclic cascade**. The interconversion of these different enzyme forms involves distinct, enzyme-catalyzed **covalent modification and demodification reactions**.

Compared with other regulatory enzymes, enzymatically interconvertible enzyme systems:

1. Can respond to a greater number of allosteric stimuli.
2. Exhibit greater flexibility in their control patterns.
3. Possess enormous amplification potential in their responses to variations in effector concentrations.

**Figure 18-12** A monocyclic enzyme cascade. (a) General scheme, where F and R are, respectively, the modifying and demodifying enzymes. These are allosterically converted from their inactive to their active conformations on binding their respective effectors,  $e_1$  and  $e_2$ . The target enzyme, E, is more

This is because *the enzymes that modify and demodify a target enzyme are themselves under allosteric control. It is therefore possible for a small change in concentration of an allosteric effector of a modifying enzyme to cause a large change in the concentration of an active, modified target enzyme*. Such a cyclic cascade is diagrammed in Fig. 18-12.

#### a. Description of a General Cyclic Cascade

Figure 18-12a shows a general scheme for a cyclic cascade where, by convention, the more active target enzyme form has the subscript  $a$  and the less active form has the subscript  $b$ . Here, modification, in this case, phosphorylation, activates the enzyme. Note that the modifying enzymes, F and R, are active only when they have bound their respective allosteric effectors  $e_1$  and  $e_2$ . The kinetic mechanisms for the interconversion of the unmodified and modified forms of the target enzyme,  $E_b$  and  $E_a$ , are indicated in Fig. 18-12b.

In the steady state, the fraction of E in the active form,  $[E_a]/[E]_T$  (where  $[E]_T = [E_a] + [E_b]$  is the total enzyme concentration), determines the rate of the reaction catalyzed by E. This fraction is a function of the total concentrations of the modifying enzymes,  $[F]_T$  and  $[R]_T$ , the concentrations of their allosteric effectors,  $e_1$  and  $e_2$ , the dissociation constants of these effectors,  $K_1$  and  $K_2$ , and the substrate dissociation constants,  $K_f$  and  $K_r$ , of the target enzymes, as well as the rate constants,  $k_f$  and  $k_r$ , for the interconversions themselves (Fig. 18-12). This relationship is obviously quite complex. Nevertheless, it can be shown that, in a cyclic cascade, a relatively small change in the concentration of  $e_1$ , the allosteric effector of the modifying enzyme F, can result in a much larger change in  $[E_a]/[E]_T$ , the fraction of E in the active form. In other words, *the cascade functions to amplify the sensitivity of the system to an allosteric effector*.

We have so far considered the covalent modification of only one enzyme, a **monocyclic cascade**. Imagine a **bicyclic cascade** involving the covalent modification of one of the modifying enzymes (F), as well as the metabolic target enzyme (E) (Fig. 18-13). As you might expect, the amplification potential of a "signal,"  $e_1$ , as well as the control flexibility of such a system, is enormous.

active in the modified form ( $E_a$ ) and less active in the unmodified form ( $E_b$ ). Dashed arrows symbolize catalysis of the indicated reactions. (b) Chemical equations for the interconversion of the target enzyme's unmodified and modified forms  $E_b$  and  $E_a$ .

The activities of both glycogen phosphorylase and glycogen synthase are controlled by bicyclic cascades. Let us now examine the enzymatic interconversions involved in these bicyclic cascades. We shall specifically focus on the covalent modifications of glycogen phosphorylase and glycogen synthase, the structural effects of these covalent modifications, and how these structural changes affect the interactions of their allosteric effectors. We shall then consider the cyclic cascades as a whole, studying the various modification enzymes involved and their “ultimate” allosteric effectors. Finally, we shall see how the various cyclic cascades of glycogen metabolism function in different physiological situations.

### C. Glycogen Phosphorylase Bicyclic Cascade

In 1938, Carl and Gerty Cori found that glycogen phosphorylase exists in two forms, the *b* form that requires AMP for activity, and the *a* form that is active without AMP. It nevertheless took 20 years for the development of the protein chemistry techniques through which Edwin Krebs and Edmond Fischer demonstrated, in 1959, that phosphorylases *a* and *b* correspond to forms of the protein in which a specific residue, Ser 14, is enzymatically phosphorylated or dephosphorylated, respectively.

#### a. Glycogen Phosphorylase: The Cascade's Target Enzyme

The activity of glycogen phosphorylase is allosterically controlled, as we saw, through AMP activation and ATP, G6P, and glucose inhibition (Section 18-3A). Superim-

posed on this allosteric control is control by enzymatic interconversion through a bicyclic cascade involving the actions of three enzymes (Figs. 18-13 and 18-14, left):

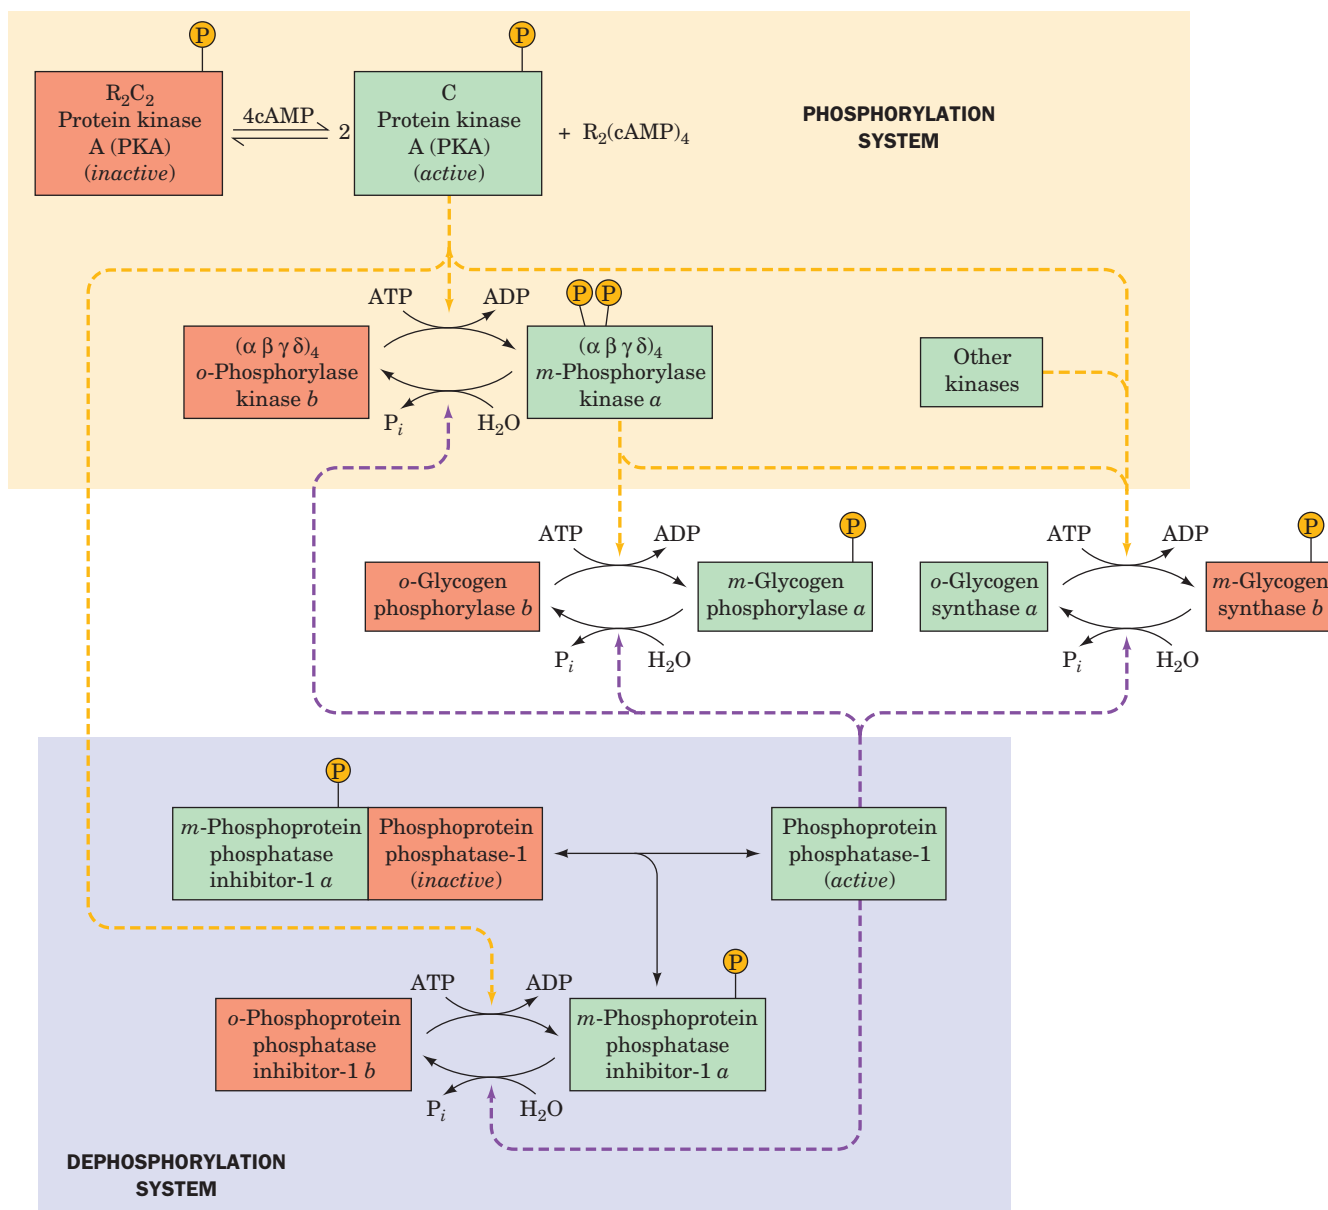

- 1. Phosphorylase kinase**, which specifically phosphorylates Ser 14 of glycogen phosphorylase *b* (Fig. 18-13, enzyme  $F_2$ ).
- 2. Protein kinase A**, which phosphorylates and thereby activates phosphorylase kinase (Fig. 18-13, enzyme  $F_1$ ).
- 3. Phosphoprotein phosphatase-1**, which dephosphorylates and thereby deactivates both glycogen phosphorylase *a* and phosphorylase kinase (Fig. 18-13, enzymes  $R_1$  and  $R_2$ ).

In an interconvertible enzyme system, the “modified” form of the enzyme bears the prefix *m* and the “original” (unmodified) form bears the prefix *o*, whereas the enzyme’s most active and least active forms are identified by the suffixes *a* and *b*, respectively. In this case, *o*-phosphorylase *b* (unmodified, least active) is the form under allosteric control by AMP, ATP, and G6P (Fig. 18-10, left). Phosphorylation to yield *m*-phosphorylase *a* (modified, most active) all but removes the effects of these allosteric modulators. In terms of the symmetry model of allosterism (Section 10-4B), the phosphorylation of Ser 14 shifts the enzyme’s *T* (inactive)  $\rightleftharpoons$  *R* (active) equilibrium in favor of the *R* state (Fig. 18-10, right). Indeed, phosphorylase *a*’s Ser 14-phosphoryl group is analogous to an allosteric activator: It forms ion pairs with two Arg side chains on the opposite subunit, thereby knitting the subunits together in much the same way as does AMP when it binds tightly to a site between the subunits (Fig. 18-11b).

**Figure 18-13** A bicyclic enzyme cascade. See the legend of Fig. 18-12 for symbol definitions. In a bicyclic cascade, one of the modifying enzymes ( $F_2$ ) is also subject to covalent

modification. It is active in the modified state ( $F_{2a}$ ) and inactive in the unmodified state ( $F_{2b}$ ).

**Figure 18-14** Schematic diagram of the major enzymatic modification/demodification systems involved in the control of glycogen metabolism in muscle. Modification (phosphorylation) systems are shaded in yellow, demodification (dephosphorylation) systems are shaded in lavender, active enzymes/inhibitors are shaded in green, and inactive enzymes/inhibitors are shaded in orange. Dashed yellow and purple arrows indicate facilitation of a modification and demodification reaction. Note that glycogen phosphorylase activity is controlled by a bicyclic enzyme cascade

(left) and glycogen synthase activity is controlled by both a bicyclic and a monocyclic enzyme cascade (right). By convention, the modified form of the enzyme bears the prefix *m* and the “original” (unmodified) form bears the prefix *o*. The most active and least active forms of the enzymes are identified by the suffixes *a* and *b*, respectively. Further control of phosphoprotein phosphatase-1 covalent modification is diagrammed in Fig. 18-22.  See Guided Exploration 15: Control of Glycogen Breakdown, and the Animated Figures

In the resting cell, the concentrations of ATP and G6P are high enough to inhibit phosphorylase *b*. The level of phosphorylase activity is therefore largely determined by the fraction of the enzyme present as phosphorylase *a*. The steady-state fraction of phosphorylated enzyme ( $E_a$ ) depends on the relative activities of phosphorylase kinase ( $F_2$ ), protein kinase A ( $F_1$ ), and phosphoprotein phos-

phatase-1 ( $R_1$  and  $R_2$ ). This interrelationship is remarkably elaborate for glycogen phosphorylase. Let us consider the actions of these enzymes.

#### b. Protein Kinase A: A Crucial Regulatory Link

Phosphorylase kinase, which converts phosphorylase *b* to phosphorylase *a*, is itself subject to covalent modification

(Fig. 18-14). For phosphorylase kinase to be fully active,  $\text{Ca}^{2+}$  must be present (see below) and the protein must be phosphorylated.

In both the glycogen phosphorylase and glycogen synthase cascades, the primary intracellular signal,  $e_1$ , is **adenosine-3',5'-cyclic monophosphate (3',5'-cyclic AMP or cAMP)**. The cAMP concentration in a cell is a function of the ratio of its rate of synthesis from ATP by **adenylate cyclase (AC; also called adenylyl cyclase)** and its rate of breakdown to AMP by a enzymes known as **cAMP-phosphodiesterases (cAMP-PDEs; Section 19-2E)**:

AC is, in turn, activated by certain hormones (Sections 18-3Ea and 19-2D).

cAMP is absolutely required for the activity of **protein kinase A [PKA; also called cAMP-dependent protein kinase (cAPK)]**, an enzyme that phosphorylates specific Ser and/or Thr residues of numerous cellular proteins, including phosphorylase kinase and glycogen synthase. These proteins all contain PKA's consensus recognition sequence, Arg-Arg-X-Ser/Thr-Y, where Ser/Thr is the phosphorylation site, X is any small residue, and Y is a large hydrophobic residue. In the absence of cAMP, PKA is an inactive heterotetramer consisting of two regulatory (R) and two catalytic (C) subunits, R<sub>2</sub>C<sub>2</sub>. The cAMP binds to the regulatory subunits so as to cause the dissociation of active catalytic monomers (Fig. 18-14; top). The intracellular concentration of cAMP therefore determines the fraction of PKA in its active form and thus the rate at which it phosphorylates its substrates. In fact, in all known eukaryotic cases, the physiological effects of cAMP are exerted through the activation of specific protein kinases.

The X-ray structure of the 350-residue C subunit of mouse PKA in complex with  $\text{Mg}^{2+}$ -ATP and a 20-residue inhibitor peptide was determined by Susan Taylor and Janusz Sowadski (Fig. 18-15), and that of a similar complex of the porcine heart enzyme was determined by Robert Huber. The C subunit, as are other kinases of known structure (e.g., Figs. 17-5 and 17-15), is bilobal. It has an N-terminal domain that consists of a 5-stranded  $\beta$  sheet and an  $\alpha$  helix, and a larger C-terminal domain that is mainly  $\alpha$  helical. A deep cleft between the lobes is occupied by the  $\text{Mg}^{2+}$ -ATP and the segment of the inhibitor peptide that includes the above 5-residue consensus sequence. This cleft therefore contains PKA's catalytic site, with the small domain contributing the nucleotide-binding site and the large subunit supplying the substrate-binding and catalytic residues.

The C subunit of PKA must be phosphorylated at Thr 197 for activity. Thr 197 is part of the so-called activation loop (comprising residues 184–208), which is located at the "mouth" of the cleft between PKA's N- and C-terminal domains. The phosphoryl group at Thr 197 knits together the various components of PKA into its active conformation via extensive interactions with the protein. Most notably, the phosphoryl group interacts with Arg 165, a conserved residue that is adjacent to Asp 166, the catalytic base that activates the substrate protein's target Ser/Thr hydroxyl group for phosphorylation, thereby properly orienting PKA's active site residues.

Protein kinases play key roles in the signaling pathways by which many hormones, growth factors, neurotransmitters, and toxins affect the functions of their target cells (Chapter 19), as well as in controlling metabolic pathways. Indeed, 518 human proteins constituting ~2.3% of human genes are predicted to be protein kinases, which accounts for the observation that ~30% of the proteins in mammalian cells are phosphorylated. The >1000 different protein kinases that have been sequenced share a conserved catalytic core corresponding to residues 40 to 280 of PKA's

**Figure 18-15** X-ray structure of the catalytic (C) subunit of mouse protein kinase A (PKA). The protein is in complex with ATP and a 20-residue peptide segment of a naturally occurring protein kinase inhibitor. The N-terminal domain is pink and its C-terminal domain is cyan with its activation loop blue. The polypeptide inhibitor is orange and its pseudo-target sequence, Arg-Arg-Asn-Ala-Ile, is purple, with the Ala replacing the Ser to be phosphorylated green (note that the enzyme's true target sequence is Arg-Arg-X-Ser/Thr-Y, where X is a small residue, Y is a large hydrophobic residue, and Ser/Thr, which is replaced by Ala in the polypeptide inhibitor, is the residue that the enzyme phosphorylates). The ATP and the phosphoryl group of phosphoThr 197 are shown in space-filling form and the side chains of the catalytically essential Arg 165, Asp 166, and Thr 197 are shown in stick form, all colored according to atom type (C green, N blue, O red, and P orange). Note that the inhibitor's pseudo-target sequence is in close proximity to the ATP's  $\gamma$  phosphate group, the group that the enzyme transfers. [Based on an X-ray structure by Susan Taylor and Janusz Sowadski, University of California at San Diego. PDBid 1ATP.]  See Interactive Exercise 10 and Kinemage Exercise 15-1

C subunit. In addition to phosphorylating other proteins, many protein kinases are themselves phosphoproteins whose activities are controlled by phosphorylation, often at their activation loops. However, since PKA is normally fully phosphorylated at Thr 197 and resistant to dephosphorylation, it is unclear whether its activity is regulated *in vivo* by phosphorylation/dephosphorylation.

### c. PKA's R Subunit Competitively Inhibits Its C Subunit

The R subunit of PKA has a well-defined domain structure that was first characterized by limited proteolysis. It consists of, from N- to C-terminus, a dimerization domain, an autoinhibitor segment, and two tandem homologous cAMP-binding domains, A and B. In the  $R_2C_2$  complex, the autoinhibitor segment, which resembles the C subunit's substrate peptide, binds in the C subunit's active site (as does the inhibitory peptide in Fig. 18-15) so as to block substrate binding. Thus, the R subunit is a competitive inhibitor of PKA's substrate proteins.

Each R subunit cooperatively binds two cAMPs. When the B domain lacks bound cAMP, it masks the A domain so as to prevent it from binding cAMP. However, the binding of cAMP to the B domain triggers a conformational change that permits the A domain to bind cAMP, which, in turn, releases the C subunits from the complex (see below).

Taylor determined the X-ray structure of the R subunit lacking its N-terminal 91 residues and in complex with two

cAMPs (Fig. 18-16a). This truncated protein is unable to dimerize but, in the absence of cAMP, forms a tight inactive complex with the C subunit, and on binding cAMP releases active C subunits as do intact  $R_2$  dimers. As previously predicted by sequence alignments, the A and B domains are structurally similar to each other and to the prokaryotic cAMP-binding transcriptional regulator named **catabolite gene activator protein (CAP; Section 31-3Cb)**. The autoinhibitory segment, which in the free R subunit is extremely sensitive to proteolysis, has its first 21 residues disordered in the X-ray structure.

The X-ray structure of the truncated R subunit in complex with the C subunit binding AMPPNP (Fig. 18-16b), also determined by Taylor, reveals that the R subunit has undergone a massive conformational reorganization relative to its cAMP-binding structure. The most striking such change is that the 25-residue, bent 2-helix segment linking domains A and B (purple in Fig. 18-16a) has coalesced to form a single straight helix such that the  $\beta$  sandwich in the R subunit's B domain has rotated by  $\sim 180^\circ$  relative to that in the A domain and separated from it. As a consequence of this  $\sim 60$ -Å screwlike shift of the B domain, the elongated globular structure of the cAMP complex changes to a dumbbell-like shape in which the interface between the A and B domains in the cAMP complex is replaced by extensive interactions with the large domain of the C subunit. In addition, the helical regions of the A and B domains undergo extensive conformational changes that eliminate their cAMP binding sites by separating their phosphate-binding pockets from their adenine-binding pockets. All of this positions the R subunit's autoinhibitor segment in the C subunit's active site cleft, thereby inactivating it.

(a)

**Figure 18-16** X-ray structures of the regulatory (R) subunit of bovine protein kinase A (PKA). (a) The R subunit lacking its N-terminal 91 residues (which form its dimerization domain) in complex with cAMP. The N-terminal region, which includes its autoinhibitor segment, is red, domain A is green, domain B is orange, and the 2-helix segment linking domains A and B is purple. The cAMPs, which are drawn in space-filling form colored according to atom type (C cyan, N blue, O red, and P orange), each bind at the opening of an 8-stranded  $\beta$  sandwich with their phosphate group abutting the N-terminal end of a short helical segment. (b) The truncated R subunit in complex with the C subunit that is binding AMPPNP. The R subunit is

(b)

colored as in Part a and the C subunit is colored as in Fig. 18-15. The C subunit is rotated 180° about the vertical axis relative to Fig. 18-15 and the  $\beta$  sandwich of domain A is oriented similarly to that in Part a. Note the dramatic conformational differences between the R subunit in Parts a and b, which in large part is caused by the coalescence and straightening of the two helices linking domains A and B in the cAMP complex. Also note that the now ordered N-terminal portion of the R subunit's autoinhibitor segment occupies the C subunit's active site cleft. [Based on X-ray structures by Susan Taylor, University of California at San Diego. PDBids 1RGS and 2QCS.]

#### d. Phosphorylase Kinase: Coordination of Enzyme Activation with $[Ca^{2+}]$

Phosphorylase kinase (PhK) is activated by  $Ca^{2+}$  concentrations as low as  $10^{-7}$  M as well as by covalent modification. This 1300-kD enzyme consists of four nonidentical subunits that form the active oligomer  $(\alpha\beta\gamma\delta)_4$ . The isolated  $\gamma$  subunit is capable of full catalytic activity (ability to convert phosphorylase b to phosphorylase a), whereas the  $\alpha$ ,  $\beta$ , and  $\delta$  subunits are inhibitors of the catalytic reaction.

The  $\delta$  subunit, which is known as **calmodulin (CaM)**, confers  $Ca^{2+}$  sensitivity on the complex. When  $Ca^{2+}$  binds to calmodulin's four  $Ca^{2+}$ -binding sites, this ubiquitous eukaryotic regulatory protein undergoes an extensive conformational change (see below) that activates phosphorylase kinase. Glycogen phosphorylase therefore becomes

phosphorylated and the rate of glycogen breakdown increases. The physiological significance of this  $Ca^{2+}$  activation process is that nerve impulses trigger muscle contraction through the release of  $Ca^{2+}$  from intracellular reservoirs (Section 35-3C). This transient increase in cytosolic  $[Ca^{2+}]$  induces both muscle contraction and the increase in glycogen breakdown that supplies glycolysis, which in turn, generates the ATP required for muscle contraction.

#### e. Calmodulin: A $Ca^{2+}$ -Activated Switch

Calmodulin is a ubiquitous eukaryotic  $Ca^{2+}$ -binding protein that participates in numerous cellular regulatory processes. In some of these, CaM functions as a monomeric protein, whereas in others (e.g., PhK) it is a subunit of a larger protein. The X-ray structure of this highly conserved

**Figure 18-17** X-ray structure of rat testis calmodulin. This monomeric 148-residue protein, which is colored in rainbow order from N-terminus (*blue*) to C-terminus (*red*), contains two remarkably similar globular domains separated by a seven-turn  $\alpha$  helix. The two  $\text{Ca}^{2+}$  ions bound to each domain are represented by cyan spheres. The side chains ligating the  $\text{Ca}^{2+}$  ions are drawn in stick form colored according to atom type (C green, N blue, and O red). [Based on an X-ray structure by Charles Bugg, University of Alabama at Birmingham. PDBid 3CLN.]  See Kinemage Exercise 16-1

148-residue protein, determined by Charles Bugg, has a curious dumbbell-like shape in which CaM's two globular domains are connected by a seven-turn  $\alpha$  helix (Fig. 18-17). CaM has two high-affinity  $\text{Ca}^{2+}$ -binding sites on each of its globular domains, both of which are formed by nearly superimposable helix-loop-helix motifs known as **EF hands** (Fig. 18-18) that also occur in numerous other  $\text{Ca}^{2+}$ -sensing proteins of known structure. The  $\text{Ca}^{2+}$  ion in each of these sites is octahedrally coordinated by oxygen atoms from the backbone and side chains of the loop as well as from a protein-associated water molecule.

The binding of  $\text{Ca}^{2+}$  to either domain of CaM induces a conformational change in that domain, which exposes an otherwise buried Met-rich hydrophobic patch. This patch, in turn, binds with high affinity to the CaM-binding domain of the phosphorylase kinase  $\gamma$  subunit, as well as to the CaM-binding domains of numerous other  $\text{Ca}^{2+}$ -regulated proteins (many of which interact with CaM that is free in solution), and in doing so modulates the activities of these proteins. These CaM-binding domains have little mutual sequence similarity but are all basic amphiphilic  $\alpha$  helices. In fact,  $\sim 20$ -residue segments of these helices, as well as

synthetic amphiphilic helices composed of only Leu, Lys, and Trp residues, are bound by  $\text{Ca}^{2+}$ -CaM as tightly as the target proteins themselves.

Despite uncomplexed CaM's extended appearance in its X-ray structure (Fig. 18-17), a variety of studies indicate that both of its globular domains can simultaneously bind to a single target helix. Evidently, CaM's central  $\alpha$  helix serves as a flexible linker rather than as a rigid spacer, a property that probably further increases the range of target sequences to which CaM can bind. This idea is confirmed by the NMR structure (Fig. 18-19) of  $(\text{Ca}^{2+})_4$ -CaM in complex with its 26-residue CaM-binding target polypeptide of skeletal muscle **myosin light chain kinase (MLCK)**; a homolog of the PKA C subunit, which phosphorylates and thereby activates the light chains of the muscle protein **myosin**; Section 35-3Da), which was determined by Marius Clore, Angela Gronenborn, and Ad Bax. Indeed, the extended conformation of CaM's central helix in Fig. 18-17 is probably an artifact arising from crystal packing forces, considering that this helix's central two turns contact no other portion of the protein and hence are maximally solvent-exposed (almost all other known  $\alpha$  helices are at least partially buried in a protein). Moreover, a polypeptide with the sequence of this helix assumes a random coil conformation in aqueous solution. Nevertheless, the flexible linker is essential to the function of CaM: In the presence of  $\text{Ca}^{2+}$ , CaM's individual domains (obtained by

**Figure 18-18** EF hand. The  $\text{Ca}^{2+}$ -binding sites in many proteins that function to sense the level of  $\text{Ca}^{2+}$  are formed by helix-loop-helix motifs named EF hands. [After Kretsinger, R.H., *Annu. Rev. Biochem.* **45**, 241 (1976).]  See Kinemage Exercise 16-1

**Figure 18-19** NMR structure of  $(\text{Ca}^{2+})_4\text{-CaM}$  from *Drosophila melanogaster* in complex with its 26-residue target polypeptide from rabbit skeletal muscle myosin light chain kinase (MLCK). The N terminal domain of CaM is blue, its C-terminal domain is red, the target polypeptide is green, and the  $\text{Ca}^{2+}$  ions are represented by cyan spheres. (a) A view of the complex in which the N-terminus of the target polypeptide is on the right, and (b) the perpendicular view as seen from the right side of Part a. In both views, the pseudo-2-fold axis relating the N- and C-terminal domains of CaM is approximately vertical. Note how the middle segment of the long central helix in uncomplexed CaM (Fig. 18-17) has unwound and bent (bottom

loop in Part b) such that CaM forms a globular protein that largely encloses the helical target polypeptide within a hydrophobic tunnel in a manner resembling two hands holding a rope (the target polypeptide assumes the random coil conformation in solution). However, the conformations of CaM's two globular domains are essentially unchanged by the complexation. Evidently, CaM's bound  $\text{Ca}^{2+}$  ions serve to organize and stabilize the target binding conformations of its globular domains. [Based on an NMR structure by Marius Clore, Angela Gronenborn, and Ad Bax, National Institutes of Health. PDBid 2BBM.] 🔗 See Kinemage Exercise 16-2

tryptic cleavage), when in high concentration, are able to bind their target proteins but fail to even marginally activate them unless present in several hundred-fold excess.

How does  $\text{Ca}^{2+}\text{-CaM}$  activate its target protein kinases? MLCK contains a C-terminal segment whose sequence resembles that of MLCK's target polypeptide on the light chain of myosin but lacks a phosphorylation site. A model of MLCK, based on the X-ray structure of the 30% identical C subunit of PKA, strongly suggests that this autoinhibitor peptide inactivates MLCK by binding in its active site. Indeed, the excision of MLCK's autoinhibitor peptide by limited proteolysis permanently activates this enzyme. MLCK's CaM-binding segment overlaps this autoinhibitor peptide. Evidently, *the binding of  $\text{Ca}^{2+}\text{-CaM}$  to this peptide segment extracts the autoinhibitor from MLCK's active site, thereby activating this enzyme* (Fig. 18-20).

$\text{Ca}^{2+}\text{-CaM}$ 's other target proteins, including the phosphorylase kinase  $\gamma$  subunit, are presumably activated in the

**Figure 18-20** Schematic diagram of the  $\text{Ca}^{2+}\text{-CaM}$ -dependent activation of protein kinases. Autoinhibited kinases have an N- or C-terminal “pseudosubstrate” sequence (red) that binds at or near the enzyme's active site (brown) so as to inhibit its function. This autoinhibitory segment is in close proximity with or overlaps a  $\text{Ca}^{2+}\text{-CaM}$ -binding sequence. Consequently,  $\text{Ca}^{2+}\text{-CaM}$  (green) binds to this sequence so as to extract it from the enzyme's active site, thereby activating the enzyme to phosphorylate other proteins (purple). [After Crivici, A. and Ikura, M., *Annu. Rev. Biophys. Biomol. Struct.* **24**, 88 (1995).]

same way. The X-ray structures of two homologous protein kinases support this so-called **intra-steric mechanism**, those of **calmodulin-dependent protein kinase I (CaMKI)** and **twitchin kinase**. Although the details of binding of the autoinhibitory sequence differ for each of these protein kinases, the general mode of autoinhibition and activation by  $\text{Ca}^{2+}$ -CaM is the same.

PKA's R subunit, as we have seen, contains a similar autoinhibitory sequence adjacent to its two tandem cAMP-binding domains. In this case, however, the autoinhibitory peptide is allosterically ejected from the C subunit's active site by the binding of cAMP to the R subunit (which lacks a  $\text{Ca}^{2+}$ -CaM binding site).

#### f. Phosphorylase Kinase's $\gamma$ Subunit Is Controlled by Multiple Autoinhibitors

Phosphorylase kinase's 386-residue  $\gamma$  subunit consists of an N-terminal kinase domain, which is 36% identical in sequence to the C subunit of PKA, and a C-terminal regulatory domain, which contains a CaM-binding peptide and an overlapping autoinhibitor segment. Evidently,  $\text{Ca}^{2+}$ -CaM relieves this inhibition, as is diagrammed in Fig. 18-20. This explains why the N-terminal 298-residue segment of the PhK  $\gamma$  subunit, termed **PhK $\gamma_t$**  (t for truncated), displays catalytic activity comparable to that of fully activated PhK but is unaffected by  $\text{Ca}^{2+}$  or phosphorylation signals.

The X-ray structure of PhK $\gamma_t$  in complex with ATP and a heptapeptide related to the natural substrate was determined by Johnson (Fig. 18-21). It reveals, as expected, that PhK $\gamma_t$  structurally resembles PKA (Fig. 18-15) as well as other protein kinases of known structure including CaMKI and twitchin kinase. Comparisons of these various structures shed light on how the catalytic activity of PhK is regulated. Numerous protein kinases, including PKA, are activated by the phosphorylation of Ser, Thr, and/or Tyr residues in their activation loops, which, as we saw in Fig. 18-15, interacts with a conserved Arg residue that thereby correctly positions the adjacent catalytically important Asp residue. However, the PhK  $\gamma$  subunit is not subject to phosphorylation. Rather, its activation loop residue that might otherwise be phosphorylated is Glu 182, whose negative charge mimics the presence of a phosphate group by interacting with Arg 148 so as to correctly position Asp 149 (Fig. 18-21). Thus, the PhK catalytic site maintains an active conformation but, in the absence of  $\text{Ca}^{2+}$ , is inactivated by the binding of its C-terminal autoinhibitor segment.

Sites on both the  $\alpha$  and  $\beta$  subunits of PhK are subject to phosphorylation by PKA (Fig. 18-14). This activates PhK at much lower  $\text{Ca}^{2+}$  concentrations than otherwise, and full enzyme activity is obtained in the presence of  $\text{Ca}^{2+}$  only when both these subunits are phosphorylated. The  $\beta$  subunit does, in fact, have an autoinhibitory sequence, suggesting that phosphorylation changes its conformation so as to make it unavailable for inhibiting the  $\gamma$  subunit's active site. This would explain the synergistic effect of phosphorylation and  $\text{Ca}^{2+}$  on the activity of PhK:  $\text{Ca}^{2+}$ -CaM sequesters the  $\gamma$  subunit's autoinhibitory segment, whereas phosphorylation of the  $\beta$  subunit removes yet another au-

**Figure 18-21** X-ray structure of rabbit muscle PhK $\gamma_t$  in complex with ATP and a heptapeptide (RQMSFRL). This heptapeptide is related in sequence to the enzyme's natural substrate (KQISVRG). The protein is shown in the "standard" protein kinase orientation with its N terminal domain pink, its C-terminal domain cyan, and its activation loop blue. The heptapeptide is orange, with its residue to be phosphorylated (Ser) green. The ATP is shown in space-filling form and the side chains of the catalytically essential Arg 148, Asp 149, and Glu 182 are shown in stick form, all colored according to atom type (C green, N blue, O red, and P orange). Note the structural similarities and differences between this protein and the homologous C subunit of PKA (Fig. 18-15). [After an X-ray structure by Louise Johnson, Oxford University, Oxford, U.K. PDBid 2PHK.]

toinhibitor. The way in which the phosphorylation of the  $\alpha$  subunit modulates the activity of PhK is, as yet, unknown.

#### g. Phosphoprotein Phosphatase-1

The steady-state phosphorylation levels of most enzymes involved in cyclic cascades are maintained by the opposition of kinase-catalyzed phosphorylations and the hydrolytic dephosphorylations catalyzed by phosphoprotein phosphatases. The phosphatase involved in the cyclic cascades controlling glycogen metabolism is phosphoprotein phosphatase-1. This enzyme, as is indicated in Fig. 18-14, hydrolyzes the phosphoryl groups from *m*-glycogen phosphorylase *a*, both the  $\alpha$  and  $\beta$  subunits of phosphorylase kinase, and two other proteins involved in glycogen metabolism, as discussed below.

The catalytic subunit of phosphoprotein phosphatase-1 (**PP1**), which is designated **PP1c**, hydrolyzes phosphoryl groups on Ser/Thr residues via a single step mechanism.

The X-ray structure of PP1c indicates that it contains a binuclear metal ion center (both metals are  $Mn^{2+}$  in the recombinant enzyme) which, it is proposed, activates a water molecule (promotes its ionization to  $OH^-$ , Section 15-1Cb) for nucleophilic attack on the phosphoryl group.

PP1c binds to glycogen through the intermediacy of regulatory proteins in both muscle and liver. In muscle, PP1c is only active when it is bound to glycogen through this glycogen-binding  **$G_M$  subunit**. The activity of PP1c and its affinity for the  $G_M$  subunit are regulated by phosphorylation of the  $G_M$  subunit at two separate sites (Fig. 18-22). Phosphorylation of site 1 by **insulin-stimulated protein kinase** activates phosphoprotein phosphatase-1, whereas phosphorylation of site 2 by PKA (which can also phosphorylate site 1) causes the enzyme to be released into the cytoplasm, where it cannot dephosphorylate the glycogen-bound enzymes of glycogen metabolism.

In the cytosol, PP1c is also inhibited by its binding to the protein **phosphoprotein phosphatase inhibitor 1 (inhibitor-1)**. This latter protein provides yet another example of control by enzymatic interconversion: It too is modified by PKA and demodified by PP1c (Fig. 18-14, bottom), although, in this case, a Thr, not a Ser, is phosphorylated/dephosphorylated. The protein is a functional inhibitor only when it is phosphorylated. *The concentration of cAMP therefore controls the fraction of an enzyme in its phosphorylated form, not only by increasing the rate at which it is phosphorylated, but also by decreasing the rate at which it is dephosphorylated. In the case of glycogen phosphorylase, an increase in [cAMP] results not only in an*

*increase in this enzyme's rate of activation, but also in a decrease in its rate of deactivation.*

The activity of phosphoprotein phosphatase-1 in liver is also controlled by its binding to glycogen through the intermediacy of a glycogen-binding subunit, here named  **$G_L$** . When bound to  $G_L$ , PP1c is activated toward dephosphorylation of the glycogen-bound enzymes of glycogen metabolism. However,  $G_L$  is not subject to control via phosphorylation as is  $G_M$  in the muscle. Rather, the binding of *m*-phosphorylase *a* to  $G_L$  strongly inhibits the activity of PP1c by an allosteric mechanism.

Among the major conformational changes that glycogen phosphorylase undergoes in converting from the T to the R state is the movement of the Ser 14-phosphoryl group from the surface of the T-state (inactive) enzyme to a position buried a few angstroms beneath the protein's surface at the dimer interface in the R-state (active) enzyme (Figs. 18-11b). Both the R and T forms of phosphorylase *a* strongly bind the  $G_L \cdot PP1c$  complex, but only in the T-state enzyme is the Ser 14-phosphoryl group accessible for hydrolysis by PP1c. Consequently, under the conditions that phosphorylase *a* converts to the T state (Section 18-3G), PP1c hydrolyzes its now exposed Ser 14-phosphoryl group. This converts *m*-phosphorylase *a* to *o*-phosphorylase *b*, which has only a low affinity for binding the  $G_L \cdot PP1c$  complex and hence does not inhibit PP1c. One effect of phosphorylase *a* demodification, therefore, is to relieve the inhibition of PP1c and thus allow it to excise the phosphoryl groups of other susceptible phosphoproteins. Since phosphorylase *a* has a high affinity for the  $G_L \cdot PP1c$  complex and is in  $\sim 10$ -fold greater concentration, relief of PP1c inhibition only occurs when more than

**Figure 18-22** The antagonistic effects of insulin and epinephrine on glycogen metabolism in muscle. This occurs through their effects on the phosphoprotein phosphatase-1

catalytic subunit, PP1c, via its glycogen-bound  $G_M$  subunit. Green discs and dashed arrows indicate activation.

~90% of the glycogen phosphorylase is in the *o*-phosphorylase *b* form. Glycogen synthase is among the proteins that are dephosphorylated by the  $G_L \cdot PP1c$  complex when it is no longer inhibited by phosphorylase. However, in contrast to phosphorylase, dephosphorylation activates glycogen synthase. This enzyme is involved in its own bicyclic cascade whose properties we shall now examine.

#### D. Glycogen Synthase Bicyclic Cascade

Like glycogen phosphorylase, glycogen synthase exists in two enzymatically interconvertible forms:

1. The modified (*m*; phosphorylated) form that is inactive under physiological conditions (the *b* form).
2. The original (*o*; dephosphorylated) form that is active (the *a* form).

*m*-Glycogen synthase *b* is under allosteric control; it is strongly inhibited by physiological concentrations of ATP, ADP, and  $P_i$  and hence the modified enzyme is almost totally inactive *in vivo*. The activity of the unmodified enzyme is essentially independent of these effectors, so a cell's glycogen synthase activity varies with the fraction of the enzyme in its unmodified form.

The mechanistic details of the interconversion of modified and unmodified forms of glycogen synthase are particularly complex and are therefore not as well understood as those of glycogen phosphorylase. It has been clearly established that the fraction of unmodified glycogen synthase is, in part, controlled by a bicyclic cascade involving phosphorylase kinase (PhK) and phosphoprotein phosphatase-1, enzymes that are also involved in the glycogen phosphorylase bicyclic cascade (Fig. 18-14, *right*). This demodification process is facilitated by G6P, whose binding to *m*-glycogen synthase *b* induces it to undergo a conformational change that exposes its phosphoryl groups to the surface of the protein, thereby making them available for dephosphorylation by phosphoprotein phosphatase-1.

Glycogen synthase is phosphorylated at several sites. Several protein kinases are known to at least partially deactivate human muscle glycogen synthase by phosphorylating this homotetramer at 1 or more of 9 Ser residues in the N- and C-terminal segments on its 737-residue subunits. These enzymes include PhK, PKA (so glycogen synthase deactivation may also be considered to occur via a monocyclic cascade), CaMKI (which is activated by the presence of  $Ca^{2+}$ ), **protein kinase C (PKC)**; which responds to the extracellular presence of certain hormones via a mechanism described in Sections 18-3G and 19-4Cb), **AMP-dependent protein kinase (AMPK)**; which responds to ATP availability and hence acts as a fuel gauge; Sections 25-5a and 27-1), **glycogen synthase kinase-3 [GSK3]**; which is inhibited by **insulin** (Sections 18-3Ea and 18-3F), whose presence therefore results in the dephosphorylation and hence activation of glycogen synthase], and **casein kinases 1 and 2** (which participate in a variety of cellular control processes). Why glycogen synthase deactivation is so elaborately controlled compared to its activation or the activa-

tion/deactivation of glycogen phosphorylase is unclear, although, whatever the reasons, it closely monitors the organism's metabolic state.

#### E. Integration of Glycogen Metabolism Control Mechanisms

Whether there is net synthesis or degradation of glycogen and at what rate depends on the relative balance of the active forms of glycogen synthase and glycogen phosphorylase. This, in turn, largely depends on the rates of the phosphorylation and dephosphorylation reactions of the two bicyclic cascades. These cascades, one controlling the rate of glycogen breakdown and the other controlling the rate of glycogen synthesis, are intimately related. They are linked by protein kinase A and phosphorylase kinase, which, through phosphorylation, activate glycogen phosphorylase as they inactivate glycogen synthase (Fig. 18-14). The cascades are also linked by phosphoprotein phosphatase-1, which in liver is inhibited by phosphorylase *a* and therefore is unable to activate (dephosphorylate) glycogen synthase unless it first inactivates (also by dephosphorylation) phosphorylase *a*.

##### a. Hormones Are Important Regulators of Glycogen Metabolism

Glycogen metabolism is largely regulated by the peptide hormone **insulin** (Fig. 7-2) acting in opposition to **glucagon**, another peptide hormone,

##### Glucagon

together with the adrenal hormones **epinephrine (adrenaline)** and **norepinephrine (noradrenaline)**:

Hormonal stimulation of cells at their plasma membranes occurs through the mediation of transmembrane proteins called **receptors**. Different cell types have different complements of receptors and thus respond to different sets of hormones. For example, both muscle and liver cells have abundant insulin and **adrenergic receptors** (receptors responsive to epinephrine and norepinephrine), whereas glucagon receptors are more prevalent in liver than in skeletal muscle.

### b. Second Messengers Mediate Glucagon- and Epinephrine-Stimulated Glycogen Breakdown

The response to glucagon and epinephrine involves the release inside the cell of molecules known as **second messengers**, that is, intracellular mediators of the externally received hormonal message. Different receptors act to release different second messengers. Indeed, cAMP was identified by Earl Sutherland as the first known instance of a second messenger through his demonstration that glucagon and epinephrine act at cell surfaces to stimulate adenylyl cyclase (AC) to increase [cAMP] [the mechanism of AC activation, as well as a discussion of other second messengers, including  $\text{Ca}^{2+}$ , **inositol-1,4,5-trisphosphate (IP<sub>3</sub>)**, and **diacylglycerol (DAG)**, is elaborated in Sections 19-2D and 19-4A]. Following this discovery, it was realized that cAMP, which is present in all forms of life, is an essential control element in many biological processes.

When hormonal stimulation by glucagon or epinephrine increases the intracellular cAMP concentration, the protein kinase A activity increases, increasing the rates of phosphorylation of many proteins and decreasing their dephosphorylation rates as well. A decrease in dephosphorylation rates, as previously noted, increases the phosphorylation level of phosphoprotein phosphatase inhibitor-1, which in turn inhibits phosphoprotein phosphatase-1. An increase in the concentration of phosphorylase *a* also contributes to the inhibition of phosphoprotein phosphatase-1.

Because of the amplifying properties of the cyclic cascades, a small change in [cAMP] results in a large change in the fraction of enzymes in their phosphorylated forms. When a large fraction of the glycogen metabolism enzymes are present in their phosphorylated forms, the metabolic flux is in the direction of glycogen breakdown, since glycogen phosphorylase is active and glycogen synthase is inactive. When [cAMP] decreases, phosphorylation rates decrease, dephosphorylation rates increase, and the fraction of enzymes in their dephospho forms increases. The resultant activation of glycogen synthase and the inhibition of glycogen phosphorylase cause a change in the flux direction toward net glycogen synthesis.

### F. Maintenance of Blood Glucose Levels

An important function of the liver is to maintain the blood concentration of glucose, the brain's primary fuel source, at  $\sim 5$  mM. When blood [glucose] decreases beneath this level, usually during exercise or well after meals have been digested, the liver releases glucose into the bloodstream. The process is mediated by the hormone glucagon as follows:

1. Glucose inhibits the pancreatic  $\alpha$  cells from secreting glucagon into the bloodstream. When the blood glucose concentration falls, this inhibition is released causing the  $\alpha$  cells to secrete glucagon.
2. Glucagon receptors on liver cell surfaces respond to the presence of glucagon by activating adenylyl cyclase, thereby increasing the [cAMP] inside these cells.

3. The [cAMP] increase, as described above, triggers an increase in the rate of glycogen breakdown, leading to increased intracellular [G6P].

4. G6P, in contrast to glucose, cannot pass through the cell membrane. However, in liver, which does not employ glucose as a major energy source, the enzyme **glucose-6-phosphatase (G6Pase)** hydrolyzes G6P:

The resulting glucose enters the bloodstream, thereby increasing the blood glucose concentration. Muscle and brain cells, however, lack G6Pase so that they retain their G6P.

G6P hydrolysis requires intracellular G6P transport. G6P is produced in the cytosol, whereas G6Pase is a TM protein that resides in the endoplasmic reticulum (ER) membrane with its active site in the ER lumen. G6P must therefore be imported into the ER by a **G6P translocase** before it can be hydrolyzed. The resulting glucose and  $\text{P}_i$  are then returned to the cytosol via specific transport proteins (Section 18-3G). A defect in any of the components of this G6P hydrolysis system results in **type I glycogen storage disease** (Section 18-4).

How does this delicately balanced system respond to an increase in blood [glucose]? When blood sugar is high, normally immediately after meals have been digested, glucagon levels decrease and insulin is released from the pancreatic  $\beta$  cells. *The rate of glucose transport across many cell membranes increases in response to insulin (through the insulin-dependent glucose transporter GLUT4; Section 20-2E), [cAMP] decreases, and glycogen metabolism therefore shifts from glycogen breakdown to glycogen synthesis.* The mechanism of insulin action is quite complex and is not fully understood (Sections 19-3 and 19-4F), but one of its target enzymes appears to be phosphoprotein phosphatase-1.

In muscle, insulin and epinephrine have antagonistic effects on glycogen metabolism. Epinephrine promotes glycogenolysis by activating the cAMP-dependent phosphorylation cascade, which stimulates glycogen breakdown while inhibiting glycogen synthesis. Insulin, as we saw in Section 18-3Cg, activates insulin-stimulated protein kinase to phosphorylate site 1 on the glycogen-binding  $G_M$  subunit of phosphoprotein phosphatase-1 so as to activate this protein to dephosphorylate the enzymes of glycogen metabolism (Fig. 18-22). The storage of glucose as glycogen is thereby stimulated through the inhibition of glycogen breakdown and the stimulation of glycogen synthesis.

In liver, it appears that glucose and glucose-6-phosphate themselves may be the messengers to which the glycogen metabolism system responds. *Glucose inhibits phosphorylase a by binding only to the active site of the enzyme's inactive T state, but in a manner different from that of substrate.* The presence of glucose therefore shifts phosphorylase *a*'s  $\text{T} \rightleftharpoons \text{R}$  equilibrium toward the T state (Fig. 18-10, right). This conformational shift, as we saw in Section 18-3Cg, exposes the Ser 14-phosphoryl group to phosphoprotein phosphatase-1, resulting in the demodification of phosphorylase *a*. An increase in glucose concentration therefore

**Figure 18-23** The enzymatic activities of phosphorylase  $\alpha$  and glycogen synthase in mouse liver in response to an infusion of glucose. Phosphorylase  $\alpha$  is rapidly inactivated and, somewhat later, glycogen synthase is activated. [After Stalmans, W., De Wulf, H., Hue, L., and Hers, H.-G., *Eur. J. Biochem.* **41**, 129 (1974).]

promotes inactivation of glycogen phosphorylase  $a$  through the enzyme's conversion to phosphorylase  $b$  (Fig. 18-23; i.e., phosphorylase  $a$  acts as a glucose receptor). The concomitant release of phosphoprotein phosphatase-1 inhibition (recall that it specifically binds to and is thereby inactivated by phosphorylase  $a$ ), moreover, results in the activation (dephosphorylation) of  $m$ -glycogen synthase  $b$ . In addition, glucose is converted to G6P by **glucokinase** (see below), which facilitates the dephosphorylation and activation of  $m$ -glycogen synthase  $b$  to  $o$ -glycogen synthase  $a$ . Above a glucose concentration of 7 mM, these processes reverse the flux of glycogen metabolism from breakdown to synthesis. The liver can thereby store the excess glucose as glycogen.

#### a. Glucokinase Forms G6P at a Rate Proportional to the Glucose Concentration

The liver's function in "buffering" the blood [glucose] is made possible because this organ contains a variant of hexokinase (the first glycolytic enzyme; Section 17-2A) known as glucokinase (**GK**; also called **hexokinase D** and **hexokinase IV**). The hexokinase in most cells obeys Michaelis–Menten kinetics, has a high glucose affinity ( $K_M < 0.1$  mM; the value of [glucose] at which the enzyme achieves half-maximal velocity; Section 14-2A), and is inhibited by its reaction product, G6P. GK, in contrast, has a much lower glucose affinity (reaching half of its maximal velocity at  $\sim 5$  mM) and displays sigmoidal kinetics with a Hill constant (Section 10-1Bb) of 1.5, so its activity increases rapidly with the blood [glucose] over the normal physiological range (Fig. 18-24; see Problem 7 of this chapter). GK, moreover, is not inhibited by physiological concentrations of G6P. Consequently, the higher the blood [glucose], the faster the liver converts glucose to G6P [liver

cells, unlike most cells, contain ample quantities of the insulin-independent glucose transporter **GLUT2** (Section 20-2Eb) and are therefore freely permeable to glucose; their glucose transport rate is unresponsive to insulin]. Thus at low blood [glucose], the liver does not compete with other tissues for the available glucose supply, whereas at high blood [glucose], when the glucose needs of these tissues are met, glucose in the liver is converted to G6P. The excess glucose in the liver induces the inactivation of glycogen phosphorylase and the release of phosphoprotein phosphatase-1, whereas the resulting G6P allosterically facilitates the activation of glycogen synthase via dephosphorylation. The net result is that the liver converts the excess glucose to glycogen. (Note that GK is a monomeric enzyme, so that its sigmoidal rate increase with [glucose] is a puzzling observation in light of the various allosteric models indicating that monomeric enzymes are incapable of cooperative behavior. Since GK does not exhibit Michaelis–Menten kinetics, the glucose concentration when this enzyme has half its maximal activity is known as its  $K_{0.5}$  in analogy with the operational definition of  $K_M$ .)

GK is subject to metabolic controls. Emile Van Schaftingen isolated **glucokinase regulatory protein (GGRP**; a 625-residue monomer) from rat liver, which, in the presence of the glycolytic intermediate fructose-6-phosphate (F6P), is a competitive inhibitor of glucokinase. Fructose-1-phosphate (F1P), an intermediate in liver fructose metabolism (Section 17-5A), overcomes this inhibition. Since fructose is normally available only from dietary sources (e.g., sucrose), fructose may be the signal that triggers the uptake of dietary glucose by the liver.

**Figure 18-24** Comparison of the relative enzymatic activities of hexokinase and glucokinase over the physiological blood glucose range. The affinity of glucokinase for glucose ( $K_{0.5} = 5$  mM) is much lower than that of hexokinase ( $K_M = 0.1$  mM) and exhibits sigmoidal rather than hyperbolic variation with [glucose]. [The glucokinase curve was generated using the Hill equation (Eq. [10.7]) with  $K = 10$  mM and  $n = 1.5$  as determined by Cardenas, M.L., Rabajille, E., and Niemyer, H., *Eur. J. Biochem.* **145**, 163–171 (1984).]

### b. Glucokinase Regulates Glucose Homeostasis via an Intracellular Localization Mechanism

Intracellular localization plays an important role in GK inhibition by GKR. GK translocates freely between the nucleus and cytoplasm. However, GKR is located exclusively in the nucleus. When the glucose concentration is low, GK remains bound to GKR in the nucleus, where it is unavailable to phosphorylate glucose. At increased concentrations of glucose and/or F1P, GK dissociates from GKR and translocates to the cytoplasm, where it phosphorylates glucose to G6P, starting it on its way toward glycogen synthesis. The antagonism of GK and GKR provides a major mechanism for controlling glucose phosphorylation and glycogen metabolism in the liver. Their flux control coefficients (Section 17-4Ca) in liver cells are close to +1 for GK and -1 for GKR (a negative flux control coefficient is indicative of inhibition). This countervailing relationship provides a sensitive mechanism for maintaining glucose homeostasis.

Phosphoglucomutase, which has a high enough activity to equilibrate its substrate and product and therefore functions in either direction, transforms G6P to G1P, which is then converted to glycogen. Some of the G6P is also reconverted to glucose by the action of glucose-6-phosphatase in what amounts to a “futile” cycle. This is apparently the energetic price of effective glucose “buffering” of the blood.

### c. Fructose-2,6-Bisphosphate Activates Glycolysis

#### $\beta$ -D-Fructose-2,6-bisphosphate (F2,6P)

$\beta$ -D-Fructose-2,6-bisphosphate (F2,6P)

is also an important factor in the liver's maintenance of blood [glucose]. F2,6P, which is not a glycolytic metabolite, is an extremely potent allosteric activator of animal phosphofructokinase (PFK) and an inhibitor of fructose biphosphatase (FBPase). F2,6P, which was independently discov-

ered in 1980 by Simon Pilkis, by Emile Van Schaftingen and Henri-Géry Hers, and by Kosaku Uyeda, therefore stimulates glycolytic flux (the F6P-FBP substrate cycle is discussed in Section 17-4Ff).

The concentration of F2,6P in the cell depends on the balance between its rates of synthesis and degradation by **phosphofructokinase-2 (PFK-2; also called 6PF-2-K)** and **fructose biphosphatase-2 (FBPase-2; also called F-2,6-Pase)**, respectively (Fig. 18-25). These enzyme activities are located on different domains of a single ~100-kD homodimeric protein named **PFK-2/FBPase-2**. The X-ray structure of the H256A mutant of rat testis PFK-2/FBPase-2 in complex with F6P,  $P_i$ , succinate, and the nonhydrolyzable ATP analog **adenosine-5'-( $\beta$ , $\gamma$ -imido)triphosphate (AMPPNP)**

Adenosine-5'-( $\beta$ , $\gamma$ -imido)triphosphate (AMPPNP)

was determined by Uyeda and Charles Hasemann (Fig. 18-26). It indicates, in agreement with a variety of studies, that the PFK-2 activity resides on each subunit's 246-residue N-terminal domain, whereas the FBPase-2 activity resides on each subunit's 213-residue C-terminal domain. The succinate, which binds in the vicinity of AMPPNP's  $\gamma$  phosphate group, presumably occupies the F6P binding pocket in the PFK-2 active site, whereas the F6P and  $P_i$  mark the F2,6P binding site in the FBPase-2 active site. The FBPase-2 domain is structurally related to the glycolytic enzyme phosphoglycerate mutase (PGM; Section 17-2H) and shares a common catalytic mechanism involving a covalent phospho-His intermediate (His 256 in FBPase-2). The PFK-2 domain is structurally related to adenylate kinase (Section 17-4Fe) but not, as had been speculated, to PFK (also called **PFK-1** to distinguish this glycolytic enzyme from PFK-2).

The enzyme activities of PFK-2/FBPase-2 are subject to allosteric regulation by a variety of metabolic intermediates

**Figure 18-25** Formation and degradation of  $\beta$ -D-fructose-2,6-bisphosphate as catalyzed by PFK-2 and FBPase-2. These two enzyme activities occur on different domains of the same

molecule. Dephosphorylation of the liver enzyme activates PFK-2 but deactivates FBPase-2.

**Figure 18-26** X-ray structure of the H256A mutant of rat testis PFK-2/FBPase-2. The N-terminal PFK-2 domain is blue and the C-terminal FBPase-2 domain is yellow-green. The bound  $Mg^{2+}$ -AMPPNP, succinate, F6P, and  $P_i$  are shown in space-filling form colored according to atom type (AMPPNP C green, succinate C magenta, F6P C cyan, N blue, O red,  $Mg^{2+}$  light green, and P orange). The  $P_i$ , which occupies the binding site of the F2,6P's 2-phosphate group, is opposite the site that would be occupied by the side chain of the wild-type enzyme's His 256 (magenta), to which it would be transferred in the catalytic reaction. The succinate occupies the presumed F6P-binding pocket of the PFK-2 domain. [Based on an X-ray structure by Kosaku Uyeda and Charles Hasemann, University of Texas Southwestern Medical Center. PDBid 2BIF.]

as well as to phosphorylation/dephosphorylation by protein kinase A and a phosphoprotein phosphatase. Phosphorylation of the liver enzyme at its Ser 32 inhibits its PFK-2 activity and activates its FBPase-2 activity. Thus, the pancreatic  $\alpha$  cell's release of glucagon in response to low blood [glucose] results, through an increase in liver [cAMP], in a decreased liver [F2,6P]. This situation, in turn, decreases the PFK-1 activity, thereby inhibiting glycolysis. Hence, the G6P resulting from the concurrent stimulation of glycogen degradation is converted to glucose and secreted as described above rather than being metabolized. Simultaneously, the deinhibition of FBPase (also called **FBPase-1** to distinguish it from FBPase-2) by the decrease of [F2,6P] stimulates **gluconeogenesis**, the formation of glucose from nonglucose precursors such as amino acids by a pathway that effectively reverses glycolytic flux (and in

which FBPase-1 is a key regulatory enzyme; Section 23-1). This process provides a second means of glucose production. Conversely, when the blood [glucose] is high, cAMP levels decrease, the liver PFK-2/FBPase-2 is dephosphorylated by phosphoprotein phosphatase-1 activating PFK-2, which, in turn, causes a rise in [F2,6P]. PFK-1 is therefore activated, FBPase-1 is inhibited, and the net glycolytic flux changes from gluconeogenesis to glycolysis.

The F2,6P control systems in skeletal muscle and in heart muscle function quite differently from that in liver due to the presence in these tissues of different PFK-2/FBPase-2 isozymes. In heart and skeletal muscles, increased glycogen breakdown is coordinated with increased glycolysis rather than increased glucose secretion. This is because phosphorylation of the heart muscle PFK-2/FBPase-2 isozyme occurs at entirely different sites (Ser 406 and Thr 475 of the 530-residue protein) from that of the liver isozyme (Ser 32 of the 470-residue protein) and activates rather than inhibits PFK-2. Consequently, hormones that stimulate glycogen breakdown also increase heart muscle [F2,6BP], thereby stimulating glycolysis as well. The skeletal muscle and testis isozymes lack phosphorylation sites altogether and are therefore not subject to cAMP-dependent phosphorylation control.

### G. Response to Stress

Epinephrine and norepinephrine, which are often called the “fight or flight” hormones, are released into the bloodstream by the adrenal glands in response to stress. Epinephrine receptors (known as  **$\beta$ -adrenergic receptors**; Section 19-1F) present on the surfaces of liver and muscle cells respond to these hormones just as glucagon receptors respond to the presence of glucagon; they activate adenylate cyclase, thereby increasing intracellular [cAMP]. Indeed, epinephrine also stimulates the pancreatic  $\alpha$  cells to release glucagon, which further increases liver [cAMP]. The G6P produced by the consequent glycogen breakdown in muscle enters the glycolytic pathway, thereby generating ATP and helping the muscles cope with the stress that triggered the epinephrine release.

The liver's response to stress, in addition to its response to the glucagon released by pancreatic epinephrine stimulation, involves response to epinephrine stimulation via two types of receptors,  **$\beta$ -adrenergic receptors**, as discussed above, and  **$\alpha$ -adrenergic receptors**.  $\alpha$ -Adrenergic receptors act by stimulating **phospholipase C** to release other second messengers, namely inositol-1,4,5-trisphosphate ( $IP_3$ ), diacylglycerol (DAG), and  $Ca^{2+}$  (Fig. 18-27a), which act to reinforce the cells' response to cAMP. As we mentioned in Section 18-3Cf, phosphorylase kinase, which both activates phosphorylase and inactivates glycogen synthase, is fully active only when both phosphorylated and in the presence of increased [ $Ca^{2+}$ ]. In addition, glycogen synthase is inactivated by phosphorylation by several other  $Ca^{2+}$ -dependent protein kinases, including protein kinase C (Section 18-3D). Protein kinase C requires both  $Ca^{2+}$  and DAG for activity (Section 19-4C). This dual stimulation of receptors in response to epinephrine causes the liver to produce

**Figure 18-27 The liver's response to stress.** (a) Stimulation of  $\alpha$ -adrenergic receptors by epinephrine activates phospholipase C to hydrolyze phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub>) to inositol-1,4,5-trisphosphate (IP<sub>3</sub>) and diacylglycerol (DAG). (b) The participation of two second messenger systems: the cAMP-mediated stimulation of glycogenolysis and inhibition of glycogen synthesis triggered by glucagon and  $\beta$ -adrenergic receptor activation; and the IP<sub>3</sub>, DAG, and Ca<sup>2+</sup>-mediated stimulation of glycogenolysis and inhibition of glycogen synthesis triggered by  $\alpha$ -adrenergic receptor activation. IP<sub>3</sub> stimulates the release of Ca<sup>2+</sup> from the endoplasmic reticulum, whereas DAG, together with Ca<sup>2+</sup>, activates protein kinase C to phosphorylate and thereby inactivate glycogen synthase. G6Pase occupies the endoplasmic reticulum. Consequently, the cytosolically produced G6P is transported into the endoplasmic reticulum via the **T1 G6P translocase**, where it is hydrolyzed to glucose and P<sub>i</sub>. The P<sub>i</sub> and glucose are then returned to the cytosol by the **T2** and **T3** transporters, respectively, and the glucose is exported from the cell via the GLUT2 glucose transporter.

G6P, which is hydrolyzed by G6Pase, resulting in the release of glucose into the bloodstream, thereby further fueling the muscles (Fig. 18-27b).

#### 4 GLYCOGEN STORAGE DISEASES

With glycogen metabolism being such a finely controlled system, it is not surprising that genetically determined enzyme deficiencies result in disease states. The study of these disease states and the enzyme deficiencies that cause them has provided insights into the system's balance. In this sense, genetic diseases are valuable research tools. Conversely, the biochemical characterization of the pathways affected by a genetic disease often leads, as we shall see, to useful strategies for its treatment. Many diseases have been characterized that result from inherited deficiencies of one or another of the enzymes of glycogen metabolism. These defects are listed in Table 18-1 and discussed in this section.

##### Type I: Glucose-6-Phosphatase Deficiency (von Gierke's Disease)

G6Pase catalyzes the final step leading to the release of glucose into the bloodstream by the liver. Deficiency of this enzyme results in an increase of intracellular [G6P], which leads to a large accumulation of glycogen of normal structure in the liver and kidney (recall that G6P inhibits glycogen phosphorylase and activates glycogen synthase) and an inability to increase blood glucose concentration in response to glucagon or epinephrine. Similar difficulties occur when there are defects in the protein that transports glucose across the liver cell plasma membrane (Section 20-2Eb) or in any of the proteins that transport glucose, G6P, or  $P_i$  across the endoplasmic reticulum membrane (Section 18-3F; Fig. 18-27b). The symptoms of Type I glycogen storage disease include massive liver enlargement, severe **hypoglycemia** (low blood sugar) after a few

hours' fast, and a general failure to thrive. Treatment of the disease has included drug-induced inhibition of glucose uptake by the liver to increase blood [glucose], continuous intragastric feeding overnight, again to increase blood [glucose], oral administration of uncooked corn starch (which is only slowly broken down to glucose), and surgical transposition of the portal vein, which ordinarily feeds the liver directly from the intestines, so as to allow this glucose-rich blood to reach peripheral tissues before it reaches the liver. This latter treatment has the added benefit of allowing the tissues to receive more glucose while decreasing the storage of this glucose as liver glycogen. Liver transplantation has also been successful in the few patients in which this treatment has been tried.

A gene therapy protocol (Section 5-5H) is being developed to correct type I glycogen storage disease. G6Pase-deficient knockout mice (Section 5-5H) have been treated with a viral vector containing the mouse G6Pase gene. This treatment, which delivers G6Pase to the livers of these mice, greatly increases their survival rate and corrects the metabolic abnormalities associated with this glycogen storage disease.

##### Type II: $\alpha$ -1,4-Glucosidase Deficiency (Pompe's Disease)

This is the most devastating glycogen storage disease. It results in a large accumulation of glycogen of normal structure in the lysosomes of all cells and causes death by cardiorespiratory failure, usually before the age of 1 year. We have not discussed  **$\alpha$ -1,4-glucosidase** in the sections on the pathways of glycogen synthesis and breakdown since it is not among those enzymes. It occurs in lysosomes, where it functions to hydrolyze the disaccharide maltose (Section 11-2B) and linear oligosaccharides, as well as the outer branches of glycogen, thereby yielding free glucose. However, this second pathway of glycogen metabolism is not quantitatively important. The reason that lysosomes normally take up and degrade glycogen granules is unknown.

**Table 18-1 Hereditary Glycogen Storage Diseases**

Type	Enzyme Deficiency	Tissue	Common Name	Glycogen Structure
I	Glucose-6-phosphatase	Liver	von Gierke's disease	Normal
II	$\alpha$ -1,4-Glucosidase	All lysosomes	Pompe's disease	Normal
III	Amylo-1,6-glucosidase (glycogen debranching enzyme)	All organs	Cori's disease	Outer chains missing or very short
IV	Amylo-(1,4 $\rightarrow$ 1,6)- transglycosylase (glycogen branching enzyme)	Liver, probably all organs	Andersen's disease	Very long unbranched chains
V	Glycogen phosphorylase	Muscle	McArdle's disease	Normal
VI	Glycogen phosphorylase	Liver	Hers' disease	Normal
VII	Phosphofructokinase	Muscle	Tarui's disease	Normal
VIII	Phosphorylase kinase	Liver	X-Linked phosphorylase kinase deficiency	Normal
IX	Phosphorylase kinase	All tissues		Normal
0	Glycogen synthase	Liver		Normal, deficient in quantity

**Type III: Amylo-1,6-Glucosidase (Glycogen Debranching Enzyme) Deficiency (Cori's Disease)**

In this disease, glycogen of abnormal structure containing very short outer chains accumulates in both liver and muscle since, in the absence of debranching enzyme, the glycogen cannot be further degraded. Its hypoglycemic symptoms are similar to, but not as severe as, those of von Gierke's disease (Type I). The low blood sugar, which in this case is a result of the decreased efficiency of glycogen breakdown, is treated with frequent feeding and a high-protein diet [in response to low blood sugar, the liver, through gluconeogenesis (Section 23-1), synthesizes glucose from amino acids]. For unknown reasons, the symptoms of Cori's disease often disappear at puberty.

**Type IV: Amylo-(1,4 → 1,6)-Transglycosylase (Glycogen Branching Enzyme) Deficiency (Andersen's Disease)**

This is one of the most severe glycogen storage diseases; victims rarely survive past the age of 5 years because of liver dysfunction. Glycogen concentration in liver is not increased but its structure is abnormal, with very long unbranched chains resulting from the lack of glycogen branching enzyme. This decreased branching greatly reduces the solubility of glycogen. It has been suggested that the liver dysfunction may be caused by a "foreign body" immune reaction to the abnormal glycogen.

**Type V: Muscle Glycogen Phosphorylase Deficiency (McArdle's Disease)**

We have mentioned this condition in connection with the realization that glycogen synthesis and breakdown must occur by different pathways (Section 18-2). Its major symptom, which is most severely manifested in early adulthood, is painful muscle cramps on exertion. This situation is a result of the inability of the glycogen breakdown system to provide sufficient fuel for glycolysis to keep up with the metabolic demand for ATP. Studies by  $^{31}\text{P}$  NMR on human forearm muscle have noninvasively corroborated this conclusion by demonstrating that exercise in individuals with McArdle's disease leads to elevated muscle ADP levels compared to those of normal individuals (Fig. 18-28). Curiously, if McArdle's victims continue their exertions after a short rest, their cramps subside. This "second wind" effect has been attributed to the muscles' switch from anaerobic to aerobic metabolism as well as vasodilation, which gives the muscles increased access to the glucose and fatty acids in the blood for use as alternative fuels to glycogen. Liver glycogen phosphorylase is normal in these individuals, implying the presence of different glycogen phosphorylase isozymes in muscle and liver.

**Type VI: Liver Glycogen Phosphorylase Deficiency (Hers' Disease)**

Patients with a deficiency of liver phosphorylase have symptoms similar to those with mild forms of Type I glycogen storage disease. The hypoglycemia in this case results from the inability of glycogen phosphorylase to respond to the need for glucose production by the liver.

**Figure 18-28** The ADP concentration in human forearm muscles during rest and following exertion in normal individuals and those with McArdle's disease. The ADP concentration was determined from  $^{31}\text{P}$  NMR measurements on intact forearms. [After Radda, G.K., *Biochem. Soc. Trans.* **14**, 522 (1986).]

**Type VII: Muscle Phosphofructokinase Deficiency (Tarui's Disease)**

The result of a deficiency of the glycolytic enzyme PFK-1 in muscle is an abnormal buildup of the glycolytic metabolites G6P and F6P. High concentrations of G6P increase the activities of glycogen synthase (G6P activates glycogen synthase and inactivates glycogen phosphorylase) and UDP-glucose pyrophosphorylase (G6P is in equilibrium with G1P, a substrate for the enzyme) so that glycogen accumulates in muscle. Other symptoms are similar to those of Type V glycogen storage disease, muscle phosphorylase deficiency, since PFK deficiency prevents glycolysis from keeping up with the ATP demand of muscle contraction.

**Type VIII: Liver Phosphorylase Kinase Deficiency (X-Linked Phosphorylase Kinase Deficiency)**

Some individuals with symptoms of Type VI glycogen storage disease have liver phosphorylase of normal structure. However, they have a defective phosphorylase kinase, which results in their inability to convert phosphorylase *b* to phosphorylase *a*. The gene encoding the  $\alpha$  subunit of phosphorylase kinase resides on the X chromosome and hence Type VIII disease is X-linked rather than autosomal, as are the other glycogen storage diseases.

**Type IX: Phosphorylase Kinase Deficiency**

Phosphorylase kinase deficiency, when it is autosomal recessive, is caused by a mutation in one of the genes encoding a  $\beta$ ,  $\gamma$ , or  $\delta$  subunit of phosphorylase kinase. Since different organs contain different isozymes of phosphorylase kinase, the symptoms and severity of Type IX disease vary with the affected organs.

**Type 0: Liver Glycogen Synthase Deficiency**

The activity of liver glycogen synthase is extremely low in individuals with this disease and hence they exhibit hyperglycemia after meals and hypoglycemia at other times. However, the primary lesion may not always be in the synthase itself because other metabolic defects may lead to an imbalance of the glycogen synthase cyclic cascade. The root cause of Type 0 glycogen storage disease is still under investigation. Muscle glycogen synthase deficiency disease has recently been described. Its victims are easily fatigued

and develop heart abnormalities that may cause sudden cardiac arrest. Note these are the only known glycogen storage diseases in which there is a deficiency rather than an overabundance of glycogen. This suggests that the complete absence of glycogen is lethal.

Since many of the glycogen storage diseases have similar clinical symptoms, these diseases are best diagnosed via genetic testing.

## CHAPTER SUMMARY

**1 Glycogen Breakdown** In animals, when glucose is not needed as a source of metabolic energy, it is stored, predominantly in liver and muscle cells, as glycogen, an  $\alpha(1 \rightarrow 4)$ -linked glucan with  $\alpha(1 \rightarrow 6)$  branches every 8 to 14 residues. Glycogen breakdown to glucose-6-phosphate (G6P) is a two-step process. Glycogen phosphorylase catalyzes the phosphorolysis of the glycosidic linkage of a terminal glucosyl residue to form glucose-1-phosphate (G1P). Phosphoglucomutase interconverts G1P and G6P. Glycogen debranching enzyme allows complete degradation of glycogen by catalyzing the transfer of three-residue chains onto the nonreducing ends of other chains and catalyzing the hydrolysis of the remaining  $\alpha(1 \rightarrow 6)$ -linked glucosyl unit to glucose.

**2 Glycogen Synthesis** Glycogen is synthesized from G6P by a pathway different from that of glycogen breakdown. G6P is converted to G1P under the influence of phosphoglucomutase. UDP-glucose pyrophosphorylase utilizes UTP to convert G1P to UDP-glucose, the activated intermediate in glycogen synthesis. The hydrolysis of the  $PP_i$  product by inorganic pyrophosphatase drives the reaction to completion. Glucosyl units are transferred from UDP-glucose to the C4—OH group of a terminal residue on a growing glycogen chain by glycogen synthase. The chain is initiated on glycogenin. Branching occurs through the action of glycogen branching enzyme, which transfers  $\sim 7$ -residue segments of  $\alpha(1 \rightarrow 4)$ -linked chains to the C6—OH group of a glucosyl residue on the same or another glycogen chain.

**3 Control of Glycogen Metabolism** The rates at which glycogen is synthesized by glycogen synthase and degraded by glycogen phosphorylase are controlled by the levels of their allosteric effectors such as ATP, AMP, G6P, and glucose. Superimposed on this allosteric control is control by the phosphorylation/dephosphorylation of these enzymes. The kinases and phosphatases that catalyze these modifications are part of amplifying cascades that are ultimately controlled by the hormones glucagon, insulin, and epinephrine, and by  $Ca^{2+}$ . Glucagon and epinephrine stimulate glycogen breakdown by stimulating adenylate cyclase to increase the intracellular

[cAMP]. cAMP is a “second messenger” that activates protein kinase A (PKA), which, through its activation of phosphorylase kinase, results in the phosphorylation of both glycogen phosphorylase and glycogen synthase. Phosphorylation activates glycogen phosphorylase but inactivates glycogen synthase. In addition, epinephrine causes an increase in the concentrations of other second messengers, namely, inositol-1,4,5-trisphosphate ( $IP_3$ ), diacylglycerol (DAG), and  $Ca^{2+}$ , that reinforce the cAMP-dependent responses.  $Ca^{2+}$ , which is also released into muscle cytosol by nerve impulses, binds to calmodulin so as to induce this protein to activate protein kinases via an intracellular mechanism by which  $Ca^{2+}$ -CaM extracts autoinhibitory sequences from the kinases' active sites. A decrease in [cAMP] and/or the presence of insulin leads to the activation of phosphoprotein phosphatase-1 to dephosphorylate glycogen phosphorylase and glycogen synthase.

The phosphoproteins that participate in glycogen metabolism are dephosphorylated through the action of phosphoprotein phosphatase-1, which is only active when it is associated with a glycogen particle through the intermediacy of glycogen-binding  $G_M$  or  $G_L$  subunits. When [glucose] is high, the liver synthesizes glucose-6-phosphate (G6P) and ultimately glycogen from glucose via the action of glucokinase (GK), which has kinetic properties distinct from those of other hexokinases. When [glucose] is low, GK is inhibited by glucokinase regulatory protein (GKRP) and G6Pase hydrolyzes the G6P product of glycogen breakdown (which is favored at low [glucose]) for export to other tissues. The concentration in liver of F2,6P, an activator of PFK and an inhibitor of FBPase, is also dependent on the rates of cAMP-dependent phosphorylation and dephosphorylation. It is both synthesized and degraded through the action of PFK-2/FBPase-2, whose enzymatic activities are oppositely controlled by both allosteric regulation and phosphorylation/dephosphorylation.

**4 Glycogen Storage Diseases** Glycogen storage diseases are caused by a genetic deficiency of one or another of the enzymes of glycogen metabolism. Ten different deficiencies of varying severity have been reported in humans.

## PROBLEMS

- A glycogen molecule consisting of 100,000 glucose residues is branched, on average, every 10 residues with one branch per tier. (a) How many reducing ends does it have? (b) How many tiers of branches does it have, on average?
- A mature glycogen particle typically has 12 tiers of branches with 2 branches per tier and 13 residues per branch. How many glucose residues are in such a particle?
- Calculations based on the volume of a glucose residue and the branching pattern of cellular glycogen indicate that a glycogen molecule could have up to 28 branching tiers before becoming impossibly dense. What are the advantages of such a molecule and why is it not found *in vivo*?
- The free energy of hydrolysis of an  $\alpha(1 \rightarrow 4)$  glycosidic bond is  $-15.5 \text{ kJ} \cdot \text{mol}^{-1}$ , whereas that of an  $\alpha(1 \rightarrow 6)$  glycosidic bond is  $-7.1 \text{ kJ} \cdot \text{mol}^{-1}$ . Use these data to explain why glycogen debranching includes three reactions [breaking and reforming  $\alpha(1 \rightarrow 4)$  bonds and hydrolyzing  $\alpha(1 \rightarrow 6)$  bonds], while glycogen branching requires only two reactions [breaking  $\alpha(1 \rightarrow 4)$  bonds and forming  $\alpha(1 \rightarrow 6)$  bonds].
- The complete metabolic oxidation of glucose to  $\text{CO}_2$  and  $\text{O}_2$  yields 32 ATPs (Section 22-2Bc). What is the fractional energetic cost of storing glucose as glycogen and later metabolizing the glycogen rather than directly metabolizing the glucose? (Recall that glycogen's branched structure results in its degradation to 92% G1P and 8% glucose.)
- What are the effects of the following on the rates of glycogen synthesis and glycogen degradation: (a) increasing the  $\text{Ca}^{2+}$  concentration, (b) increasing the ATP concentration, (c) inhibiting adenylate cyclase, (d) increasing the epinephrine concentration, and (e) increasing the AMP concentration?
- Show that hexokinase activity but not glucokinase activity is insensitive to blood [glucose] over the physiological range. Calculate the ratio of glucokinase to hexokinase activities when [glucose] is 2 mM (hypoglycemic), 5 mM (normal), and 25 mM (diabetic). Assume that  $K_M = 0.1 \text{ mM}$  for hexokinase and that both enzymes have the same  $V_{\max}$ .
- Compare the properties of a bicyclic cascade with those of a monocyclic cascade.
- The  $V_{\max}$  of muscle glycogen phosphorylase is much larger than that of liver. Discuss the functional significance of this phenomenon.
- How does epinephrine act on muscles to prepare them for "fight or flight"?
- A complication of glycogen metabolism that we have not discussed is that many protein kinases, including phosphorylase kinase, are autophosphorylating; that is, they can specifically phosphorylate and thereby activate themselves. Discuss how this phenomenon affects glycogen metabolism, taking into consideration the possibilities that phosphorylase kinase autophosphorylation may be an intramolecular or an intermolecular process.
- Explain the symptoms of von Gierke's disease.
- A sample of glycogen from a patient with liver disease is incubated with  $\text{P}_i$ , normal glycogen phosphorylase, and normal debranching enzyme. The ratio of glucose-1-phosphate to glucose formed in this reaction mixture is 100. What is the patient's most likely enzymatic deficiency? What is the probable structure of the patient's glycogen?

- Epilog: Complex Systems and Emergent Properties

Living things coordinate their activities at every level of their organization through complex chemical signaling systems. Intercellular signals occur through the mediation of chemical messengers known as **hormones** and, in higher animals, via neuronally transmitted electrochemical impulses. Intracellular communications are maintained by the synthesis or alteration of a great variety of different substances that are often integral components of the processes

they control. For example, metabolic pathways, as we have seen, are regulated by the feedback control of allosteric enzymes by metabolites in those pathways or by the covalent modification of these enzymes. In this chapter we consider chemical signaling and how these signals are mediated. We begin by discussing the functions of the major human hormone systems. We then discuss the three major pathways whereby intercellular signals are transduced (converted) to intracellular signals, namely, those that utilize (1) heterotrimeric G proteins, (2) receptor tyrosine kinases, and (3) phosphoinositide cascades. Neurotransmission is discussed in Section 20-5.

## 1 HORMONES

Hormones are classified according to the distance over which they act (Fig. 19-1):

**1. Endocrine hormones** act on cells distant from the site of their release. Endocrine hormones, for example, insulin and epinephrine, are synthesized and released in the bloodstream by specialized ductless **endocrine glands**.

**2. Paracrine hormones** (alternatively, **local mediators**) act only on cells close to the cell that released them. For example, an essential element of the immune response is initiated when a white blood cell known as a **macrophage** that has encountered a specific antigen binds a so-called **T cell** specific for that antigen. The macrophage thereupon releases a **protein growth factor** named **interleukin-1 (IL-1)** that stimulates the bound T cell to proliferate and differentiate (Section 35-2Aa).

**3. Autocrine hormones** act on the same cell that released them. For example, the response of a T cell to interleukin-1 is enhanced by the T cell's autostimulatory release of the protein growth factor **interleukin-2 (IL-2)**.

We are already familiar with certain aspects of hormonal control. For instance, we have considered how epinephrine, insulin, and glucagon regulate energy metabolism through the intermediacy of cAMP (Sections 18-3E and 18-3G). In this section we extend and systematize this information. Before we do so, you should note that biochemical communications are not limited to intracellular and intercellular signals. Many organisms release substances called **pheromones** that alter the behavior of other organisms of the same species in much the same way as

**Figure 19-1** Classification of hormones. Hormonal communications are classified according to the distance over which the signal acts: (a) endocrine signals are directed at distant

cells through the intermediacy of the bloodstream, (b) paracrine signals are directed at nearby cells, and (c) autocrine signals are directed at the cell that produced them.

hormones. Pheromones are commonly sexual attractants but some have other functions in species, such as ants, that have complex social interactions.

The human endocrine system (Fig. 19-2) secretes a wide variety of hormones (Table 19-1) that enable the body to:

1. Maintain homeostasis (e.g., insulin and glucagon maintain the blood glucose level within rigid limits during feast or famine).
2. Respond to a wide variety of external stimuli (such as the preparation for “fight or flight” engendered by epinephrine and norepinephrine).
3. Follow various cyclic and developmental programs (for instance, sex hormones regulate sexual differentiation, maturation, the menstrual cycle, and pregnancy; Sections 19-1Gb and 19-1I).

Most hormones are either polypeptides, amino acid derivatives, or steroids, although there are important exceptions to this generalization. In any case, *only those cells with a specific receptor for a given hormone will respond to its presence even though nearly all cells in the body may be exposed to the hormone.* Hormonal messages are therefore quite specifically addressed.

In this section, we outline the hormonal functions of the various endocrine glands. Throughout this discussion keep in mind that these glands are not just a collection of independent secretory organs but form a complex and highly interdependent control system. Indeed, as we shall see, the secretion of many hormones is under feedback control through the secretion of other hormones to which the original hormone-secreting gland responds. Much of our

**Figure 19-2** Major glands of the human endocrine system. Other tissues, the intestines, for example, also secrete endocrine hormones.

**Table 19-1** Some Human Hormones

Hormone	Origin	Major Effects
<b>Polypeptides</b>		
Corticotropin-releasing factor (CRF)	Hypothalamus	Stimulates ACTH release
Gonadotropin-releasing factor (GnRF)	Hypothalamus	Stimulates FSH and LH release
Thyrotropin-releasing factor (TRF)	Hypothalamus	Stimulates TSH release
Growth hormone-releasing factor (GRF)	Hypothalamus	Stimulates growth hormone release
Somatostatin	Hypothalamus	Inhibits growth hormone release
Adrenocorticotropic hormone (ACTH)	Adenohypophysis	Stimulates the release of adrenocorticosteroids
Follicle-stimulating hormone (FSH)	Adenohypophysis	In ovaries, stimulates follicular development, ovulation, and estrogen synthesis; in testes, stimulates spermatogenesis
Luteinizing hormone (LH)	Adenohypophysis	In ovaries, stimulates oocyte maturation and follicular synthesis of estrogens and progesterone; in testes, stimulates androgen synthesis
Chorionic gonadotropin (CG)	Placenta	Stimulates progesterone release from the corpus luteum
Thyrotropin (TSH)	Adenohypophysis	Stimulates T <sub>3</sub> and T <sub>4</sub> release
Somatotropin (growth hormone)	Adenohypophysis	Stimulates growth and synthesis of somatomedins
Met-enkephalin	Adenohypophysis	Opioid effects on central nervous system
Leu-enkephalin	Adenohypophysis	Opioid effects on central nervous system
β-Endorphin	Adenohypophysis	Opioid effects on central nervous system
Vasopressin	Neurohypophysis	Stimulates water resorption by kidney and increases blood pressure
Oxytocin	Neurohypophysis	Stimulates uterine contractions
Glucagon	Pancreas	Stimulates glucose release through glycogenolysis and stimulates lipolysis
Insulin	Pancreas	Stimulates glucose uptake through gluconeogenesis, protein synthesis, and lipogenesis
Gastrin	Stomach	Stimulates gastric acid and pepsinogen secretion
Secretin	Intestine	Stimulates pancreatic secretion of HCO <sub>3</sub> <sup>-</sup>
Cholecystokinin (CCK)	Intestine	Stimulates gallbladder emptying and pancreatic secretion of digestive enzymes and HCO <sub>3</sub> <sup>-</sup>
Gastric inhibitory peptide (GIP)	Intestine	Inhibits gastric acid secretion and gastric emptying; stimulates pancreatic insulin release
Parathyroid hormone	Parathyroid	Stimulates Ca <sup>2+</sup> uptake from bone, kidney, and intestine
Calcitonin	Thyroid	Inhibits Ca <sup>2+</sup> uptake from bone and kidney
Somatomedins	Liver	Stimulates cartilage growth; have insulinlike activity
<b>Steroids</b>		
Glucocorticoids	Adrenal cortex	Affect metabolism in diverse ways, decrease inflammation, increase resistance to stress
Mineralocorticoids	Adrenal cortex	Maintain salt and water balance
Estrogens	Gonads	Maturation and function of secondary sex organs, particularly in females
Androgens	Gonads	Maturation and function of secondary sex organs, particularly in males; male sexual differentiation
Progestins	Ovaries and placenta	Mediate menstrual cycle and maintain pregnancy
Vitamin D	Diet and sun	Stimulates Ca <sup>2+</sup> absorption from intestine, kidney, and bone
<b>Amino Acid Derivatives</b>		
Epinephrine	Adrenal medulla	Stimulates contraction of some smooth muscles and relaxes others, increases heart rate and blood pressure, stimulates glycogenolysis in liver and muscle, stimulates lipolysis in adipose tissue
Norepinephrine	Adrenal medulla	Stimulates arteriole contraction, decreases peripheral circulation, stimulates lipolysis in adipose tissue
Triiodothyronine (T <sub>3</sub> )	Thyroid	General metabolic stimulation
Thyroxine (T <sub>4</sub> )	Thyroid	General metabolic stimulation

understanding of hormonal function has come from careful measurements of hormone concentrations, the effects of changes of these concentrations on physiological functions, and measurements of the affinities with which hormones bind to their receptors. We begin, therefore, with a consideration of how physiological hormone concentrations are measured and how receptor–ligand interactions are quantified.

## A. Quantitative Measurements

### a. Radioimmunoassays

The serum concentrations of hormones are extremely small, generally between  $10^{-12}$  and  $10^{-7}$  M, so they usually must be measured by indirect means. Biological assays were originally employed for this purpose but they are generally slow, cumbersome, and imprecise. Such assays have therefore been largely supplanted by **radioimmunoassays**. In this technique, which was developed by Rosalyn Yalow, the unknown concentration of a hormone, H, is determined by measuring how much of a known amount of the radioactively labeled hormone, H\*, binds to a fixed quantity of anti-H antibody in the presence of H. This competition reaction is easily calibrated by constructing a standard curve indicating how much H\* binds to the antibody as a function of [H]. The high ligand affinity and specificity that antibodies possess gives radioimmunoassays the advantages of great sensitivity and specificity.

### b. Receptor Binding

Receptors, as do other proteins, bind their corresponding ligands according to the laws of mass action:

Here R and L represent receptor and ligand, and the reaction's dissociation constant is expressed:

$$K_L = \frac{[R][L]}{[R \cdot L]} = \frac{([R]_T - [R \cdot L])[L]}{[R \cdot L]} \quad [19.1]$$

where the total receptor concentration,  $[R]_T = [R] + [R \cdot L]$ . Equation [19.1] may be rearranged to a form analogous to the Michaelis–Menten equation of enzyme kinetics (Section 14-2A):

$$Y = \frac{[R \cdot L]}{[R]_T} = \frac{[L]}{K_L + [L]} \quad [19.2]$$

where Y is the fractional occupation of the ligand-binding sites. Equation [19.2] represents a hyperbolic curve (Fig. 19-3a) in which  $K_L$  may be operationally defined as the ligand concentration at which the receptor is half-maximally occupied by ligand.

Although  $K_L$  and  $[R]_T$  may, in principle, be determined from an analysis of a hyperbolic plot such as Fig. 19-3a, the analysis of a linear form of the equation is a simpler procedure. Equation [19.1] may be rearranged to:

$$\frac{[R \cdot L]}{[L]} = \frac{([R]_T - [R \cdot L])}{K_L} \quad [19.3]$$

**Figure 19-3** Binding of ligand to receptor. (a) A hyperbolic plot. (b) A Scatchard plot. Here  $B \equiv [R \cdot L]$ ,  $F \equiv [L]$ , and  $B_{\max} \equiv [R]_T$ .

Now, in keeping with customary receptor-binding nomenclature, let us redefine  $[R \cdot L]$  as B (for bound ligand), [L] as F (for free ligand), and  $[R]_T$  as  $B_{\max}$ . Then Eq. [19.3] becomes:

$$\frac{B}{F} = \frac{(B_{\max} - B)}{K_L} = -\frac{1}{K_L} \cdot B + \frac{B_{\max}}{K_L} \quad [19.4]$$

A plot of B/F versus B, which is known as a **Scatchard plot** (after George Scatchard, its originator), therefore yields a straight line of slope  $-1/K_L$  whose intercept on the B axis is  $B_{\max}$  (Fig. 19-3b). Here, both B and F may be determined by filter-binding assays as follows. Most receptors are insoluble membrane-bound proteins and may therefore be separated from soluble free ligand by filtration (receptors that have been solubilized may be separated from free ligand by filtration, for example, through nitrocellulose since proteins nonspecifically bind to nitrocellulose). Hence, through the use of radioactively labeled ligand, the values of B and F ( $[R \cdot L]$  and  $[L]$ ) may be determined, respectively, from the radioactivity on the filter and that remaining in solution. The rate of  $R \cdot L$  dissociation is generally so slow (half-times of minutes to hours) as to cause insignificant errors when the filter is washed to remove residual free ligand.

### c. Competitive-Binding Studies

Once the receptor-binding parameters for one ligand have been determined, the dissociation constant of other ligands for the same ligand-binding site may be determined through competitive-binding studies. The model describing this competitive binding is analogous to the competitive inhibition of a Michaelis–Menten enzyme (Section 14-3A):

where I is the competing ligand whose dissociation constant with the receptor is expressed:

$$K_I = \frac{[R][I]}{[R \cdot I]} \quad [19.5]$$

Thus, in direct analogy with the derivation of the equation describing competitive inhibition:

$$[R \cdot L] = \frac{[R]_T[L]}{K_L \left(1 + \frac{[I]}{K_I}\right) + [L]} \quad [19.6]$$

The relative affinities of a ligand and an inhibitor may therefore be determined by dividing Eq. [19.6] in the presence of inhibitor with that in the absence of inhibitor:

$$\frac{[R \cdot L]_I}{[R \cdot L]_0} = \frac{K_L + [L]}{K_L \left(1 + \frac{[I]}{K_I}\right) + [L]} \quad [19.7]$$

When this ratio is 0.5 (50% inhibition), the competitor concentration is referred to as  $[I_{50}]$  in analogy with the  $[IC_{50}]$  of drugs that inhibit enzymes (Section 15-4Aa). Thus, solving Eq. [19.7] for  $K_I$  at 50% inhibition:

$$K_I = \frac{[I_{50}]}{1 + \frac{[L]}{K_L}} \quad [19.8]$$

### B. Pancreatic Islet Hormones

The pancreas is a large glandular organ, the bulk of which is an **exocrine gland** dedicated to producing digestive enzymes such as trypsin, RNase A,  $\alpha$ -amylase, and phospholipase A<sub>2</sub> that it secretes via the pancreatic duct into the small intestine. However, ~1 to 2% of pancreatic tissue consists of scattered clumps of cells known as **islets of Langerhans**, which comprise an endocrine gland that functions to maintain energy metabolite homeostasis. Pancreatic islets contain three types of cells, each of which secretes a characteristic polypeptide hormone:

1. The  $\alpha$  cells secrete glucagon (29 residues; Section 18-3Ea).
2. The  $\beta$  cells secrete insulin (51 residues; Fig. 9-4).
3. The  $\delta$  cells secrete **somatostatin** (14 residues).

Insulin, which is secreted in response to high blood glucose levels, primarily functions to stimulate muscle, liver, and adipose cells to store glucose for later use by synthesizing glycogen, protein, and fat (Section 27-2). Glucagon, which is secreted in response to low blood glucose, has essentially the opposite effects: It stimulates liver to release glucose through glycogenolysis (Section 18-3E) and gluconeogenesis (Section 23-1) and it stimulates adipose tissue to release fatty acids through lipolysis. Somatostatin, which is also secreted by the hypothalamus (Section 19-1H), inhibits the release of insulin and glucagon from their islet cells and is

therefore thought to have a paracrine function in the pancreas.

Polypeptide hormones, as are other proteins destined for secretion, are ribosomally synthesized as preprohormones, processed in the rough endoplasmic reticulum and Golgi apparatus to form the mature hormone, and then packaged in secretory granules to await the signal for their release by exocytosis (Sections 12-4B, 12-4C, and 12-4D). The most potent physiological stimuli for the release of insulin and glucagon are, respectively, high and low blood glucose concentrations, so that islet cells act as the body's primary glucose sensors. However, the release of these hormones is also influenced by the autonomic (involuntary) nervous system and by hormones secreted by the gastrointestinal tract (Section 19-1C).

### C. Gastrointestinal Hormones

The digestion and absorption of nutrients are complicated processes that are regulated by the autonomic nervous system in concert with a complex system of polypeptide hormones. Indeed, gastrointestinal peptide hormones are secreted into the bloodstream by a system of specialized cells lining the gastrointestinal tract whose aggregate mass is greater than that of the rest of the endocrine system. Over 20 gastrointestinal hormones have been described. Four of the better characterized gastrointestinal hormones are:

1. **Gastrin** (17 residues), which is produced by the gastric mucosa, stimulates the gastric secretion of HCl and **pepsinogen** (the zymogen of the digestive protease pepsin). Gastrin release is stimulated by amino acids and partially digested protein as well as by the vagus nerve (which innervates the stomach) in response to stomach distension. Gastrin release is inhibited by HCl and by other gastrointestinal hormones.

2. **Secretin** (27 residues), which is produced by the mucosa of the duodenum (upper small intestine) in response to acidification by gastric HCl, stimulates the pancreatic secretion of  $HCO_3^-$  so as to neutralize this acid.

3. **Cholecystokinin (CCK; 8 residues)**, which is produced by the duodenum, stimulates gallbladder emptying, the pancreatic secretion of digestive enzymes and  $HCO_3^-$  (and thus enhances the effect of secretin), and inhibits gastric emptying. CCK is released in response to the products of lipid and protein digestion, that is, fatty acids, monoacylglycerols, amino acids, and peptides.

4. **Gastric inhibitory peptide (GIP, also known as glucose-dependent insulinotropic polypeptide; 42 residues)**, which is produced by specialized cells lining the small intestine, is a potent inhibitor of gastric acid secretion, gastric mobility, and gastric emptying. However, GIP's major physiological function is to stimulate pancreatic insulin release. Indeed, the release of GIP is stimulated by the presence of glucose in the gut, which accounts for the observation that, after a meal, the blood insulin level increases before the blood glucose level does.

These gastrointestinal hormones form families of related polypeptides: The C-terminal pentapeptides of gastrin and CCK are identical; secretin, GIP, and glucagon are closely similar. Two other gastrointestinal peptide hormones are discussed in Section 27-3C.

#### D. Thyroid Hormones

The thyroid gland produces two related hormones, **triiodothyronine (T<sub>3</sub>)** and **thyroxine (T<sub>4</sub>)**,

X = H **Triiodothyronine (T<sub>3</sub>)**

X = I **Thyroxine (T<sub>4</sub>)**

that stimulate metabolism in most tissues (adult brain is a conspicuous exception). The production of these unusual iodinated amino acids begins with the synthesis of **thyroglobulin**, a 2748-residue protein. Thyroglobulin is post-translationally modified in a series of biochemically unique reactions (Fig. 19-4):

1. Around 20% of thyroglobulin's 140 Tyr residues are iodinated in a **thyroperoxidase (TPO)**-catalyzed reaction forming **2,5-diiodotyrosyl** residues.

2. Two such residues are oxidatively coupled to yield T<sub>3</sub> and T<sub>4</sub> residues.

3. Mature thyroglobulin itself is hormonally inactive. However, some five or six molecules of the active hormones, T<sub>3</sub> and T<sub>4</sub>, are produced by the proteolysis in the lysosome of thyroglobulin on hormonal stimulation of the thyroid (Section 19-1H).

How do thyroid hormones work? T<sub>3</sub> and T<sub>4</sub>, being non-polar substances, are transported by the blood in complex

**Figure 19-4** Biosynthesis of T<sub>3</sub> and T<sub>4</sub> in the thyroid gland. The pathway involves the iodination, coupling, and hydrolysis

(proteolysis) of thyroglobulin Tyr residues. The relatively scarce I<sup>-</sup> is actively sequestered by the thyroid gland.

with plasma carrier proteins, primarily **thyroxine-binding globulin**, but also **prealbumin** and **albumin**. The hormones then pass through the cell membranes of their target cells into the cytosol, where they bind to a specific protein. Since the resulting hormone–protein complex does not enter the nucleus, it is thought that this complex acts to maintain an intracellular reservoir of thyroid hormones. The true **thyroid hormone receptor** is a chromosomally associated protein and therefore does not leave the nucleus. *The binding of  $T_3$ , and to a lesser extent  $T_4$ , activates this receptor as a transcription factor (Section 5-4Aa), resulting in increased rates of expression of numerous metabolic enzymes.* High affinity thyroid hormone–binding sites also occur on the inner mitochondrial membrane (the site of electron transport and oxidative phosphorylation; Section 22-1), suggesting that these receptors may directly regulate  $O_2$  consumption and ATP production.

Abnormal levels of thyroid hormones are common human afflictions. **Hypothyroidism** is characterized by lethargy, obesity, and cold dry skin, whereas **hyperthyroidism** has the opposite effects. The inhabitants of areas in which the soil has a low iodine content often develop hypothyroidism accompanied by an enlarged thyroid gland, a condition known as **goiter**. The small amount of NaI usually added to commercially available table salt (“iodized” salt) easily prevents this iodine deficiency disease. Young mammals require thyroid hormone for normal growth and development: Hypothyroidism during the fetal and immediate postnatal periods results in irreversible physical and mental retardation, a syndrome named **cretinism**.

### E. Control of Calcium Metabolism

$Ca^{2+}$  forms **hydroxyapatite**,  $Ca_5(PO_4)_3OH$ , the major mineral constituent of bone, and is an essential element in many biological processes including the mediation of hormonal signals as a second messenger, the triggering of mus-

cle contraction, the transmission of nerve impulses, and blood clotting. The extracellular  $[Ca^{2+}]$  must therefore be closely regulated to keep it at its normal level of  $\sim 1.2$  mM. Three hormones have been implicated in maintaining  $Ca^{2+}$  homeostasis (Fig. 19-5):

**1. Parathyroid hormone (PTH)**, an 84-residue polypeptide secreted by the parathyroid gland, which increases serum  $[Ca^{2+}]$  by stimulating its resorption from bone and kidney and by increasing the dietary absorption of  $Ca^{2+}$  from the intestine.

**2. Vitamin D**, a group of steroidlike substances that act in a synergistic manner with PTH to increase serum  $[Ca^{2+}]$ .

**3. Calcitonin**, a 33-residue polypeptide synthesized by specialized thyroid gland cells, which decreases serum  $[Ca^{2+}]$  by inhibiting the resorption of  $Ca^{2+}$  from bone and kidney.

We shall briefly discuss the functions of these hormones.

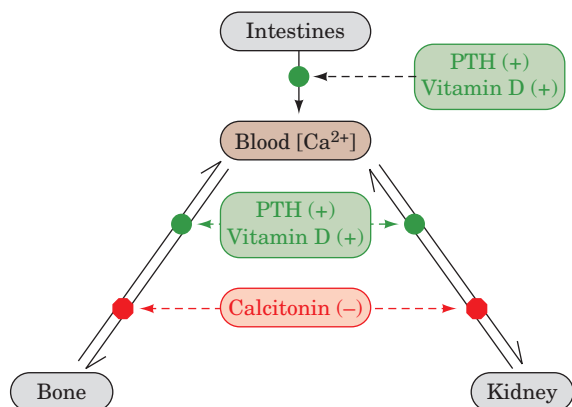

#### a. Parathyroid Hormone

The bones, the body’s main  $Ca^{2+}$  reservoir, are by no means metabolically inert. They are continually “remodeled” through the action of two types of bone cells: **osteoblasts** which synthesize the collagen fibrils that form the bulk of bone’s organic matrix, the scaffolding on which its  $Ca_5(PO_4)_3OH$  mineral phase is laid down; and **osteoclasts**, which participate in bone resorption (Section 15-4Ab). *PTH inhibits collagen synthesis by osteoblasts and stimulates bone resorption by osteoclasts. The main effect of PTH, however, is to increase the rate at which the kidneys excrete phosphate, the counterion of  $Ca^{2+}$  in bone.* The consequent decreased serum  $[P_i]$  causes  $Ca_5(PO_4)_3OH$  to leach out of bone through mass action and thus increase serum  $[Ca^{2+}]$ . In addition, PTH stimulates the production of the active form of vitamin D by the kidney, which, in turn, enhances the transfer of intestinal  $Ca^{2+}$  to the blood (see below).

#### b. Vitamin D

Vitamin D is a group of fat-soluble dietary substances that prevent **rickets**, a disease of children characterized by stunted growth and deformed bones stemming from insufficient bone mineralization (vitamin D deficiency in adults is known as **osteomalacia**, a condition characterized by weakened, demineralized bones). Although rickets was first described in 1645, it was not until the early twentieth century that it was discovered that animal fats, particularly fish liver oils, are effective in preventing this deficiency disease. Moreover, rickets can also be prevented by exposing children to sunlight or just UV light in the wavelength range 230 to 313 nm, regardless of their diets.

The D vitamins, which we shall see are really hormones, are sterol derivatives (Section 12-1E) in which the steroid B ring is disrupted at its 9,10 position. The natural form of the vitamin, **vitamin D<sub>3</sub> (cholecalciferol)**, is nonenzymatically

**Figure 19-5** Roles of PTH, vitamin D, and calcitonin in controlling  $Ca^{2+}$  metabolism.

formed in the skin of animals through the photolytic action of UV light on **7-dehydrocholesterol**:

**Vitamin D<sub>2</sub> (ergocalciferol)**, which differs from vitamin D<sub>3</sub> only by a side chain double bond and methyl group, is formed by the UV irradiation of the plant sterol **ergosterol**. Since vitamins D<sub>2</sub> and D<sub>3</sub> have essentially identical biological activities, vitamin D<sub>2</sub> is commonly used as a vitamin supplement, particularly in milk.

Vitamins D<sub>2</sub> and D<sub>3</sub> are hormonally inactive as such; they gain biological activity through further metabolic processing, first in the liver and then in the kidney (Fig. 19-6):

1. In the human liver, vitamin D<sub>3</sub> is hydroxylated to form **25-hydroxycholecalciferol** in an O<sub>2</sub>-requiring reaction catalyzed by either of two cytochrome P450's (Section 15-4Bc), **CYP27A1** and **CYP2R1**.

2. The 25-hydroxycholecalciferol is transported to the kidney, where it is further hydroxylated by **CYP27B1** to yield the active hormone **1 $\alpha$ ,25-dihydroxycholecalciferol [1,25(OH)<sub>2</sub>D]**. *CYP27B1* is activated by PTH, so this reaction is an important control point in Ca<sup>2+</sup> homeostasis.

These various nonpolar substances are transported in the bloodstream in complex with **vitamin D-binding protein**.

1,25(OH)<sub>2</sub>D acts to increase serum [Ca<sup>2+</sup>] by promoting the intestinal absorption of dietary Ca<sup>2+</sup> and by stimulating Ca<sup>2+</sup> release from bone. Intestinal Ca<sup>2+</sup> absorption is stimulated through increased synthesis of a **Ca<sup>2+</sup>-binding protein**, which functions to transport Ca<sup>2+</sup> across the intestinal mucosa. 1,25(OH)<sub>2</sub>D binds to cytoplasmic receptors in intestinal epithelial cells that, on transport to the nucleus, function as transcription factors for the Ca<sup>2+</sup>-binding protein. The maintenance of electroneutrality requires that Ca<sup>2+</sup> transport be accompanied by that of counterions, mostly P<sub>i</sub>, so that 1,25(OH)<sub>2</sub>D also stimulates the intestinal absorption of P<sub>i</sub>. The observation that 1,25(OH)<sub>2</sub>D, like PTH, stimulates the release of Ca<sup>2+</sup> and P<sub>i</sub> from bone seems paradoxical in view of the fact that low levels of 1,25(OH)<sub>2</sub>D result in subnormal bone mineralization. Presumably the increased serum [Ca<sup>2+</sup>] resulting from 1,25(OH)<sub>2</sub>D-stimulated intestinal uptake of Ca<sup>2+</sup> causes bone to take up more Ca<sup>2+</sup> than it loses through direct hormonal stimulation. In addition, vitamin D has been shown to modulate the immune response, provide protection against certain types of cancers, and has been implicated in preventing/reversing heart disease.

Vitamin D, unlike the water-soluble vitamins, is retained by the body, so that excessive intake of vitamin D over long periods causes **vitamin D intoxication** (although note that most individuals, particularly the elderly and those with limited sun exposure, have less than the recommended levels of vitamin D in their blood). The consequent high serum [Ca<sup>2+</sup>] results in aberrant calcification of a wide variety of soft tissues. The kidneys are particularly prone to calcification, a process that can lead to the formation of kidney stones and ultimately kidney failure. In addition, vitamin D intoxication promotes bone demineralization to the extent that bones are easily fractured. The observation that the level of skin pigmentation in indigenous human populations tends to increase with their proximity to the equator is explained by the hypothesis that skin pigmentation functions to prevent vitamin D intoxication by filtering out excessive solar radiation.

### c. Calcitonin

*Calcitonin has essentially the opposite effect of PTH; it lowers serum [Ca<sup>2+</sup>].* It does so primarily by inhibiting osteoclastic resorption of bone. Since PTH and calcitonin both stimulate the synthesis of cAMP in their target cells (Section 19-2A), it is unclear how these hormones can oppositely affect osteoclasts. Calcitonin also inhibits kidney from resorbing Ca<sup>2+</sup>, but in this case the kidney cells that calcitonin influences differ from those that PTH stimulates to resorb Ca<sup>2+</sup>.

### d. Osteoporosis

**Osteoporosis** (Section 15-4Ab) is a degenerative bone disease that results in an increased risk of bone fracture due to bone demineralization as well as changes in the amounts and variety of noncollagenous bone proteins. It is most common in postmenopausal women, although it also

**Figure 19-6** Activation of vitamin D<sub>3</sub> as a hormone in liver and kidney. Vitamin D<sub>2</sub> (ergocalciferol) is similarly activated.

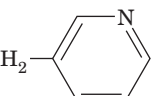

occurs in elderly men and as a consequence of certain hormonal disorders or the long-term administration of glucocorticoids (Section 19-1G).

Osteoporosis is most commonly treated by the administration of **bisphosphonates** (Fig. 19-7). These drugs bind to bone tissue from which they are absorbed by osteoclasts. There they inhibit **prenyltransferase** (Section 25-6Ac), an enzyme in the pathway forming the prenyl groups that anchor certain proteins to the cell membrane (Section 12-3Ba). This disrupts the contact region between the osteoclast and the bone surface, thus decreasing bone resorption. Bisphosphonate treatment is usually accompanied by calcium and vitamin D supplements and by load-bearing exercise.

### F. Epinephrine and Norepinephrine

The adrenal glands consist of two distinct types of tissue: the **medulla** (core), which is really an extension of the sympathetic nervous system (a part of the autonomic nervous system), and the more typically glandular **cortex** (outer layer). Here we consider the hormones of the adrenal medulla; those of the cortex are discussed in the following subsection.

	R <sub>1</sub>	R <sub>2</sub>
<b>Alendronate (Fosamax™)</b>	OH	(CH <sub>2</sub> ) <sub>2</sub> N(CH <sub>3</sub> ) <sub>2</sub>
<b>Ibandronate (Boniva™)</b>	OH	(CH <sub>2</sub> ) <sub>2</sub> N(CH <sub>3</sub> )(CH <sub>2</sub> ) <sub>4</sub> CH <sub>3</sub>
<b>Risedronate (Actonel™)</b>	OH	CH <sub>2</sub> - 

**Figure 19-7** Some bisphosphonates that are in clinical use against osteoporosis. Each drug has both a generic (chemical) name and proprietary trade name, here in parentheses, under which it is marketed.

The adrenal medulla synthesizes two hormonally active **catecholamines** (amine-containing derivatives of **catechol**, 1,2-dihydroxybenzene), **norepinephrine (noradrenaline)** and its methyl derivative **epinephrine (adrenaline)**:

**R = H**    **Norepinephrine (noradrenaline)**

**R = CH<sub>3</sub>**    **Epinephrine (adrenaline)**

These hormones are synthesized from tyrosine, as is described in Section 26-4B, and stored in granules to await their exocytotic release under the control of the sympathetic nervous system.

The biological effects of catecholamines are mediated by two classes of plasma transmembrane receptors, the **α-** and the **β-adrenergic receptors** (also known as **adreno-receptors**). These TM glycoproteins were originally identified on the basis of their varying responses to certain **agonists** (substances that bind to a hormone receptor so as to evoke a hormonal response) and **antagonists** (substances that bind to a hormone receptor but fail to elicit a hormonal response, thereby blocking agonist action). The β- but not the α-adrenergic receptors, for example, are stimulated by **isoproterenol** but blocked by **propranolol**, whereas α- but not β-adrenergic receptors are blocked by **phentolamine**:

**Isoproterenol**

**Propranolol**

**Phentolamine**

The α- and β-adrenergic receptors, which occur in separate tissues in mammals, generally respond differently and often oppositely to catecholamines. For instance, β-adrenergic receptors, which activate adenylate cyclase, stimulate glycogenolysis and gluconeogenesis in liver (Sections 18-3Ea and 18-3G), glycogenolysis and glycolysis in skeletal muscle,

lipolysis in adipose tissue, the relaxation of smooth (involuntary) muscle in the bronchi and the blood vessels supplying the skeletal (voluntary) muscles, and increased heart action. In contrast, α-adrenergic receptors, whose intracellular effects are mediated either by the inhibition of adenylate cyclase (**α<sub>2</sub> adrenergic receptors**; Section 19-2D) or via the phosphoinositide cascade (**α<sub>1</sub> adrenergic receptors**; Section 19-4A), stimulate smooth muscle contraction in blood vessels supplying peripheral organs such as skin and kidney, smooth muscle relaxation in the lung and gastrointestinal tract, and blood platelet aggregation. *Most of these diverse effects are directed toward a common end: the mobilization of energy resources and their shunting to where they are most needed to prepare the body for sudden action.*

The varying responses and tissue distributions of the α- and β-adrenergic receptors and their subtypes to different agonists and antagonists have important therapeutic consequences. For example, propranolol is used for the treatment of high blood pressure and protects heart attack victims from further heart attacks, whereas epinephrine's bronchodilator effects make it clinically useful in the treatment of **asthma**, a breathing disorder caused by the inappropriate contraction of bronchial smooth muscle.

## G. Steroid Hormones

### a. The Adrenocortical Steroids Mediate a Wide Variety of Metabolic Functions

The adrenal cortex produces at least 50 different **adrenocortical steroids** (whose synthesis is outlined in Section 25-6C). These have been classified according to the physiological responses they evoke:

1. The **glucocorticoids** affect carbohydrate, protein, and lipid metabolism in a manner nearly opposite to that of insulin and influence a wide variety of other vital functions, including inflammatory reactions and the capacity to cope with stress.
2. The **mineralocorticoids** largely function to regulate the excretion of salt and water by the kidney.
3. The **androgens** and **estrogens** affect sexual development and function. They are made in larger quantities by the gonads.

Glucocorticoids, the most common of which are **cortisol** (also known as **hydrocortisone**) and **corticosterone**, and the mineralocorticoids, the most common of which is **aldosterone**, are all C<sub>21</sub> compounds:

**Cortisol (hydrocortisone)**

the expression of secondary sex characteristics, and sexual behavior patterns. Although testes and ovaries both synthesize androgens and estrogens, the testes predominantly secrete androgens, which are therefore known as **male sex hormones**, whereas ovaries produce mostly estrogens, which are consequently termed **female sex hormones**.

Androgens, of which **testosterone** is prototypic,

Steroids, being water insoluble, are transported in the blood in complex with the glycoprotein **transcortin** and, to a lesser extent, by albumin. The steroids (including vitamin D) spontaneously pass through the membranes of their target cells to the cytosol, where they bind to their cognate receptors. The steroid–receptor complexes then migrate to the cell nucleus, where they function as transcription factors to induce, or in some cases repress, the transcription of specific genes (a process that is discussed in Section 34-3Bn). In this way, the glucocorticoids and the mineralocorticoids influence the expression of numerous metabolic enzymes in their respective target tissues. Thyroid hormones, which are also nonpolar, function similarly. However, as we shall see in the following sections, all other hormones act less directly in that they bind to their cognate cell-surface receptors and thereby trigger complex cascades of events within cells that ultimately influence transcription as well as other cellular processes.

Impaired adrenocortical function, either through disease or trauma, results in a condition known as **Addison's disease**, which is characterized by hypoglycemia, muscle weakness,  $\text{Na}^+$  loss,  $\text{K}^+$  retention, impaired cardiac function, loss of appetite, and a greatly increased susceptibility to stress. The victim, unless treated by the administration of glucocorticoids and mineralocorticoids, slowly languishes and dies without any particular pain or distress. The opposite problem, adrenocortical hyperfunction, which is usually caused by a tumor of the adrenal cortex or the pituitary gland (Section 19-1H), results in **Cushing's syndrome**, which is characterized by fatigue, hyperglycemia, edema (water retention), and a redistribution of body fat to yield a characteristic “moon face.” Long-term treatments of various diseases with synthetic glucocorticoids result in similar symptoms.

### b. Gonadal Steroids Mediate Sexual Development and Function

The **gonads** (*testes in males, ovaries in females*), in addition to producing sperm or ova, secrete steroid hormones (*androgens and estrogens*) that regulate sexual differentiation,

lack the  $\text{C}_2$  substituent at  $\text{C}_{17}$  present in glucocorticoids and are therefore  $\text{C}_{19}$  compounds. Estrogens, such as  **$\beta$ -estradiol**, resemble androgens but lack a  $\text{C}_{10}$  methyl group because they have an aromatic A ring and are therefore  $\text{C}_{18}$  compounds. Interestingly, testosterone is an intermediate in estrogen biosynthesis (Section 25-6C). A second class of ovarian steroids,  $\text{C}_{21}$  compounds called **progestins**, help mediate the menstrual cycle and pregnancy (Section 19-1I). **Progesterone**, the most abundant progestin, is, in fact, a precursor of glucocorticoids, mineralocorticoids, and testosterone (Section 25-6C).

### c. Sexual Differentiation Is Both Hormonally and Genetically Controlled

What factors control sexual differentiation? If the gonads of an embryonic male mammal are surgically removed, that individual will become a phenotypic female. Evidently, *mammals are programmed to develop as females unless embryonically subjected to the influence of testicular hormones*. Indeed, genetic males with absent or nonfunctional cytosolic androgen receptors are phenotypic females, a condition named **testicular feminization**. Curiously, estrogens appear to play no part in embryonic female sexual development, although they are essential for female sexual maturation and function.

Normal individuals have either the XY (male) or the XX (female) genotypes (Section 1-4C). However, those with the abnormal genotypes XXY (**Klinefelter's syndrome**) and X0 (only one sex chromosome; **Turner's syndrome**) are, respectively, phenotypic males and phenotypic females, although both are sterile. Apparently, *the normal Y chromosome confers the male phenotype, whereas its absence results in the female phenotype*. There are, however, rare (1 in 20,000) XX males and XY females. These XX males (who are sterile and have therefore been identified through infertility clinics) have a small segment of a normal Y chromosome translocated onto one of their X chromosomes, whereas XY females are missing this segment.

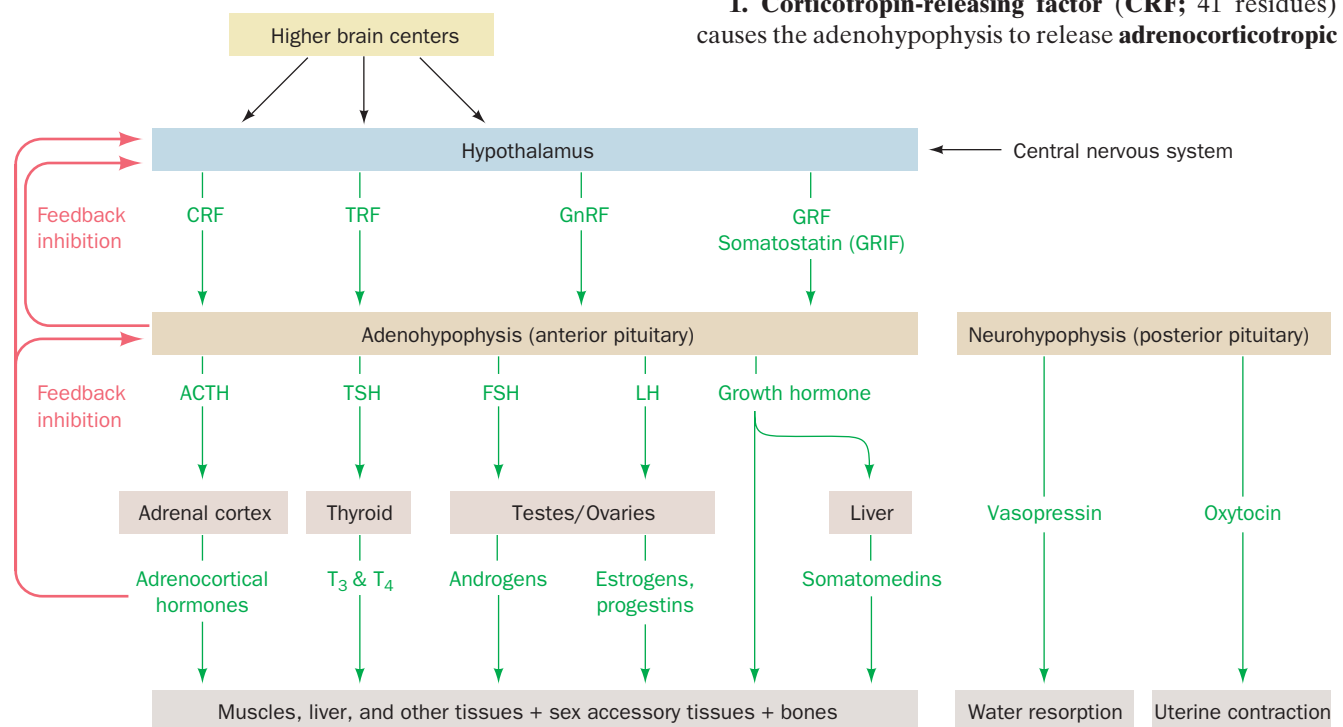

Early male and female embryos—through the sixth week of development in humans—have identical undifferentiated genitalia. Evidently, the Y chromosome contains a gene, **testes-determining factor (TDF)**, that induces the differentiation of testes, whose hormonal secretions, in turn, promote male development. The misplaced chromosomal segments in XY females and XX males have a common 140-kb sequence that contains a structural gene dubbed **SRY** (for sex-determining region of Y) that encodes an 80-residue DNA-binding motif. Several sex-reversed XY women have a mutation in the region of their *SRY* gene encoding this DNA-binding domain that eliminates its ability to bind DNA, a mutation that is not present in their father's gene. *SRY* is expressed in embryonic go-

nadal cells previously shown to be responsible for testis determination. Moreover, of eleven XX mice that were made transgenic for *Sry* (the mouse analog of *SRY*), three were males. Thus, *TDF/SRY* is the first clear example of a mammalian gene that controls the development of an entire organ system (development is discussed in Section 34-4B).

#### H. Control of Endocrine Function: The Hypothalamus and Pituitary Gland

The anterior lobe of the **pituitary gland** (the **adenohypophysis**) and the **hypothalamus**, a nearby portion of the brain, constitute a functional unit that hormonally controls much of the endocrine system. *The neurons of the hypothalamus synthesize a series of polypeptide hormones known as releasing factors and release-inhibiting factors which, on delivery to the adenohypophysis via a direct circulatory connection (their half-lives are on the order of a few minutes), stimulate or inhibit the release of the corresponding trophic hormones into the bloodstream.* Trophic hormones, by definition, stimulate their target endocrine tissues to secrete the hormones they synthesize. Since releasing and release-inhibiting factors, trophic hormones, and endocrine hormones are largely secreted in nanogram, microgram, and milligram quantities per day, respectively, and tend to have progressively longer half-lives, these hormonal systems can be said to form amplifying cascades. Four such systems are prominent in humans (Fig. 19-8; left):

**1. Corticotropin-releasing factor (CRF; 41 residues)** causes the adenohypophysis to release **adrenocorticotropic**

**Figure 19-8** Hormonal control circuits, indicating the relationships between the hypothalamus, pituitary, and target tissues. Releasing factors and release-inhibiting factors secreted by the hypothalamus signal the adenohypophysis to secrete or stop secreting the corresponding trophic hormones, which, for the most part, stimulate the corresponding endocrine gland(s) to

secrete their respective endocrine hormones. The endocrine hormones, in addition to controlling the growth, differentiation, and metabolism of their corresponding target tissues, influence the secretion of releasing factors and trophic hormones through feedback inhibition. The levels of trophic hormones likewise influence the levels of their corresponding releasing factors.

**hormone (ACTH; 39 residues)**, which stimulates the release of adrenocortical steroids. *The entire system is under feedback control: ACTH inhibits the release of CRF and the adrenocortical steroids inhibit the release of both CRF and ACTH. Moreover, the hypothalamus, being part of the brain, is also subject to neuronal control, so the hypothalamus forms the interface between the nervous system and the endocrine system.*

**2. Thyrotropin-releasing factor (TRF)**, a tripeptide with an N-terminal **pyroGlu** residue (a Glu derivative in which the side chain carboxyl group forms an amide bond with its amino group),

**Thyrotropin-releasing factor (TRF)**

stimulates the adenohypophysis to release the trophic hormone **thyrotropin (thyroid-stimulating hormone; TSH)** which, in turn, stimulates the thyroid to synthesize and release  $T_3$  and  $T_4$ . TRF, as are other releasing factors, is present in the hypothalamus in only vanishingly small quantities. It was independently characterized in 1969 by Roger Guillemin and Andrew Schally using extracts of the hypothalami from over 2 million sheep and 1 million pigs.

**3. Gonadotropin-releasing factor (GnRF; 10 residues)**

stimulates the adenohypophysis to release **luteinizing hormone (LH)** and **follicle-stimulating hormone (FSH)**, which are collectively known as **gonadotropins**. In males, LH stimulates the testes to secrete androgens, whereas FSH promotes spermatogenesis. In females, FSH stimulates the development of ovarian follicles (which contain the immature ova), whereas LH triggers ovulation.

**4. Growth hormone-releasing factor (GRF; 44 residues) and somatostatin [14 residues; also known as growth hormone release-inhibiting factor (GRIF)],** stimulate/inhibit the release of **growth hormone (GH)** from the adenohypophysis. GH (also called **somatotropin**), in turn, stimulates generalized growth (see Fig. 5-5 for a striking example of its effect). GH directly accelerates the growth of a variety of tissues (in contrast to TSH, LH, and FSH, which act only indirectly by activating endocrine glands) and induces the liver to synthesize a series of polypeptide growth factors termed **somatomedins** that stimulate cartilage growth and have insulinlike activities.

TSH, LH, and FSH are heterodimeric glycoproteins, which in a given species, all have the same  $\alpha$  subunit (92 residues) and a homologous  $\beta$  subunit (114, 114, and 118 residues, respectively, in humans). Human GH consists of a single 191-residue polypeptide chain, which is unrelated to TSH, LH, or FSH.

### a. The Neurohypophysis Secretes Oxytocin and Vasopressin

The posterior lobe of the pituitary, the **neurohypophysis**, which is anatomically distinct from the adenohypophysis, secretes two homologous nonapeptide hormones (Fig. 19-8, right): **vasopressin** [also known as **antidiuretic hormone (ADH)**], which increases blood pressure and stimulates the kidneys to retain water; and **oxytocin**, which causes contraction of uterine smooth muscle and therefore induces labor:

**Human vasopressin**

**Human oxytocin**

The rate of vasopressin release is largely controlled by osmoreceptors, which monitor the osmotic pressure of the blood.

### I. Control of the Menstrual Cycle

The menstrual cycle and pregnancy are particularly illustrative of the interactions among hormonal systems. The ~28-day human menstrual cycle (Fig. 19-9) begins during menstruation with a slight increase in the FSH level that initiates the development of a new ovarian follicle. As the follicle matures, it secretes estrogens that act to sensitize the adenohypophysis to GnRF. This process culminates in a surge of LH and FSH, which triggers ovulation. The ruptured ovarian follicle, the **corpus luteum**, secretes progesterone and estrogens, which inhibit further gonadotropin

**Figure 19-9** Patterns of hormone secretion during the menstrual cycle in the human female.

secretion by the adenohypophysis and stimulate the uterine lining to prepare for the implantation of a fertilized ovum. If fertilization does not occur, the corpus luteum regresses, progesterone and estrogen levels fall, and menstruation (the sloughing off of the uterine lining) ensues. The reduced steroid levels also permit a slight increase in the FSH level, which initiates a new menstrual cycle.

A fertilized ovum that has implanted into the hormonally prepared uterine lining soon commences synthesizing **chorionic gonadotropin (CG)**. This heterodimeric glycoprotein hormone contains a 145-residue  $\beta$  subunit that has a high degree of sequence identity with those of LH (85%), FSH (45%), and TSH (36%) over their N-terminal 114 residues and the same  $\alpha$  subunit. CG stimulates the corpus luteum to continue secreting progesterone rather than regressing and thus prevents menstruation. Pregnancy tests utilize immunoassays that can detect CG in blood or urine within a few days after embryo implantation. Most female oral contraceptives (birth control pills) contain progesterone derivatives, whose ingestion induces a state of pseudopregnancy in that they inhibit the midcycle surge of FSH and LH so as to prevent ovulation.

### J. Growth Hormone and Its Receptor

The binding of growth hormone activates its receptor to stimulate growth and metabolism in muscle, bone, and cartilage cells. This 620-residue receptor is a member of a large family of structurally related protein growth factor receptors, which includes those for various interleukins (Section 19-3Eb). All of these receptors consist of an N-terminal extracellular ligand-binding domain, a single transmembrane segment that is almost certainly helical, and a C-terminal cytoplasmic domain that is not homologous within the superfamily but in many cases contains a tyrosine kinase function (Section 19-3A).

The X-ray structure of the 191-residue human growth hormone (**hGH**) in complex with the 238-residue **ectodomain** (extracellular portion; Greek: *ectos*, outside) of its binding protein (**hGHbp**), determined by Abraham de Vos and Anthony Kossiakoff, revealed that this complex consists of two molecules of hGHbp bound to a single hGH molecule (Fig. 19-10). hGH consists largely of an up–up–down–down four-helix bundle, which closely resembles that in the previously determined X-ray structure of porcine GH, although with significant differences that may be caused by the binding of hGH to its receptor. A variety of other protein growth factors with known structures, including many interleukins (Section 19-3Eb), contain similar four-helix bundles. Each hGHbp molecule consists of two structurally similar  $\sim$ 100-residue **fibronectin type III domains**, each of which forms a topologically identical sandwich of a three- and a four-stranded antiparallel  $\beta$  sheet that resembles the immunoglobulin fold (Fig. 8-48). Fibronectin type III domains, so called because they were first observed in the multidomain extracellular matrix glycoprotein **fibronectin**, are among the most common structural modules in receptor ectodomains.

**Figure 19-10** X-ray structure of human growth hormone (hGH) in complex with two molecules of its receptor's extracellular domain (hGHbp). The proteins are drawn in ribbon form, with the hGH magenta and the two hGHbp molecules, which together bind one molecule of hGH, each colored in rainbow order from N-terminus (blue) to C-terminus (red). The view is along the axis of the hGH's four-helix bundle with the approximate 2-fold axis relating the two hGHbp molecules vertical. The dotted red lines represent the pathways that the hGHbp chains take in penetrating the membrane. Note that the width of a membrane is actually nearly the  $\sim$ 75-Å height of the hGHbp–hGH–hGHbp complex. [Based on an X-ray structure by Abraham de Vos and Anthony Kossiakoff, Genentech Inc., South San Francisco, California. PDBid 3HHR.]  See Interactive Exercise 11

The two hGHbp molecules bind to hGH with near 2-fold symmetry about an axis that is roughly perpendicular to the helical axes of the hGH four-helix bundle and, presumably, to the plane of the cell membrane to which the intact hGH receptor is anchored (Fig. 19-10). The C-terminal domains of the two hGHbp molecules are almost parallel and in contact with one another. Intriguingly, the two hGHbp molecules use essentially the same residues to bind to sites that are on opposite sides of hGH's four-helix bundle and that have no structural similarity. The X-ray structure is largely consistent with the results of mutational studies designed to identify the hGH and hGHbp residues important for receptor binding.

*The ligand-induced dimerization of hGHbp has important implications for the mechanism of signal transduction.* The dimerization, which does not occur in the absence of hGH, apparently brings together the intact receptors' intracellular domains in a way that activates an effector protein such as a tyrosine kinase (Section 19-3A). Indeed, hGH mutants that cannot induce receptor

**Figure 19-13 X-ray structure of rat nNOS.** (a) Its N-terminal oxygenase domain in complex with heme, L-arginine, and H<sub>4</sub>B. (b) Its C-terminal reductase domain in complex with FMN, FAD, and NADP<sup>+</sup>. In both structures the homodimeric protein is viewed in semitransparent ribbon form with its 2-fold axis vertical and with one subunit colored in rainbow order from N-terminus (*blue*) to C-terminus (*red*) and the other subunit blue-gray. The various bound groups are drawn in space-filling

form colored according to atom type (heme and FMN C green, L-arginine and FAD C cyan, H<sub>4</sub>B and NADP<sup>+</sup> C magenta, N blue, O red, P orange, and Fe red-brown). [Part *a* based on an X-ray structure by Thomas Poulos, University of California at Irvine; and Part *b* based on an X-ray structure by John Tainer and Elizabeth Getzoff, The Scripps Research Institute, La Jolla, California. PDBids 1OM4 and 1TLL.]

binding site was in the full-length subunit, the enzymatic activity of this heterodimer was unaffected, but if it was in the oxygenase domain-only subunit, activity was abolished.

The heme Fe atom is 5-coordinated with its axial ligand supplied by a specific Cys S atom. The L-arginine substrate binds on the opposite side of the heme from this Cys with the N atom to be hydroxylated ~4.0 Å distant from the Fe atom, a distance too large for covalent bond formation. Since O<sub>2</sub> is known to react with the heme Fe atom, it presumably binds between it and this N atom.

NOS requires bound H<sub>4</sub>B to produce NO. In the absence of this prosthetic group, NOS efficiently catalyzes the NADPH-mediated oxidation of O<sub>2</sub> to H<sub>2</sub>O<sub>2</sub>. Investigations by Steuhr have established that H<sub>4</sub>B functions as an internal redox agent in that, during the reactions forming both NOHA and NO, it is oxidized to its radical form (H<sub>4</sub>B<sup>•</sup>) and then re-reduced to its reduced form (H<sub>4</sub>B). Thus, H<sub>4</sub>B does not undergo net oxidation in the NOS reaction (as it does in the reaction hydroxylating phenylalanine to tyrosine; Section 26-3Ha).

NO rapidly diffuses across cell membranes, although its high reactivity prevents it from traveling >1 mm from its site of synthesis (in particular, it efficiently reacts with both oxyhemoglobin and deoxyhemoglobin: NO + HbO<sub>2</sub> → NO<sub>3</sub><sup>-</sup> + metHb; and NO + Hb → HbNO; Section 10-1A). *The physiological target of NO in smooth muscle cells is*

*guanylate cyclase (GC)*, which catalyzes the reaction of GTP to yield **3',5'-cyclic GMP (cGMP)**,

**3',5'-Cyclic GMP (cGMP)**

an intracellular second messenger that resembles 3',5'-cyclic AMP (cAMP; GC is a homolog of adenylate cyclase; Section 19-2D). cGMP causes smooth muscle relaxation through its stimulation of protein phosphorylation by **cGMP-dependent protein kinase**. NO reacts with GC's heme prosthetic group to yield **nitrosoheme**, whose presence increases GC's activity by up to 200-fold, presumably via a conformation change resembling that in hemoglobin on binding O<sub>2</sub> (Section 10-2Ba; although GC binds O<sub>2</sub> quite poorly).

### b. eNOS and nNOS but Not iNOS Are Regulated by $[Ca^{2+}]$

$Ca^{2+}$ -calmodulin activates eNOS and nNOS by binding to the ~30-residue segments linking their oxygenase and reductase domains. Thus, for example, the stimulatory action of vasodilatory agents on the phosphoinositide signaling system (Section 19-4A) in endothelial cells to produce an influx of  $Ca^{2+}$  results in the synthesis of NO. Hence, *NO functions to transduce hormonally induced increases in intracellular  $[Ca^{2+}]$  in endothelial cells to increased rates of production of cGMP in neighboring smooth muscle cells.*

NO produced by nNOS mediates vasodilation through endothelium-independent neural stimulation of smooth muscle. In this signal transduction pathway, which is responsible for the dilation of cerebral and other arteries as well as penile erection (see Section 19-2E), nerve impulses cause an increased  $[Ca^{2+}]$  in nerve terminals, thereby stimulating neuronal NOS. The resultant NO diffuses to nearby smooth muscle cells, where it binds to guanylate cyclase and activates it to synthesize cGMP as described above.

Inducible NOS (iNOS) is unresponsive to  $Ca^{2+}$  even though it has two tightly bound calmodulin subunits. However, it is transcriptionally induced in macrophages and **neutrophils** (white blood cells that function to ingest and kill bacteria), as well as in endothelial and smooth muscle cells (in contrast, eNOS and nNOS are expressed **constitutively**, that is, at a constant rate). Several hours after exposure to **cytokines** (protein growth factors that regulate the differentiation, proliferation, and activities of many types of cells; Section 19-3Eb) and/or **endotoxins** (bacterial cell wall lipopolysaccharides that elicit inflammatory responses; Section 35-2Fb), these cells begin to produce large quantities of NO and continue to do so for many hours. Activated macrophages and neutrophils also produce superoxide ion ( $O_2^-$ ), which chemically combines with NO to form the even more toxic **peroxynitrite** ( $OONO^-$ , which rapidly reacts with  $H_2O$  to yield the highly reactive **hydroxide radical**,  $OH\cdot$ , and  $NO_2$ ) that they use to kill ingested bacteria. Indeed, NOS inhibitors block the cytotoxic actions of macrophages.

Cytokines and endotoxins induce a long-lasting and profound vasodilation and a poor response to vasoconstrictors such as epinephrine. The sustained release of NO has been implicated in **septic shock** (an often fatal immune system overreaction to bacterial infection that results in a catastrophic reduction in blood pressure), in inflammation-related tissue damage as occurs in autoimmune diseases such as rheumatoid arthritis, and in the damage to neurons in the vicinity of but not directly killed by a stroke (reperfusion injury; Section 10-1Aa). Many of these conditions might be alleviated if drugs can be developed that selectively inhibit iNOS and/or nNOS, while permitting eNOS to carry out its essential function of maintaining vascular tone. Moreover, the administration of NO itself appears to be medically useful. For example, the inhalation of low levels NO has been used to reduce **pulmonary hypertension** (high blood pressure in the lung, an often fatal condition caused by constriction of its arteries) in newborn infants.

## 2 HETEROTRIMERIC G PROTEINS

We have seen (Section 18-3) that hormones such as glucagon and epinephrine regulate glycogen metabolism by stimulating adenylate cyclase (AC) to synthesize the second messenger cAMP from ATP. The cAMP then binds to protein kinase A (PKA) so as to activate this enzyme to initiate cascades of phosphorylation/dephosphorylation events that ultimately control the activities of glycogen phosphorylase and glycogen synthase. Numerous other extracellular signaling molecules (known agonists, ligands, or **effectors**) also activate the intracellular synthesis of cAMP, thereby eliciting a cellular response. But what is the mechanism through which the binding of an agonist to a receptor induces AC to synthesize cAMP in the cytosol? In answering this question we shall see that the systems that link receptors to AC as well as other effectors have a surprising complexity that endows them with immense capacity for both signal amplification and regulatory flexibility.

### A. Overview

 See **Guided Exploration 16: Mechanisms of hormone signaling involving the adenylate cyclase system** Adenylate cyclase, which is located on the plasma membrane's cytosolic surface, and the receptors that activate it, whose agonist-binding sites are exposed to the extracellular space, are separate proteins that do not physically interact. Rather, *they are functionally coupled by heterotrimeric G proteins* (Fig. 19-14), so called because they specifically bind the guanine nucleotides GTP and GDP.

AC is activated by a heterotrimeric G protein (often called just a G protein) but only when the G protein is complexed with GTP. However, G protein slowly hydrolyzes GTP to  $GDP + P_i$  (at the leisurely rate of  $2-3 \text{ min}^{-1}$ ) and thereby deactivates itself (if G proteins were efficient enzymes, they would be unable to effectively activate AC). G protein is reactivated by the exchange of its bound GDP for GTP, a process that is mediated by the agonist-receptor complex but not by unoccupied receptor. *Heterotrimeric G protein therefore mediates the transduction of an extracellular signal to an intracellular signal (the cAMP). Moreover, the receptor-G protein-AC system amplifies the extracellular signal because each agonist-receptor complex activates many G proteins before it is inactivated by the spontaneous dissociation of the agonist and, during its lifetime, each G protein · GTP-AC complex catalyzes the formation of many cAMP molecules.* In this section, we discuss how this process occurs.

Heterotrimeric G proteins are members of the superfamily of regulatory GTPases that are collectively known as **G proteins** (whether one is referring to a heterotrimeric or some other species of G protein is usually clear from context). G proteins other than heterotrimeric G proteins have a wide variety of essential functions including signal transduction (e.g., **Ras**; Section 19-3Cf), vesicle trafficking (e.g., Arf, dynamin, and Rab; Sections 12-4Cd and 12-4Db), translation (as ribosomal accessory factors; Section 32-3), and targeting [as components of the signal recognition

**Figure 19-14** Activation/deactivation cycle for hormonally stimulated AC. (a) In the absence of hormone, heterotrimeric G protein binds GDP and AC is catalytically inactive. (b) The hormone–receptor complex stimulates the G protein to exchange its bound GDP for GTP. (c) The G protein · GTP

complex, in turn, binds to and thereby activates AC to produce cAMP. (d) The eventual G protein-catalyzed hydrolysis of its bound GTP to GDP causes G protein to dissociate from and hence deactivate AC.

particle (SRP) and the SRP receptor; Section 12-4Ba]. The many G proteins share common structural motifs that bind guanine nucleotides (GDP and GTP) and catalyze the hydrolysis of GTP to GDP + P<sub>i</sub> (see below).

### B. G Protein-Coupled Receptors

The receptors responsible for activating AC and other targets of heterotrimeric G proteins are all integral proteins with 7 transmembrane helices (Fig. 19-15) that have their N-termini in the extracellular space and their C-termini in the cytosol. These **G protein-coupled receptors (GPCRs)**; also called **heptahelical, 7TM, and serpentine receptors** constitute one of the largest known protein families (>800

**Figure 19-15** General structure of a G protein-coupled receptor (GPCR).

species in humans, which constitutes 3.5% of the ~23,000 genes in the human genome). They include receptors for nucleosides, nucleotides, Ca<sup>2+</sup>, catecholamines [epinephrine and norepinephrine as well as **dopamine** (Section 26-4B)] and other biogenic amines (e.g., **histamine** and **serotonin**; Section 26-4B), **eicosanoids (prostaglandins, prostacyclins, thromboxanes, leukotrienes, and lipoxins**, derivatives of the C<sub>20</sub> fatty acid arachidonic acid, which are potent local mediators of numerous important physiological processes; Section 25-7), and for most of the large variety of peptide and protein hormones discussed in Section 19-1. In addition, GPCRs have important sensory functions: They constitute the olfactory (odorant) and gustatory (taste) receptors (of which there are estimated to be 460 different types in humans), as well as the several light-sensing proteins in the retina, which are known as **rhodopsins**. In addition, the GPCRs constitute the most important class of drug targets in the pharmaceutical arsenal (Section 15-4): ~50% of approved drugs elicit their therapeutic effects by selectively interacting with specific GPCRs.

#### a. GPCRs Have Similar Structures

Despite the foregoing, the structures of only few species of GPCRs have yet been elucidated, mainly due to the apparent flexibilities of their extramembranous segments and the general difficulty of crystallizing transmembrane proteins (Section 12-3Aa). The first GPCR whose X-ray

**Figure 19-16** X-ray structure of bovine rhodopsin. The protein is viewed parallel to the plane of the plasma membrane with its approximate position therein indicated. The protein is represented by its transparent molecular surface with its polypeptide chain in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). Note its bundle of seven nearly parallel transmembrane helices. The protein's retinal prosthetic group (*magenta*) is drawn in space-filling form as are its two Cys-linked palmitoyl groups and its two N-linked oligosaccharide groups (colored according to atom type with C green, N blue, O red, and S yellow). [Based on an X-ray structure by Tetsuji Okada, National Institute of Advanced Industrial Science and Technology, Kyoto, Japan; and Volker Buss, University of Duisberg-Essen, Duisberg, Germany. PDBid 1U19.]

structure was reported was bovine rhodopsin (Fig. 19-16). Rhodopsin consists of the 348-residue protein **opsin** that is covalently linked to the chromophore **retinal** (Fig. 12-24) via a Schiff base to Lys 296, much as occurs in the homologous bacteriorhodopsin (Section 12-3Ab), which is a heptahelical light-driven proton pump (Section 22-3Bh). The absorption of a photon causes the rhodopsin-bound retinal to isomerize from its ground state 11-*cis* form to its all-*trans* form. This isomerization is accompanied by a transient conformational change in opsin before the all-*trans*-retinal is hydrolyzed and dissociated from the opsin (which is subsequently regenerated by the addition of 11-*cis*-retinal delivered from adjacent epithelial cells in the retina). It is this conformational change, which occurs mainly on rhodopsin's cytosolic surface, that activates its cognate G protein.

Rhodopsins are unique among GPCRs in that their 11-*cis* retinal "agonist" is covalently bound to the protein. All

other GPCRs bind diffusible ligands. The X-ray structures of  $\beta_1$ - and  $\beta_2$ -adrenergic receptors and the human  $A_{2A}$  adenosine receptor, the only other species of GPCRs whose structures have yet been determined, reveal that their transmembrane portions closely resemble each other and that of rhodopsin, and that their bound ligands occupy positions similar to that of retinal in rhodopsin. Note that the transmembrane helices of the GPCRs are more or less uniform in size (20–27 residues), but their extramembranous segments, which largely form their ligand- and G protein-binding sites, vary widely in length with the identity of the GPCR (7–595 residues for the N- and C-termini and 5–230 residues for the loops connecting their TM helices).

### C. Heterotrimeric G Proteins: Structure and Function

Heterotrimeric G proteins, which were first characterized by Alfred Gilman and Martin Rodbell, are more complex than Fig. 19-14 implies: They consist, as their name indicates, of three different subunits,  $\alpha$ ,  $\beta$ , and  $\gamma$  (45, 37, and 9 kD, respectively), of which it is  $G_\alpha$  that binds GDP and GTP (Fig. 19-17) and hence is a member of the G protein superfamily. The binding of  $G_\alpha \cdot \text{GDP} - G_{\beta\gamma}$  to its cognate ligand-GPCR complex induces the  $G_\alpha$  to exchange its bound GDP for GTP and, in so doing, to dissociate from  $G_{\beta\gamma}$ . In contrast,  $G_\beta$  and  $G_\gamma$  bind one another with such high affinity that they only dissociate under denaturing conditions. Consequently, we shall henceforth refer to their complex as  $G_{\beta\gamma}$ .

Both  $G_\alpha$  and  $G_{\beta\gamma}$  are membrane-anchored proteins:  $G_\alpha$  through its myristoylation or palmitoylation or both at or near its N-terminus (Section 12-3Bb), and  $G_{\beta\gamma}$  through the prenylation of  $G_\gamma$  at its C-terminus (Section 12-3Ba). These lipid modifications stabilize the interactions of  $G_\alpha$  with  $G_{\beta\gamma}$ , as they localize both to the inner surface of the plasma membrane.

GTP binding, in addition to decreasing  $G_\alpha$ 's affinity for its cognate ligand-GPCR complex, increases its affinity for its effector, AC. Thus, *it is the binding of  $G_\alpha \cdot \text{GTP}$  that activates AC* (Fig. 19-17, left).

$G_{\beta\gamma}$  can also directly participate in signal transduction: It activates a wide variety of signaling proteins including several isoforms of AC (Section 19-2D), certain  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Ca}^{2+}$ -specific ion channels, various **protein tyrosine kinases** (Section 19-3A), and **phospholipase C- $\beta$  (PLC- $\beta$ )**; a component of the phosphoinositide signaling system; Section 19-4Ba).  $G_{\beta\gamma}$  thereby provides an important source of cross talk between signaling systems.

On the eventual  $G_\alpha$ -catalyzed hydrolysis of GTP, the resulting  $G_\alpha \cdot \text{GDP}$  complex dissociates from AC and reassociates with  $G_{\beta\gamma}$  to reform inactive G protein. *Since  $G_\alpha$  hydrolyzes its bound GTP at a characteristic rate, it functions as a molecular clock that limits the length of time that both  $G_\alpha \cdot \text{GTP}$  and  $G_{\beta\gamma}$  can interact with their effectors.*

*Several types of ligand-GPCR complexes may activate the same G protein.* This occurs, for example, in liver cells in response to the binding of the corresponding hormones to

**Figure 19-17 Mechanism of receptor-mediated activation/inhibition of AC.** The binding of hormone to a stimulatory receptor,  $R_s$  (left), induces it to bind  $G_s$  protein, which, in turn, stimulates the  $G_{s\alpha}$  subunit of this  $G_{s\alpha}G_{\beta\gamma}$  heterotrimer to exchange its bound GDP for GTP. The  $G_{s\alpha} \cdot GTP$  complex then dissociates from  $G_{\beta\gamma}$  and, until it catalyzes the hydrolysis of its bound GTP to GDP, stimulates adenylyl cyclase (AC) to convert ATP to cAMP. The binding of hormone to the inhibitory

receptor,  $R_i$  (right), triggers an almost identical chain of events except that the presence of  $G_{i\alpha} \cdot GTP$  complex inhibits AC from synthesizing cAMP.  $R_2C_2$  represents protein kinase A (PKA), whose catalytic subunit, C, when activated by the dissociation of the regulatory dimer as  $R_2 \cdot cAMP_4$  (Section 18-3Cb), activates its target cellular proteins by catalyzing their phosphorylation. The sites of action of cholera and pertussis toxins are indicated.

glucagon receptors and to  $\beta$ -adrenergic receptors. In such cases, the amount of cAMP produced is the sum of that induced by the individual hormones. G proteins may also act in other ways than by activating AC: They are known, for example, to stimulate the opening of  $K^+$  channels in heart cells and to participate in the phosphoinositide signaling system (Section 19-4A).

Some ligand-GPCR complexes inhibit rather than activate AC (Fig. 19-17, right). These include the  $\alpha_2$ -adrenergic receptor and receptors for somatostatin and opioids. The inhibitory effect is mediated by “inhibitory” G protein,  $G_i$ , which may have the same  $\beta$  and  $\gamma$  subunits as does “stimulatory” G protein,  $G_s$ , but has a different  $\alpha$  subunit,  $G_{i\alpha}$  (41 kD).  $G_i$  acts analogously to  $G_s$  in that on binding to its corresponding ligand-GPCR complex, its  $G_{i\alpha}$  subunit exchanges

bound GDP for GTP and dissociates from  $G_{\beta\gamma}$ . However,  $G_{i\alpha}$  inhibits rather than activates AC, through direct interactions and possibly because the liberated  $G_{\beta\gamma}$  binds to and sequesters  $G_{s\alpha}$ . The latter mechanism is supported by the observation that liver cell membranes contain far more  $G_i$  than  $G_s$ . The activation of  $G_i$  in such cells would therefore release enough  $G_{\beta\gamma}$  to bind the available  $G_{s\alpha}$ .

$G_{s\alpha}$  and  $G_{i\alpha}$  are members of a family of related proteins, many of which have downstream effectors other than AC. This family also includes:

1.  $G_{q\alpha}$ , which forms a link in the phosphoinositide signaling system (Section 19-4Ba).
2. **Transducin ( $G_{t\alpha}$ )**, a variant of  $G_{i\alpha}$ , which transduces visual stimuli by coupling the light-induced conformational

change of rhodopsin to the activation of a specific phosphodiesterase, which then hydrolyzes cGMP to GMP. This **cGMP-phosphodiesterase (cGMP-PDE)** is an  $\alpha\beta\gamma_2$  heterotetramer that is activated by the displacement of its inhibitory  $\gamma$  subunits (**PDE $\gamma$** ) by their tighter binding to  $G_{\text{t}\alpha} \cdot \text{GTP}$ . A cation-specific transmembrane channel (Section 20-3A) that is held open by the binding of cGMP closes on the resulting reduction in [cGMP], thereby triggering a nerve impulse (Section 20-5B) indicating that light has been detected.

**3.  $G_{\text{olf}\beta}$**  a variant of  $G_{\text{sc}\alpha}$ , which is expressed only in olfactory sensory neurons and participates in odorant signal transduction.

**4.  $G_{\text{I}2\alpha}$  and  $G_{\text{I}3\alpha}$** , which participate in the regulation of the cytoskeleton.

This heterogeneity in G proteins occurs in the  $\beta$  and  $\gamma$  subunits as well as in the  $\alpha$  subunits. In fact, 21 different  $\alpha$  subunits, 6 different  $\beta$  subunits, and 12 different  $\gamma$  subunits have been identified in humans, some of which appear to be ubiquitously expressed whereas others are expressed only in specific cells. Thus, a cell may contain several closely related G proteins of a given type that interact with varying specificities with receptors and effectors. This complex signaling system presumably permits cells to respond in a graded manner to a variety of stimuli.

#### a. G Proteins Often Require Accessory Proteins to Function

The proper physiological functioning of a G protein often requires the participation of several other types of proteins:

**1. A GTPase-activating protein (GAP)**, which as its name implies, stimulates its corresponding G protein to hydrolyze its bound GTP. This rate enhancement can be >2000-fold. The downstream effectors of  $G_{\text{t}\alpha}$  and  $G_{\text{q}\alpha}$ , cGMP-PDE (Section 19-3E) and PLC- $\beta$  (Section 19-4Ba), respectively, exhibit GAP activities toward  $G_{\text{t}\alpha}$  and  $G_{\text{q}\alpha}$  (which otherwise would hydrolyze GTP at physiologically insignificant rates), but AC does not exhibit GAP activity toward either  $G_{\text{sc}\alpha}$  or  $G_{\text{I}\alpha}$ . However, in humans, a diverse family of 37 **RGS proteins** (for regulators of G protein signaling) function as GAPs for  $G_{\alpha}$  subunits by binding most avidly to them when they are in the transition state conformation for hydrolyzing GTP.

**2. A guanine nucleotide exchange factor [GEF; alternatively guanine nucleotide releasing factor (GRF)]**, which induces its corresponding G protein to release its bound GDP. The G protein subsequently binds another guanine nucleotide (GTP or GDP, which most G proteins bind with approximately equal affinities), but since cells maintain a GTP concentration that is 10-fold higher than that of GDP, this, in effect, exchanges the bound GDP for GTP. For heterotrimeric G proteins, the agonist-GPCR complexes function as GEFs.

**3. A guanine nucleotide-dissociation inhibitor (GDI).** A  $G_{\beta\gamma}$  may be regarded as its associated  $G_{\alpha}$ 's GDI because

GDP dissociates slowly from isolated  $G_{\alpha}$  subunits but is essentially irreversibly bound by heterotrimers.

#### b. The X-Ray Structures of $G_{\alpha}$ Proteins Rationalize Their Functions

The X-ray structures of the C-terminal 325 residues of the 350-residue bovine transducin- $\alpha$  ( $G_{\text{t}\alpha}$ ) in its complexes with GDP (Fig. 19-18a,b) and with the poorly hydrolyzable GTP analog **GTP $\gamma$ S**

(Fig. 19-18c,d) were determined by Heidi Hamm and Paul Sigler.  $G_{\text{t}\alpha}$  consists of two clearly delineated domains connected by two polypeptide linkers: (1) a highly conserved GTPase domain that is structurally similar to those in other G proteins of known structure (and hence is often described as a Ras-like domain), and (2) a helical domain that is unique to heterotrimeric G proteins. Guanine nucleotides bind to  $G_{\text{t}\alpha}$  in a deep cleft that is flanked by these domains. The X-ray structures of  $G_{\text{I}\alpha} \cdot \text{GTP}\gamma\text{S}$  and  $G_{\text{sc}\alpha} \cdot \text{GTP}\gamma\text{S}$ , both determined by Gilman and Stephen Sprang, closely resemble that of the  $G_{\text{t}\alpha} \cdot \text{GTP}\gamma\text{S}$ .

Comparison of the structures of the  $G_{\text{t}\alpha} \cdot \text{GDP}$  and  $G_{\text{t}\alpha} \cdot \text{GTP}\gamma\text{S}$  complexes reveals that the presence of GTP's  $\gamma$  phosphate group promotes significant conformational shifts in three loops known as switch regions, all of which are located on the facing side of  $G_{\text{t}\alpha}$  in Fig. 19-18. The  $\gamma$  phosphate hydrogen bonds to side chains on Switches I and II, thereby pulling these polypeptide segments in toward it and causing Switch II to contact Switch III in a way that pulls it to the right in Fig. 19-18. These concerted conformational shifts cause an extensive cavity over the GDP-binding site to largely fill in the GTP $\gamma$ S complex.

Switches I and II have counterparts in other G proteins of known structure. Portions of these polypeptide segments have been implicated in the interactions of  $G_{\text{t}\alpha}$  with the cGMP-PDE it activates and in the interactions between the closely related  $G_{\text{sc}\alpha}$  with its target AC (Section 19-2D).

#### c. The X-Ray Structures of Heterotrimeric G Proteins

The X-ray structures of heterotrimeric G proteins were determined by Gilman and Sprang ( $G_i \cdot \text{GDP}$ ; Fig. 19-19) and by Hamm and Sigler ( $G_i \cdot \text{GDP}$ ). These structures reveal that the  $G_{\beta}$  subunit (Fig. 19-19b) consists of an N-terminal helical domain followed by a C-terminal domain comprising seven 4-stranded antiparallel  $\beta$  sheets arranged like the blades of a propeller—a  $\beta$  propeller whose blades are each formed by a WD40 sequence motif (Section 12-4Cb)—that surround a water-filled central channel. The WD40 motif occurs in a functionally diverse group of 4- to 8-bladed  $\beta$ -propeller proteins, including the 7-bladed N-terminal domain of the clathrin heavy chain (Section 12-4Cb). The  $G_{\gamma}$  subunit consists mainly of two helical

(a)

(b)

(c)

(d)

**Figure 19-18** Structural differences between the inactive and active forms of  $G_{\alpha}$  (transducin). The change in structure is indicated by the comparison of the X-ray structure of  $G_{\alpha} \cdot \text{GDP}$  in its (a) ribbon and (b) space-filling forms with that of  $G_{\alpha} \cdot \text{GTP}\gamma\text{S}$  in its (c) ribbon and (d) space-filling forms, all viewed from the same direction. In the ribbon drawings, helices and sheets are green; the segments linking them are gold; the guanine nucleotides are magenta, except for the  $\gamma$  phosphate of  $\text{GTP}\gamma\text{S}$ , which is yellow; and the bound  $\text{Mg}^{2+}$  ion is represented by a blue ball. The protein's three switch regions (I, II, and III) are highlighted in cyan. In Part c, the two loop regions of the protein that are implicated in its interaction with the

segments joined by a polypeptide link (Fig. 19-19b). It is closely associated with  $G_{\beta}$  along its entire extended length through mainly hydrophobic interactions and hence has no tertiary structure. The X-ray structure of isolated  $G_{\beta\gamma}$  is essentially identical to that in the  $G_{\alpha} \cdot \text{GDP}-G_{\beta\gamma}$  complex, thereby indicating that the structure of  $G_{\beta\gamma}$  is unchanged by its association with  $G_{\alpha} \cdot \text{GDP}$ .

cGMP-phosphodiesterase subunit to which it binds ( $\text{PDE}\gamma$ ) are pointed out with yellow labels, whereas the three loop regions that are implicated in the interaction of the homologous  $G_{s\alpha}$  with adenylate cyclase (AC) are indicated with pink labels. The space-filling models are colored similarly to the ribbon diagrams except for the yellow residues, which here represent those that appear to propagate or stabilize the structural transitions induced by the binding of the  $\gamma$  phosphate group. The box in the space-filling models outlines the cavity in  $G_{\alpha} \cdot \text{GDP}$  that closes when the GDP is replaced by  $\text{GTP}\gamma\text{S}$  and that has been implicated in modulating the affinity of  $G_{\alpha}$  for  $G_{\beta\gamma}$  and for the receptor. [Courtesy of Paul Sigler, Yale University. PDBids 1TAG and 1TND.]

$G_{\alpha}$  and  $G_{\beta\gamma}$  associate mainly via highly conserved contacts between the Switch I and II regions of  $G_{\alpha}$  and the loops and turns at the bottom of  $G_{\beta\gamma}$ 's  $\beta$  propeller (Fig. 19-19). In addition, there is a less extensive interaction between the N-terminal helix of  $G_{\alpha}$  (which is disordered in  $G_{\alpha}$  alone) and the first blade of the  $G_{\beta}$  propeller (back side of Fig. 19-19a). Comparison of the structure

**Figure 19-19** X-ray structure of the heterotrimeric  $G_i$ . (a) The  $G_\alpha$  subunit is violet with its Switch I, II, and III segments green, blue, and red, respectively, and with its bound GDP shown in space-filling form with C green, N blue, O red, and P yellow. The  $G_\beta$  subunit's N-terminal segment is blue and each blade of its  $\beta$  propeller has a different color. The  $G_\gamma$  subunit is gold. The view is perpendicular to the axis of the  $G_\beta$  subunit's  $\beta$  propeller. The plasma membrane would be at the top of the drawing as inferred from the positions of the N terminus of  $G_\alpha$  and the neighboring C terminus of  $G_\gamma$ , which, *in vivo*, are

of  $G_\alpha \cdot \text{GDP} - G_{\beta\gamma}$  with that of  $G_\alpha \cdot \text{GTP}\gamma\text{S}$  reveals why  $G_\alpha$  cannot simultaneously bind GTP and  $G_{\beta\gamma}$ : *In  $G_\alpha \cdot \text{GDP} - G_{\beta\gamma}$ , the Switch II segment of  $G_\alpha$  contacts  $G_\beta$  in a way that prevents Switch II from assuming the conformation it requires to bind GTP's  $\gamma$  phosphate.* Moreover, the conformational changes in Switch II are coordinated with those in Switch I so that, together, they close over the GDP bound to  $G_\alpha - G_{\beta\gamma}$ , thereby accounting for its tight binding relative to that in  $G_\alpha \cdot \text{GDP}$ .

The question remains, how does a liganded GCPR induce its target  $G_\alpha$  subunit to exchange its bound GDP for GTP? The X-ray structure of opsin in an activated conformation in complex with the 11-residue C-terminal segment of  $G_{i\alpha}$ , determined by Oliver Ernst, suggests a partial answer to this question. This helical segment (the right end of helix  $\alpha 5$  in Fig. 19-18a and the left end of the nearly horizontal gray helix at the top of Fig. 19-19b), which has been shown to be a major site of interaction with activated opsin, binds at the cytosolic face of opsin. This prompted the construction of the model in which the remainder of  $G_{i\alpha}G_{\beta\gamma}$  is appended onto the  $G_{i\alpha}$  C-terminal segment (Fig. 19-20). To avoid a steric clash between  $G_{i\alpha}G_{\beta\gamma}$  and the membrane,  $G_{i\alpha}G_{\beta\gamma}$  must be tilted upward by  $40^\circ$ . A simple mechanism for this process is a reorientation of the loop connecting helix  $\alpha 5$  and strand  $\beta 6$  (Fig. 19-18a). Since this

lipid-linked to the plasma membrane. However, the orientation of the protein relative to the plasma membrane is unknown (but see Fig. 19-20). (b) View related to that in Part a by a  $90^\circ$  rotation about its horizontal axis and thus looking from the general direction of the plasma membrane. The protein is colored as in Part a except that the  $G_\alpha$  subunit is mainly gray. [Based on an X-ray structure by Alfred Gilman and Stephan Sprang, University of Texas Southwestern Medical Center. PDBid 1GP2.]  See Interactive Exercise 12

loop participates in binding the guanine ring of GDP, a reasonable assumption is that this conformational adjustment expels GDP from its binding pocket, which when opsin subsequently releases  $G_{i\alpha}G_{\beta\gamma}$ , allows GTP to bind in its place.

#### d. Cholera Toxin Stimulates Adenylate Cyclase by Permanently Activating $G_{s\alpha}$

The major symptom of **cholera**, an intestinal disorder caused by the bacterium *Vibrio cholerae*, is massive diarrhea that, if untreated, frequently results in death from dehydration. This dreaded disease is not an infection in the usual sense since the vibrio neither invades nor damages tissues but merely colonizes the intestine, much like *E. coli*. The catastrophic fluid loss that cholera induces (often over 6 liters per hour!) occurs in response to a bacterial toxin. Indeed, merely replacing cholera victims' lost water and salts enables them to survive the few days necessary to immunologically eliminate the bacterial infestation.

**Cholera toxin (CT; also known as cholera toxin)** is an 87-kD protein of subunit composition  $AB_5$  in which the B subunits (103 residues each) form a pentagonal ring to which the A subunit (240 residues) is bound. Previous to CT's secretion, its A subunit is cleaved at a single site by a bacterial protease to yield two fragments, A1 (the N-terminal

**Figure 19-20 Model for signal transmission from an activated GPCR to its target heterotrimeric G protein.** (a) The X-ray structure of activated bovine opsin (orange, oriented relative to that in Fig. 19-16 by an  $\sim 90^\circ$  rotation about the vertical axis) in a complex with the 11-residue C-terminal helical segment from  $G_{\text{ta}}$  (blue). The X-ray structure of  $G_{\text{ta}}G_{\beta\gamma}$  (gray) is positioned over the opsin structure such that this portion of the  $G_{\text{ta}}$ 's C-terminal helix (the remainder of which is red) is superimposed on the helical segment bound to opsin. The dashed lines delineate the membrane in which opsin is embedded. Note that this model results in a steric clash between the G protein and the membrane. (b) To alleviate this steric clash, the G protein has been rotated by  $40^\circ$  (lower yellow arrow) through a conformational change in the loop preceding the C-terminal helix of  $G_{\text{ta}}$ . This loop participates in binding guanine nucleotides (GDP and GTP) and hence it is postulated that its reorganization expels GDP (drawn in space-filling form with C magenta, N blue, and O and P orange) from its binding pocket (upper yellow arrow). On the subsequent dissociation of opsin, the  $G_{\text{ta}}$  binds GTP (which the cell maintains at an  $\sim 10$ -fold higher concentration than GDP), and consequently dissociates from  $G_{\beta\gamma}$ . [Courtesy of Oliver Ernst, Charit -Universit tsmedizin Berlin, Germany. PDBids 3DQB and 1GOT.]

$\sim 195$  residues) and A2 (the C-terminal  $\sim 45$  residues), that remain joined by a disulfide bond. On the binding of CT to its cell surface receptor, ganglioside  $G_{\text{M1}}$  (Sections 12-1D and 25-8Cd), the nicked A subunit (but not the B subunits) is taken into the cell via receptor-mediated endocytosis and travels backward through the secretory pathway (Section 12-4B) to the Golgi apparatus. From there, it is conducted into the endoplasmic reticulum (ER) via the binding of A2's C-terminal KDEL sequence to a KDEL receptor (which normally functions to retrieve ER-resident proteins that have escaped the ER; Section 12-4Ch). The A1 fragment is then released from A2 and enters the cytoplasm

through the translocon (which normally conducts growing and still unfolded polypeptides into the ER; Section 12-4Bd) via a process in which A1 is unfolded through the chaperonelike action of protein disulfide isomerase (PDI; Section 9-2A).

In the cytoplasm, A1 catalyzes the irreversible transfer of the ADP-ribose unit from  $\text{NAD}^+$  to a specific Arg side chain of  $G_{\text{s}\alpha}$  (Fig. 19-21). This reaction is greatly accelerated by the interaction of A1 with the small Ras-like G protein **ADP-ribosylation factor (ARF)** in complex with GTP, which normally functions to prime the formation of clathrin-coated vesicles (Section 12-4Cd).

**Figure 19-21 Mechanism of action of cholera toxin.** The cholera toxin's A1 fragment in complex with ARF  $\cdot$  GTP catalyzes the ADP-ribosylation of a specific Arg residue on  $G_{\text{s}\alpha}$

by  $\text{NAD}^+$ , thereby rendering this subunit incapable of hydrolyzing GTP.

ADP-ribosylated  $G_{\text{src}} \cdot \text{GTP}$  can activate AC but is incapable of hydrolyzing its bound GTP. As a consequence, the AC remains “locked” in its active state. The epithelial cells of the small intestine normally secrete digestive fluid (an  $\text{HCO}_3^-$ -rich salt solution) in response to small increases in [cAMP] that activate intestinal  $\text{Na}^+$  pumps through their phosphorylation by PKA (ion pumps are discussed in Sections 20-3 and 20-4). The  $\sim 100$ -fold rise in intracellular [cAMP] induced by CT causes these epithelial cells to pour out enormous quantities of digestive fluid, thereby producing the symptoms of cholera. CT also affects other tissues *in vitro* but does not do so *in vivo* because CT is not absorbed from the gut into the bloodstream.

The remarkable X-ray structure of CT (Fig. 19-22a), determined by Graham Shipley and Edwin Westbrook, reveals that its A2 segment forms an unusual extended helix whose C-terminal end inserts into the  $B_5$  pentamer’s solvent-filled central pore, where it is noncovalently anchored. The N-terminal segment of A2 extends beyond the  $B_5$  pentamer so as to tether the wedge-shaped A1 segment to  $B_5$ , much like a balloon on a string. The X-ray structure of only  $B_5$  in complex with the pentasaccharide from its  $G_{\text{M1}}$  receptor (Fig. 19-22b), determined by Wim Hol, indicates that this pentasaccharide binds through an extensive hydrogen bonded network to each B subunit on the face of  $B_5$  opposite

that which binds A. The binding of the A subunit or the receptor pentasaccharide to  $B_5$  causes only modest structural changes at their respective binding sites without altering  $B_5$ ’s subunit interfaces. A1 contains an elongated crevice in the vicinity of a catalytically implicated residue, Glu 112, that presumably forms its active site.

Certain strains of *E. coli* cause a diarrheal disease (travelers’ diarrhea) similar to, although considerably less severe than, cholera through their production of **heat-labile enterotoxin (LT)**, a protein that closely resembles CT (their A and B subunits are  $>80\%$  identical and form  $\text{AB}_5$  toxins that have closely similar X-ray structures) and has the same mechanism of action. The reasons for the difference in severity of these infections are unclear (cholera can be fatal within hours, whereas enterotoxic strains of *E. coli* usually only temporarily incapacitate adults, although they are responsible for the deaths of hundreds of thousands of children annually). It might be due to the modest structural differences between the toxins, differences in the amounts of toxin secreted, and/or variations in microbial ecology.

The foregoing results provide a structural basis for the design of ligands that interfere with the binding of CT and LT to their receptors. Since these receptors occur on the surface of the intestinal epithelium, ligands that compete with them need not pass through any membrane. This

**Figure 19-22 X-ray structure of cholera toxin.** (a) The entire  $\text{AB}_5$  complex as viewed parallel to the presumed direction of the plane of the plasma membrane to which it binds, extracellular side up. The A1 segment is cyan, the A2 segment is gray, and each B subunit has a different color. Although the A1 and A2 segments in this structure form a continuous polypeptide chain, residues 193–195, which immediately precede the peptide bond that is cleaved on toxin activation, are disordered and hence not visible here (*upper left*). The C-terminal end of the A2 helix binds in the pentamer’s central pore. [Based on an X-ray

structure by Graham Shipley, Boston University School of Medicine, and Edwin Westbrook, Northwestern University. PDBid 1XTC.] (b) The structure of only the  $B_5$  pentamer in which each subunit is binding CT’s  $G_{\text{M1}}$  receptor pentasaccharide. The structure is viewed as from the bottom of Part a. The subunits of the  $B_5$  pentamer are colored as in Part a and the pentasaccharides are shown in ball-and-stick form with C green, N blue, and O red. Note the pentamer’s large central pore. [Based on an X-ray structure by Wim Hol, University of Washington. PDBid 2CHB.]

greatly increases the usual ~500-D size limit for an effective drug candidate (Section 15-4Ba). Moreover, a large ligand is unlikely to enter the bloodstream and hence would have minimal side effects. Consequently, the synthesis of multivalent ligands that simultaneously bind with high affinity to all five receptor binding sites on an AB<sub>5</sub> molecule has yielded promising lead compounds against CT and LT.

#### e. Pertussis Toxin ADP-Ribosylates G<sub>iα</sub>

*Bordetella pertussis*, the bacterium that causes **pertussis** (whooping cough; a disease that is still responsible for ~300,000 infant deaths per year worldwide), produces an AB<sub>5</sub> protein, **pertussis toxin (PT)**, that ADP-ribosylates a specific Cys residue in G<sub>iα</sub>. In doing so, it prevents G<sub>iα</sub> from exchanging its bound GDP for GTP and therefore from inhibiting AC. PT's X-ray structure, determined by Randy Read, reveals that its A and B subunits are structurally homologous to those of CT and LT, although the A subunit of PT extends from the opposite face of its B pentamer relative to that in CT. Moreover, PT's B pentamer consists of four different subunits (one in two copies), each of which is only ~15% identical to the B subunits of CT and LT.

#### f. Receptors Are Subject to Desensitization

One of the hallmarks of biological signaling systems is that they adapt to long-term stimuli by reducing their response to them, a process named **desensitization**. *These signaling systems therefore respond to changes in stimulation levels rather than to their absolute values.* What is the mechanism of desensitization? In the case of β-adrenergic receptors, an epinephrine-receptor complex, but not receptor alone, is phosphorylated at one or more of the Ser or Thr residues on its C-terminal tail by **β-adrenergic receptor kinase (BARK)**. This cytosolic protein is recruited to the plasma membrane through its interaction with G<sub>βγ</sub> when it is not bound to G<sub>sα</sub>, which is also a consequence of receptor activation. The phosphorylation of the receptor decreases the ability of epinephrine to influence it, at least in part by reducing the receptor's epinephrine-binding affinity. The phosphorylated receptor, in turn, is bound by either of two 78% identical proteins known as **β-arrestins** in a way that blocks the activated receptor from activating its target G protein. Moreover, the β-arrestin binds to the adaptor protein AP2 in clathrin-coated pits (Section 12-4Cd), whereupon the β-adrenergic receptor-β-arrestin complex is endocytotically sequestered (Section 12-5Bc) in specialized vesicles. The receptor's otherwise extracellular, epinephrine-binding surface then faces the interior of the vesicle and the β-arrestin is located on its outside, from which it is subsequently released. The vesicles are devoid of both heterotrimeric G protein and AC, thus further attenuating the cell's response to epinephrine. If, however, the epinephrine level is reduced, the receptor is slowly dephosphorylated by a phosphatase and exocytotically returned to the cell surface, thus restoring the cell's epinephrine sensitivity. Alternatively, the vesicles may fuse with endosomes for the delivery of their contents to lysosomes, where the receptor is proteolytically degraded (Fig. 12-91). In this latter

case, the restoration of epinephrine sensitivity requires the synthesis of additional receptor.

BARK is a member of a family of seven proteins known as **GPCR kinases (GRKs)** that, together with several other types of protein kinases including PKA, phosphorylate the C-terminal tails and/or the cytosolic loops of most agonist-occupied GPCRs. As above, the phosphorylated GPCRs are bound by a β-arrestin and sequestered into endocytotic vesicles, thereby isolating them from their corresponding heterotrimeric G proteins. Moreover, the sites of a given GPCR that are phosphorylated vary in a tissue-specific way that provides further regulatory flexibility.

#### D. Adenylate Cyclases

The heterotrimeric G proteins G<sub>s</sub> and G<sub>i</sub> function to control the activities of adenylate cyclase (AC). In fact, mammals have 9 known membrane-bound isoforms of AC, AC1 through AC9 (alternatively, AC-I through AC-IX), which are each expressed in a tissue-specific manner and differ in their regulatory properties. These ~120-kD transmembrane glycoproteins each consist of a small N-terminal domain (N), followed by two repeats of a unit consisting of a transmembrane domain (M) followed by two consecutive cytoplasmic domains (C), thus forming the sequence NM<sub>1</sub>C<sub>1a</sub>C<sub>1b</sub>M<sub>2</sub>C<sub>2a</sub>C<sub>2b</sub> (Fig. 19-23). The ~30% identical C<sub>1a</sub> and C<sub>2a</sub> domains associate to form the AC's catalytic core, whereas C<sub>1b</sub>, as well as C<sub>1a</sub> and C<sub>2a</sub>, bind regulatory molecules. Thus, G<sub>iα</sub> inhibits AC1, 5, and 6 by binding to C<sub>1a</sub>; G<sub>sα</sub> activates all AC isoforms but AC9 by binding to C<sub>2a</sub>; G<sub>βγ</sub> inhibits AC1, 3, and 8 but activates AC2, 4, and 7 by binding

**Figure 19-23** Schematic diagram of a typical mammalian AC.

The M<sub>1</sub> and M<sub>2</sub> domains are each predicted to contain six transmembrane helices. C<sub>1a</sub> and C<sub>2a</sub> form the enzyme's pseudosymmetric catalytic core. The domains with which various regulatory proteins are known to interact are indicated. [After Tesmer, J.J.G. and Sprang, S.R., *Curr. Opin. Struct. Biol.* 8, 713 (1998).]

to  $C_{2a}$ ; and  $Ca^{2+}$ -calmodulin ( $Ca^{2+}$ -CaM; Section 18-3Ce) activates AC1, 3, and 8 by binding to  $C_{1b}$ . Moreover, the  $C_{2a}$  of AC2, 5, and 7 are activated by the phosphorylation of specific Ser/Thr control sites, for example, by **protein kinase C (PKC; Section 19-4C)**, whereas the  $C_{1b}$  of AC5 and 6 are similarly inhibited by PKA, for example. Clearly, cells can respond to a great variety of stimuli in determining their cAMP levels.

No X-ray structure of an intact AC isoform has yet been reported. However, Sprang has determined the X-ray structure of a hybrid catalytic core consisting of the  $C_{1a}$  domain of AC5 ( $VC_1$ ) and the  $C_{2a}$  domain of AC2 ( $IIC_2$ ) in complex with  $G_{s\alpha} \cdot GTP\gamma S$ , **ATP $\alpha S$**  (an isomer of ATP $\gamma S$  with the S atom on the  $\alpha$  phosphate), and **forskolin**

(a product of the plant *Coleus forskohlii* that activates all ACs but AC9 and functions to lower blood pressure). The  $VC_1 \cdot IIC_2$  catalytic core is enzymatically active and is sensitive to both  $G_{s\alpha} \cdot GTP$  and forskolin. Its X-ray structure (Fig. 19-24) reveals that  $VC_1$  and  $IIC_2$  form a pseudosymmetric heterodimer that binds ATP $\gamma S$  and forskolin at pseudosymmetrically related sites of their interface.  $G_{s\alpha} \cdot GTP\gamma S$  interacts with  $IIC_2$  mainly via its Switch II helix, which binds in a cleft on  $IIC_2$ .

The X-ray structure of the catalytically inactive  $C_{2a}$  homodimer in complex with two symmetrically arranged forskolin molecules, by James Hurley, provides a perhaps crude model for the inactivated heterodimer. Comparison of these structures (Fig. 19-24) suggests that the binding of  $G_{s\alpha} \cdot GTP$  to the  $C_{1a} \cdot C_{2a}$  catalytic core pries open the Switch II binding cleft on  $C_{2a}$  in a way that mechanically forces  $C_{1a}$  to rotate  $\sim 10^\circ$  with respect to  $C_{2a}$ . This is postulated to reorient the complex's active site residues such that they can efficiently catalyze the conversion of ATP to cAMP. The conformational change that  $G_{s\alpha}$  undergoes on hydrolyzing its bound GTP to GDP (Fig. 19-18) apparently reorients its Switch II region such that it no longer can bind to  $C_{2a}$ , thereby causing AC to revert to its inactive conformation.

$VC_1$  has a cleft that corresponds to the  $G_{s\alpha}$ -binding cleft on  $IIC_2$ . This suggests that this cleft on  $VC_1$  provides the binding site for  $G_{i\alpha}$ . Indeed, mutagenesis studies on  $VC_1$  are consistent with this hypothesis. However, the cleft on  $VC_1$  is too narrow to accommodate the binding of a Switch II helix. This further suggests that the binding of  $G_{i\alpha} \cdot GTP$  to  $C_{1a}$  pries open this cleft in a way that reorients

**Figure 19-24** X-ray structure of an AC catalytic core. This core consists of dog  $VC_1$  and rat  $IIC_2$  in complex with bovine  $G_{s\alpha} \cdot GTP\gamma S$  and forskolin, and is shown with a model of ATP.  $VC_1$  is tan,  $IIC_2$  is violet, and  $G_{s\alpha}$ , which is only shown in part, is dark gray, with its  $IIC_2$ -contacting segments, Switch II and the  $\alpha 3$ - $\beta 5$  loop, highlighted in red and blue. The forskolin and the ATP are shown in stick form with C gray, N cyan, O red, and P green. The brown ribbon shows the nonoverlapping portions of the catalytically inactive rat  $IIC_2$  homodimer in which one of its subunits is superimposed on  $IIC_2$  in the  $VC_1$ - $IIC_2$  complex. [Courtesy of Heidi Hamm, Northwestern University Medical School. The X-ray structures of the  $VC_1$ - $IIC_2$ - $G_{s\alpha}$  complex and the  $IIC_2$  homodimer were determined by John Tesmer and Stephen Sprang, University of Texas Southwestern Medical Center, and by James Hurley, NIH. PDBids 1AZS and 1AB8.]

the complex's catalytic residues so as to reduce its catalytic activity.

### E. Phosphodiesterases

*In any chemically based signaling system, the signal molecule must eventually be eliminated in order to control the amplitude and duration of the signal and to prevent interference with the reception of subsequent signals.* In the case of cAMP, this second messenger is hydrolyzed to AMP by enzymes known as **cAMP-phosphodiesterases (cAMP-PDEs)**.

The PDE superfamily, which includes both cAMP-PDEs and cGMP-PDEs, is encoded in mammals by at least 20 different genes grouped into 12 families (PDE1 through PDE12). Moreover, many of the mRNAs transcribed from these genes have alternative initiation sites and alternative splice sites (Section 34-3C), so that mammals express  $\sim 50$  PDE isoforms. These are functionally distinguished by their substrate specificities (for cAMP, cGMP, or both) and kinetic properties, their responses (or lack of them) to various activators and inhibitors (see below), and their tissue,

cellular, and subcellular distributions. The PDEs have characteristic modular architectures with a conserved ~270-residue catalytic domain near their C-termini and widely divergent regulatory domains or motifs, usually in their N-terminal portions. Some PDEs are membrane-anchored, whereas others are cytosolic.

PDE activity, as might be expected, is elaborately controlled. Depending on its isoform, a PDE may be activated by one or more of a variety of agents including  $\text{Ca}^{2+}$ -CaM; phosphorylation by PKA, insulin-stimulated protein kinase (Section 18-3Cg), and **calmodulin-dependent protein kinase II**; and the binding of cGMP to a noncatalytic site. However, for some PDEs, cGMP is inhibitory. Phosphorylated PDEs are dephosphorylated by a variety of protein phosphatases including  $\text{Ca}^{2+}$ -CaM-dependent phosphatase and **protein phosphatase-2A**. Thus, the PDEs provide a means for cross talk between cAMP-based signaling systems and those using other types of signals.

PDEs are inhibited by a variety of drug agents that influence such widely divergent disorders as asthma, congestive heart failure, depression, erectile dysfunction, inflammation, and retinal degeneration. **Sildenafil** (trade name **Viagra**),

**Sildenafil (Viagra™)**

a compound used to treat erectile dysfunction, specifically inhibits PDE5, which hydrolyzes only cGMP. Sexual stimulation in males causes penile nerves to release NO, which activates guanylate cyclase to produce cGMP. This induces vascular smooth muscle relaxation in the penis, thereby increasing the inflow of blood, which results in an erection. This cGMP is eventually hydrolyzed by PDE5. Sildenafil is therefore an effective treatment in men who produce insufficient NO and hence cGMP to otherwise generate a satisfactory erection.

### 3 TYROSINE KINASE–BASED SIGNALING

 See **Guided Exploration 17: Mechanisms of hormone signaling involving the receptor tyrosine kinase system** We have seen that glycogen synthesis and breakdown are regulated by the phosphorylation/dephosphorylation of the enzymes that

catalyze these metabolic processes as well as of many of the enzymes that catalyze these modification/demodification processes (Section 18-3). Numerous other processes in multicellular organisms are similarly regulated. In fact, over one-third of the proteins in vertebrates are subject to reversible phosphorylation, and the human genome contains 518 protein kinase genes (the so-called **kinome**; the Protein Kinase Resource at <http://pkr.genomics.purdue.edu/> and [kinase.com](http://kinase.com) at <http://kinase.com/> are databases for the kinome). The vast majority of the phosphorylated amino acid residues are Ser or Thr; only about 1 in 2000 is Tyr. Nevertheless, as we discuss in this section, Tyr phosphorylation is of central importance in regulating a variety of essential cellular processes.

#### A. Receptor Tyrosine Kinases

Many protein growth factors variously control the differentiation, proliferation, migration, metabolic state, and survival of their target cells by binding to their cognate **receptor tyrosine kinases (RTKs)**. The RTKs form a diverse family of 58 transmembrane glycoproteins (Fig. 19-25) that each have a C-terminal cytoplasmic **protein tyrosine kinase (PTK)** domain and a single-pass transmembrane segment that is presumably an  $\alpha$  helix. As their name indicates, PTKs catalyze the ATP-dependent phosphorylation of their target proteins at specific Tyr residues:

The PTK domains of RTKs are homologous to and, as we shall see, structurally resemble the far more abundant Ser/Thr-specific protein kinases such as PKA (Fig. 18-15).

RTKs are activated by the binding of a cognate protein growth factor to their ectodomains. It seems unlikely that the single transmembrane helix of monomeric RTKs such as **platelet-derived growth factor receptor (PDGFR)** and **epidermal growth factor receptor (EGFR)** (Fig. 19-25) has the structural complexity to transmit the ligand-binding state of its ectodomain to its cytoplasmic tyrosine kinase domain. Rather, as we have seen for human growth hormone receptor (which is not an RTK), ligand binding induces receptor dimerization (Fig. 19-10). This, in turn, activates the RTK's PTK activity, as we discuss below. For RTKs that are permanent dimers, such as the **insulin receptor (InsR)** (Fig. 19-25), the PTK is thought to be activated by a ligand-induced structural change (probably a counter-rotation of the two protomers that preserves the dimer's 2-fold axis of symmetry) that is transmitted across the membrane.

**Figure 19-25 Domain organization in a variety of receptor tyrosine kinase (RTK) subfamilies.** One to five members of each subfamily are depicted. The narrow rectangle that extends horizontally across the diagram represents the plasma membrane, with the extracellular region above it and the cytosol below. The polypeptides are shown only approximately to scale, with their N-termini above. **EGFR**, **InsR**, **PDGFR**, and **FGFR** refer to **epidermal growth factor receptor**, **insulin receptor**, **platelet-derived growth factor receptor**, and **fibroblast growth**

**factor receptor**, respectively. The RTKs' extracellular portions are modularly constructed from a variety of often repeating domains that are identified at the right of the diagram. Note that the tyrosine kinase domains of **PDGFR** and **Flt1** subfamilies are interrupted by ~100-residue **kinase inserts** and that the members of the **InsR** subfamily are  $\alpha_2\beta_2$  heterotetramers, whose subunits are disulfide-linked (short horizontal lines). [Courtesy of Stevan Hubbard, New York University School of Medicine.]

### a. FGF and Heparin Sulfate Are Required to Activate FGF Receptor

The mammalian **fibroblast growth factors (FGFs)** form a family of at least 21 structurally related proteins (FGF1–21) that regulate a variety of critical biological processes including cell growth, differentiation, and migration and that are expressed in specific spatial and temporal patterns in embryos and adults. FGF-stimulated processes are mediated by four FGF receptors (FGFR1–4), which each bind a unique subset of the FGFs, thereby accounting for the diversity and tight regulation of the foregoing processes. FGFR dimerization in solution requires the presence of heparan sulfate proteoglycans (Section 11-3A) in addition to that of FGF.

FGF receptors each consist of, from N- to C-terminus (Fig. 19-25), three extracellular immunoglobulin-like domains (D1–D3 for domains 1–3), a single transmembrane helix, and a cytoplasmic domain with PTK activity. Of these, only the D2 and D3 domains are involved in FGF binding (in general, only a few of the domains in the extracellular portions of RTKs participate in ligand binding). Moosa Mohammadi determined the X-ray structure of the 2:2:2 complex of FGF2, the D2–D3 segment of FGFR1, and a heparin decasaccharide (Fig. 11-21). It reveals

(Fig. 19-26) that each FGF monomer binds to the D2 and D3 domain on one FGFR subunit and, more tenuously, to the D2 domain on the other subunit, whereas the heparin cross-links each FGF monomer to both D2 domains (whose contacts in the absence of FGF and heparin are insufficient to support appreciable FGFR dimerization).

### b. RTK Dimers Are Activated by Autophosphorylation

*The dimerization of an RTK (or its conformational change in the case of the insulin receptor subfamily) brings its cytoplasmically located PTK domains into apposition, such that they cross-phosphorylate each other on specific Tyr residues on their activation loops (Fig. 19-27a). This **autophosphorylation** activates the PTK in much the same way as we saw that activation loop phosphorylation induces PKA to phosphorylate its target proteins (Section 18-3Cb). In many cases, the activated PTK further phosphorylates the opposing RTK subunit at specific Tyr residues outside of the PTK domain (Fig. 19-27). This, as we shall see in Sections 19-3Cb and 19-3Cc, provides binding sites for certain cytoplasmic proteins. The activated PTK may also phosphorylate specific Tyr residues on a variety of cytoplasmic proteins. In both cases, as we discuss in Section*

**Figure 19-26** X-ray structure of the 2:2:2 complex of FGF2, the D2–D3 portion of FGFR1, and a heparin decasaccharide. The view is normal to the dimeric complex’s 2-fold axis of symmetry, with the plasma membrane below. The polypeptides are represented in ribbon form with the FGF molecules cyan and blue, the D2 and D3 domains of one FGFR monomer lavender and gold, and those of the other magenta and orange. The two heparin decasaccharides are shown in space-filling form with C green, N blue, O red, and S yellow. The D2 and D3 domains of FGFR each have an immunoglobulin fold: a  $\beta$  sandwich comprised of a 3-stranded and a 4-stranded antiparallel  $\beta$  sheet (Section 8-3Bg). [Based on an X-ray structure by Moosa Mohammadi, New York University School of Medicine. PDBid 1FQ9.]

**Figure 19-27** Schematic diagrams of RTKs. (a) The PDGF receptor and (b) the EGF receptor. Their autophosphorylation sites and the proteins that are activated by binding to these sites via their SH2 domains (all of which are discussed in this chapter) are indicated. Note that almost all of the autophosphorylated Tyr residues that bind to other proteins lie outside the tyrosine kinase domains. [After Pawson, T. and Schlessinger, J., *Curr. Biol.* **3**, 435 (1993).]

19-3D, this causes the activation of the proteins that participate in executing the instructions implied by the extracellular presence of the protein growth factor.

### c. The Insulin Receptor PTK Undergoes Major Conformational Changes on Autophosphorylation

How does autophosphorylation activate a PTK? The comparison of the X-ray structures of the PTK domain of the insulin receptor in its inactive unphosphorylated and active triphosphorylated states has done much to answer this question. The insulin receptor is expressed as a single 1382-residue precursor peptide that is proteolytically processed to yield the disulfide-linked  $\alpha$  and  $\beta$  subunits (731 and 619 residues) of the mature receptor (Fig. 19-25). The X-ray structure of a 306-residue PTK-containing segment of the  $\beta$  subunit that was phosphorylated at its three

autophosphorylation sites, Tyr residues 1158, 1162, and 1163 (using the precursor numbering system), and in complex with the nonhydrolyzable ATP analog AMPPNP and an 18-residue peptide substrate, was determined by Stevan Hubbard. It reveals (Fig. 19-28a) that this PTK structurally resembles other PTKs of known structure as well as protein Ser/Thr kinases such as PKA (Fig. 18-15) and the phosphorylase kinase  $\gamma$  subunit (Fig. 18-21).

Comparison of this structure with that of the unphosphorylated and uncomplexed protein, determined by Hubbard and Wayne Hendrickson, reveals that, on phosphorylation and substrate binding, the PTK's N-terminal lobe undergoes a nearly rigid  $21^\circ$  rotation relative to the C-terminal lobe about the long axis of the protein (Fig. 19-28b). This dramatic conformational change closes the active site cleft about the AMPPNP and, presumably, correctly positions

(a)

**Figure 19-28** X-ray structure of the PTK domain of the insulin receptor. (a) The PTK phosphorylated at Tyr residues 1158, 1162, and 1163 and in complex with AMPPNP and an 18-residue polypeptide substrate. The PTK is shown in the “standard” protein kinase orientation with its N-terminal domain pink, its C-terminal domain cyan, and its activation loop light blue. Its three phosphorylated Tyr side chains are shown in ball-and-stick form with C green, N blue, O red, and P yellow. The AMPPNP, which is identically colored, is shown in space-filling form. The substrate polypeptide is orange (only 6 of its residues are visible) and its phosphorylatable Tyr residue is shown in ball-and-stick form with C magenta and O red. (b) The

(b)

polypeptide backbones of the phosphorylated and unphosphorylated forms of the insulin receptor PTK domain as superimposed on their C-terminal lobes. The phosphorylated protein is green with its activation loop blue, and the unphosphorylated protein is yellow with its activation loop red. The axis (black line) and arrow (blue) indicate the rotation required to align the N-terminal domain of the unphosphorylated protein with that of the phosphorylated protein. [Part a based on an X-ray structure by and Part b courtesy of Stevan Hubbard, New York University Medical School. PDBids 1IR3 for the phosphorylated protein and 1IRK for the unphosphorylated protein.]  See Interactive Exercise 13

critical residues for substrate binding and catalysis. All three phosphorylated Tyr residues occur on the PTK's activation loop (residues 1149–1170; recall that many Ser/Thr kinases are also phosphorylated on their activation loops; Section 18-3Cb). The unphosphorylated activation loop threads through the PTK's active site so as to prevent the binding of both ATP and protein substrates. However, on phosphorylation, the activation loop assumes a conformation that does not occlude the active site (Fig. 19-28*b*) but instead forms part of the substrate recognition site. The phosphate group on Tyr 1163 bridges the activation loop by forming a hydrogen bond with the side chain of the conserved Arg 1155 on one side of the loop and with the main chain N of Gly 1166 on its other side. The phosphate group of Tyr 1162 makes two hydrogen bonds to the side chain of the conserved Arg 1164. However, the phosphate group of Tyr 1168 makes no protein contacts, which suggests that it forms a docking site for downstream signaling proteins (see below). These observations are in agreement with experiments indicating that the tyrosine kinase activity of the insulin receptor increases with the degree of phosphorylation at its three autophosphorylatable Tyr side chains and that full activity is not achieved until Tyr 1163 is phosphorylated. Indeed, nearly all known RTKs have between one and three autophosphorylatable Tyr residues in their activation loops (a major exception being the members of EGFR subfamily; Fig. 19-27*b*) and, in all phosphorylated protein kinases of known structure, assume similar conformations.

Only the 6 centrally located residues, G DY M N M, of the 18-residue substrate peptide are seen in the foregoing X-ray structure. These include the YMXM sequence found in all efficient substrates of the insulin receptor. This segment associates with the kinase as a strand in a  $\beta$  sheet. Its Met side chains fit into adjacent hydrophobic pockets of the protein, whereas its phosphorylatable Tyr side chain extends toward the  $\gamma$  phosphate group of the AMPPNP (Fig. 19-28*a*). The specificity of the protein for phosphorylating Tyr rather than Ser or Thr is explained by the observation that the side chain of Tyr, but not those of Ser or Thr, are long enough to reach the active site.

### B. Cancer: The Loss of Control of Growth

Before we continue our discussion of signaling pathways, let us consider cancer, a group of diseases that is characterized by defects in signal transduction causing uncontrolled growth. Indeed, studies of cancer have greatly increased our understanding of signal transduction and vice versa.

*The cells of the body normally remain under strict developmental control.* For instance, during embryogenesis, cells must differentiate, proliferate, migrate, and even die in the correct spatial arrangement and temporal sequence to yield a normally functioning organism. In the adult, the cells of certain tissues, such as the intestinal epithelium, the blood-forming tissues of the bone marrow, and those of hair follicles, continue to proliferate. Most adult body cells, however, have permanently ceased doing so.

Cells occasionally lose their developmental controls and commence excessive proliferation. The resulting tumors can be of two types:

**1. Benign tumors**, such as warts and moles, grow by simple expansion and often remain encapsulated by a layer of connective tissue. Benign tumors are rarely life threatening, although if they occur in an enclosed space such as in the brain or secrete large quantities of certain hormones, they can be lethal.

**2. Malignant tumors or cancers** grow in an invasive manner and shed cells that, in a process known as **metastasis**, colonize new sites in the body. Malignant tumors are almost invariably life threatening; they are responsible for 20% of the mortalities in the United States.

*The most obvious and the medically most significant property of cancer cells is that they proliferate uncontrollably.* For instance, when grown in a tissue culture dish, normal cells form a monocellular layer on the bottom of the dish and then, through a process termed **contact inhibition**, cease dividing (Fig. 19-29*a*). In contrast, the growth of malignant cells is unhampered by intercellular contacts; in culture they form multicellular layers (Fig. 19-29*b*). Moreover, even in the absence of contact inhibition, normal cells are far more limited in their capacity to reproduce than are cancer cells. Normal cells, depending on the species and age of the animal from which they were taken, will only divide in culture 20 to 60 times before they reach **senescence** (a stage at which they cease dividing) and die (a phenomenon that, no doubt, is at the heart of the aging process; Section 30-4Db). *Cancer cells, on the other hand, are immortal; there is no limit to the number of times they can divide.* In fact, some cancer cell lines have been maintained in culture through thousands of divisions spanning 6 decades. Immortal cells, however, are not necessarily malignant: *The hallmark of cancer is immortality combined with uncontrolled growth.*

(a) Normal cells

(b) Transformed cells

**Figure 19-29 Growth pattern of vertebrate cells in culture.** (a) Normal cells stop growing through contact inhibition once they have formed a confluent monolayer. (b) In contrast, transformed cells lack contact inhibition; they pile up to form a multilayer.

**Figure 19-30** Variation of the cancer death rate in humans with age. The linearity of this log–log plot can be explained by the hypothesis that several randomly occurring mutations are required to generate a malignancy. The slope of the line suggests that, on the average, five such mutations are required for a malignant transformation.

#### a. Cancer Is Caused by Carcinogens, Radiation, and Viruses

Most cancers are caused by agents that damage DNA or interfere with its replication or repair. These include a great variety of man-made and naturally occurring substances known as **chemical carcinogens** (Section 30-5F), as well as radiation, both electromagnetic and particulate,

with sufficient energy to break chemical bonds. In addition, *certain viruses induce the formation of malignant tumors in their hosts* (see below).

Almost all malignant tumors result from the **transformation** of a single cell [conversion to the cancerous state; this term should not be confused with the acquisition of genetic information from exogenously supplied DNA (Section 5-2A)], which, then being free of its normal developmental constraints, proliferates. Yet, considering, for example, that the human body consists of around  $10^{14}$  cells, transformation must be a very rare event. One of the major reasons for this, as the age distribution of the cancer death rate indicates (Fig. 19-30), is that *transformation requires a cell or its ancestors to have undergone several independent and presumably improbable carcinogenic changes*. Consequently, exposure to a carcinogen may prime many cells for transformation, but a malignant tumor may not form until decades later when one of these cells suffers a final transforming event.

The viral induction of cancer was first observed in 1911 by Peyton Rous, who demonstrated that cell-free filtrates from certain chicken **sarcomas** (malignant tumors arising from connective tissues) promote new sarcomas in chickens (Fig. 19-31). Although decades were to pass before the significance of this work was appreciated (Rous was awarded the Nobel prize in 1966 at the age of 85), many other such **tumor viruses** have since been characterized. The **Rous sarcoma virus (RSV)**, as are all known RNA tumor viruses, is a retrovirus (an RNA virus that replicates its chromosome by copying it to DNA in a process mediated by a virally encoded reverse transcriptase, inserting the DNA into the host's genome, and then transcribing this DNA). It contains a gene, *v-src* ("v" for viral, "src" for sarcoma), which encodes a protein named **v-Src** that mediates

(a)

(b)

**Figure 19-31** Transformation of cultured chicken fibroblasts by Rous sarcoma virus. (a) Normal cells adhere to the surface of the culture dish, where they assume a flat extended

conformation. (b) On infection with RSV, these cells become rounded and cluster together in piles. [Courtesy of G. Steven Martin, University of California at Berkeley.]

host cell transformation. *v-src* has therefore been termed an **oncogene** (Greek: *onkos*, mass or tumor).

What is the origin of *v-src* and what is its viral function? Hybridization studies (Section 5-3Cb) by Michael Bishop and Harold Varmus in 1976 led to the remarkable discovery that *uninfected chicken cells contain a gene, c-src* (“*c*” for cellular), that is homologous to *v-src*. Moreover, *c-src* is highly conserved in a wide variety of eukaryotes that span the evolutionary scale from *Drosophila* to humans. This observation strongly suggests that *c-src*, which antibodies directed against *v-Src* indicated is expressed in normal cells, is an essential cellular gene. In fact, *both v-Src and its normal cellular analog, c-Src, function to stimulate cell proliferation* (Section 19-3Ea). Apparently, *v-src* was originally acquired from a cellular source by an initially non-transforming ancestor of RSV. By maintaining the host cell in a proliferative state (cells are usually not killed by RSV infection), *v-Src* presumably enhances the viral replication rate.

#### b. Viral Oncogene Products Mimic the Effects of Protein Growth Factors and Hormones

*The proteins encoded by many viral oncogenes are analogs of various growth factor and hormone system components. For instance:*

1. The ***v-sis*** oncogene of **simian sarcoma virus** encodes a protein secreted by infected cells that is nearly identical to PDGF. Hence, the uncontrolled growth of simian sarcoma virus-infected cells apparently results from the continuous and inappropriate presence of this PDGF homolog.

2. Nearly half of the more than 20 known retroviral oncogenes, including *v-src*, encode PTKs. For example, the ***v-erbB*** oncogene specifies a truncated version of the EGF receptor (Fig. 19-27b) that lacks the EGF-binding domain but retains its transmembrane segment and its protein kinase domain. *Evidently, oncogene-encoded PTKs inappropriately phosphorylate the target proteins normally recognized by RTKs, thereby driving the afflicted cells to a state of unrestrained proliferation.*

3. The ***v-ras*** oncogene encodes a protein, ***v-Ras***, that functionally resembles the monomeric G-protein ***c-Ras*** (Section 19-3Cf) in that it is localized on the cytoplasmic side of the mammalian plasma membrane where, when binding GTP, it activates a variety of cellular processes by stimulating the phosphorylation of numerous proteins at specific Ser and Thr residues. Although *v-Ras* hydrolyzes GTP to GDP, it does so much more slowly than *c-Ras*. The restraint to protein phosphorylation that GTP hydrolysis would normally impose on *c-Ras* is thus greatly reduced in *v-Ras*, thereby transforming the cell.

4. Several viral oncogenes, including ***v-jun*** and ***v-fos***, encode nuclear proteins whose corresponding normal cellular analogs are synthesized in response to growth factors such as EGF and PDGF that induce mitosis (cell division). Many such proteins, including the *v-jun* and *v-fos* gene products, bind to DNA, strongly suggesting that they influence

its transcription and/or replication. Indeed, ***v-jun*** is 80% identical in sequence to the **proto-oncogene** (normal cellular analog of an oncogene) ***c-jun***, which encodes a transcription factor named **Jun** (also called **AP-1**; Section 19-3D). Moreover, Jun/AP-1 forms a tight complex with the protein encoded by the proto-oncogene ***c-fos***, which greatly increases the ability of Jun/AP-1 to stimulate transcription from Jun-responsive genes.

*Oncogene products therefore appear to be functionally modified or inappropriately expressed components of elaborate control networks that regulate cell growth and differentiation.* The complexity of these networks (as we shall see, cells generally respond to a variety of growth factors, hormones, and transcription factors in partially overlapping ways) is probably why malignant transformation requires several independent carcinogenic events. Note, however, that few human cancers are virally induced; nearly all of them arise from genetic alterations involving proto-oncogenes. We discuss the nature of these alterations in Section 34-4C.

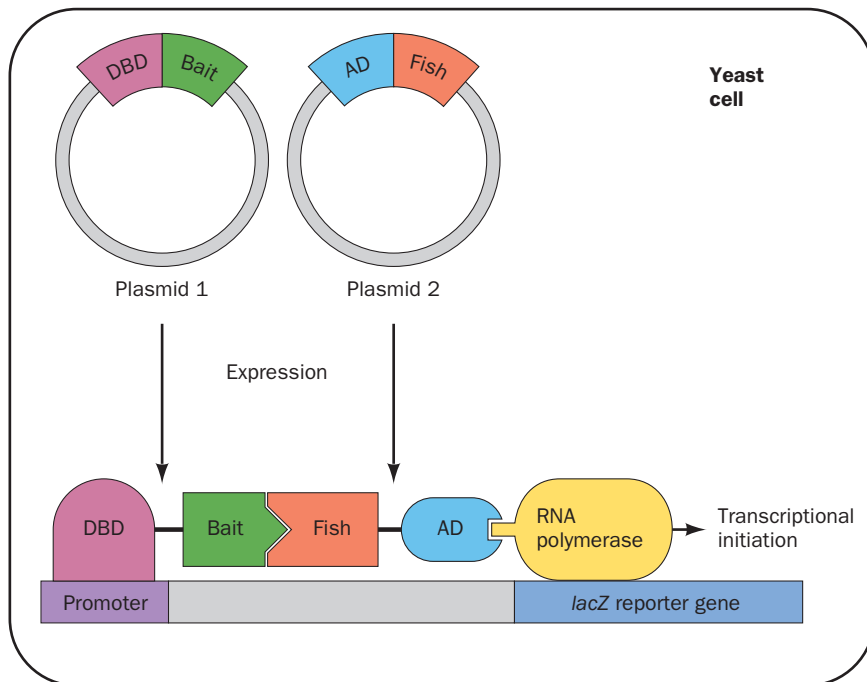

#### C. Relaying the Signal: Binding Modules, Adaptors, GEFs, and GAPs

Many autophosphorylated RTKs can directly phosphorylate their target proteins. Surprisingly, however, not all RTKs do so. How, then, do they activate their target proteins? The answer, as we shall see, is through a highly diverse and complicated set of interconnected signaling pathways involving cascades of associating proteins.

##### a. Two-Hybrid Systems Identify Proteins That Interact *in vivo*

Before we consider the interacting proteins that participate in RTK-mediated signal transduction, let us discuss one of the most often used methods to detect their associations *in vivo*, the **two-hybrid system**. This ingenious experimental technique, which was formulated by Stanley Fields, is based on the peculiar bipartite nature of many transcription factors (proteins that bind to the promoters and other upstream control regions of eukaryotic genes and, in doing so, influence the rate at which RNA polymerase initiates the transcription of these genes; Section 5-4Ab). Such transcription factors, as we further discuss in Section 34-3Bi, contain a DNA-binding domain (DBD) that targets the transcription factor to a specific DNA sequence and an activation domain (AD) that recruits RNA polymerase to initiate transcription at a nearby transcriptional initiation site. These two domains function independently, so that a genetically engineered hybrid protein with the DBD of one transcription factor and the AD of another will activate the transcription of the gene for which the DBD is targeted. Moreover, it makes little difference as to whether the DBD is on the N-terminal or the C-terminal side of the AD, regardless of how they are arranged in their parent proteins. Evidently, as long as a DBD and an AD are held in proximity, they function as a transcription factor for the gene(s) to which the DBD is targeted.

**Figure 19-32 The two-hybrid system.**

Two plasmids are expressed in yeast: One encodes a hybrid protein consisting of the DNA-binding domain (DBD) of a transcription factor fused to a “bait” protein, and the other encodes the activation domain (AD) of a transcription factor fused to a “fish” protein. The DBD specifically binds to the promoter of a reporter gene, here *lacZ*. If the “fish” protein associates with the “bait” protein, its attached AD recruits RNA polymerase to initiate the transcription of the reporter gene. The  $\beta$ -galactosidase encoded by the *lacZ* gene is readily detected through the use of X-gal, which turns blue when hydrolyzed by  $\beta$ -galactosidase. Yeast colonies expressing “bait” and “fish” proteins that do not interact remain colorless, as do colonies that do not express both plasmids.

The two-hybrid system employs two different plasmids in yeast (Fig. 19-32): One encodes a hybrid protein consisting of a DBD fused to a so-called bait or probe protein; the other encodes a hybrid protein consisting of an AD fused to a so-called fish or target protein. The DBD is targeted to a reporter gene that has been engineered into the yeast chromosome such as the *E. coli lacZ* gene, which encodes the enzyme  $\beta$ -galactosidase. On culture plates containing X-gal (a colorless compound that turns blue on being hydrolyzed by  $\beta$ -galactosidase; Section 5-5Ca), yeast colonies expressing  $\beta$ -galactosidase turn blue, thereby indicating that the bait and fish proteins they encode associate with one another. Using this technique, cells can be screened for fish proteins that specifically interact with a particular bait protein by properly inserting the various cDNAs (Section 5-5F) derived from the cells into the AD-containing plasmid. A fish protein selected in this way can then be identified by sequencing its cDNA.

#### b. SH2 Domains Mediate Signal Transduction

Now let us return to our discussion of RTK-mediated signaling. Many (>100) of the diverse cytoplasmic proteins that bind to autophosphorylated receptors, for example, the cytoplasmic PTK **c-Src** (henceforth referred to as just Src), certain GTPase activating proteins (GAPs), and **phospholipase C- $\gamma$**  (Section 19-4Bc), contain one or two conserved ~100-residue modules known as **Src homology domain 2 (SH2)**; so named because they were first noticed in tyrosine kinases related to Src; **SH1** refers to their catalytic domains). *SH2 domains specifically bind phosphoTyr residues in their target peptides with high affinity*; they bind their unphosphorylated target peptides weakly if at all. Most of the phosphoTyr residues to which SH2 binds are located in the juxtamembrane (just after the transmem-

brane helix), kinase insert, and C-terminal regions of RTKs; those in the activation loop function mainly to stimulate PTK activity. Indeed, RTK autophosphorylation occurs in two phases: First the activation loops of the RTK are phosphorylated and then the resulting activated PTK phosphorylates the other sites on the opposing subunit of the RTK.

The X-ray and NMR structures of SH2 domains from several proteins, both alone and in complex with phospho-Tyr (pY)-containing polypeptides, have been determined. SH2 is a hemispherically shaped domain, which contains a central 5-stranded antiparallel  $\beta$  sheet that is sandwiched between two nearly parallel  $\alpha$  helices. The N- and C-terminal residues of SH2 are in close proximity on the surface opposite the peptide-binding site, which suggests that this domain can be inserted between any two surface residues on a protein without greatly disturbing its fold or function. Indeed, the sequences of a variety of SH2-containing proteins reveal no apparent preference for the location of this domain in a protein.

John Kuriyan determined the X-ray structure of the SH2 domain of Src in complex with an 11-residue polypeptide containing the sequence pYEEI, a tetrapeptide segment that binds to this SH2 domain with high affinity. The 11-residue peptide binds to the SH2 domain in an extended conformation, with contact being made primarily by the pYEEI tetrapeptide (Fig. 19-33a). The phosphoTyr side chain inserts into a small cleft formed, in part, by three highly conserved positively charged residues, including the side chain of an invariant Arg, which contacts the phosphate group. The Ile side chain is similarly inserted into a nearby hydrophobic pocket and the entire tetrapeptide segment interacts very tightly with SH2, although the side chains of the peptide's two central Glu residues do not

(a)

**Figure 19-33** X-ray structure of the 104-residue Src SH2 domain in complex with an 11-residue polypeptide (EPQpYEEIPIYL) containing the protein's pYEEI target tetrapeptide. (a) A cutaway view of the complex, in which its solvent-accessible surface is represented by red dots, the protein (pink) is shown in ribbon form with its side chains in stick form (light blue), and the N-terminal 8-residue segment of the bound polypeptide is shown in space-filling form with its backbone yellow, its side chains green, and its phosphate group white [the

(b)

N-terminal Pro side chain (left) is largely obscured in this view and the C-terminal three residues are disordered]. (b) The molecular surface of the protein only, as viewed toward the peptide binding site and colored according to its local electrostatic potential with the most positive regions deep blue and the most negative regions deep red. The binding pockets for the phosphoTyr (right) and Ile (left) side chains are circled in yellow and important residues are identified by red arrows. [Courtesy of John Kuriyan, The Rockefeller University.]

project toward SH2. Thus, the peptide resembles a two-pronged plug that is inserted into a two-holed socket on SH2 (Fig. 19-33b). Comparison of this structure with that of uncomplexed Src SH2 indicates that, on binding peptide, SH2 undergoes only small conformational changes that are localized at its peptide-binding site. These structures provide a simple explanation for why SH2 does not bind the far more abundant phosphoSer- and phosphoThr-containing peptides: The side chains of these residues are too short for their phosphate groups to contact the invariant Arg side chain at the bottom of the phosphoTyr-binding pocket.

### c. PTB Domains Also Bind PhosphoTyr-Containing Peptides

A second type of motif that specifically binds to phosphoTyr-containing target peptides is known as the **phosphotyrosine-binding (PTB) domain**. PTB domains specifically bind the consensus sequence NPXpY (where X is any residue) and hence recognize the sequence on the N-terminal side of pY rather than that on its C-terminal side, as do SH2 domains.

The NMR structure of the 195-residue PTB domain of **Shc**, an adaptor protein (see below), in complex with a 12-residue target peptide containing the centrally located sequence NPQpY was determined by Stephen Fesik. The structure consists of a  $\beta$  sandwich comprising two nearly perpendicular antiparallel  $\beta$  sheets flanked by three  $\alpha$  helices (Fig. 19-34). The N-terminal segment of the target phosphopeptide assumes an extended conformation that,

**Figure 19-34** The NMR structure of the PTB domain of Shc in complex with a 12-residue polypeptide (HIENPQpYFSDA) from the Shc binding site of a nerve growth factor (NGF) receptor. The PTB domain is colored in rainbow order from its N-terminus (blue) to its C-terminus (red) and the target peptide is magenta. The target peptide's phosphoTyr (pY) side chain and the side chain of Arg 67, which form a salt bridge (dashed line), are drawn in stick form with C green, N blue, O red, and P orange. Note that the pY side chain extends from a  $\beta$  turn on the peptide ligand. [Based on an NMR structure by Stephen Fesik, Abbott Laboratories, Abbott Park, Illinois. PDBid 1SHC.]

in effect, forms an additional antiparallel  $\beta$  strand of one of the  $\beta$  sheets. The NPQpY segment forms a  $\beta$  turn in which the phosphate group contacts an Arg side chain that mutational studies indicate is essential for the binding of target peptide.

#### d. SH3 Domains Bind to Proline-Rich Peptides

Many of the RTKs that contain SH2 domains also have one or more 50- to 75-residue **SH3 domains**. Moreover, SH3 is contained in several membrane-associated proteins that lack an SH2. The SH3 domain, which is unrelated to SH2, binds Pro-rich sequences of 9 or 10 residues containing the motif Pro-X-X-Pro, with the residues surrounding this motif targeting these sequences to specific SH3 domains. The physiological function of SH3 is less apparent than that of SH2 because SH3 occurs in a greater variety of proteins, including receptor and nonreceptor tyrosine kinases, adaptor proteins such as **Grb2** (see below), and structural proteins such as spectrin and myosin. However, the observation that the deletion of the SH3 domain-encoding segments from the proto-oncogenes *Src* and *Abl* (which both encode PTKs) converts them to oncogenes suggests that SH3, much like SH2 and PTB, functions to mediate the interactions between kinases and regulatory proteins. SH2, PTB, and SH3 have therefore been called “molecular velcro.”

The X-ray and NMR structures of SH3 domains from several proteins indicate that the SH3 core consists of two 3-stranded, antiparallel  $\beta$  sheets that pack against each other with their strands nearly perpendicular. As with SH2, the close proximity of SH3's N- and C-termini suggests that this domain could be modularly inserted between two residues on the surface of another protein without greatly perturbing either structure. The X-ray structures of the SH3 domains from the tyrosine kinases *Abl* and *Fyn* in complex with two different 10-residue Pro-rich polypeptides to which they tightly bind were determined by Andrea Musacchio and Matti Saraste. Both decapeptides assume nearly identical conformations with their C-terminal 7 residues in the polyproline II helix conformation (Section 8-1Bb). The peptides bind to SH3 over their entire length in three geometrically complementary cavities (Fig. 19-35), which are mostly occupied by Pro side chains.

#### e. Other Binding Modules

Several other binding modules have been implicated in mediating signal transduction. These include:

1. The **WW domain** (named after its two highly conserved Trp residues), an  $\sim$ 40-residue module that binds to Pro-rich sequences on its target proteins.

2. The **pleckstrin homology (PH) domain** (so named because was first recognized in **pleckstrin** [for *platelet and leukocyte C kinase substrate protein*]), an  $\sim$ 120-residue module that is present in  $>$ 100 proteins. It structurally resembles the PTB domain (Fig. 19-34) but binds to the inositol head groups of phosphoinositides (Section 19-4). It therefore targets its attached proteins to the inner surface

**Figure 19-35** X-ray structure of the SH3 domain from *Abl* protein in complex with its 10-residue target Pro-rich polypeptide (APTMPPLPP). The protein is represented by its surface diagram (cyan) and the peptide is drawn in stick form with Pro C magenta, other C green, N blue, O red, and S yellow. [Based on an X-ray structure by Andrea Musacchio, European Molecular Biology Laboratory, Heidelberg, Germany. PDB ID 1ABO.]

of the plasma membrane. In addition to its role in intracellular signaling, the PH domain participates in cytoskeletal organization, regulation of intracellular membrane transport, and modification of membrane lipids. Its structure is discussed in Section 19-4Bb.

3. The **PDZ domain** (named after the three proteins in which it was first described: *PSD-95*, *Dlg*, and *ZO-1*), an  $\sim$ 100-residue module that mainly binds to the C-terminal tripeptide, Ser/Thr-X-Val, of its target proteins.

Many of the proteins that participate in signal transduction consist of several modular units that also occur in several, if not many, other such proteins. These modules may have enzymatic activities (e.g., PTK activity) or bind to specific molecular motifs, such as a phosphoTyr residue within a specific sequence (e.g., SH2 domains) or another protein module (e.g., SH3 domains). Apparently, *signaling proteins have arisen through the evolutionary shuffling of these modules to generate different combinations of interactions and activities*. Indeed, we shall see that the complex behavior of these signaling proteins is a consequence of the interactions among their various modules.

#### f. Ras Is Activated by Phosphorylated RTKs via a Grb2-Sos Complex

**c-Ras** (or just *Ras*), a proto-oncogene product, is a monomeric membrane-anchored (by prenylation) G protein

that lies at the center of an intracellular signaling system: It regulates such essential cellular functions as growth and differentiation through the phosphorylation and hence activation of a variety of proteins. Ras is the prototypic member of the superfamily of small G proteins, whose 154 members form five principal families, those of (1) Ras; (2) Arf and (3) Rab, which both participate in vesicle trafficking (Sections 12-4Cd and 12-4Db); (4) **Rho**, which is mainly involved in regulating the cytoskeleton (Section 35-3Ed); and (5) **Ran**, which regulates nuclear import and export.

In the signaling pathway described in Section 19-3D, the binding of ligand to RTKs ultimately activates a guanine nucleotide exchange factor (GEF; Section 19-2Ca) to exchange a Ras-bound GDP for GTP. Only Ras · GTP is capable of further relaying the signal. However, as do the homologous and structurally similar  $\alpha$  subunits of the heterotrimeric G proteins, Ras eventually hydrolyzes its bound GTP to GDP, thereby halting further signal transduction and limiting the magnitude of the signal generated by the binding of ligand to the receptor. Indeed, the structure of Ras closely resembles those of the GTPase domains of the heterotrimeric G protein  $G_{\alpha}$  subunits, including their Switch I and Switch II regions (Fig. 19-18). Mammalian cells express four Ras homologs: H-Ras, N-Ras, K-Ras 4A, and K-Ras 4B.

Molecular genetic analyses of signaling in a variety of distantly related organisms (notably humans, mice, *Xenopus*, *Drosophila*, and the nematode worm *Caenorhabditis elegans*) have revealed a remarkably conserved pathway in which RTKs funnel the signal that they have bound ligand to Ras, which, in turn, relays the signal, via a so-called MAP kinase cascade, to the transcriptional apparatus in the nucleus (Section 19-3D). Nevertheless, the way in which messages are passed between the RTKs and Ras remained enigmatic for several years until investigations in numerous laboratories revealed their major details. In particular, these studies demonstrated that two previously characterized proteins, **Grb2** and **Sos**, form a complex that bridges activated RTKs and Ras in a way that induces Ras to exchange its bound GDP for GTP, thereby activating it (i.e., they act as a GEF).

The mammalian protein Grb2, a 217-residue homolog of **drk** in *Drosophila* and **Sem-5** in *C. elegans*, consists almost entirely of an SH2 domain flanked by two SH3 domains. Sos protein (the 1596-residue product of the *Son of Sevenless* gene, so named because Sos interacts with the *Sevenless* gene product, an RTK that regulates the development of the R7 photoreceptor cell in the *Drosophila* compound eye), which is required for Ras-mediated signaling, contains a central domain homologous to known Ras-GEFs and a Pro-rich sequence in its C-terminal segment similar to known SH3-binding motifs. Moreover, mammalian homologs of Sos (**mSos**) have been shown to specifically stimulate guanine nucleotide exchange in mammalian Ras proteins. Western blotting techniques (Section 6-4Bc) using anti-Grb2 and anti-mSos antibodies indicated that Grb2 binds to the C-terminal segment of mSos but not when one of the Pro residues in Sos' SH3-binding motif has been replaced by Leu or in the presence

of synthetic polypeptides that have these Pro-rich sequences. Similar studies indicated that in the presence of epidermal growth factor (EGF), the EGF receptor (an RTK; Figs. 19-25 and 19-27b) specifically binds the Grb2–mSos complex. However, this interaction is blocked by the presence of a phosphopeptide with the sequence of the peptide segment containing one of the activated EGF receptor's phosphoTyr residues. Evidently, Grb2's SH2 domain binds a phosphoTyr-containing peptide segment in an activated RTK while its two SH3 domains bind the Pro-rich sequences of Sos. The GEF function of Sos is thereby stimulated to activate Ras.

#### g. Grb2, Shc, and IRS Are Adaptors That Recruit Sos to the Vicinity of Ras

The X-ray structure of Grb2, determined by Arnaud Ducruix, reveals that neither of its SH3 domains contacts its SH2 domain (Fig. 19-36). Moreover, although the two SH3 domains are in contact, their interface area is relatively small and hence is more likely to be an artifact of crystallization than a structural feature of Grb2 in solution. It therefore appears that Grb2's SH3 domains are flexibly linked to its SH2 domain. How does the binding of such a pliable adaptor (a linker that lacks enzymatic activity) to a phosphorylated RTK stimulate Sos to act as Ras's GEF? Grb2 and Sos bind one another so tightly that they are essentially permanently associated in the cell. Hence, when

**Figure 19-36** X-ray structure of Grb2. Its SH2 domain (green) is linked to its flanking SH3 domains (cyan and orange) via apparently unstructured and hence flexible 4-residue linkers. [Based on an X-ray structure by Arnaud Ducruix, Université de Paris-Sud, Gif sur Yvette Cedex, France. PDBid 1GRI.]

**Figure 19-37 Structure of an insulin receptor substrate (IRS).** An IRS contains a PH and a PTB domain at its N-terminus followed by multiple phosphoTyr-containing binding sites for the SH2 domains of downstream signaling proteins.

Grb2 binds its target phosphorylated RTK, it recruits Sos to the inner surface of the plasma membrane, where Sos's then increased local concentration causes it to more readily bind to the membrane-anchored Ras.

Shc proteins are also adaptors that link activated RTKs to Ras. Shc proteins consist of an N-terminal PTB domain (Fig. 19-34), a central effector region (CH1), and a C-terminal SH2 domain that binds to certain activated RTKs. Moreover, Shc proteins are also major targets of various RTKs, which phosphorylate them within their CH1 domains at sequences that then form binding sites for the Grb2 SH2 domain. Activated RTKs may therefore bind Grb2 indirectly via Shc as well as directly. Moreover, in some cases, an Shc-Grb2-Sos complex that lacks a bound RTK may activate Ras.

The activated (autophosphorylated) insulin receptor does not directly interact with SH2 domain-containing proteins. Rather, it mainly phosphorylates an ~1300-residue protein named the **insulin receptor substrate (IRS)**; actually a family of four homologous proteins named IRS1–4, each of which is expressed in a tissue-specific manner). The IRS proteins all have an N-terminal “targeting” region consisting of a PH domain that localizes the IRS to the inner surface of the plasma membrane, followed by a PTB domain that binds the IRS to a phosphoTyr residue of an activated insulin receptor (Fig. 19-37). The insulin receptor thereupon phosphorylates the IRS at one or more of its 6 to 8 Tyr residues, converting them to SH2-binding sites that then couple this system to SH2-containing proteins (Section 19-4F). Adaptors with multiple SH2-binding sites such as the IRS proteins and Shc are also known as **docking proteins** because they function as platforms for the recruitment of a variety of downstream signaling molecules in response to the activation of their corresponding RTK. Thus, a docking protein increases the complexity and regulatory flexibility of its RTK-initiated signaling pathway as well as amplifying its signal.

#### h. Sos Functions to Pry Open Ras's Nucleotide Binding Site

The X-ray structure, determined by Kuriyan, of Ras in complex with a 506-residue GEF-containing segment of Sos reveals how Sos induces Ras to exchange its normally tightly bound GDP for GTP. This Sos segment consists of two  $\alpha$  helical domains, of which only the C-terminal

so-called catalytic domain contacts Ras. Ras is packed against the center of the elongated bowl-shaped catalytic domain (Fig. 19-38). Those portions of Ras that interact with the catalytic domain include both its Switch I and Switch II regions as well as the loop that binds the  $\alpha$  and  $\beta$  phosphates of GDP and GTP, the so-called **P-loop** (although GMP binds to Ras with  $10^6$ -fold less affinity than does GDP, so that the  $\beta$  phosphate of GDP is largely responsible for its tight binding to Ras). This interaction displaces Switch I relative to its position in the X-ray structure of Ras in complex with the nonhydrolyzable GTP analog **GMPPNP**:

**Guanosine-5'-( $\beta,\gamma$ -imido)triphosphate (GMPPNP)**

Ras's nucleotide binding site is thereby partially opened up and a Leu and a Glu side chain from Sos are, respectively, introduced into Ras'  $Mg^{2+}$ -binding site and the site that binds the  $\alpha$  phosphate group of GDP/GTP. However, this interaction does not significantly occlude Ras's guanine and ribose binding sites. This rationalizes how the Sos-Ras interaction can be strong enough to displace the normally tightly bound GDP from Ras but yet weak enough so that

**Figure 19-38 X-ray structure of the complex between Ras and the GEF-containing region of Sos.** The N-terminal domain of the Sos region is blue, its catalytic domain is green, and Ras is mainly gray, with its Switch I and II regions orange and its P loop red. Conserved regions (the SCRs) among the Ras family of GEFs are cyan. [Courtesy of John Kuriyan, The Rockefeller University. PDBid 1BDK.]

GTP (or the 10-fold less abundant GDP) can subsequently displace Sos from Ras.

The different families of small G proteins interact with different classes of GEFs, whose catalytic domains share no sequence similarity and are structurally unrelated [e.g., rhodopsin (Fig. 19-16) is a GEF for  $G_{\alpha}$ ]. Nevertheless, many of these GEFs share the same general mechanism for promoting GDP–GTP exchange, which suggests that this mechanism arose on several occasions through convergent evolution.

#### i. GAPs Function to Turn Off Ras-Mediated Signals

Ras hydrolyzes its bound GTP with a rate constant of  $0.02 \text{ min}^{-1}$  (vs  $2\text{--}3 \text{ min}^{-1}$  for  $G_{\alpha}$  subunits), too slowly for effective signal transduction. This led to the discovery of a 120-kD GTPase activating protein, **RasGAP**, that, on binding Ras · GTP, accelerates the rate of GTP hydrolysis by a factor of  $10^5$ . RasGAP's physiological importance as a regulator of Ras-mediated signal transduction is demonstrated by the observation that the relative biological activities of Ras mutants are better correlated with their

resistance to regulation by RasGAP than by their intrinsic GTPase activity.

The mechanism whereby RasGAP activates the GTPase activity of Ras was revealed by the X-ray structure, determined by Alfred Wittinghofer, of the 334-residue GTPase-activating domain of RasGAP (GAP334) bound to Ras in its complex with GDP and  $\text{AlF}_3$  (Fig. 19-39). GAP334, which consists of two all-helical domains, interacts with Ras over an extensive surface that includes its Switch I and II regions. The  $\text{AlF}_3$ , which has trigonal planar symmetry, binds to Ras at the expected position of GTP's  $\gamma$  phosphate group, with the Al atom opposite a bound water molecule that presumably would be the attacking nucleophile in the GTPase reaction. Since Al–F and P–O bonds have similar lengths and phosphoryl-transfer reactions occur via a trigonal bipyramidal transition state (Fig. 16-6b), the  $\text{GDP–AlF}_3\text{–H}_2\text{O}$  assembly presumably resembles the GTPase reaction's transition state, with the  $\text{AlF}_3$  mimicking the planar  $\text{PO}_3$  group. Note that Ras · GDP does not by itself bind  $\text{AlF}_3$ .

GAP334 binds to Ras with GAP334's exposed so-called finger loop inserted into the Ras active site such that the finger loop's Arg 789 side chain interacts with both the Ras-bound GDP's  $\beta$  phosphate and the  $\text{AlF}_3$  (Fig. 19-39). In Ras · GTP, this Arg side chain would be in an excellent position to stabilize the developing negative charge in the GTPase reaction's transition state. Indeed, the catalytically more efficient  $G_{\alpha}$  subunits contain an Arg residue (Arg 178 in  $G_{i\alpha}$ ), whose guanidinium group occupies a nearly identical position (in  $G_{s\alpha}$ , this is the Arg side chain that is ADP-ribosylated by cholera toxin; Section 19-2Cd). The main chain carbonyl O of Arg 789 hydrogen bonds to the side chain N of Ras' catalytically important Gln 61. The O of this side chain is thereby positioned to hydrogen bond with the nucleophilic water molecule while its  $\text{NH}_2$  group interacts with an F atom of  $\text{AlF}_3$  (Fig. 19-37), an arrangement that presumably stabilizes the GTPase reaction's transition state.

#### j. Oncogenic Mutants of Ras Are GAP-Insensitive

Mutations in Ras of Gly 12 and Gln 61 are its most common oncogenic mutations (an oncogenic form of which is found in  $\sim 30\%$  of human cancers). These mutations prevent RasGAP from activating Ras to hydrolyze its bound GTP and hence lock Ras into its active conformation. The foregoing X-ray structure reveals why these mutants are GAP-insensitive. Gly 12 is in such close proximity to the finger loop that even the smallest possible residue change (to Ala) would sterically interfere with the geometry of the transition state through steric clashes with the main chain of Arg 789 (of RasGAP) and the side chain  $\text{NH}_2$  of Gln 61. The observation that Gly 12 mutants of Ras bind GTP with nearly wild-type affinity therefore suggests that larger side chains can be tolerated at Ras residue 12 in the Ras–RasGAP Michaelis complex but not in the transition state. The apparent participation of Gln 61 in transition state stabilization confirms that this residue has an essential role in catalysis.

**Figure 19-39** X-ray structure of the GAP334 · Ras · GDP ·  $\text{AlF}_3$  complex. The active site regions of the proteins are shown as ribbons with Ras cyan, its Gly 12 magenta, GAP334 yellow, and its finger loop red. The GDP,  $\text{AlF}_3$ , and the side chains of Ras Asn 61 and GAP334 Arg 789 are drawn in stick form with C green, N blue, O red, F yellow-green, P orange, and Al pink; the nucleophilic water molecule is represented by a red sphere; and hydrogen bonds are shown as dashed lines. [Based on an X-ray structure by Alfred Wittinghofer, Max-Planck-Institut für Molekulare Physiologie, Dortmund, Germany. PDBid 1WQ1.]

**D. MAP Kinase Signaling Cascades**

The signaling pathway downstream of Ras consists of a linear series of Ser/Thr kinases that form a so-called **MAP kinase cascade** (Fig. 19-40). Many of the proteins that par-

ticipate in MAP kinase cascades are the products of proto-oncogenes:

**1. Raf**, a Ser/Thr protein kinase, is activated by direct interaction with Ras · GTP (although other signaling

**Figure 19-40 The Ras-activated MAP kinase cascade.** This signaling cascade begins when an RTK binds its cognate growth factor, thereby inducing the autophosphorylation of this RTK's cytosolic domain. Grb2/Sem-5 binds to the resulting phosphoTyr-containing peptide segment via its SH2 domain and simultaneously binds to Pro-rich segments on Sos via its two SH3 domains. This activates Sos as a guanine nucleotide exchange factor (GEF) to exchange Ras' bound GDP for GTP, which activates Ras to bind to Raf. Then, Raf, a Ser/Thr kinase,

phosphorylates MEK, which in turn phosphorylates MAPK, which then migrates to the nucleus, where it phosphorylates transcription factors such as Fos, Jun, and Myc, thereby modulating gene expression. The MAP kinase cascade eventually returns to its resting state through the actions of protein phosphatases (Section 19-3F) after a GTPase activating protein (GAP) deactivates Ras by inducing it to hydrolyze its bound GTP to GDP. [After Egan, S.E. and Weinberg, R.A., *Nature* 365, 782 (1993).]  See the Animated Figures

**Figure 19-41** X-ray structure of the Ras binding domain of Raf (RafRBD; orange) in complex with Rap1A · GMPPNP (blue). The Switch I and II regions of Rap1A are magenta and green, and its bound GMPPNP is shown in space-filling form with C green, N blue, O red, and P yellow. Rap1A · GMPPNP and Ras · GMPPNP have nearly identical structures. [Based on an X-ray structure by Alfred Wittinghofer, Max-Planck-Institut für Molekulare Physiologie, Dortmund, Germany. PDBid 1GUA.]

pathways may activate Raf by phosphorylating it at multiple Ser and Thr residues; see below). The X-ray structure of the Ras homolog **Rap1A** in complex with GMPPNP and the Ras binding domain of Raf (RafRBD), determined by Wittinghofer, reveals that the two proteins associate largely by mutually extending their antiparallel  $\beta$  sheets across a mainly polar interface (Fig. 19-41). Although Ras · GTP has 1300-fold greater affinity for binding to Raf than does Ras · GDP, it is unclear from this structure how GTP hydrolysis by Ras affects the Ras–Raf interface. Quite possibly the conformational change in Ras Switch I perturbs the Ras–Raf interface to the point that it dissociates.

2. Activated Raf phosphorylates a protein alternatively known as **MEK** and **MAP kinase kinase (MKK)** at specific Ser and Thr residues, thereby activating it as a Ser/Thr kinase. [Raf is therefore a **MAP kinase kinase kinase (MKKK)**].

3. Activated MEK phosphorylates a family of proteins named **mitogen-activated protein kinases (MAP kinases or MAPKs)** or **extracellular-signal-regulated kinases (ERKs)**. For more than marginal activation, a MAPK must be phosphorylated at both its Thr and Tyr residues in the sequence Thr-X-Tyr. MEK (which stands for *MAP kinase/ERK-activating kinase*) catalyzes both phosphorylations and thus has dual specificity for Ser/Thr and Tyr. The X-ray structure of the unphosphorylated MAP kinase ERK2, determined by Elizabeth Goldsmith, reveals that this protein structurally resembles other protein kinases of known structure and that its Tyr residue that becomes phosphorylated blocks the peptide-binding site in its unphosphorylated form.

4. The activated MAPKs phosphorylate a variety of cytoplasmic and membrane-associated proteins, including Sos and EGFR, at Ser/Thr-Pro motifs. In addition, the MAPKs migrate from the cytosol to the nucleus, where they phosphorylate a large variety of transcription factors including Jun/AP-1, Fos, and **Myc**. These activated transcription factors, in turn, induce the transcription of their target genes (Section 34-4Bd). The effects commissioned by the extracellular presence of the protein growth factor that initiated the signaling cascade are thereby produced.

MAP kinase cascades can be activated in other ways besides by liganded RTKs. For example, Raf may also be activated via its Ser/Thr phosphorylation by **protein kinase C**,

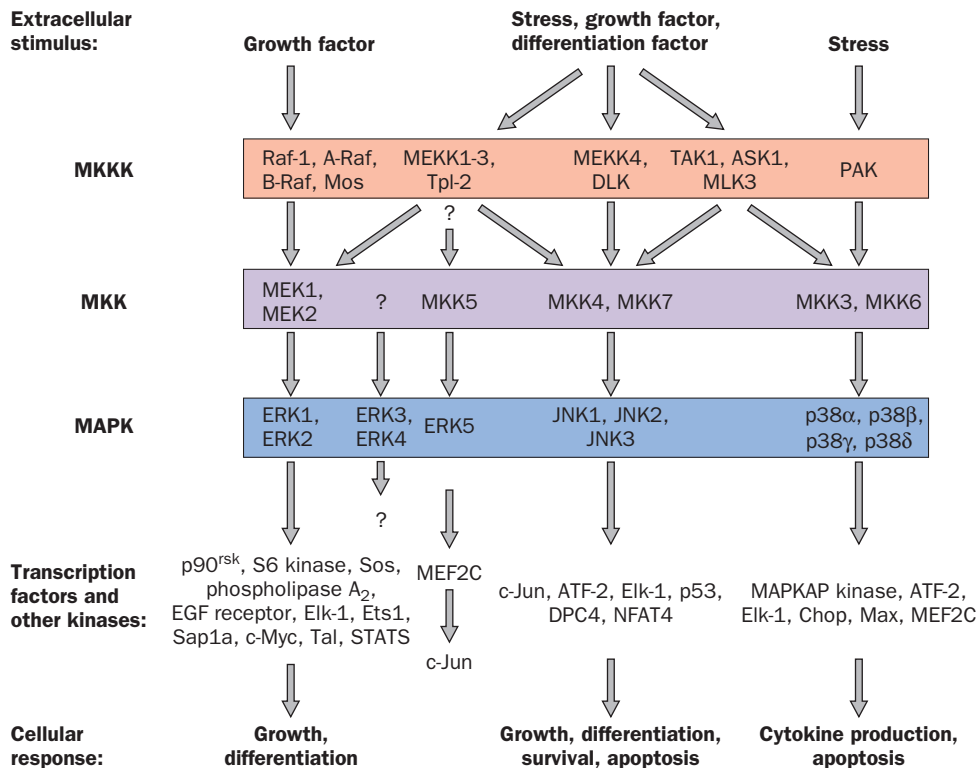

which is activated via the phosphoinositide signaling system described in Section 19-4. Alternatively, Ras may be activated by subunits of certain heterotrimeric G proteins. Thus, *the MAP kinase cascade serves to integrate a variety of extracellular signals*.

#### a. Scaffold and Anchoring Proteins Organize and Position Protein Kinases

Eukaryotic cells contain numerous different MAPK signaling cascades, each with a characteristic set of component kinases, which in mammals comprise at least 14 MKKKs, 7 MKKs, and 12 MAPKs (Fig. 19-42). Although each MAPK is activated by a specific MKK, a given MKK can be activated by more than one MKKK. Moreover, several pathways may be activated by a single type of receptor. How then does a cell prevent inappropriate cross talk between closely related signaling pathways? One way that this occurs is through the use of **scaffold proteins**, proteins that bind some or all of the component protein kinases of a particular signaling cascade so as to ensure that the protein kinases of a given pathway interact only with one another. In addition, a scaffold protein can control the subcellular location of its associated kinases.

The first known scaffold protein was discovered through the genetic analysis of a MAP kinase cascade in yeast, which demonstrated that this protein, **Ste5p**, binds the MKKK, MKK, and MAPK components of the pathway and that, *in vivo*, the scaffold's absence inactivates the pathway. Evidently, the interactions between successive kinase components of this MAP kinase cascade are, by themselves, insufficient for signal transmission.

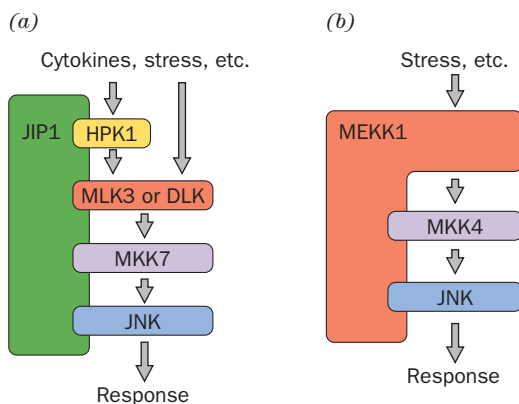

**Figure 19-42** MAP kinase cascades in mammalian cells. Each MAP kinase cascade consists of an MKKK, an MKK, and an MAPK. Various external stimuli may each activate one or more MKKKs, which in turn may activate one or more MKKs. However, the MKKs are relatively specific for their target MAPKs. The activated MAPKs phosphorylate specific

transcription factors (e.g., **Elk-1**, **Ets1**, **p53**, **NFAT4**, **Max**) as well as specific kinases (e.g., **p90<sup>rsk</sup>**, **S6 kinase**, **MAPKAP kinase**). The resulting activated transcription factors and kinases then induce cellular responses such as growth, differentiation, and **apoptosis** (programmed cell death; Section 34-4E). [After Garrington, T.P. and Johnson, G.L., *Curr. Opin. Cell Biol.* **11**, 212 (1999).]

**JIP-1** (for *JNK interacting protein-1*; Fig. 19-43a) is a scaffold protein that simultaneously binds **HPK1** (for *hematopoietic progenitor kinase-1*), a Ras analog and

hence an **MKKK kinase (MKKKK)**; the MKKKs **MLK3** and **DLK**; **MKK7**; and the MAPK **JNK** (for *Jun N-terminal kinase*). **MEKK1** is a somewhat different type of scaffold protein (Fig. 19-43b); this functional MKKK binds its substrate, **MKK4**, as well as the latter's substrate, JNK.

Protein Ser/Thr kinases may similarly be individually tethered to their sites of action by **anchoring proteins**. For example, protein kinase A (PKA), which participates in numerous parallel signaling pathways including that regulating glycogen metabolism (Section 18-3), associates with several unrelated so-called **A-kinase anchoring proteins (AKAPs)**. The different AKAPs, which all bind the regulatory (R) subunits of PKA, target PKA to different subcellular locations (e.g., to vesicle or plasma membranes or to particular receptors) and may also bind other signaling proteins (e.g., PP1, the protein phosphatase that removes phosphate groups installed by PKA; Section 18-3Cg), thus functioning to integrate intracellular signals.

**Figure 19-43** Some examples of scaffold proteins that modulate mammalian MAP kinase cascades. (a) JIP-1 binds all protein components of the MAP kinase cascade in which HPK1 phosphorylates MKL3 or DLK (MKKKs), which then phosphorylates MKK7, which then phosphorylates JNK (an MAPK). (b) MEKK1 (an MKKK) is the kinase for MKK4 and also binds JNK, MKK4's target MAPK. [After Garrington, T.P. and Johnson, G.L., *Curr. Opin. Cell Biol.* **11**, 213 (1999).]

#### b. Anthrax Lethal Factor Specifically Cleaves MAPKKs

**Anthrax**, an infectious disease caused by the bacterium *Bacillus anthracis*, affects mainly herbivorous animals such as cattle, sheep, and goats. On rare occasions, however, it may be transmitted to humans (but not between humans), in whom it is often fatal, if untreated, through massive

septic shock (Section 19-1Lb). Anthrax spores are significant agents of biological warfare because their inhalation results in inhalational anthrax, a form of the disease that is nearly always fatal. This is because by the time the symptoms of inhalational anthrax become apparent, the bacterial infection has already released so much toxin that eliminating the infection through antibiotic treatment does not reverse the progress of the disease.

**Anthrax toxin** consists of three proteins that act in concert: **protective antigen (PA)**, **lethal factor (LF)**, and **edema factor (EF)** (oedema factor in British English). PA, which is named for its use in vaccines, is a 735-residue, 4-domain protein that binds to its host cell-surface receptor (a single pass transmembrane protein) via its C-terminal domain. Most of PA's N-terminal domain is then cleaved away by a cell-surface protease, whereon the remaining membrane-bound portions of PA form cyclic heptamers reminiscent of the cyclic pentamers formed by cholera toxin (Fig. 19-22). The heptameric PA then binds LF and/or EF by their homologous N-terminal domains and mediates their endocytotic uptake into the cell. Indeed, the intravenous administration of only PA and LF rapidly kills animals. EF is a calmodulin-activated adenylate cyclase whose action upsets water homeostasis and hence is probably responsible for the massive **edema** (abnormal buildup of intercellular fluids) seen in cutaneous anthrax infections.

LF is a 776-residue monomeric protease that has only one known cellular target: *It cleaves members of the MAAPKK family of proteins near their N-termini so as to excise the docking sequences for their cognate downstream MAPKs.* It thereby disrupts the signal transduction pathways in which these proteins participate. However, anthrax infection targets mainly macrophages, a type of white blood cell (mice whose blood has been depleted of macrophages are resistant to anthrax). Low levels of LF, which occur in early stages of anthrax infection, cleave MAPKK-3, which inhibits macrophages from releasing but

not producing the inflammatory mediators NO (Section 19-1Lb) and **tumor necrosis factor- $\alpha$  (TNF $\alpha$ )**; a cytokine that has opposite effects to most protein growth factors and is largely responsible for the wasting seen in chronic infections). This has the effect of reducing and/or delaying the immune response. In contrast, high levels of LF, which occur in late stages of infection, trigger macrophage lysis, causing the sudden release of NO and TNF- $\alpha$ , which presumably results in the massive septic shock that causes death.

### E. Tyrosine Kinase–Associated Receptors

Many cell-surface receptors are not members of the receptor families that we have discussed and do not respond to ligand binding by autophosphorylation. These include the receptors for the cytokines (Section 19-3Eb) and **T cell receptors** [which control the proliferation of immune system cells known as T lymphocytes (T cells); Section 35-2D]. *Ligand binding induces these tyrosine kinase–associated receptors to dimerize (and, in some cases, to trimerize or form even higher oligomers), often with different types of subunits, in a way that activates associated nonreceptor tyrosine kinases (NRTKs).* The domain organization for the major subfamilies of NRTKs is diagrammed in Fig. 19-44.

#### a. The Structure of Src Reveals Its Autoinhibitory Mechanism

Many of the NRTKs that are activated by tyrosine kinase–associated receptors belong to the **Src family**, which contains at least nine members including Src, Fyn, and **Lck**. Most of these ~530-residue membrane-anchored (by myristoylation) proteins have both an SH2 and an SH3 domain and all have a PTK domain. Hence, an Src-related kinase may also be activated by association with an autophosphorylated RTK. Although Src-related kinases are each associated with different receptors, they phosphorylate

**Figure 19-44** Domain organization of the major NRTK subfamilies. The N-termini for these polypeptides, which are drawn approximately to scale, are on the left and the domain

identification is provided on the right. [Courtesy of Stevan Hubbard, New York University School of Medicine.]

overlapping sets of target proteins. This complex web of interactions explains why different ligands often activate some of the same signaling pathways.

Src, as indicated in Fig. 19-44, consists of, from N- to C-terminus, a myristoylated N-terminal “unique” domain that differs among Src family members, an SH3 domain, an SH2 domain, a PTK domain, and a short C-terminal tail. Phosphorylation of Tyr 416 in the PTK’s activation loop activates Src, whereas phosphorylation of Tyr 527 in its C-terminal tail deactivates it. *In vivo*, Src is phosphorylated at either Tyr 416 or Tyr 527, but not at both. The dephosphorylation of Tyr 527 or the binding of external ligands to the SH2 or the SH3 domain activates Src, a state that is then maintained by the autophosphorylation of Tyr 416. When Tyr 527 is phosphorylated and no activating phosphopeptides are available, Src’s SH2 and SH3 domains function to deactivate its PTK domain, that is, Src is then autoinhibited.

The X-ray structure of Src · AMPPNP lacking its N-terminal domain and with Tyr 527 phosphorylated, determined by Stephen Harrison and Michael Eck, reveals the structural basis of Src autoinhibition (Fig. 19-45). As biochemical studies had previously shown, the SH2 domain binds phosphoTyr 527, which occurs in the sequence pYNPG rather than the pYEEI sequence characteristic of high affinity Src SH2 target peptides. Although the pYNP segment binds to SH2 as does the pYEE segment in Fig. 19-33*b*, the succeeding residues are poorly ordered in the X-ray structure and, moreover, the SH2 pocket in which the Ile side chain of pYEEI binds is unoccupied. Apparently, the phosphoTyr 527-containing peptide segment binds to the Src SH2 domain with reduced affinity relative to its target peptides.

The SH3 domain binds to the linker connecting the SH2 domain to the N-terminal lobe of the PTK domain. Residues 249 to 253 of this linker form a polyproline II helix that binds to the SH3 domain in much the same way as do SH3’s Pro-rich target peptides (Fig. 19-33). However, the only Pro in this segment is residue 250. The polar side chain of Gln 253, which occupies the position of the second Pro in SH3’s normal Pro-X-X-Pro target sequence, does not enter the hydrophobic binding pocket that this second Pro would occupy (Fig. 19-35), and hence the path of the peptide deviates from that of Pro-rich target peptides at this point. Apparently, this interaction is also weaker than those with Src’s SH3 target peptides.

Src’s SH2 and SH3 domains bind on the opposite side of the PTK domain from its active site. How, then, does the conformation shown in Fig. 19-45 inhibit the PTK’s activity? The two lobes of Src’s PTK domain are, for the most part, closely superimposable on their counterparts in the PTK domain of phosphorylated and hence activated Lck (a Src family member) as well as the C subunit of activated PKA (Fig. 18-15). However, Src helix C (the only helix in the PTK’s N-terminal lobe) is displaced from the interface between the N- and C-terminal lobes relative to its counterparts in Lck and PKA. Helix C contains the conserved residue Glu 310 (using Src numbering), which in activated

**Figure 19-45** X-ray structure of Src · AMPPNP lacking its N-terminal domain and with Tyr 527 phosphorylated. The SH3 domain is orange, the SH2 domain is magenta, the linker joining the SH2 domain to the PTK domain is green with its 5-residue polyproline II helix gold, the N-terminal lobe of the PTK domain is pink, the C-terminal lobe is cyan with its activation loop blue, and the C-terminal tail is orange. The AMPPNP is shown in space-filling form and Y416 and pY527 are shown in ball-and-stick form, all with C green, N blue, O red, and P yellow. [Based on an X-ray structure by Stephen Harrison and Michael Eck, Harvard Medical School. PDBid 2SRC.]

Lck and PKA projects into the catalytic cleft, where it forms a salt bridge with Lys 295, an important ligand of the substrate ATP’s  $\alpha$  and  $\beta$  phosphates. However, in inactive Src, Glu 310 forms an alternative salt bridge with Arg 409, whereas Lys 295 instead interacts with Asp 404. In activated Lck, Arg 409 forms a salt bridge with phosphoTyr 416.

The foregoing structural observations suggest the following scenario for Src activation (Fig. 19-46):

1. The dephosphorylation of Tyr 527 and/or the binding of the SH2 and/or SH3 domains to their target peptides (for which SH2 and SH3 have greater affinity than their internal Src binding sites) releases these domains from their PTK-bound positions shown in Fig. 19-45, thus relaxing conformational constraints on the PTK domain. This allows the PTK’s active site cleft to open, thereby disrupting the structure of its partially helical activation loop (which occupies a blocking position in the active site cleft; Fig. 19-45) so as to expose Tyr 416 to autophosphorylation.

2. The resulting phosphoTyr 416 forms a salt bridge with Arg 409, which sterically requires the structural reorganization of the activation loop to its active, nonblocking conformation. The consequent rupture of the Glu 310–Arg 409 salt bridge frees helix C to assume its active orientation which, in turn, allows Glu 310 to form its catalytically important salt bridge to Lys 295, thereby activating the Src PTK activity.

**Figure 19-46 Schematic model of Src activation.** See the text for an explanation. The coloring scheme largely matches that in Fig. 19-45, as does the viewpoint. [After Young, M.A.,

Gonfloni, F., Superti-Furga, G., Roux, B., and Kuriyan, J., *Cell* **105**, 115 (2001).]

The above mechanism is, perhaps unexpectedly, critically dependent on the rigidity of the 8-residue linker joining the SH2 and SH3 domains. Thus, replacing three of these linker residues with Gly (whose lack of a  $C_{\beta}$  atom makes it the least conformationally restricted residue) results in a protein that is no longer deactivated by the phosphorylation of Tyr 527. This is corroborated by molecular dynamics simulations (Section 9-4) indicating that the thermal motions of the SH2 and SH3 domains are highly correlated (move as a unit) when Tyr 527 is phosphorylated but that this correlation is significantly reduced when Tyr 527 is dephosphorylated or when Gly replaces the three linker residues.

#### b. The JAK-STAT Pathway Relays Cytokine-Based Signals

Cytokines form a diverse group of small soluble proteins that, when secreted by cells, act in an autocrine, paracrine, or endocrine fashion to induce a great variety of responses, including the immune response (Section 35-2Aa), cell proliferation, growth, differentiation, **apoptosis** (programmed cell death; Section 34-4E), and **chemotaxis** (the movement of a motile cell along a concentration gradient of a specific substance). They include the 35 different **interleukins (IL-1 to IL-35)**, the colony stimulating factors [which include **macrophage colony-stimulating factor (M-CSF)**, **granulocyte colony-stimulating factor (G-CSF)**, and **granulocyte macrophage colony-stimulating factor (GM-CSF)**;

macrophages and granulocytes are types of white blood cells], growth hormone (Section 19-1J), **erythropoietin (EPO)** (which stimulates the production of erythrocytes), the **interferons** (which protect against viral infection; Section 32-4Ab), the **tumor necrosis factors (TNFs)**, **nerve growth factor (NGF)**, and the **chemokines** (which induce chemotaxis in responsive cells). Abnormalities in specific cytokines or their receptors have been implicated in a large variety of diseases and, conversely, several cytokines are therapeutically useful in alleviating certain pathological states [e.g., EPO is used to treat anemia resulting from chronic kidney disease (EPO is produced by the kidneys) and GM-CSF is used to stimulate white cell production following chemotherapy (which kills fast-growing cells such as white cells)].

Most **cytokine receptors**, as we saw for human growth hormone (Section 19-1J), are activated through ligand-induced receptor aggregation of two or more receptor components. For example, the **GM-CSF receptor** consists of two different types of subunits: **GMR $\alpha$** , which is specific for GM-CSF, and  **$\beta_c$** , which is a common subunit for the GM-CSF, **IL-3**, and **IL-5** receptors. Both of these subunits consist of an N-terminal cytosolic domain, a single transmembrane helix, and a C-terminal ectodomain, which in GMR $\alpha$  consists of two fibronectin type III domains (Section 19-1J) and in  $\beta_c$  consists of four such domains.

The X-ray structure of GM-CSF in complex with its receptor's ectodomain, determined by Angel Lopez and

**Figure 19-47** X-ray structure of the extracellular portions of the GM-CSF receptor in complex with GM-CSF. The structure of this 2-fold symmetric 2:2:2 complex of GM-CSF, GMR $\alpha$ , and  $\beta_c$  is viewed (a) parallel to the plane of the plasma membrane and (b) from the extracellular side of the membrane. The GM-CSF is purple, the GMR $\alpha$  is yellow, one  $\beta_c$  monomer (chain a) is magenta and the other (chain b) is green. The labels indicate the domain names. The observed N-linked carbohydrates are drawn

Michael Parker, reveals that it consists of a 2:2:2 complex of GM-CSF, GMR $\alpha$ , and  $\beta_c$  (Fig. 19-47). GM-CSF, as had previously been determined, consists of an up-up-down-down four-helix bundle, a topology that occurs only in helical cytokines. Each GM-CSF molecule interacts with both domains of a GMR $\alpha$  subunit and with the N-terminal domain of one  $\beta_c$  subunit (D1) and with the C-terminal domain of the other  $\beta_c$  subunit (D4). The latter phenomenon, in which the domain from one subunit is exchanged with the same domain from an identical subunit to form an intertwined dimer, is known as **domain swapping**. It is a common mechanism for oligomer assembly.

Although the X-ray structures of the ectodomains of several cytokine receptors have been determined, the structures of their cytosolic domains are, as yet, unknown. However, as James Darnell elucidated, the signal that helical cytokines have been bound by their cognate receptors is transmitted within the cell by the **JAK-STAT pathway**. These cytokine receptors form complexes with proteins of the **Janus kinase (JAK)** family of NRTKs, so named because each of its four ~1150-residue members (**JAK1**, **JAK2**, **JAK3**, and **Tyk2**) has two PTK domains (Janus is the two-faced Roman god of gates and doorways), although only the C-terminal domain is functional (Fig. 19-44). **STATs** (for signal transducers and activators of transcription) comprise a family of seven ~800-residue proteins that are the only known transcription factors whose activities are regulated by Tyr phosphorylation and that have SH2 domains.

The JAK-STAT pathway functions as is diagrammed in Fig. 19-48:

1. Cytokine binding induces the cytokine receptor to oligomerize.
2. The cytokine receptor's two associated JAKs are thereby brought into apposition (in the case of the GM-CSF

receptor, JAK2 binds to the cytosolic domain of  $\beta_c$ ), whereupon they reciprocally phosphorylate each other and then their associated receptors, a process resembling the autophosphorylation of dimerized RTKs (Section 19-3Ab). Note that unlike most NRTKs, JAKs lack both SH2 and SH3 domains.

3. STATs bind to the phosphoTyr group on their cognate activated receptor via their SH2 domain and are then phosphorylated on a conserved Tyr residue by the associated JAK.

4. Following their dissociation from the receptor, the phosphorylated STATs homo- or heterodimerize via the association of their phosphoTyr residue with the SH2 domain on the opposing subunit.

5. The STAT dimers are translocated to the nucleus, where these now functional transcription factors induce the expression of their target genes in much the same way as do the transcription factors that are phosphorylated by the MAPKs (Fig. 19-40).

### c. PTKs Are Targets of Anticancer Drugs

The hallmark of **chronic myelogenous leukemia (CML)** is a specific chromosomal translocation (Section 34-4C) forming the so-called **Philadelphia chromosome** in which the *Abl* gene (which encodes the NRTK Abl) is fused with the *Bcr* gene (which encodes the protein Ser/Thr kinase **Bcr**). The Abl portion of this Bcr-Abl fusion protein is constitutively (continuously, without regulation) activated, probably because its Bcr portion oligomerizes. Hematopoietic stem cells (from which all blood cells are descended) bearing the Philadelphia chromosome are therefore primed to develop CML (malignancy requires several independent genetic alterations; Section 19-3Ba). Without a bone marrow transplant (a high-risk procedure that is unavailable to

**Figure 19-48** The JAK-STAT pathway for the intracellular relaying of cytokine signals. See the text for details. [After Carpenter, L.R., Yancopoulos, G.D., and Stahl, N., *Adv. Protein Chem.* **52**, 109 (1999).]

most individuals due to the lack of a suitable donor), CML is invariably fatal, with an average survival time of ~6 years.

An inhibitor of Abl would be expected to prevent the proliferation of, and even kill, CML cells. However, to be an effective anti-CML agent, such a substance must not inhibit other protein kinases because this would almost certainly cause serious side effects. Derivatives of 2-phenylaminopyrimidine bind to Abl with exceptionally high affinity and specificity. One such derivative, **imatinib** (trade name **Gleevec**),

which was developed by Brian Druker and Nicholas Lydon, has caused the remission of symptoms in ~90% of CML patients with almost no serious side effects. This unprecedented performance occurs, in part, because Gleevec is essentially inactive against other PTKs (an exception being the PDGF receptor) as well as protein Ser/Thr kinases.

Abl resembles Src (Fig. 19-44) but lacks Src's C-terminal regulatory phosphorylation site (Figs. 19-45 and 19-46). The X-ray structure of Abl's PTK domain in complex with a truncated form of Gleevec,

determined by Kuriyan (Fig. 19-49), reveals, as expected, that the truncated Gleevec binds in Abl's ATP-binding site [the piperazinyl group that this inhibitor lacks relative to Gleevec does not significantly alter its target discrimination but does increase Gleevec's solubility and hence its bioavailability (Section 15-4Ba); it probably binds in a solvent accessible groove at the back of Abl]. Abl thereby adopts an inactive conformation in which its activation loop, which is not phosphorylated, appears to mimic the way in which substrate peptides bind to PTKs (such as the insulin receptor, Fig. 19-28a); that is, the activation loop assumes an autoinhibitory conformation. As a consequence, the N-terminal end of the activation loop, which has the highly conserved sequence Asp-Phe-Gly (whose Asp side chain, in the active PTK, ligates an  $Mg^{2+}$  ion that is essential for catalysis), assumes a conformation that is quite different from that observed in the X-ray structures of

inactive Abl and Src (Fig. 19-45) because this latter conformation would block the binding of Gleevec.

Gleevec was the first of several compounds that inhibit specific protein kinases to be approved by the FDA for clinical use against certain cancers. In addition, several monoclonal antibodies (Section 6-1Da) that bind to specific PTKs or their ligands are in clinical use as anticancer agents. For example, **cetuximab** (trade name **Erbix**), a chimeric mouse/human monoclonal antibody, is effective against colorectal and certain head and neck cancers. It specifically binds to the ectodomain of EGFR so as to block its ligand binding and hence prevent its activation, thus resulting in impaired cell growth and proliferation. Such receptor-targeted therapies hold enormous promise for controlling, if not curing, cancers by specifically targeting the aberrant proteins that cause the cancers. In contrast, most chemotherapeutic agents that are presently in use indiscriminately kill fast-growing cells and hence almost always have debilitating side effects.

#### d. Increased Chaperone Activity Facilitates Cancer

Epidemiological studies have shown that individuals with age-related neurodegenerative diseases such as Alzheimer's and Parkinson's diseases have a far lower incidence of cancer than the general population. What is the biochemical basis of this intriguing observation? These neurodegenerative diseases are all characterized by the deposition of plaques containing amyloid fibrils (Section 9-5) in the affected brain cells. In Alzheimer's disease, these fibrils consist mainly of A $\beta$  protein (Section 9-5B) and in Parkinson's disease they contain mainly  $\alpha$ -synuclein (a 140-residue soluble protein of unknown function that normally occurs in presynaptic terminals). These amyloid fibrils apparently form because of age-associated reductions in the levels of activity of the chaperone proteins that normally prevent their aggregation.

Many oncogene products, as we have seen, are mutant forms of proteins that participate in signal transduction and hence have altered functionality. Such mutant proteins are usually less stable than their unmutated forms and hence require greater than normal attention from chaperone proteins to maintain their active conformations. In particular, the Hsp90 chaperone proteins (Section 9-2C) facilitate the late stage folding of numerous signaling proteins and, presumably, their oncogenic mutants. In fact, many unmutated signaling proteins are unstable unless they are binding their corresponding ligand or protein and hence are present in cells in complex with Hsp90 (which accounts for Hsp90's high abundance, normally 1–2% of a cell's soluble proteins).

Hsp90 is overexpressed in many types of cancers, a situation that is correlated with resistance to therapy and hence a poor prognosis (and which accounts for the observation that individuals with neurodegenerative diseases rarely get cancer). Consequently, Hsp90 inhibitors are anticancer drugs. Several Hsp90 inhibitors, all of which interfere with its ATPase function, are presently in clinical trials. These substances, unlike most targeted anticancer drugs (e.g., Gleevec), are likely to be effective against a broad range of cancers.

**Figure 19-49** X-ray structure of the Abl PTK domain in complex with a truncated derivative of Gleevec. The protein is viewed from the right of the “standard” view of protein kinases (e.g., Figs. 19-28a and 19-45), with its N-terminal lobe pink, its C-terminal lobe cyan, and its activation loop blue. The truncated Gleevec, which occupies the PTK's ATP-binding site, is shown in space-filling form with C green, N blue, and O red. [Based on an X-ray structure by John Kuriyan, The Rockefeller University. PDBid 1FPU.]

## F. Protein Phosphatases

As we previously discussed (Section 19-2E), to prevent an intracellular signaling pathway from being stuck in the “on” position, its signals must be rapidly eliminated once the message has been delivered. For proteins with phosphoTyr or phospho-Ser/Thr residues, this task is carried out by a variety of protein phosphatases, of which ~500 are encoded by the human genome (around the same number as species of protein kinases, which suggests that these families have similar levels of complexity). The protein phosphatases, as we shall see, are not just simple housekeeping enzymes but are signal transducers in their own right. Thus, whereas kinases control the amplitude of a signaling response, protein phosphatases control its rate and duration.

### a. Protein Tyrosine Phosphatases Also Mediate Signal Transduction

The enzymes that dephosphorylate Tyr residues, the **protein tyrosine phosphatases (PTPs)**, which were discovered by Nicholas Tonks, form a large family of diverse proteins that are present in all eukaryotes (humans have 107 PTP genes vs 90 PTK genes). Each PTP contains at least one conserved ~280-residue phosphatase domain that has the 11-residue signature sequence (I/V)HCXAGXGR(S/T)G, the so-called HCX<sub>5</sub>R motif, which contains the enzyme’s catalytically essential Cys and Arg residues. The reaction proceeds via the nucleophilic attack of the Cys thiolate group on the P atom of the bound phosphoTyr to yield Tyr and a cysteinyl–phosphate intermediate that is subsequently hydrolyzed. The Arg side chain participates in substrate binding and stabilizes the cysteinyl–phosphate intermediate.

The PTPs have been classified into three groups: (1) receptorlike PTPs, (2) intracellular PTPs, and (3) dual-specificity PTPs, which can also dephosphorylate phospho-Ser/Thr residues. The receptorlike PTPs are constructed much like the RTKs (Fig. 19-25); that is, they have, from N- to C-terminus, an ectodomain consisting of often multiple repeating modules that occur in other proteins, a single transmembrane helix, and a cytosolic domain consisting of a catalytically active PTP domain that, in most cases, is followed by a second PTP domain with little or no catalytic activity. Nevertheless, these inactive PTP domains, which are highly conserved, are important for the activity, specificity, and stability of the PTP as a whole.

Biochemical and structural analyses indicate that ligand-induced dimerization of a receptorlike PTP reduces its catalytic activity, probably by blocking its active sites. Intracellular PTPs contain only one PTP domain, which is flanked by regions containing motifs, such as SH2 domains, that participate in protein–protein interactions. Structural studies reveal that the active sites of receptorlike and intracellular PTPs are too deep to bind phospho-Ser/Thr side chains—as we also saw to be the case for both PTK and SH2 domains (Sections 19-3Ac and 19-3Cb). However, the active site pockets of dual-specificity PTPs are sufficiently shallow to bind both phosphoTyr and phospho-Ser/Thr residues.

### b. SHP-2 Is Inactivated by Binding Its Unliganded N-Terminal SH2 Domain

The cytoplasmic PTP **SHP-2** (for SH2 domain-containing phosphatase 2), which is expressed in all mammalian cells, binds to PTKs that are activated by a variety of ligands, including cytokines, growth factors, and hormones. The 591-residue SHP-2 consists of two tandem SH2 domains, followed by a PTP domain and a 66-residue C-terminal tail that contains Tyr-phosphorylation sites as well as a Pro-rich segment that may bind SH3- or WW-containing proteins. SHP-2’s PTP activity is increased ~10-fold on binding peptides with a single phosphoTyr residue and ~100-fold with those having two phosphoTyr residues and at much lower peptide concentrations. SHP-2 binds to both growth factors and certain cytokine receptors via its SH2 domains and, when its C-terminal tail is phosphorylated, also functions as an adaptor to recruit Grb2 so as to activate MAP kinase pathways (Section 19-3D). Mutations in the gene encoding SHP-2 are responsible for ~50% of the cases of **Noonan syndrome**, a relatively common (1 in ~2000 live births) disorder principally characterized by cardiac abnormalities, short stature, learning disabilities, and distinctive facial features.

The X-ray structure of SHP-2 lacking its C-terminal tail (Fig. 19-50), determined by Eck and Steven Shoelson, reveals that the N-terminal SH2 domain (N-SH2) interacts extensively with the PTP domain. N-SH2 inhibits the PTP by inserting its D’E loop far into the PTP’s 9-Å-deep catalytic cleft, where the loop interacts with the PTP’s catalytic Arg and Cys residues and prevents the active site closure observed in the X-ray structure of a PTP in complex with a phosphopeptide. In contrast, the more C-terminal SH2 domain (C-SH2) does not have a significant interface with either the N-SH2 or the PTP domains.

**Figure 19-50** X-ray structure of the protein tyrosine phosphatase SHP-2. In this structure, its N-SH2 domain is gold with its D’E loop red, its C-SH2 domain is green, and its PTP domain is cyan, with its 11-residue signature sequence, its CX<sub>5</sub>R motif, blue and the side chain of its catalytically essential Cys residue shown in ball-and-stick form with C green and S yellow. [Based on an X-ray structure by Michael Eck and Steven Shoelson, Harvard Medical School. PDBid 2SHP.]

The phosphopeptide-binding sites on both SH2 domains face away from the PTP domain and are therefore fully exposed on the protein surface. However, the comparison of the structure of N-SH2 complexed to a phosphopeptide with that in the above autoinhibited form of SHP-2 indicates that, in the autoinhibited form, N-SH2 adopts a conformation in which it is unable to bind phosphoTyr. Evidently, the conformations of N-SH2's PTP-binding surface and phosphopeptide binding site are allosterically linked such that its binding of PTP and phosphopeptide are mutually exclusive. The C-SH2 domain does not participate in PTP activation, although it almost certainly contributes binding energy and specificity to the binding of a phosphopeptide.

### c. Bubonic Plague Virulence Requires a PTP

Bacteria lack PTKs and hence do not synthesize phosphoTyr residues. Nevertheless, PTPs are expressed by bacteria of the genus *Yersinia*, most notably *Yersinia pestis*, the pathogen that causes **bubonic plague** (the flea-transmitted "Black Death," which, since the sixth century, has been responsible for an estimated ~200 million human deaths including about one-third of the European population in the years 1347–1350). The *Y. pestis* PTP, **YopH**, which is required for bacterial virulence, is far more active than other known PTPs. Hence, when *Yersinia* injects YopH into a cell, the cell's phosphoTyr-containing proteins are catastrophically dephosphorylated. Although YopH is only ~15% identical in sequence to mammalian PTPs, it contains all of their invariant residues and their X-ray structures are closely similar. This suggests that an ancestral *Yersinia* acquired a PTP gene from a eukaryote. However, the discovery of a dual-specificity protein phosphatase in a free-living cyanobacterium raises the possibility that PTPs arose before the divergence of eukaryotes and prokaryotes.

### d. Cells Contain Several Types of Protein Ser/Thr Phosphatases

The **protein Ser/Thr phosphatases** were first characterized by Earl Sutherland (who also discovered the role of cAMP as a second messenger; Section 18-3Eb) and by Edmond Fischer and Edwin Krebs (who discovered the role of protein phosphorylation in controlling glycogen metabolism; Section 18-3C). The majority of these enzymes are members of two protein families: the **PPP family**, which consists of **PP1**, **PP2A**, and **PP2B** (PP for *phosphoprotein phosphatase*); and the **PPM family**, which consists of **PP2C**. The PPP and PPM families are unrelated to each other or to the PTKs. We have already considered PP1 in connection with the role of its catalytic subunit, PP1c, in dephosphorylating the proteins that regulate glycogen metabolism as well as the roles of its targeting subunits,  $G_M$  and  $G_L$ , in binding PP1c to glycogen in muscle and liver (Section 18-3Cg). Indeed, all PP1c's are associated with one or two regulatory (R) subunits that function to modulate the activity of their bound PP1c's, target them to substrates in specific subcellular locations, or modify their substrate specificities. It is the large variety of these mostly

unrelated R subunits that permits the limited number (1–8) of genetically distinct but closely similar (~90% sequence identity) PP1c's in a eukaryotic cell to carry out their diverse functions.

X-ray structures have shown that PPP catalytic centers each contain an  $Fe^{2+}$  (or possibly an  $Fe^{3+}$ ) ion and a  $Zn^{2+}$  (or possibly an  $Mn^{2+}$ ) ion, whereas PPM catalytic centers each contain two  $Mn^{2+}$  ions. These binuclear metal ion centers nucleophilically activate water molecules to dephosphorylate substrates in a single reaction step.

### e. PP2A Is Structurally Variable and Functionally Diverse

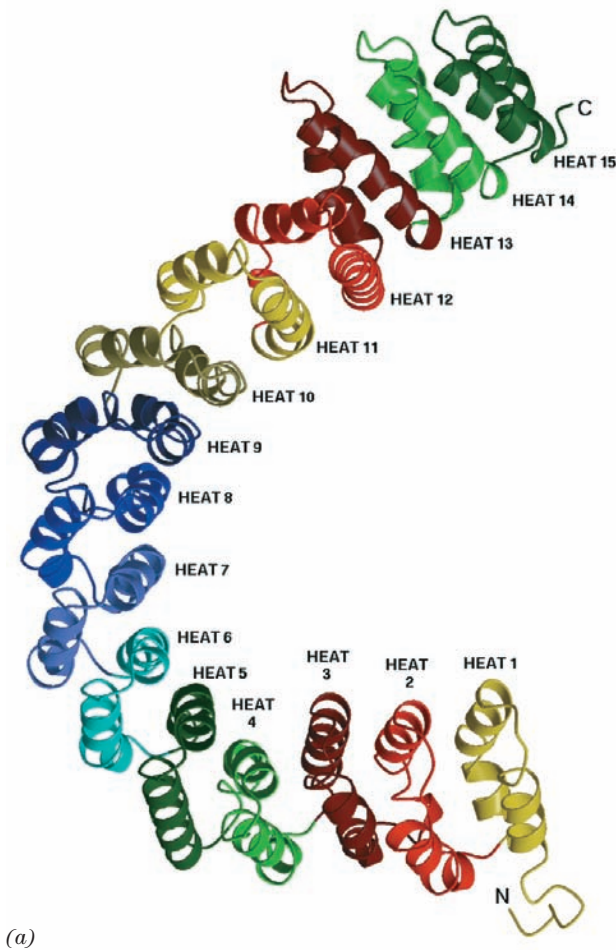

PP2A participates in a wide variety of regulatory processes including those governing metabolism, DNA replication, transcription, and development. It consists of three different subunits:

1. An ~36 kD catalytic subunit (C), whose N-terminal catalytic domain contains the ~280-residue catalytic core common to all PPP family members. Its C-terminal regulatory domain contains an activating binding site for  $Ca^{2+}$ -calmodulin, an inactivating Tyr phosphorylation site that is targeted by a variety of PTKs including the EGF and insulin receptors, and a C-terminal autoinhibitory tail. The C subunit is highly conserved from yeast to mammals.
2. An ~65 kD scaffold subunit (A; also called PR65), with which the C subunit is tightly associated in the cell.
3. One of four dissimilar types of regulatory subunits (B, B', B'', and B9'') that bind to both the A and C subunits and, to a large extent, control the substrate specificity of PP2A.

All of PP2A's subunits have multiple isoforms and splice variants that are expressed in a tissue-specific and developmentally specific manner, thereby generating an enormous panoply of enzymes that are targeted to different phosphoproteins in distinct subcellular sites. This complexity is a major cause of our limited understanding of how PP2A carries out its diverse cellular functions, even though it comprises between 0.3 and 1% of cellular proteins and, together with PP1, accounts for >90% of the Ser/Thr phosphatase activity in most cells.

The X-ray structure of PP2A's A subunit (Fig. 19-51a), determined by David Barford, reveals a remarkable solenoidal protein that consists of 15 imperfect tandem repeats of a 39-residue sequence termed HEAT (because it occurs in proteins named *Huntingtin*, *EF3*, A subunit of PP2A, and *TOR1*). Successive HEAT repeats, which each consist of two antiparallel helices joined by a short linker, stack on one another with their corresponding helices nearly parallel so as to form an ~100-Å-long right-handed superhelix (helix of helices) with a hooklike shape.

The X-ray structure of a PP2A **holoenzyme** (complete enzyme; Fig. 19-51b), determined independently by Yigong Shi and Wenqing Xu, reveals, unexpectedly, that its regulatory subunit consists of 8 tandem HEAT-like repeats arranged like those of the A subunit, despite their lack of

sequence similarity. The C subunit binds to the A subunit's concave surface along a ridge of conserved hydrophobic side chains spanning HEAT repeats 11 to 15. The regulatory subunit similarly interacts with the A subunit's HEAT repeats 2 to 8 and also binds to the C subunit via a ridge spanning its own HEAT-like repeats 6 to 8. The highly acidic, convex side of the regulatory subunit (lower part of Fig. 19-51*b*) is thereby left unoccupied, which suggests that it interacts with substrate proteins. The C subunit is structurally similar to the catalytic subunits of PP1 and PP2B.

**Figure 19-51 X-ray structure of protein phosphatase PP2A.** (a) The structure of an isolated scaffold (A) subunit. HEAT repeats, which are drawn here in different colors, each consist of two antiparallel helices joined by a short linker. These stack on one another with their corresponding helices nearly parallel to form an  $\sim 100$ -Å-long right-handed superhelix (helix of helices) with a hooklike shape. Compare this structure to that of a portion of human ankyrin (Fig. 12-39), which also forms a right-handed solenoid, although consisting of ankyrin repeats. [Courtesy of Bostjan Kobe, St. Vincent's Institute of Medical Research, Fitzroy, Victoria, Australia. X-ray structure by David Barford, University of Oxford, U.K. PDBid 1B3U.] (b) The structure of a PP2A heterotrimer viewed with the scaffold subunit oriented approximately as in Part *a*. Here the scaffold (A; 589 residues) and regulatory (B'; 449 residues) subunits are drawn in worm form, each colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). In addition, the A subunit is embedded in its transparent molecular surface. The catalytic (C; 309 residues) subunit (*magenta*) is drawn in ribbon form. Note the close structural resemblance of the A and B' subunits. [Based on an X-ray structure by Yigong Shi, Princeton University. PDBid 2NPP.]

### f. PP2B Is the Target of Immunosuppressant Drugs

PP2B, which is also known **calcineurin (CaN)**, is unique among protein Ser/Thr phosphatases in that it is activated by  $\text{Ca}^{2+}$ . CaN is a heterodimer composed of a catalytic A subunit (CaNA) and a regulatory B subunit (CaNB). CaNA contains an N-terminal catalytic domain followed by a CaNB-binding domain, a calmodulin (CaM)-binding domain, and a C-terminal autoinhibitory segment. CaNB, which has 35% sequence identity with CaM, binds four  $\text{Ca}^{2+}$  ions via its four EF hand motifs (Section 18-3Ce). CaN is activated by the binding of  $\text{Ca}^{2+}$  to CaNB and  $\text{Ca}^{2+}$ -CaM to CaNA.

Calcineurin plays an essential role in the antigen induced proliferation of T cells. As we discuss in Section 35-2D, the binding of an antigenic peptide to a **T cell receptor**, a tyrosine kinase-associated receptor, initiates a complex series of signaling events involving the Src-like PTKs Lck and Fyn, a MAP kinase cascade, and the phosphoinositide cascade (Section 19-4), which, among other things, releases  $\text{Ca}^{2+}$  into the cytosol. The  $\text{Ca}^{2+}$ , in turn, activates CaN to dephosphorylate the transcription factor **NFAT<sub>p</sub>** (for *nuclear factor of activated T cells*). NFAT<sub>p</sub> in complex with CaN is then translocated to the nucleus where, in concert with other transcription factors, it induces some of the early steps in T cell proliferation.

As we discussed Section 9-2B, the fungal products **cyclosporin A (CsA)** and **FK506** are highly effective immunosuppressants that are in clinical use for the prevention of organ-transplant rejection and for the treatment of autoimmune disorders (processes that are mediated by T cells). CsA and FK506, respectively, bind to the peptidyl

prolyl cis-trans isomerases (rotamases) **cyclophilin** and **FK506 binding protein (FKBP12)**, which are therefore collectively known as **immunophilins**. However, the observation that both CsA and FK506 (also known as **tacrolimus**) are effective immunosuppressants at concentrations far below those of the immunophilins suggests that it is the presence of the cyclophilin · CsA and FKBP12 · FK506 complexes themselves, rather than the inhibition of their rotamase activity, that interferes with T cell proliferation. It is, in fact, the binding of either complex to CaN that prevents it from dephosphorylating NFAT<sub>p</sub> and thereby suppresses T cell proliferation.

The X-ray structures of the bovine complex FKBP12 · FK506-CaN, by Manuel Navia, and the corresponding human complex, by Ernest Villafranca, reveal how the FKBP12 · FK506 complex binds to CaN (Fig. 19-52a). The catalytic domain of CaNA, with its binuclear  $\text{Fe}^{2+}$ - $\text{Zn}^{2+}$  center marking its active site, resembles those of other protein Ser/Thr phosphatases of known structure. A 22-residue  $\alpha$  helix at the C-terminal end of this phosphatase domain, which extends out from the phosphatase domain by up to 40 Å, provides much of the CaNB-binding site. Beyond this helix, the C-terminal portion of CaNA, which contains the CaM-binding site and the autoinhibitory segment, is not visible due to disorder. However, in the X-ray structure of CaN alone, the autoinhibitory segment is seen to bind in the CaNA active site so as to block the access of substrate phosphoproteins. The structure of CaNB, which

**Figure 19-52 Calcineurin.** (a) The X-ray structure of bovine FKBP12 · FK506-CaN. The CaNA subunit is orange, the CaNB subunit is blue, and the FKBP12 is cyan. The FK506 is drawn in stick form with C green, N blue, and O red; the  $\text{Fe}^{2+}$  and  $\text{Zn}^{2+}$  ions in the CaNA active site are, respectively, represented by red and green spheres; and the four  $\text{Ca}^{2+}$  ions bound to CaNB are represented by pale green spheres. [Based on an X-ray structure by Manuel Navia, Vertex Pharmaceuticals, Cambridge,

Massachusetts. PDBid 1TCO.] (b) The X-ray structure of human cyclophilin · CsA-CaN. The CaN and its bound metal ions are represented and oriented as in Part a, the cyclophilin is magenta, and the CsA is drawn in stick form with C green, N blue, and O red. Note the close resemblance between the two structures. [Based on an X-ray structure by Hengming Ke, University of North Carolina, Chapel Hill, North Carolina. PDBid 1M63.]

has four bound  $\text{Ca}^{2+}$  ions, resembles that of  $\text{Ca}^{2+}$ -CaM in complex with a helical target peptide (Fig. 18-19) except that CaNB's two globular domains are on the same side of its bound peptide rather than on opposite sides as are those of  $\text{Ca}^{2+}$ -CaM. CaNB thereby forms a continuous groove in which the CaNA helix binds.

FKBP12 · FK506, a mixed inhibitor of CaN (Section 14-3C), binds to it so as to contact both CaNA and CaNB, with the portion of FK506 that extends out from its FKBP12-binding site forming a significant part of this interface. The structures of FKBP12 and CaN in this complex closely resemble those in the X-ray structures of these proteins alone. It therefore appears that FK506 provides a critical component of this contact. Nevertheless, no part of the FKBP12 · FK506 complex is within 10 Å of CaN's phosphatase site (although the CaN autoinhibitory segment has been displaced). This accounts for the observations that FKBP12 · FK506 strongly inhibits CaN from dephosphorylating a 20-residue phosphopeptide but actually increases the rate at which CaN dephosphorylates the much smaller *p*-nitrophenylphosphate by a factor of 3.

The X-ray structure of human cyclophilin · CsA-CaN (Fig. 19-52b), independently determined by Hengming Ke and Harrison, is strikingly similar to that of FKBP12 · FK506-CaN despite the fact that there is no structural resemblance of cyclophilin · CsA to FKBP12 · FK506. Cyclophilin binds to essentially the same region of CaNA as does FKBP12 with CsA forming an essential component of this contact, thereby limiting access to the CaN active site in the same way as does FKBP12 · FK506. However, the characteristics of rotamases that apparently uniquely suit them for their roles in CaN inhibition remain enigmatic.

#### 4 THE PHOSPHOINOSITIDE CASCADE

*Extracellular signals often cause a transient rise in the cytosolic  $[\text{Ca}^{2+}]$ , which, in turn, activates a great variety of enzymes through the intermediacy of calmodulin and its homologs. An increase in cytosolic  $[\text{Ca}^{2+}]$  triggers such diverse cellular processes as glycogenolysis (Section 18-3Ce) and muscle contraction (Section 35-3C). What is the source of this  $\text{Ca}^{2+}$  and how does it enter the cytosol? In certain types of cells, neurons (nerve cells; Fig. 1-10d), for example, the  $\text{Ca}^{2+}$  originates in the extracellular fluid. However, the observation that the absence of extracellular  $\text{Ca}^{2+}$  does not inhibit certain  $\text{Ca}^{2+}$ -mediated processes led to the discovery that, in these cases, cytosolic  $\text{Ca}^{2+}$  is obtained from intracellular reservoirs, mostly the endoplasmic reticulum (and its equivalent in muscle, the sarcoplasmic reticulum). Extracellular stimuli leading to  $\text{Ca}^{2+}$  release must therefore be mediated by an intracellular signal.*

The first clue as to the nature of this signal came from observations that the intracellular mobilization of  $\text{Ca}^{2+}$  and the turnover of **phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub> or PtdIns-4,5-P<sub>2</sub>)** (Fig. 19-53), which occurs mainly in the plasma membrane as a minor (<1%) component of its cytosolic leaflet, are strongly correlated. This information

**Figure 19-53 Molecular formula of the phosphatidylinositides.** The head group of these glycerophospholipids is *myo*-inositol that may be phosphorylated at its 3-, 4-, and/or 5-positions. R<sub>1</sub> is predominantly the hydrocarbon tail of stearic acid (an 18:0 fatty acid; Table 12-1) and R<sub>2</sub> is predominantly the hydrocarbon tail of arachidonic acid (a 20:4 fatty acid).

led Robert Michell to propose, in 1975, that PIP<sub>2</sub> hydrolysis is somehow associated with  $\text{Ca}^{2+}$  release.

#### A. $\text{Ca}^{2+}$ , Inositol Trisphosphate, and Diacylglycerol Are Second Messengers

Investigations, notably by Mabel and Lowell Hokin, Michael Berridge, and Michell, eventually revealed that *PIP<sub>2</sub> is part of an important second messenger system, the phosphoinositide cascade, that mediates the transmission of numerous hormonal signals including those of vasopressin, CRF, TRF (Section 19-1H), acetylcholine (a neurotransmitter; Section 20-5Cb), epinephrine (with  $\alpha_1$ -adrenergic receptors; Section 19-1F), EGF, and PDGF. Remarkably, this system yields up to three separate types of second messengers through the following sequence of events (Fig. 19-54):*

**1-3.** The ligand-receptor interactions described below activate a phosphoinositide-specific **phospholipase C (PLC; Section 19-4B)** to hydrolyze PIP<sub>2</sub> to **inositol-1,4,5-trisphosphate (IP<sub>3</sub> or Ins-1,4,5-P<sub>3</sub>)** and ***sn*-1,2-diacylglycerol (DAG or DG)**

**Figure 19-54 Role of PIP<sub>2</sub> in intracellular signaling.** (1) The binding of a ligand to a cell-surface receptor, R, activates a phosphoinositide-specific phospholipase C through the intermediacy of what is shown here as (2) a G protein ( $G_q$ ; Fig. 19-17) but in many cases is an RTK, an NRTK, or, possibly,  $Ca^{2+}$ . Phospholipase C catalyzes the hydrolysis of PIP<sub>2</sub> to IP<sub>3</sub> and DAG (3). The water-soluble IP<sub>3</sub> stimulates the release of  $Ca^{2+}$  sequestered in the endoplasmic reticulum (4), which in turn

activates numerous cellular processes through the intermediacy of calmodulin and its homologs (5). The nonpolar DAG remains associated with the inner leaflet of the membrane, where it activates protein kinase C to phosphorylate and thereby modulate the activities of a number of cellular proteins (6). This latter activation process also requires the presence of the membrane lipid phosphatidylserine (PS) and  $Ca^{2+}$ . See the Animated Figures

[the stereospecific numbering (*sn*) system is described in the legend of Fig. 12-3]. PLCs catalyze the hydrolysis of the bond linking a glycerophospholipid to its phosphoryl group as indicated in Fig. 19-55 (which also shows the actions of other types of phospholipases). Note that this reaction occurs at the interface between the aqueous phase and the membrane in such a way that both PIP<sub>2</sub> and its amphipathic hydrolysis product DAG remain associated with the membrane during the catalytic reaction.

4. The water-soluble IP<sub>3</sub>, acting as a second messenger, diffuses through the cytoplasm to the ER, from which it stimulates the release of  $Ca^{2+}$  into the cytoplasm by binding to and thereby opening an ER-bound transmembrane  $Ca^{2+}$ -specific ion channel known as the **IP<sub>3</sub> receptor** (ion channels are discussed in Chapter 20).

**Figure 19-55 A phospholipase is named according to the bond that it cleaves on a glycerophospholipid.** X is a phosphoinositol group for this discussion.

5. The  $\text{Ca}^{2+}$ , in turn, stimulates a variety of cellular processes, mainly through the intermediacy of calmodulin and its homologs.

6. The amphipathic DAG is constrained to remain in the inner leaflet of the plasma membrane, where it nevertheless also acts as a second messenger by activating **protein kinase C (PKC; Section 19-4C)** in the presence of  $\text{Ca}^{2+}$  and phosphatidylserine (PS; which is located exclusively on the cytosolic face of the plasma membrane). This membrane-bound enzyme (actually a family of enzymes; Section 19-4C), in turn, Ser/Thr-phosphorylates and thereby modulates the activities of several different proteins including glycogen synthase (Sections 18-3D). DAG, which predominantly has a stearyl group at its 1-position and an arachidonoyl group at its 2-position, is further degraded in some cells by **cytosolic phospholipase A<sub>2</sub> (cPLA<sub>2</sub>)** to yield arachidonate, the major substrate for the biosynthesis of prostaglandins, prostacyclins, thromboxanes, leukotrienes, and lipoxins. These paracrine hormones, as we discuss in Section 25-7, mediate or modulate a wide variety of physiological functions.

## B. The Phospholipases C

The phosphoinositide-specific PLCs in mammals are classified in six families comprising 13 isozymes according to their sequences and modes of regulation:  $\beta(1-4)$ ,  $\gamma(1-2)$ ,  $\delta(1, 3, 4)$ ,  $\epsilon$ ,  $\eta(1-2)$ , and  $\zeta$  (Fig. 19-56; the isozyme originally named PLC- $\alpha$  is actually a proteolytic fragment of PLC- $\delta(1)$ ), several of which have splice variants. All of these PLCs require the presence of  $\text{Ca}^{2+}$  ion for enzymatic activity. The PLC- $\delta$  isozymes (~760 residues) consist of, from N- to C-terminus, an ~120-residue pleckstrin homology (PH) domain (Section 19-3Ce); an ~130-residue EF hand domain that contains four EF hand motifs (Fig. 18-18); two conserved regions known as X and Y that together form the ~250-residue PLC catalytic domain and which are separated by an ~60-residue linker; and an ~120-residue **C2 domain**, a domain that in many cases binds  $\text{Ca}^{2+}$  and which occurs in ~650 human proteins that mainly participate in signal transduction and membrane interactions. The PLC- $\beta$  isozymes (~1200 residues) have an additional ~420-residue C-terminal tail that has been implicated in both membrane association and regulation by G proteins (see below). In contrast, the PLC- $\gamma$  isozymes (~1270 residues) contain an ~420-residue insert between X and Y that consists of an additional PH domain that is split by two SH2 domains that are implicated in binding to activated PTKs (see below) as well as an SH3 domain. PLC- $\epsilon$  (~2300 residues), which is activated by several Ras-related G-proteins, has an N-terminal RasGEF domain and two C-terminal Ras-binding (RA) domains. PLC- $\eta$  (~1000 residues), which occurs only in nerve tissue, contains a C-terminal Ser/Pro (S/P)-rich region of unknown function. PLC- $\zeta$  (~650 residues), the smallest of the PLCs and the only one that lacks a PH domain, occurs only in sperm. The observation that the PLCs in plants and lower eukaryotes such as yeast are

**Figure 19-56** Domain organization of the six classes of phosphoinositide-specific PLCs.

$\delta$ -like suggests that the various PLC isozymes in mammals evolved from a primordial PLC- $\delta$ .

### a. $G_{q\alpha} \cdot \text{GTP}$ , $G_{\beta\gamma}$ , and $\text{Rac} \cdot \text{GTP}$ Activate PLC- $\beta$ s by Bringing Them Into Contact with the Membrane

The PLC- $\beta$ s are hormonally regulated by certain G protein-coupled receptors (e.g., those for histamine, vasopressin, TSH, thromboxane A<sub>2</sub>, and angiotensin II) via their associated heterotrimeric G proteins, as indicated in Fig. 19-54. In particular, they are activated through their interactions with the  $\alpha$  subunits of the  $G_q$  subfamily (Section 19-2C) in complex with GTP.  $G_{q\alpha} \cdot \text{GTP}\gamma\text{S}$  activates the PLC- $\beta$  isoforms in order of potency  $\beta_1 > \beta_3 > \beta_2$ , with the position of  $\beta_4$  in this hierarchy indeterminate because it is inhibited by GTP $\gamma$ S. Moreover, an important aspect of the regulation of PLC- $\beta$ s by  $G_{q\alpha} \cdot \text{GTP}$  is that the PLC- $\beta$ s function as GAPs to increase the GTPase activity of  $G_{q\alpha}$  by >50-fold, thereby limiting the activating function of  $G_{q\alpha}$ .

The PLC- $\beta$  isoforms are independently activated by  $G_{\beta\gamma}$  complexes, which may be supplied by the dissociation of heterotrimeric G proteins other than  $G_{q\alpha}G_{\beta\gamma}$ . Moreover, their order of efficacy with  $G_{\beta\gamma}$  differs from that with  $G_{q\alpha} \cdot \text{GTP}$ :  $\beta_3 > \beta_2 > \beta_1$ , with  $\beta_4$  insensitive to the presence of  $G_{\beta\gamma}$ . Although the concentration of  $G_{\beta\gamma}$  required for maximal activation of the PLC- $\beta$ s is much greater than that of  $G_{q\alpha} \cdot \text{GTP}$ , their final extents of activation are similar. The sites on PLC- $\beta_2$  that interact with  $G_{\beta\gamma}$  are its PH domain and a 10-residue segment near the N-terminus of its Y region. The region of  $G_{\beta\gamma}$  that interacts with PLC- $\beta$ s overlaps the region through which it binds  $G_\alpha$  subunits, thereby explaining why a  $G_{\beta\gamma}$  cannot simultaneously bind a PLC- $\beta$  and a  $G_\alpha \cdot \text{GDP}$ .

The Rho family small G protein named **Rac1**, in complex with GTP, activates PLC- $\beta_2$ ,  $\beta_3$ , and  $\gamma_2$ . The X-ray structure of a complex of PLC- $\beta_2$  lacking its C-terminal tail (but still catalytically active *in vitro*) with Rac1  $\cdot$  GTP $\gamma$ S was

**Figure 19-57** X-ray structure of PLC-β2 lacking its C-terminal tail in complex with Rac1 · GTPγS. The pleckstrin homology (PH) domain of PCL-β2 is blue, its EF hand (EF) domain is orange, its TIM ( $\alpha/\beta$ ) barrel is red, and its C2 domain is yellow. The Rac1 is green with its switch regions (Sw1 and Sw2) red and its bound GTPγS drawn in stick form in cyan. (a) View toward the cytosolic surface of the membrane. (b) View rotated 90° about the horizontal axis relative to Part a. The geranylgeranyl group at the C-terminus of Rac1 and the PIP<sub>2</sub> substrate (*black sticks*) are modeled as sites of membrane attachment. Note that the three loops of the TIM barrel, which form a hydrophobic ridge, are inserted into the membrane. [Courtesy of John Sondek, University of North Carolina School of Medicine. PDBid 2FJU.]

determined by John Sondek. It reveals (Fig. 19-57) that PLC-β2's remaining four domains are linked by extended polypeptide segments that form tight interactions with these domains. EF hand motifs 1 and 2 form a lobe that is closely superimposable on the N- and C-terminal lobes of calmodulin (Figs. 18-17 and 18-19), as do EF hands 3 and 4. Although EF hands are usually associated with Ca<sup>2+</sup> ions, the residues necessary to do so are poorly conserved in the PLCs. Thus, although mutations to this domain are generally deleterious to a PLC's catalytic activity, its function is unclear.

The X and Y regions of PLC-β2's catalytic domain form a TIM (or  $\alpha/\beta$ ) barrel (Section 8-3B). The X region contributes a typical  $\beta\alpha\beta\alpha\beta\alpha$  motif to form nearly half the barrel with the Y region contributing its remaining portion. The visible parts of the partially disordered ~70-residue peptide linking X and Y occlude the enzyme's active site, which as is the case for all TIM barrel enzymes, is located in

the mouth of the barrel at the C-terminal ends of its  $\beta$  strands. Deletion of this apparently autoinhibitory X–Y linker increases the enzyme's phospholipase activity by ~10-fold, although it can still be further activated by various G proteins. Although the X–Y linkers of the several PLCs share little sequence identity, all of them contain clusters of negatively charged residues. This suggests that when a PLC approaches the negatively charged cytosolic face of a membrane, its X–Y linker is electrostatically repelled from the PLC's active site, thereby permitting these enzymes access to their membrane-bound PIP<sub>2</sub> substrates.

All PLCs require a bound Ca<sup>2+</sup> ion for catalytic activity. The constellation of active site residues in the PLC-β2 structure closely resemble that in the X-ray structure of PLC-δ1 in complex with IP<sub>3</sub> and Ca<sup>2+</sup> ion. In this latter structure, a 6-coordinate Ca<sup>2+</sup> is bound at the bottom of the active site, with one of its ligands contributed by the 2-hydroxyl group of IP<sub>3</sub> and the remainder formed by highly conserved Asp, Glu, and Asn side chains. The catalytic reaction is therefore postulated to occur via a mechanism analogous to that of the RNase A-catalyzed hydrolysis of RNA (Fig. 15-3) in which PIP<sub>2</sub>'s 2-hydroxyl group nucleophilically attacks the neighboring 1-phosphate group to form DAG and a cyclic phosphodiester intermediate that is subsequently hydrolyzed to yield IP<sub>3</sub>. The Ca<sup>2+</sup> ion (rather than a His side chain as in RNase A) is properly positioned to promote the deprotonation of the 2-hydroxyl group so as to enhance its nucleophilicity and to subsequently help stabilize the developing negative charge on the pentavalent phosphorus in the catalytic reaction's transition state (Fig. 16-6b). This explains why **2-deoxy-PIP<sub>2</sub>** is not hydrolyzed by mammalian phosphoinositide-specific PLCs.

Rac1 · GTPγS binds to the PH domain of PLC-β2 exclusively via Rac1's switch regions (Fig. 19-57), which explains why Rac1 · GDP does not bind to PLC-β2. However, comparison of the X-ray structure of PLC-β2 alone with that of its Rac1 · GTPγS complex indicates that the binding of Rac1 · GTPγS does not alter the conformation of PLC-β2. How, then, does Rac1 · GTPγS activate PLC-β2? Most PH domains bind membrane-associated phosphoinositides (see below) but those of PLC-β2 and -β3 lack the residues necessary to do so. Instead, Rac1's C-terminal geranylgeranyl membrane anchor (Section 12-3Ba) functions to localize PLC-β2 and probably PLC-β3 to the cytosolic face of the plasma membrane (Fig. 19-57b), where they can efficiently hydrolyze phosphoinositides. Similarly, the membrane anchored G<sub>qα</sub> · GTP and G<sub>βγ</sub> serve to localize PLC-β2 to the membrane.

The C2 domain consists of a sandwich of two 4-stranded antiparallel  $\beta$  sheets with variable interstrand loops. The X-ray structure of PLC-δ1 complexed with the calcium analog lanthanum revealed that the C2 domain contains three Ca<sup>2+</sup> ions sites in close proximity to one another. All of these metal ions lie in a crevice at one end of the  $\beta$  sandwich, where they are exposed on the surface of the enzyme. It therefore seems likely that, *in vivo*, they associate with anionic head groups such as that of phosphatidylserine on the surface of a membrane. Since the extensive interface between the C2 and catalytic domain appears to be rigid, this interaction probably helps bind the catalytic domain to the membrane such that it can productively interact with

PIP<sub>2</sub> molecules. This association appears to be supplemented through the interactions of a hydrophobic ridge comprised of three loops from one side of the active site opening that is postulated to penetrate into the membrane's nonpolar region during catalysis (Fig. 19-57b). This would explain how the enzyme can catalyze the hydrolysis of PIP<sub>2</sub> to DAG and IP<sub>3</sub> while the former two compounds remain associated with the membrane.

The C-terminal tail that is unique to PLC-β isoforms (Fig. 19-56) has been implicated, via studies of truncated enzymes, in binding to G<sub>qα</sub> · GTP. The X-ray structure of this ~420-residue segment reveals that it consists almost entirely of three long helices which form a coiled coil that dimerizes along its long axis. It contains a large number of basic residues that are clustered on one face of the dimer and whose mutation results in reduced responses to G<sub>qα</sub> · GTP. This positively charged surface is likely to interact with acidic phospholipids so as to recruit its attached PLC-β to the membrane. It therefore appears that *the activation of PLC-βs is almost entirely the result of their close association with the negatively charged membrane.*

#### b. The Pleckstrin Homology Domain Tethers PLC-δ1 to the Membrane

The X-ray structure of PLC-δ1's N-terminal PH domain in complex with IP<sub>3</sub>, determined by Joseph Schlessinger and Sigler, reveals that the IP<sub>3</sub> binds to a positively charged surface of the protein (Fig. 19-58). This is consistent with the PH domain's proposed role as a membrane anchor, as are the observations that this PH domain binds PIP<sub>2</sub> with much greater affinity ( $K_D = 1.7 \mu M$ ) than does PLC-δ1's catalytic domain ( $K_D > 0.1 mM$ ). Since the peptide segment linking the PH domain to the rest of the enzyme is probably flexible, it appears that the PH domain in PLC-δ1 functions to tether the enzyme to the membrane. This accounts for kinetic measurements indicating that the enzyme catalyzes multiple cycles of PIP<sub>2</sub> hydrolysis without releasing the membrane.

Despite the foregoing, the way in which the PLC-δ isozymes are regulated is poorly understood. The higher sensitivities of the PLC-δ isozymes to Ca<sup>2+</sup> ion compared to those of the other PLCs suggests that the PLC-δ isozymes are regulated by changes in intracellular [Ca<sup>2+</sup>]. Thus, the activation of PLC-δ isozymes may occur secondarily to the receptor-mediated activation of other PLC isozymes through their induction of the opening of Ca<sup>2+</sup> channels (Fig. 19-54).

#### c. Protein Tyrosine Kinases Recruit PLC-γ Isozymes to the Membrane

The PLC-γ isozymes in a wide variety of cells are activated by certain protein growth factors including EGF, PDGF, FGF, and NGF. These growth factors cause their corresponding receptors, which are RTKs (Section 19-3A), to autophosphorylate at particular Tyr residues. Some of these phosphoTyr sites are specifically bound, as mutational studies indicate, by the more N-terminal SH2 (N-SH2) domain on PLC-γ1 (Figs. 19-56 and 19-27a) but not its C-SH2 domain. The N-SH2 domain binds peptides containing a phosphoTyr residue followed by at least 5 predominantly

**Figure 19-58** X-ray structure of the pleckstrin homology domain of PLC-δ1 in complex with PIP<sub>3</sub>. The peptide chain is shown in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The PIP<sub>3</sub> is drawn in stick form with C green, O red, and P orange. The PH domain consists largely of the β barrel/ sandwich of 7 antiparallel strands and C-terminal α helix common to the numerous PH domains of known structure. [Based on an X-ray structure by Joseph Schlessinger, New York University Medical Center, and Paul Sigler, Yale University. PDBid 1MAI.]

hydrophobic residues, in contrast to the SH2 domain of Src, which preferentially binds pYEEI containing peptides (Section 19-3Cb).

The activated receptors for all four of the above growth factors phosphorylate PLC-γ1 at the same three Tyr residues, 771, 783 (located between the C-SH2 and SH3 domains), and 1254 (located in the C-terminal tail). In fact, mutating Tyr 783 to Phe completely blocks the activation of PLC-γ1 by PDGF, although this mutant PLC-γ1 still associates with the PDGF receptor. Conversely, mutating certain RTK autophosphorylation sites (e.g., the PDGF receptor's Tyr 1021) disrupts their binding of PLC-γ1 and hence its activation, even though these mutant receptors catalyze detectable levels of growth factor-dependent Tyr phosphorylation on PLC-γ1. Evidently, growth factor-induced activation of PLC-γ1 requires both the activating Tyr phosphorylation of PLC-γ1 and its association with the growth factor receptor, the latter presumably bringing PLC-γ1 into contact with its PIP<sub>2</sub> substrate in the cytosolic leaflet of the plasma membrane. The PLC-γ isozymes may also be activated by NRTKs, such as members of the Src and JAK families (all of which are membrane associated), that have been activated by tyrosine kinase-associated receptors (Section 19-3E). The function of the PLC-γ SH3 domain is unclear.

**d. PLC- $\epsilon$  Is Activated by Ras  $\cdot$  GTP**

The presence of RasGEF and Ras-binding (RA) domains on PLC- $\epsilon$  suggests that PLC- $\epsilon$  is activated by Ras  $\cdot$  GTP. This is, in fact, the case, as indicated by the observation that PLC- $\epsilon$  binds Ras  $\cdot$  GTP with high affinity but does not bind Ras  $\cdot$  GDP. Since Ras is membrane-anchored, this interaction brings PLC- $\epsilon$  into proximity with the membrane, much as we saw with the Rac1  $\cdot$  GTP activation of PLC- $\beta$ 2 (Section 19-4Ba). Although the growth factor-induced activation of Ras is terminated by the hydrolysis of its bound GTP to GDP, the resulting Ras  $\cdot$  GDP may be rapidly converted to Ras  $\cdot$  GTP by the RasGEF domain of PLC- $\epsilon$ , thereby prolonging the receptor-mediated activation of PLC- $\epsilon$ . PLC- $\epsilon$  may also be activated by G<sub>12 $\alpha$</sub> .

**C. The Protein Kinases C**

Protein kinase C (PKC), a member of the **AGC family** of protein kinases (AGC for PKA, PKG, and PKC), is the Ser/Thr protein kinase that transduces the numerous signals mediated by the release of DAG (Fig. 19-54). In mammals, it comprises a family of ten  $\sim$ 700-residue monomeric isozymes classified in three subfamilies: the “conventional” PKCs ( $\alpha$ ,  $\beta$ I,  $\beta$ II, and  $\gamma$ , of which  $\beta$ I and  $\beta$ II are splice variants of the same gene), the “novel” PKCs ( $\delta$ ,  $\epsilon$ ,  $\eta$ , and  $\theta$ ), and the “atypical” PKCs [ $\zeta$  and  $\iota$ (human)/ $\lambda$ (mouse)]. The conventional PKCs, which are activated by both DAG and Ca<sup>2+</sup>, each consist of an N-terminal autoinhibitory pseudosubstrate (which resembles the enzyme’s target peptide but with the Ser/Thr phosphorylation site replaced by Ala) followed by four conserved domains, C1 through C4 (C1 for conserved region 1 of PKC, etc.). The DAG-binding **C1 domain**, which occurs in  $>$ 50 other proteins including Raf (in which it does not bind DAG), consists of two tandemly repeated  $\sim$ 50-residue Cys-rich motifs, C1A and C1B. However, only C1B binds DAG. C2, which often binds Ca<sup>2+</sup> ion, is also a component of PLC (Fig. 19-57) as well as numerous other signaling proteins. C3 and C4 form the N- and C-terminal lobes of the protein kinase, which is similar in sequence and structure to the catalytic subunit of PKA (Fig. 18-15). The protein kinase is maintained in its inactive state through its binding of the pseudosubstrate (as with MLCK; Section 18-3Ce). The novel PKCs, which are activated by DAG but not by Ca<sup>2+</sup>, resemble the conventional PKCs except that their C2 domains do not bind Ca<sup>2+</sup>. The atypical PKCs, which are unresponsive to both DAG and Ca<sup>2+</sup>, have only one Cys-rich motif in their C1 domains and lack C2 domains.

In addition to their different regulatory properties, the various PKCs are localized to different subcellular compartments (e.g., plasma membrane, nuclear membrane, endoplasmic reticulum, Golgi apparatus, mitochondria) in ways that vary with the cell type and external stimuli. This specificity is provided both by targeting sequences on the PKC as well as by scaffolding proteins that localize individual PKCs to specific membrane microdomains in close proximity to their substrate and regulatory proteins. For example, the members of a family of membrane-associated proteins known as **RACKs** (for receptors of activated C-kinases) each anchor a specific activated PKC to a particular subcellular location.

**a. The C1 and C2 Domains Anchor PKC to the Plasma Membrane**  
**Phorbol esters such as 12-O-myristoylphorbol-13-acetate****12-O-Myristoylphorbol-13-acetate**

(which occurs in croton seed oil and was used as a drastic purgative in folk medicine) are potent activators of protein kinase C; they structurally resemble DAG but bind to PKC with  $\sim$ 250-fold greater affinity. Consequently, phorbol esters are the most effective known **tumor promoters**, substances that are not in themselves carcinogenic but increase the potency of known carcinogens. They do so by inhibiting the apoptosis (programmed cell death; Section 34-4E) and stimulating the proliferation of precancerous cells (cells with only some of the mutations that make them cancerous but which nevertheless reduce the cell’s sensitivity to apoptotic signals and increase it for proliferative signals) as well as stimulating metabolic processes that generate carcinogenic agents (e.g., free radicals). This increases the probability that such a cell will complete its malignant transformation. Not surprisingly, therefore, altered PKC activity is associated with various types of cancers.

The X-ray structure of the C1B motif of PKC $\delta$  in complex with 12-O-myristoylphorbol-13-acetate, determined by Hurley, reveals that this 50-residue motif is largely knit together by two Zn<sup>2+</sup> ions, each of which is tetrahedrally liganded by one His and three Cys side chains (Fig. 19-59). The phorbol ester binds in a narrow groove between two loops that consist mainly of nonpolar residues. Since phorbol esters are also nonpolar, the entire top third of the complex, as shown in Fig. 19-59, forms a highly conserved hydrophobic surface. Very few soluble proteins have such a large fraction of their surface formed by a continuous nonpolar region. Moreover, the middle third of the protein surface, that below the nonpolar region, forms a positively charged belt about the protein. This suggests that, *in vivo*, the hydrophobic portion of the complex is inserted into the nonpolar region of its associated membrane such that the motif’s positively charged belt interacts with the membrane’s negatively charged head groups. This hypothesis is supported by NMR measurements indicating that residues on the ligand-binding portion of C1B interact with lipid. The fatty acyl group that is esterified to phorbol’s 12-position in effective tumor promoters presumably extends into the membrane so as to help anchor the C1 domain to the membrane.

The comparison of this structure with that of C1B alone indicates that C1B does not undergo significant structural change on binding phorbol ester. Evidently, phorbol esters, and presumably DAG, activate PKC by anchoring it to the membrane rather than by an allosteric mechanism. The C2

**Figure 19-59 X-ray structure of the C1B motif of PKC $\delta$  in complex with 12-*O*-myristoylphorbol-13-acetate.** The protein tetrahedrally ligands two Zn<sup>2+</sup> ions (cyan spheres), each via a His side chain and three Cys side chains. These side chains are shown in ball-and-stick form with C green, N blue, O red, and S yellow, as is the bound 12-*O*-myristoylphorbol-13-acetate. The C1B domains of PKC $\alpha$  and  $\gamma$  have similar structures. [Based on an X-ray structure by James Hurley, NIH. PDBid 1PTR.]

domain, as we have seen for PLC (Section 19-4Ba), also does so via Ca<sup>2+</sup>-mediated binding to the membrane's phosphatidylserine head groups. These interactions are synergistic in that the greater the Ca<sup>2+</sup> concentration, the lower the concentration of phorbol ester or DAG necessary to activate PKC and vice versa. Nevertheless, both the C1 and C2 domains must be membrane anchored in order to activate the protein kinase. This is because the conformation required to do so extracts the N-terminal pseudo-substrate from the protein kinase active site.

#### b. PKC Is Primed by Phosphorylation

The activation of all mammalian PKCs but the atypical PKCs is accompanied by their phosphorylation at three conserved Ser or Thr residues. One of these residues (Thr 500 in PKC $\beta$ II) is in the protein kinase's activation loop, whereas the remaining two are in its C-terminal segment (Thr 641 and Ser 660 of the 673-residue PKC $\beta$ II). In the atypical PKCs, the latter Ser/Thr residue is replaced by a phosphate-mimicking Glu residue. The sequence of events that activate PKCs, which was largely elucidated by Alexandra Newton, occurs as follows (Fig. 19-60):

1. Newly synthesized PKC binds to the membrane (or possibly to the underlying cytoskeleton), where

**phosphoinositide-dependent protein kinase-1 (PDK1)** phosphorylates its activation loop (at Thr 500 in PKC $\beta$ II). The resulting negative charge on the activation loop is postulated to properly align the active site residues of PKC for catalysis, much as we have seen for PKA (Section 18-3Cb;

**Figure 19-60 Activation of PKC.** (1) Newly synthesized PKC is phosphorylated on its activation loop (here represented by Thr 500 of PKC $\beta$ II; yellow ball) by phosphoinositide-dependent protein kinase-1 (PDK1), which is tethered to the membrane via its C-terminal pleckstrin homology domain (PH). (2) The now catalytically competent PKC autophosphorylates 2 sites on its C-terminal segment (here represented by Thr 641 and Ser 660 of PKC $\beta$ II). However, the N-terminal pseudosubstrate segment now binds to PKC's active site, so that the enzyme remains inactive. (3) On the binding of PKC's C1 domain to membrane-bound DAG (the product of extracellular signals

inducing phosphoinositide hydrolysis) together with the Ca<sup>2+</sup>-mediated binding of the C2 domain to phosphatidylserine (PS) in the membrane, the pseudosubstrate is ejected from the PKC active site, thereby yielding active enzyme. [After a drawing by Toker, A. and Newton, A.C., *Cell* **103**, 187 (2000).]

PKA's activation loop is also phosphorylated by PDK1). In fact, the mutagenic replacement of PKC $\alpha$ 's activation loop Thr with a neutral nonphosphorylatable residue yields an inactivatable enzyme, whereas its replacement with Glu yields an enzyme that requires only DAG and Ca<sup>2+</sup> for activation.

2. The now catalytically competent PKC rapidly autophosphorylates its other two phosphorylation sites. The autophosphorylation of Thr 641 appears to lock PKC into its active conformation, as suggested by the observation that in PKC $\beta$ II, which has been phosphorylated at only Thr 500 and Thr 641, the selective dephosphorylation of Thr 500 yields active enzyme. The autophosphorylation of the third phosphorylation site correlates with the release of PKC into the cytosol, where PKC is maintained in its inactive state by the binding of its pseudosubstrate to its active site.

3. This autoinhibition is relieved, as described above, when PKC again binds to the membrane via DAG binding to its C1 domain and Ca<sup>2+</sup>-mediated binding of its C2 domain to phosphatidylserine (PS).

The activity of PKC is regulated by the protein phosphatase **PHLPP** (for *PH* domain *leucine-rich repeat protein phosphatase*), which specifically dephosphorylates its Thr 641.

#### D. The Phosphoinositide 3-Kinases

The inositol head group of phosphatidylinositol has 5 free hydroxyl groups that can be phosphorylated (Fig. 19-53). However, only its 3-, 4-, and 5-positions are known to be

**Figure 19-61** Flowchart of reactions in the synthesis of phosphoinositides in mammalian cells. **PtdIns**, **PtdIns-4-P**, and **PtdIns-4,5-P<sub>2</sub>** (PIP<sub>2</sub>) are written in bold type to indicate their abundance: Together they comprise ~90% of the cell's total phosphoinositides. **PtdIns-3-P** and **PtdIns-5-P** each comprise 2–5% of the total, whereas the levels of **PtdIns-3,4-P<sub>2</sub>** and **PtdIns-3,4,5-P<sub>3</sub>** (PIP<sub>3</sub>) are barely detectable in quiescent cells but rise to 1 to 3% of the total in stimulated cells. **PtdIns-3,5-P<sub>2</sub>** comprises ~2% of the phosphoinositides in fibroblasts. [After Fruman, D.A., Meyers, R.E., and Cantley, L.C., *Annu. Rev. Biochem.* **67**, 501 (1998).]

phosphorylated *in vivo*, and these occur in all seven possible combinations (Fig. 19-61), each of which participates in signaling. In addition to the plasma membrane, they occur in ER, Golgi, and endosome membranes, although with different distributions in each of these several subcellular compartments.

The phosphorylations of these various phosphoinositides are catalyzed by ATP-dependent enzymes known as **phosphoinositide 3-kinases (PI3Ks)**, **phosphoinositide 4-kinases (PIP4Ks)**, and **phosphoinositide 5-kinases (PIP5Ks)**. Their various products function as second messengers by recruiting the proteins that bind them to the cytosolic surface of the plasma membrane (see below). The resulting colocalization of enzymes and substrates results in further signaling activity that controls such vital functions as cell survival, proliferation, cytoskeletal rearrangement, endocytosis, and vesicle trafficking.

The PI3Ks are the presently best understood phosphoinositide kinases. Consequently, in this subsection, we discuss the PI3Ks and their products as a paradigm of all phosphoinositide kinases and the signals they produce.

##### a. PI3Ks Have Three Classes

Mammalian PI3Ks are divided into three classes according to their structures (Fig. 19-62), substrate specificities, and modes of regulation:

1. Class I PI3Ks are heterodimeric receptor-regulated enzymes that preferentially phosphorylate PIP<sub>2</sub> (alternatively, PtdIns-4,5-P<sub>2</sub>). Their ~1070-residue catalytic subunits interact with Ras · GTP via a Ras-binding domain (RBD) near their N-termini. Their regulatory subunits are adaptor proteins that link the catalytic subunits to upstream signaling events and hence form two subclasses according to the type of upstream effectors with which they interact:

(a) The class IA PI3Ks (PI3K $\alpha$ ,  $\beta$ , and  $\delta$ ) are activated by RTKs via the mediation of the adaptor subunit **p85** (of which there are seven isoforms), which contains SH2 and SH3 domains and may be phosphorylated on specific Tyr side chains. The gene encoding PI3K $\alpha$  is one of the two most frequently mutated oncogenes in human cancers, thus indicating this enzyme's central regulatory role. Several of its most common oncogenic mutations result in enhanced enzymatic activity by altering the interactions between its kinase domain and its regulatory domains or p85.

**Figure 19-62** Domain organization of the three classes of PI3Ks. [After Walker, E.H., Persic, O., Ried, C., Stephens, L., and Williams, R.L., *Nature* **402**, 314 (1999).]

(b) The class IB PI3K, of which PI3K $\gamma$  is its only member, is activated by the G $_{\beta\gamma}$  dimers of heterotrimeric G proteins, with its adaptor subunit **p101** rendering it far more sensitive to G $_{\beta\gamma}$ .

2. Class II PI3Ks (PI3K-C2 $\alpha$ ,  $\beta$ , and  $\gamma$ ) are ~1650-residue monomers that are characterized by a C-terminal C2 domain that does not bind Ca<sup>2+</sup>. They preferentially phosphorylate PtdIns and **PtdIns-4-P**. Since they lack adaptors, the way in which class II PI3Ks are controlled is unknown.

3. Class III PI3K, which has one known isoform, phosphorylates only PtdIns. It is a heterodimer with an 887-residue catalytic subunit and an adaptor subunit known as **p150**. Class III PI3K is constitutively active, that is, it is unregulated and hence is thought to be the cell's main provider of **PtdIns-3-P**, whose level is essentially unaltered by cellular stimulation. It is thought to be the evolutionary predecessor of the other classes because it is the only class of PI3K present in yeast.

In addition to their lipid kinase activities, all PI3Ks have Ser/Thr protein kinase activity, although the physiological significance of this dual specificity is unclear.

#### b. PI3K $\gamma$ Is a Multidomain Protein

The X-ray structure of PI3K $\gamma$  · ATP, in which the PI3K $\gamma$  lacks its N-terminal 143 residues (which are important for interaction with the p101 adaptor; the analogous portion of PI3K $\alpha$  interacts with its p85 adaptor), was determined by

Roger Williams. It reveals that its RBD, C2, and helical domains form a relatively compact layer that packs against the “back” of the kinase domain (Fig. 19-63). As expected, the kinase domain is grossly similar to those of protein kinases in that it is bilobal, with its N-lobe consisting largely of a 5-stranded  $\beta$  sheet and its C-lobe being predominantly helical. However, there are also major differences between these kinase domains, as can be seen by comparing the catalytic domain in Fig. 19-63 with that in, for example, Fig. 19-28a.

The RBD domain of PI3K $\gamma$  has the same fold as that of RafRBD (Fig. 19-41). Indeed, in the X-ray structure of PI3K $\gamma$ -Ras · GMPPNP (Fig. 19-64), also determined by Williams, the PI3K RBD interacts with Ras in a similar manner as we have seen that RafRBD interacts with the Ras homolog Rap1A (Fig. 19-41) in that they continue each other's central  $\beta$  sheets. However, Ras bound to PI3K $\gamma$  is rotated by 35° relative to Rap1A bound to RafRBD. Contacts between the Switch I region of Ras and the PI3K $\gamma$  stabilize this interaction and ensure its dependence on Ras · GTP. This complex also contains intermolecular contacts involving the Switch II region of Ras. Such an interaction had previously only been observed between Ras and its upstream effectors. Comparison of the structure of the PI3K $\gamma$ -Ras complex with that of PI3K $\gamma$  · ATP (Fig. 19-63) indicates that Ras binding induces the C-lobe of PI3K $\gamma$ 's catalytic domain to pivot relative to its N-lobe in a way that substantially alters the putative binding pocket for the phosphoinositide head group. This, presumably, accounts for the ~15-fold activation of PI3K $\gamma$  on binding Ras · GTP.

**Figure 19-63** X-ray structure of PI3K $\gamma$  · ATP. The protein is shown in ribbon form with its Ras-binding domain (RBD) green, its C2 domain magenta, its helical domain orange, the N- and C-lobes of its kinase domain pink and cyan, and interdomain segments gray. The ATP is shown in space-filling form with C green, N blue, O red, and P yellow. The protein is oriented such that its kinase domain is seen in “standard” view. The protein appears fragmented because several of its segments are disordered, including much of the kinase's activation loop. [Based on an X-ray structure by Roger Williams, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1E8X.]

**Figure 19-64** X-ray structure of PI3K $\gamma$ -Ras · GMPPNP. Here only the PI3K $\gamma$  RBD (green) and the Ras · GMPPNP (gold) are drawn, with the Switch I and Switch II regions of Ras magenta and cyan and its bound GMPPNP shown in space-filling form (C green, N blue, O red, and P yellow). The view, which is similar to that of Fig. 19-41, is related to that in Fig. 19-63 by rotating it clockwise by ~40° about its vertical axis and then turning it 180° about the axis perpendicular to the page. [Based on an X-ray structure by Roger Williams, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1HE8.]

The C2 domain of PI3K $\gamma$  forms the same sandwich of two 4-stranded antiparallel  $\beta$  sheets seen in the C2 domain of PLC- $\delta$ 1 (Section 19-4Ba). However, in contrast to the C2 domain of PLC- $\delta$ 1, that of PI3K $\gamma$  does not bind Ca<sup>2+</sup> ions. Nevertheless, the PI3K $\gamma$  C2 domain appears to participate in membrane association, as indicated by the observation that this isolated C2 domain binds to phospholipid vesicles with an affinity similar to that of the intact enzyme. This interaction is presumably mediated by patches of basic residues on the surface of the C2 domain.

The PI3K $\gamma$  helical domain consists of five repeating pairs of antiparallel helices that form a superhelix, which closely resembles that formed by the HEAT repeats in the A subunit of protein phosphatase 2A (PP2A; Fig. 19-51a), even though PI3K $\gamma$  does not contain a HEAT sequence motif. In analogy with the function of the A subunit of PP2A to bind other proteins (Section 19-3Fe), it is proposed that the largely solvent-exposed helical domain of PI3K $\gamma$  functions to interact with the proteins that bind PI3K $\gamma$ , such as its p101 adaptor and G $\beta\gamma$ .

### c. Akt Activation Requires Its PH Domain-Mediated Binding to 3-Phosphoinositides

The PtdIns-3,4-P<sub>2</sub> and PtdIns-3,4,5-P<sub>3</sub> products of PI3Ks (Fig. 19-61) bind to their downstream effectors mainly via pleckstrin homology (PH) domains that preferentially bind the head groups of these 3-phosphoinositides rather than that of PIP<sub>2</sub> (as does the PH domain of PLC- $\delta$ ; Fig. 19-58). Another example of a PH domain-containing protein that does so is the 556-residue phosphoinositide-dependent protein kinase-1 (PDK1), which, as we have seen, phosphorylates the activation loops of PKA and PKC (Section 19-4Cb).

PDK1 also phosphorylates the Ser/Thr protein kinase **Akt** [also called **protein kinase B (PKB)**], a proto-oncogene product that is implicated in regulating multiple biological processes including gene expression, apoptosis, glucose uptake, and cellular proliferation, and hence phosphorylates many target proteins. The ~480-residue Akt consists of an N-terminal PH domain that binds 3-phosphoinositides and a C-terminal kinase domain that is homologous to those of PKA and PKC (and is thus a member of the AGC family of protein kinases). Akt is present in multicellular organisms in three isoforms (**Akt1/PKB $\alpha$** , **Akt2/PKB $\beta$** , and **Akt3/PKB $\gamma$** ) but is absent in yeast, which suggests that it evolved from another AGC family member coincidentally with multicellular organisms.

The full activation of Akt requires its phosphorylation at both its Ser 473 and Thr 308. Ser 473 is phosphorylated by **mTORC2** [for mammalian target of rapamycin complex 2; **rapamycin** is an immunosuppressant similar to FK506 (Section 9-2B)]. This stimulates PDK1 to phosphorylate Thr 308, which is located in Akt's activation loop. Mutations of the residues in Akt's PH domain responsible for lipid binding block its phosphorylation *in vitro* by PDK1. However, the deletion of Akt's PH domain overcomes this enzyme's need for binding to 3-phosphoinositides. This suggests that the binding of Akt to these membrane-bound lipids induces a conformational change that permits PDK1

to phosphorylate and hence activate Akt. It therefore appears that it is the 3-phosphoinositide-mediated colocalization of Akt and PDK1 that leads to Akt activation and hence that it is the action of PI3K that is functionally responsible for this process. In contrast, the PDK1-mediated phosphorylation of PKA and PKC, which lack PH domains, occurs in the absence of 3-phosphoinositides and is therefore constitutive. The protein phosphatase PHLPP regulates Akt activity by dephosphorylating its Ser 473, in much the same way as we have seen that PHLPP dephosphorylates PKC (Section 19-4Cb).

### d. The FYVE Domain Binds the PtdIns-3-P Head Group

The singly phosphorylated PtdIns-3-P is rarely bound by PH domains. Rather, its direct effects are mediated by **FYVE domains** [named after the four proteins in which it was first identified: *Fab1p*, *YOTB*, *Vac1p*, and **early endosome antigen 1 (EEA1)**], which have been identified in ~60 proteins. For instance, the 1410-residue eukaryotic protein EEA1, which has a 65-residue, C-terminal FYVE domain, initiates endosome fusion in eukaryotic cells (Fig. 12-91) by recruiting the membrane-anchored small G protein **Rab5** and the transmembrane SNARE protein **syn-taxin** (Section 12-4Db).

The NMR structure of the EEA1 FYVE domain, determined by Michael Overduin, reveals that it assumes similar conformations in the free state, when binding dibutanoyl-PtdIns-3-P (Fig. 19-65), and when bound to dodecylphosphocholine (DPC) micelles enriched with this PtdIns-3-P. The protein is largely held together by two bound Zn<sup>2+</sup> ions, each of which is tetrahedrally liganded by four conserved Cys side chains. The PtdIns-3-P head group is held in its binding pocket by a network of electrostatic, hydrogen bonding, and hydrophobic interactions involving a highly conserved (R/K)(R/K)HHCR motif (RRHHCR in EEA1).

The NMR evidence indicates that, on the addition of DPC micelles, the FYVE domain · PtdIns-3-P complex inserts a hydrophobic 5-residue loop (FSVTV; orange in Fig. 19-65), which is flanked by basic residues (blue in Fig. 19-65), into the lipid layer. This also occurs in the absence of PtdIns-3-P but to a much lesser extent. Conversely, membrane insertion increases the binding affinity of the FYVE domain for PtdIns-3-P 20-fold (from 1  $\mu$ M to 50 nM). The origin of this latter effect appears to be that the 10-residue segment preceding the membrane insertion loop, the unliganded protein's most disordered region, becomes more ordered and moves toward the binding pocket on binding PtdIns-3-P. This has led to the proposal that the FYVE domain is recruited to membranes via the insertion of its hydrophobic loop into the lipid bilayer. This, in turn, primes the protein for the recognition of PtdIns-3-P, whose binding induces the protein's otherwise mobile N-terminal segment to clamp down over the PtdIns-3-P head group.

### E. Inositol Polyphosphate Phosphatases

Signaling via the phosphoinositide cascade is terminated through the actions of a variety of inositol phosphatases that

**Figure 19-65** NMR structure of the EEA1 FYVE domain in complex with PtdIns-3-P. The head group of PtdIns-3-P is drawn in ball-and-stick form (C green, O red, P magenta, H gray). The protein binds two  $Zn^{2+}$  ions (cyan spheres) that are each tetrahedrally liganded by four Cys side chains that are drawn in stick form (C green and S yellow). The 5-residue loop that inserts into DPC micelles is orange and its flanking basic residues are blue. [Based on an NMR structure by Michael Overduin, University of Colorado Health Sciences Center. PDBid 1HYI.]

are functionally classified as 1-, 3-, 4-, and 5-phosphatases. We end our consideration of the phosphoinositide cascade by discussing the characteristics of these essential enzymes.

#### a. The Inositol Polyphosphate 5-Phosphatases Act In Numerous Signaling Pathways

The first **inositol polyphosphate 5-phosphatases** that were studied hydrolyze  $IP_3$  (Ins-1,4,5- $P_3$ ) to  $IP_2$  (Ins-1,4- $P_2$ ) and thereby terminate cellular  $Ca^{2+}$  mobilization (Fig. 19-54, *bottom*). Mammals express >10 isozymes that have 5-phosphatase activity. These enzymes share a common catalytic core and have been classified according to their substrate specificities into two groups: Type I enzymes dephosphorylate inositol phosphates, whereas type II enzymes, in addition, hydrolyze the corresponding phosphoinositides.

**Type I 5-phosphatases**, which hydrolyze only  $IP_3$  and **Ins-1,3,4,5- $P_4$** , are membrane-anchored via prenylation. That expressed in blood platelets (a type of blood cell that participates in blood clotting; Section 35-1), which is

representative of this group, forms a stoichiometric complex with **pleckstrin**, a 350-residue protein that consists largely of two PH domains. When platelets are stimulated by the proteolytic clotting enzyme **thrombin** (Section 35-1B), pleckstrin is phosphorylated on Ser and Thr residues by PKC, which in turn activates its associated 5-phosphatase. Note that PKC is activated by DAG, a product of PLC, which simultaneously generates the type I 5-phosphatase substrate  $IP_3$  (Fig. 19-54). Hence, the PLC product  $IP_3$  activates  $Ca^{2+}$  ion release, whereas its coproduct DAG activates type I 5-phosphatase through pleckstrin phosphorylation to terminate the  $Ca^{2+}$  signal. This termination is apparently important for normal cell growth as a decrease in the expression of type I 5-phosphatase causes increased and even uncontrolled (malignant) cell growth.

Type II 5-phosphatases share increased similarities in their catalytic cores relative to type I enzymes and, in addition, have a so-called type II domain on the N-terminal side of their catalytic cores. They occur in three main subtypes: **GIPs**, **SHIPs**, and **SCIPs**. GIPs are so called because they have a C-terminal GAP domain (GAP-containing inositol phosphatase), although they have no demonstrated GAP activity. GIPs hydrolyze  $IP_3$  and Ins-1,3,4,5- $P_4$  and their corresponding lipids, PtdIns-4,5- $P_2$  and PtdIns-3,4,5- $P_3$ , although with varying catalytic efficiencies.

There are only two known GIPs, **5-phosphatase II** and **OCRL**. OCRL is so called because its mutation causes the X-linked hereditary disease **oculocerebrorenal dystrophy** (also called **Lowe syndrome**), which is characterized by congenital cataracts, progressive retinal degeneration, mental retardation, and renal tubule defects leading to kidney failure in early adulthood. The 901-residue OCRL occurs mainly on the surface of lysosomes, where it is anchored through prenylation. Renal tubule cells from Lowe syndrome patients are deficient in PtdIns-4,5- $P_2$  and PtdIns-3,4,5- $P_3$  hydrolytic activity, whereas the corresponding inositol phosphates are hydrolyzed normally, thereby indicating that OCRL is a lipid phosphatase. PtdIns-4,5- $P_2$  stimulates the budding of membrane vesicles from lysosomes, so that the accumulation of this lipid probably leads to abnormally increased trafficking of enzymes from the lysosome to the extracellular space. Indeed, the lysosomal enzymes in these cells appear to be missorted (as are various lysosomal hydrolases in I-cell disease; Section 12-4Cg). It is therefore proposed that this lifelong leakage of enzymes from the lysosomes in Lowe syndrome patients causes tissue damage that eventually results in kidney failure and blindness.

SHIPs only hydrolyze substrates that also have a phosphate in their 3-positions. The two known members of this group, **SHIP** (for *SH2*-containing inositol-5-phosphatase) and **SHIP2**, are ~1200-residue proteins that have an N-terminal SH2 domain. Thus, these proteins can bind to PTKs and, in fact, are phosphorylated by them to yield a consensus binding sequence for PTB domains (NPXpY; Section 19-3Cc). Moreover, they also contain a C-terminal Pro-rich domain that may bind to SH3-containing proteins. Thus, it appears that SHIP activity may be under the control of several systems. Indeed, SHIP, which is expressed only in hematopoietic (blood-forming) cells, associates

with the adaptor proteins Grb2 and Shc (Section 19-3Cf). It functions to hydrolyze  $\text{PtdIns-3,4,5-P}_3$ , which is implicated in activating Akt and PLC. SHIP2 functions similarly in nonhematopoietic cells, where it limits cellular responses to insulin, EGF, and PDGF.

SCIPs (Sac1-containing inositol phosphatases) are so named because they contain an N-terminal domain that is homologous to the yeast phosphatidylinositol phosphatase **Sac1**. The first SCIP to be characterized is named **synaptojanin1** because it was purified from synaptic vesicles and because the presence of two phosphatase domains is reminiscent of the two kinase domains in Janus kinases (JAKs; Section 19-3Eb). The 1575-residue synaptojanin1's 5-phosphatase domain hydrolyzes  $\text{PIP}_3$  and  $\text{PtdIns-4,5-P}_2$  and its Sac1 phosphatase domain hydrolyzes  $\text{PtdIns-3-P}$  and  $\text{PtdIns-4-P}$ . Synaptojanin1 is expressed only in neurons, where it forms complexes with the G protein dynamin (Section 12-4Cd) and thereby participates in synaptic vesicle recycling. The closely similar **synaptojanin2** is ubiquitously expressed but its functions are largely unknown.

#### b. Inositol Polyphosphate 1-Phosphatase Is Implicated in Bipolar Disorder

Mammals express only one type of **inositol polyphosphate 1-phosphatase**, a 399-residue enzyme that hydrolyzes **Ins-1,4- $\text{P}_2$**  and **Ins-1,3,4- $\text{P}_3$**  ( $\text{IP}_3$ ) but does not act on lipid substrates. This enzyme is inhibited by  $\text{Li}^+$  ion. The therapeutic efficacy of  $\text{Li}^+$  in controlling the incapacitating mood swings of manic-depressive individuals (those with **bipolar disorder**) therefore suggests that this mental illness is caused by an aberration of 1-phosphatase in the brain, possibly resulting in abnormal activation of  $\text{Ca}^{2+}$ -mobilizing receptors (Fig. 19-54, *bottom*). Indeed, *Drosophila* in which this 1-phosphatase has been deleted exhibit neurological deficits (the so-called “shaker” phenotype) that appear identical to those of wild-type *Drosophila* treated with  $\text{Li}^+$ .

#### c. The Inositol Polyphosphate 3-Phosphatase PTEN Is a Tumor Suppressor

The **inositol polyphosphate 3-phosphatases** undo the actions of the PI3Ks. The best characterized of these enzymes is the 403-residue **PTEN** (for *phosphatase and tensin* homolog; **tensin** is a cytoskeletal actin-binding protein), which *in vitro* dephosphorylates all 3-phosphorylated phosphoinositides and **Ins-1,3,4,5- $\text{P}_4$** . PTEN is a **tumor suppressor** (a protein whose loss of function is a cause of cancer), presumably because its 3-phosphatase activity functions to downregulate the  $\text{PtdIns-3,4,5-P}_3$ -activated Akt. In fact, PTEN mutation or loss commonly occur in many types of cancers. PTEN can also dephosphorylate Ser-, Thr-, and Tyr-phosphorylated peptides, although this activity requires the peptides to be highly acidic.

The X-ray structure of PTEN, determined by Jack Dixon and Nikola Pavletich, reveals the protein to consist of an N-terminal phosphatase domain and a C-terminal C2 domain (Fig. 19-66). The structure of its phosphatase domain resembles that common to protein tyrosine phosphatase (PTP) domains (e.g., Fig. 19-50), but with a larger active site pocket, presumably to accommodate the large size of its  $\text{PtdIns-}$

**Figure 19-66** X-ray structure of PTEN. The protein is shown with its phosphatase domain blue, its C2 domain red, and the P loop, which interacts with the substrate, tan. The dotted line represents a 24-residue segment that was deleted from the protein to facilitate its crystallization. [Courtesy of Nikola Pavletich, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBid 1D5R.]

$\text{3,4,5-P}_3$  substrate. The C2 domain lacks bound  $\text{Ca}^{2+}$  ion as well as the ligands to bind it but, nevertheless, binds to phospholipid membranes, as does the C2 domain of  $\text{PI3K}\gamma$  (Fig. 19-63). The phosphatase and C2 domains associate across an extensive interface, whose residues are frequently mutated in cancer. A similar tight interface between the C2 and kinase domain occurs in  $\text{PLC-}\beta\text{II}$  (Fig. 19-57). This suggests that PTEN's C2 domain functions to productively position its attached phosphatase domain at the membrane.

#### d. The Inositol Polyphosphate 4-Phosphatases Control the Level of $\text{PtdIns-3,4-P}_2$

There are two isoforms of inositol 4-phosphatases, **4-phosphatases I and II**, which catalyze the hydrolysis of **Ins-1,3,4- $\text{P}_3$** , **Ins-2,4- $\text{P}_2$** , and  $\text{PtdIns-3,4-P}_2$ . In fact, these ~940-residue proteins account for >95% of the observed  $\text{PtdIns-3,4-P}_2$  phosphatase activity in many human tissues, thereby suggesting that they play an important role in the metabolism of this second messenger. This is supported by the observation that stimulating human platelets by thrombin or  $\text{Ca}^{2+}$  ion results in the inactivation of 4-phosphatase I through its proteolytic cleavage by the  $\text{Ca}^{2+}$ -dependent protease **calpain**. This inactivation of 4-phosphatase I correlates with the  $\text{Ca}^{2+}$ -and/or aggregation-dependent accumulation of  $\text{PtdIns-3,4-P}_2$  characteristic of human platelets (which aggregate in the initial stages of blood clot formation; Section 35-1).

#### F. Epilog: Complex Systems and Emergent Properties

Complex systems are, by definition, difficult to understand and substantiate. Familiar examples include Earth's weather system, the economies of large countries, the ecologies of even small areas, and the human brain. Biological signal transduction systems, as is amply evident from a reading of this chapter, are complex systems. Thus, as we

have seen, a hormonal signal is typically transduced through several intracellular signaling pathways, each of which consists of numerous components, many of which interact with components of other signaling pathways. For example, the **insulin signaling system** (Fig. 19-67), although not yet fully elucidated, is clearly highly complex. On binding insulin, the insulin receptor autophosphorylates itself

at several Tyr residues (Section 19-3Ac) and then Tyr-phosphorylates its target proteins, thereby activating several signaling pathways that control a diverse array of effects:

1. Phosphorylation of Shc (Section 19-3Cc) results in stimulation of a MAP kinase cascade (Section 19-3D), ultimately affecting growth and differentiation.

**Figure 19-67 Insulin signal transduction.** The binding of insulin to the insulin receptor (**IR**) induces its autophosphorylation at several Tyr residues on its  $\beta$  subunits. Several proteins, including Shc, Gab-1, the APS/Cbl complex, and IRS proteins, bind to these pY residues where they are Tyr-phosphorylated by the activated insulin receptor, thereby activating MAPK and PI3K phosphorylation cascades as well as a lipid raft and caveolae-associated regulation process. The MAPK cascade regulates the expression of genes involved in cellular growth and differentiation. The PI3K cascade leads to changes in the phosphorylation states of several enzymes, so as to stimulate glycogen synthesis, as well as other pathways. The PI3K cascade also participates in the control of vesicle trafficking, leading to the translocation of the **GLUT4** glucose transporter to the cell surface and thus increasing the rate of glucose transport into the cell (Section 20-2Ec). Glucose transport control is also exerted

by the APS/Cbl system in a PI3K-independent manner involving lipid rafts and caveolae. Other symbols: Myc, Fos, and Jun (transcription factors; Section 19-3D), SHP-2 (an SH2-containing PTP; Section 19-3Fb), **CAP** (Cbl-associated protein), **C3G** [a guanine nucleotide exchange factor (GEF)], **CrkII** [an SH2/SH3-containing adaptor protein], **PDK1** (phosphoinositide-dependent protein kinase-1; Section 19-4Cb), **PKB** (protein kinase B, also named Akt; Section 19-4Dc), **mTOR** [for *mammalian target of rapamycin*, a PI3K-related protein kinase (Section 9-2B); mTOR is also known as **FKBP12-rapamycin-associated protein (FRAP)**], **S6** [a protein subunit of the eukaryotic ribosome's small subunit (Section 32-3Ab); its phosphorylation stimulates translation], and **PKC $\zeta$**  and **PKC $\lambda$**  (atypical isoforms of protein kinase C; Section 19-4C). [After Zick, Y., *Trends Cell Biol.* **11**, 437 (2001)].

2. Phosphorylation of **Gab-1 (Grb2-associated binder-1)** similarly activates this MAP kinase cascade.

3. Phosphorylation of insulin receptor substrate (IRS) proteins (Section 19-3Cg) activates a phosphoinositide cascade via a PI3K (Section 19-4Da), ultimately stimulating a variety of metabolic processes including glycogen synthesis (Section 18-3E) and glucose transport (Section 20-2E), as well as cell growth and differentiation.

4. Phosphorylation of the **APS/Cbl** complex (APS for adaptor protein containing pleckstrin homology and Src homology-2 domains; Cbl is an SH2/SH3-binding docking protein that is a proto-oncogene product) leads to the stimulation of **TC10** [a G protein in the Rho family (Section 35-3E)], and to the PI3K-independent regulation of glucose transport involving the participation of lipid rafts and caveolae (Section 12-3Cb).

The predominant approach in science is reductionist: the effort to understand a system in terms of its component parts. Thus chemists and biochemists explain the properties of molecules in terms of the properties of their component atoms, cell biologists explain the nature of cells in terms of the properties of their component macromolecules, and biologists explain the characteristics of multicellular organisms in terms of the properties of their component cells. However, complex systems have **emergent properties**, properties that are not readily predicted from an understanding of their

component parts (i.e., the whole is greater than the sum of its parts). Indeed, life itself is an emergent property that arises from the numerous chemical reactions that occur in a cell.

In order to elucidate the emergent properties of a complex system, an integrative approach is required. For signal transduction systems, such an approach would entail determining how each of the components of each signaling pathway in a cell interacts with all of the other such components under the conditions that each of these components experiences within its local environment. Yet techniques for doing so are not often available. Moreover, these systems are by no means static but vary, over multiple time scales, in response to cellular and organismal programs. Consequently, the means for understanding the holistic performance of cellular signal transduction systems are only in their earliest stages of development. Such an understanding is likely to have important biomedical consequences since many diseases, including cancer, diabetes, and a variety of neurological disorders, are caused by malfunctions of signal transduction systems.

Finally, you should note that we have only outlined the major signal transduction pathways that occur in eukaryotic cells. Moreover, we have not considered numerous other such pathways that control cellular functions (although many of them are discussed in later chapters). Nevertheless, it is clear that a full understanding of a cell's signal transduction pathways and how they interact is the key to understanding the molecular basis of life.

## CHAPTER SUMMARY

**1 Hormones** Chemical messengers are classified as autocrine, paracrine, or endocrine hormones if they act on the same cell, cells that are nearby, or cells that are distant from the cell that secreted them, respectively. The body contains a complex endocrine system that controls many aspects of its metabolism. Hormone levels may be determined through radioimmunoassays. Receptors are membrane-bound proteins that bind their ligands according to the laws of mass action. The parameters describing the binding of a radiolabeled ligand to its receptor can be determined from Scatchard plots. The dissociation constants of additional ligands for the same receptor-binding site can then be determined through competitive binding studies.

The pancreatic islet cells secrete insulin and glucagon, polypeptide hormones that induce liver and adipose tissue to store or release glucose and fat, respectively. Gastrointestinal polypeptide hormones coordinate various aspects of digestion. The thyroid hormones,  $T_3$  and  $T_4$ , are iodinated amino acid derivatives that generally stimulate metabolism by activating cellular transcription factors.  $Ca^{2+}$  metabolism is regulated by the levels of PTH, vitamin D, and calcitonin. PTH and vitamin D induce an increase in blood  $[Ca^{2+}]$  by stimulating  $Ca^{2+}$  release from bone and its absorption from kidney and intestine, whereas calcitonin has the opposite effects. Vitamin D is a steroid derivative that must be obtained in the diet or by exposure to UV radiation. Vitamin D, after being sequentially processed in the liver and kidney to  $1,25(OH)_2D$ , stimulates the synthesis of a  $Ca^{2+}$ -binding protein in the intestinal epithelium. The adrenal medulla secretes the catecholamines epinephrine

and norepinephrine, which bind to  $\alpha$ - and  $\beta$ -adrenergic receptors on a great variety of cells so as to prepare the body for "fight or flight." The adrenal cortex secretes glucocorticoid and mineralocorticoid steroids. Glucocorticoids affect metabolism in a manner opposite to that of insulin as well as mediating a wide variety of other vital functions. Mineralocorticoids regulate the excretion of salt and water by the kidney. The gonads secrete steroid sex hormones, the androgens (male hormones) and estrogens (female hormones), which regulate sexual differentiation, the development of secondary sex characteristics, and sexual behavior patterns. Ovaries, in addition, secrete progestins that help mediate the menstrual cycle and pregnancy. Mammalian embryos develop as females unless subjected to the influence of the androgen testosterone. *SRY*, a gene that encodes a DNA-binding protein and that is normally located on the Y chromosome, induces the development of testes, which in turn secrete testosterone. The hypothalamus secretes a series of polypeptide releasing factors and release-inhibiting factors such as CRF, TRF, GnRF, and somatostatin that control the secretion of the corresponding trophic hormones from the pituitary gland's adenohypophysis. Most of these trophic hormones, such as ACTH, TSH, LH, and FSH, stimulate their target endocrine glands to secrete the corresponding hormones. However, growth hormone acts directly on tissues as well as stimulating liver to synthesize growth factors known as somatomedins. The pituitary gland's neurohypophysis secretes the polypeptides vasopressin, which stimulates the kidneys to retain water, and oxytocin, which stimulates uterine contraction. The menstrual cycle results from a complex interplay of hypothalamic,

adenohypophyseal, and steroid sex hormones. A fertilized and implanted ovum secretes CG, which binds to the same receptor and has similar effects as LH, thus preventing menstruation. The binding of hGH to its receptor causes the receptor to dimerize, thereby providing the intracellular signal that the receptor has bound hCG. Many other hormonal signals are similarly mediated. The adenohypophysis also secretes opioid peptides that have opiate-like effects on the central nervous system. Nitric oxide (NO), a highly reactive radical gas, functions as a local mediator that regulates vasodilation, serves as neurotransmitter, and functions in the immune response. In mammals, it is synthesized by three isozymes of nitric oxide synthase (NOS), an enzyme that contains 5 redox-active prosthetic groups. eNOS and nNOS are activated by  $\text{Ca}^{2+}$  through their binding of  $\text{Ca}^{2+}$ -calmodulin; iNOS is transcriptionally controlled. NO activates guanylate cyclase to produce cGMP, which in turn activates cGMP-dependent protein kinase.

**2 Heterotrimeric G Proteins** Ligand (hormone) binding to G protein-coupled receptors (GPCRs) activates the  $G_{\text{sa}}$  subunit of a stimulatory G protein to replace its bound GDP with GTP, release its associated  $G_{\beta\gamma}$  subunits, and activate adenylate cyclase (AC) to synthesize cAMP. Activation continues until  $G_{\text{sa}}$  hydrolyzes its bound GTP to GDP and recombines with  $G_{\beta\gamma}$ . Several types of activated hormone receptors in a cell may stimulate the same  $G_s$  protein. There are also inhibitory G proteins, which may have the same  $G_{\beta}$  and  $G_{\gamma}$  subunits as does  $G_s$ , but which have an inhibitory  $G_{\text{ia}}$  subunit that deactivates adenylate cyclase. Cholera toxin (CT) and heat-labile enterotoxin (LT), related bacterial  $\text{AB}_5$  proteins, induce uncontrolled cAMP production by ADP-ribosylating  $G_{\text{sa}}$  so as to render it incapable of hydrolyzing GTP. Pertussis toxin, also an  $\text{AB}_5$  protein, similarly ADP-ribosylates  $G_{\text{ia}}$ . Biological signaling systems are subject to desensitization through the phosphorylation and endocytotic sequestering of the cell-surface receptors. The catalytic core of the numerous isoforms of AC are pseudosymmetric heterodimers that are activated, in most cases, by the binding of the Switch II region of  $G_{\text{sa}} \cdot \text{GTP}$  to a cleft in an AC's  $C_{1a}$  domain. cAMP and cGMP are eliminated through the actions of numerous phosphodiesterases (PDEs), whose activities are controlled by a variety of agents, thereby providing for cross talk between signaling systems.

**3 Tyrosine Kinase-Based Signaling** The binding of ligands such as hormones and protein growth factors activates receptor tyrosine kinases (RTKs) by inducing them to dimerize and then autophosphorylate specific Tyr residues in the activation loops of their tyrosine kinase domains. This is usually followed by the autophosphorylation of Tyr residues on other cytoplasmic domains. Cancer cells' immortality and their uncontrolled proliferation endow them with the capacity to form invasive and metastatic tumors. Rous sarcoma virus, a retrovirus causing sarcomas in chickens, carries an oncogene, *v-src*, that is homologous to the normal cellular gene *c-src*. Both genes encode a protein tyrosine kinase (PTK) that stimulates cell division. Oncogene products include analogs of growth factors, growth factor receptors, nuclear proteins that stimulate transcription and/or cell division, and G proteins.

Two-hybrid systems are used to identify interacting proteins. An autophosphorylated RTK may activate other proteins by phosphorylating them on specific Tyr side chains. It can also modulate the activities of specific proteins through the binding of an RTK's phosphoTyr-containing peptide segment to SH2 and PTB domains on these proteins or on adaptors that bind to these

proteins. Grb2, an adaptor protein, binds to certain activated RTKs in this way and simultaneously, via its SH3 domains, to Sos protein. The bound Sos, in turn, functions as a guanine nucleotide exchange factor (GEF) to induce the small G protein Ras to exchange its bound GDP for GTP. Ras is a poor GTPase but it is aided in eventually hydrolyzing its bound GTP to GDP by the GTPase activating protein (GAP) RasGAP, which insinuates a catalytically important Arg side chain into Ras's otherwise inefficient active site. Mutations that interfere with the ability of Ras–RasGAP to hydrolyze Ras's bound GTP are oncogenic.

The binding of Ras  $\cdot$  GTP to Raf, a protein Ser/Thr kinase, activates Raf to phosphorylate MEK, a MAP kinase kinase (MKK), which in turn phosphorylates MAP kinase (MAPK). The activated MAPK phosphorylates various cytoplasmic and membrane-associated proteins and, in addition, is translocated to the nucleus where it phosphorylates certain transcription factors, which then induce the transcription of their target genes. The proteins of such MAP kinase cascades are organized by their binding to scaffold proteins, which also prevents the members of different MAP kinase cascades in a cell from inappropriately phosphorylating one another. However, activated members of a MAP kinase cascade may phosphorylate other regulatory proteins, thereby eliciting cross talk between different signal transduction pathways.

Tyrosine kinase-associated receptors, such as cytokine receptors, transduce the signal that they have bound effector by activating associated nonreceptor tyrosine kinases (NRTKs), many of which are members of the Src or JAK families. Activated JAK proteins phosphorylate STAT proteins, which then dimerize and are translocated to the nucleus, where they function as transcription factors. Gleevec is a highly selective Abl inhibitor that is clinically effective in the treatment of chronic myelogenous leukemia (CML). Many cancers require elevated levels of Hsp90 activity for viability because their oncogenic proteins tend to be relatively unstable. Phosphorylated proteins are deactivated by protein phosphatases. Some protein tyrosine phosphatases (PTPs) are transmembrane receptors that are deactivated by ligand-induced dimerization. Other PTPs are cytoplasmic and are activated by their binding to activated PTKs, for example, via SH2 domains, as does SHP-2.

Cells contain several types of Ser/Thr protein phosphatases: PP1 participates in the regulation of glycogen metabolism; PP2A, which participates in a wide variety of regulatory processes, is a heterotrimer with numerous variants and hence specificities and cellular locations; and calcineurin (CaN; also called PP2B) is a  $\text{Ca}^{2+}$ -activated heterodimeric phosphatase that is the target of the immunosuppressive drugs cyclosporin A and FK506 via the binding of their complexes with the rotamases cyclophilin and FKBP12 to CaN so as to prevent the binding of CaN's target phosphopeptides.

**4 The Phosphoinositide Cascade**  $\text{PIP}_2$ , a minor phospholipid component of the plasma membrane's inner leaflet, can yield up to three types of second messengers. Hormone-receptor interactions, through the intermediacy of a G protein or an RTK, stimulate the corresponding phospholipase C (PLC) to hydrolyze  $\text{PIP}_2$  to the water-soluble  $\text{IP}_3$  and the membrane-bound DAG. The  $\text{IP}_3$  stimulates the release of  $\text{Ca}^{2+}$  from the endoplasmic reticulum through ligand-gated channels. The  $\text{Ca}^{2+}$  binds to calmodulin, which in turn activates a variety of cellular processes. The DAG activates protein kinase C (PKC) to phosphorylate and thereby modulate the activities of numerous cellular proteins. DAG may also be

degraded to yield arachidonate, an obligate intermediate in the biosynthesis of prostaglandins and related compounds.

The various classes of PLCs are activated in different ways, all of which bring the PLC into contact with its  $\text{PIP}_2$  substrate in the membrane: PLC- $\beta$ 's by binding  $G_{\alpha} \cdot \text{GTP}$ ,  $G_{\beta\gamma}$ , and the membrane-anchored  $\text{Rac1} \cdot \text{GTP}$ ; PLC- $\gamma$ 's by binding to phosphorylated PTKs via SH2 domains followed by phosphorylation of the PLC by the PTK; PLC- $\delta$ 's by  $\text{Ca}^{2+}$ ; and PLC- $\epsilon$  by binding  $\text{Ras} \cdot \text{GTP}$ . "Conventional" PKCs are activated by both  $\text{Ca}^{2+}$  and DAG. Phorbol esters, which are DAG mimics that activate PKC, are the most potent known tumor promoters. DAG and  $\text{Ca}^{2+}$  synergistically bind PKC to the membrane via its C1 and C2 domains, which conformationally extracts PKC's N-terminal pseudosubstrate from the kinase's active site. The kinase is catalytically activated by phosphorylation on its activation loop by PDK1 followed by autophosphorylation at two more sites.

Phosphoinositides may be phosphorylated at their inositol head group's 3-, 4-, and 5-positions in all seven combinations, yielding membrane-bound second messengers that function by recruiting the proteins that bind them to the membrane surface. Mammalian phosphoinositide 3-kinases (PI3Ks) form three

classes that differ according to their structures, substrate specificities, and modes of regulation. The  $\text{PtdIns-3,4-P}_2$  and  $\text{PtdIns-3,4,5-P}_3$  products of PI3Ks bind to the PH domain of the proto-oncogene product Akt (PKB), thereby colocalizing Akt with PDK1, which is also tethered to the membrane via its PH domain, so that PDK1 phosphorylates and thereby activates Akt.  $\text{PtdIns-3-P}$  is bound by FYVE domains, which, like PH domains, are held together by two tetrahedrally liganded  $\text{Zn}^{2+}$  ions.

The various types of inositide polyphosphate phosphatases function to terminate signaling by the phosphoinositide cascade. OCRL, a type II 5-phosphatase that participates in controlling vesicle budding from the lysosome, is mutated in oculocerebrorenal disease (Lowe syndrome). The only 1-phosphatase expressed by mammals, which hydrolyzes  $\text{Ins-1,4-P}_2$  and  $\text{PIP}_3$ , is inhibited by  $\text{Li}^+$  ion and is thereby implicated in bipolar disorder. The 3-phosphatase PTEN, a tumor suppressor whose mutant forms are common to many cancers, undoes the actions of PI3Ks. Type I 4-phosphatase in blood platelets is inactivated through proteolytic cleavage by the  $\text{Ca}^{2+}$ -activated protease calpain. Cellular signal transduction systems, such as the insulin signaling system, are complex systems with emergent properties that are, as yet, poorly understood.

## PROBLEMS

1. Explain the following observations: (a) Thyroidectomized rats, when deprived of food, survive for 20 days while normal rats starve to death within 7 days. (b) Cushing's syndrome, which results from excessive secretion of adrenocortical steroids, can be caused by a pituitary tumor. (c) **Diabetes insipidus**, which is characterized by unceasing urination and unquenchable thirst, results from an injury to the pituitary. (d) The growth of malignant tumors derived from sex organs may be slowed or even reversed by the surgical removal of the gonads and the adrenal glands.

2. How does the presence of the nonhydrolyzable GTP analog GMPPNP affect cAMP-dependent receptor systems?

3. Explain why individuals who regularly handle dynamite (which is nitroglycerin soaked into an absorbant such as wood pulp) as part of their jobs have an unusually high incidence of heart attacks on weekends.

4. A dose-dependent side effect of sildenafil (Viagra) is the transient impairment of blue/green color discrimination. What is the biochemical basis for this phenomenon?

5. Retroviruses bearing oncogenes will infect cells from their corresponding host animal but will usually not transform them. Yet these retroviruses will readily transform immortalized cells derived from the same organism. Explain.

6. Explain why mutations of the Arg residue in G<sub>src</sub> that is

ADP-ribosylated by cholera toxin are oncogenic mutations. Why doesn't cholera toxin cause cancer?

7. Would the following alterations to Src be oncogenic? Explain. (a) The deletion or inactivation of the SH3 domain. (b) The mutation of Tyr 416 to Phe. (c) The mutation of Tyr 527 to Phe. (d) The replacement of Src residues 249 to 253 with the sequence APTMP.

8. JIP-1 was originally so named because, when it was first characterized by overexpression in mammalian cells, it appeared to act as a "JNK inhibitor protein." What is the basis of this observation?

9. Why does pertussis toxin appear to inhibit certain isozymes of PLC? Identify these isozymes.

10. Phosphatidylethanolamine and PIP<sub>2</sub> containing identical fatty acyl residues can be hydrolyzed with the same efficiency by a certain phospholipase C. Will the hydrolysis products of the two lipids have the same effect on protein kinase C? Explain.

11. PKC's autoinhibitory pseudosubstrate occurs at its N-terminus, whereas that of MLCK occurs at its C-terminus (Fig. 18-20). To further investigate this phenomenon, a colleague proposes to construct a PKC with its pseudosubstrate attached to the protein's C-terminus with a sufficiently long linker so that the pseudosubstrate could bind in the enzyme's active site. Would you expect this variant PKC to be activatable? Explain.

# Transport through Membranes

## CHAPTER 20

### 1 Thermodynamics of Transport

#### 2 Kinetics and Mechanisms of Transport

- A. Nonmediated Transport
- B. Kinetics of Mediated Transport: Glucose Transport Into Erythrocytes
- C. Ionophores
- D. Maltoporin: The Structural Basis of Sugar Discrimination
- E. Passive-Mediated Glucose Transport
- F.  $K^+$  Channels: Ion Discrimination
- G.  $Cl^-$  Channels
- H. Aquaporins

#### 3 ATP-Driven Active Transport

- A.  $(Na^+ - K^+) - ATPase$  of Plasma Membranes
- B.  $Ca^{2+} - ATPase$
- C.  $(H^+ - K^+) - ATPase$  of Gastric Mucosa
- D. Group Translocation
- E. ABC Transporters

#### 4 Ion Gradient-Driven Active Transport

- A.  $Na^+$ -Glucose Symport
- B. Lactose Permease
- C. ATP-ADP Translocator

#### 5 Neurotransmission

- A. Voltage-Gated Ion Channels
- B. Action Potentials
- C. Neurotransmitters and Their Receptors

Metabolism occurs within cells that are separated from their environments by plasma membranes. Eukaryotic cells, in addition, are compartmentalized by intracellular membranes that form the boundaries and internal structures of their various organelles. The nonpolar cores of biological membranes make them highly impermeable to most ionic and polar substances, so that *these substances can traverse membranes only through the action of specific transport proteins*. Such proteins are therefore required to mediate all transmembrane movements of ions, such as  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ , and  $Cl^-$ , as well as metabolites such as pyruvate, amino acids, sugars, and nucleotides, and even water (despite its relatively high permeability in bilayers; Section 12-2B). Transport proteins are also responsible for all biological electrochemical phenomena such as neurotransmission. In this chapter, we discuss the thermodynamics, kinetics, and chemical mechanisms of these membrane transport

systems and end with a discussion of the mechanism of neurotransmission.

### 1 THERMODYNAMICS OF TRANSPORT

As we saw in Section 3-4A, the free energy of a solute, A, varies with its concentration:

$$\bar{G}_A - \bar{G}_A^\circ = RT \ln[A] \quad [20.1]$$

where  $\bar{G}_A$  is the **chemical potential** (partial molar free energy) of A (the bar indicates quantity per mole) and  $\bar{G}_A^\circ$  is the chemical potential of its standard state. Strictly speaking, this equation applies only to ideal solutions; for non-ideal (real) solutions, molar concentrations must be replaced by activities (Appendix to Chapter 3). In the dilute (millimolar) solutions that are characteristic of laboratory conditions, the activity of a substance closely approaches its molar concentration in value. However, this is not the case in the highly concentrated cellular milieu (Appendix to Chapter 3). Yet it is difficult to determine the activity of a substance in a cellular compartment. Hence, in the following derivations, we shall make the simplifying assumption that activities are equal to molar concentrations.

The diffusion of a substance between two sides of a membrane

thermodynamically resembles a chemical equilibration. A difference in the concentrations of the substance on two sides of a membrane generates a chemical potential difference:

$$\Delta\bar{G}_A = \bar{G}_A(in) - \bar{G}_A(out) = RT \ln\left(\frac{[A]_{in}}{[A]_{out}}\right) \quad [20.2]$$

Consequently, if the concentration of A outside the membrane is greater than that inside,  $\Delta\bar{G}_A$  for the transfer of A from outside to inside will be negative and the spontaneous net flow of A will be inward. If, however, [A] is greater inside than outside,  $\Delta\bar{G}_A$  is positive and an inward net flow of A can only occur if an exergonic process, such as ATP hydrolysis, is coupled to it to make the overall free energy change negative.

### a. Membrane Potentials Arise from Transmembrane Concentration Differences of Ionic Substances

The permeabilities of biological membranes to ions such as  $H^+$ ,  $Na^+$ ,  $K^+$ ,  $Cl^-$ , and  $Ca^{2+}$  are controlled by specific membrane-embedded transport systems that we shall discuss in later sections. *The resulting charge differences across a biological membrane generate an electric potential difference,  $\Delta\Psi = \Psi(in) - \Psi(out)$ , where  $\Delta\Psi$  is termed the **membrane potential**.* Consequently, if A is ionic, Eq. [20.2] must be amended to include the electrical work required to transfer a mole of A across the membrane from outside to inside:

$$\Delta\bar{G}_A = RT \ln\left(\frac{[A]_{in}}{[A]_{out}}\right) + Z_A \mathcal{F} \Delta\Psi \quad [20.3]$$

where  $Z_A$  is the ionic charge of A;  $\mathcal{F}$ , the Faraday constant, is the charge of one mole of electrons ( $96,485 \text{ C} \cdot \text{mol}^{-1}$ ); and  $\bar{G}_A$  is now termed the **electrochemical potential** of A.

Membrane potentials in living cells can be measured directly with microelectrodes.  $\Delta\Psi$  values of  $-100 \text{ mV}$  (inside negative) are not uncommon (note that  $1 \text{ V} = 1 \text{ J} \cdot \text{C}^{-1}$ ). Thus the last term of Eq. [20.3] is often significant for ionic substances.

## 2 KINETICS AND MECHANISMS OF TRANSPORT

*Thermodynamics indicates whether a given transport process will be spontaneous but, as we saw for chemical and enzymatic reactions, provides no indication of the rates of these processes.* Kinetic analyses of transport processes together with mechanistic studies have nevertheless permitted these processes to be characterized. There are two types of transport processes: **nonmediated transport** and **mediated transport**. Nonmediated transport occurs through simple diffusion. In contrast, *mediated transport occurs through the action of specific carrier proteins* that are variously called **carriers**, **permeases**, **porters**, **translocases**, **translocators**, and **transporters**. Mediated transport is further classified into two categories depending on the thermodynamics of the system:

**1. Passive-mediated transport or facilitated diffusion** in which specific molecules flow from high concentration to low concentration so as to equilibrate their concentration gradients.

**2. Active transport** in which specific molecules are transported from low concentration to high concentration, that is, against their concentration gradients. Such an endergonic process must be coupled to a sufficiently exergonic process to make it favorable.

In this section, we consider the nature of nonmediated transport and then compare it to passive-mediated transport as exemplified by ionophores, porins, glucose transporters,  $K^+$  channels,  $Cl^-$  channels, and aquaporins. Active transport is examined in succeeding sections.

### A. Nonmediated Transport

*The driving force for the nonmediated flow of a substance A through a medium is A's electrochemical potential gradient.* This relationship is expressed by the **Nernst-Planck equation**:

$$J_A = -[A]U_A(d\bar{G}_A/dx) \quad [20.4]$$

where  $J_A$  is the **flux** (rate of passage per unit area) of A,  $x$  is distance,  $d\bar{G}_A/dx$  is the electrochemical potential gradient of A, and  $U_A$  is its **mobility** (velocity per unit force) in the medium. If we assume, for simplicity, that A is an uncharged molecule so that  $\bar{G}_A$  is given by Eq. [20.1], the Nernst-Planck equation reduces to

$$J_A = -D_A(d[A])/dx \quad [20.5]$$

where  $D_A \equiv RTU_A$  is the **diffusion coefficient** of A in the medium of interest. This is **Fick's first law of diffusion**, which states that *a substance diffuses in the direction that eliminates its concentration gradient,  $d[A]/dx$ , at a rate proportional to the magnitude of this gradient.*

For a membrane of thickness  $x$ , Eq. [20.5] is approximated by

$$J_A = \frac{D_A}{x}([A]_{out} - [A]_{in}) = P_A([A]_{out} - [A]_{in}) \quad [20.6]$$

where  $D_A$  is the diffusion coefficient of A inside the membrane and  $P_A = D_A/x$  is termed the membrane's **permeability coefficient** for A. The permeability coefficient is indicative of the solute's tendency to transfer from the aqueous solvent to the membrane's nonpolar core. It should therefore vary with the ratio of the solute's solubility in a nonpolar solvent resembling the membrane's core (e.g., olive oil) to that in water, a quantity known as the solute's **partition coefficient** between the two solvents. Indeed, the fluxes of many nonelectrolytes across erythrocyte membranes vary linearly with their concentration differences across the membrane as predicted by Eq. [20.6] (Fig. 20-1). Moreover, their permeability coefficients, as obtained from the slopes of plots such as Fig. 20-1, correlate rather well

**Figure 20-1** Linear relationship between diffusional flux ( $J_A$ ) and  $([A]_{out} - [A]_{in})$  across a semipermeable membrane. See Eq. [20.6].

**Figure 20-2 Permeability correlates with membrane solubility.** The permeability coefficients of various organic molecules in plasma membranes from the alga *Nitella mucronata* versus their partition coefficients between olive oil and water (a measure of a molecule's polarity). This more or less linear log-log plot

indicates that the rate-limiting step for the nonmediated entry of a molecule into a cell is its passage through the membrane's hydrophobic core. [Based on data from Collander, R., *Physiol. Plant.* **7**, 433–434 (1954).]

with their measured partition coefficients between nonpolar solvents and water (Fig. 20-2).

### B. Kinetics of Mediated Transport: Glucose Transport Into Erythrocytes

Despite the success of the foregoing model in predicting the rates at which many molecules pass through membranes, there are numerous combinations of solutes and membranes that do not obey Eq. [20.6]. The flux in such a system is not linear with the solute concentration difference across the corresponding membrane (Fig. 20-3) and, furthermore, the solute's permeability coefficient is much larger than is expected on the basis of its partition coefficient. Such behavior indicates that *these solutes are conveyed across membranes in complex with carrier molecules; that is, they undergo mediated transport.*

The system that transports glucose across the erythrocyte membrane provides a well-characterized example of passive-mediated transport: It invariably transports glucose down its concentration gradient but not at the rate predicted by Eq. [20.6]. Indeed, the **erythrocyte glucose transporter** exhibits four characteristics that differentiate mediated from nonmediated transport: (1) *speed and*

**Figure 20-3 Variation of glucose flux into human erythrocytes with the external glucose concentration at 5°C.** The black dots are experimentally determined data points, and the solid green line is computed from Eq. [20.7] with  $J_{\max} = 1.0 \times 10^{-6} \text{ mM} \cdot \text{cm} \cdot \text{s}^{-1}$  and  $K_M = 0.5 \text{ mM}$ . The nonmediated glucose flux increases linearly with [glucose] (Fig. 20-1) but would not visibly depart from the baseline on the scale of this drawing. [Based on data from Stein, W.D., *Movement of Molecules across Membranes*, p. 134, Academic Press (1967).]

specificity, (2) saturation kinetics, (3) susceptibility to competitive inhibition, and (4) susceptibility to chemical inactivation. In the following paragraphs we shall see how the erythrocyte glucose transporter exhibits these qualities.

### a. Speed and Specificity

Table 20-1 indicates that the permeability coefficients of D-glucose and D-mannitol in synthetic bilayers, and that of D-mannitol in the erythrocyte membrane, are in reasonable agreement with the values calculated from the diffusion and partition coefficients of these sugars between water and olive oil. However, the experimentally determined permeability coefficient for D-glucose in the erythrocyte membrane is four orders of magnitude greater than its predicted value. *The erythrocyte membrane must therefore contain a system that rapidly transports glucose and that can distinguish D-glucose from D-mannitol.*

### b. Saturation Kinetics

The concentration dependence of glucose transport indicates that its flux obeys the relationship

$$J_A = \frac{J_{\max} [A]}{K_M + [A]} \quad [20.7]$$

This **saturation function** has a familiar hyperbolic form (Fig. 20-3). We have seen it in the equation describing the binding of O<sub>2</sub> to myoglobin (Eq. [10.4]) and in the Michaelis–Menten equation describing the rates of enzymatic reactions (Eq. [14.24]). Here, as before,  $K_M$  may be defined operationally as the concentration of glucose when the transport flux is half of its maximal rate,  $J_{\max}/2$ . *This observation of **saturation kinetics** for glucose transport was the first evidence that a specific, saturable*

**Figure 20-4** General kinetic scheme for membrane transport. The scheme involves four steps: binding, transport, dissociation, and recovery. T is the transport protein whose binding site for solute A is located on either the inner or the outer side of the membrane at any one time.

**Table 20-1** Permeability Coefficients of Natural and Synthetic Membranes to D-Glucose and D-Mannitol at 25°C

Membrane Preparation	Permeability Coefficient (cm · s <sup>-1</sup> )	
	D-Glucose	D-Mannitol
Synthetic lipid bilayer	$2.4 \times 10^{-10}$	$4.4 \times 10^{-11}$
Calculated nonmediated diffusion	$4 \times 10^{-9}$	$3 \times 10^{-9}$
Intact human erythrocyte	$2.0 \times 10^{-4}$	$5 \times 10^{-9}$

Source: Jung, C.Y., in Surgenor, D. (Ed.), *The Red Blood Cell*, Vol. 2, p. 709, Academic Press (1975).

*number of sites on the membrane were involved in the transport of any substance.*

The transport process can be described by a simple four-step kinetic scheme involving binding, transport, dissociation, and recovery (Fig. 20-4). Its binding and dissociation steps are analogous to the recognition of a substrate and the release of product by an enzyme. The mechanisms of transport and recovery are discussed in Section 20-2D.

### c. Susceptibility to Competitive Inhibition

Many compounds structurally similar to D-glucose inhibit glucose transport. A double-reciprocal plot (Section 14-2B) for the flux of glucose into erythrocytes in the presence or absence of 6-O-benzyl-D-galactose (Fig. 20-5) shows behavior typical of competitive inhibition of glucose transport (competitive inhibition of enzymes is discussed in Section 14-3A). *Susceptibility to competitive inhibition indicates that there is a limited number of sites available for mediated transport.*

**Figure 20-5** Double-reciprocal plots for the net flux of glucose into erythrocytes in the presence and absence of 6-O-benzyl-D-galactose. The pattern is that of competitive inhibition. [After Barnett, J.E.G., Holman, G.D., Chalkley, R.A., and Munday, K.A., *Biochem. J.* **145**, 422 (1975).]

**d. Susceptibility to Chemical Inactivation**

Treatment of erythrocytes with  $\text{HgCl}_2$ , which reacts with protein sulfhydryl groups

and thus inactivates many enzymes, causes the rapid, saturatable flux of glucose to disappear so that its permeability constant approaches that of mannitol. *The erythrocyte glucose transport system's susceptibility to such protein-modifying agents indicates that it, in fact, is a protein.*

All of the above observations indicate that *glucose transport across the erythrocyte membrane is mediated by a limited number of protein carriers.* Before we discuss the mechanism of this transport system, however, we shall examine some simpler models of facilitated diffusion.

**C. Ionophores**

Our understanding of mediated transport has been enhanced by the study of **ionophores** (Greek: *phoros*, bearer), substances that vastly increase the permeability of membranes to particular ions.

**a. Ionophores May Be Carriers or Channel Formers**

Ionophores are organic molecules of diverse types, many of which are antibiotics of bacterial origin. Cells and organelles actively maintain concentration gradients of various ions across their membranes (Section 20-3A). The antibiotic properties of ionophores arise from their tendency to discharge these vital concentration gradients.

There are two types of ionophores:

**1. Carriers**, which increase the permeabilities of membranes to their selected ion by binding it, diffusing through the membrane, and releasing the ion on the other side (Fig. 20-6a). For net transport to occur, the uncomplexed ionophore must then return to the original side of the membrane ready to repeat the process. Carriers therefore share the common property that *their ionic complexes are soluble in nonpolar solvents.*

**2. Channel formers**, which form transmembrane channels or pores through which their selected ions can diffuse (Fig. 20-6b).

Both types of ionophores transport ions at a remarkable rate. For example, a single molecule of the carrier antibiotic **valinomycin** transports up to  $10^4 \text{ K}^+$  ions per second across a membrane. Channel formers have an even greater ion throughput; for example, each membrane channel composed of the antibiotic **gramicidin A** permits the passage of over  $10^7 \text{ K}^+$  ions  $\cdot \text{s}^{-1}$ . Clearly, the presence of either type of ionophore, even in small amounts, greatly increases the permeability of a membrane toward the specific ions transported. However, *since ionophores passively permit ions to diffuse across a membrane in either direction, their effect can only be to equilibrate the concentrations of their selected ions across the membrane.*

Carriers and channel formers are easily distinguished experimentally through differences in the temperature

**Figure 20-6** Ion transport modes of ionophores. (a) Carrier ionophores transport ions by diffusing through the lipid bilayer. (b) Channel-forming ionophores span the membrane with a channel through which ions can diffuse.

dependence of their action. Carriers depend on their ability to diffuse freely across the membrane. Consequently, cooling a membrane below its transition temperature (the temperature below which it becomes a gel-like solid; Section 12-2Cb) essentially eliminates its ionic permeability in the presence of carriers. In contrast, membrane permeability in the presence of channel formers is rather insensitive to temperature because, once in place, channel formers need not move to mediate ion transport.

**b. The  $\text{K}^+$ -Valinomycin Complex Has a Polar Interior and a Hydrophobic Exterior**

Valinomycin, a product of several strains of *Streptomyces* bacteria that specifically binds  $\text{K}^+$  (and the biologically unimportant  $\text{Rb}^+$ ), is perhaps the best characterized carrier ionophore. It is a **cyclic depsipeptide** that contains both D- and L-amino acid residues (Fig. 20-7a; a depsipeptide contains ester linkages as well as peptide bonds). The X-ray structure of valinomycin's  $\text{K}^+$  complex (Fig. 20-7b) indicates that the  $\text{K}^+$  is octahedrally coordinated by the carbonyl groups of its six Val residues, which also form its ester linkages. The cyclic, intramolecularly hydrogen bonded valinomycin backbone follows a zigzag path that surrounds the  $\text{K}^+$  coordination shell with a sinuous molecular bracelet. *Its methyl and isopropyl side chains project outward from the bracelet to provide the spheroidal complex with a hydrophobic exterior that makes it soluble in nonpolar solvents and in the hydrophobic cores of lipid bilayers.* Uncomplexed valinomycin has a more open conformation than its  $\text{K}^+$  complex, which presumably facilitates the rapid binding of  $\text{K}^+$ .

$\text{K}^+$  (ionic radius,  $r = 1.33 \text{ \AA}$ ) and  $\text{Rb}^+$  ( $r = 1.49 \text{ \AA}$ ) fit snugly into valinomycin's coordination site. However, the rigidity of the valinomycin complex makes this site too large to accommodate  $\text{Na}^+$  ( $r = 0.95 \text{ \AA}$ ) or  $\text{Li}^+$  ( $r = 0.60 \text{ \AA}$ ) properly; that is, valinomycin's six carbonyl oxygen atoms cannot simultaneously coordinate these ions. Complexes of these ions with water are therefore energetically more favorable than their complexes with valinomycin. This

**Figure 20-7 Valinomycin.** (a) This cyclic depsipeptide (has both ester and amide bonds) contains both D- and L-amino acids. (b) The X-ray structure of valinomycin in complex with a  $K^+$  ion shown in stick form colored according to atom type (C green, H white, N blue, O red, and  $K^+$  purple) and embedded in its molecular surface. Note that the  $K^+$  ion is octahedrally coordinated by the carbonyl atoms of valinomycin's six Val residues and that the surface of the complex is largely covered with methyl groups. [Based on an X-ray structure by Max Dobler, ETH, Zürich, Switzerland.]

accounts for valinomycin's 10,000-fold greater binding affinity for  $K^+$  over  $Na^+$ . No other substance discriminates more acutely between  $Na^+$  and  $K^+$ . A variety of carrier ionophores with similar characteristics but with different chemical structures and metal ion specificities are known.

#### D. Maltoporin: The Structural Basis of Sugar Discrimination

The **porins** are homotrimeric transmembrane proteins that facilitate the transport of small molecules and ions across the outer membranes of gram-negative bacteria

and mitochondria. Each subunit consists mainly of a 16- to 22-stranded antiparallel  $\beta$  barrel that forms a solvent-accessible channel along the barrel axis (Section 12-3Ad). In the *E. coli* OmpF porin (Fig. 12-27), this  $\sim 50$ -Å-long channel is constricted near its center to an elliptical pore that has a minimum cross section of  $7 \times 11$  Å. Consequently, solutes of more than  $\sim 600$  D are too large to pass through this channel.

**Maltoporin** is a bacterial porin that facilitates the diffusion of **maltodextrins** [the  $\alpha(1 \rightarrow 4)$ -linked glucose oligosaccharide degradation products of starch; e.g., maltose (Fig. 11-13)]. The X-ray structure of *E. coli* maltoporin (Fig. 20-8), determined by Tilman Schirmer, reveals that maltoporin is structurally similar to OmpF porin (Fig. 12-27), but with an 18-stranded rather than a 16-stranded antiparallel  $\beta$  barrel

**Figure 20-8 X-ray structure of a subunit of *E. coli* maltoporin in complex with a maltodextrin of six glucosyl units ( $Glc_6$ ).** The structure is viewed from within the bacterial outer membrane with its extracellular surface above. The polypeptide backbone is represented by a multithreaded ribbon (cyan). The  $Glc_6$  (only five of whose glucosyl units are observed) and the aromatic side chains lining the constricted region of the protein's centrally located transport channel are shown in space-filling form colored according to atom type (protein side chain C gold, glucosyl C green, N blue, and O red). Note the pronounced left-handed helical twist of the  $Glc_6$  unit. The so-called greasy slide, which consists of the aromatic side chains of six residues (W74' is contributed by an overhanging loop from an adjacent subunit), conforms closely to this shape. The side chain of Y118 protrudes into the channel opposite the greasy slide so as to allow only the transit of near planar groups such as glucosyl residues. The maltodextrin's hydroxyl groups are arranged in two strips flanking the greasy slide (only one of which is seen here) that form an extensive hydrogen bonded network with mainly charged side chains (not shown). [Based on an X-ray structure by Tilman Schirmer, University of Basel, Switzerland. PDBid 1MPO.]

enclosing each subunit's transport channel. Three long loops from the extracellular face of each maltoporin subunit fold inward into the barrel, thereby constricting the channel near the center of the membrane to a diameter of  $\sim 5 \text{ \AA}$  (which is considerably smaller than OmpF's aperture) and giving the channel an hourglasslike cross section. The channel is lined on one side with a series of six contiguous aromatic side chains arranged in a left-handed helical path that matches the left-handed helical curvature of  $\alpha$ -amylose (Fig. 11-18). This "greasy slide" extends from the channel's vestibule floor, through its constriction, to its periplasmic outlet.

The way in which oligosaccharides interact with maltoporin was investigated by determining the X-ray structures of maltoporin in its complexes with the maltodextrins Glc<sub>2</sub> (maltose), Glc<sub>3</sub>, Glc<sub>6</sub>, and sucrose (a glucose–fructose disaccharide; Fig. 11-13). Two Glc<sub>2</sub> molecules, one Glc<sub>3</sub> molecule, and a Glc<sub>5</sub> segment of Glc<sub>6</sub> occupied the maltoporin channel in contact and conformity with the greasy slide. Thus the hydrophobic faces of the maltodextrin's glycosyl residues stack on aromatic side chains, as is often observed in complexes of sugars with proteins. The glucose hydroxyl groups, which are arranged in two strips along opposite edges of the maltodextrins, form numerous hydrogen bonds with polar side chains that line these strips. Six of these seven polar side chains are charged, which probably strengthens their hydrogen bonds, as has also been observed in complexes of sugars with proteins. Tyr 118, which protrudes into the channel opposite the greasy slide, apparently functions as a steric barrier that permits only the passage of near-planar groups such as glucosyl residues. Thus the hook-shaped sucrose, which maltoporin transports quite slowly, binds to maltoporin with only its glucose residue inserted into the constricted part of the channel and its bulky fructose residue extending into the extracellular vestibule.

The above structures suggest a model for the selective transport of maltodextrins by maltoporin. At the start of the translocation process, the entering glucosyl residue interacts with the readily accessible end of the greasy slide in the extracellular vestibule of the channel. Further translocation along the helical channel requires the maltodextrin to follow a screwlike path that maintains the helical structure of the oligosaccharide, much like the movement of a bolt through a nut, thereby excluding molecules of comparable size that have different shapes. The translocation process is unlikely to encounter any large energy barrier due to the smooth surface of the greasy slide and the multiple polar groups at the channel constriction that would permit the essentially continuous exchange of hydrogen bonds as a maltodextrin moves through the constriction. Thus, maltoporin can be regarded as an enzyme that catalyzes the translocation of its substrate from one compartment to another.

### E. Passive-Mediated Glucose Transport

The human erythrocyte glucose transporter is a 492-residue glycoprotein which, according to sequence hydrophathy analysis (Sections 8-4C and 12-3Aa), has 12 membrane-

**Figure 20-9** Predicted secondary structure and membrane orientation of the glucose transporter.

spanning  $\alpha$  helices (Fig. 20-9) that are thought to form a hydrophobic cylinder. Five of these helices (3, 5, 7, 8, and 11) are amphipathic and hence most likely form a hydrophilic channel through which glucose is transported. A highly charged 66-residue domain located between helices 6 and 7, together with the 43-residue C-terminal domain, occupy the cytoplasm, whereas a 34-residue carbohydrate-bearing domain located between helices 1 and 2 is externally located. The glucose transporter accounts for 2% of erythrocyte membrane proteins and runs as band 4.5 in SDS-PAGE gels of erythrocyte membranes (Section 12-3Da; it is not visible on the gel depicted in Fig. 12-37 because the heterogeneity of its oligosaccharides makes the protein band diffuse).

#### a. Glucose Transport Occurs via a Gated Pore Mechanism

The erythrocyte glucose transporter has glucose binding sites on each side of the erythrocyte membrane but these have different steric requirements. Thus, John Barnett showed that 1-propylglucose will not bind to the extracellular surface of the glucose transporter but will bind to its cytoplasmic surface, whereas the converse is true of 6-propylglucose. He therefore proposed that the glucose transporter has two alternate conformations: one with the glucose binding site facing the external cell surface, requiring O1 contact and leaving O6 free, and the other with the glucose binding site facing the cytoplasm, requiring O6 contact and leaving O1 free (Fig. 20-10). *Transport apparently takes place by binding glucose to the protein on one face of the membrane, followed by a conformational change that closes the first site while exposing the other.* Glucose can then dissociate from the protein, having been translocated across the membrane. The transport cycle of this so-called **gated pore** is completed by the reversion of the glucose transporter to its initial conformation in the absence of bound glucose. Since this cycle can occur in either direction, the direction of net glucose transport is from high to low glucose concentrations. The glucose transporter thereby provides a means of equilibrating the glucose concentration across the erythrocyte

**Figure 20-10** Alternating conformation model for glucose transport. Such a system is also known as a “gated pore.” [After Baldwin, S.A. and Lienhard, G.E., *Trends Biochem. Sci.* 6, 210 (1981).] See the Animated Figures

membrane without any accompanying leakage of small molecules or ions.

### b. Eukaryotes Express a Variety of Glucose Transporters

The erythrocyte glucose transporter, known also as **GLUT1** (for *glucose transporter 1*) has a highly conserved amino acid sequence (98% sequence identity between humans and rats), which suggests that all segments of this protein are functionally significant. GLUT1 is expressed in most tissues, although in liver and muscle, tissues that are highly active in glucose transport, it is present in only tiny amounts. Three other glucose transporters, **GLUT2**, **GLUT3**, and **GLUT4**, have been well characterized (**GLUT5** was originally thought to be a glucose transporter but was later shown to be a fructose transporter). They are 40 to 65% identical to GLUT1 but have different tissue distributions. For example, GLUT2 is prominent in pancreatic  $\beta$  cells (which secrete insulin in response to increased [glucose] in blood; Section 18-3F), liver (where its defects result in symptoms resembling Type I glycogen storage disease; Section 18-4), and the intestine (which absorbs dietary glucose; Section 20-4A); GLUT3 is expressed in neurons and the placenta, and GLUT4 occurs mainly in muscle and fat cells. Note that the tissue distributions of these glucose transporters correlate with the response of these tissues to insulin: Liver is unresponsive to insulin (liver functions, in part, to maintain the level of blood glucose; Section 18-3Fb), whereas muscle and fat cells take up glucose when stimulated by insulin. Analysis of the human genome has identified eight other members of the GLUT family, **GLUT6** through **GLUT12** and **HMIT** (for  $H^+$ -coupled

*myo-inositol* transporter), although they have yet to be well characterized. All of them are members of the **major facilitator superfamily (MFS)**.

### c. Cellular Glucose Uptake Is Regulated through the Insulin-Sensitive Exocytosis/Endocytosis of Glucose Transporters

*Insulin stimulates fat and muscle cells to take up glucose.* Within 2 or 3 min after the administration of insulin to fat cells, the  $J_{\max}$  for passive-mediated glucose transport into these cells increases 20- to 30-fold, whereas the  $K_M$  remains constant. On withdrawal of the insulin, the rate of glucose uptake returns to its basal level within 20 min to 2 h depending on conditions. Neither the increase nor the decrease in the rate of glucose transport is affected by the presence of protein synthesis inhibitors, so that these observations cannot be a consequence of the synthesis of new glucose transporter or of a protein that inhibits it. How, then, does insulin regulate glucose transport?

GLUT4 is the dominant glucose transporter in skeletal muscle and adipose (fat) cells. In their *basal state*, these cells store most of their GLUT4 in specialized **GLUT4 storage vesicles**. On insulin stimulation, these vesicles fuse with the plasma membrane in a process known as **exocytosis** (Fig. 20-11). The consequent increased number of

**Figure 20-11** Regulation of glucose uptake in muscle and fat cells. Regulation is mediated by the insulin-stimulated exocytosis (the opposite of endocytosis; Section 12-5Bc) of membranous vesicles containing GLUT4 glucose transporters (*left*). On insulin withdrawal, the process reverses itself through endocytosis (*right*). See the Animated Figures

cell-surface glucose transporters results in a proportional increase in the cell's glucose uptake rate. On insulin withdrawal, the process is reversed through the endocytosis of plasma membrane-embedded glucose transporters. The deletion or mutation of GLUT4's N-terminal eight residues, particularly Phe 5, causes this transporter to accumulate in the plasma membrane. A Leu-Leu sequence and an acidic motif near GLUT4's C-terminus are likewise essential for its sequestration by the cell's endocytotic machinery. The way in which insulin controls this system, which accounts for most of insulin's effects on muscle and fat cells, is imperfectly understood. However, it is clear that this mechanism involves a tyrosine phosphorylation cascade that is triggered by the binding of insulin to the insulin receptor (Section 19-3Ac and Fig. 19-67) and includes the activation of a class IA phosphoinositide 3-kinase (PI3K; Section 19-4Da).

### F. $K^+$ Channels: Ion Discrimination

Potassium ions diffuse from the cytoplasm (where  $[K^+] > 100 \text{ mM}$ ) to the extracellular space (where  $[K^+] < 5 \text{ mM}$ ) through transmembrane proteins known as  **$K^+$  channels**, a process that underlies numerous important biological processes including maintenance of cellular osmotic balance, neurotransmission (Section 20-5), and signal transduction (Chapter 19). Although there is a large diversity of  $K^+$  channels, even within single organisms, all of them have similar sequences, exhibit comparable permeability characteristics, and most importantly, are at least 10,000-fold more permeable to  $K^+$  than  $Na^+$ . Since this high selectivity (around the same as that of valinomycin; Section 20-2Cb) implies energetically strong interactions between  $K^+$  and the protein, how can the  $K^+$  channel maintain its observed nearly diffusion-limited throughput rate of up to  $10^8$  ions per second (a  $10^4$ -fold greater rate than that of valinomycin)?

#### a. The X-Ray Structure of KcsA Reveals the Basis of $K^+$ Channel Selectivity

**KcsA**, the  $K^+$  channel from *Streptomyces lividans*, is a tetramer of identical 158-residue subunits. The X-ray structure of its N-terminal 125-residue segment, determined by Roderick MacKinnon, reveals that each KcsA subunit forms two nearly parallel transmembrane helices that are inclined  $\sim 25^\circ$  from the normal to the membrane plane and which are connected by an  $\sim 20$ -residue pore region (Fig. 20-12a). As is true of all known  $K^+$  channels, four such subunits associate to form a 4-fold rotationally symmetric assembly surrounding a central pore. The four inner (C-terminal) helices, which largely form the pore, pack against each other near the cytoplasmic side of the membrane much like the poles of an inverted teepee. The four outer helices, which face the lipid bilayer, buttress the inner helices but do not contact the adjacent outer helices. The pore regions, which each consist of a so-called turret, pore helix, and selectivity filter, occupy the open extracellular end of the teepee, with the pore helices fitting in between its poles. Several  $K^+$  ions and ordered

water molecules are seen to occupy the central pore (Figs. 20-12b and 20-13a).

The 45-Å-long central pore has variable width: It starts at its cytoplasmic side (Fig. 20-12b, bottom) as an  $\sim 6$ -Å-diameter and 18-Å-long tunnel, the so-called internal pore, whose entrance is lined with four anionic side chains that presumably help exclude anions (red area at the bottom of Fig. 20-12b). The internal pore then widens to form a cavity  $\sim 10$  Å in diameter. These regions of the central pore are both wide enough so that a  $K^+$  ion could move through them in its hydrated state. However, the upper part of the pore, the so-called selectivity filter, narrows to 3 Å, thereby forcing a transiting  $K^+$  ion to shed its waters of hydration. The walls of the internal pore and the cavity are lined with hydrophobic groups that interact minimally with diffusing ions (yellow area of the pore in Fig. 20-12b). However, the selectivity filter (red area of the pore at the top of Fig. 20-12b) is lined with closely spaced main chain carbonyl oxygens of residues (Fig. 20-13a, top) that are highly conserved in all  $K^+$  channels (their so-called signature sequence, TVGYG) and whose mutations disrupt the ability of the channel to discriminate between  $K^+$  and  $Na^+$  ions.

What is the function of the cavity? Energy calculations indicate that an ion moving through a narrow transmembrane pore must surmount an energy barrier that is maximal at the center of the membrane. The existence of the cavity reduces this electrostatic destabilization by surrounding the ion with polarizable water molecules (Fig. 20-12c). In addition, the C-terminal ends of the four pore helices point directly at the center of the cavity, so that their helix dipoles impose a negative electrostatic potential on the cavity that lowers the electrostatic barrier facing a cation crossing a lipid bilayer.

Remarkably, the  $K^+$  ion occupying the cavity is liganded by 8 ordered water molecules located at the corners of a square antiprism (a cube with one face twisted by  $45^\circ$  with respect to the opposite face) in which the  $K^+$  ion is centered (Fig. 20-13a, bottom;  $K^+$  in aqueous solution was known to have such an inner hydration shell but it had never before been visualized). The  $K^+$  ion is precisely centered in the cavity but yet its liganding water molecules are not in van der Waals contact with the walls of the cavity. Indeed, there is room in the cavity for  $\sim 40$  additional water molecules although they are unseen in the X-ray structure because they are disordered. This disorder arises because the cavity is lined with hydrophobic groups (mainly the side chains of Ile 100 and Phe 103; Fig. 20-13a) that interact but weakly with water molecules, thus allowing them to interact freely with the  $K^+$  ion so as to form an outer hydration shell. What, then, holds the hydrated  $K^+$  ion in place? Apparently, it is very weak indirect hydrogen bonds involving such protein groups as the hydroxyl group of Thr 107 and possibly carbonyl O atoms from the pore and inner helices. The absence of such an ordered hydration complex when  $Na^+$  rather than  $K^+$  occupies the cavity is indicative of a precise geometric match between the hydrated  $K^+$  and the cavity (the ionic radii of  $Na^+$  and  $K^+$  are 0.95 Å and

(a)

**Figure 20-12** X-ray structure of the KcsA K<sup>+</sup> channel.

(a) Ribbon diagram of the tetramer as viewed from within the plane of the membrane with the cytoplasm below and the extracellular region above. The protein's 4-fold axis of rotation is vertical and each of its identical subunits is differently colored. (b) A cutaway diagram viewed similarly to Part a in which the K<sup>+</sup> channel is represented by its solvent-accessible surface. The surface is colored according to its physical properties, with negatively charged areas red, uncharged areas white, positively charged areas blue, and hydrophobic areas of the central pore yellow. K<sup>+</sup> ions are represented by green spheres. (c) A schematic diagram indicating how the K<sup>+</sup> channel stabilizes a cation in the center of the membrane. The central pore's 10-Å-diameter aqueous cavity (which contains ~50 water molecules) stabilizes a K<sup>+</sup> ion (green spheres) in the otherwise hydrophobic membrane interior. In addition, the C-terminal ends of the pore helices (red) all point toward the K<sup>+</sup> ion, thereby electrostatically stabilizing it via their dipole moments (an  $\alpha$  helix has a strong dipole moment with its negative end pointing toward the helix's C-terminal end because the bond dipoles of its component carbonyl and N—H groups are

(b)

(c)

all parallel to the helix axis with their negative ends pointing toward its C-terminal end; Fig. 8-11). This effect is magnified by the low dielectric constant at the center of the membrane interior. Electrostatic calculations indicate that the cavity is tuned to maximally stabilize monovalent cations. [Courtesy of Roderick MacKinnon, Rockefeller University. PDBid 1BL8.]

1.33 Å, respectively). The cavity thereby provides a high effective K<sup>+</sup> concentration (~2M) at the center of the membrane and positions the K<sup>+</sup> ion on the pore axis ready to enter the selectivity filter.

How does the K<sup>+</sup> channel discriminate so acutely between K<sup>+</sup> and Na<sup>+</sup> ions? The main chain O atoms lining the

selectivity filter form a stack of rings (Fig. 20-13a, top) that provide a series of closely spaced sites of appropriate dimensions for coordinating dehydrated K<sup>+</sup> ions but not the smaller Na<sup>+</sup> ions. If the observed diameter of the selectivity filter is rigidly maintained, it would make the energy of a dehydrated Na<sup>+</sup> in the selectivity filter considerably

**Figure 20-13** Portions of the KcsA K<sup>+</sup> channel responsible for its ion selectivity viewed similarly to Fig. 20-12. (a) The X-ray structure of the residues forming the cavity (bottom) and selectivity filter (top) but with the front and back subunits omitted for clarity. Atoms are colored according to type, with C yellow, N blue, O red, and K<sup>+</sup> ions represented by green spheres. The water and protein O atoms that ligand the K<sup>+</sup> ions, including those contributed by the front and back subunits, are represented by red spheres. The coordination polyhedra formed by these O atoms are outlined by thin white lines. (b and c) Two alternative K<sup>+</sup> binding states of the selectivity filter, whose superposition is

presumed to be responsible for the electron density observed in the X-ray structure of KcsA. Atoms are colored as in Part a. Note that K<sup>+</sup> ions occupying the selectivity filter are interspersed with water molecules and that the K<sup>+</sup> ion immediately above the selectivity filter in Part b is farther above the protein than that in Part c. Hence these ions maintain a constant spacing while traversing the selectivity filter. [Part a based on an X-ray structure by, and Parts b and c courtesy of, Roderick MacKinnon, Rockefeller University. PDBid 1K4C.]  See Interactive Exercise 14

higher than that of hydrated Na<sup>+</sup> and thus account for the K<sup>+</sup> channel's high selectivity for K<sup>+</sup> ions. However, proteins are not static structures. In fact, both X-ray evidence and molecular dynamics simulations (Section 9-4a) indicate that, at physiological temperatures, the atoms forming

the KcsA selectivity filter undergo thermal excursions averaging  $\sim 1$  Å, fluctuations sufficient to snugly cradle Na<sup>+</sup> ions with little energetic cost. Instead, as free energy calculations have demonstrated, it is the electrostatic interactions of the carbonyl groups with the cation and with each

other that confer specificity for binding  $K^+$  ions. This is consistent with the observation that no  $Na^+$ -specific protein channels have evolved by refining the structure of a KcsA-like channel.

Since the selectivity filter appears designed to specifically bind  $K^+$  ions, how does it support such a high throughput of these ions (up to  $10^8$  ions  $\cdot$  s $^{-1}$ )? The structure in Fig. 20-13a shows what appear to be 4  $K^+$  ions in the selectivity filter and two more just outside it on its extracellular side. Such closely spaced positive ions would strongly repel one another and hence represent a high energy situation. However, a variety of evidence suggests that this structure is really a superposition of two sets of  $K^+$  ions, one with  $K^+$  ions at the topmost position in Fig. 20-13a and at positions 1 and 3 in the selectivity filter (Fig. 20-13b) and the second with  $K^+$  ions at the second position from the top in Fig. 20-13a and at positions 2 and 4 in the selectivity filter (Fig. 20-13c; X-ray structures can show overlapping atoms because they are averages of many unit cells). Within the selectivity filter, the positions not occupied by  $K^+$  ions are instead occupied by water molecules that coordinate the neighboring  $K^+$  ions.

The electron density that is represented as the topmost 4 water molecules in Fig. 20-13a is highly elongated in the vertical direction in this otherwise high-resolution (2.0 Å) structure. Hence it is thought to actually arise from 8 water molecules that ligand the topmost  $K^+$  ion in Fig. 20-13b to form an inner hydration shell similar to that of the  $K^+$  in the central cavity (Fig. 20-13a, *bottom*). Moreover, the four water molecules liganding the topmost  $K^+$  ion in Fig. 20-13c also contribute to this electron density. This latter ring of 4 waters provides half of the associated  $K^+$  ion's 8 liganding O atoms. The others are contributed by the carbonyl O atoms of the 4 Gly 79 residues, which are properly oriented to do so. It therefore appears that a dehydrated  $K^+$  ion transits the selectivity filter (moves to successive positions in Figs. 20-13b,c) by exchanging the properly spaced ligands extending from its walls and then exits into

the extracellular solution by exchanging protein ligands for water molecules and hence again acquiring a hydration shell. These ligands are spaced and oriented such that there is little free energy change (estimated to be  $<12$  kJ  $\cdot$  mol $^{-1}$ ) along the reaction coordinate via which a  $K^+$  ion transits the selectivity filter and enters the extracellular solution. The rapid dehydration of the  $K^+$  ion entering the selectivity channel from the cavity is, presumably, similarly managed. The essentially level free energy landscape throughout this process is, of course, conducive to the rapid transit of  $K^+$  ions through the ion channel and hence must be a product of evolutionary fine-tuning. Energy calculations indicate that mutual electrostatic repulsions between successive  $K^+$  ions, whose movements are concerted, balances the attractive interactions holding these ions in the selectivity filter and hence further facilitates their rapid transit.

### G. $Cl^-$ Channels

$Cl^-$  channels, which occur in all cell types, permit the transmembrane movement of chloride ions along their concentration gradient. In mammals, the extracellular  $Cl^-$  concentration is  $\sim 120$  mM and the intracellular concentration is  $\sim 4$  mM.

**ClC channels** form a large family of  $Cl^-$  channels that occur widely in all kingdoms of life. The X-ray structures of ClC channels from two species of bacteria, determined by Raimund Dutzler and MacKinnon, reveal, as biophysical measurements had previously suggested, that ClC channels are homodimers with each  $\sim 470$ -residue subunit forming an anion-selective pore (Fig. 20-14). Each subunit consists mainly of 18 mostly transmembrane  $\alpha$  helices that are remarkably tilted with respect to the membrane plane and have variable lengths compared to the transmembrane helices in other integral proteins of known structures. The N- and C-terminal halves of each subunit are related by a pseudo-2-fold axis parallel to the plane of the membrane and hence these two halves have opposite orientations in

**Figure 20-14** X-ray structure of the ClC  $Cl^-$  channel from *E. coli*. Each subunit of the homodimer contains 18  $\alpha$  helices of variable lengths. The subunits are drawn in ribbon form with one colored in rainbow order from its N-terminus (blue) to its C-terminus (red) and the other pink. The two  $Cl^-$  ions bound in the selectivity filter of each subunit are represented by pale

green spheres. (a) View from within the membrane with the extracellular surface above and the 2-fold axis relating the two subunits vertical. the membrane. This suggests that the CIC channel arose through gene duplication although its two halves exhibit only weak sequence similarity. Such antiparallel architecture occurs in several types of transmembrane transport proteins.

The CIC  $\text{Cl}^-$  channel is located at the interface between its N- and C-terminal halves. The specificity of the CIC channel results from an electrostatic field established by basic amino acids on the protein surface, which helps funnel anions toward the pore, and by a selectivity filter formed by the dipoles of several  $\alpha$  helices oriented with their positively charged N-terminal ends pointing toward the  $\text{Cl}^-$  ions (opposite to their orientation in the KcsA channel; Fig. 20-12c). This feature of the selectivity filter helps attract  $\text{Cl}^-$  ions, which are specifically coordinated by main chain amide nitrogens and side chain hydroxyls from Ser and Tyr residues. A positively charged residue such as Lys or Arg, if it were present in the selectivity filter, would probably bind a  $\text{Cl}^-$  ion too tightly to facilitate its rapid transit through the channel.

Unlike the KcsA channel, which has a central aqueous cavity (Fig. 20-12c), the  $\text{Cl}^-$  channel is hourglass-shaped, with its narrowest part in the center of the membrane and flanked by wider aqueous vestibules. A conserved Glu side chain projects into the pore. This group would repel other anions, suggesting that rapid  $\text{Cl}^-$  flux requires a protein conformational change in which the Glu side chain moves aside. Another anion could push the Glu away, which explains why some  $\text{Cl}^-$  channels appear to be activated by  $\text{Cl}^-$  ions; that is, they open in response to a certain concentration of  $\text{Cl}^-$  in the extracellular fluid.

## H. Aquaporins

The observed rapid passage of water molecules across biological membranes had long been assumed to occur via simple diffusion that was made possible by the small size and high concentration of water molecules. However, certain cells, such as erythrocytes and those of the kidney, can sustain particularly rapid rates of water transport, which are reversibly inhibited by mercuric ion. This suggested the existence of previously unrecognized protein pores that conduct water through biological membranes. The first of these proteins was discovered in 1992 by Peter Agre, who named them **aquaporins**.

Aquaporins occur widely in all kingdoms of life. Plants have up to 50 different aquaporins, which is indicative of the importance of water transport to plant physiology. The 13 known mammalian aquaporins, **AQP0** through **AQP12**, are selectively expressed at high levels in tissues that rapidly transport water, such as kidneys, salivary glands, sweat glands, and lacrimal glands (which produce tears). In fact, kidneys alone employ seven different aquaporins, each with specific locations and regulatory properties. There are two subfamilies of aquaporins: those that permit only the passage of water and those that also allow the passage of small neutral molecules such as glycerol and urea and hence are named **aquaglyceroporins**. Aquaporins permit the passage of water molecules at extremely high rates (up

to  $\sim 3 \times 10^9$  per second) but, quite surprisingly, not protons (really hydronium ions;  $\text{H}_3\text{O}^+$ ), whose free passage would discharge the cell's membrane potential.

All known aquaporins are homotetramers, each of whose subunits contain a water-transport channel (unlike  $\text{K}^+$  channels, whose transport channels lie along their 4-fold axes; Section 20-2Fa). The X-ray structure of the most extensively studied aquaporin, bovine **AQP1**, reveals that each of its 271-residue subunits consists mainly of six transmembrane  $\alpha$  helices plus two shorter helices that are components of loops that extend only to the middle of the bilayer (Fig. 20-15a). Other aquaporins of known structure have similar structures. The N- and C-terminal halves of aquaporins are  $\sim 20\%$  identical in sequence and related by a pseudo-2-fold axis of symmetry that is parallel to the plane of the membrane (Fig. 20-15a). Evidently, these segments arose through gene duplication. CIC channels have a similar antiparallel architecture (Section 20-2G).

The helices in AQP1 surround an elongated hourglass-shaped channel through the membrane (Fig. 20-16) that at its narrowest point is  $\sim 2.8 \text{ \AA}$  wide, the diameter of a water molecule. This region is formed by the side chains of the highly conserved Phe 58, His 182, and Arg 197 (Fig. 20-15b, *lower right subunit*) and hence is known as the **ar/R constriction** (ar for *aromatic*). The side chain of Cys 191, which also forms part of the ar/R constriction, is the site of channel blockage by the binding of mercuric ion. For a water molecule to pass through the ar/R constriction, it must shed its shell of associated water molecules. This is facilitated by the side chains of His 182 and Arg 197. The water molecules then continue in single file through the  $\sim 25\text{-\AA}$ -long and  $\sim 4\text{-\AA}$ -wide portion of the channel, which is lined with hydrophobic groups interspersed with several hydrogen bonding groups. The water molecules' lack of interaction with the hydrophobic walls of the channel facilitates their rapid passage through the channel, whereas the hydrogen bonding groups reduce the energy barrier to water transport. It is the balancing of these opposing factors that is presumably responsible for aquaporin's selective permeability to water and its rapid transport rate.

If water were to pass through aquaporin as an uninterrupted chain of hydrogen-bonded molecules, then protons would pass even more rapidly through the channel via proton jumping (Fig. 2-10; in order for more than one such series of proton jumps to occur, each water molecule in the chain must reorient such that one of its protons forms a hydrogen bond to the next water molecule in the chain). However, aquaporin interrupts this process by forming hydrogen bonds from the side chain  $\text{NH}_2$  groups of the highly conserved Asn 78 and Asn 194, to a water molecule that is centrally located in the channel (Fig. 20-16). Consequently, although this central water molecule can readily donate hydrogen bonds to its neighboring water molecules in the hydrogen bonded chain, it cannot accept one from them nor reorient, thereby severing the "proton-conducting wire." Both of these Asn residues occur in the sequence Asn-Pro-Ala (NPA), the signature sequence of aquaporins, in which the Ala is located at the N-terminal end of each of the half-spanning helices.

**Figure 20-15** X-ray structure of the aquaporin AQP1 from bovine erythrocytes. (a) Ribbon diagram of an aquaporin subunit colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The view is from within the membrane with its extracellular surface above and along the subunit's pseudo-2-fold axis of symmetry. Note that the two helices closest to the viewer (*orange* and *blue-green*) are both portions of loops that extend only to the center of the bilayer. The four water molecules that occupy the central portion of AQP1's water-transport channel are represented by red spheres. (b) View of the aquaporin homotetramer from the extracellular surface along its

4-fold axis. The subunit in the upper right is drawn in space-filling form with C green, N blue, and O red; that in the upper left is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*), that in the lower left is represented by its solvent-accessible surface; and that in the lower right displays the side chains forming the ar/R constriction (those of Phe 58, His 182, Cys 191, and Arg 197) in stick form. Each subunit forms a water-transport channel, which is most clearly visible in the subunit drawn in space-filling form. [Based on an X-ray structure by Bing Jap, University of California at Berkeley. PDBid 1J4N.]

**Figure 20-16** Schematic drawing of the water-conducting pore of bovine aquaporin AQP1. The pore is viewed from within the membrane with the extracellular surface above. The positions of residues critical for preventing the passage of protons, other ions, and small molecule solutes are indicated. [Courtesy of Peter Agre, Johns Hopkins School of Medicine.]

### 3 ATP-DRIVEN ACTIVE TRANSPORT

Mediated transport is categorized according to the stoichiometry of the transport process (Fig. 20-17):

1. A **uniport** involves the movement of a single molecule at a time. Maltoporin and GLUT1 are uniports.
2. A **symport** simultaneously transports two different molecules in the same direction.
3. An **antiport** simultaneously transports two different molecules in opposite directions.

The electrical character of ion transport is further specified as:

1. **Electroneutral** (electrically silent) if there is simultaneous charge neutralization, either by symport of oppositely charged ions or antiport of similarly charged ions. Aquaporin is electroneutral.
2. **Electrogenic** if the transport process results in a charge separation across the membrane. KcsA and ClC are electrogenic.

Since the glucose concentration in blood plasma is generally higher than that in cells, GLUT1 normally transports glucose into the erythrocyte, where it is metabolized via glycolysis. Many substances, however, are available on one side of a membrane in lower concentrations than are required on the other side of the membrane. Such substances must be actively and selectively transported across the membrane against their concentration gradients.

*Active transport is an endergonic process that is often coupled to the hydrolysis of ATP.* How is this coupling accomplished? In endergonic biosynthetic reactions, it often occurs through the direct phosphorylation of a substrate by

**Figure 20-17** Uniport, symport, and antiport translocation systems.

ATP; for example, the formation of UTP in the synthesis of glycogen (Section 18-2B). Membrane transport, however, is usually a physical rather than a chemical process; the transported molecule is not chemically altered. Determining the mechanism by which the free energy of ATP hydrolysis is coupled to endergonic physical processes has therefore been a challenging problem.

Three types of ATP hydrolyzing, transmembrane proteins have been identified that actively transport cations:

1. **P-type ATPases** are located mostly in plasma membranes and are so named because they are phosphorylated by ATP during the transport process. P-type ATPases are known that transport  $H^+$ ,  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ ,  $Cu^{2+}$ ,  $Cd^{2+}$ , and  $Mg^{2+}$  against their concentration gradients. They are distinguished from the other types of cation-translocating ATPases by their inhibition by **vanadate** ( $VO_4^{3-}$ , a phosphate analog; see Problem 8 in this chapter).

2. **F-type ATPases ( $F_1F_0$ )** function to translocate protons into mitochondria and bacterial cells, which in turn powers ATP synthesis. They are discussed in Section 22-3C.

3. **V-type ATPases** are located in plant vacuolar membranes and acidic vesicles, such as animal lysosomes, and are homologous to the F-type ATPases.

Anions are transported by a fourth type of ATPase, the so-called **A-type ATPases**. In this section, we discuss P-type ATPases. We also examine a bacterial active transport process, in which the molecules transported are concomitantly phosphorylated, and the ABC transporters, which transport a wide variety of substances across membranes. In the next section, we study secondary active transport systems, so called because they utilize the free energy of electrochemical gradients generated by ion-pumping ATPases to transport ions and neutral molecules against their concentration gradients.

#### A. $(Na^+ - K^+) - ATPase$ of Plasma Membranes

One of the most thoroughly studied active transport systems is the  $(Na^+ - K^+) - ATPase$  of plasma membranes. This transmembrane protein, which was first isolated in 1957 by Jens Skou, is often called the  $(Na^+ - K^+) - pump$  because it pumps  $Na^+$  out of and  $K^+$  into the cell with the concomitant hydrolysis of intracellular ATP. Unlike most P-type ATPases, which are monomeric,  $(Na^+ - K^+) - ATPases$  consist of  $\alpha$  and  $\beta$  subunits. The  $\sim 1000$ -residue, nonglycosylated  $\alpha$  subunit contains the enzyme's ATP and ion binding sites. It is highly conserved (98% identical among mammals) and homologous to single-subunit P-type ATPases such as the  $Ca^{2+} - ATPase$  (Section 20-3B). The  $\sim 300$ -residue, glycosylated  $\beta$  subunit facilitates the correct insertion of the  $\alpha$  subunit into the plasma membrane and has been implicated in  $K^+$  transport.

The overall stoichiometry of the  $(Na^+ - K^+) - ATPase$  reaction is

The  $(\text{Na}^+-\text{K}^+)$ -ATPase is therefore an electrogenic antiport: Three positive charges exit the cell for every two that enter. This extrusion of  $\text{Na}^+$  enables animal cells to control their water content osmotically; without functioning  $(\text{Na}^+-\text{K}^+)$  pumps, animal cells, which lack cell walls, would swell and burst (recall that lipid bilayers are permeable to  $\text{H}_2\text{O}$ ; Section 12-2Ba). Moreover, the electrochemical potential gradient generated by the  $(\text{Na}^+-\text{K}^+)$  pump is responsible for the electrical excitability of nerve cells (Section 20-5Ba) and provides the free energy for the active transport of glucose and amino acids into some cells (Section 20-4A). In fact, *all cells expend a large fraction of the ATP they produce (typically 30% and up to 70% in nerve cells) to maintain their required cytosolic  $\text{Na}^+$  and  $\text{K}^+$  concentrations.*

### a. ATP Phosphorylates an Essential Asp during the Transport Process

The free energy of ATP hydrolysis powers the endergonic transport of  $\text{Na}^+$  and  $\text{K}^+$  against an electrochemical gradient. In coupling these two processes, a kinetic barrier must somehow be erected against the “downhill” transport of  $\text{Na}^+$  and  $\text{K}^+$  along their ion concentration gradients, while simultaneously facilitating their “uphill” transport. In addition, futile ATP hydrolysis must be prevented in the absence of uphill transport. How the enzyme does so is by no means well understood, although many of its mechanistic aspects have been elucidated.

**Figure 20-18** Reaction of  $[^3\text{H}]\text{NaBH}_4$  with phosphorylated  $(\text{Na}^+-\text{K}^+)$ -ATPase. The isolation of  $[^3\text{H}]$ homoserine following acid hydrolysis of the protein indicates that the original phosphorylated amino acid residue is Asp.

A key discovery was that the protein is phosphorylated by ATP in the presence of  $\text{Na}^+$  during the transport process. The use of chemical trapping techniques demonstrated that this phosphorylation occurs on an Asp residue to form a highly reactive **aspartyl phosphate** intermediate. For instance, sodium borohydride reduces acyl phosphates to their corresponding alcohols. In the case of an aspartyl phosphate residue, the alcohol is **homoserine**. By use of  $[^3\text{H}]\text{NaBH}_4$  to reduce the phosphorylated enzyme, radioactive homoserine was, in fact, isolated from the acid hydrolysate (Fig. 20-18). The phosphorylated residue, Asp 374, begins the highly conserved sequence DKTG that occurs in the central region of the polypeptide chain.

### b. The $(\text{Na}^+-\text{K}^+)$ -ATPase Has Two Major Conformational States

The observations that ATP phosphorylates the  $(\text{Na}^+-\text{K}^+)$ -ATPase only in the presence of  $\text{Na}^+$ , while the aspartyl phosphate residue is only subject to hydrolysis in the presence of  $\text{K}^+$ , led to the realization that *the enzyme has two major conformational states, E1 and E2*. These states have different tertiary structures, different catalytic activities, and different ligand specificities:

1. E1 has an inward-facing high-affinity  $\text{Na}^+$  binding site ( $K_M = 0.2 \text{ mM}$ , well below the intracellular  $[\text{Na}^+]$ ) and reacts with ATP to form the activated product  $\text{E1} \sim \text{P}$  only when  $\text{Na}^+$  is bound.
2.  $\text{E2} \sim \text{P}$  has an outward-facing high-affinity  $\text{K}^+$  binding site ( $K_M = 0.05 \text{ M}$ , well below the extracellular  $[\text{K}^+]$ ) and hydrolyzes to form  $\text{P}_i + \text{E2}$  only when  $\text{K}^+$  is bound.

### c. An Ordered Sequential Kinetic Reaction Mechanism Accounts for the Coupling of Active Transport with ATP Hydrolysis

The  $(\text{Na}^+-\text{K}^+)$ -ATPase is thought to operate in accordance with the following ordered sequential reaction scheme (Fig. 20-19):

1.  $\text{E1} \cdot \text{ATP}$ , which acquired its ATP inside the cell, binds  $3\text{Na}^+$  to yield the ternary complex  $\text{E1} \cdot \text{ATP} \cdot 3\text{Na}^+$ .
2. The ternary complex reacts to form the “high-energy” aspartyl phosphate intermediate  $\text{E1} \sim \text{P} \cdot 3\text{Na}^+$ .
3. This “high-energy” intermediate relaxes to its “low-energy” conformation,  $\text{E2} \sim \text{P} \cdot 3\text{Na}^+$ , and releases its bound  $\text{Na}^+$  outside the cell; that is,  $\text{Na}^+$  is transported through the membrane.
4.  $\text{E2} \sim \text{P}$  binds  $2\text{K}^+$  from outside the cell to form  $\text{E2} \sim \text{P} \cdot 2\text{K}^+$ .
5. The phosphate group is hydrolyzed, yielding  $\text{E2} \cdot 2\text{K}^+$ .
6.  $\text{E2} \cdot 2\text{K}^+$  changes conformation to E1, binds ATP, and releases its  $2\text{K}^+$  inside the cell, thereby completing the transport cycle.

The enzyme appears to have only one set of cation binding sites, which apparently changes both its orientation and its specificity during the course of the transport cycle.

**Figure 20-19** Kinetic scheme for the active transport of  $\text{Na}^+$  and  $\text{K}^+$  by  $(\text{Na}^+-\text{K}^+)\text{-ATPase}$ . Here (*in*) refers to the cytosol and (*out*) refers to the exterior of the cell.

The obligatory order of the reaction requires that ATP can be hydrolyzed only as  $\text{Na}^+$  is transported “uphill.” Conversely,  $\text{Na}^+$  can be transported “downhill” only if ATP is concomitantly synthesized. Consequently, although each of the above reaction steps is, in fact, individually reversible, the cycle, as is diagrammed in Fig. 20-19, circulates only in the clockwise direction under normal physiological conditions; that is, ATP hydrolysis and ion transport are coupled processes. Note that the **vectorial** (unidirectional) nature of the reaction cycle results from the alternation of the steps of the exergonic ATP hydrolysis reaction (Step 2, Step 5, and ATP binding in Step 6) with the steps of the endergonic ion transport process (Step 1, Steps 3 + 4, and  $\text{K}^+$  release in Step 6). Thus, neither reaction can go to completion unless the other one also does.

#### d. Mutual Destabilization Accounts for the Rate of $\text{Na}^+$ and $\text{K}^+$ Transport

The above ordered kinetic mechanism accounts only for the coupling of active transport with ATP hydrolysis. *In order to maintain a reasonable rate of transport, the free energies of all its intermediates must be roughly equal. If some intermediates were much more stable than others, the stable intermediates would accumulate, thereby severely reducing the overall transport rate.* For example, in order for  $\text{Na}^+$  to be transported out of the cell, uphill, its binding must be strong to E1 on the inside and weak to E2 on the outside. Strong binding means greater stability and a potential bottleneck. This difficulty is counteracted by the phosphorylation of  $\text{E1} \cdot 3\text{Na}^+$  and its subsequent conformational change to yield the low  $\text{Na}^+$  affinity  $\text{E2-P}$  (Steps 2 and 3, Fig. 20-19). Likewise, the strong binding of  $\text{K}^+$  to  $\text{E2-P}$  on the outside is attenuated by its dephosphorylation and conformational change to yield the low  $\text{K}^+$  affinity E1 (Steps 5

and 6, Fig. 20-19). It is these mutual destabilizations that permit  $\text{Na}^+$  and  $\text{K}^+$  to be transported at a rapid rate.

#### e. The X-Ray Structure of the $(\text{Na}^+-\text{K}^+)\text{-ATPase}$

Chikashi Toyoshima determined the X-ray structure of shark  $(\text{Na}^+-\text{K}^+)\text{-ATPase}$  in complex with  $\text{K}^+$  ions, an  $\text{MgF}_4^{2-}$  ion (a  $\text{P}_i$  mimic), and a 74-residue subunit named FXYP that functions as a tissue-specific regulator. This X-ray structure (Fig. 20-20) is that of the  $\text{E2-P} \cdot 2\text{K}^+$  complex (Fig. 20-19). The  $\alpha$  subunit of this  $\sim 160\text{-\AA}$ -long protein consists of a transmembrane domain (M) composed of 10 helices ( $\alpha\text{M1}-\alpha\text{M10}$ ) of varied lengths and, from top to bottom in Fig. 20-20, three well-separated cytoplasmic domains: the nucleotide-binding domain (N), which binds ATP; the actuator domain (A), so named because it participates in the transmission of major conformational changes (see below); and the phosphorylation domain (P), which contains the protein’s phosphorylatable Asp residue. The  $\beta$  subunit’s single transmembrane helix is tilted  $\sim 32^\circ$  from the normal to the plane of the membrane. The FXYP subunit also has a single transmembrane helix but it is nearly perpendicular to the plane of the membrane. The  $\text{MgF}_4^{2-}$  ion marks the ATPase’s catalytic site and is coordinated by conserved residues from both its A and P domains. Two  $\text{K}^+$  ions are located  $\sim 4.1\text{ \AA}$  apart in a common binding cavity near the center of the  $\alpha$  subunit’s transmembrane domain that is formed, in large part, by the partial unwinding of helices  $\alpha\text{M5}$  and  $\alpha\text{M7}$ , and where they are each liganded by several main chain carbonyl and side chain oxygen atoms. The same cavity is implicated in binding the three  $\text{Na}^+$  ions bound to the enzyme’s E1 form, with two of these binding sites probably formed by the same side chains that coordinate the  $\text{K}^+$  ions and the third such site formed, in part, by the side chains of the  $\alpha$  subunit’s

**Figure 20-20** X-ray structure of shark  $(\text{Na}^+-\text{K}^+)\text{-ATPase}$  in complex with  $\text{K}^+$  and  $\text{MgF}_4^{2-}$  ions. The protein is drawn in ribbon form viewed parallel to the plane of the membrane (gray box) with the cytosol above. The  $\alpha$  subunit is colored in rainbow order from its N-terminus (blue) to its C-terminus (red), the  $\beta$  subunit is magenta, and the FXYD subunit is brown. The  $\alpha$  subunit's bound  $\text{K}^+$  and  $\text{MgF}_4^{2-}$  ions are drawn in space-filling form with K light blue, Mg pink, and F light green. [Based on an X-ray structure by Chikashi Toyoshima, University of Tokyo, Japan. PDBid 2ZXE.]

**Figure 20-21** Cardiac glycosides. (a) The leaves of the purple foxglove plant are the source of the heart muscle stimulant digitalis. [iStockphoto.] (b) Digitalin, a major component of

small C-terminal helix. No channel leading from either side of the membrane to this binding cavity is apparent.

#### f. Cardiac Glycosides Specifically Inhibit the $(\text{Na}^+-\text{K}^+)\text{-ATPase}$

Study of the  $(\text{Na}^+-\text{K}^+)\text{-ATPase}$  has been greatly facilitated by the use of **cardiac glycosides** (also called **cardiotonic steroids**), natural products that increase the intensity of heart muscle contraction. Indeed, **digitalis**, an extract of purple foxglove leaves (Fig. 20-21a), which contains a mixture of cardiac glycosides including **digitalin** (Fig. 20-21b), has been used to treat congestive heart failure for centuries. The cardiac glycoside **ouabain** (pronounced wabane; Fig. 20-21b), a product of the East African ouabio tree, has been long used as an arrow poison. These two steroids, which are still among the most commonly prescribed cardiac drugs, inhibit the  $(\text{Na}^+-\text{K}^+)\text{-ATPase}$  by binding strongly to an externally exposed portion of the enzyme (the drugs are ineffective when injected inside cells) so as to block Step 5 in Fig. 20-19. The resultant increase in intracellular  $[\text{Na}^+]$  stimulates the cardiac  $(\text{Na}^+-\text{Ca}^{2+})$  antiporter system, which pumps  $\text{Na}^+$  out of and  $\text{Ca}^{2+}$  into the cell (Section 22-1Bb). The increased cytosolic  $[\text{Ca}^{2+}]$  boosts the  $[\text{Ca}^{2+}]$  in other cellular organelles, principally the sarcoplasmic reticulum (**SR**). Thus, the release of  $\text{Ca}^{2+}$  to trigger

(b)

digitalis, and ouabain, a cardiac glycoside isolated from the East African ouabio tree, are among the most commonly prescribed cardiac drugs.

muscle contraction (Section 35-3Cb) produces a larger than normal increase in cytosolic  $[Ca^{2+}]$ , thereby intensifying the force of cardiac muscle contraction. Ouabain, which was once thought to be produced only by plants, is now known to also be an animal hormone that is secreted by the adrenal cortex and functions to regulate cell  $[Na^+]$  and overall body salt and water balance.

### B. $Ca^{2+}$ -ATPase

Calcium ion often acts as a second messenger in a manner similar to cAMP (Section 19-4). Transient increases in cytosolic  $[Ca^{2+}]$  trigger numerous cellular responses, including muscle contraction (Section 35-3Ca), release of neurotransmitters (Section 20-5Cb), and, as we have seen, glycogen

**Figure 20-22 Mechanism of SERCA based on four X-ray structures.** (a) The X-ray structures of the SERCA complexes indicated in lightface are models for the conformational states indicated in boldface. These states roughly correspond to those in the corners of Fig. 20-19. The structures are represented by their ribbon diagrams embedded in their transparent surfaces (gray) as viewed along the plane of the membrane with the cytosol above. The A, N, and P domains are colored yellow, red, and blue, the transmembrane helices M1-2, M3-4, M5-6, and M7-10 are purple, green, tan, and gray, and bound  $Ca^{2+}$  ions are represented by gray spheres. ATP and its mimics are drawn in stick form with C green, N blue, O red, and P orange. A conserved TGES

sequence is drawn in space-filling form in magenta. In the lower right drawing, the position of the lipid bilayer is indicated by the yellow rectangle. (b) Schematic diagram of the conformational changes made by SERCA during its catalytic cycle. The protein components are colored as in Part a except that helices M5-10 are all tan and  $Ca^{2+}$  ions are represented by green spheres. In addition, protons are represented by gray spheres, and the residues that ligand  $Ca^{2+}$  ions in the binding cavity are indicated by red spheres. [Modified from drawings by Poul Nissen, University of Aarhus, Denmark. PDBids 2C88, 3BA6, 3B9B, and 3B9R.]

breakdown (Section 18-3Ce). Moreover,  $\text{Ca}^{2+}$  is an important activator of oxidative metabolism (Section 22-4).

The use of phosphate as a basic energy currency requires cells to maintain a low internal  $[\text{Ca}^{2+}]$  because, for example,  $\text{Ca}_3(\text{PO}_4)_2$  has a maximum aqueous solubility of  $65 \mu\text{M}$ . Thus, the  $[\text{Ca}^{2+}]$  in the cytosol ( $\sim 0.1 \mu\text{M}$ ) is four orders of magnitude less than it is in the extracellular spaces ( $\sim 1500 \mu\text{M}$ ). This large concentration gradient is maintained by the active transport of  $\text{Ca}^{2+}$  across the plasma membrane, the endoplasmic reticulum (ER; SR in muscle), and the mitochondrial inner membrane. We discuss the mitochondrial system in Section 22-1Bb. The plasma membrane and sarco(endo)plasmic reticulum each contain a P-type  $\text{Ca}^{2+}$ -ATPase ( $\text{Ca}^{2+}$  pump) that actively pumps  $\text{Ca}^{2+}$  out of the cytosol at the expense of ATP hydrolysis. Their kinetic mechanisms match that of the  $(\text{Na}^+-\text{K}^+)$ -ATPase (Fig. 20-19) except that two  $\text{Ca}^{2+}$  ions replace the three  $\text{Na}^+$  ions, two to three  $\text{H}^+$  ions replace the three  $\text{K}^+$  ions, and (*out*) refers to the outside of the cell for plasma membrane  $\text{Ca}^{2+}$ -ATPase or to the lumen of the sarco(endo)plasmic reticulum for the  $\text{Ca}^{2+}$ -ATPase of that membrane.

### a. X-Ray Structures of the $\text{Ca}^{2+}$ -ATPase Suggest Its Mechanism

The X-ray structures of the 994-residue  $\text{Ca}^{2+}$ -ATPase from rabbit muscle sarcoplasmic reticulum [also known as **SERCA** for sarco(endo)plasmic reticulum  $\text{Ca}^{2+}$ -ATPase] in its complexes with a variety of analogs of ATP and its components have been determined, the first of which were reported by Toyoshima. SERCA, which constitutes 90% of SR membrane protein, is a 140-Å-long monomeric protein that closely resembles the  $\alpha$  subunit of the  $(\text{Na}^+-\text{K}^+)$ -ATPase (Fig. 20-20). It contains a 10-helix transmembrane domain (M), an actuator domain (A), a nucleotide-binding domain (N) to which the ATP binds, and a phosphorylation domain (P) that contains the phosphorylatable Asp 351. The two  $\text{Ca}^{2+}$  ions are bound in a cavity, similar to that in the  $(\text{Na}^+-\text{K}^+)$ -ATPase, which is formed, in large part, by the disruption of helices M4 and M6 in this region.

Four of these structures, all determined by Poul Nissen, collectively suggest a mechanism of action of P-type ATPases resulting from a vectorial series of conformational changes driven by ATP binding, hydrolysis, and release (Figs. 20-22):

1. Let us start with the X-ray structure of SERCA in its E2 conformation in complex with the inhibitor **thapsigargin (TG)** (Fig. 22-23a), which stabilizes SERCA's E2 state, and the nonhydrolyzable ATP analog **adenosine-5'-( $\beta,\gamma$ -methylene)triphosphate (AMPPCP)** (Fig. 22-23b). This structure provides a model for the E2  $\cdot$  ATP state (Fig. 20-22, *upper left*). The exchange of 2 to 3 protons for 2 cytosolic  $\text{Ca}^{2+}$  ions causes a rotation of the A domain that occludes the binding cavity. This activates the ATPase catalytic site to phosphorylate Asp 351 yielding ADP, which releases the N domain from the P domain due to the cleavage of the ATP's  $\beta,\gamma$ -phosphodiester bond that had previously linked these two domains. A model for the resulting  $\text{Ca}_2\text{E1}\sim\text{P}\cdot\text{ADP}$  state is provided by the X-ray structure of SERCA in its E1 state with Asp 351

(a) **Thapsigargin (TG)**

(b) **Adenosine-5'-( $\beta,\gamma$ -methylene)triphosphate (AMPPCP)**

(c) **Adenosine-5'-( $\beta$ -amino)diphosphate (AMPPN)**

**Figure 20-23 Molecular formulas of several SERCA inhibitors.** (a) Thapsigargin (TG), a product of the plant *Thapsia garganica*, (b) AMPPCP, and (c) AMPPN.

phosphorylated [via a “high energy” bond, which is represented by a squiggle ( $\sim$ )] and in complex with the ADP analog **adenosine-5'-( $\beta$ -amino)diphosphate (AMPPN)** (Fig. 22-23c).

2. The A domain rotates toward the phosphorylation site, thereby contacting the P and N domains. This movement pushes down on the M3–4 segment and pulls up on the M1–2 segment, thereby separating the lower portions of these segments from that of the M5–6 segment. This exposes the  $\text{Ca}^{2+}$ -binding cavity to the lumen of the SR and forces apart the residues that had bound the  $\text{Ca}^{2+}$  ions in the cavity, resulting in the release of these ions into the lumen. A model for this E2–P state is provided by the X-ray structure of SERCA in its E2 state in which  $\text{BeF}_3^-$  is covalently linked to Asp 351 to form a mimic of a phosphate group.

3. Two or three protons bind in the lumenally exposed binding cavity. This, together with the exchange of the ADP bound to the N domain for ATP results in movements of transmembrane helices that again occludes the cavity from the lumen. A model for the resulting E2–P\*  $\cdot$  ATP state [where the star (\*) is indicative of a transition state] is provided by the X-ray structure of SERCA in its E2 state in

complex with AMPPCP and  $\text{AlF}_4^-$ , which is covalently linked to Asp 351 to form a trigonal bipyramidal mimic of the hydrolytic transition state (Fig. 16-6b).

4. The dephosphorylation of Asp 351, as stimulated by the previous binding of ATP, motivates conformational changes that opens a channel to the cytosol that permits the exchange of protons with  $\text{Ca}^{2+}$  ions, thereby completing the catalytic cycle.

This mechanism explains how P-type ATPases transport cations against their steep electrochemical gradients.

### b. Calmodulin Regulates the Plasma Membrane $\text{Ca}^{2+}$ Pump

For a cell to maintain its proper physiological state, it must regulate the activities of its ion pumps precisely. *The regulation of the  $\text{Ca}^{2+}$  pump in the plasma membrane is controlled by the level of  $\text{Ca}^{2+}$  through the mediation of calmodulin (CaM).* This ubiquitous eukaryotic  $\text{Ca}^{2+}$ -binding protein participates in numerous cellular regulatory processes including, as we have seen, the control of glyco-gen metabolism (Section 18-3Ce).

*$\text{Ca}^{2+}$ -Calmodulin activates the  $\text{Ca}^{2+}$ -ATPase of plasma membranes.* The activation, as deduced from the study of the isolated ATPase, results in a decrease in its  $K_M$  for  $\text{Ca}^{2+}$  from 20 to 0.5  $\mu\text{M}$ .  $\text{Ca}^{2+}$ -CaM activates the  $\text{Ca}^{2+}$  pump by binding to an inhibitory polypeptide segment of the pump in a manner similar to the way in which  $\text{Ca}^{2+}$ -CaM activates its target protein kinases (Section 18-3Cf). Evidence supporting this mechanism comes from proteolytically excising the  $\text{Ca}^{2+}$  pump's CaM-binding polypeptide, yielding a truncated pump that is active even in the absence of CaM. Synthetic peptides corresponding to this CaM-binding segment not only bind  $\text{Ca}^{2+}$ -CaM but inhibit the truncated pump by increasing its  $K_M$  for  $\text{Ca}^{2+}$  and decreasing its  $V_{\text{max}}$ . This suggests that, in the absence of  $\text{Ca}^{2+}$ -CaM, the CaM-binding segment of the pump interacts with the rest of the protein so as to inhibit its activity. When the  $\text{Ca}^{2+}$  concentration increases,  $\text{Ca}^{2+}$ -CaM forms and binds to the CaM-binding segment of the pump in a way that causes it to dissociate from the rest of the pump, thereby relieving the inhibition.

Now we can see how  $\text{Ca}^{2+}$  regulates its own cytoplasmic concentration: At  $\text{Ca}^{2+}$  levels below calmodulin's  $\sim 1 \mu\text{M}$  dissociation constant for  $\text{Ca}^{2+}$ , the  $\text{Ca}^{2+}$ -ATPase is relatively inactive due to autoinhibition by its CaM-binding segment. If, however, the  $[\text{Ca}^{2+}]$  rises to this level,  $\text{Ca}^{2+}$  binds to calmodulin, which, in turn, binds to the CaM-binding segment so as to relieve the inhibition, thereby activating the  $\text{Ca}^{2+}$  pump:

(CaM\* indicates activated calmodulin). This interaction decreases the pump's  $K_M$  for  $\text{Ca}^{2+}$  to below the ambient  $[\text{Ca}^{2+}]$ , thereby causing  $\text{Ca}^{2+}$  to be pumped out of the cytosol. When the  $[\text{Ca}^{2+}]$  decreases sufficiently,  $\text{Ca}^{2+}$  dissociates from calmodulin and this series of events reverses itself, thereby inactivating the pump. The entire system is therefore analogous to a basement sump pump that is automatically activated by a float when the water reaches a preset level.

### C. ( $\text{H}^+$ - $\text{K}^+$ )-ATPase of Gastric Mucosa

Parietal cells of the mammalian gastric mucosa secrete HCl at a concentration of 0.15M (pH 0.8). Since the cytosolic pH of these cells is 7.4, this represents a pH difference of 6.6 units, the largest known in eukaryotic cells. The secreted protons are derived from the intracellular hydration of  $\text{CO}_2$  by carbonic anhydrase:

The secretion of  $\text{H}^+$  involves the participation of an ( $\text{H}^+$ - $\text{K}^+$ )-ATPase, an electroneutral antiport with structure and properties similar to that of  $\text{Ca}^{2+}$ -ATPase. Like other P-type ATPases, it is phosphorylated during the transport process. In this case, however, the  $\text{K}^+$ , which enters the cell as  $\text{H}^+$  is pumped out, is subsequently externalized by its electroneutral cotransport with  $\text{Cl}^-$ . HCl is therefore the overall transported product.

#### a. Cimetidine and Omeprazole Prevent Gastric Ulcers and Heartburn

For many years, effective treatment of **peptic ulcers**, which was a frequently fatal condition caused by the attack of stomach acid on the gastric mucosa, often required surgical removal of the affected portions of the stomach or sometimes the entire stomach. The discovery, by James Black, of **cimetidine**,

which inhibits stomach acid secretion, all but eliminated the need for this dangerous and debilitating surgery. The ( $\text{H}^+$ - $\text{K}^+$ )-ATPase of the gastric mucosa is activated by histamine stimulation of the  **$\text{H}_2$ -receptor** in a process mediated by cAMP. Cimetidine (trade name **Tagamet**), which became available in 1976, was the first of several widely used drugs that competitively inhibit the binding of histamine to this receptor. These drugs likewise alleviate the symptoms of **gastroesophageal reflux disease (GERD)**, commonly known as **heartburn**, which is caused by the regurgitation of stomach acid into the esophagus, a widespread and painful condition that, when chronic, can damage the esophagus and cause esophageal cancer. Heartburn can also be relieved by antacids but the effects of cimetidine and its analogs are longer lasting (6–10 hours vs 1–2 hours for antacids, although the former require  $\sim 30$  minutes to take effect) and can be taken before meals to prevent heartburn from occurring. A drawback of most of these substances is that they inhibit several cytochrome P450s and thereby interfere with the metabolism of numerous widely used drugs (Section 15-4Bc).

**Omeprazole** (trade names **Prilosec** and **Nexium**),

**Omeprazole**

directly inhibits the  $(\text{H}^+-\text{K}^+)$ -ATPase by forming an adduct with the side chain of its Cys 831. Since its introduction in 1989, omeprazole has greatly supplanted the use of cimetidine and its analogs due to the irreversible nature of its inhibition (which reduces acid secretion by up to 99%) and its lack of drug–drug interactions. Hence, omeprazole is presently one of the most frequently used drugs worldwide.

#### D. Group Translocation

**Group translocation** is a variation of ATP-driven active transport that most bacteria use to import certain sugars. It is required for many bacterial processes, both useful and harmful (to humans), such as those that produce cheese, soy sauce, and dental cavities. *It differs from active transport in that the molecules transported are simultaneously modified chemically.* The most extensively studied example of group translocation is the **phosphoenolpyruvate-dependent phosphotransferase system (PTS)** of *E. coli* discovered by Saul Roseman in 1964. Phosphoenolpyruvate (PEP) is the phosphoryl donor for this system (recall that PEP is the “high-

**Table 20-2** Some of the Sugars Transported by the *E. coli* PEP-Dependent Phosphotransferase System (PTS)

Glucose	Galactitol
Fructose	Mannitol
Mannose	Sorbitol
<i>N</i> -Acetylglucosamine	Xylitol

energy” phosphoryl donor for ATP synthesis in the pyruvate kinase reaction of glycolysis; Section 17-2J). *The PTS simultaneously transports and phosphorylates sugars. Since the cell membrane is impermeable to sugar phosphates, once they enter the cell, they remain there.* Some of the PTS-transported sugars are listed in Table 20-2.

The PTS system involves two soluble cytoplasmic proteins, **Enzyme I (EI)** and **HPr** (for *histidine*-containing phosphocarrier protein), which participate in the transport of all sugars (Fig. 20-24). In addition, for each sugar the system transports, there is a specific transmembrane transport protein **EII**, which consists of at least three functional components: two that are cytoplasmic, **EIIA** and **EIIB**, and a transmembrane channel, **EIIC**. These three components associate differently in different EII's. In *E. coli*, for example, EIIA, EIIB, and EIIC are separate subunits in cellobiose-specific EII; EIIB and EIIC are covalently linked and EIIA is separate in glucose-specific EII; and all three components are present on a single peptide in mannitol-specific EII.

Glucose transport, which resembles that of other sugars, involves the transfer of a phosphoryl group from PEP to glucose with net inversion of configuration about the phosphorus atom. Since each phosphoryl transfer involves inversion (Section 16-2A), an odd number of transfers must be

**Figure 20-24** Transport of glucose by the PEP-dependent phosphotransferase system (PTS). HPr and EI are cytoplasmic proteins common to all sugars transported. EIIA<sup>glc</sup> and EIIBC<sup>glc</sup> are proteins specific for glucose. EIIA<sup>glc</sup> inhibits non-PTS transport proteins such as the lactose permease (Section 20-4B) and enzymes such as glycerol kinase. Adenylate cyclase is activated by the presence of EIIA<sup>glc</sup>~P (or possibly inhibited by the presence of EIIA<sup>glc</sup>).

involved. Four phosphorylated protein intermediates have been identified, indicative of five phosphoryl transfers:

The transport process occurs as follows (Fig. 20-24):

1. PEP phosphorylates EI at N3 ( $N_\epsilon$ ) of His 189 to form a reactive phosphohistidine adduct.

**Phosphohistidine residue**

2. The phosphoryl group is transferred to N1 ( $N_\delta$ ) of His 15 on HPr. His is apparently a favored phosphoryl group acceptor in phosphoryl-transfer reactions. It also participates in the phosphoglycerate mutase reaction of glycolysis (Section 17-2Ha).

3.  $\text{HPr} \sim \text{P}$  continues the phosphoryl-transfer chain by phosphorylating  $\text{EIIA}^{glc}$  at N3 of His 90.

4. The fourth phosphoryl transfer is to Cys 421 of  $\text{EIIBC}^{glc}$ .

5. The phosphoryl group is finally transferred from  $\text{EIIBC}^{glc}$  to glucose, which, in the process, is transported across the membrane by  $\text{EIIC}^{glc}$ . Glucose is released into the cytoplasm only after it has been phosphorylated to glucose-6-phosphate (G6P).

Thus the transport of glucose is driven by its indirect, exergonic phosphorylation by PEP. The PTS is an energy-efficient system since only one ATP equivalent is required to both transport and phosphorylate glucose. When the active transport and phosphorylation steps occur separately, as they do in many cells, two ATPs are hydrolyzed per glucose processed.

#### a. Bacterial Sugar Transport Is Genetically Regulated

The PTS is more complex than the other transport systems we have encountered, probably because it is part of a complicated regulatory system governing sugar transport. When any of the sugars transported by the PTS is abundant, the active transport of sugars, which enter the cell via other transport systems, is inhibited. This inhibition, called **catabolite repression**, is mediated through the cAMP concentration (Section 31-3C). cAMP activates the transcription of genes that encode various sugar transport proteins, including **lactose permease** (Section 20-4B). The presence of glucose results in a decrease in [cAMP], which, in turn, represses the synthesis of these other sugar transport proteins. Direct inhibition of the sugar transport proteins themselves, as well as of certain enzymes, also occurs.

The mechanism for control of [cAMP] is thought to reside in  $\text{EIIA}^{glc}$ , which is transiently phosphorylated in Step 3 of the PTS transport process (Fig. 20-24). When glucose is plentiful, this enzyme is present mostly in its dephospho form since

$\text{EIIA}^{glc} \sim \text{P}$  rapidly transfers its phosphoryl group through  $\text{EIIBC}^{glc}$  to glucose. Under these conditions, adenylate cyclase is inactive, although whether dephospho  $\text{EIIA}^{glc}$  inhibits this enzyme or  $\text{EIIA}^{glc} \sim \text{P}$  activates it is unclear. However, dephospho  $\text{EIIA}^{glc}$  binds to and inhibits many non-PTS transporters and enzymes that participate in the metabolism of sugars other than glucose (the metabolite of choice for many bacteria), including lactose permease and **glycerol kinase** (Section 17-5A). In the absence of glucose,  $\text{EIIA}^{glc}$  is converted to  $\text{EIIA}^{glc} \sim \text{P}$ , thereby relieving the inhibition of non-PTS transporters. In addition, adenylate cyclase is activated to produce cAMP, which, in turn, induces the increased production of some of the non-PTS transporters and enzymes that  $\text{EIIA}^{glc}$  inhibits. This is a form of energy conservation for the cell. Why synthesize the proteins required for the transport and metabolism of all sugars when the metabolism of only one sugar at a time will do?

#### b. The X-Ray Structure of $\text{EIIA}^{glc}$ in Complex with Glycerol Kinase

The X-ray structures of  $\text{EIIA}^{glc}$ , both alone and in complex with one of its regulatory targets, glycerol kinase, which were determined by James Remington and Roseman, have revealed how  $\text{EIIA}^{glc}$  inhibits at least some of its targets and why  $\text{EIIA}^{glc} \sim \text{P}$  does not do so.  $\text{EIIA}^{glc}$  contains two His residues, His 75 and His 90, that are required for phosphoryl transfer, although only His 90 is necessary for  $\text{EIIA}^{glc}$  to accept a phosphate from HPr. The X-ray structure of *E. coli*  $\text{EIIA}^{glc}$  alone reveals that these two His residues lie in close proximity (their N3 atoms are 3.3 Å apart) in a depression on the surface of the protein that is surrounded by a remarkable  $\sim 18$ -Å-diameter hydrophobic ring consisting of 11 Phe, Val, and Ile side chains.

The X-ray structure of  $\text{EIIA}^{glc}$  in complex with glycerol kinase (Fig. 20-25) confirms that this hydrophobic gasket is indeed the site of interaction between the two proteins and reveals how the phosphorylation of His 90 disrupts this interaction. The two active site His residues, which are completely buried within the hydrophobic interaction surface, coordinate a previously unanticipated  $\text{Zn}^{2+}$  ion, which is additionally coordinated to Glu 478 of glycerol kinase and a water molecule. The phosphorylation of  $\text{EIIA}^{glc}$  His 90 to yield  $\text{EIIA}^{glc} \sim \text{P}$  no doubt disrupts this intermolecular interaction, thereby releasing glycerol kinase and reversing its inhibition.

### E. ABC Transporters

The **ABC transporters**, which widely occur in all kingdoms of life, are named for their highly conserved,  $\sim 100$ -residue ATP-binding cassette. They form a large superfamily of transmembrane proteins that collectively transport a wide variety of substances across membranes, including ions, sugars, peptides, lipids, metabolites, and numerous toxins and drugs. For example, the acquired resistance of cancer cells to chemotherapeutic agents is often due to the selection of cells that overexpress the ABC transporter named **multidrug resistance (MDR) transporter** (also called **P-glycoprotein**), which pumps a wide assortment of amphiphilic substances—including many drugs—out of the cell. Similar proteins in bacteria are, in many cases, responsible for their antibiotic resistance. The

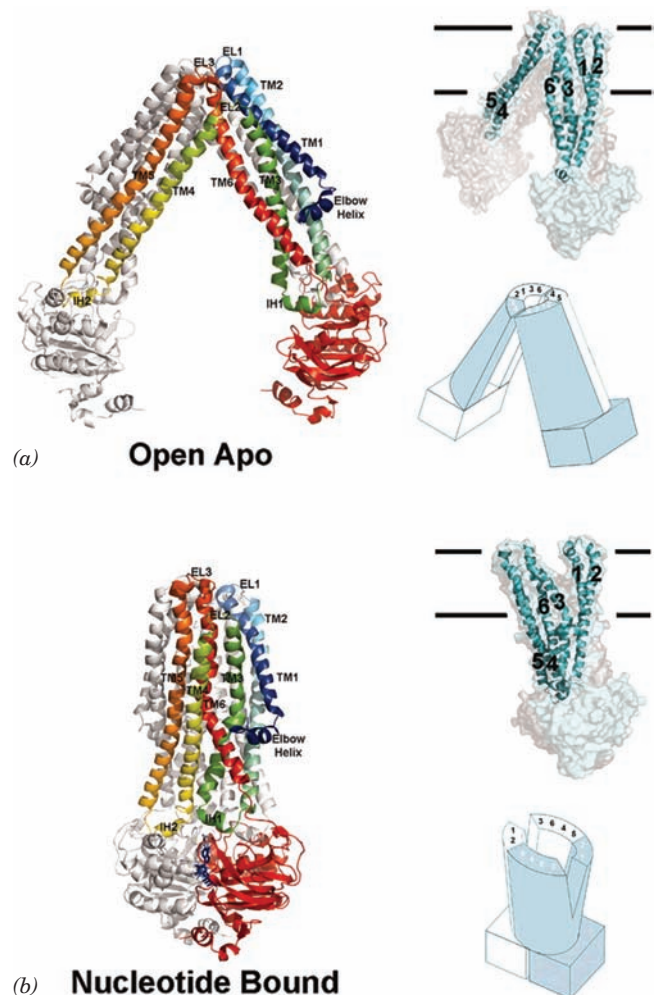

**Figure 20-25** X-ray structure of *E. coli* EIIA<sup>glc</sup> (yellow, a 168-residue monomer) in complex with one of its regulatory targets, glycerol kinase (blue, a tetramer of identical 501-residue subunits). The two proteins associate, in part, by tetrahedrally coordinating a Zn<sup>2+</sup> ion via the side chains of His 75 and His 90 of EIIA<sup>glc</sup>, a carboxylate oxygen from Glu 478 of glycerol kinase, and a water molecule. These groups are shown in ball-and-stick form with C gray, N blue, O red, and Zn<sup>2+</sup> white. The Zn<sup>2+</sup>-mediated interaction between EIIA<sup>glc</sup> and glycerol kinase inactivates glycerol kinase, presumably through an induced-fit mechanism. The phosphorylation of EIIA<sup>glc</sup> at His 90 disrupts this interaction, thereby reversing the inhibition of glycerol kinase. [Courtesy of James Remington, University of Oregon. PDBid 1GLA.]

human genome encodes 48 ABC transporters and their defects are responsible for several inherited diseases including cystic fibrosis (Section 12-4Bf), Tangier disease (Section 12-5Cd), and **adrenoleukodystrophy** (Section 25-2Fa).

ABC transporters consist minimally of four modules: two highly conserved cytosolic nucleotide-binding domains, and two transmembrane domains that typically contain six transmembrane helices each. In bacteria, the four domains are contained on two or four separate polypeptides. In eukaryotes, a single polypeptide includes all four domains. Bacterial ABC transporters mediate the import as well as the export of a variety of compounds, whereas their eukaryotic counterparts function only as exporters that transport molecules out of the cell or into intracellular compartments such as the ER.

The ABC transporter of gram-negative bacteria named **MsbA**, a close homolog of the MDR transporter, functions to transport lipopolysaccharides (Section 11-3Bc) and their

glycolipid component, **lipid A**, from the cytoplasmic leaflet of the plasma membrane to its periplasmic leaflet; that is, MsbA is a flippase (Section 12-4Aa). X-ray structures of MsbA, determined by Geoffrey Chang, reveal that its two identical 582-residue subunits are extensively intertwined (Fig. 20-26). In the nucleotide-free (apo) structure (Fig. 20-26a), each subunit contributes four of its six transmembrane helices

**Figure 20-26** X-ray structures of the ABC transporter MsbA. (a) *E. coli* MsbA in the absence of bound nucleotide (Open Apo). (b) *S. typhimurium* MsbA in complex with AMPPNP (Nucleotide Bound). On the left, the structures are drawn in ribbon form viewed along the plane of the membrane with the periplasmic space above. One subunit in each homodimer is colored in rainbow order from N-terminus (blue) to C-terminus (red) and the other subunit is gray. The AMPPNP in Part b is drawn in stick form in blue. Transmembrane helices (TM1–6), extracellular loops (EL1–3), and intracellular helices (IH1–2) are labeled. On the upper right, the structures are drawn as semitransparent surface diagrams with one subunit cyan and the other gray, and showing the embedded transmembrane helices (1–6) of the cyan subunit. The horizontal lines delineate the lipid bilayer. On the lower right, the structures are represented by schematic diagrams with one subunit cyan and the other white and with the positions of the transmembrane helices indicated. [Modified from drawings by Geoffrey Chang, The Scripps Research Institute, La Jolla, California. PDBids 3B5W and 3B60.]

(TM1–3 and 6) to one leg of the  $\Lambda$ -shaped homodimer and two (TM4–5) to the other leg. The nucleotide-binding domains (NBDs; globular portions at the end of each leg) are  $\sim 50$  Å apart. However, in its complex with AMPPNP (Fig. 20-26b), the two legs of the  $\Lambda$  have swung together by  $\sim 60^\circ$  to bring the NBDs into contact, with TM3 and 6 having swung away from TM1–2 to contact TM4–5. This opens a space between the subunits on the periplasmic side of the membrane, which presumably permits a lipopolysaccharide that had bound to MsbA from the cytosolic leaflet of the plasma membrane to be released into its periplasmic leaflet. The unidirectional transport of substrate may be facilitated by the different sizes of the openings, and possibly, by a reduced affinity for substrate by MsbA's ATP-bound form.

#### 4 ION GRADIENT-DRIVEN ACTIVE TRANSPORT

Systems such as the  $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$  discussed above utilize the free energy of ATP hydrolysis to generate electrochemical potential gradients across membranes. Conversely, *the free energy stored in an electrochemical potential gradient may be harnessed to power various endergonic physiological processes*. Indeed, ATP synthesis by mitochondria and chloroplasts is powered by the dissipation of proton gradients generated through electron transport and photosynthesis (Sections 22-3C and 24-2D). In this section we discuss active transport processes that are driven by the dissipation of ion gradients. We consider three examples: intestinal uptake of glucose by the  **$\text{Na}^+$ -glucose symport**,

uptake of lactose by *E. coli* **lactose permease**, and the mitochondrial **ATP-ADP translocator**.

##### A. $\text{Na}^+$ -Glucose Symport

Nutritionally derived glucose is actively concentrated in **brush border cells** of the intestinal epithelium by an  $\text{Na}^+$ -dependent symport (Fig. 20-27). It is transported from these cells to the circulatory system via GLUT2 (Section 20-2Eb), a passive-mediated glucose uniport located on the capillary side of the cell. Note that *although the immediate energy source for glucose transport from the intestine is the  $\text{Na}^+$  gradient, it is really the free energy of ATP hydrolysis that powers this process through the maintenance of the  $\text{Na}^+$  gradient by the  $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$* . Nevertheless, since glucose enhances  $\text{Na}^+$  resorption, which in turn osmotically enhances water resorption, glucose (possibly as sucrose), in addition to salt and water, should be fed to individuals suffering from severe salt and water losses resulting from diarrhea (drinking only water or a salt solution is ineffective since they are rapidly excreted from the gastrointestinal tract). It is estimated that the introduction of this simple and inexpensive treatment, called **oral rehydration therapy**, has decreased the annual number of human deaths from severe diarrhea, mostly in children in less-developed countries, from 4.6 to 1.6 million.

##### a. Active and Passive Glucose Transporters Exhibit Differential Drug Susceptibilities

The two glucose transport systems are inhibited by different drugs:

##### 1. Phlorizin inhibits $\text{Na}^+$ -dependent glucose transport.

**Figure 20-27** Glucose transport in the intestinal epithelium.

The brushlike villi lining the small intestine greatly increase its surface area (a), thereby facilitating the absorption of nutrients. The brush border cells from which the villi are formed (b) actively concentrate glucose from the intestinal lumen in

symport with  $\text{Na}^+$  (c), a process that is driven by the  $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ , which is located on the capillary side of the cell and functions to maintain a low internal  $[\text{Na}^+]$ . The glucose is exported to the bloodstream via GLUT2, a separate passive-mediated uniport system (Section 20-2Eb).

**Figure 20-28** The  $\text{Na}^+$ -glucose symport system represented as a Random Bi Bi kinetic mechanism. Binding of  $\text{Na}^+$  increases the affinity of the transporter for glucose to such an extent that the upper pathway is heavily favored.  $T_o$  and  $T_i$ , respectively,

represent the transport protein with its binding sites exposed to the outer and inner surfaces of the membrane. [After Crane, R.K. and Dorando, F.C., in Martonosi, A.N. (Ed.), *Membranes and Transport*, Vol. 2, p. 154, Plenum Press (1982).]

**2. Cytochalasin B** inhibits  $\text{Na}^+$ -independent glucose transport.

Phlorizin binds only to the external surface of the  $\text{Na}^+$ -dependent glucose transporter, whereas cytochalasin B binds to the cytoplasmic surface of the  $\text{Na}^+$ -independent glucose transporter. This further indicates that these proteins are asymmetrically inserted into membranes. The use of these inhibitors permits the actions of the two glucose transporters to be studied separately in intact cells.

Kinetic studies indicate that the  $\text{Na}^+$ -glucose symport binds its substrates,  $\text{Na}^+$  and glucose, in random order (Fig. 20-28), although binding of  $\text{Na}^+$  increases the affinity of the transporter for glucose to such an extent that the upper pathway is heavily favored. Only when both substrates are bound, however, does the protein change its conformation to expose the binding sites to the inside of the cell. This requirement for concomitant  $\text{Na}^+$  and glucose transport prevents the wasteful dissipation of the  $\text{Na}^+$  gradient.

## B. Lactose Permease

Gram-negative bacteria such as *E. coli* contain several active transport systems for concentrating sugars. We have already discussed the PTS system. Another extensively studied system, **lactose permease** (also known as **galactoside permease**), utilizes the proton gradient across the bacterial cell membrane to cotransport  $\text{H}^+$  and lactose (Fig. 20-29). The proton gradient is metabolically generated through oxidative metabolism in a manner similar to that in mitochondria (Section 22-3B). The electrochemical potential gradient created by both these systems is used mainly to drive the synthesis of ATP.

**Figure 20-29** Kinetic mechanism of lactose permease in *E. coli*.  $\text{H}^+$  binds first to E-2 outside the cell, followed by lactose. They are released in random order from E-1 inside the cell. E-2 must bind both lactose and  $\text{H}^+$  in order to change conformation to E-1, thereby cotransporting these substances into the cell. E-1 changes conformation to E-2 when neither lactose nor  $\text{H}^+$  is bound, thus completing the transport cycle.

How do we know that lactose transport requires the presence of a proton gradient? Ronald Kaback has established the requirement for this gradient through the following observations:

1. The rate of lactose transport into bacteria is increased enormously by the addition of D-lactate, an energy source for transmembrane proton gradient generation. Conversely, inhibitors of oxidative metabolism, such as cyanide, block both the formation of the proton gradient and lactose transport.

2. 2,4-Dinitrophenol, a proton ionophore that dissipates transmembrane proton gradients (Section 22-3D), inhibits lactose transport into both intact bacteria and membrane vesicles.

3. The fluorescence of **dansylaminoethylthiogalactoside**,

a competitive inhibitor of lactose transport, is sensitive to the polarity of its environment and thus changes when it binds to lactose permease. Fluorescence measurements indicate that it does not bind to membrane vesicles that contain lactose permease in the absence of a transmembrane proton gradient.

### a. Lactose Permease Has Two Major Conformational States

Lactose permease is a 417-residue monomer that, like the mammalian glucose transporters (Section 20-2Eb), to which it is distantly related, consists mainly of 12 transmembrane helices with its N- and C-termini in the cytoplasm. Like the  $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$ , it has two major conformational states (Fig. 20-29):

1. E-1, which has a low-affinity lactose binding site facing the interior of the cell.
2. E-2, which has a high-affinity lactose binding site facing the exterior of the cell.

E-1 and E-2 can interconvert only when their  $\text{H}^+$  and lactose binding sites are either both filled or both empty. This prevents not only dissipation of the  $\text{H}^+$  gradient without cotransport of lactose into the cell, but also transport of

lactose out of the cell without cotransport of  $\text{H}^+$  against its concentration gradient.

The X-ray structure of lactose permease in complex with a tight-binding lactose analog, determined by Kaback and So Iwata, reveals that this protein consists of two structurally similar and 2-fold pseudosymmetrically related domains containing six transmembrane helices each (Fig. 20-30a). A large internal hydrophilic cavity is open to

**Figure 20-30** X-ray structure of lactose permease from *E. coli*.

(a) Ribbon diagram as viewed from the membrane with the cytoplasmic side up. The protein's 12 transmembrane helices are colored in rainbow order with the N-terminus purple and the C-terminus pink. The bound lactose analog is represented by black spheres. (b) Surface model viewed as in Part a but with the two helices closest to the viewer in Part a removed to reveal the lactose-binding cavity. PDBid 1PV7.]

the cytoplasmic side of the membrane (Fig. 20-30b) so that the structure represents the E-1 state of the protein. The lactose analog is bound in the cavity at a position that is approximately equidistant from both sides of the membrane, consistent with the model that the lactose binding site is alternately accessible from each side of the membrane (e.g., Fig. 20-10). Arg, His, and Glu residues that mutational studies have implicated in proton translocation are located in the vicinity of the lactose binding site.

### C. ATP-ADP Translocator

ATP generated in the mitochondrial matrix (its inner compartment; Section 1-2A) through oxidative phosphorylation (Section 22-3C) is largely utilized in the cytosol to drive such endergonic processes as biosynthesis, active transport, and muscle contraction. The inner mitochondrial membrane contains a transmembrane protein that exports ATP out of the matrix and then imports ADP produced in the cytosol by ATP hydrolysis. This antiport, the **ATP-ADP translocator** (also called the **ADP/ATP carrier**), is electrogenic since it exchanges  $\text{ADP}^{3-}$  for  $\text{ATP}^{4-}$ . It is the most abundant member of the **mitochondrial carrier family** of proteins that transport a variety of metabolites through the inner mitochondrial membrane; it constitutes ~10% of mitochondrial membrane proteins.

Several natural products inhibit the ATP-ADP translocator. **Atractyloside** (a poison produced by the Mediterranean thistle *Atractylis gummifera* that was known to the ancient Egyptians) and its derivative **carboxyatractyloside (CATR)** inhibit the process only from the external surface of the inner mitochondrial membrane; **bongkreki acid** (a product of the bacterium *Pseudomonas cocovenenans*) exerts its effects only on the internal surface.

R = H      **Atractyloside**  
 R = COOH   **Carboxyatractyloside**

These differentially acting inhibitors have been valuable tools in the isolation of the ATP-ADP translocator and in the elucidation of its mechanism of action. For example, the translocator has been purified by affinity chromatography (Section 6-3C) using atractyloside derivatives as affinity ligands. Atractyloside binding is also a convenient means of identifying the translocator.

The ATP-ADP translocator, a dimer of identical ~300-residue subunits, has characteristics similar to those of other transport proteins. It has one binding site for which ADP and ATP compete. It has two major conformations, one with its ATP-ADP binding site facing the matrix, and the other with this site facing outward. In its X-ray structure in complex with CATR (Fig. 20-31), determined by Eva Pebay-Peyroula, each subunit's six transmembrane helices surround a deep cone-shaped cavity open to the matrix that is occupied by the CATR. The translocator is an antiport because it must bind ligand to change from one conformational state to the other at a physiologically reasonable rate.

The ATP-ADP translocator is not itself an active transport system. However, its electrogenic export of one negative charge per transport cycle in the direction of ATP export-ADP import is driven by the membrane potential difference,  $\Delta\Psi$ , across the inner mitochondrial membrane (positive outside). This results in the formation of gradients in ATP and ADP across the membrane.

## 5 NEUROTRANSMISSION

In higher animals, the most rapid and complex intercellular communications are mediated by nerve impulses. A neuron (nerve cell; e.g., Fig. 1-10d) electrically transmits such a signal along its highly extended length (its **axon**, which is commonly over 1 m in larger animals) as a traveling wave of ionic currents. Signal transmission between neurons, as well as between neurons and muscles or glands, is usually chemically mediated by neurotransmitters. In this section we discuss both the electrical and chemical aspects of nerve impulse transmission.

### A. Voltage-Gated Ion Channels

Ion gradients across cell membranes, as we have seen, are generated by specific energy-driven pumps (Section 20-3). These ion gradients are, in turn, discharged through ion channels such as  $\text{K}^+$  channels (Section 20-2F). However, the pumps cannot keep up with the massive fluxes of ions passing through the channels. Hence ion channels are normally shut and only open transiently to perform some specific task for the cell. The opening and closing of ion channels, a process known as **gating**, occurs in response to a variety of stimuli:

**1. Ligand-gated channels** open in response to extracellular stimuli. For example, the KcsA  $\text{K}^+$  channel (Section 20-2F) opens when the extracellular pH is less than ~4 (the X-ray structure in Fig. 20-12 is that of its closed conformation),

(a)

molecules that cocrystallized with the protein are drawn in stick form with C green, O red, and P orange. (b) The molecular surface as viewed from the intermembrane space and colored according to its surface charge with blue positive, white neutral, and red negative. Note the deep positively charged cavity in which the anionic ATP binds. [Based on an X-ray structure by Eva Pebay-Peyroula, Université Joseph Fourier, Grenoble, France. PDBid 2C3E.]

whereas the ligand-gated ion channels in nerve cells open on extracellularly binding specific neurotransmitters (Section 20-5C).

**2. Signal-gated channels** open on intracellularly binding a second messenger such as  $\text{Ca}^{2+}$  ion or the  $G_{\beta\gamma}$  subunit of a heterotrimeric G protein (Section 19-2C).

**3. Mechanosensitive** channels open under the influence of stretch, pressure, or displacement. In bacteria, these appear to function as safety valves to relieve high internal osmotic pressures that would otherwise burst the cell wall, whereas in animals they are important in such sensory functions as touch and hearing.

**4. Voltage-gated channels** open in response to a change in membrane potential. Multicellular organisms contain numerous varieties of voltage-gated channels. For example, nerve impulses arise from the sequential opening of voltage-gated channels along the length of a single nerve cell (Section 20-5Ba).

#### a. Voltage Gating in Kv Channels Is Triggered by the Motion of a Positively Charged Protein Helix

All voltage-gated  $\text{K}^+$  channels are transmembrane homotetramers, each subunit of which contains an  $\sim 220$ -residue N-terminal cytosolic segment, an  $\sim 250$ -residue transmembrane segment consisting of six helices, S1 to S6, and an  $\sim 150$ -residue C-terminal cytosolic segment (Fig. 20-32). S5 and S6 are homologous to the KcsA channel's outer and inner helices (Fig. 20-12a), with their intervening so-called P loop containing the  $\text{K}^+$  channel's TVGYG signature sequence.

Voltage-gated  $\text{Na}^+$  channels and  $\text{Ca}^{2+}$  channels are  $\sim 2000$ -residue monomers that consist of four consecutive domains, each of which is homologous to the  $\text{K}^+$  channel transmembrane domain, separated by often large cytosolic loops. These domains presumably assume a pseudotetrameric arrangement about a central pore resembling that of the subunits in voltage-gated  $\text{K}^+$  channels. This structural homology suggests that voltage-gated ion channels

**Figure 20-32** Secondary structure and membrane orientation of voltage-gated  $K^+$  channels.

share a common architecture in which differences in ion selectivity arise from precise stereochemical variations within the central pore. However, outside of their conserved transmembrane core, voltage-gated ion channels with different ion selectivities are highly divergent. For example, voltage-gated  $K^+$  channels, which are known as **Kv channels**, have a conserved  $\sim 100$ -residue domain, the so-called T1 domain (Fig. 20-32), that precedes the transmembrane domain and that is absent in other types of voltage-gated ion channels. The T1 domain confers specificity in subunit oligomerization: It prevents Kv subunits of different subfamilies from coassembling in the same tetramer.

What is the nature of the gating machinery in voltage-gated ion channels? The X-ray structure of the rat brain Kv

channel named **Kv1.2** in its open form, determined by MacKinnon (Fig. 20-33), reveals that its helices S1 through S4 form separate paddlelike domains that extend radially out from the channel-forming helices, S5 and S6. The 19-residue S4 helices, which each contain five positively charged residues (four Arg and one Lys) spaced every  $\sim 3$  residues, act as voltage sensors. This was shown by covalently linking a dye whose fluorescence spectrum varies with the polarity of the environment to any of several residues in S4. Fluorescence measurements on each of these labeled ion channels revealed that when the membrane potential decreases (cytosol becomes more negative, which causes the channel to close), a stretch of at least 7 residues at the N-terminal end of S4 moves from a position near the extracellular environment to the center of the membrane. This suggests that the five positively charged residues on the S4 helix are drawn toward the cytosol (down in Fig. 20-34*a,b*) by  $\sim 15$  Å, pushing down on the S4–S5 linker helix, which in turn pushes down on the S6 helix, thus collapsing together the ends of the S6 helices so as to close the cytosolic entrance to the  $K^+$  channel (Fig. 20-34*c,d*).

#### b. The Kv Channel Has Two Gates

Electrophysiological measurements indicate that, a few milliseconds after opening, the Kv channel spontaneously (without a further change in membrane potential) closes, a process termed **inactivation**, and does not reopen until after the membrane has repolarized (regained its resting membrane potential). Evidently, *the Kv channel contains two voltage-sensitive gates, one to open the channel on an increase in membrane potential and one to close it a short time*

**Figure 20-33** X-ray structure of the Kv1.2 voltage-gated  $K^+$  channel. (a) View along the tetrameric protein's 4-fold axis from the extracellular side of the membrane in which it is embedded. Each of its four identical subunits is colored differently, and the T1 domain has been omitted for clarity. The fragmented appearance of the polypeptide chains is due to the high mobilities of the missing segments. The S5 and S6 helices with their intervening P loops form the pore for  $K^+$  ions (delineated by green spheres). Helices S1 to S4 form a separate intramembrane voltage-sensing domain that associates with the S5 and S6

helices of the clockwise adjacent subunit. (b) View perpendicular to that in Part (a) with the extracellular side of the membrane above. The pore and voltage sensing domains span a distance of  $\sim 30$  Å, the thickness of the membrane's hydrophobic core. The T1 domain, which occupies the cytoplasm, forms the vestibule of the transmembrane  $K^+$  channel. The four large openings between the T1 domain and the  $K^+$  channel are the portals through which  $K^+$  ions enter the  $K^+$  channel. [Based on an X-ray structure by Roderick MacKinnon, Rockefeller University. PDBid 2A79.]

**Figure 20-34** Proposed mechanism of voltage gating in the Kv1.2 voltage-gated  $K^+$  channel. (a) The voltage-sensing domain in the X-ray structure of Kv1.2 in its open conformation as viewed from the pore parallel to the plane of the membrane with the extracellular solution above. The polypeptide chain is drawn in ribbon form with helices S1 through S4 white and the S4–S5 linker helix orange. Side chains are shown in ball-and-stick form with those of the Arg and Lys residues of S4, the so-called gating charges, cyan, those of Asp and Glu in the so-called external and internal clusters red, and that of Phe 233, which separates the external and internal clusters, green. Note that the gating charges extend upward into the extracellular solution and associate with the external cluster. (b) The voltage-sensing domain in the hypothetical closed conformation displayed as in Part a. S4, together with S3, has moved downward relative to S1 and S2 toward the now more negatively charged cytosol, thereby pivoting the S4–S5 helix in the direction of the white arrow in Part a. Here the gating charges extend downward toward the cytosol and associate with the internal cluster. (c) The S4–S6 linkers and the  $K^+$  pore assembly, which includes helices S5 and S6, in the X-ray structure of Kv1.2 as viewed in the opposite direction from Part a. The S6 helices are blue, the S4–S5 linkers, which contact S6, are orange, and the remainder of the pore assembly is green. (d) Hypothetical model of the S4–S5 linker in the closed conformation, displayed as in Part c, with the structure of the  $K^+$  pore assembly based on the X-ray structure of the KscA channel (Fig. 20-12a). [Courtesy of Roderick MacKinnon, Rockefeller University. PDBid 2R9R.]

later, a phenomenon that has important consequences for the transmission of nerve impulses (Section 20-5B). In fact, minute “gating currents” arising from the movements of these positively charged gates in opening and closing can be detected (electrical current is the movement of charge) if the much larger currents of  $K^+$  ions through the membrane are first blocked by plugging the Kv channel from its

cytosolic side by high concentrations of  $Cs^+$  or tetraethylammonium ions (which are too large to pass through the  $K^+$  pore but apparently become stuck within it).

### c. Inactivation Occurs through the Insertion of the Kv Channel’s N-Terminal Peptide into Its Central Pore

The inactivation of the Kv channel is abolished by proteolytically excising its N-terminal  $\sim 20$ -residue segment (its inactivation peptide), which NMR studies indicate forms a ball-like structure. However, when chemically synthesized inactivation peptide is injected into the cytosol, the truncated Kv channel inactivates at a rate proportional to the concentration of inactivation peptide. This suggests that inactivation occurs when the inactivation ball swings around at the end of the  $\sim 65$ -residue peptide linking it to the T1 domain so as to bind to the open  $K^+$  pore in a way that physically blocks the passage of  $K^+$  ions—the so-called ball-and-chain mechanism. Indeed, the time the Kv channel stays open varies with the length of this “chain,” as mutationally adjusted.

Where is the inactivation peptide’s binding site? Mutational analysis by MacKinnon revealed that the hydrophobic residues lining the Kv channel’s internal pore and central cavity form the receptor site for the inactivation peptide. Since the  $\sim 6$ -Å-diameter cytosolic entrance to the internal pore is too narrow to admit the ball, the ball peptide must unfold in order to enter the internal pore. The first 10 residues of ball peptides are predominantly hydrophobic, whereas the succeeding 10 residues are largely hydrophilic and contain several basic residues. It therefore appears that inactivation occurs through the binding of the N-terminus of the fully extended inactivation peptide inside the internal pore via hydrophobic interactions, an association that is augmented by the binding of the basic residues in the ball peptide’s C-terminal segment to the acidic residues lining the entrance of the internal pore. Thus, the inactivation peptide acts more like a snake than a ball and chain.

How does the inactivation peptide gain access to the internal pore, which appears to be covered by the T1 tetramer? The passage through the center of the T1 tetramer, as seen in its X-ray structure (Fig. 20-33b), is too narrow to permit the passage of the inactivation peptide. Moreover, Christopher Miller eliminated the possibility that the individual T1 domains in a tetramer can ever separate far enough to admit the inactivation peptide by showing that cross-linking adjacent T1 domains by genetically engineered disulfide bonds (whose positions were selected by referring to the T1 X-ray structure) does not significantly affect the Kv channel’s gating properties. This strongly suggests that the inactivation peptide gains access to the bottom of the transmembrane pore through lateral windows between the transmembrane and T1 domains, whose sides are formed by the  $\sim 35$ -residue peptide segment linking these domains. Presumably,  $K^+$  ions pass through these same windows when the Kv channel is open.

A Kv channel engineered so that only one subunit has an inactivation peptide still inactivates but at one-fourth the rate of normal Kv channels. Apparently, any of the normal Kv channel’s four inactivation peptides can block the

**Table 20-3** Ionic Concentrations and Membrane Permeability Coefficients in Mammals

Ion	Cell (mM)	Blood (mM)	Permeability Coefficient (cm · s <sup>-1</sup> )
K <sup>+</sup>	139	4	5 × 10 <sup>-7</sup>
Na <sup>+</sup>	12	145	5 × 10 <sup>-9</sup>
Cl <sup>-</sup>	4	116	1 × 10 <sup>-8</sup>
X <sup>-a</sup>	138	9	0

<sup>a</sup>X<sup>-</sup> represents macromolecules that are negatively charged under physiological conditions.

channel and it is simply a matter of chance as to which one does so. In contrast, voltage-gated Na<sup>+</sup> channels have only a single inactivation peptide, which is located on the segment linking the Na<sup>+</sup> channel's third and fourth homologous transmembrane domains. Consequently, a genetically engineered cut of the peptide chain in this region abolishes Na<sup>+</sup> channel inactivation.

### B. Action Potentials

Neurons, like other cells, generate ionic gradients across their plasma membranes through the actions of the corresponding ion-specific pumps. In particular, an (Na<sup>+</sup>-K<sup>+</sup>)-ATPase (Section 20-3A) pumps K<sup>+</sup> into and Na<sup>+</sup> out of the neuron to yield intracellular and extracellular concentrations of these ions similar to those listed in Table 20-3. The consequent membrane potential, ΔΨ, across a cell membrane is described by the **Goldman equation**, an extension of Eq. [20.3] that explicitly takes into account the various ions' different membrane permeabilities:

$$\Delta\Psi = \frac{RT}{\mathcal{F}} \ln \frac{\sum P_c [C(out)] + \sum P_a [A(in)]}{\sum P_c [C(in)] + \sum P_a [A(out)]} \quad [20.8]$$

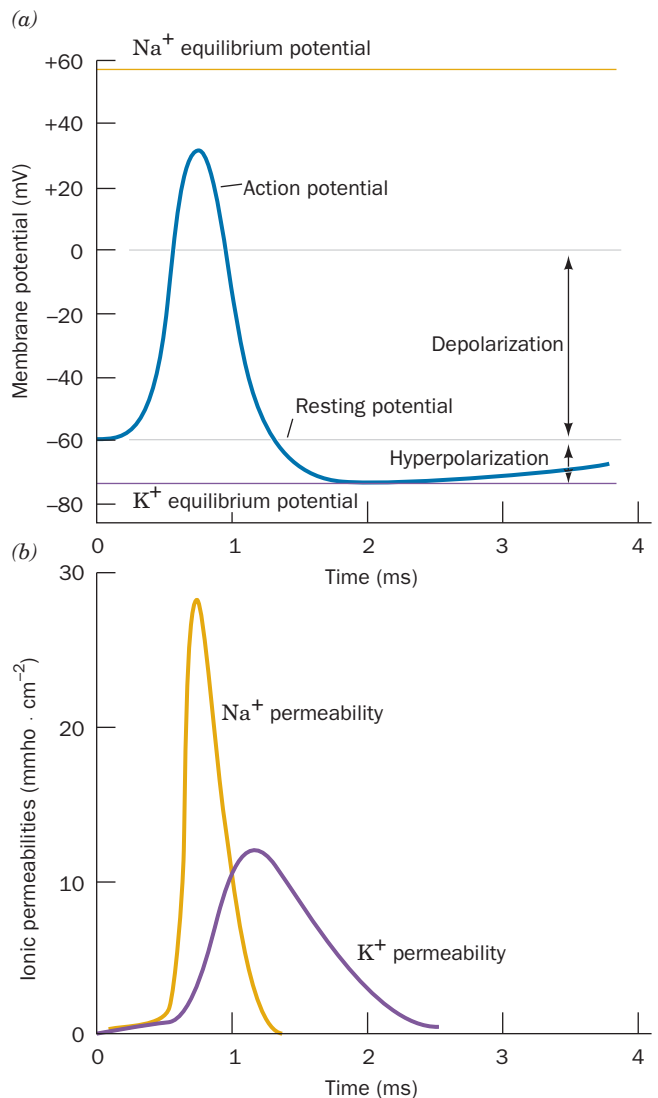

Here, C and A represent cations and anions, respectively, and, for the sake of simplicity, we have made the physiologically reasonable assumption that only monovalent ions have significant concentrations. The quantities  $P_c$  and  $P_a$ , the respective **permeability coefficients** for the various cations and anions, are indicative of how readily the corresponding ions traverse the membrane (each is equal to the corresponding ion's diffusion coefficient through the membrane divided by the membrane's thickness; Section 20-2A). Note that Eq. [20.8] reduces to Eq. [20.3] if the permeability coefficients of all mobile ions are assumed to be equal.

Applying Eq. [20.8] to the data in Table 20-3 and assuming a temperature of 25°C yields ΔΨ = -83 mV (negative inside), which is in good agreement with experimentally measured membrane potentials for mammalian cells. This value is somewhat greater than the K<sup>+</sup> equilibrium potential, the value of ΔΨ = -91 mV obtained assuming the membrane is permeable to only K<sup>+</sup> ions ( $P_{Na^+} = P_{Cl^-} = 0$ ). The membrane potential is generated by a surprisingly small imbalance in the ionic distribution across the membrane: Only ~1 ion pair per million is separated by the membrane with

the anion going to the cytosolic side and the cation going to the external side. The resulting electric field is, nevertheless, enormous by macroscopic standards: Assuming a typical membrane thickness of 50 Å, it is nearly 170,000 V · cm<sup>-1</sup>.

#### a. Nerve Impulses Are Propagated by Action Potentials

A nerve impulse consists of a wave of transient membrane depolarization known as an **action potential** that passes along a nerve cell. A microelectrode implanted in an axon will record that during the first ~0.5 ms of an action potential, ΔΨ increases from its resting potential of around -60 mV to about ~30 mV (Fig. 20-35a). This depolarization is followed by a nearly as rapid repolarization

**Figure 20-35** Time course of an action potential. (a) The axon membrane undergoes rapid depolarization, followed by a nearly as rapid hyperpolarization and then a slow recovery to its resting potential. (b) The depolarization is caused by a transient increase in Na<sup>+</sup> permeability (conductance), whereas the hyperpolarization results from a more prolonged increase in K<sup>+</sup> permeability that begins a fraction of a millisecond later. The unit of conductance, 1 mho = 1 ohm<sup>-1</sup>. [After Hodgkin, A.L. and Huxley, A.F., *J. Physiol.* **117**, 530 (1952).]

past the resting potential to the  $K^+$  equilibrium potential (hyperpolarization) and then a slower recovery to the resting potential. What is the origin of this complicated electrical behavior? In 1952, Alan Hodgkin and Andrew Huxley demonstrated that the action potential results from a transient increase in the membrane's permeability to  $Na^+$  ( $P_{Na^+}$ ) followed, within a fraction of a millisecond, by a transient increase in its permeability to  $K^+$  ( $P_{K^+}$ ; Fig. 20-35b).

The ion-specific permeability changes that characterize an action potential result from the presence of  $Na^+$ - and  $K^+$ -specific voltage-gated channels. As a nerve impulse reaches a given patch of nerve cell membrane, the increased membrane potential induces the transient opening of the  $Na^+$  channels, so that  $Na^+$  ions diffuse into the nerve cell at the rate of  $\sim 6000$  ions  $\cdot$  ms $^{-1}$  per channel. This increase in  $P_{Na^+}$  causes  $\Delta\Psi$  to increase (Eq. [20.3]), which, in turn, induces more  $Na^+$  channels to open, etc., leading to an explosive entry of  $Na^+$  into the cell. Yet, before this process can equilibrate at its  $Na^+$  equilibrium potential of around  $\sim 60$  mV, the  $K^+$  channels open ( $P_{K^+}$  increases) while the  $Na^+$  channels close (inactivate;  $P_{Na^+}$  returns to its resting value).  $\Delta\Psi$  therefore reverses sign and overshoots its resting potential to approach its  $K^+$  equilibrium value. Eventually the  $K^+$  channels also inactivate and the membrane patch regains its resting potential. The  $Na^+$  channels, which remain open only 0.5 to 1.0 ms, do not reopen until the membrane has returned to its resting state, thereby limiting the axon's firing rate.

An action potential is triggered by an  $\sim 20$ -mV rise in  $\Delta\Psi$  to about  $-40$  mV. Action potentials therefore propagate along an axon because the initially rising value of  $\Delta\Psi$  in a given patch of axonal membrane triggers the action potential in an adjacent membrane patch that does so in an adjacent membrane patch, etc. (Fig. 20-36). The nerve impulse is thereby continuously amplified so that its signal amplitude remains constant along the length of the axon (in contrast, an electrical impulse traveling down a wire dissipates as a consequence of resistive and capacitive effects). Note, however, that since the relative ion imbalance responsible for the resting membrane potential is small, only a tiny fraction of a nerve cell's  $Na^+$ - $K^+$  gradient is discharged by a single nerve impulse (only one  $K^+$  ion per 3000–300,000 in the cytosol is exchanged for extracellular  $Na^+$ , as indicated by measurements with radioactive  $Na^+$ ). An axon can therefore transmit a nerve impulse every few milliseconds without letup. This capacity to fire rapidly is an essential feature of neuronal communications: *Since nerve impulses all have the same amplitude, the magnitude of a stimulus is conveyed by the rate at which a nerve fires.*

### b. The Voltage-Gated $Na^+$ Channel Is the Target of Numerous Neurotoxins

Neurotoxins have proved to be invaluable tools for dissecting the various mechanistic aspects of neurotransmission. Many neurotoxins, as we shall see, interfere with the action of neuronal voltage-gated  $Na^+$  channels but, curiously,

**Figure 20-36** Action potential propagation along an axon. Membrane depolarization at the leading edge of an action potential triggers an action potential at the immediately downstream portion of the axon membrane by inducing the opening of its voltage-gated  $Na^+$  channels. As the depolarization wave moves farther downstream, the  $Na^+$  channels close and the  $K^+$  channels open to hyperpolarize the membrane. After a brief refractory period, during which the  $K^+$  channels close and the hyperpolarized membrane recovers its resting potential, a second

impulse can follow. The indicated impulse propagation speed is that measured in the giant axon of the squid, which, because of its extraordinary width ( $\sim 1$  mm), is a favorite experimental subject of neurophysiologists. Note that the action potential in this figure appears backward from that in Fig. 20-35 because this figure shows the distribution of the membrane potential along an axon at an instant in time, whereas Fig. 20-35 shows the membrane potential's variation with time at a fixed point on the axon.

few are known that affect voltage-gated  $K^+$  channels.

### Tetrodotoxin,

**Tetrodotoxin**

a paralytic poison of enormous potency, which occurs mainly in the skin, ovaries, liver, and intestines of the puffer fish (known as fugu in Japan, where it is a delicacy that may be prepared only by chefs certified for their knowledge of puffer fish anatomy), acts by specifically blocking the  $Na^+$  channel. The  $Na^+$  channel is similarly blocked by **saxitoxin**,

**Saxitoxin**

a product of marine dinoflagellates (a type of plankton known as the “red tide”) that is concentrated by filter-feeding shellfish to such an extent that a small mussel can contain sufficient saxitoxin to kill 50 people. Both of these neurotoxins have a cationic guanidino group, and both are effective only when applied to the external surface of a neuron (their injection into the cytosol elicits no response). It is therefore thought that these toxins specifically interact with an anionic carboxylate group located at the mouth of the  $Na^+$  channel on its extracellular side.

### Batrachotoxin,

**Batrachotoxin**

a steroidal alkaloid secreted by the skin of a Colombian

arrow-poison frog, *Phyllobates aurotaenia*, is the most potent known venom ( $2 \mu\text{g} \cdot \text{kg}^{-1}$  body weight is 50% lethal in mice). This substance also specifically binds to the voltage-gated  $Na^+$  channel but, in contrast to the actions of tetrodotoxin and saxitoxin, renders the axonal membrane highly permeable to  $Na^+$ . Indeed, batrachotoxin-induced axonal depolarization is reversed by tetrodotoxin. The observation that the repeated electrical stimulation of a neuron enhances the action of batrachotoxin indicates that this toxin binds to the  $Na^+$  channel in its open state.

Venoms from American scorpions contain families of 60- to 70-residue protein neurotoxins that also act to depolarize neurons by binding to their  $Na^+$  channels (the different neurotoxins in the same venom appear to be specialized for binding to the  $Na^+$  channels in the various species the scorpion is likely to encounter). Scorpion toxins and tetrodotoxin do not, however, compete with each other for binding to the  $Na^+$  channel and therefore must bind at separate sites.

### c. Nerve Impulse Velocity Is Increased by Myelination

The axons of the larger vertebrate neurons are sheathed with **myelin**, a biological “electrical insulating tape” that is wrapped about the axon (Fig. 20-37a) so as to electrically isolate it from the extracellular medium. Impulses in myelinated nerves propagate with velocities of up to  $100 \text{ m} \cdot \text{s}^{-1}$ , whereas those in unmyelinated nerves are no faster than  $10 \text{ m} \cdot \text{s}^{-1}$  (imagine the coordination difficulties that, say, a giraffe would have if it had to rely on only unmyelinated nerves).

How does myelination increase the velocity of nerve impulses? Myelin sheaths are interrupted every millimeter or so along the axon by narrow unmyelinated gaps known as **nodes of Ranvier** (Fig. 20-37b), where the axon contacts the extracellular medium. Binding studies using radioactive tetrodotoxin indicate that the voltage-gated  $Na^+$  channels of unmyelinated axons have rather sparse although uniform distributions in the axonal membrane of  $\sim 20 \text{ channels} \cdot \mu\text{m}^{-2}$ . In contrast, the  $Na^+$  channels of myelinated axons occur only at the nodes of Ranvier, where they are concentrated with a density of  $\sim 10^4 \text{ channels} \cdot \mu\text{m}^{-2}$ . The action potential of a myelinated axon evidently hops between these nodes, a process named **saltatory conduction** (Latin: *saltare*, to jump). Nerve impulse transmission between the nodes must therefore occur by the passive conduction of an ionic current, a mechanism that is inherently much faster than the continuous propagation of an action potential but that is also dissipative. The nodes act as amplification stations to maintain the intensity of the electrical impulse as it travels down the axon. Without the myelin insulation, the electrical impulse would become too attenuated through transmembrane ion leakage and capacitive effects to trigger an action potential at the next node. In fact, **multiple sclerosis**, an autoimmune disease that demyelinates nerve fibers in the brain and spinal cord, results in serious although rarely fatal neurological deficiencies.

**Figure 20-37 Myelination.** (a) An electron micrograph of myelinated nerve fibers in cross section. The myelin sheath surrounding an axon is the plasma membrane of a **Schwann cell**, which, as it spirally grows around an axon, extrudes its cytoplasm from between the layers. The resulting double bilayer, which makes between 10 and 150 turns about the axon, is a good electrical insulator because of its particularly high (79%) lipid content. [Courtesy of Cedric Raine, Albert Einstein College of Medicine of Yeshiva University.] (b) A schematic diagram of a myelinated axon in longitudinal section, indicating that in the nodes of Ranvier (the relatively short gaps between adjacent myelinating cells), the axonal membrane is in contact with the extracellular medium. A depolarization generated by an action potential at one node hops, via ionic conduction, down the myelinated axon (red arrows), to the neighboring node, where it induces a new action potential. Nerve impulses in myelinated axons are therefore transmitted by saltatory conduction.

(a)

### C. Neurotransmitters and Their Receptors

The junctions at which neurons pass signals to other neurons, muscles, or glands are called **synapses**. In **electrical synapses**, which are specialized for rapid signal transmission, the cells are separated by a gap, the **synaptic cleft**, of only 20 Å, which is spanned by gap junctions (Section 12-3F). Hence, an action potential arriving at the presynaptic side of the cleft can sufficiently depolarize the postsynaptic membrane to trigger its action potential directly. However, the >200-Å gap of most synapses is too large a distance for such direct electrical coupling. In these **chemical synapses**, the arriving action potential triggers the release from the presynaptic neuron of a specific substance known as a **neurotransmitter**, which diffuses across the cleft and binds to its corresponding receptors on the postsynaptic membrane. In **excitatory synapses**, neurotransmitter binding induces membrane depolarization, thereby triggering an action potential on the postsynaptic membrane. Conversely, neurotransmitter binding in **inhibitory synapses** alters postsynaptic membrane permeability so as to inhibit an action potential and thus attenuate excitatory signals. What is the mechanism through which an arriving action potential stimulates the release of a neurotransmitter, and by what means does its binding to a receptor alter

the postsynaptic membrane's permeability? To answer these questions let us consider the workings of **cholinergic synapses**; that is, synapses that use **acetylcholine (ACh)** as a neurotransmitter:

Two types of cholinergic synapses are known:

1. Those containing **nicotinic receptors** (receptors that respond to **nicotine**).
2. Those containing **muscarinic receptors** (receptors that respond to **muscarine**, an alkaloid produced by the poisonous mushroom *Amanita muscaria*).

In what follows, we shall focus on cholinergic synapses containing nicotinic receptors since this best characterized type of synapse occurs at all excitatory neuromuscular junctions in vertebrates and at numerous sites in the nervous system.

### a. Electric Organs of Electric Rays Are Rich Sources of Cholinergic Synapses

The study of synaptic function has been greatly facilitated by the discovery that the homogenization of nerve tissue causes its presynaptic endings to pinch off and reseal to form **synptosomes** (Section 12-4Da). The use of synptosomes, which can be readily isolated by density gradient ultracentrifugation, has the advantage that they can be manipulated and analyzed without interference by other neuronal components.

The richest known source of cholinergic synapses is the electric organs of the freshwater electric eel *Electrophorus electricus* and saltwater electric rays of the genus *Torpedo*. Electric organs, which these organisms use to stun or kill their prey, consist of stacks of ~5000 thin flat cells called **electroplaques** that begin their development as muscle cells but ultimately lose their contractile apparatus. One side of an electroplaque is richly innervated and has high electrical resistance, whereas its opposite side lacks innervation and has low electrical resistance. Both sides maintain a resting membrane potential of around -90 mV. On neuronal stimulation, all the innervated membranes in a stack of electroplaques simultaneously depolarize to a membrane potential of around +40 mV, yielding a potential difference across each cell of 130 mV (Fig. 20-38). Since the 5000 electroplaques in a stack are “wired” in series like the batteries in a flashlight, the total potential difference across the stack is  $\sim 5000 \times 0.130 \text{ V} = 650 \text{ V}$ , enough to kill a human being.

### b. Acetylcholine Is Released by the $\text{Ca}^{2+}$ -Triggered Exocytosis of Synaptic Vesicles

ACh is synthesized near the presynaptic end of a neuron by the transfer of an acetyl group from **acetyl-CoA** [the

structure of coenzyme A (CoA) is given in Fig. 21-2] to **choline** in a reaction catalyzed by **choline acetyltransferase**.

Much of this ACh is sequestered in  $\sim 400\text{-\AA}$ -diameter membrane-enveloped **synaptic vesicles**, which typically contain  $\sim 10^4$  ACh molecules each.

The arrival of an action potential at the presynaptic membrane triggers the opening of **voltage-gated  $\text{Ca}^{2+}$  channels**, which transiently raises the local  $[\text{Ca}^{2+}]$  from its resting level of  $0.1 \mu\text{M}$  to 10 to  $100 \mu\text{M}$ . The resulting influx of extracellular  $\text{Ca}^{2+}$ , in turn, stimulates the exocytosis of the synaptic vesicles in the vicinity of the  $\text{Ca}^{2+}$  channel so that they release their packets of ACh into the synaptic cleft (Fig. 12-73). The mechanism by which synaptic vesicles fuse with the presynaptic membrane is discussed in Section 12-4D.

The mechanism through which  $\text{Ca}^{2+}$  induces synaptic vesicle exocytosis is beginning to come into focus. The major  $\text{Ca}^{2+}$ -sensing protein appears to be **synaptotagmin I**, a protein with a single helix passing through the synaptic vesicle membrane, whose cytosolic domain contains four  $\text{Ca}^{2+}$  binding sites. At resting levels of  $\text{Ca}^{2+}$ , synaptotagmin I binds to the Q-SNARE syntaxin (Section 12-4Db) so as to block its binding to the R-SNARE synaptobrevin and the Q-SNARE SNAP25, thereby preventing vesicle fusion. However, on binding  $\text{Ca}^{2+}$ , synaptotagmin I releases syntaxin, permitting vesicle fusion to commence.

Once triggered, the fusion of the synaptic vesicles with the presynaptic membrane occurs very rapidly (in  $<0.3 \text{ ms}$ )

**Figure 20-38** The simultaneous depolarization (red, right) of the innervated membranes in a stack of electroplaques “wired” in series results in a large voltage difference between the two

ends of the stack. This is because the total voltage across the stack is the sum of the voltages generated by each of its numerous electroplaques.

because many synaptic vesicles are already docked with the presynaptic membrane. Each  $\text{Ca}^{2+}$  pulse triggers the exocytosis of  $\sim 10\%$  of these docked vesicles. However, they are rapidly replaced because most of the remaining synaptic vesicles are held in reserve in a so-called active zone within 20 nm of the presynaptic membrane. Vesicles are held in the active zone by a fibrous phosphoprotein named **synapsin I** that also binds the cytoskeletal proteins actin and spectrin (Section 12-3Db). Synapsin I is a substrate for calmodulin-dependent protein kinase (Section 18-3Ce), so that a rise in  $[\text{Ca}^{2+}]$  causes its phosphorylation. This apparently releases the synaptic vesicles from the active zone, thereby permitting them to dock to the presynaptic membrane in preparation for exocytosis. The 20-nm distance between the active zone and the presynaptic membrane may be close enough for Q- and R-SNAREs to initiate the formation of their coiled coil complex (Fig. 12-74), which may thereby facilitate the docking process.

The black widow spider takes advantage of this system: Its highly neurotoxic venom protein,  **$\alpha$ -latrotoxin** (130 kD), causes massive release of ACh at the neuromuscular junction, in part by forming homotetrameric transmembrane channels through the presynaptic membrane that act as  $\text{Ca}^{2+}$  ionophores. In contrast, **botulinus toxin**, as we have seen (Section 12-4Dd), interferes with the exocytosis of

synaptic vesicles by proteolytically cleaving specific SNARE proteins, thereby preventing ACh release.

Exocytosed synaptic vesicle proteins are rapidly recovered from the presynaptic membrane via endocytosis mainly in clathrin-coated vesicles (Section 12-4C). However, once the resulting endocytotic vesicles lose their clathrin coats, they do not fuse with endosomes, as is usually the case (Fig. 12-91). Rather, they are immediately refilled with ACh by an  $\text{H}^+$ -ACh antiport, which is driven by the protons pumped into the vesicle by a V-type ATPase (Section 20-3), and then translocated to the active zone. This rapid recycling of the synaptic vesicles (which takes  $< 1$  min) permits neurons to fire continuously at a rate of  $\sim 50$  times per second.

### c. The Acetylcholine Receptor Is a Ligand-Gated Cation Channel

After its release at the presynaptic membrane, acetylcholine quickly diffuses across the synaptic cleft to the postsynaptic membrane, where it binds to the 290-kD **acetylcholine receptor (AChR)**, an  $\alpha_2\beta\gamma\delta$  transmembrane glycoprotein, whose four different  $\sim 490$ -residue subunits are homologous. *The binding of two ACh molecules to the AChR allosterically induces the opening of a channel through the AChR that permits  $\text{Na}^+$  ions to diffuse into the cell at a peak rate of  $\sim 30,000$  ions per millisecond. The*

**Figure 20-39** Electron crystal structure of the nicotinic acetylcholine receptor from the electric ray *Torpedo marmorata*. (a) View from the synaptic cleft. The extracellular domains of each type of subunit are differently colored and their remaining portions are gray. The side chains of  $\alpha$ Trp 149, which mark the ACh-binding sites, are drawn in stick form (gold). (b) View

parallel to the membrane with the synaptic cleft above. Only the front two subunits are highlighted in color. The horizontal gray bars delineate the position of the postsynaptic membrane. [Courtesy of Nigel Unwin, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 2BG9.]

resulting depolarization of the postsynaptic membrane initiates a new action potential. The AChR is also permeable to  $K^+$  and  $Ca^{2+}$  ions. However, since the thermodynamic driving forces exerted by the resting membrane potential and the  $K^+$  concentration gradient oppose each other and largely balance, relatively few  $K^+$  ions are transferred (for  $Na^+$  ions, these forces reinforce each other). The extracellular concentration of  $Ca^{2+}$  is so much less than that of  $Na^+$  that it makes only a negligible contribution to the inward ionic current. After 1 to 2 ms, the ACh spontaneously dissociates from the receptor and the channel closes.

The electron crystallography-based structure (Section 12-3Ab) of the AChR in its closed (unliganded) form, determined by Nigel Unwin, when viewed from the synaptic cleft, is an 80-Å-diameter 5-fold pseudosymmetric assembly whose subunits are arranged in the clockwise order  $\alpha$ - $\beta$ - $\delta$ - $\alpha$ - $\gamma$ - (Fig. 20-39a). When viewed parallel to the plane of the postsynaptic membrane, it is a 160-Å-long wedge-shaped particle (Fig. 20-39b). Each of its subunits consists of three domains: an N-terminal extracellular assembly that consists mainly of a 10-stranded  $\beta$  barrel; a transmembrane 4-helix down-up-down-up bundle (M1–M4); and an intracellular component composed mainly of a disordered segment extending from M3 followed by a curved helix (MA) that precedes M4. The ACh-binding sites are located between the  $\alpha$ - $\gamma$  and  $\alpha$ - $\delta$  interfaces of their extracellular domains.

The ACh receptor's most striking structural feature is an  $\sim 20$ -Å-diameter and  $\sim 65$ -Å-long water-filled central channel that extends from the receptor's synaptic entrance to the level of the lipid bilayer. There it forms a more constricted  $\sim 30$ -Å-long pore, constructed from the ring of the five M2 helices, that is blocked near the middle of the bilayer. This blockage, which is presumably the channel's gate, consists of rings of conserved Leu 264 and Val/Ile 268 side chains that project inward from the M2 helices. Unwin has proposed that the binding of ACh to the AChR allosterically induces clockwise rotations (viewed from the synaptic cleft) of its  $\alpha$  subunit's M2 helices that results in the opening of the gate.

The intracellular end of the AChR contains an  $\sim 20$ -Å-diameter central cavity that is  $\sim 20$  Å long and is connected to the cytosol via lateral openings between adjacent MA helices at a level that is  $\sim 30$  Å below the membrane surface. These openings are largely formed by anionic residues and have widths of  $\sim 8$  Å, which is comparable to the diameters of  $K^+$  and  $Na^+$  ions surrounded by their first hydration shells. Thus, they likely serve as filters that prevent the passage of cytoplasmic anions and large cations. Recall that Kv channels have similar lateral openings to the cytoplasm (Section 20-5Ac).

The ACh receptor is the target of some of the most deadly known neurotoxins (death occurs through respiratory arrest), whose use has greatly aided in the elucidation of receptor function. **Histrionicotoxin**, an alkaloid secreted by the skin of the Colombian arrow-poison frog *Dendrobates histrionicus*, and **d-tubocurarine**, the active ingredient of the Amazonian arrow-poison **curare** as well as a med-

ically useful paralytic agent, are both ACh antagonists that prevent ACh receptor channel opening:

Similarly, a family of homologous 7- to 8-kD venom proteins from some of the world's most poisonous snakes, including  **$\alpha$ -bungarotoxin** from snakes of the genus *Bungarus*, **erabutoxin** from sea snakes, and **cobratoxin** from cobras, prevent ACh receptor channel opening by binding specifically and all but irreversibly to its  $\alpha$  subunits. Indeed, detergent-solubilized ACh receptor has been purified by affinity chromatography on a column containing covalently attached cobra toxin. **Myasthenia gravis** (Greek: *mys*, muscle + *astheneia*, weakness and Latin: *gravis*, serious), an autoimmune disease characterized by muscle weakness, is caused by circulating antibodies that bind to the AChR so as to lead to its destruction or block its binding of ACh.

#### d. Acetylcholine Is Rapidly Degraded by Acetylcholinesterase

An ACh molecule that participates in the transmission of a given nerve impulse must be degraded in the few milliseconds before the potential arrival of the next nerve impulse. This essential task is accomplished by **acetylcholinesterase (AChE)**, a 75-kD fast-acting enzyme that is GPI anchored (Section 12-3B) to the surface of the postsynaptic membrane:

(the turnover number of AChE,  $k_{\text{cat}} = 14,000 \text{ s}^{-1}$ ; the enzyme's catalytic efficiency,  $k_{\text{cat}}/K_M = 1.5 \times 10^8 \text{ M}^{-1} \cdot \text{s}^{-1}$ , is close to the diffusion-controlled limit, so that it is a nearly perfect catalyst; Section 14-2Bb). The resulting choline is taken up by the presynaptic cell via a  $\text{Na}^+$ -choline symport for use in the resynthesis of ACh. The operation of this transporter is similar to that of the  $\text{Na}^+$ -glucose symport of intestinal brush border cells (Section 20-4A).

AChE is a serine esterase; that is, its catalytic mechanism resembles that of serine proteases such as trypsin. These enzymes, as we have seen in Section 15-3Ab, are irreversibly inhibited by alkylphosphofluoridates such as diisopropylphosphofluoridate (DIPF). Indeed, related compounds such as **tabun** and **sarin**

are military nerve gases because their efficient inactivation of human AChE by reaction with the active site Ser causes paralysis stemming from cholinergic nerve impulse blockade and thus death by suffocation. **Succinylcholine**,

which is used as a muscle relaxant during surgery, is an ACh agonist that, although rapidly released by the ACh receptor, is but slowly hydrolyzed by AChE. Succinylcholine therefore produces persistent depolarization of the postsynaptic membrane. Its effects are short-lived, however, because it is rapidly hydrolyzed by the relatively nonspecific liver and plasma enzyme **butyrylcholinesterase**. Certain snake venoms, such as that of the green mamba snake, inactivate AChE, although they do so by binding to a site on AChE distinct from its active site.

#### e. X-Ray Structure of Acetylcholinesterase

The X-ray structure of the 537-residue AChE from the electric ray *Torpedo californica*, determined by Joel Sussman, Israel Silman, and Michal Harel, confirms that the previously identified Ser 200 and His 440 are members of AChE's catalytic triad. The structure further reveals that the third member of AChE's catalytic triad is Glu 327 rather than an Asp residue, only the second instance of a Glu in this position among the many serine proteases, lipases, and esterases of known structure. AChE's catalytic triad is arranged in what appears to be the mirror image of the catalytic triads in trypsin and subtilisin, for example (Figure 15-20), although, of course, this is not actually the case since all proteins consist of L-amino acid residues.

**Figure 20-40** X-ray structure of *Torpedo californica* acetylcholinesterase in complex with its inhibitor decamethonium ion  $[(\text{CH}_3)_3\text{N}^+(\text{CH}_2)_{10}\text{N}^+(\text{CH}_3)_3]$ . In this cutaway drawing through the enzyme's active site gorge, the protein's ribbon diagram is embedded in its semitransparent surface diagram, which is tinted blue with the exception of the aromatic residues (Phe, Trp, and Tyr) lining the active site gorge, which are yellow. The decamethonium ion that is bound in the active site gorge is drawn in stick form with C green and N blue. [Based on an X-ray structure by Joel Sussman, Israel Silman, and Michal Harel, The Weizmann Institute of Science, Rehovot, Israel. PDBid 1ACL.]

AChE's catalytic site is near the bottom of a narrow and 20-Å-deep gorge that extends halfway through the protein and widens out near its base (Fig. 20-40). The sides of this so-called active site gorge are lined with the side chains of 14 aromatic residues that comprise 40% of its surface area. Since the side chain O atom of the active site Ser is only 4 Å from the bottom of the gorge, ACh must bind in the gorge with its positively charged trimethylammonium group surrounded by aromatic side chains. This conclusion came as a surprise since it had been understandably expected that the trimethylammonium group would be bound at an anionic site. Perhaps the weak binding provided by the interactions of the trimethylammonium group with the  $\pi$  electrons of the aromatic rings facilitates the rapid diffusion of ACh to the bottom of the gorge, thereby accounting for the enzyme's high turnover number. In fact, model aromatic compounds have been synthesized that also bind quaternary ammonium compounds.

#### f. Amino Acids and Their Derivatives Function as Neurotransmitters

The mammalian nervous system employs well over 30 substances as neurotransmitters. Some of these substances, such as glycine and glutamate, are amino acids; many others are amino acid decarboxylation products or their derivatives (often referred to as **biogenic amines**). For example, as we

shall see in Section 26-4B, **dopamine**, norepinephrine, and epinephrine [which are collectively termed catecholamines because they are derivatives of catechol (1,2-dihydroxybenzene)] are sequentially synthesized from tyrosine, whereas  **$\gamma$ -aminobutyric acid (GABA)**, **histamine**, and **serotonin** are derived from glutamate, histidine, and tryptophan, respectively (Fig. 20-41). Many of these compounds are hormonally active substances that are present in the bloodstream. However, since the brain is largely isolated from the general circulation by a selective filtration system known as the **blood-brain barrier** (Section 15-4Ba), the presence of these substances in the blood has no direct effect on the brain. The use of the same compounds as hormones and neurotransmitters apparently has no physiological significance but, rather, is thought to reflect evolutionary opportunism in adapting already available systems to new roles.

The use of selective staining techniques has established that each of the different neurotransmitters is used in discrete and often highly localized regions of the nervous system. The various neurotransmitters are, nevertheless, not simply functional equivalents of acetylcholine. Rather, many of them have distinctive physiological roles. For example, both GABA and glycine are inhibitory rather than excitatory neurotransmitters. The receptors for these substances are ligand-gated channels that are selectively permeable to  $\text{Cl}^-$ . Hence, their opening tends to hyperpolarize the membrane (make its membrane potential more negative) rather than depolarize it. A neuron inhibited in this manner must therefore be more intensely depolarized than otherwise to trigger an action potential (note that these neurons respond to more than one type of neurotransmitter). Thus, anion channels are inhibitory, whereas cation channels are excitatory. Ethanol, the oldest and most widely used psychoactive drug, is thought to act by inducing GABA receptors in the brain to open their  $\text{Cl}^-$  channels.

The subunits of the various neurotransmitter-gated cation channels have 20 to 40% sequence identity, as do those of the anion channels. However, the two families of

channel proteins appear to be unrelated. Despite this lack of homology, the sequences of the two types of channels suggest that they have considerable structural similarity.

The actual nature of a neuron's response to a neurotransmitter depends more on the characteristics of the corresponding receptor than on the neurotransmitter's identity. Thus, as we have seen, nicotinic ACh receptors, which trigger the rapid contraction of skeletal muscles, respond to ACh within a few milliseconds by depolarizing the postsynaptic membrane. In contrast, the binding of ACh to muscarinic ACh receptors in heart muscle inhibits muscle contraction over a period of several seconds (several heartbeats). This is accomplished by hyperpolarizing the postsynaptic membrane through the closure of otherwise open  $\text{K}^+$  channels. Slow-acting neurotransmitters may act by inducing the formation of a second messenger such as cAMP. In fact, the brain has the highest concentration of cAMP-dependent kinases in the body. The binding of catecholamines to their respective neuronal receptors, through the intermediacy of adenylate cyclase and cAMP, activates protein kinases to phosphorylate ion channels so as to alter the neuron's electrical properties. The ultimate effect of this process can be either excitatory or inhibitory. Thus catecholamines, whether acting as hormones (Section 19-1F) or as neurotransmitters, have similar mechanisms of receptor activation.

#### g. Neuropeptides Are Neurotransmitters

A large and growing list of hormonally active polypeptides known as **neuropeptides** also act as neurotransmitters. Not surprisingly, perhaps, the opioid peptides  $\beta$ -endorphin, met-enkephalin, and leu-enkephalin (Section 19-1K), as well as the hypothalamic releasing factors TRF, GnRF, and somatostatin (Section 19-1H), are in this category. What is less expected is that several gastrointestinal polypeptides, including the hormones gastrin, secretin, and cholecystokinin

Figure 20-41 A selection of neurotransmitters.

(CCK; Section 19-1C), may also act as neurotransmitters in discrete regions of the brain, as do the pituitary hormones oxytocin and vasopressin (Section 19-1Ha). Such neuropeptides differ from the simpler neurotransmitters in that they seem to elicit complex behavior patterns. For example, intracranially injecting rats with a nanogram of

vasopressin greatly enhances their ability to learn and remember new tasks. Similarly, injecting a male or a female rat with GnRF evokes the respective postures they require for copulation. Just how these neuropeptides operate is but one of the many enigmas of brain function and organization.

## CHAPTER SUMMARY

**1 Thermodynamics of Transport** Polar molecules and ions are transported across biological membranes by specific transmembrane transport proteins. The free energy change of the species transported depends on the ratio of its concentrations on the two sides of the membrane and, if the species is charged, on the membrane potential,  $\Delta\Psi$ .

**2 Kinetics and Mechanisms of Transport** The rate of nonmediated diffusion across a membrane is a linear function of the difference in concentration of the species on the two sides of the membrane as governed by Fick's first law of diffusion. Mediated transport is characterized by rapid saturation kinetics and specificity for the substance transported. It is also subject to competitive inhibition and chemical inactivation. Ionophores transport ions through membranes. Carrier ionophores, such as valinomycin, do so by wrapping a specific ion in a hydrophobic, membrane-soluble coat that can freely diffuse through the membrane. Maltoporin is specific for the passage of maltodextrins because its transport channel matches their left-handed helical shape and is lined with aromatic side chains that form a so-called greasy slide. Glucose transport across erythrocyte membranes is mediated by dimeric transmembrane glycoproteins that can assume two conformations: one with a glucose binding site facing the external cell surface and the other with the glucose site facing the cytosol. Transport occurs by the binding of glucose to the protein on one face of the membrane, followed by a conformational change that closes this site and exposes the other (a gated pore). GLUT4 is stored in specialized vesicles, which on insulin stimulation fuse with the plasma membrane.

The KcsA  $K^+$  channel, a transmembrane homotetramer, permits the rapid passage of  $K^+$  ions, for which it is highly selective. It does so, in part, because it forms an aqueous cavity surrounded by the negative ends of helix dipoles that stabilizes  $K^+$  ions in the middle of the bilayer.  $K^+$  ions, but not the smaller  $Na^+$  ions, are transported because the  $K^+$  channel's selectivity filter selectively coordinates  $K^+$  ions by rings of O atoms in a way that allows their dehydration, passage, and subsequent hydration without significant activation barriers. CIC  $Cl^-$  channels are TM homodimers, each subunit of which contains an hourglass-shaped channel. Aquaporins are TM homotetramers with an hourglass-shaped channel through each subunit. They facilitate the rapid passage of water molecules through membranes but inhibit the passage of protons via proton jumping by preventing the reorientation of a centrally located water molecule.

**3 ATP-Driven Active Transport** Active transport of molecules or ions against a concentration gradient requires an input of free energy. The free energy of ATP hydrolysis is coupled to the transport of three  $Na^+$  ions out of and two  $K^+$  ions into the cell by the  $(Na^+-K^+)$ -ATPase. This electrogenic process involves phosphorylation of an Asp residue (by ATP) in the pres-

ence of  $Na^+$  and its dephosphorylation (hydrolysis) in the presence of  $K^+$ . Phosphorylation and dephosphorylation are accompanied by conformational changes that ensure rapid interconversion of all intermediates along the transport pathway. The X-ray structure of the  $(Na^+-K^+)$ -ATPase reveals that it has a 10-helix transmembrane domain that binds 3  $Na^+$  ions or 2  $K^+$  ions near its center and three well-separated cytoplasmic domains. The X-ray structures of four different conformational states of the sarcoplasmic reticulum  $Ca^{2+}$ -ATPase (SERCA) indicate its transport mechanism and that of P-type ATPases in general. Plasma membrane  $Ca^{2+}$ -ATPase is activated by  $Ca^{2+}$ -calmodulin. The  $(H^+-K^+)$ -ATPase in the stomach is indirectly inhibited by cimetidine and its analogs, and directly inhibited by omeprazole. Bacteria transport sugars by group translocation, a process in which the transported substance is chemically modified. The PTS system, which has important regulatory functions, phosphorylates sugars as they are transported by utilizing phosphoenolpyruvate as a phosphoryl donor. ABC transporters use ATP to power conformational changes that transport a wide variety of substances across membranes.

**4 Ion Gradient-Driven Active Transport** Active transport may be driven by the free energy stored in ion gradients (secondary active transport). Glucose is transported into intestinal epithelial cells against its concentration gradient by an  $Na^+$ -glucose symport. This process is ultimately powered by the free energy of ATP hydrolysis since the  $Na^+$  gradient is constantly being replenished via the  $(Na^+-K^+)$ -ATPase. The system conforms to a Random Bi Bi kinetic mechanism, implying that both  $Na^+$  and glucose must be bound for the transport-producing conformational change to occur. Lactose is transported into *E. coli* by lactose permease, an  $H^+$ -lactose symport. This process is driven by the cell's electrochemical  $H^+$  gradient, which is, in turn, maintained by a proton pump coupled with oxidative metabolism. The mitochondrial ATP-ADP translocator also interacts with the membrane potential in the asymmetric transport of ATP out of and ADP into the mitochondrion.

**5 Neurotransmission** Voltage-gated cation channels such as  $Kv$  channels open in response to the membrane potential and close a short time later through the action of a second gate that functions via a modified "ball-and-chain" mechanism. Nerve impulses are traveling waves of electrical excitation along axon plasma membranes known as action potentials that are generated by the transient opening of voltage-gated  $Na^+$  channels to let  $Na^+$  ions into the cell followed a short time later by the transient opening of voltage-gated  $K^+$  channels to let  $K^+$  ions out of the cell. Nerve impulses are chemically transmitted across most synapses by the release of neurotransmitters. Acetylcholine (ACh), the best characterized neurotransmitter, is packaged in synaptic vesicles that are exocytotically released

into the synaptic cleft. This process is triggered by an increase in cytosolic  $[Ca^{2+}]$  resulting from the arriving action potential's opening of voltage-gated  $Ca^{2+}$  channels. The ACh diffuses across the synaptic cleft, where it binds to the ACh receptor, a transmembrane cation channel that opens in response to ACh binding. The resultant flow of  $Na^+$  into and  $K^+$  out of the postsynaptic cell depolarizes the postsynaptic membrane, which, if sufficient neurotransmitter has been released, triggers a postsynaptic action potential. The ACh receptor is the target of numerous deadly neurotoxins, including histrionicotoxin, *d*-tubocurarine, and cobra toxin, which all bind to the ACh receptor so as to prevent its opening. The ACh is rapidly degraded, before the possible arrival of the next nerve impulse, through the action of acetylcholinesterase, a fast-acting serine esterase that has an unusual aromatic side chain-lined active site gorge. Nerve gases and succinylcholine inhibit acetyl-

cholinesterase and therefore block nerve impulse transmission at cholinergic synapses.

Many specific regions of the nervous system employ neurotransmitters other than ACh. Most of these neurotransmitters are amino acids, such as glycine and glutamate, or their decarboxylation products and their derivatives, including catecholamines, GABA, histamine, and serotonin. Many of these compounds are also hormonally active, but they are excluded from the brain by the blood-brain barrier. Although many neurotransmitters, such as ACh, are excitatory, others are inhibitory. The latter stimulate the opening of anion ( $Cl^-$ ) channels, thereby causing the postsynaptic membrane to become hyperpolarized, so that it must be more highly depolarized than otherwise to trigger an outgoing action potential. There is also a growing list of polypeptide neurotransmitters, many of which are also polypeptide hormones, that elicit complex behavior patterns.

## PROBLEMS

**1.** If the glucose concentration outside a cell is 10 mM but that inside a cell is 0.1 mM, what is glucose's chemical potential difference across the membrane at 37°C?

**\*2.** If a solution of an ionic macromolecule is equilibrated with a salt solution from which it is separated by a membrane through which the salt ions but not the macromolecule can pass, a membrane potential is generated across the membrane. This so-called **Donnan equilibrium** arises because the impermeability of the membrane to some ions but not others prevents the equalization of the ionic concentrations on the two sides of the membrane. To demonstrate this effect, assume that the  $\text{Cl}^-$  salt of a monocationic protein,  $\text{P}^+$ , is dissolved in water to the extent that  $[\text{Cl}^-] = 0.1M$  and is separated by a membrane impermeable to the protein but not NaCl from an equal volume of 0.1M NaCl solution. Assuming no volume change in either compartment, what are the concentrations of the various ionic species on either side of the membrane after the system has equilibrated? What is the membrane potential across the membrane? (*Hint:* Mass is conserved and the solution on each side of the membrane must be electrically neutral. At equilibrium,  $\Delta G_{\text{Na}^+} + \Delta G_{\text{Cl}^-} = 0$ .)

**3. Gramicidin A**, a dimer of 15-residue polypeptides that forms a hollow helix, is a channel-forming ionophore that permits the passage of  $\sim 10^7$  alkali metal ions per second through a membrane. How long would it take one molecule of gramicidin A to transport enough  $\text{Na}^+$  to change the concentration inside an erythrocyte of volume  $80 \mu\text{m}^3$  by 10 mM? Assume the erythrocyte's  $\text{Na}^+$  pumps are inoperative and that gramicidin A does not also transport ions out of the cell, which it really does.

**4.** Predict whether the following compounds can cross a membrane without mediation or will require facilitation. Indicate the criteria you used to make these predictions. (a) Ethanol, (b) glycine, (c) cholesterol, and (d) ATP.

**5.** The rate of movement (flux) of a substance X into cells was measured at different concentrations of X to construct the graph below.

- (a) Does this information suggest that the movement of X into the cells is mediated by a protein transporter? Explain.  
 (b) What additional experiment could you perform to verify that a transport protein is or is not involved?

**6.** You have isolated a new strain of bacteria and would like to know whether leucine and ethylene glycol enter the cells by mediated diffusion or only by a nonmediated route. To do this you measure the initial rates of uptake of these molecules as a function of external concentration and obtain the data in the following table.

Compound	Concentration (M)	Initial Uptake Rate (arbitrary units)
Leucine	$1 \times 10^{-6}$	110
	$2 \times 10^{-6}$	220
	$5 \times 10^{-6}$	480
	$1 \times 10^{-5}$	830
	$3 \times 10^{-5}$	1700
	$1 \times 10^{-4}$	2600
Ethylene glycol	$5 \times 10^{-4}$	3100
	$1 \times 10^{-3}$	3200
	$1 \times 10^{-3}$	1
	$5 \times 10^{-3}$	5
	0.01	10
	0.05	50
	0.1	100
0.5	500	
1.0	1000	

Which compound(s) enters by a mediated route? What criteria did you use for this decision?

**7.** Aquaporin AQP1 (Fig. 20-15) forms an hourglass-shaped pore that, in its narrowest region, is 3 Å in diameter. AQP1 is impermeable to glycerol  $[\text{CHOH}(\text{CH}_2\text{OH})_2]$ . However, a homologous and structurally similar aquaglyceroporin, which is minimally 3.4 Å wide, permits the passage of glycerol but is only poorly permeable to water. Discuss the possible differences between these channels that would account for their different permeabilities.

**8.** The  $(\text{Na}^+ - \text{K}^+) - \text{ATPase}$  is inhibited by nanomolar concentrations of vanadate, which forms a pentavalent ion,  $\text{VO}_5^{5-}$ , with trigonal bipyramidal symmetry. Explain the mechanism of this inhibition. (*Hint:* See Section 16-2B.)

**9.** What function might the synthesis of digitalis serve in the purple foxglove plant?

**10.** The  $(\text{H}^+ - \text{K}^+) - \text{ATPase}$  secretes  $\text{H}^+$  at a concentration of 0.18M from cells that have an internal pH of 7. What is the  $\Delta G$  required for the transport of 1 mol of  $\text{H}^+$  under these conditions? Assuming that the  $\Delta G$  for ATP hydrolysis is  $-31.5 \text{ kJ} \cdot \text{mol}^{-1}$  under these conditions, and that the membrane potential is 0.06 V, inside negative, how much ATP must be hydrolyzed per mole of  $\text{H}^+$  transported in order to make this transport exergonic?

**11.** A 100-Å-thick membrane has a membrane potential of 100 mV. What is the magnitude of this potential difference in  $V \cdot \text{cm}^{-1}$ ? Comment on the magnitude of this potential field in macroscopic terms.

**12.** The resting membrane potential ( $\Delta\Psi$ ) of a neuron at 37°C is  $-60$  mV (inside negative). If the free energy change associated with the transport of one  $\text{Na}^+$  ion from outside to inside is  $-11.9 \text{ kJ} \cdot \text{mol}^{-1}$ , and  $[\text{Na}^+]$  outside the cell is 260 mM, what is  $[\text{Na}^+]$  inside the cell?

**13.** Write a kinetic scheme for the  $(\text{H}^+ - \text{K}^+) - \text{ATPase}$  that provides for coupled ATP hydrolysis with  $\text{H}^+$  transport. Discuss the order of substrate addition required for coupling. Identify the steps in which mutual destabilization results in reasonable rates of transport.

**14.** If the ATP supply in the cell shown in Fig. 20-27c suddenly vanished, would the intracellular glucose concentration increase, decrease, or remain the same?

**15.** Endothelial cells and pericytes in the retina of the eye have different mechanisms for glucose uptake. The figure below shows the rate of glucose uptake for each type of cell in the presence of increasing amounts of sodium. What do these results reveal about the glucose transporter in each cell type?

**16.** Why don't nerve impulses propagate in the reverse direction?

**17.** What is the resting membrane potential across an axonic membrane at 25°C (a) in the presence of tetrodotoxin or (b) with a high concentration of  $\text{Cs}^+$  inside the axon (use the data in Table 20-3)? How do these substances affect the axon's action potential?

**18.** Decamethonium ion  $[(\text{CH}_3)_3\text{N}^+(\text{CH}_2)_{10}\text{N}^+(\text{CH}_3)_3]$  is a synthetic muscle relaxant. What is its mechanism of action?

### 4 Regulation of the Citric Acid Cycle

### 5 The Amphibolic Nature of the Citric Acid Cycle

In this chapter we continue our metabolic explorations by examining the **citric acid cycle**, the common mode of oxidative degradation in eukaryotes and prokaryotes. This cycle, which is alternatively known as the **tricarboxylic acid (TCA) cycle** and the **Krebs cycle**, marks the “hub” of the metabolic system: *It accounts for the major portion of carbohydrate, fatty acid, and amino acid oxidation and generates numerous biosynthetic precursors.* The citric acid cycle is therefore **amphibolic**, that is, it operates both catabolically and anabolically.

We begin our study of the citric acid cycle with an overview of its component reactions and a historical synopsis of its elucidation. Next, we explore the origin of the cycle’s starting compound, **acetyl-coenzyme A (acetyl-CoA)**, the common intermediate formed by the breakdown of most metabolic fuels. Then, after discussing the reaction mechanisms of the enzymes that catalyze the cycle, we consider the various means by which it is regulated. Finally, we deal with the citric acid cycle’s amphibolic nature by examining its interrelationships with other metabolic pathways.

### 1 CYCLE OVERVIEW

 See **Guided Exploration 18: Citric acid cycle overview** *The citric acid cycle (Fig. 21-1) is an ingenious series of reactions that oxidizes the acetyl group of acetyl-CoA to two molecules of CO<sub>2</sub> in a manner that conserves the liberated free energy for utilization in ATP generation.* Before we study these reactions in detail, let us consider the cycle’s chemical strategy by “walking” through the cycle and noting the fate of the acetyl group at each step. Following this preview, we shall consider some of the major discoveries that led to our present understanding of the citric acid cycle.

#### A. Reactions of the Cycle

*The eight enzymes of the citric acid cycle (Fig. 21-1) catalyze a series of well-known organic reactions that cumulatively oxidize an acetyl group to two CO<sub>2</sub> molecules with the concomitant generation of three NADHs, one FADH<sub>2</sub>, and one GTP:*

**1. Citrate synthase** catalyzes the condensation of acetyl-CoA and **oxaloacetate** to yield **citrate**, giving the cycle its name.

**2.** The strategy of the cycle’s next two steps is to rearrange citrate to a more easily oxidized isomer and then oxidize it. **Aconitase** isomerizes citrate, a not readily oxidized tertiary alcohol, to the easily oxidized secondary alcohol **isocitrate**. The reaction sequence involves a dehydration, producing enzyme-bound **cis-aconitate**, followed by a hydration, so that citrate’s hydroxyl group is, in effect, transferred to an adjacent carbon atom.

**3. Isocitrate dehydrogenase** oxidizes isocitrate to the β-keto acid intermediate **oxalosuccinate** with the coupled reduction of NAD<sup>+</sup> to NADH; oxalosuccinate is then decarboxylated, yielding **α-ketoglutarate**. This is the first step in which oxidation is coupled to NADH production and also the first CO<sub>2</sub>-generating step.

**4.** The multienzyme complex **α-ketoglutarate dehydrogenase** oxidatively decarboxylates α-ketoglutarate to **succinyl-coenzyme A**. The reaction involves the reduction of a second NAD<sup>+</sup> to NADH and the generation of a second molecule of CO<sub>2</sub>. At this point in the cycle, two molecules of CO<sub>2</sub> have been produced, so that the net oxidation of the acetyl group is complete. Note, however, that it is not the carbon atoms of the entering acetyl-CoA that have been oxidized.

**Figure 21-1** Reactions of the citric acid cycle. The reactants and products of this catalytic cycle are boxed. The pyruvate  $\rightarrow$  acetyl-CoA reaction (top) supplies the cycle's substrate via carbohydrate metabolism but is not considered to be part of the cycle. The bracketed compounds are enzyme-bound

intermediates. An isotopic label at C4 of oxaloacetate (\*) becomes C1 of  $\alpha$ -ketoglutarate and is released as  $\text{CO}_2$  in Reaction 4. An isotopic label at C1 of acetyl-CoA ( $\ddagger$ ) becomes C5 of  $\alpha$ -ketoglutarate and is scrambled in Reaction 5 between C1 and C4 of succinate ( $1/2\ddagger$ ).  See the Animated Figures

**5. Succinyl-CoA synthetase** converts succinyl-coenzyme A to **succinate**. The free energy of the thioester bond is conserved in this reaction by the formation of “high-energy” GTP from GDP + P<sub>i</sub>.

**6.** The remaining reactions of the cycle serve to oxidize succinate back to oxaloacetate in preparation for another round of the cycle. **Succinate dehydrogenase** catalyzes the oxidation of succinate’s central single bond to a trans double bond, yielding **fumarate** with the concomitant reduction of the redox coenzyme FAD to FADH<sub>2</sub> (the molecular formulas of FAD and FADH<sub>2</sub> and the reactions through which they are interconverted are given in Fig. 16-8).

**7. Fumarase** then catalyzes the hydration of fumarate’s double bond to yield **malate**.

**8.** Finally, **malate dehydrogenase** reforms oxaloacetate by oxidizing malate’s secondary alcohol group to the corresponding ketone with concomitant reduction of a third NAD<sup>+</sup> to NADH. Acetyl groups are thereby completely oxidized to CO<sub>2</sub> with the following stoichiometry:

*The citric acid cycle functions catalytically as a consequence of its regeneration of oxaloacetate: An endless number of acetyl groups can be oxidized through the agency of a single oxaloacetate molecule.*

NADH and FADH<sub>2</sub> are vital products of the citric acid cycle. Their reoxidation by O<sub>2</sub> through the mediation of the electron-transport chain and oxidative phosphorylation (Chapter 22) completes the breakdown of metabolic fuel in a manner that drives the synthesis of ATP. Other functions of the cycle are discussed in Section 21-5.

## B. Historical Perspective

The citric acid cycle was proposed in 1937 by Hans Krebs, a contribution that ranks as one of the most important achievements of metabolic chemistry. We therefore outline the intellectual history of this cycle’s discovery.

By the early 1930s, significant progress had been made in elucidating the glycolytic pathway (Section 17-1A). Yet the mechanism of glucose oxidation and its relationship to cellular respiration (oxygen uptake) was still a mystery. Nevertheless, the involvement of several metabolites in cellular oxidative processes was recognized. It was well known, for example, that in addition to lactate and acetate, the dicarboxylates succinate, malate, and α-ketoglutarate, as well as the tricarboxylate citrate, are rapidly oxidized by muscle tissue during respiration. It had also been shown that **malonate** (Section 21-3F), a potent inhibitor of succinate oxidation to fumarate, also inhibits cellular respiration, thereby suggesting that succinate plays a central role in oxidative metabolism rather than being just another metabolic fuel.

In 1935, Albert Szent-Györgyi demonstrated that cellular respiration is dramatically accelerated by catalytic amounts of succinate, fumarate, malate, and oxaloacetate;

that is, *the addition of any of these substances to minced muscle tissue stimulates O<sub>2</sub> uptake and CO<sub>2</sub> production far in excess of that required to oxidize the added dicarboxylic acid.* Szent-Györgyi further showed that these compounds were interconverted according to the reaction sequence:

Shortly afterward, Carl Martius and Franz Knoop demonstrated that citrate is rearranged, via *cis*-aconitate, to isocitrate and then dehydrogenated to α-ketoglutarate. α-Ketoglutarate was already known to undergo oxidative decarboxylation to succinate and CO<sub>2</sub>. This extended the proposed reaction sequence to

What was necessary to close the circle so as to make the system catalytic was to establish that oxaloacetate is converted to citrate. In 1936, Martius and Knoop demonstrated that citrate could be formed nonenzymatically from oxaloacetate and pyruvate by treatment with hydrogen peroxide under basic conditions. Krebs used this chemical model as the point of departure for the biochemical experiments that led to his proposal of the citric acid cycle.

Krebs’ hypothesis was based on his investigations, starting in 1936, on respiration in minced pigeon breast muscle (which has a particularly high rate of respiration). The idea of a catalytic cycle was not new to him: In 1932, he and Kurt Henseleit had elucidated the outlines of the **urea cycle**, a process in which ammonia and CO<sub>2</sub> are converted to urea (Section 26-2). The most important observations Krebs made in support of the existence of the citric acid cycle were as follows:

1. Succinate is formed from fumarate, malate, or oxaloacetate in the presence of the metabolic inhibitor malonate. Since malonate inhibits the direct reduction of fumarate to succinate, the succinate must be formed by an oxidative cycle.

2. Pyruvate and oxaloacetate can form citrate enzymatically. Krebs therefore suggested that the metabolic cycle is closed with the reaction:

3. The interconversion rates of the cycle’s individual steps are sufficiently rapid to account for observed respiration rates, so it must be (at least) the major pathway for pyruvate oxidation in muscle.

Although Krebs had established the existence of the citric acid cycle, some major gaps still remained in its complete elucidation. The mechanism of citrate formation did not become clear until Nathan Kaplan and Fritz Lipmann discovered **coenzyme A** in 1945 (Section 21-2), and Severo Ochoa and Feodor Lynen established, in 1951, that acetyl-CoA is the intermediate that condenses with oxaloacetate to form citrate. Oxidative decarboxylation of α-ketoglutarate to succinate was also shown to involve coenzyme A with succinyl-CoA as an intermediate.

The elucidation of the citric acid cycle was a major achievement and, like all achievements of this magnitude, required the efforts of numerous investigators. Indeed, biochemists are still working to understand the cycle on a molecular and enzymatic level. We shall study the eight enzymes that catalyze the cycle after first discussing the cycle's major fuel, acetyl-CoA, and its formation from pyruvate.

## 2 METABOLIC SOURCES OF ACETYL-COENZYME A

Acetyl groups enter the citric acid cycle as **acetyl-coenzyme A (acetyl-SCoA or acetyl-CoA; Fig. 21-2)**, the common product of carbohydrate, fatty acid, and amino acid breakdown. **Coenzyme A (CoASH or CoA)** consists of a  $\beta$ -mercaptoethylamine group bonded through an amide linkage to the vitamin **pantothenic acid**, which, in turn, is attached to a 3'-phosphoadenosine moiety via a pyrophosphate bridge. The acetyl group of acetyl-CoA is bonded as a thioester to the sulfhydryl portion of the  $\beta$ -mercaptoethylamine group. *CoA* thereby functions as a carrier of acetyl and other acyl groups (the *A* in *CoA* stands for "Acetylation").

*Acetyl-CoA* is a "high-energy" compound: The  $\Delta G^\circ$  for the hydrolysis of its thioester bond is  $-31.5 \text{ kJ} \cdot \text{mol}^{-1}$ , which makes this reaction slightly ( $1 \text{ kJ} \cdot \text{mol}^{-1}$ ) more exergonic than that of ATP hydrolysis (Section 16-4A). The formation of this thioester bond in a metabolic intermediate therefore conserves a portion of the free energy of oxidation of a metabolic fuel.

### A. Pyruvate Dehydrogenase Multienzyme Complex (PDC)

The immediate precursor to acetyl-CoA from carbohydrate sources is the glycolytic product pyruvate. As we saw in Section 17-3, under anaerobic conditions the NADH produced by glycolysis is reoxidized with concomitant reduction of pyruvate to lactate (in muscle) or ethanol (in yeast). Under aerobic conditions, however, NADH is reoxidized by the mitochondrial electron-transport chain (Section 22-2), so that pyruvate, which enters the mitochondrion via a specific pyruvate- $\text{H}^+$  symport (membrane transport nomenclature is discussed in Section 20-3), can undergo further oxidation. (The formation of acetyl-CoA from fatty acids and amino acids is discussed in Sections 25-2 and 26-3.)

Acetyl-CoA is synthesized from pyruvate and CoA through oxidative decarboxylation by a **multienzyme complex** named **pyruvate dehydrogenase**. In general, multienzyme complexes are groups of noncovalently associated enzymes that catalyze two or more sequential steps in a metabolic pathway. The **pyruvate dehydrogenase multienzyme complex (PDC)** consists of three enzymes: **pyruvate dehydrogenase (E1)**, **dihydrolipoyl transacetylase (E2)**, and **dihydrolipoyl dehydrogenase (E3)**. The *E. coli* pyruvate dehydrogenase complex, whose characterization was pioneered by Lester Reed, is an  $\sim 4600\text{-kD}$  polyhedral particle that is  $\sim 300 \text{ \AA}$  in diameter (Fig. 21-3a). Isolated *E. coli* E2 forms a particle with 24 identical subunits, which electron micrographs (Figs. 21-3b and 21-4a), together with an X-ray structure by Wim Hol (Fig. 21-5a), indicate are arranged with cubic symmetry. The E1 subunits form dimers that associate with the E2 cube at the centers of the cube's 12 edges (Fig. 21-4b,c), whereas the E3 subunits form dimers that are located at the centers of this cube's 6 faces. We discuss the X-ray structures of the E1, E2, and E3 subunits below.

#### a. Some PDCs Have a Dodecahedral Form

Although all PDCs catalyze the same reactions by similar mechanisms, they may have different quaternary structures. Whereas the PDCs of *E. coli* and most other gram-negative bacteria have the foregoing cubic symmetry, those of

**Figure 21-2** Chemical structure of acetyl-CoA. The thioester bond is drawn with a squiggle (~) to indicate that it is a "high-energy" bond. In CoA, the acetyl group is replaced by a hydrogen atom.

**Figure 21-3** Electron micrographs of the *E. coli* pyruvate dehydrogenase multienzyme complex. (a) The intact complex. (b) The dihydrolipoyl transacetylase (E2) “core” complex. [Courtesy of Lester Reed, University of Texas.]

**Figure 21-4** Structural organization of the *E. coli* PDC. (a) The dihydrolipoyl transacetylase (E2) “core.” Its 24 subunits (green spheres) associate as trimers located at the corners of a cube to form a particle that has cubic symmetry (*O* symmetry; Section 8-5B). (b) The 24 pyruvate dehydrogenase (E1) subunits (orange spheres) form dimers that associate with the E2 core (shaded cube) at the centers of each of its 12 edges, whereas the 12 dihydrolipoyl dehydrogenase (E3) subunits (purple spheres) form dimers that attach to the E2 cube at the centers of each of its 6 faces. (c) Parts a and b combined to form the entire 60-subunit complex.

**Figure 21-5** Comparison of the X-ray structures of the dihydrolipoyl transacetylase (E2) cores of PDCs. Both complexes are drawn mainly in space-filling representation and viewed along their respective 2-fold axes of symmetry. (a) The 125-Å high cubic (*O* symmetry; Fig. 8-65c) E2 core from the gram-negative bacterium *Azotobacter vinelandii*. It consists of 24 subunits that form 8 trimers, shown here in different colors. The positions of a 2-fold, a 3-fold, and a 4-fold axis of symmetry are indicated. The inset (upper right) is a perspective drawing of a cube. (b) The 237-Å-diameter dodecahedral (*I* symmetry; Fig. 8-65c) E2 core from the gram-positive bacterium *Bacillus stearothermophilus*. It consists of 60 subunits that form 20 trimers, shown here in different colors. The positions of a 2-fold, a 3-fold, and a 5-fold axis of symmetry are indicated. The inset (upper

right) is a perspective drawing of a dodecahedron. The rear portion of each complex, which is largely eclipsed by the front portion, is gray. The subunits forming the trimers closest to the viewer in each drawing are individually colored with the lower trimer drawn in ribbon form. Note that the subunits in each trimer are extensively associated and that the trimers in the two complexes have closely similar structures. In contrast, the interactions between contacting trimers in both types of complexes are relatively tenuous. Also note that these contacting trimers form the 4- and 5-membered rings that comprise the square and pentagonal faces of the cubic and dodecahedral complexes, respectively. [Based on X-ray structures by Wim Hol, University of Washington. PDBids 1EAB and 1B5S.]

eukaryotes and some gram-positive bacteria have an analogous dodecahedral form [Fig. 21-5*b*; a dodecahedron is a regular polyhedron with *I* symmetry (Section 8-5B) that has 20 vertices, each lying on a 3-fold axis, and 12 pentagonal faces having an aggregate of 30 edges]. Thus, the mitochondrially located ~10,000-kD eukaryotic complex, the largest known multienzyme complex, consists of a dodecahedral core of 20 E2 trimers (one centered on every vertex) surrounded by 30 E1  $\alpha_2\beta_2$  heterotetramers (one centered on every edge) and 12 E3 dimers (one centered in every face).

### b. Multienzyme Complexes Are Catalytically Efficient

Multienzyme complexes are a step forward in the evolution of catalytic efficiency. They offer the following mechanistic advantages:

1. Enzymatic reaction rates are limited by the frequency at which enzymes collide with their substrates (Section 14-2Ba). If a series of reactions occurs within a multienzyme complex, the distance that substrates must diffuse between active sites is minimized, thereby achieving a rate enhancement.
2. Complex formation provides the means for **channeling** (passing) metabolic intermediates between successive enzymes in a metabolic pathway, thereby minimizing side reactions.
3. The reactions catalyzed by a multienzyme complex may be coordinately controlled.

### c. Acetyl-CoA Formation Occurs in Five Reactions

The PDC catalyzes five sequential reactions (Fig. 21-6) with the overall stoichiometry:

The coenzymes and prosthetic groups required in this reaction sequence are thiamine pyrophosphate (TPP; Fig. 17-26), flavin adenine dinucleotide (FAD; Fig. 16-8), nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ; Fig. 13-2), and **lipoamide**

(Fig. 21-7); their functions are listed in Table 21-1. Lipoamide consists of **lipoic acid** joined in amide linkage to the  $\epsilon$ -amino group of a Lys residue. Reduction of its cyclic disulfide to a dithiol, **dihydrolipoamide**, and its reoxidation (Fig. 21-7) are the “business” of this prosthetic group.

The five reactions catalyzed by the PDC are as follows (Fig. 21-6):

1. Pyruvate dehydrogenase (E1), a TPP-requiring enzyme, decarboxylates pyruvate, with the intermediate formation of hydroxyethyl-TPP. This reaction is identical with that catalyzed by yeast pyruvate decarboxylase (Section 17-3B):

**Figure 21-6** The five reactions of the PDC. E1 (pyruvate dehydrogenase) contains TPP and catalyzes Reactions 1 and 2. E2 (dihydrolipoyl transacetylase) contains lipoamide and

catalyzes Reaction 3. E3 (dihydrolipoyl dehydrogenase) contains FAD and a redox-active disulfide and catalyzes Reactions 4 and 5.

2. Unlike pyruvate decarboxylase, however, pyruvate dehydrogenase does not convert the hydroxyethyl-TPP intermediate into acetaldehyde and TPP. Instead, the hydroxyethyl group is transferred to the next enzyme in the multienzyme sequence, dihydrolipoyl transacetylase (E2). The reaction occurs by attack of the hydroxyethyl group carbanion on the lipoamide disulfide, followed by the elimination of TPP from the intermediate adduct to form acetyl-dihydrolipoamide and regenerate active E1. The hydroxyethyl carbanion is thereby oxidized to an acetyl group by the concomitant reduction of the lipoamide disulfide bond:

3. E2 then catalyzes the transfer of the acetyl group to CoA, yielding acetyl-CoA and dihydrolipoamide-E2:

This is a transesterification in which the sulfhydryl group of CoA attacks the acetyl group of acetyl-dihydrolipoamide-E2 to form a tetrahedral intermediate (not shown), which decomposes to acetyl-CoA and dihydrolipoamide-E2.

**Figure 21-7** Interconversion of lipoamide and dihydrolipoamide. Lipoamide is lipoic acid covalently joined to the  $\epsilon$ -amino group of a Lys residue via an amide linkage.

**Table 21-1** The Coenzymes and Prosthetic Groups of Pyruvate Dehydrogenase

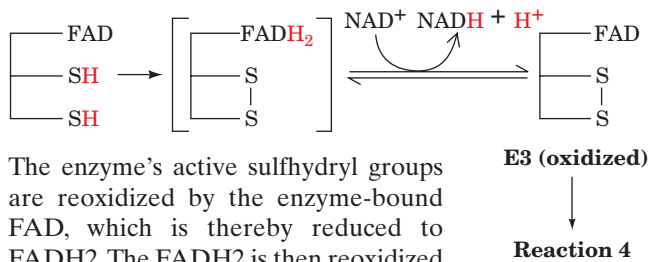

Cofactor	Location	Function
Thiamine pyrophosphate (TPP)	Bound to E1	Decarboxylates pyruvate, yielding a hydroxyethyl-TPP carbanion
Lipoic acid	Covalently linked to a Lys on E2 (lipoamide)	Accepts the hydroxyethyl carbanion from TPP as an acetyl group
Coenzyme A (CoA)	Substrate for E2	Accepts the acetyl group from acetyl-dihydrolipoamide
Flavin adenine dinucleotide (FAD)	Bound to E3	Reduced by dihydrolipoamide
Nicotinamide adenine dinucleotide ( $\text{NAD}^+$ )	Substrate for E3	Reduced by $\text{FADH}_2$

4. Dihydrolipoyl dehydrogenase (E3; also called **dihydrolipoamide dehydrogenase**) reoxidizes dihydrolipoamide, thereby completing the catalytic cycle of E2:

Oxidized E3 contains a reactive disulfide group and a tightly bound FAD. The oxidation of dihydrolipoamide is a disulfide interchange reaction (Section 9-1A): The lipoamide disulfide bond forms with concomitant reduction of E3's reactive disulfide to two sulfhydryl groups.

5. Reduced E3 is reoxidized by NAD<sup>+</sup>:

The enzyme's active sulfhydryl groups are reoxidized by the enzyme-bound FAD, which is thereby reduced to FADH<sub>2</sub>. The FADH<sub>2</sub> is then reoxidized to FAD by NAD<sup>+</sup>, producing NADH.

#### d. The Structure of E2

Dihydrolipoyl transacetylase (E2) consists of several domains (Fig. 21-8): one to three N-terminal lipoyl domains (~80 residues) that each covalently bind a lipoyl group; a **peripheral subunit-binding domain (PSBD)**; ~35 residues) that binds to both E1 and E3 and hence holds the complex together; and a C-terminal catalytic domain (~250 residues) that contains the enzyme's catalytic center and its intersubunit binding sites. These domains are linked by 20- to

**Figure 21-8** Domain structure of the dihydrolipoyl transacetylase (E2) subunit of the PDC. The number of lipoyl domains,  $n$ , is species dependent:  $n = 3$  for *E. coli* and *A. vinelandii*,  $n = 2$  for mammals and *Streptococcus faecalis*, and  $n = 1$  for *B. stearothermophilus* and yeast.

40-residue Pro- and Ala-rich segments that are largely extended and highly flexible and thereby provide the lipoyl domains with the mobility they require to interact with E1 and E3 and with neighboring E2 subunits (see below).

The hollow cagelike structures formed by the E2 catalytic domains (Fig. 21-5) contain channels large enough to allow substrates to diffuse in and out. In fact, coenzyme A and lipoamide bind in extended conformations at opposite ends of a 30-Å-long channel that is located at the interface between each pair of the subunits in a trimer (Fig. 21-9). This arrangement requires CoA to approach its binding site from inside the cage.

The NMR structures of the lipoyl domains of E2 from several sources verify the exposed nature of the site of the lipoyl group. They consist of a  $\beta$  barrel/sandwich containing a 4-stranded and a 3-stranded antiparallel  $\beta$  sheet, with the Lys to which the lipoyl group would be attached extending from an exposed position on a type I  $\beta$  bend linking two of the  $\beta$  strands in the 4-stranded sheet (Fig. 21-10a).

The NMR structure of the PSBD from *B. stearothermophilus*, determined by Richard Perham, reveals that its ~35-residue ordered region consists of two parallel helices separated by a loop that form a close-packed hydrophobic

**Figure 21-9** X-ray structure of a trimer of *A. vinelandii* dihydrolipoyl transacetylase (E2) catalytic domains in complex with CoA and lipoamide. The trimer, a portion of the cubic complex (Fig. 21-5a), is drawn in ribbon form and viewed along its 3-fold axis (the cubic complex's body diagonal) from inside the cube. The three identical domains have different colors with the upper domain colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The CoA and lipoamide bound to the upper and lower left subunits are drawn in space-filling form and those bound to the lower right subunit are drawn in stick form, with CoA C green, lipoamide C cyan, N blue, O red, P orange, and S yellow. Note how the N-terminal "elbow" of each subunit extends behind the counterclockwise adjacent subunit; its deletion greatly destabilizes the complex. [Based on an X-ray structure by Wim Hol, University of Washington. PDBid 1EAB.]

**Figure 21-10** NMR structures of the lipoyl and peripheral subunit-binding domains of dihydrolipoyl transacetylase (E2). (a) The NMR structure of the *A. vinelandii* dihydrolipoyl transacetylase (E2) lipoyl domain. The polypeptide chain is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). The Lys side chain to which the lipoyl group would be bound is shown in stick form colored according to atom type (C green, H white, and N blue) and is located in a type I  $\beta$  turn. [Based on an NMR structure by Aart de Kok, Wageningen Agricultural University, Wageningen, Netherlands. PDBid 11YU.] (b) The NMR structure of the peripheral subunit-binding domain (PSBD) from *B. stearrowthermophilus* E2. The polypeptide chain is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). [Based on an NMR structure by Richard Perham, Cambridge University, U.K. PDBid 2PDD.]

core (Fig. 21-10b). It is one of the smallest known polypeptides that have a globular structure but lack disulfide bonds or prosthetic groups.

### e. Intermediates Are Transferred between Enzyme Subunits by Flexible Tethers

How are reaction intermediates transferred between the component enzymes of the PDC? The group between the lipoamide disulfide bond and the E2 polypeptide backbone, the so-called **lipoyllysyl arm**, has a fully extended length of 14 Å:

Evidently, the lipoyllysyl arm, in combination with the  $>140\text{-\AA}$ -long outer linker (Fig. 21-8), acts as a long flexible tether that swings its attached lipoyl group among the active sites of E1, E2, and E3. Moreover, there is rapid interchange of acetyl groups among the lipoyl groups of the E2 core ( $3 \times 24 = 72$  lipoyl groups in an *E. coli* PDC;  $2 \times 60 = 120$  in mammals); the tethered arms also swing among themselves, exchanging both acetyl groups and disulfides:

One E1 subunit can therefore acetylate numerous E2 subunits and one E3 subunit can reoxidize several dihydrolipoamide groups.

### f. Mammalian and Yeast PDCs Contain Additional Subunits

In mammals and yeast, the dodecahedral PDC's already complicated structure has a further level of complexity in that it contains additional subunits: About 12 copies of **E3 binding protein (E3BP)** facilitate the binding of E3 to the E2 core of the eukaryotic dodecahedral complex. E3BP has a lipoyllysine-containing domain similar to E2 and can accept an acetyl group, but its C-terminal domain has no catalytic activity, and the removal of its lipoyllysine domain does not diminish the catalytic activity of the complex. E3BP's main role seems to be to aid in the binding of E3, since limited proteolysis of E3BP decreases E3's binding ability.

### g. Cryoelectron Microscopy Reveals the Structure of the Dodecahedral PDC

James Stoops and Reed have determined the organization of the bovine kidney dodecahedral complex through cryoelectron microscopy (Fig. 21-11). As expected, the E2 subunits form a dodecahedral core that is surrounded by a concentric dodecahedron of E1 subunits (Fig. 21-11*a,b*). The E2 subunits bind the E1 subunits via the radially extending,  $\sim 50$ -Å-long inner linkers that precede the PSBD of E2 (Fig. 21-8; these linkers are not present in Fig. 21-5*b* because that X-ray structure only contains E2's catalytic domain). Although the bovine kidney PDC used in the structure determination lacked sufficient E3BP · E3 to be visible, its position in the electron microscopy-based structure of yeast PDC indicates that an E3 dimer occupies and largely fills each pentagonal opening of the E2 core (Fig. 21-11*c*). Hence the E3 subunits are not arranged with dodecahedral symmetry (similarly, the E3 subunits in the cubic *E. coli* PDC are not arranged with cubic symmetry;

**Figure 21-11** Electron microscopy-based images of the bovine kidney pyruvate dehydrogenase complex at  $\sim 35$  Å resolution.

(*a*) The entire particle as viewed along its 3-fold axis of symmetry. E1 is yellow, the E2 catalytic core is green, and the inner linkers that connect E2's catalytic domains to its E1-binding domains, the PSBDs (Fig. 21-8), are cyan. The particle is viewed along a 3-fold axis of symmetry with the positions of a 5-fold axis and a 2-fold axis also marked. (*b*) A cutaway diagram viewed and colored as in Part *a* but with the particle's closest half removed to reveal the E2 catalytic core and the inner linkers. Compare the green portion with the X-ray structure of a dodecahedral E2 catalytic core as viewed along a 2-fold axis (Fig. 21-5*b*). (*c*) A cutaway diagram as in Part *b* but with E3 dimers (Fig. 21-13*a*) shown at 20 Å resolution (red) modeled into the pentagonal openings of the E2 core. The position of a peripheral subunit-binding site at the end of an E2 inner linker is marked by an asterisk (\*). [From Zhou, Z.H., McCarthy, D.B., O'Connor, C.M., Reed, L.J., and Stoops, J.K., *Proc. Natl. Acad. Sci.* **98**, 14802 (2001).]

Fig. 21-4b). The PSBD, which is located at the end of the E2 inner linker (\* in Fig. 21-11c), is the point from which the E2 lipoyl domains (Fig. 21-10a) swing. It is  $\sim 50$  Å from the nearest active sites of E1, E2, and E3.

In addition to E3BP, the mammalian PDC contains one to three copies each of **pyruvate dehydrogenase kinase** and **pyruvate dehydrogenase phosphatase**. The kinase and phosphatase function to regulate the catalytic activity of the complex (Section 21-2Cb).

### h. Two Other Multienzyme Complexes Closely Resemble the PDC

In addition to the PDC, most cells contain two other closely related multienzyme complexes: the  **$\alpha$ -ketoglutarate dehydrogenase complex** [also called **2-oxoglutarate dehydrogenase (OGDH)**], which catalyzes Reaction 4 of the citric acid cycle; Fig. 21-1] and the **branched-chain  $\alpha$ -keto acid dehydrogenase complex (BCKDH)**; which participates in the degradation of isoleucine, leucine, and valine; Section 26-3Ee). These multienzyme complexes all catalyze similar reactions: the  $\text{NAD}^+$ -linked oxidative decarboxylation of an  $\alpha$ -keto acid with the transfer of the resulting acyl group to CoA. In fact, all three members of this **2-ketoacid dehydrogenase** family (alternatively, the **2-oxo acid dehydrogenase** family) of multienzyme complexes share the same E3 subunit, and their E1 and E2 subunits, which are specific for their corresponding substrates, are homologous and use identical cofactors. Thus, to differentiate them, the E1s for PDC, OGDH, and BCKDH are often referred to as **E1p**, **E1o**, and **E1b**, respectively, and likewise, their E3s are called **E3p**, **E3o**, and **E3b**.

### i. Arsenic Compounds Are Poisonous because They Sequester Lipoamide

Arsenic has been known to be a poison since ancient times. As(III) compounds, such as **arsenite** ( $\text{AsO}_3^{3-}$ ) and organic arsenicals, are toxic because of their ability to covalently bind sulfhydryl compounds. This is particularly true of vicinal (adjacent) sulfhydryls such as those of lipoamide because they can form bidentate adducts:

The resultant inactivation of lipoamide-containing enzymes, especially pyruvate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase (Section 21-3D), brings respiration to a halt.

Organic arsenicals are more toxic to microorganisms than to humans, apparently because of differences in the sensitivities of their various enzymes to these compounds. This differential toxicity is the basis for the early twentieth century use of organic arsenicals in the treatment of **syphilis** (now superseded by penicillin) and **trypanosomiasis** (trypanosomes are parasitic protozoa that cause several diseases including **African sleeping sickness** and **Chagas-Cruz disease**). These compounds were really the first antibiotics, although, not surprisingly, they had severe side effects.

### j. Arsenic Poisoning, Napoleon, and Darwin

Arsenic is often suspected as a poison in untimely deaths. In fact, it has long been thought that Napoleon Bonaparte died from arsenic poisoning while in exile on St. Helena, an island in the Atlantic Ocean. This suspicion, and the chemical analyses it sparked, makes a fascinating chemical anecdote. The finding that a lock of Napoleon's hair indeed contains a high level of arsenic strongly supports the notion that arsenic poisoning at least contributed to his death. But was it murder or environmental pollution? A sample of the wallpaper from Napoleon's drawing room was found to contain the commonly used (at the time) green pigment copper arsenate ( $\text{CuHAsO}_4$ ). It was eventually determined that in a damp climate, as occurs on St. Helena, fungi growing on the wallpaper eliminate the arsenic by converting it to the volatile and highly toxic trimethyl arsine [ $(\text{CH}_3)_3\text{As}$ ]. Indeed, Napoleon's regular visitors also suffered from symptoms of arsenic poisoning (e.g., gastrointestinal disturbances), which appeared to moderate when they spent much of their time outdoors. Thus, Napoleon's arsenic poisoning may have been unintentional.

Retrospective detective work also suggests that Charles Darwin was a victim of chronic arsenic poisoning. For most of his life after he returned from his epic voyage, Darwin complained of numerous ailments, including eczema, vertigo, headaches, arthritis, gout, palpitations, and nausea, all symptoms of arsenic poisoning. Fowler's solution, a common nineteenth century tonic, contained 10 mg of arsenite  $\cdot \text{mL}^{-1}$ . Many individuals, quite possibly Darwin himself, took this "medication" for years.

### k. The Structure of E1

In dodecahedral PDCs, E1 (pyruvate dehydrogenase) is a 2-fold symmetric  $\alpha_2\beta_2$  heterotetramer. However, in cubic PDCs and in  $\alpha$ -ketoglutarate dehydrogenase, which is also cubic, the  $\alpha$  and  $\beta$  subunits are genetically fused to form a single polypeptide and hence a homodimeric enzyme.

The X-ray structure of E1 from the (dodecahedral) *B. stearothermophilus* PDC in complex with TPP and a

PSBD (Fig. 21-12a), determined by Perham and Ben Luisi, reveals a tightly associated  $\alpha_2\beta_2$  heterotetramer, whose 368-residue  $\alpha$  subunits and 324-residue  $\beta$  sub-

(a)

(b)

**Figure 21-12** X-ray structure of *B. stearotherophilus* E1 in complex with TPP and the peripheral subunit-binding domain (PSBD). (a) The E1  $\alpha_2\beta_2$  heterotetramer, viewed with its 2-fold axis of symmetry vertical and the E2 dodecahedron below, is drawn with its  $\alpha$  subunits in worm form and its  $\beta$  subunits in ribbon form. The  $\alpha$  and  $\beta$  subunits that are closest to the viewer and predominantly on the left are each colored in rainbow order from their N-termini (blue) to their C-termini (red); the remaining  $\alpha$  and  $\beta$  subunits are pale cyan and pale green. The PSBD (below) is light blue. The TPP is shown in space-filling form with C green, N blue, O red, P orange, and S yellow. The entrances to the enzyme's active site channels are indicated by black arrows. (b) A cutaway surface diagram of the solvent-filled tunnel connecting the enzyme's two active sites. The hydroxyethyl-TPPs bound at the enzyme's active sites and the Asp and Glu side chains lining the tunnel are drawn in stick form with C gray, N blue, O red, P green, and S yellow. Water molecules and  $Mg^{2+}$  ions are represented by red and magenta spheres. [Part a based on an X-ray structure by and Part b courtesy of Richard Perham and Ben Luisi, University of Cambridge, U.K. PDBid 1W85.]

units each consist of two domains. A single PSBD binds to the C-terminal domains of the  $\beta$  subunits along the 2-fold axis relating them in a way that sterically prevents the binding of a second PSBD. Hence the PSBD interacts asymmetrically with the two chemically identical domains in a manner reminiscent of the way that human growth hormone interacts with its homodimeric receptor (Section 19-1J). E1's conserved  $\sim 310$ -residue core occurs in other TPP-utilizing enzymes of known structure, including pyruvate decarboxylase (Section 17-3Ba). Each TPP is bound between the N-terminal domains of an  $\alpha$  and a  $\beta$  subunit at the end of an  $\sim 21$ -Å-deep funnel-shaped channel with its thiazolium ring (its reactive group) closest to the channel entrance. Apparently, the lipoyl arm at the end of an E2 lipoyl domain is inserted into this channel in an extended conformation for the transfer of the TPP's hydroxyacyl substituent to lipamide.

### I. E1 Active Sites Are Coordinated via a Proton Wire

When apo-E1 is mixed with TPP, the first TPP to bind to this apparently 2-fold symmetric protein does so orders of magnitude faster than the second TPP. This indicates that these two binding sites, which are  $\sim 20$  Å apart, somehow communicate. In fact, the enzyme's two active sites in the foregoing X-ray structure have different structures in that two conserved loops (residues 203–212 and 276–287 of the  $\alpha$  subunits) at the entrance to the channel leading to TPP are ordered in one subunit in a way that blocks the active site but are disordered in the other subunit. That this is not an artifact of crystallization was demonstrated by the observation that limited proteolysis cleaves the more C-terminal of these loops on one subunit, but not the other. Similar asymmetries have been observed in all TPP-dependent enzymes of known structure.

The X-ray structure of E1 reveals a solvent-filled tunnel linking its two active sites that is lined with 10 conserved acidic residues (Fig. 21-12b). Similar acidic tunnels are present in all TPP-dependent enzymes of known structure, all of which are either dimeric or tetrameric. This led Luisi and Perham to propose that as pyruvate proceeds through the E1-catalyzed Reactions 1 and 2 discussed in Section 21-2Ac, the proton required by Reaction 1 in one active site is supplied by the proton released in Reaction 2 in the other active site. The protons are presumably transferred between the two active sites via series of proton jumps (Section 2-1C) through the acidic tunnel, which thereby functions as a **proton wire**. Consequently, as the two active sites progress through their catalytic cycles, they must remain out of phase with one another; that is, one site requires a general base when the other site requires a general acid and vice versa so that they reciprocate their catalytic needs via the proton wire. This explains the observed negative cooperativity of substrate binding exhibited by E1. Structurally, this is rationalized by the alternate closing and opening of the active sites through the out of phase ordering and disordering of the loops at the entrance of each active site channel.

### B. The Mechanism of Dihydrolipoyl Dehydrogenase

The reaction catalyzed by dihydrolipoyl dehydrogenase (E3) is more complex than Reactions 4 and 5 in Fig. 21-6 suggest. Vincent Massey demonstrated that oxidized dihydrolipoyl dehydrogenase contains a “redox-active” disulfide bond, which in the enzyme’s reduced form has accepted an electron pair through bond cleavage to form a dithiol:

He established this through the following observations involving arsenite (which, as we saw in Section 21-2Ai, reacts with vicinal sulfhydryl groups but not with disulfides).

1. The spectrum of oxidized dihydrolipoyl dehydrogenase (E) is unaffected by arsenite.

2. When NADH reacts with the oxidized enzyme in the presence of arsenite, the resulting reduced enzyme (EH<sub>2</sub>) binds arsenite to form an enzymatically inactive species.

3. The oxidation state of the flavin in a **flavoprotein** (flavin-containing protein) is readily established from its characteristic UV–visible spectrum: FAD is an intense yellow, whereas FADH<sub>2</sub> is pale yellow. The spectrum of the arsenite-inactivated EH<sub>2</sub> indicates that its FAD prosthetic group is fully oxidized.

Oxidized dihydrolipoyl dehydrogenase must therefore have a second electron acceptor in addition to FAD; arsenite’s known specificity suggests that the acceptor is a disulfide. Dihydrolipoyl dehydrogenase’s amino acid sequence indicates that its redox-active disulfide bond forms between its Cys 43 and Cys 48, which occur on a highly conserved segment of the enzyme’s polypeptide chain.

#### a. The X-Ray Structures of Dihydrolipoyl Dehydrogenase and Glutathione Reductase

The X-ray structures of dihydrolipoyl dehydrogenase from several microorganisms, mostly determined by Hol, reveal that each ~470-residue subunit of these homodimeric enzymes is folded into four domains, all of which participate in forming the subunit’s catalytic center (Fig. 21-13a). An E2 PSBD (not present in Fig. 21-13) binds to the bottom of the enzyme along its 2-fold axis in much the same way that it binds to E1 (Fig. 21-12). The flavin is almost completely buried in the protein, which prevents the surrounding solution from interfering with the electron-transfer reaction catalyzed by the enzyme (FADH<sub>2</sub>, but not NADH or thiol, is rapidly oxidized by O<sub>2</sub>). The redox-active disulfide, which is located on the opposite side of the flavin ring from the nicotinamide ring (Fig. 21-13b), links successive turns in a distorted segment of an α helix (in an undistorted helix, the C<sub>α</sub> atoms of Cys 43 and Cys 48 would be too far apart to permit the disulfide bond to form).

(a)

(b)

**Figure 21-13** X-ray structure of dihydrolipoyl dehydrogenase (E3) from the gram-negative bacterium *Pseudomonas putida* in complex with FAD and NAD<sup>+</sup>. (a) The homodimeric enzyme is viewed with its 2-fold axis of symmetry vertical and the E2 dodecahedron below. One subunit is gray and the other is colored according to domain, with its FAD-binding domain (residues 1–142) light orange, its NAD<sup>+</sup>-binding domain (residues 143–268) purple, its central domain (residues 269–337) yellow-green, and its interface domain (residues 338–458) pink. The NAD<sup>+</sup> and FAD in both subunits are shown in stick form with FAD C green, NAD<sup>+</sup> C cyan, N blue, O red, and P orange. (b) The active site region of the left subunit in Part a in which the central and interface domains have been deleted for clarity. The view is very roughly in the same direction as in Part a. The redox-active portions of the bound NAD<sup>+</sup> and FAD cofactors, the side chains of Cys 43 and Cys 48 forming the redox-active disulfide bond, and the side chain of Tyr 181 are shown in ball-and-stick form with FAD C green, NAD<sup>+</sup> C cyan, side chain C magenta, N blue, O red, P magenta, and S yellow. Note that the side chain of Tyr 181 is interposed between the flavin and the nicotinamide rings. [Based on an X-ray structure by Wim Hol, University of Washington. PDBid 1LVL.]

E3’s catalytic mechanism has been largely determined in analogy with that of the homologous (~33% identical) but structurally more extensively characterized **glutathione reductase (GR)**. This nearly ubiquitous enzyme catalyzes

**Figure 21-14** Catalytic reaction cycle of dihydrolipoil dehydrogenase. The catalytic center is surrounded by protein so that the NAD<sup>+</sup> and dihydrolipoamide binding sites are in deep pockets. The catalytic cycle consists of six steps: **(1)** The oxidized enzyme, E, which contains a redox-active disulfide bond between Cys 43 and Cys 48, binds dihydrolipoamide, LH<sub>2</sub>, the enzyme's first substrate, to form an enzyme-substrate complex, E · LH<sub>2</sub>. **(2)** A substrate S atom nucleophilically attacks S<sub>43</sub> to yield a disulfide bond and release S<sub>48</sub> as a thiolate ion. The proton on the substrate's second thiol group is abstracted by His 451' to yield a second thiolate ion, E-S-S-L · S<sup>-</sup>. **(3)** The substrate thiolate ion nucleophilically displaces S<sub>43</sub> aided by general acid catalysis by

His 451' to yield the enzyme's lipoamide product in its complex with the stable reduced enzyme, EH<sub>2</sub> · L, in which S<sub>48</sub> forms a charge-transfer complex with the flavin ring (dotted red line to the red flavin ring). **(4)** The lipoamide product is released, yielding EH<sub>2</sub>. The phenol side chain of Tyr 181 continues to block access to the flavin ring of FAD, so as to prevent the enzyme's oxidation by O<sub>2</sub>. **(5)** The enzyme's second substrate, NAD<sup>+</sup>, binds to EH<sub>2</sub> to form EH<sub>2</sub> · NAD<sup>+</sup>. The phenol side chain of Tyr 181 is pushed aside by the nicotinamide ring of NAD<sup>+</sup>. **(6)** The catalytic cycle is then closed by the reduction of the NAD<sup>+</sup> by EH<sub>2</sub> to reform the oxidized enzyme E and yield the enzyme's second product, NADH.

which an electron pair is partially transferred from a donor, in this case  $S_{48}^-$ , to an acceptor, in this case the oxidized flavin ring; the red color of this complex is indicative of the formation of the charge-transfer complex).

Stage II of this Ping Pong reaction (Fig. 21-14, Steps 5 and 6) involves the binding and reduction of  $NAD^+$  followed by the release of NADH to regenerate the oxidized enzyme. The path of the electrons from the reactive disulfide in its reduced form through the FAD to  $NAD^+$  has been elucidated by spectroscopic studies and the chemistry of model compounds. These indicate that an electron pair is rapidly transferred from  $S_{48}^-$  to the flavin ring through the transient formation of a covalent bond from  $S_{48}$  to flavin atom 4a (Fig. 21-16, Step 1). His 451' then abstracts the proton from the  $S_{43}$  thiol to form a thiolate ion, which nucleophilically attacks  $S_{48}$  to reform the redox-active disulfide group (Fig. 21-16, Step 2). The resulting reduced flavin anion ( $FADH^-$ ) has but transient existence. The H atom substituent to its N5 is immediately transferred (formally as a hydride ion) to the juxtaposed C4 atom of the nicotinamide ring (Fig. 21-15), yielding FAD and the reaction's second product, NADH, thereby completing the catalytic cycle. Thus, the FAD appears to function more like an electron conduit between the reduced form of the redox-active disulfide and  $NAD^+$  than as a source or sink of electrons.

### C. Control of Pyruvate Dehydrogenase

The PDC regulates the entrance of acetyl units derived from carbohydrate sources into the citric acid cycle. The decarboxylation of pyruvate by E1 is irreversible and, since there are no other pathways in mammals for the synthesis of acetyl-CoA from pyruvate, it is crucial that the reaction be carefully controlled. Two regulatory systems are employed:

1. Product inhibition by NADH and acetyl-CoA (Fig. 21-17a).

2. Covalent modification by phosphorylation/dephosphorylation of the pyruvate dehydrogenase (E1) subunit (Fig. 21-17b; enzymatic regulation by covalent modification is discussed in Section 18-3Ba).

#### a. Control by Product Inhibition

*NADH* and *acetyl-CoA* compete with *NAD<sup>+</sup>* and *CoA* for binding sites on their respective enzymes. They also drive the reversible *transacetylase* (E2) and *dihydrolipoyl dehydrogenase* (E3) reactions backward (Fig. 21-17a). High ratios of  $[NADH]/[NAD^+]$  and  $[acetyl-CoA]/[CoA]$  therefore maintain E2 in the acetylated form, incapable of accepting the hydroxyethyl group from the TPP on E1. This, in turn, ties up the TPP on the E1 subunit in its hydroxyethyl form, decreasing the rate of pyruvate decarboxylation.

#### b. Control by Phosphorylation/Dephosphorylation

Control by phosphorylation/dephosphorylation occurs only in eukaryotic enzyme complexes. These complexes contain pyruvate dehydrogenase kinase and pyruvate

**Figure 21-16** The reaction transferring an electron pair from dihydrolipoyl dehydrogenase's redox-active disulfide in its reduced form to the enzyme's bound flavin ring. (1) The collapse of the charge-transfer complex between the Cys 48 thiolate ion and the flavin ring (dashed red line) to form a covalent bond between  $S_{48}$  and flavin atom C4a.  $S_{48}$  is located out of the plane of the flavin, as Fig. 21-15 indicates. Flavin atom N5 acquires a proton, possibly from  $S_{43}$ , which becomes a thiolate ion. (2) The  $S_{43}$  thiolate nucleophilically attacks  $S_{48}$  to form the redox-active disulfide bond, thereby releasing the reduced flavin anion  $FADH^-$ .

**Figure 21-17 Factors controlling the activity of the PDC.**

(a) Product inhibition. NADH and acetyl-CoA, respectively, compete with  $NAD^+$  and CoA in Reactions 3 and 5 of the pyruvate dehydrogenase reaction sequence. When the relative concentrations of NADH and acetyl-CoA are high, the reversible reactions catalyzed by E2 and E3 are driven backward (red arrows), thereby inhibiting further formation of acetyl-CoA. (b) Covalent modification in the eukaryotic

complex. Pyruvate dehydrogenase (E1) is inactivated by the specific phosphorylation of one of its Ser residues in a reaction catalyzed by pyruvate dehydrogenase kinase (right). This phosphoryl group is hydrolyzed through the action of pyruvate dehydrogenase phosphatase (left), thereby reactivating E1. The activators and inhibitors of the kinase are listed on the right and the activators of the phosphatase are listed on the left.

dehydrogenase phosphatase bound to the dihydrolipoyl transacetylase (E2) core. The kinase inactivates the pyruvate dehydrogenase (E1) subunit by catalyzing the ATP-dependent phosphorylation of a Ser residue on the more C-terminal loop at the entrance of the active site channel (Fig. 21-17b). Moreover, phosphorylation at only one of E1's two active sites inactivates the entire enzyme, thereby further demonstrating the obligatory nature of the out of phase coupling between these two active sites (Section 21-2A1). Hydrolysis of this phosphoSer residue by the phosphatase reactivates the complex.

Pyruvate dehydrogenase kinase is activated through its interaction with the acetylated form of E2. Consequently, the products of the reaction, NADH and acetyl-CoA, in addition to their direct effects on the PDC, indirectly activate pyruvate dehydrogenase kinase. The resultant phosphorylation inactivates the complex just as the products themselves inhibit it. Acetyl-CoA and NADH are products of fatty acid oxidation (Section 25-2) so that this inhibition

of PDC serves to preserve carbohydrate stores when lipid fuels are available.

Calcium ion is an important second messenger signaling the need for increased energy (e.g., for muscle contraction). Increasing  $[Ca^{2+}]$  enhances pyruvate dehydrogenase phosphatase activity, thus activating PDC.

Insulin is involved in the control of this system through its indirect activation of pyruvate dehydrogenase phosphatase. Recall that insulin activates glycogen synthesis as well by activating phosphoprotein phosphatase-1 (Section 18-3Cg). Insulin, in response to increases in blood glucose, is now seen as promoting the synthesis of acetyl-CoA as well as glycogen. As we shall see in Section 25-4, acetyl-CoA is the precursor to fatty acids in addition to being the fuel for the citric acid cycle. Various other activators and inhibitors regulate the pyruvate dehydrogenase system (Fig. 21-17b); in contrast to the glycogen metabolism control system (Section 18-3), however, it is unaffected by cAMP.

### 3 ENZYMES OF THE CITRIC ACID CYCLE

In this section we discuss the reaction mechanisms of the eight citric acid cycle enzymes. Our knowledge of these mechanisms rests on an enormous amount of experimental work; as we progress, we shall pause to examine some of these experimental details. Consideration of how this cycle is regulated and its relationship to cellular metabolism are the subjects of the following sections.

#### A. Citrate Synthase

*Citrate synthase* (originally named *citrate condensing enzyme*) catalyzes the condensation of acetyl-CoA and oxaloacetate (Reaction 1 of Fig. 21-1). This initial reaction of the citric acid cycle is the point at which carbon atoms are “fed into the furnace” as acetyl-CoA. The citrate synthase reaction proceeds via an Ordered sequential kinetic mechanism (Section 14-5Aa), with oxaloacetate adding to the enzyme before acetyl-CoA.

The X-ray structure of the free dimeric enzyme, determined by James Remington and Robert Huber, shows it to

adopt an “open form” in which the two domains of each sub-unit form a deep cleft that contains the oxaloacetate binding site (Fig. 21-18a). On binding oxaloacetate, however, the smaller domain undergoes a remarkable 18° rotation relative to the larger domain, which closes the cleft (Fig. 21-18b).

The X-ray structures of two inhibitors of citrate synthase in ternary complex with the enzyme and oxaloacetate have also been determined. **Acetonyl-CoA**, an inhibitory analog of acetyl-CoA in the ground state, and **carboxymethyl-CoA**, a proposed transition state analog (see below),

**Figure 21-18** Conformational changes in citrate synthase. (a) The open conformation. (b) The closed, substrate-binding conformation. In both forms, the homodimeric protein is viewed along its 2-fold axis and is represented by its transparent molecular surface with its polypeptide chains drawn in worm form colored in rainbow order from blue at their N-termini to red at their C-termini. The reaction product citrate, which is bound to both enzymatic forms, and coenzyme A, which is also bound to the closed form, are shown in space-filling form with

citrate C cyan, CoA C green, N blue, O red, and P orange. The large conformational shift between the open and closed forms entails 18° rotations of the small domains (*upper left and lower right*) relative to the large domains resulting in relative interatomic movements of up to 15 Å. [Based on X-ray structures by James Remington and Robert Huber, Max-Planck-Institut für Biochemie, Martinsried, Germany. PDBids 1CTS and 2CTS.] See Interactive Exercise 15

bind to the enzyme in its “closed” form, thereby identifying the acetyl-CoA binding site. The existence of the “open” and “closed” forms explains the enzyme’s ordered sequential kinetic behavior: *The conformational change induced by oxaloacetate binding generates the acetyl-CoA binding site while sealing off the solvent’s access to the bound oxaloacetate.* This is a classic example of the induced-fit model of substrate binding (Section 10-4C). Hexokinase exhibits similar behavior (Section 17-2Aa).

The citrate synthase reaction is a mixed aldol–Claisen ester condensation, subject to general acid–base catalysis and the intermediate participation of the enol(ate) form of acetyl-CoA. The X-ray structure of the enzyme in ternary complex with oxaloacetate and carboxymethyl-CoA reveals that three of its ionizable side chains are properly oriented to play catalytic roles: His 274, Asp 375, and His 320. The N1 atoms in both of these His side chains are hydrogen bonded to two backbone NH groups indicating that these N1 atoms are not protonated. The participation of His 274, Asp 375, and His 320 has been confirmed by kinetic studies of mutant enzymes generated by site-directed mutagenesis. The following three-step mechanism, formulated mainly by Remington, takes into account these observations (Fig. 21-19):

1. The enolate of acetyl-CoA is generated in the rate-limiting step of the reaction, with the catalytic participation of Asp 375 acting as a base to remove a proton from the methyl group and His 274, in its neutral form, H-bonding the enolate oxygen (whose protonated carbonyl form is normally far more acidic than a neutral His side chain). Much as we discussed for a similar step in the triose phosphate isomerase reaction (Section 17-2Eb), the  $pK$  of the protonated form of the substrate thioester carbonyl oxygen increases to  $\sim 14$  on enolization, which approximates that of neutral His 274. Hence, it has been proposed that this step is facilitated through the formation of a low-barrier hydrogen bond (which, it will be recalled, is a particularly strong form of hydrogen bonding interaction in which the hydrogen atom is more or less equally shared between the “donor” and “acceptor” atoms; Section 15-3Dd). However, whether or not this low-barrier hydrogen bond actually forms is a subject of controversy. The presence of the thioester bond to CoA facilitates the enolization; enolization of acetate alone would require the generation of a much more highly charged and therefore less stable intermediate.

2. Citryl-CoA is formed in a second acid–base-catalyzed reaction step in which the acetyl-CoA enolate nucleophilically attacks oxaloacetate while His 320, also in its neutral form, donates a proton to oxaloacetate’s carbonyl group. The citryl-CoA remains bound to the enzyme.

3. Citryl-CoA is hydrolyzed to citrate and CoA, with His 320, now in the anionic form, abstracting a proton from water as it attacks the carbonyl group of the citryl-CoA and the acidic form of Asp 375 donating a proton to the CoA as it leaves. This hydrolysis provides the reaction’s thermodynamic driving force ( $\Delta G^{\circ} = -31.5 \text{ kJ} \cdot \text{mol}^{-1}$ ). We shall see presently why the reaction requires such a large, seemingly wasteful, release of free energy.

**Figure 21-19** Mechanism and stereochemistry of the citrate synthase reaction. His 274 and His 320 in their neutral forms and Asp 375 have been implicated as general acid–base catalysts. The overall reaction’s rate-limiting step is the formation of the acetyl-CoA enolate, which may be stabilized by a low-barrier hydrogen bond to His 274. The acetyl-CoA enolate then nucleophilically attacks the *si* face of oxaloacetate’s carbonyl carbon. The resulting intermediate, (*S*)-citryl-CoA, is hydrolyzed to yield citrate and CoA. [Mostly after Remington, S.J., *Curr. Opin. Struct. Biol.* **2**, 732 (1992)].

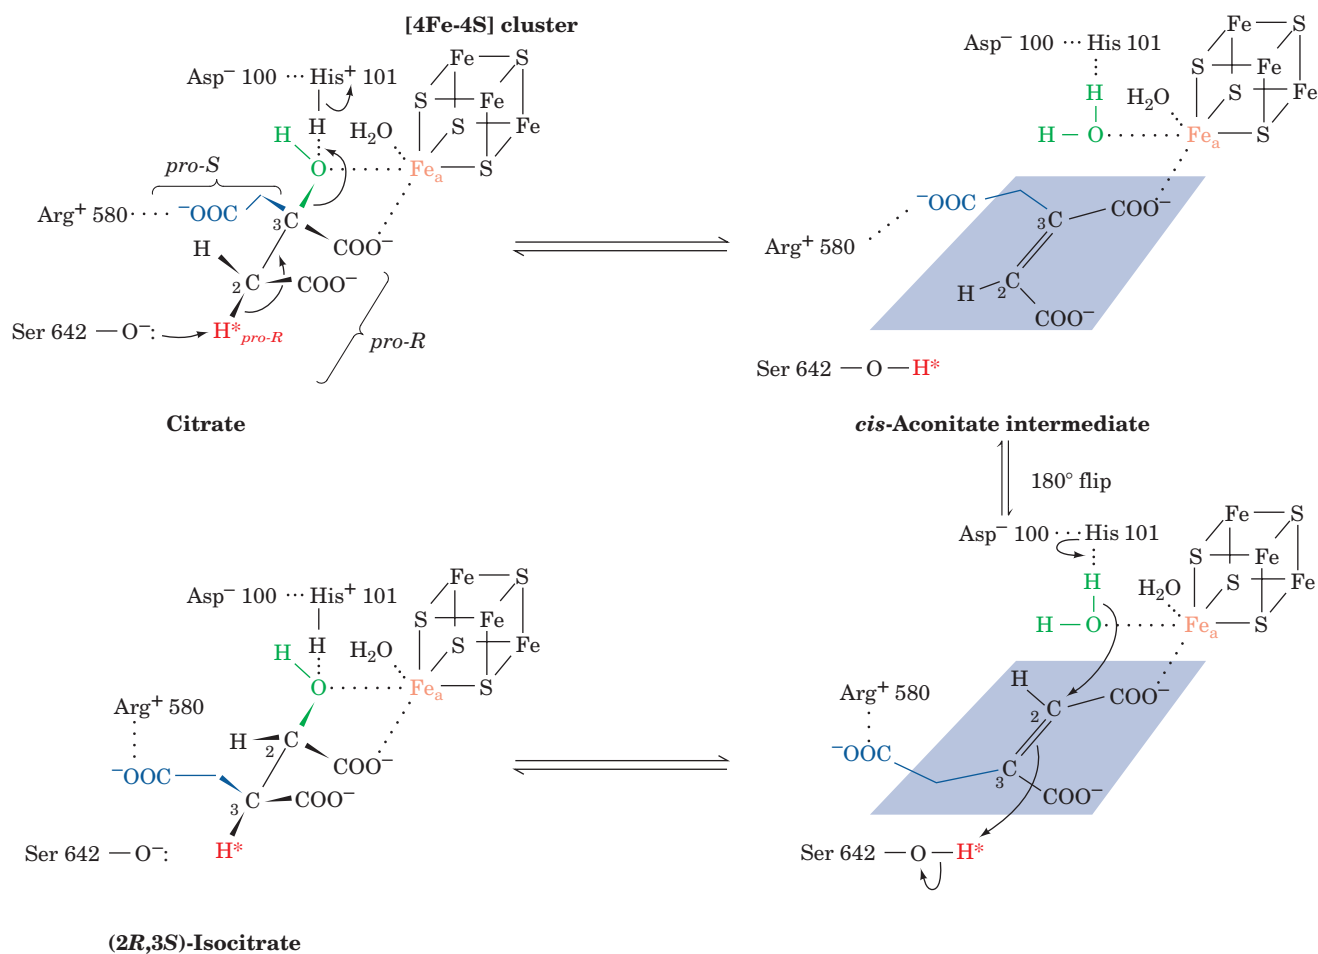

Enzyme-catalyzed reactions, as we have previously noted, are stereospecific. The aldol–Claisen condensation that occurs here involves attack of the acetyl-CoA enolate exclusively at the *si* face of oxaloacetate's carbonyl carbon atom, thereby yielding (*S*)-citryl-CoA (chirality nomenclature is presented in Section 4-2C). The acetyl group of acetyl-CoA thereby only forms citrate's *pro-S* carboxymethyl group.

## B. Aconitase

Aconitase catalyzes the reversible isomerization of citrate and isocitrate with *cis*-aconitate as an intermediate (Reaction 2 of Fig. 21-1). Although citrate has a plane of symmetry and is therefore not optically active, it is nevertheless prochiral; aconitase can distinguish between citrate's *pro-R* and *pro-S* carboxymethyl groups.

A combination of X-ray crystallography and site-directed mutagenesis by Helmut Beinert and David Stout

identified several amino acid residues that participate in catalysis. Formation of the *cis*-aconitate intermediate involves a dehydration in which Ser 642 alkoxide, acting as a general base, abstracts the *pro-R* proton at C2 of citrate's *pro-R* carboxymethyl group (Fig. 21-20, top). [The O<sub>γ</sub> of Ser 642 occupies a sort of oxyanion hole (Section 15-3Db) that apparently stabilizes its otherwise highly basic alkoxide form. The carbanion formed in the transition state of this reaction is not shown.] This is followed by the loss of the OH group at C3 in a trans elimination of H<sub>2</sub>O to form the *cis*-aconitate intermediate. The latter reaction step is facilitated through general acid catalysis by His 101, whose imidazolium group is polarized through ion pairing to the side chain of Asp 100. This model is corroborated by the observations that the mutagenesis of Asp 100, His 101, or Ser 642 results in a 10<sup>3</sup>- to 10<sup>5</sup>-fold reduction in aconitase's catalytic activity without greatly affecting its substrate binding affinity.

**Figure 21-20** Mechanism and stereochemistry of the aconitase reaction. Fe<sub>a</sub> of the enzyme's [4Fe-4S] cluster coordinates the citrate hydroxyl and central carboxyl groups; Arg 580 forms a salt bridge with the *pro-S* carboxyl group; Ser 642, in its alkoxide form, acts as a general base; and the Asp 100-polarized His 101 acts as a general acid in the elimination of water to form

*cis*-aconitate. Note the unusual 180° flip that *cis*-aconitate apparently undergoes, possibly while remaining bound to the active site. Thus rehydration takes place on the opposite face of the substrate from which dehydration occurred, yielding (2*R*,3*S*)-isocitrate.

Aconitase contains a covalently bound [4Fe–4S] iron–sulfur cluster, which is required for catalytic activity (the properties of iron–sulfur clusters are discussed in Section 22-2Ca). A specific Fe(II) atom in this cluster, the so-called Fe<sub>a</sub> atom, is thought to coordinate the OH group of the substrate so as to facilitate its elimination. Iron–sulfur clusters are almost always associated with redox processes although, intriguingly, not in the case of aconitase. It has been postulated that the electronic properties of the [4Fe–4S] cluster permit the Fe<sub>a</sub> atom to expand its coordination shell from the four ligands observed in the X-ray structure of the free enzyme (three S<sup>2-</sup> ions and a OH<sup>-</sup> ion) to the six octahedrally arranged ligands observed in the enzyme–substrate complex. A single metal ion, such as Zn<sup>2+</sup> or Cu<sup>2+</sup>, is unable to do so, and hence would require that some of its ligands be displaced on binding substrate.

The second stage of the aconitase reaction is rehydration of *cis*-aconitate's double bond to form isocitrate (Fig. 21-20, *bottom*). The nonenzymatic addition of H<sub>2</sub>O across the double bond of *cis*-aconitate would yield four stereoisomers. Aconitase, however, catalyzes the stereospecific trans addition of OH<sup>-</sup> and H<sup>+</sup> across the double bond to form only (2*R*,3*S*)-isocitrate in the forward reaction and citrate in the reverse reaction.

Although citrate's OH group is lost to the solvent in the aconitase reaction, the abstracted H<sup>+</sup> is retained by Ser 642. Remarkably, it adds to the opposite faces of *cis*-aconitate's double bond in forming citrate and isocitrate. The *cis*-aconitate must expose a different face to the sequestered H<sup>+</sup> for the formation of isocitrate. This is thought to occur by a 180° flip of the intermediate on the enzyme's surface while maintaining its association with Arg 580 or else by dissociation from the enzyme and replacement by another *cis*-aconitate in the “flipped” orientation.

#### a. Fluorocitrate Inhibits Aconitase

**Fluoroacetate**, one of the most toxic small molecules known (LD<sub>50</sub> = 0.2 mg · kg<sup>-1</sup> of body weight in rats), occurs in the leaves of certain African, Australian, and South American poisonous plants. Interestingly, fluoroacetate itself has little toxic effect on cells; instead, cells enzymatically convert it first to fluoroacetyl-CoA and then to (2*R*,3*R*)-2-fluorocitrate, which specifically inhibits aconitase (see Problem 9):

It is not clear, however, that the inhibition of aconitase fully accounts for fluorocitrate's high toxicity. Indeed, fluorocitrate also inhibits the transport of citrate across the mitochondrial membrane.

#### C. NAD<sup>+</sup>-Dependent Isocitrate Dehydrogenase

*Isocitrate dehydrogenase catalyzes the oxidative decarboxylation of isocitrate to α-ketoglutarate to produce the citric acid cycle's first CO<sub>2</sub> and NADH (Reaction 3 of Fig. 21-1). Mammalian tissues contain two isoforms of this enzyme. Although they both catalyze the same reaction, one isoform participates in the citric acid cycle, is located entirely in the mitochondrion, and utilizes NAD<sup>+</sup> as a cofactor. The other isoform occurs in both the mitochondrion and the cytosol, utilizes NADP<sup>+</sup> as a cofactor, and generates NADPH for use in reductive biosynthesis.*

NAD<sup>+</sup>-dependent isocitrate dehydrogenase, which requires an Mn<sup>2+</sup> or Mg<sup>2+</sup> cofactor, catalyzes the oxidation of a secondary alcohol (isocitrate) to a ketone (oxalosuccinate) followed by the decarboxylation of the carboxyl group β to the ketone (Fig. 21-21). In this sequence, the keto group β to the carboxyl group facilitates the decarboxylation by acting as an electron sink. The oxidation occurs with the stereospecific reduction of NAD<sup>+</sup> at its *re* face (A-side addition; Section 13-2Aa). Mn<sup>2+</sup> coordinates the newly formed carbonyl group so as to polarize its electronic charge.

**Figure 21-21** Probable reaction mechanism of isocitrate dehydrogenase. Oxalosuccinate is shown in brackets because it does not dissociate from the enzyme.

Although the intermediate formation of oxalosuccinate is a logical chemical prediction, evidence for it has been difficult to obtain because it has only a transient existence in reactions catalyzed by the wild-type enzyme. However, an enzymatic reaction rate can be slowed by the mutation of particular catalytically important residues, resulting in the accumulation of specific intermediates. Thus, when Lys 230, which facilitates the decarboxylation of the oxalosuccinate intermediate (Fig. 21-21) is mutated to Met in NADP<sup>+</sup>-dependent isocitrate dehydrogenase, the oxalosuccinate intermediate accumulates. This accumulated intermediate was directly visualized in the X-ray structure of the mutant enzyme, in the presence of a steady-state flow of substrate, through the use of fast X-ray intensity measurements.

#### D. $\alpha$ -Ketoglutarate Dehydrogenase

$\alpha$ -Ketoglutarate dehydrogenase catalyzes the oxidative decarboxylation of an  $\alpha$ -keto acid ( $\alpha$ -ketoglutarate), releasing the citric acid cycle's second CO<sub>2</sub> and NADH (Reaction 4 of Fig. 21-1). The overall reaction, which chemically resembles that catalyzed by the PDC (Fig. 21-6), is mediated by a homologous multienzyme complex consisting of  **$\alpha$ -ketoglutarate dehydrogenase (E1<sub>o</sub>)**, **dihydrolipoyl transsuccinylase (E2<sub>o</sub>)**, and dihydrolipoyl dehydrogenase (E3) in which the E3 subunits are identical to those in the PDC (Section 21-2A).

Individual reactions catalyzed by the complex occur by mechanisms identical to those of the pyruvate dehydrogenase reaction (Section 21-2A), the product likewise being a "high-energy" thioester, in this case succinyl-CoA. There are no covalent modification enzymes in the  $\alpha$ -ketoglutarate dehydrogenase complex, however.

#### E. Succinyl-CoA Synthetase

Succinyl-CoA synthetase (also called **succinate thiokinase**) hydrolyzes the "high-energy" compound succinyl-CoA with the coupled synthesis of a "high-energy" nucleoside triphosphate (Reaction 5 of Fig. 21-1). (Note: Enzyme names can refer to either the forward or the reverse reaction; in this case, succinyl-CoA synthetase and succinate thiokinase refer to the reverse reaction.) GTP is synthesized from GDP + P<sub>i</sub> by the mammalian enzyme; plant and bacterial enzymes utilize ADP + P<sub>i</sub> to form ATP. These reactions are nevertheless equivalent since ATP and GTP are rapidly interconverted through the action of nucleoside diphosphate kinase (Section 16-4C):

##### a. The Succinyl-CoA Thioester Bond Energy Is Preserved through the Formation of a Series of "High-Energy" Phosphates

How does succinyl-CoA synthetase couple the exergonic hydrolysis of succinyl-CoA ( $\Delta G^{\circ'} = -32.6 \text{ kJ} \cdot \text{mol}^{-1}$ ) to the endergonic formation of a nucleoside triphosphate ( $\Delta G^{\circ'} = 30.5 \text{ kJ} \cdot \text{mol}^{-1}$ )? This question was answered

through the creative use of isotope tracers. In the absence of succinyl-CoA, the spinach enzyme (which utilizes adenine nucleotides) catalyzes the transfer of ATP's  $\gamma$  phosphoryl group to ADP as detected by <sup>14</sup>C-labeling ADP and observing the label to appear in ATP. Such an isotope exchange reaction (Section 14-5D) suggests the participation of a phosphoryl-enzyme intermediate that mediates the reaction sequence:

Indeed, this information led to the isolation of a kinetically active phosphoryl-enzyme in which the phosphoryl group is covalently linked to the N3 position of a His residue.

When the succinyl-CoA synthetase reaction, which is freely reversible, is run in the direction of succinyl-CoA synthesis (opposite to its direction in the citric acid cycle) using [<sup>18</sup>O]succinate as a substrate, <sup>18</sup>O is transferred from succinate to phosphate. Evidently, succinyl phosphate, a "high-energy" mixed anhydride, is transiently formed during the reaction.

These observations suggest the following three-step sequence for the mammalian succinyl-CoA synthetase reaction (Fig. 21-22):

1. Succinyl-CoA reacts with P<sub>i</sub> to form succinyl phosphate and CoA (accounting for the <sup>18</sup>O-exchange reaction).
2. Succinyl phosphate's phosphoryl group is transferred to an enzyme His residue, releasing succinate (accounting for the 3-phosphoHis residue).
3. The phosphoryl group on the enzyme is transferred to GDP, forming GTP (accounting for the nucleoside diphosphate exchange reaction).

Note how in each of these steps the "high-energy" succinyl-CoA's free energy of hydrolysis is conserved through the successive formation of "high-energy" compounds: First succinyl phosphate, then a 3-phosphoHis residue, and finally GTP. The process is reminiscent of passing a hot potato.

##### b. A Pause for Perspective

Up to this point in the cycle, one acetyl equivalent has been completely oxidized to two CO<sub>2</sub>. Two NADHs and one GTP (in equilibrium with ATP) have also been generated. In order to complete the cycle, succinate must be converted back to oxaloacetate. This is accomplished by the cycle's remaining three reactions.

**Figure 21-22** Reactions catalyzed by succinyl-CoA synthetase. **(1)** Formation of succinyl phosphate, a "high-energy" mixed anhydride. **(2)** Formation of phosphoryl-His, a "high-energy" inter-

mediate. **(3)** Transfer of the phosphoryl group to GDP, forming GTP. The symbol  $\ddagger$  represents  $^{18}O$  in isotopic labeling reactions.

## F. Succinate Dehydrogenase

Succinate dehydrogenase catalyzes stereospecific dehydrogenation of succinate to fumarate (Reaction 6 of Fig. 21-1):

The enzyme is strongly inhibited by **malonate**, a structural analog of succinate and a classic example of a competitive inhibitor:

Recall that malonate inhibition of cellular respiration was one of the observations that led Krebs to hypothesize the citric acid cycle (Section 21-1B).

Succinate dehydrogenase contains an FAD, the reaction's electron acceptor. In general, FAD functions biochemically to oxidize alkanes to alkenes, whereas  $NAD^+$  oxidizes alcohols to aldehydes or ketones. This is because the oxidation of an alkane (such as succinate) to an alkene (such as fumarate) is sufficiently exergonic to reduce FAD to  $FADH_2$  but not to reduce  $NAD^+$  to  $NADH$ . Alcohol oxidation, in contrast, can reduce  $NAD^+$  (Table 16-4).

Succinate dehydrogenase's FAD is covalently bound via its C8a atom to an enzyme His residue (Fig. 21-23). A covalent link between FAD and a protein is unusual; in most cases FAD is noncovalently although tightly bound to its associated enzyme (e.g., to dihydrolipoyl dehydrogenase; Section 21-2Ba). How does succinate dehydrogenase's  $FADH_2$  become reoxidized? Being permanently linked to the enzyme, this prosthetic group cannot function as a metabolite as does  $NADH$ . Rather, *succinate dehydrogenase* (also known as *Complex II*) is reoxidized by the membrane-soluble coenzyme *Q* in the electron-transport chain, an aspect of its function that we discuss in Section 22-2C. This rationalizes why succinate dehydrogenase is the only citric acid cycle enzyme that is anchored in the inner mitochondrial membrane; all the others are dissolved in the mitochondrial matrix (mitochondrial anatomy is described in Section 22-1A).

**Figure 21-23** Covalent attachment of FAD to a His residue of succinate dehydrogenase.

### G. Fumarase

*Fumarase (fumarate hydratase)* catalyzes the hydration of fumarate's double bond to form (*S*)-malate (*L*-malate) (Reaction 7 of Fig. 21-1). Consideration of experiments that have contributed to our understanding of the fumarase mechanism illustrates the role played by independent investigations.

#### a. Conflicting Mechanistic Evidence: What Is the Sequence of $H^+$ and $OH^-$ Addition?

Experiments designed to establish whether the fumarase reaction occurs by a carbanion ( $OH^-$  addition first)

**Figure 21-24** Possible mechanisms for the hydration of fumarate as catalyzed by fumarase.

or carbocation ( $H^+$  addition first) mechanism have provided contradictory information (Fig. 21-24). Evidence favoring the carbocation mechanism was obtained by studying the dehydration of (*S*)-malate (the fumarase reaction run in reverse) in  $H_2^{18}O$ . [ $^{18}O$ ]Malate appears in the reaction mixture more rapidly than it would if the  $^{18}O$  were incorporated via a back reaction of the newly formed fumarate. This suggests the rapid formation of a carbocation intermediate at C2, from which  $OH^-$  could exchange with  $^{18}OH^-$ , followed by slow hydrogen removal at C3 (Fig. 21-24, lower route).

Other observations, however, indicate that the reaction occurs via the formation of a carbanion intermediate at C3 (Fig. 21-24, upper route). David Porter synthesized **3-nitro-2-(*S*)-hydroxypropionate**, which sterically resembles (*S*)-malate:

The nitro group's electron-withdrawing character renders the C3 protons relatively acidic ( $pK \approx 10$ ). The resulting anion is an analog of the postulated C3 carbanion transition state of the fumarase reaction but not of the C2 carbocation transition state (Fig. 21-24; transition state analogs are discussed in Section 15-1Fa). This anion is, in fact, an

In one landmark experiment, [4-<sup>11</sup>C]oxaloacetate was generated from <sup>11</sup>CO<sub>2</sub> and pyruvate,

reacted in the citric acid cycle of metabolizing muscle cells, and the resulting cycle intermediates were isolated. Identification of the labeled position in the isolated  $\alpha$ -ketoglutarate caused a furor. As we have seen in Sections 21-3A and 21-3B, citrate synthase and aconitase catalyze stereospecific reactions in which citrate synthase can distinguish between the two faces of oxaloacetate's carbonyl group and aconitase can distinguish between citrate's *pro-R* and *pro-S* carboxymethyl groups. In the early 1940s, however, the concept of prochirality had not been established; it was assumed that the two halves of citrate were indistinguishable (in nonenzymatic systems, this is, in effect, the case). It was therefore assumed that the radioactivity originally located at C4 in oxaloacetate (\* in Fig. 21-1) would be scrambled in citrate so that its C1 and C6 atoms would be equally labeled, resulting in  $\alpha$ -ketoglutarate labeled at both C1 and C5. In fact, only C1, the carboxyl group  $\alpha$  to the keto group of  $\alpha$ -ketoglutarate, was found to be radioactive (Fig. 21-1). This result threw the identity of the condensation product of oxaloacetate and acetyl-CoA into doubt. How could it be the symmetrical citrate molecule in light of such "conclusive" labeling experiments? This problem of which tri-carboxylic acid was the cycle's original condensation product resulted in a name change from the citric acid cycle (proposed by Krebs) to the tricarboxylic acid (TCA) cycle.

In 1948, Alexander Ogston pointed out that citric acid, while symmetrical, is prochiral and thus can interact asymmetrically with the surface of aconitase (Section 13-2A). Even though citrate is now accepted as a cycle intermediate, the duality of the cycle's name persists.

While the net reaction of the cycle is oxidation of the carbon atoms of acetyl units to CO<sub>2</sub>, the CO<sub>2</sub> lost in a given turn of the cycle is derived from the carbon skeleton of oxaloacetate. This can be shown by following the fate of isotopically labeled C4 of oxaloacetate (\* in Fig. 21-1) through the citric acid cycle. We can see (Fig. 21-1) that it is lost as CO<sub>2</sub> at the  $\alpha$ -ketoglutarate dehydrogenase reaction.

Experiments have been performed using [1-<sup>14</sup>C]acetate, which cells convert to [1-<sup>14</sup>C]acetyl-CoA:

Tracing the path of this label (‡ in Fig. 21-1) allows the reader to ascertain that the label is not lost as CO<sub>2</sub>. It becomes

scrambled (1/2‡ in Fig. 21-1) during the cycle, but not until the formation of succinate, the cycle's first rotationally symmetric (nonprochiral) intermediate.

### J. Evolution of the Citric Acid Cycle

The citric acid cycle is ubiquitous in aerobic organisms, where it has a central role in energy metabolism. However, an eight-step catalytic cycle such as the citric acid cycle could not have arisen as a whole and must therefore have evolved from simpler sets of enzyme-catalyzed reactions. Clues to the citric acid cycle's origins can be found by examining the metabolism of cells that resemble early life-forms. Such organisms emerged over 3 billion years ago (Section 1-5), before significant quantities of atmospheric O<sub>2</sub> were available. These cells probably used sulfur as their ultimate oxidizing agent, reducing it to H<sub>2</sub>S. Their modern counterparts are anaerobic autotrophs (cells that synthesize all their components from simple molecules such as H<sub>2</sub>O, CO<sub>2</sub>, NH<sub>3</sub>, and H<sub>2</sub>S) that harvest free energy by pathways, which are independent of those that oxidize carbon-containing compounds. These organisms therefore do not use the citric acid cycle to generate reduced cofactors such as NADH that are subsequently oxidized by O<sub>2</sub>.

The task of divining an organism's metabolic capabilities has been facilitated by bioinformatics. By comparing the sequences of prokaryotic genomes and assigning functions to various homologous genes, it is possible to reconstruct their central metabolic pathways. This approach has been fruitful because the genes that encode the enzymes that generate free energy and a cell's most common metabolites are highly conserved among different species and hence are relatively easy to recognize.

Many prokaryotes lack the citric acid cycle. However, these organisms harbor genes for some citric acid cycle enzymes. The last three reactions of the cycle, leading from succinate to oxaloacetate, appear to be the most highly conserved. This pathway fragment constitutes a mechanism for accepting electrons that are released during sugar fermentation. For example, the reverse of this pathway could regenerate NAD<sup>+</sup> from the NADH produced by the glyceraldehyde-3-phosphate dehydrogenase step of glycolysis.

The resulting succinate could then be used as a starting material for the biosynthesis of other compounds.

Many archaeal cells have a **pyruvate:ferredoxin oxidoreductase** that converts pyruvate to acetyl-CoA (but

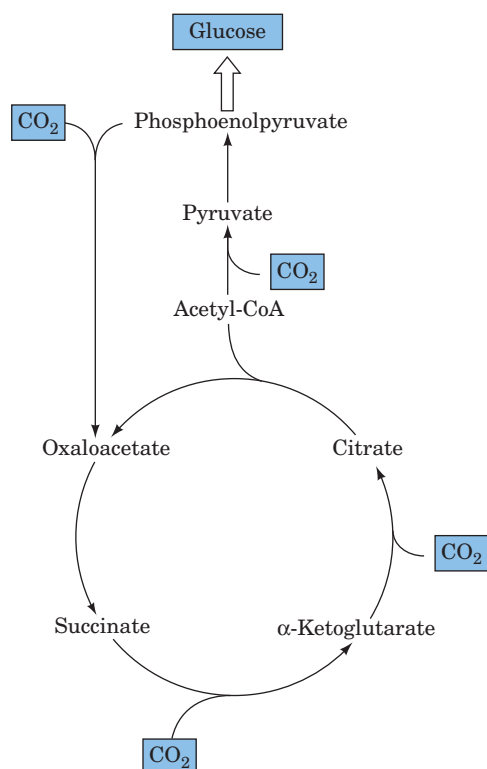

without producing NADH). In a primitive cell, the resulting acetyl groups could have condensed with oxaloacetate (by the action of a citrate synthase), eventually giving rise to an oxidative sequence of reactions resembling the first few steps of the modern citric acid cycle.

The  $\alpha$ -ketoglutarate produced in this way can be converted to glutamate and other amino acids (Section 26-5Ab).

The reductive and oxidative branches of the citric acid cycle outlined so far function in modern bacterial cells such as *E. coli* cells when they are growing anaerobically, suggesting that similar pathways could have filled the metabolic needs of primordial cells. The evolution of a complete citric acid cycle in which the two branches are linked and both proceed in an oxidative direction (clockwise) would have required an enzyme such as  **$\alpha$ -ketoglutarate:ferredoxin reductase** (a homolog of pyruvate:ferredoxin oxidoreductase) to link  $\alpha$ -ketoglutarate and succinate.

Interestingly, a primitive citric acid cycle that operated in the reverse (counterclockwise) direction could have provided a pathway for incorporating CO<sub>2</sub> into biological molecules.

The genes encoding enzymes that catalyze the steps of such a pathway have been identified in several modern autotrophic bacteria. This reductive pathway, which occurs in some deeply rooted archaeal species, possibly predates the CO<sub>2</sub>-fixing pathway used in some photosynthetic bacteria and in the chloroplasts of green plants (Section 24-3A).

## 4 REGULATION OF THE CITRIC ACID CYCLE

In this section we consider how metabolic flux through the citric acid cycle is regulated. In our discussions of metabolic flux control (Section 17-4), we established that to understand how a metabolic pathway is controlled, we must identify the enzyme(s) that catalyzes its rate-determining step(s), the *in vitro* effectors of these enzymes, and the *in vivo* concentrations of these substances. A proposed mechanism of flux control must demonstrate that an increase or decrease in flux is correlated with an increase or decrease in the concentration of the proposed effector.

### a. Citrate Synthase, Isocitrate Dehydrogenase, and $\alpha$ -Ketoglutarate Dehydrogenase Are the Citric Acid Cycle's Rate-Controlling Enzymes

Establishing the rate-determining steps of the citric acid cycle is more difficult than it is for glycolysis because most of the cycle's metabolites are present in both mitochondria and cytosol and we do not know their distribution between these two compartments [recall that identifying a pathway's rate-determining step(s) requires determining the  $\Delta G$  of each of its reactions from the concentrations of its substrates and products]. If, however, we assume equilibrium between the two compartments, we can use the total cell contents of these substances to estimate their mitochondrial concentrations. Table 21-2 gives the standard free energy changes for the eight citric acid cycle enzymes

**Table 21-2** Standard Free Energy Changes ( $\Delta G^{\circ}$ ) and Physiological Free Energy Changes ( $\Delta G$ ) of Citric Acid Cycle Reactions

Reaction	Enzyme	$\Delta G^{\circ}$ (kJ · mol <sup>-1</sup> )	$\Delta G$ (kJ · mol <sup>-1</sup> )
1	Citrate synthase	-31.5	Negative
2	Aconitase	~5	~0
3	Isocitrate dehydrogenase	-21	Negative
4	$\alpha$ -Ketoglutarate dehydrogenase multienzyme complex	-33	Negative
5	Succinyl-CoA synthetase	-2.1	~0
6	Succinate dehydrogenase	+6	~0
7	Fumarase	-3.4	~0
8	Malate dehydrogenase	+29.7	~0

**Figure 21-25 Regulation of the citric acid cycle.** This diagram of the citric acid cycle and the pyruvate dehydrogenase reaction indicates their points of inhibition (red octagons) and the pathway intermediates that function as inhibitors (dashed red arrows). ADP and  $\text{Ca}^{2+}$  (green dots) are activators. See the Animated Figures

and estimates of the physiological free energy changes for the reactions in heart muscle or liver tissue. We can see that three of the enzymes are likely to function far from equilibrium under physiological conditions (negative  $\Delta G$ ): citrate synthase,  $\text{NAD}^+$ -dependent isocitrate dehydrogenase, and  $\alpha$ -ketoglutarate dehydrogenase. We shall therefore focus our discussion on how these enzymes are regulated (Fig. 21-25).

### b. The Citric Acid Cycle Is Largely Regulated by Substrate Availability, Product Inhibition, and Inhibition by Other Cycle Intermediates

In heart muscle, where the citric acid cycle functions mainly to generate ATP for use in muscle contraction, the enzymes of the cycle almost always act as a functional unit, with their metabolic flux proportional to the rate of cellular oxygen consumption. *Since oxygen consumption, NADH reoxidation, and ATP production are tightly coupled (Section 22-4), the citric acid cycle must be regulated by feedback mechanisms that coordinate its NADH production with energy expenditure.* Unlike the rate-limiting enzymes of glycolysis and glycogen metabolism, which utilize elaborate systems of allosteric control, substrate cycles, and

covalent modification as flux control mechanisms, the regulatory enzymes of the citric acid cycle seem to be controlled almost entirely in three simple ways: (1) substrate availability, (2) product inhibition, and (3) competitive feedback inhibition by intermediates farther along the cycle. We shall encounter several examples of these straightforward mechanisms in the following discussion.

*Perhaps the most crucial regulators of the citric acid cycle are its substrates, acetyl-CoA and oxaloacetate, and its product NADH.* Both acetyl-CoA and oxaloacetate are present in mitochondria at concentrations that do not saturate citrate synthase. The metabolic flux through the enzyme therefore varies with substrate concentration and is subject to control by substrate availability. The production of acetyl-CoA from pyruvate is regulated by the activity of pyruvate dehydrogenase (Section 21-2C). Oxaloacetate is in equilibrium with malate, its concentration fluctuating with the  $[\text{NADH}]/[\text{NAD}^+]$  ratio according to the equilibrium expression

$$K = \frac{[\text{oxaloacetate}][\text{NADH}]}{[\text{malate}][\text{NAD}^+]}$$

In the transition from low to high work and respiration rates, mitochondrial  $[\text{NADH}]$  decreases. The consequent increase in  $[\text{oxaloacetate}]$  stimulates the citrate synthase reaction, which controls the rate of citrate formation.

The observation that  $[\text{citrate}]$  invariably falls as the workload increases indicates that the rate of citrate removal increases more than its rate of formation. The rate of citrate removal is governed by  $\text{NAD}^+$ -dependent isocitrate dehydrogenase (aconitase functions close to equilibrium), which is strongly inhibited *in vitro* by NADH (product inhibition). Citrate synthase is also inhibited by NADH. Evidently,  $\text{NAD}^+$ -dependent isocitrate dehydrogenase is more sensitive to  $[\text{NADH}]$  changes than citrate synthase.

The decrease in  $[\text{citrate}]$  that occurs on transition from low to high work and respiration rates results in a domino effect:

1. Citrate is a competitive inhibitor of oxaloacetate for citrate synthase (product inhibition); the fall in  $[\text{citrate}]$  caused by increased isocitrate dehydrogenase activity increases the rate of citrate formation.
2.  $\alpha$ -Ketoglutarate dehydrogenase is also strongly inhibited by its products, NADH and succinyl-CoA. Its activity therefore increases when  $[\text{NADH}]$  decreases.
3. Succinyl-CoA also competes with acetyl-CoA in the citrate synthase reaction (competitive feedback inhibition).

This interlocking system serves to keep the citric acid cycle coordinately regulated.

### c. ADP, ATP, and $\text{Ca}^{2+}$ Are Allosteric Regulators of Citric Acid Cycle Enzymes

*In vitro* studies on the enzymes of the citric acid cycle have identified a few allosteric activators and inhibitors. Increased workload is accompanied by increased  $[\text{ADP}]$  resulting from the consequent increased rate of ATP hydrolysis. ADP acts as an allosteric activator of isocitrate

dehydrogenase by decreasing its apparent  $K_M$  for isocitrate. ATP, which builds up when muscle is at rest, inhibits this enzyme.

$\text{Ca}^{2+}$ , among its many biological functions, is an essential metabolic regulator. It stimulates glycogen breakdown (Section 18-3Ce), triggers muscle contraction (Section 35-3Ca), and mediates many hormonal signals as a second messenger (Section 19-4A).  $\text{Ca}^{2+}$  also plays an important role in the regulation of the citric acid cycle (Fig. 21-25). It activates pyruvate dehydrogenase phosphatase and inhibits pyruvate dehydrogenase kinase, thereby activating the PDC to produce acetyl-CoA (Fig. 21-17b). In addition,  $\text{Ca}^{2+}$  activates both isocitrate dehydrogenase and  $\alpha$ -ketoglutarate dehydrogenase. Thus, the same signal stimulates muscle contraction and the production of the ATP to fuel it.

In the liver, the role of the citric acid cycle is more complex than in heart muscle. The liver synthesizes many substances required by the body including glucose, fatty acids, cholesterol, amino acids, and porphyrins. Reactions of the citric acid cycle play a part in many of these biosynthetic pathways in addition to their role in energy metabolism. In the next section, we discuss the contribution of the citric acid cycle to these processes.

#### d. Are the Enzymes of the Citric Acid Cycle Organized Into a Metabolon?

Considerable efficiency can be gained by organizing the enzymes of a metabolic pathway such that the enzymes catalyzing its sequential steps interact to channel intermediates between them. Indeed, we saw this to be the case with the PDC (Section 21-2A). The advantages of such an assembly, termed a **metabolon**, include the protection of labile intermediates and the increase of their local concentration for more efficient catalysis. Considerable effort has been expended to obtain evidence for such interactions in the major metabolic pathways including glycolysis and the citric acid cycle. However, since citric acid cycle intermediates must be available for use in other metabolic pathways, any complexes between citric acid cycle enzymes are likely to be weak and therefore unable to withstand the laboratory manipulations necessary to isolate them.

Despite the foregoing, specific interactions have been demonstrated *in vivo* between the members of several pairs of citric acid cycle enzymes, including those between citrate synthase and malate dehydrogenase. For example, Paul Srere isolated the gene for a mutant citrate synthase in yeast that he termed an “assembly mutant” because it has normal enzymatic activity *in vitro* but nevertheless causes a citric acid cycle deficiency *in vivo*. This mutation occurs in a highly conserved 13-residue segment of the enzyme (Pro 354–Pro 366 in yeast), which forms a solvent-exposed loop that could interact with other proteins. To further investigate this phenomenon, Srere constructed a plasmid expressing a fusion protein (Section 5-5Ga) consisting of the wild-type citrate synthase peptide grafted to the C-terminal end of green fluorescent protein (GFP; Section 5-5Gd). If the peptide actually binds to malate dehydrogenase, the expression of this enzymatically inactive fusion protein in yeast would be expected to inhibit the citric

acid cycle. This is, in fact, the case as judged by the severely decreased ability of such yeast to grow on acetate, a metabolite that can only be metabolized via the citric acid cycle. Moreover, replacing the citrate synthase peptide in the fusion protein with an unrelated peptide only slightly decreases the normal growth rate on acetate, thereby demonstrating that the specific sequence of the citrate synthase peptide is the major cause of this growth inhibition. If the decrease in growth rate is actually caused by competition of the peptide with citrate synthase for an interacting partner in a metabolon, then this should be overcome by the overexpression of either citrate synthase or its interaction partner. Indeed, when either citrate synthase or malate dehydrogenase was overexpressed in yeast expressing the GFP–citrate synthase peptide fusion protein, the growth rate on acetate was restored. However, the overexpression of aconitase did not overcome this growth inhibition. These observations support the hypothesis that malate dehydrogenase and citrate synthase must interact for optimal citric acid cycle function and identify the interaction site for malate dehydrogenase on citrate synthase as the 13-residue Pro 354–Pro 366 peptide.

#### e. A Bacterial Isocitrate Dehydrogenase Is Regulated by Phosphorylation

*Escherichia coli* isocitrate dehydrogenase is a dimer of identical 416-residue subunits that is inactivated by phosphorylation of its Ser 113, an active site residue. In contrast, most other enzymes that are known to be subject to covalent modification/demodification, for example, glycogen phosphorylase (Section 18-3), are phosphorylated at allosteric sites. In the case of isocitrate dehydrogenase, phosphorylation renders the enzyme unable to bind its substrate, isocitrate.

Comparison of the X-ray structures, determined by Daniel Koshland and Robert Stroud, of isocitrate dehydrogenase alone, in its phosphorylated form, and with bound isocitrate reveals only small conformational differences, suggesting that electrostatic repulsions between the anionic isocitrate and Ser phosphate groups prevent the enzyme from binding substrate. Evidently, phosphorylation can regulate enzyme activity by directly interfering with active site ligand binding as well as by inducing a conformational change from an allosteric site.

## 5 THE AMPHIBOLIC NATURE OF THE CITRIC ACID CYCLE

Ordinarily one thinks of a metabolic pathway as being either catabolic with the release (and conservation) of free energy, or anabolic with a requirement for free energy. The citric acid cycle is, of course, catabolic because it involves degradation and is a major free energy conservation system in most organisms. Cycle intermediates are only required in catalytic amounts to maintain the degradative function of the cycle. However, several biosynthetic pathways utilize citric acid cycle intermediates as starting materials

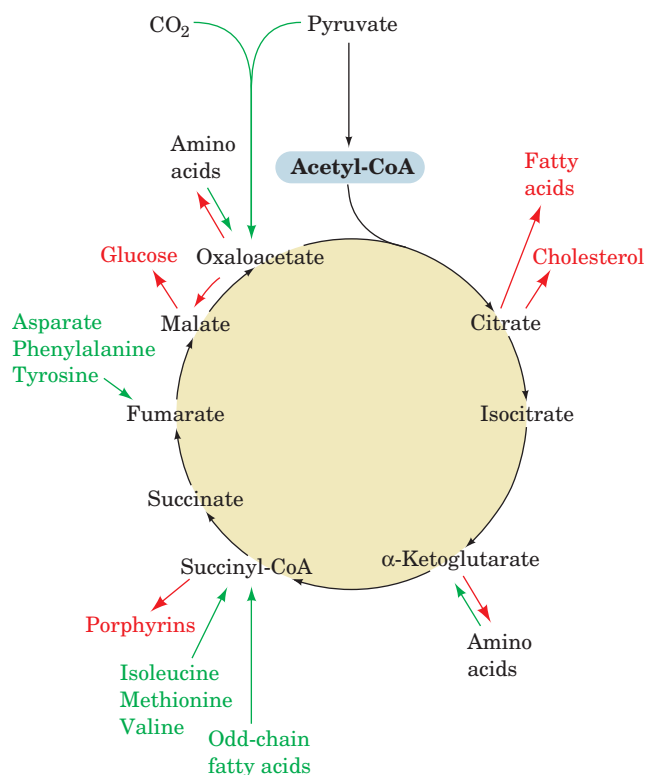

(anabolism). The citric acid cycle is therefore **amphibolic** (both anabolic and catabolic).

All of the biosynthetic pathways that utilize citric acid cycle intermediates also require free energy. Consequently, the catabolic function of the cycle cannot be interrupted; *cycle intermediates that have been siphoned off must be replaced*. Although the mechanistic aspects of the enzymes involved in the pathways that utilize and replenish citric acid cycle intermediates are discussed in subsequent chapters, it is useful to briefly mention these metabolic interconnections here (Fig. 21-26).

### a. Pathways That Utilize Citric Acid Cycle Intermediates

Reactions that utilize and therefore drain citric acid cycle intermediates are called **cataplerotic reactions** (emptying; Greek: *cata*, down + *plerotikos*, to fill). These reactions serve not only to synthesize important products but also to avoid the inappropriate buildup of citric acid cycle intermediates in the mitochondrion, for example, when there is a high rate of breakdown of amino acids to citric acid cycle intermediates (Section 26-3). Cataplerotic reactions occur in the following pathways:

**Figure 21-26 Amphibolic functions of the citric acid cycle.** This diagram indicates the positions at which intermediates are cataplerotically drawn off for use in anabolic pathways (red arrows) and the points where anaplerotic reactions replenish depleted cycle intermediates (green arrows). Reactions involving amino acid transamination and deamination are reversible, so their direction varies with metabolic demand. See the **Animated Figures**

**1. Glucose biosynthesis (gluconeogenesis;** Section 23-1), which occurs in the cytosol, utilizes oxaloacetate as its starting material. Oxaloacetate is not transported across the mitochondrial membrane, but malate is. Malate that has been transported across the mitochondrial membrane is converted to oxaloacetate in the cytosol for gluconeogenesis.

**2. Lipid biosynthesis,** which includes **fatty acid biosynthesis** (Section 25-4) and **cholesterol biosynthesis** (Section 25-6A), is a cytosolic process that requires acetyl-CoA. Acetyl-CoA is generated in the mitochondrion and is not transported across the inner mitochondrial membrane. Cytosolic acetyl-CoA is therefore generated by the breakdown of citrate, which can cross the inner mitochondrial membrane, in a reaction catalyzed by **ATP-citrate lyase** (Section 25-4D):

**3. Amino acid biosynthesis** utilizes citric acid cycle intermediates in two ways.  $\alpha$ -Ketoglutarate is converted to glutamate in a reductive amination reaction involving either  $\text{NAD}^+$  or  $\text{NADP}^+$  catalyzed by **glutamate dehydrogenase** (Section 26-1):

$\alpha$ -Ketoglutarate and oxaloacetate are also used to synthesize glutamate and aspartate in transamination reactions (Section 26-1):

and

**4. Porphyrin biosynthesis** (Section 26-4A) utilizes succinyl-CoA as a starting material.

**5. Complete oxidation of amino acids** requires that the citric acid cycle intermediates to which the amino acids are degraded be converted first to PEP [in a reaction catalyzed by **phosphoenolpyruvate carboxykinase (PEPCK;** Section 23-1):  $\text{Oxaloacetate} + \text{GTP} \rightleftharpoons \text{PEP} + \text{GDP}$ ], then to pyruvate by pyruvate kinase (Section 17-2J), and finally to acetyl-CoA by pyruvate dehydrogenase (Section 21-2A).

### b. Reactions That Replenish Citric Acid Cycle Intermediates

Reactions that replenish citric acid cycle intermediates are called **anaplerotic reactions** (filling up, Greek: *ana*, up). The main reaction of this type is catalyzed by **pyruvate carboxylase**, which produces oxaloacetate (Section 23-1Aa):

This enzyme “senses” the need for more citric acid cycle intermediates through its activator, acetyl-CoA. Any decrease in the rate of the cycle caused by insufficient oxaloacetate or other cycle intermediates results in an increased level of acetyl-CoA because of its underutilization. This activates pyruvate carboxylase, which replenishes oxaloacetate, increasing the rate of the cycle. Of course, if the citric acid cycle is inhibited at some other step, by high NADH concentration, for example, increased oxaloacetate concentration will not activate the cycle. The excess oxaloacetate instead equilibrates with malate, which is transported out of the mitochondria for use in gluconeogenesis.

Degradative pathways generate citric acid cycle intermediates:

**1. Oxidation of odd-chain fatty acids** (Section 25-2E) leads to the production of succinyl-CoA.

**2. Breakdown of the amino acids isoleucine, methionine, and valine** (Section 26-3E) also leads to the production of succinyl-CoA.

**3. Transamination and deamination of amino acids** lead to the production of  $\alpha$ -ketoglutarate and oxaloacetate. These reactions are reversible and, depending on metabolic demand, serve to remove or replenish these citric acid cycle intermediates.

The citric acid cycle is truly at the center of metabolism (see Fig. 16-1). Its reduced products, NADH and FADH<sub>2</sub>, are reoxidized by the electron-transport chain during oxidative phosphorylation and the free energy released is coupled to the biosynthesis of ATP. Citric acid cycle intermediates are utilized in the biosynthesis of many vital cellular constituents. In the next few chapters we shall explore the interrelationships of these pathways in more detail.

## CHAPTER SUMMARY

**1 Cycle Overview** The citric acid cycle, the common mode of oxidative metabolism in most organisms, is mediated by eight enzymes that collectively convert 1 acetyl-CoA to 2 CO<sub>2</sub> molecules so as to yield 3 NADHs, 1 FADH<sub>2</sub>, and 1 GTP (or ATP). The NADH and FADH<sub>2</sub> are oxidized by O<sub>2</sub> in the electron-transport chain with the concomitant synthesis of around 11 more ATPs, yielding a total of about 12 ATPs for one turn of the citric acid cycle.

**2 Metabolic Sources of Acetyl-Coenzyme A** Pyruvate, the end product of glycolysis under aerobic conditions, is converted to acetyl-CoA by the pyruvate dehydrogenase multi-enzyme complex (PDC), a cubic or dodecahedral cluster of three enzymes: pyruvate dehydrogenase (E1), dihydrolipoyl transacetylase (E2), and dihydrolipoyl dehydrogenase (E3). The pyruvate dehydrogenase subunit catalyzes the conversion of pyruvate to CO<sub>2</sub> and a hydroxyethyl-TPP intermediate. The latter is channeled to dihydrolipoyl transacetylase, which oxidizes the hydroxyethyl group to acetate and transfers it to CoA to form acetyl-CoA. The lipoamide prosthetic group, which is reduced to the dihydro form in the process, is reoxidized by dihydrolipoyl dehydrogenase in a reaction involving bound FAD that reduces NAD<sup>+</sup> to NADH. Dihydrolipoyl transacetylase is inactivated by the formation of a covalent adduct between lipoamide and As(III) compounds. Pyruvate dehydrogenase’s two active sites are connected by an acidic tunnel through which they alternately supply and abstract protons from one another and thereby keep their reactions out of phase.

Dihydrolipoyl dehydrogenase, which closely resembles glutathione reductase, catalyzes a two-stage reaction. In the first stage, dihydrolipoamide reduces the enzyme’s redox-active disulfide group, yielding the reaction’s first product, lipoamide. In the second stage, NAD<sup>+</sup> reoxidizes the reduced enzyme through the intermediacy of the enzyme’s FAD prosthetic group, thereby closing the catalytic cycle and yielding the enzyme’s second product, NADH. The activity of the pyruvate dehydrogenase complex varies with the [NADH]/[NAD<sup>+</sup>] and [acetyl-CoA]/[CoA] ratios. In eukaryotes, the pyruvate dehydrogenase subunit is also inactivated by phosphorylation of a specific Ser residue and is reactivated by its

removal. These modifications are mediated, respectively, by pyruvate dehydrogenase kinase and pyruvate dehydrogenase phosphatase, which are components of the multienzyme complex and respond to the levels of metabolic intermediates such as NADH and acetyl-CoA.

**3 Enzymes of the Citric Acid Cycle** Citrate is formed by the condensation of acetyl-CoA and oxaloacetate by citrate synthase. The citrate is dehydrated to *cis*-aconitate and then rehydrated to isocitrate in a stereospecific reaction catalyzed by aconitase. This enzyme is specifically inhibited by (2R,3R)-2-fluorocitrate, which is enzymatically synthesized from fluoroacetate and oxaloacetate. Isocitrate is oxidatively decarboxylated to  $\alpha$ -ketoglutarate by isocitrate dehydrogenase, which produces NADH and CO<sub>2</sub>. The  $\alpha$ -ketoglutarate, in turn, is oxidatively decarboxylated by  $\alpha$ -ketoglutarate dehydrogenase, a multienzyme complex homologous to the PDC. This reaction generates the second NADH and CO<sub>2</sub>. The resulting succinyl-CoA is converted to succinate with the generation of GTP (ATP in plants and bacteria) by succinyl-CoA synthetase. The succinate is stereospecifically dehydrogenated to fumarate by succinate dehydrogenase in a reaction that generates FADH<sub>2</sub>. The final two reactions of the citric acid cycle, which are catalyzed by fumarase and malate dehydrogenase, in turn hydrate fumarate to (*S*)-malate and oxidize this alcohol to its corresponding ketone, oxaloacetate, with concomitant production of the pathway’s third and final NADH. The citric acid cycle appears to have evolved through the piecing together of enzymatic reactions that originally carried out other metabolic functions.

**4 Regulation of the Citric Acid Cycle** The enzymes of the citric acid cycle act as a functional unit that keeps pace with the metabolic demands of the cell. The flux-controlling enzymes appear to be citrate synthase, isocitrate dehydrogenase, and  $\alpha$ -ketoglutarate dehydrogenase. Their activities are controlled by substrate availability, product inhibition, inhibition by cycle intermediates, and activation by Ca<sup>2+</sup>. The enzymes of the citric acid cycle may be organized, *in vivo*, into a metabolon for channeling the products of one enzyme to the next enzyme in the cycle.

**5 The Amphibolic Nature of the Citric Acid Cycle** Several anabolic pathways cataplerotically utilize citric acid cycle intermediates as starting materials. These essential substances

are replaced by anaplerotic reactions of which the major one is synthesis of oxaloacetate from pyruvate and CO<sub>2</sub> by pyruvate carboxylase.

## PROBLEMS

- Trace the course of the radioactive label in  $[2\text{-}^{14}\text{C}]\text{glucose}$  through glycolysis and the citric acid cycle. At what point(s) in the cycle will the radioactivity be released as  $^{14}\text{CO}_2$ ? How many turns of the cycle will be required for complete conversion of the radioactivity to  $\text{CO}_2$ ? Repeat this problem for pyruvate that is  $^{14}\text{C}$ -labeled at its methyl group.
- The reaction of glutathione reductase with an excess of NADPH in the presence of arsenite yields a nonphysiological four-electron reduced form of the enzyme. What is the chemical nature of this catalytically inactive species?
- Two-electron reduced dihydrolipoyl dehydrogenase ( $\text{EH}_2$ ), but not the oxidized enzyme (E), reacts with iodoacetate ( $\text{ICH}_2\text{COO}^-$ ) to yield an inactive enzyme. Explain.
- Given the following information, calculate the physiological  $\Delta G$  of the isocitrate dehydrogenase reaction at  $25^\circ\text{C}$  and pH 7.0:  $[\text{NAD}^+]/[\text{NADH}] = 8$ ;  $[\alpha\text{-ketoglutarate}] = 0.1\text{ mM}$ ;  $[\text{isocitrate}] = 0.02\text{ mM}$ ; assume standard conditions for  $\text{CO}_2$  ( $\Delta G^\circ$  is given in Table 21-2). Is this reaction a likely site for metabolic control? Explain.
- The oxidation of acetyl-CoA to two molecules of  $\text{CO}_2$  involves the transfer of four electron pairs to redox coenzymes. In which of the cycle's reactions do these electron transfers occur? Identify the redox coenzyme in each case. For each reaction, draw the structural formulas of the reactants, intermediates, and products and show, using curved arrows, how the electrons are transferred.
- The citrate synthase reaction has been proposed to proceed via the formation of the enol(ate) form of acetyl-CoA. How, then, would you account for the observation that  $^3\text{H}$  is not incorporated

into acetyl-CoA when acetyl-CoA is incubated with citrate synthase in  $^3\text{H}_2\text{O}$ ?

**7.** Malonate is a competitive inhibitor of succinate in the succinate dehydrogenase reaction. (a) Sketch the graphs that would be obtained on plotting  $1/v$  versus  $1/[\text{succinate}]$  at three different malonate concentrations. Label the lines for low, medium, and high [malonate]. (b) Explain why increasing the oxaloacetate concentration in a cell can overcome malonate inhibition.

**8.** Krebs found that malonate inhibition of the citric acid cycle could be overcome by raising the oxaloacetate concentration. Explain the mechanism of this process in light of your findings in Problem 7.

**\*9.** (2*R*,3*R*)-2-Fluorocitrate contains F in the *pro-S* carboxymethyl arm of citrate [note that the rules of organic nomenclature require that atom C2 in citrate (Fig. 21-20) be renumbered as C4 in (2*R*,3*R*)-2-fluorocitrate]. This compound, but not its diastereomer, is a potent inhibitor of aconitase. (a) Draw the aconitase-catalyzed reaction pathway of (2*R*,3*R*)-2-fluorocitrate assuming it follows the same reaction pathway as citrate (Fig. 21-20). (b) Aconitase, in fact, does not catalyze the foregoing reaction with (2*R*,3*R*)-2-fluorocitrate but, rather, yields the following tight-binding inhibitor:

Draw an alternative aconitase-catalyzed reaction that would generate this inhibitor. (c) Draw the aconitase-catalyzed reaction of

(2*S*,3*R*)-3-fluorocitrate, the diastereomer of (2*R*,3*R*)-2-fluorocitrate (fluorocitrate containing F in the *pro-R* carboxymethyl arm of citrate; here the atom numbering scheme is the same as that in Fig. 21-20). Would a tight-binding inhibitor be formed?

**10.** Which of the following metabolites undergo net oxidation by the citric acid cycle: (a)  $\alpha$ -ketoglutarate, (b) succinate, (c) citrate, and (d) acetyl-CoA?

**11.** Although there is no net synthesis of intermediates by the citric acid cycle, citric acid cycle intermediates are used in biosynthetic reactions such as the synthesis of porphyrins from succinyl-CoA. Write a reaction for the net synthesis of succinyl-CoA from pyruvate.

**12.** Oxaloacetate and  $\alpha$ -ketoglutarate are precursors of the amino acids aspartate and glutamate as well as being catalytic intermediates in the citric acid cycle. Describe the net synthesis of  $\alpha$ -ketoglutarate from pyruvate in which no citric acid cycle intermediates are depleted.

**13.** Lipoic acid is bound to enzymes that catalyze oxidative decarboxylation of  $\alpha$ -keto acids. (a) What is the chemical mode of attachment of lipoic acid to enzymes? (b) Using chemical structures, show how lipoic acid participates in the oxidative decarboxylation of  $\alpha$ -keto acids.

**14.** **British anti-lewisite (BAL)**, which was designed to counter the effects of the arsenical war gas **lewisite**, is useful in treating arsenic poisoning. Explain.

**British anti-lewisite  
(BAL)**

**Lewisite**

**15.** The first organisms on Earth may have been chemoautotrophs in which the citric acid cycle operated in reverse to “fix” atmospheric  $\text{CO}_2$  in organic compounds. Complete a catalytic cycle that begins with the hypothetical overall reaction succinate +  $2 \text{CO}_2 \rightarrow$  citrate.

**16.** Why is it advantageous for citrate, the product of Reaction 1 of the citric acid cycle, to inhibit phosphofructokinase, which catalyzes the third reaction of glycolysis?

**17.** Anaplerotic reactions permit the citric acid cycle to supply intermediates to biosynthetic pathways while maintaining the proper levels of cycle intermediates. Write the equation for the net synthesis of citrate from pyruvate.

**18.** Many amino acids are broken down to intermediates of the citric acid cycle. (a) Why can't these amino acid “remnants” be directly oxidized to  $\text{CO}_2$  by the citric acid cycle? (b) Explain why amino acids that are broken down to pyruvate can be completely oxidized by the citric acid cycle.

# Electron Transport and Oxidative Phosphorylation

- A. Control of Oxidative Phosphorylation
- B. Coordinated Control of ATP Production
- C. Physiological Implications of Aerobic versus Anaerobic Metabolism

In 1789, Armand Séguin and Antoine Lavoisier (the father of modern chemistry) wrote:

... in general, respiration is nothing but a slow combustion of carbon and hydrogen, which is entirely similar to that which occurs in a lamp or lighted candle, and that, from this point of view, animals that respire are true combustible bodies that burn and consume themselves.

Lavoisier had by this time demonstrated that living animals consume oxygen and generate carbon dioxide. It was not until the early twentieth century, however, after the rise of enzymology, that it was established, largely through the work of Otto Warburg, that biological oxidations are catalyzed by intracellular enzymes. As we have seen, glucose is completely oxidized to  $\text{CO}_2$  through the enzymatic reactions of glycolysis and the citric acid cycle. In this chapter we shall examine the fate of the electrons that are removed from glucose by this oxidation process.

The complete oxidation of glucose by molecular oxygen is described by the following redox equation:

To see more clearly the transfer of electrons, let us break this equation down into two half-reactions. In the first half-reaction the glucose carbon atoms are oxidized:

and in the second, molecular oxygen is reduced:

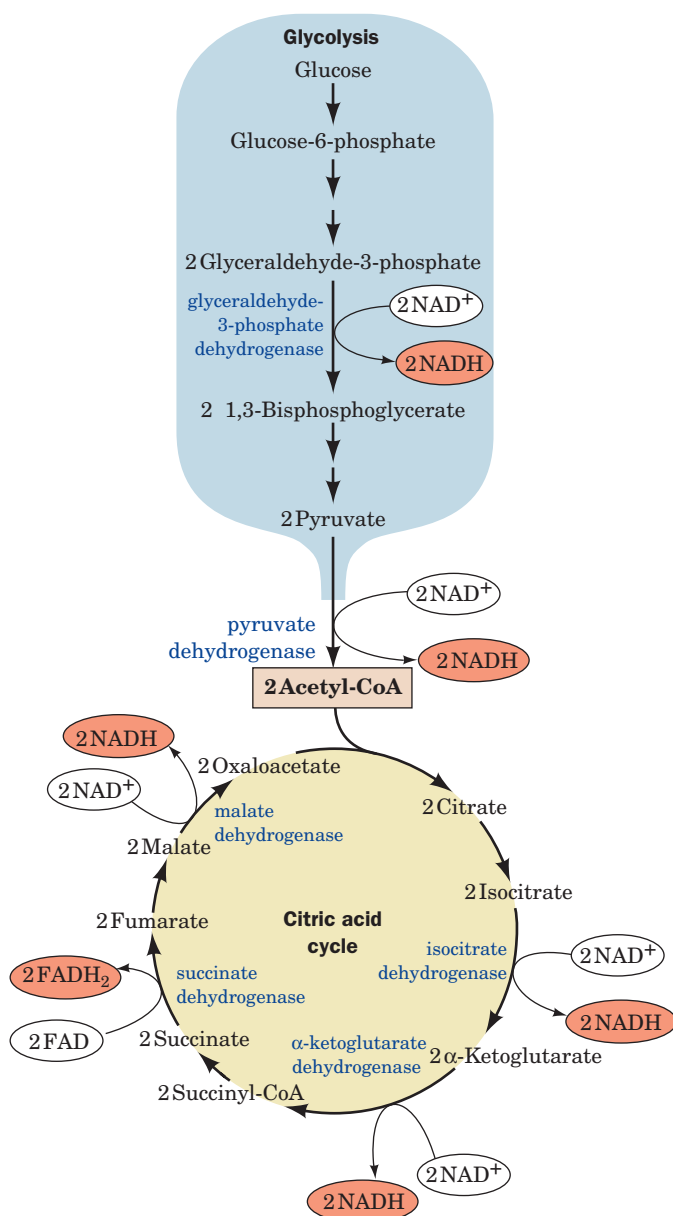

In living systems, the electron-transfer process connecting these half-reactions occurs through a multistep pathway that harnesses the liberated free energy to form ATP.

The 12 electron pairs involved in glucose oxidation are not transferred directly to  $\text{O}_2$ . Rather, as we have seen, they are transferred to the coenzymes  $\text{NAD}^+$  and  $\text{FAD}$  to form 10  $\text{NADH}$  and 2  $\text{FADH}_2$  (Fig. 22-1) in the reactions catalyzed by the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (Section 17-2F), pyruvate dehydrogenase (Section 21-2A), and the citric acid cycle enzymes isocitrate dehydrogenase,  $\alpha$ -ketoglutarate dehydrogenase, succinate dehydrogenase (the only  $\text{FAD}$  reduction), and malate dehydrogenase (Section 21-3). The electrons then pass into the **electron-transport chain** (alternatively, the **respiratory chain**), where, through reoxidation of  $\text{NADH}$  and  $\text{FADH}_2$ , they participate in the sequential oxidation–reduction of over 10 redox centers before reducing  $\text{O}_2$  to  $\text{H}_2\text{O}$ . In this process, protons are expelled from the mitochondrion. The free energy stored in the resulting pH gradient drives the synthesis of ATP from ADP and  $\text{P}_i$  through **oxidative phosphorylation**. Reoxidation of each  $\text{NADH}$  results in the synthesis of  $\sim 2.5$  ATP, and reoxidation of  $\text{FADH}_2$  yields  $\sim 1.5$  ATP for a total of  $\sim 32$  ATP for each glucose completely oxidized to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  (including the 2 ATP made in glycolysis and the 2 ATP made in the citric acid cycle).

In this chapter we explore the mechanisms of electron transport and oxidative phosphorylation and their regulation. We begin with a discussion of mitochondrial structure and transport systems.

### 1 THE MITOCHONDRION

The mitochondrion (Section 1-2Ac) is the site of eukaryotic oxidative metabolism. It contains, as Albert Lehninger and Eugene Kennedy demonstrated in 1948, the enzymes that mediate this process, including pyruvate dehydrogenase, the citric acid cycle enzymes, the enzymes catalyzing fatty acid oxidation (Section 25-2C), and the enzymes and redox proteins involved in electron transport and oxidative phosphorylation. It is therefore with good reason that the mitochondrion is described as the cell's “power plant.”

**Figure 22-1** The sites of electron transfer that form NADH and FADH<sub>2</sub> in glycolysis and the citric acid cycle.

### A. Mitochondrial Anatomy

Mitochondria vary considerably in size and shape depending on their source and metabolic state. They are typically ellipsoids  $\sim 0.5 \mu\text{m}$  in diameter and  $1 \mu\text{m}$  in length (about the size of a bacterium; Fig. 22-2). The mitochondrion is bounded by a smooth outer membrane and contains an extensively invaginated inner membrane. The number of invaginations, called **cristae**, varies with the respiratory activity of the particular type of cell. This is because the proteins mediating electron transport and oxidative phosphorylation are bound to the inner mitochondrial membrane, so that the respiration rate varies with membrane surface

area. Liver, for example, which has a relatively low respiration rate, contains mitochondria with relatively few cristae, whereas those of heart muscle contain many. Nevertheless, the aggregate area of the inner mitochondrial membranes in a liver cell is  $\sim 15$ -fold greater than that of its plasma membrane.

The inner mitochondrial compartment consists of a gel-like substance of  $<50\%$  water, named the **matrix**, which contains remarkably high concentrations of the soluble enzymes of oxidative metabolism (e.g., citric acid cycle enzymes), as well as substrates, nucleotide cofactors, and inorganic ions. The matrix also contains the mitochondrial genetic machinery—DNA, RNA, and ribosomes—that in mammals expresses only 13 mitochondrial inner membrane proteins together with 22 tRNAs and two ribosomal RNAs.

### a. The Inner Mitochondrial Membrane and Cristae Compartmentalize Metabolic Functions

The outer mitochondrial membrane contains **porin**, a protein that forms nonspecific pores that permit free diffusion of up to 10-kD molecules (the X-ray structures of bacterial porins are discussed in Sections 12-3Ad and 20-2D). The inner membrane, which is  $\sim 75\%$  protein by mass, is considerably richer in proteins than the outer membrane (Fig. 22-3). It is freely permeable only to O<sub>2</sub>, CO<sub>2</sub>, and H<sub>2</sub>O and contains, in addition to respiratory chain proteins, numerous transport proteins that control the passage of metabolites such as ATP, ADP, pyruvate, Ca<sup>2+</sup>, and phosphate (see below). *This controlled impermeability of the inner mitochondrial membrane to most ions, metabolites, and low molecular mass compounds permits the generation of ionic gradients across this barrier and results in the compartmentalization of metabolic functions between cytosol and mitochondria.*

Two-dimensional electron micrographs of mitochondria such as Fig. 22-2a suggest that cristae resemble baffles and that the intercrystal spaces communicate freely with the mitochondrion's intermembrane space, as Fig. 22-2b implies. However, electron microscopy-based three-dimensional image reconstruction methods have revealed that cristae can vary in shape from simple tubular entities to more complicated lamellar assemblies that merge with the inner membrane via narrow tubular structures (Fig. 22-4). Evidently, cristae form microcompartments that restrict the diffusion of substrates and ions between the intercrystal and intermembrane spaces. This has important functional implications because it would result in a locally greater pH gradient across cristal membranes than across inner membranes that are not part of cristae, thereby significantly influencing the rate of oxidative phosphorylation (Section 22-3).

### B. Mitochondrial Transport Systems

The inner mitochondrial membrane is impermeable to most hydrophilic substances. It must therefore contain specific transport systems to permit the following processes:

**Figure 22-2 Mitochondria.** (a) An electron micrograph of an animal mitochondrion. [K.R. Porter/Photo Researchers, Inc.] (b) Cutaway diagram of a mitochondrion.

1. Glycolytically produced cytosolic NADH must gain access to the electron-transport chain for aerobic oxidation.

2. Mitochondrially produced metabolites such as oxaloacetate and acetyl-CoA, the respective precursors for

cytosolic glucose and fatty acid biosynthesis, must reach their metabolic destinations.

3. Mitochondrially produced ATP must reach the cytosol, where most ATP-utilizing reactions take place, whereas ADP and P<sub>i</sub>, the substrates for oxidative phosphorylation, must enter the mitochondrion.

**Figure 22-3 Freeze-fracture and freeze-etch electron micrographs of the inner and outer mitochondrial membranes.** The inner membrane contains about twice the density of embedded particles as does the outer membrane. [Courtesy of Lester Packer, University of California at Berkeley.]

**Figure 22-4 Electron microscopy-based three-dimensional image reconstruction of a rat liver mitochondrion.** The outer membrane (OM) is red, the inner membrane (IM) is yellow, and the cristae (C) are green. The arrowheads point to tubular regions of the cristae that connect them to the inner membrane and to each other. [Courtesy of Carmen Mannella, Wadsworth Center, Albany, New York.]

We have already studied the ADP–ATP translocator and its dependence on  $\Delta\Psi$ , the electric potential difference across the mitochondrial membrane (Section 20-4C). The export mechanisms of oxaloacetate and acetyl-CoA from the mitochondrion are, respectively, discussed in Sections 23-1Ag and 25-4D. In the remainder of this section we examine the mitochondrial transport systems for  $P_i$  and  $Ca^{2+}$  and the shuttle systems for NADH.

### a. $P_i$ Transport

ATP is generated from  $ADP + P_i$  in the mitochondrion but is utilized in the cytosol. The  $P_i$  produced is returned to the mitochondrion by the **phosphate carrier**, an electroneutral  $P_i-H^+$  symport that is driven by  $\Delta pH$ . The proton that accompanies the  $P_i$  into the mitochondrion had, in effect, been previously expelled from the mitochondrion by the redox-driven pumps of the electron-transport chain (Section 22-3B). The electrochemical potential gradient generated by these proton pumps is therefore responsible for maintaining high mitochondrial ADP and  $P_i$  concentrations in addition to providing the free energy for ATP synthesis.

### b. $Ca^{2+}$ Transport

Since  $Ca^{2+}$ , like cAMP, functions as a second messenger (Section 18-3Ce), its concentrations in the various cellular compartments must be precisely controlled. The mitochondrion, endoplasmic reticulum, and extracellular spaces act as  $Ca^{2+}$  storage tanks. We studied the  $Ca^{2+}$ -ATPases of the plasma membrane, endoplasmic reticulum, and sarcoplasmic reticulum in Section 20-3B. Here we consider the mitochondrial  $Ca^{2+}$  transport systems.

Mitochondrial inner membrane systems separately mediate the influx and the efflux of  $Ca^{2+}$  (Fig. 22-5). The  $Ca^{2+}$  influx is driven by the inner mitochondrial membrane's membrane potential ( $\Delta\Psi$ , inside negative), which attracts positively charged ions. The rate of influx varies with the external  $[Ca^{2+}]$  because the  $K_M$  for  $Ca^{2+}$  transport by this system is greater than the cytosolic  $Ca^{2+}$  concentration.

In heart, brain, and skeletal muscle mitochondria especially,  $Ca^{2+}$  efflux is independently driven by the  $Na^+$  gradient across the inner mitochondrial membrane.  $Ca^{2+}$  exits the matrix only in exchange for  $Na^+$ , so that this system is an antiport. This exchange process normally operates at its maximal velocity. *Mitochondria (as well as the endoplasmic and sarcoplasmic reticulum) therefore can act as a "buffer" for cytosolic  $Ca^{2+}$*  (Fig. 22-6): If cytosolic  $[Ca^{2+}]$  rises, the rate of mitochondrial  $Ca^{2+}$  influx increases while that of  $Ca^{2+}$  efflux remains constant, causing the mitochondrial  $[Ca^{2+}]$  to increase while the cytosolic  $[Ca^{2+}]$  decreases to its original level (its set point). Conversely, a decrease in cytosolic  $[Ca^{2+}]$  reduces the influx rate, causing net efflux of  $[Ca^{2+}]$  and an increase of cytosolic  $[Ca^{2+}]$  back to the set point.

Oxidation carried out by the citric acid cycle in the mitochondrial matrix is controlled by the matrix  $[Ca^{2+}]$  (Section 21-4c). It is interesting to note, therefore, that in response to increases in cytosolic  $[Ca^{2+}]$  caused by increased muscle activity, the matrix  $[Ca^{2+}]$  increases, thereby activating

**Figure 22-5** The two mitochondrial  $Ca^{2+}$  transport systems. System 1 mediates  $Ca^{2+}$  influx to the matrix in response to the membrane potential (negative inside). System 2 mediates  $Ca^{2+}$  efflux in exchange for  $Na^+$ .

the enzymes of the citric acid cycle. This leads to an increase in  $[NADH]$ , whose reoxidation by oxidative phosphorylation (as we study in this chapter) generates the ATP needed for this increased muscle activity.

**Figure 22-6** The regulation of cytosolic  $[Ca^{2+}]$ . The efflux pathway operates at a constant rate independent of  $[Ca^{2+}]$ , whereas the activity of the influx pathway varies with  $[Ca^{2+}]$ . At the set point, the activities of the two pathways are equal and there is no net  $Ca^{2+}$  flux. An increase in cytosolic  $[Ca^{2+}]$  results in net mitochondrial influx, and a decrease in cytosolic  $[Ca^{2+}]$  results in net mitochondrial efflux. Both effects lead to the restoration of the cytosolic  $[Ca^{2+}]$ . [After Nicholls, D., *Trends Biochem. Sci.* **6**, 37 (1981).]

### c. Cytoplasmic Shuttle Systems “Transport” NADH Across the Inner Mitochondrial Membrane

Although most of the NADH generated by glucose oxidation is formed in the mitochondrial matrix via the citric acid cycle, that generated by glycolysis occurs in the cytosol. Yet the inner mitochondrial membrane lacks an NADH transport protein. *Only the electrons from cytosolic NADH are transported into the mitochondrion by one of several ingenious “shuttle” systems.* In the **malate–aspartate shuttle** (Fig. 22-7), which functions in heart, liver, and kidney, mitochondrial  $\text{NAD}^+$  is reduced by cytosolic NADH through the intermediate reduction and subsequent regeneration of oxaloacetate. This process occurs in two phases of three reactions each:

#### Phase A (transport of electrons into the matrix):

**1.** In the cytosol, NADH reduces oxaloacetate to yield  $\text{NAD}^+$  and malate in a reaction catalyzed by cytosolic malate dehydrogenase.

**2.** The **malate– $\alpha$ -ketoglutarate carrier** transports malate from the cytosol to the mitochondrial matrix in exchange for  $\alpha$ -ketoglutarate from the matrix.

**3.** In the matrix,  $\text{NAD}^+$  reoxidizes malate to yield NADH and oxaloacetate in a reaction catalyzed by mitochondrial malate dehydrogenase (Section 21-3H).

#### Phase B (regeneration of cytosolic oxaloacetate):

**4.** In the matrix, a transaminase (Section 26-1A) converts oxaloacetate to aspartate with the concomitant conversion of glutamate to  $\alpha$ -ketoglutarate.

**5.** The **glutamate–aspartate carrier** transports aspartate from the matrix to the cytosol in exchange for cytosolic glutamate.

**6.** In the cytosol, a transaminase converts aspartate to oxaloacetate with the concomitant conversion of  $\alpha$ -ketoglutarate to glutamate.

The electrons of cytosolic NADH are thereby transferred to mitochondrial  $\text{NAD}^+$  to form NADH, which is subject to reoxidation via the electron-transport chain. *The malate–aspartate shuttle yields ~2.5 ATPs for every cytosolic NADH.* Note, however, that every NADH that enters the matrix is accompanied by a proton which, as we shall

**Figure 22-7** The malate–aspartate shuttle. The electrons of cytosolic NADH are transported to mitochondrial NADH

(shown in red as hydride transfers) in Steps 1 to 3. Steps 4 to 6 then serve to regenerate cytosolic oxaloacetate.

**Figure 22-8** The glycerophosphate shuttle. The electrons of cytosolic NADH are transported to the mitochondrial electron-transport chain in three steps (shown in red as hydride transfers): (1) Cytosolic oxidation of NADH by dihydroxyacetone phosphate catalyzed by glycerol-3-phosphate dehydrogenase. (2) Oxidation of glycerol-3-phosphate by flavoprotein dehydrogenase with the reduction of FAD to FADH<sub>2</sub>. (3) Reoxidation of FADH<sub>2</sub> with the passage of electrons into the electron-transport chain. Note that the glycerophosphate shuttle is not a membrane transport system.

see (Section 22-3C), would otherwise be used to generate ~0.3 ATP. Consequently, every cytosolic NADH that is translocated to the matrix by the malate–aspartate shuttle yields ~2.2 ATPs.

The **glycerophosphate shuttle** (Fig. 22-8), which is simpler but less energy efficient than the malate–aspartate shuttle, occurs in brain and skeletal muscle and is particularly prominent in insect flight muscle (the tissue with the largest known sustained power output—about the same power-to-weight ratio as a small automobile engine). In it, **glycerol-3-phosphate dehydrogenase** catalyzes the oxidation of cytosolic NADH by dihydroxyacetone phosphate to yield NAD<sup>+</sup>, which reenters glycolysis. The electrons of the resulting **glycerol-3-phosphate** are transferred to **flavoprotein dehydrogenase** to form FADH<sub>2</sub>. This enzyme, which is situated on the inner mitochondrial membrane's outer surface, supplies electrons to the electron-transport chain in a manner similar to that of succinate dehydrogenase (Section 22-2C2). The glycerophosphate shuttle therefore results in the synthesis of ~1.5 ATPs for every cytoplasmic NADH reoxidized, ~0.7 ATP less than the malate–aspartate shuttle. However, the advantage of the glycerophosphate shuttle is that, being essentially irreversible, it operates efficiently even when the cytoplasmic NADH concentration is low relative to that of NAD<sup>+</sup>, as occurs in rapidly metabolizing

tissues. In contrast, the malate–aspartate shuttle is reversible and hence is driven by concentration gradients.

## 2 ELECTRON TRANSPORT

In the electron-transport process, the free energy of electron transfer from NADH and FADH<sub>2</sub> to O<sub>2</sub> via protein-bound redox centers is coupled to ATP synthesis. We begin our study of this process by considering its thermodynamics. We then examine the path of electrons through the redox centers of the system and discuss the experiments used to unravel this pathway. Finally, we study the four complexes that make up the electron-transport chain. In the next section we discuss how the free energy harvested by the electron-transport process is coupled to ATP synthesis.

### A. Thermodynamics of Electron Transport

We can estimate the thermodynamic efficiency of electron transport through knowledge of standard reduction potentials. As we have seen in our thermodynamic considerations of oxidation–reduction reactions (Section 16-5), an oxidized substrate's affinity for electrons increases with its standard reduction potential,  $\mathcal{E}^{\circ}$  [the voltage generated by the reaction of the half-cell under standard biochemical conditions (1M reactants and products with [H<sup>+</sup>] defined as 1 at pH 7) relative to the standard hydrogen electrode; Table 16-4 lists the standard reduction potentials of several half-reactions of biochemical interest]. The standard reduction potential difference,  $\Delta\mathcal{E}^{\circ}$ , for a redox reaction involving any two half-reactions is therefore expressed:

$$\Delta\mathcal{E}^{\circ} = \mathcal{E}_{(e^- \text{ acceptor})}^{\circ} - \mathcal{E}_{(e^- \text{ donor})}^{\circ}$$

#### a. NADH Oxidation Is a Highly Exergonic Reaction

The half-reactions for O<sub>2</sub> oxidation of NADH are (Table 16-4)

and

Since the O<sub>2</sub>/H<sub>2</sub>O half-reaction has the greater standard reduction potential and therefore the higher electron affinity, the NADH half-reaction is reversed, so that NADH is the electron donor in this couple and O<sub>2</sub> the electron acceptor. The overall reaction is

so that

$$\Delta\mathcal{E}^{\circ} = 0.815 - (-0.315) = 1.130 \text{ V}$$

The standard free energy change for the reaction can then be calculated from Eq. [16.7]:

$$\Delta G^{\circ} = -n\mathcal{F} \Delta\mathcal{E}^{\circ}$$

where  $\mathcal{F}$ , the Faraday constant, is 96,485 C · mol<sup>-1</sup> of electrons and  $n$  is the number of electrons transferred per

mole of reactants. Thus, since  $1 \text{ V} = 1 \text{ J} \cdot \text{C}^{-1}$ , for NADH oxidation:

$$\Delta G^{\circ'} = -2 \frac{\text{mol } e^-}{\text{mol reactant}} \times 96,485 \frac{\text{C}}{\text{mol } e^-} \times 1.13 \text{ J} \cdot \text{C}^{-1} \\ = -218 \text{ kJ} \cdot \text{mol}^{-1}$$

In other words, the oxidation of 1 mol of NADH by  $\text{O}_2$  (the transfer of  $2e^-$ ) under standard biochemical conditions is associated with the release of 218 kJ of free energy.

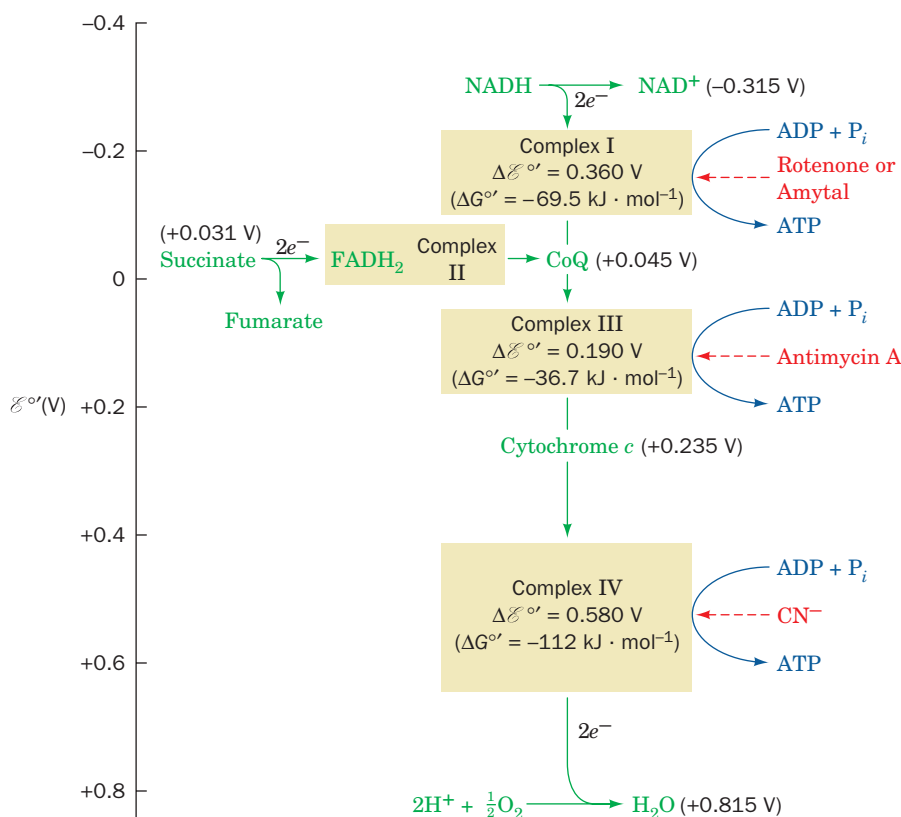

### b. Electron Transport Is Thermodynamically Efficient

The standard free energy required to synthesize 1 mol of ATP from  $\text{ADP} + \text{P}_i$  is 30.5 kJ. The standard free energy of oxidation of NADH by  $\text{O}_2$ , if coupled to ATP synthesis, is therefore sufficient to drive the formation of several moles of ATP. This coupling, as we shall see, is achieved by an electron-transport chain in which electrons are passed through three protein complexes containing redox centers with progressively greater affinity for electrons (increasing standard reduction potentials) instead of directly to  $\text{O}_2$ . This allows the large overall free energy change to be broken up into three smaller packets, each of which is coupled with ATP synthesis in a process called **oxidative phosphorylation**. Oxidation of 1 NADH therefore results in the synthesis of  $\sim 2.5$  ATP. (Oxidation of  $\text{FADH}_2$ , whose entrance

into the electron-transport chain is regulated by a fourth protein complex, is similarly coupled to the synthesis of  $\sim 1.5$  ATP.) The thermodynamic efficiency of oxidative phosphorylation is therefore  $2.5 \times 30.5 \text{ kJ} \cdot \text{mol}^{-1} \times 100/218 \text{ kJ} \cdot \text{mol}^{-1} = 35\%$  under standard biochemical conditions. However, under physiological conditions in active mitochondria (where the reactant and product concentrations as well as the pH deviate from standard conditions), this thermodynamic efficiency is thought to be  $\sim 70\%$ . In comparison, the energy efficiency of a typical automobile engine is  $<30\%$ .

### B. The Sequence of Electron Transport

 **See Guided Exploration 19: Electron transport and oxidative phosphorylation overview** The free energy necessary to generate ATP is extracted from the oxidation of NADH and  $\text{FADH}_2$  by the electron-transport chain, a series of four protein complexes through which electrons pass from lower to higher standard reduction potentials (Fig. 22-9). Electrons are carried from **Complexes I and II to Complex III** by **coenzyme Q (CoQ or ubiquinone)**; so named because of its ubiquity in respiring organisms), and from Complex III to **Complex IV** by the peripheral membrane protein **cytochrome c** (Sections 7-3B and 9-6A).

**Figure 22-9** The mitochondrial electron-transport chain. The standard reduction potentials of its most mobile components (green) are indicated, as are the points where sufficient free energy is harvested to synthesize ATP (blue) and the sites of action

of several respiratory inhibitors (red). (Note that Complexes I, III, and IV do not directly synthesize ATP but, rather, sequester the free energy necessary to do so by pumping protons outside the mitochondrion to form a proton gradient; Section 22-3.)

Complex I catalyzes oxidation of NADH by CoQ:

Complex III catalyzes oxidation of CoQ (reduced) by cytochrome c:

Complex IV catalyzes oxidation of cytochrome c (reduced) by O<sub>2</sub>, the terminal electron acceptor of the electron-transport process:

The changes in standard reduction potential of an electron pair as it successively traverses Complexes I, III, and IV correspond, at each stage, to sufficient free energy to power the synthesis of nearly one ATP molecule.

Complex II catalyzes the oxidation of FADH<sub>2</sub> by CoQ.

This redox reaction does not release sufficient free energy to synthesize ATP; it functions only to inject the electrons from FADH<sub>2</sub> into the electron-transport chain.

**Figure 22-10 The oxygen electrode.** This electrode consists of an Ag/AgCl reference electrode and a Pt electrode, both immersed in a KCl solution and in contact with the sample chamber through an O<sub>2</sub>-permeable Teflon membrane. O<sub>2</sub> is reduced to H<sub>2</sub>O at the Pt electrode, thereby generating a voltage with respect to the Ag/AgCl electrode that is proportional to the O<sub>2</sub> concentration in the sealed sample chamber. [After Cooper, T.G., *The Tools of Biochemistry*, p. 69, Wiley (1977).]

### a. The Workings of the Electron-Transport Chain Have Been Elucidated through the Use of Inhibitors

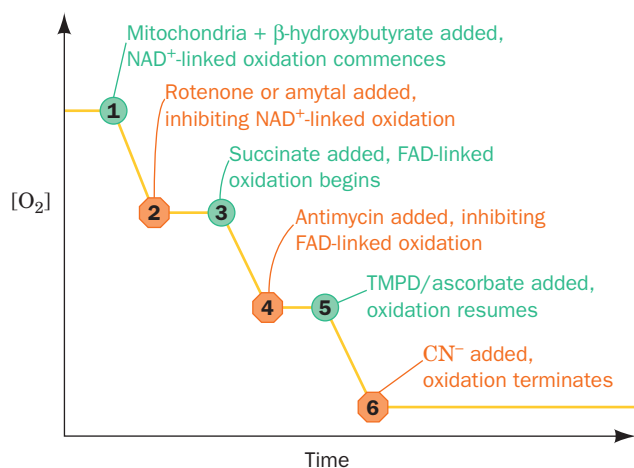

Our understanding of the sequence of events in electron transport is largely based on the use of specific inhibitors. This sequence has been corroborated by measurements of the standard reduction potentials of the redox components of each of the complexes as well as by determining the stoichiometry of electron transport and the coupled ATP synthesis.

The rate at which O<sub>2</sub> is consumed by a suspension of mitochondria is a sensitive measure of the functioning of the electron-transport chain. It is conveniently measured with an **oxygen electrode** (Fig. 22-10). Compounds that inhibit electron transport, as judged by their effect on O<sub>2</sub> disappearance in such an experimental system, have been invaluable experimental probes in tracing the path of electrons through the electron-transport chain and in determining the points of entry of electrons from various substrates. Among the most useful such substances are **rotenone** (a plant toxin used by Amazonian Indians to poison fish and which is also used as an insecticide), **amytal** (a barbiturate), **antimycin** (an antibiotic), and **cyanide**:

The following experiment illustrates the use of these inhibitors:

A buffered solution containing excess ADP and P<sub>i</sub> is equilibrated in the reaction vessel of an oxygen electrode.

**Figure 22-11** Effect of inhibitors on electron transport. This diagram shows an idealized oxygen electrode trace of a mitochondrial suspension containing excess ADP and  $P_i$ . At the numbered points, the indicated reagents are injected into the sample chamber and the resulting changes in  $[O_2]$  are recorded. The numbers refer to the discussion in the text. [After Nicholls, D.G., *Bioenergetics*, p. 110, Academic Press (1982).]

Reagents are then injected into the chamber and the  $O_2$  consumption recorded (Fig. 22-11):

1. Mitochondria and  $\beta$ -hydroxybutyrate are injected into the chamber. Mitochondria mediate the  $NAD^+$ -linked oxidation of  $\beta$ -hydroxybutyrate (Section 25-3):

As the resulting NADH is oxidized by the electron-transport chain with  $O_2$  as the terminal electron acceptor, the  $O_2$  concentration in the reaction mixture decreases.

2. Addition of rotenone or amytal completely stops the  $\beta$ -hydroxybutyrate oxidation.

3. Addition of succinate, which undergoes FAD-linked oxidation, causes the  $[O_2]$  to resume its decrease. Electrons from  $FADH_2$  are therefore still able to reduce  $O_2$  in the presence of rotenone; that is, *electrons from  $FADH_2$  enter the electron-transport chain after the rotenone-blocked step.*

4. Addition of antimycin inhibits electron transport from  $FADH_2$ .

5. Although NADH and  $FADH_2$  are the electron-transport chain's two physiological electron donors,

nonphysiological reducing agents can also be used to probe the flow of electrons. **Tetramethyl-*p*-phenylenediamine (TMPD)** is an ascorbate-reducible redox carrier that transfers electrons directly to cytochrome *c*:

Addition of TMPD and ascorbate to the antimycin-inhibited reaction mixture results in resumption of oxygen consumption; evidently *there is a third point at which electrons can enter the electron-transport chain.*

6. The addition of  $CN^-$  completely inhibits oxidation of all three electron donors, indicating that it blocks the electron-transport chain after the third point of entry of electrons.

Experiments such as these established the order of electron flow through the electron-transport chain complexes and the positions blocked by various electron-transport inhibitors (Fig. 22-9). This order was confirmed and extended by observations that the standard reduction potentials of the redox carriers forming the electron-transport chain complexes are very close to the standard reduction potentials of their electron donor substrates (Table 22-1). *The three jumps in reduction potential between NADH, CoQ, cytochrome c, and  $O_2$  are each of sufficient magnitude to drive ATP synthesis.* Indeed, these redox potential jumps correspond to the points of inhibition of rotenone (or amytal), antimycin, and  $CN^-$ .

### b. Phosphorylation and Oxidation Are Rigidly Coupled

The foregoing thermodynamic studies suggest that oxidation of NADH,  $FADH_2$ , and ascorbate by  $O_2$  is associated with the synthesis of about 2.5, 1.5, and 1 ATP, respectively. This stoichiometry, called the **P/O ratio** [the ratio of ATP synthesized to O atoms reduced (electron pairs taken up)], has been confirmed experimentally through measurements of  $O_2$  uptake by resting and active mitochondria. An example of a typical experiment used to determine the P/O ratio is as follows: A suspension of mitochondria (isolated by differential centrifugation after cell disruption; Section 6-1B) containing an excess of  $P_i$  but no ADP is incubated in an oxygen electrode reaction chamber. *Oxidation and*

Source: Mainly Wilson, D.F., Erecinska, M., and Dutton, P.L., *Annu. Rev. Biophys. Bioeng.* **3**, 205 and 208 (1974); and Wilson, D.F., *In* Bittar, E.E. (Ed.), *Membrane Structure and Function*, Vol. 1, p. 160, Wiley (1980).

phosphorylation are closely coupled in well-functioning mitochondria, so electron transport can occur only if ADP is being phosphorylated (Section 22-3). Indeed, mitochondrial metabolism is so tightly regulated that even the appearances of actively respiring and resting mitochondria are greatly different (Fig. 22-12). Since no ADP is present in the reaction mixture, the mitochondria are resting and the O<sub>2</sub> consumption rate is minimal (Fig. 22-13; Region 1). The system is then manipulated as follows:

- (a) ADP (75  $\mu\text{mol}$ ) and an excess of  $\beta$ -hydroxybutyrate (an NAD<sup>+</sup>-linked substrate) are added. The mitochondria immediately enter the active state and the rate of oxygen consumption increases (Fig. 22-13, Region 2) and is maintained at this elevated

level until all the ADP is phosphorylated. The mitochondria then return to the resting state (Fig. 22-13, Region 3). Phosphorylation of 75  $\mu\text{mol}$  of ADP under these conditions consumes 15  $\mu\text{mol}$  of O<sub>2</sub>. Since the oxidation of NADH by O<sub>2</sub> consumes twice as many moles of NADH (i.e., electron pairs) as of O<sub>2</sub>, the P/O ratio for NADH reoxidation at Region 2 is 75  $\mu\text{mol}$  of ADP/(2  $\times$  15  $\mu\text{mol}$  of O<sub>2</sub>) = 2.5; that is, *2.5 mol of ADP are phosphorylated per mole of NADH oxidized.*

- (b) The experiment is continued by inhibiting electron transfer from NADH by rotenone and adding an additional 75  $\mu\text{mol}$  of ADP (Fig. 22-13, Region 4), this time together with an excess of the FAD-linked substrate succinate. Oxygen consumption again continues until all the ADP is phosphorylated, and the system again returns to the resting state (Fig. 22-13, Region 5). Calculation of the P/O ratio for FADH<sub>2</sub> oxidation yields the value 1.5; that is, *1.5 mol of ADP are phosphorylated per mole of FADH<sub>2</sub> oxidized.*
- (c) In the same manner, *the oxidation of ascorbate/TMPD yields a P/O ratio of 1 (Fig. 22-13, Regions 6 and 7).*

These conclusions agree with the inhibitor studies indicating that there are three entry points for electrons into the electron-transport chain and with the standard reduction potential measurements exhibiting three potential jumps, each sufficient to provide the free energy for ATP synthesis (Fig. 22-9).

### c. The P/O Ratios Are Difficult to Measure Accurately

Measurements of P/O ratios are subject to systematic experimental errors for which it is difficult to correct, such as inaccuracies in the measurement of the oxygen concentration, the presence of AMP, and proton leakage through the inner mitochondrial membrane. In the older literature, these values were taken to be 3, 2, and 1. However, careful measurements by Peter Hinkle have yielded values close to 2.5, 1.5, and 1 for these quantities (we shall see in Section 22-3 that the mechanism of oxidative phosphorylation does not require that P/O ratios have integer values). If these latter values are correct, then the number of ATP molecules that are synthesized per molecule of glucose oxidized is 2.5 ATP/NADH  $\times$  10 NADH/glucose + 1.5 ATP/FADH<sub>2</sub>  $\times$  2 FADH<sub>2</sub>/glucose + 2 ATP/glucose from the citric acid cycle + 2 ATP/glucose from glycolysis = 32 ATP/glucose (rather than the value of 38 ATP/glucose implied by P/O ratios of 3, 2, and 1).

The determination of the *in vivo* yield of ATP/glucose is even more problematic. The reducing equivalents from the GAPDH-generated NADH may be imported into the mitochondrion via the glycerophosphate shuttle, which yields FADH<sub>2</sub>, or via the malate-aspartate shuttle, which yields NADH but passes a proton into the matrix (Section 22-1Bc). The mix of these two shuttle systems varies from tissue to tissue and hence so does the ATP yield. In addition, the rate of proton leakage back across the inner mitochondrial membrane, which is significant, may vary with

(a)

**Figure 22-12** Electron micrographs of mouse liver mitochondria. (a) In the actively respiring state and (b) in the resting state. The cristae in actively respiring mitochondria are

(b)

far more condensed than they are in resting mitochondria. [Courtesy of Charles Hackenbrock, University of North Carolina Medical School.]

conditions and cellular identity. Hence, the *in vivo* yield of ATP per glucose is likely to be significantly less than the above figures of 32 ATP/glucose.

How the free energy of electron transport is actually coupled to ATP synthesis, a subject of active research, is discussed in Section 22-3. We first examine the structures of the four respiratory complexes in order to understand how they are related to the function of the electron-transport chain. Keep in mind, however, that as in most areas of biochemistry, this field is under intense scrutiny and much of

the information we need for a complete understanding of these relationships has yet to be elucidated.

### C. Components of the Electron-Transport Chain

Many of the proteins embedded in the inner mitochondrial membrane are organized into the four respiratory complexes of the electron-transport chain. Each complex consists of several protein components that are associated with a variety of redox-active prosthetic groups with successively

**Figure 22-13** Determination of the stoichiometry of coupled oxidation and phosphorylation (the P/O ratio) with different electron donors. Mitochondria are incubated in excess phosphate buffer in the sample chamber of an oxygen electrode. (a) Next, 75  $\mu\text{mol}$  of ADP and excess  $\beta$ -hydroxybutyrate are added. Respiration continues until all the ADP is phosphorylated.  $\Delta[\text{O}_2]$  in Region 2 is 15  $\mu\text{mol}$ , corresponding to 30  $\mu\text{mol}$  of NADH oxidized; thus,  $\text{P/O} = 75/30 = 2.5$ . (b) Then 75  $\mu\text{mol}$  of ADP and excess succinate are added together with rotenone to inhibit electron transfer from NADH.  $\Delta[\text{O}_2]$  in Region 4 is 25  $\mu\text{mol}$ , corresponding to 50  $\mu\text{mol}$  of  $\text{FADH}_2$  oxidized;  $\text{P/O} = 75/50 = 1.5$ . (c) Finally, 75  $\mu\text{mol}$  of ADP and excess TMPD/ascorbate are added with antimycin to inhibit electron transfer from  $\text{FADH}_2$ .  $\Delta[\text{O}_2]$  in Region 6 is 37.5  $\mu\text{mol}$ , corresponding to 75  $\mu\text{mol}$  of ascorbate oxidized;  $\text{P/O} = 75/75 = 1$ .

**Figure 22-14 The mitochondrial electron-transport chain.** The pathways of electron transfer (black) and proton pumping (red) are indicated. Electrons are transferred between Complexes I and III by membrane-soluble CoQ (Q) and between Complexes

III and IV by the peripheral membrane protein cytochrome *c* (Cyt *c*). Complex II (not shown) transfers electrons from succinate to CoQ.  See the Animated Figures

increasing reduction potentials (Table 22-1). In the following paragraphs, we examine their structures and the agents that transfer electrons between them. Their relationships are summarized in Fig. 22-14.

### 1. Complex I (NADH Dehydrogenase or NADH-Coenzyme Q Oxidoreductase)

Complex I (also called *NADH dehydrogenase*) passes electrons from *NADH* to *CoQ*. This probably largest protein component of the inner mitochondrial membrane (~980 kD in mammals and ~700 kD in *Neurospora crassa*) contains one molecule of **flavin mononucleotide (FMN)**; a redox-active prosthetic group that differs from FAD only by the absence of the AMP group) and eight or nine **iron-sulfur clusters** that participate in the electron-transport process (Table 22-1). In mammals, 7 of its 45 subunits, its most hydrophobic subunits, which form the core of its transmembrane region, are encoded by mitochondrial genes, with the remainder encoded by nuclear genes. Most of its subunits are homologous to soluble redox center-containing proteins, which strongly suggests that Complex I arose through the evolutionary aggregation of these previously existing proteins.

#### a. Iron-Sulfur Clusters Are Redox Active

Iron-sulfur clusters, first discovered by Helmut Beinert, commonly occur as prosthetic groups in **iron-sulfur proteins**. There are four common types of iron-sulfur clusters (Fig. 22-15). Those designated **[2Fe-2S]** and **[4Fe-4S]**

**Figure 22-15 Structures of the common iron-sulfur clusters.** (a) An [Fe-S] cluster, (b) a [2Fe-2S] cluster, and (c) a [4Fe-4S] cluster. The [3Fe-4S] cluster resembles the [4Fe-4S] cluster with one of its Fe ions removed. Note that, whereas the Fe and  $S^{2-}$  ions of [4Fe-4S] clusters form what appears to be a distorted cube, the structure is really two interpenetrating tetrahedra of Fe ions and  $S^{2-}$  ions.

**clusters** consist of equal numbers of iron and sulfide ions and are both coordinated to four protein Cys sulfhydryl groups. The **[3Fe–4S] cluster** is essentially a [4Fe–4S] cluster that lacks one Fe. One means of identifying these clusters utilizes the fact that their sulfide ions are acid labile: They are released as H<sub>2</sub>S near pH 1. The **[Fe–S] cluster**, which occurs only in bacteria, consists of a single Fe atom liganded to four Cys residues. Note that the Fe ions in all four types of clusters are each coordinated by four S atoms, which are more or less tetrahedrally disposed around the Fe. However, in **Rieske iron–sulfur proteins** (named after their discoverer, John Rieske), one of the Fe atoms in a [2Fe–2S] cluster is coordinated by two His residues rather than two Cys residues.

The oxidized and reduced states of all iron–sulfur clusters differ by one formal charge regardless of their number of Fe ions. This is because the Fe ions in each cluster form a conjugated system and thus can have oxidation states between the +2 and +3 values possible for individual Fe ions. For example, each of the two [4Fe–4S] clusters in the protein **ferredoxin** (Fig. 22-16) contains one Fe(II) and three Fe(III) in its oxidized form and two Fe(II) and two Fe(III) in its reduced form. The standard reduction potential of a given type of iron–sulfur cluster depends on its interaction with its associated protein as well as on its oxidation state.

**Figure 22-16** X-ray structure of ferredoxin from *Peptostreptococcus asaccharolyticus*. This monomeric 55-residue protein is drawn in ribbon form colored in rainbow order from its N-terminus (blue) to its C-terminus (red). Its two [4Fe–4S] clusters are drawn in ball-and-stick form with S yellow and Fe red-brown. The Cys side chains that ligand each Fe atom are drawn in stick form with C green and S yellow. [Based on an X-ray structure by Elinor Adman, Larry Sieker, and Lyle Jensen, University of Washington. PDBid 1DUR.]  See Interactive Exercise 16

Iron–sulfur proteins also occur in the photosynthetic electron-transport chains of plants and bacteria (Section 24-2); indeed, photosynthetic electron-transport chains are thought to be the evolutionary precursors of oxidative electron-transport chains (Section 1-5Cb).

#### b. The Coenzymes of Complex I

FMN and ubiquinone (CoQ), the coenzymes of Complex I, can each adopt three oxidation states (Fig. 22-17). Although NADH can only participate in a two-electron transfer, both FMN and CoQ are capable of accepting and donating either one or two electrons because their semi-quinone forms are stable. In contrast, the cytochromes of Complex III (see below), to which reduced CoQ passes its electrons, are only capable of one-electron reductions. *FMN and CoQ therefore provide an electron conduit between the two-electron donor NADH and the one-electron acceptors, the cytochromes.*

CoQ's hydrophobic tail makes it soluble in the inner mitochondrial membrane's lipid bilayer. In mammals, this tail consists of ten C<sub>5</sub> isoprenoid units and hence the coenzyme is designated **Q<sub>10</sub>**. In other organisms, CoQ may have only six (**Q<sub>6</sub>**) or eight (**Q<sub>8</sub>**) isoprenoid units.

#### c. Electrons Follow a Multistep Path through Complex I

Complex I from prokaryotes consists of 13 to 15 subunits with an aggregate molecular mass of ~550 kD. Homologs of all of its conserved subunits occur in the mitochondrial enzyme and they contain equivalent redox components. Evidently, the prokaryotic enzyme is a stripped down version of mitochondrial Complex I. The functions of the 30 to 32 additional “accessory” subunits that are components of mitochondrial Complex I are largely unknown.

The low resolution X-ray structure of the 15-subunit Complex I from the thermophilic bacterium *Thermus thermophilus* (Fig. 22-18), determined by Leonid Sazanov, reveals an L-shaped protein with one arm of the L, the transmembrane arm, immersed in the plasma membrane (the inner mitochondrial membrane for eukaryotes) and the other, the peripheral arm, extending into the cytosol (the matrix for eukaryotes). The transmembrane arm, consists of seven subunits that collectively have 63 transmembrane helices. The three largest transmembrane subunits, Nqo12, 13, and 14, are structurally similar to each other and to previously determined structures of Na<sup>+</sup>/H<sup>+</sup> antiporters. However, the most unusual feature of the transmembrane portion is a 110-Å long amphipathic  $\alpha$  helix that extends from Nqo12 parallel to the plane of the membrane so as to span Nqo13 and 14.

The high resolution X-ray structure of the 8-subunit, hydrophilic, peripheral arm of Complex I from the thermophilic bacterium, *Thermophilus*, also determined by Sazanov, reveals a Y-shaped assembly that is 140 Å high (Fig. 22-19a). This subcomplex contains all of the enzyme's redox centers: an FMN, seven [4Fe–4S] clusters, and two [2Fe–2S] clusters. The FMN is located at the end of a solvent-exposed cavity that presumably forms the NADH

**Figure 22-17** Oxidation states of the organic coenzymes of complex I. (a) FMN and (b) CoQ. Both coenzymes form stable semiquinone free radical states.

**Figure 22-18** Low (4.5-Å) resolution X-ray structure of **Complex I from *T. thermophilus***. The structure is viewed parallel to the plane of the plasma membrane with the cytoplasm above and the periplasm below. Its 15 subunits are drawn in ribbon form in different colors with the 110-Å-long horizontal helix of Nqo12 purple. The nine Fe-S clusters in the peripheral arm are drawn in space-filling form with S yellow and Fe red-brown. At the structure's low resolution, only the transmembrane helices of the transmembrane arm can be seen; their connecting loops are not visible, which accounts for the apparent gap between the transmembrane and peripheral arms. However, the loops of the peripheral arm are visible because that part of the structure was based on the higher resolution X-ray structure of the peripheral arm alone (see Fig. 22-19). [Courtesy of Leonid Sazanov, Medical Research Council, Cambridge, U.K. PDBid 3M9S.]

**Figure 22-19** X-ray structure of the peripheral arm of Complex I from *T. thermophilus*. (a) The protein is viewed parallel to the plane of the plasma membrane but oriented differently to that in Fig. 22-18. Its eight subunits are drawn in semitransparent ribbon form in different colors (which differ from those in Fig. 22-18). The FMN (*upper left*) and the nine Fe-S clusters are shown in space-filling form with C green, N blue, O red, P orange, S yellow, and Fe red-brown. The likely CoQ binding site (Q) is indicated by a gray arrow. (b) The arrangement of redox groups viewed similarly to Part a. The FMN (stick model with C yellow and the two [Fe-S] and seven

[4Fe-4S] clusters (space-filling models) are shown together with their center-to-center distances in angstroms (shortest edge-to-edge distances are indicated in parentheses). Blue arrows represent the  $\sim 94$ -Å-long main path of electrons after their transfer from NADH to FMN. Fe-S clusters N1a and N7 lie too far off this path for electrons to pass through them but perhaps they function to fine-tune its electronic properties. Spectroscopic measurements suggest that the CoQ binding site is  $\sim 12$  Å distant from N2. [Part a based on an X-ray structure by and Part b courtesy of Leonid Sazanov, Medical Research Council, Cambridge, U.K. PDBid 2FUG.]

binding site. Model building suggests that bound NADH protects the FMN from solvent. The CoQ binding site appears to be in a cavity below the [4Fe-4S] cluster N2 that is located at the interface with Complex I's transmembrane arm.

The transit of electrons from NADH to CoQ in Complex I begins with a two-electron reduction in the form of a hydride ion ( $\text{H}^-$ ) transfer from NADH to FMN to yield  $\text{NAD}^+$  and  $\text{FMNH}^-$  (similar to the reverse of the final step of the dihydrolipoyl dehydrogenase reaction; Section 21-2Bb). The electrons are then transferred, one at a time, to Fe-S cluster N3 and then between Fe-S clusters along a gradient of increasing redox potential (Table 22-1) until they reach Fe-S cluster N2. This “downhill” process involves the transient reduction of each Fe-S cluster as it binds electrons and its reoxidation when it passes the electrons to the next cluster. Their spatial arrangement indicates the probable path of the electrons (Fig. 22-19b). Note that redox centers need not be in contact in order to transfer electrons. Finally, the electrons are passed from N2 to CoQ, which is sequentially reduced to  $\text{CoQH}\cdot$  and then to  $\text{CoQH}_2$ , which is released into the membrane and replaced by CoQ, thereby completing the catalytic cycle.

In translocating an electron pair from NADH to CoQ, Complex I pumps four protons out of the mitochondrial

matrix (the bacterial cell). How complex I accomplishes this task is discussed in Section 22-3Bj.

## 2. Complex II [Succinate Dehydrogenase or Succinate-Coenzyme Q Oxidoreductase (SQR)]

Complex II, which is also the citric acid cycle enzyme succinate dehydrogenase (Section 21-3F), passes electrons from succinate to CoQ to yield fumarate and  $\text{CoQH}_2$ . It does so with the participation of a covalently bound FAD, a [2Fe-2S] cluster, a [4Fe-4S] cluster, a [3Fe-4S] cluster, and one heme  $b_{560}$  (Table 22-1). All of its four subunits are encoded by nuclear genes.

The standard redox potential difference for electron transfer from succinate to CoQ (Fig. 22-9) is insufficient to provide the free energy necessary to drive ATP synthesis. Complex II is, nevertheless, important because it injects these relatively high-potential electrons into the electron-transport chain. Two other enzymes, in addition to Complexes I and II, synthesize and release  $\text{CoQH}_2$  in the inner mitochondrial membrane and thereby power oxidative phosphorylation via the actions of Complexes III and IV. They are glycerol-3-phosphate dehydrogenase of the glycerophosphate shuttle (Fig. 22-8) and **ETF-ubiquinone oxidoreductase**, which participates in fatty acid oxidation (Section 25-2Ca; ETF stands for *electron-transfer flavoprotein*).

### a. Cytochromes Are Heme Proteins That Transport Electrons

Cytochromes, whose function was elucidated in 1925 by David Keilin, are redox-active proteins that occur in all organisms except a few types of obligate anaerobes. These proteins contain heme groups that reversibly alternate between their Fe(II) and Fe(III) oxidation states during electron transport.

The heme groups of the reduced [Fe(II)] cytochromes have prominent visible absorption spectra consisting of three peaks: the  $\alpha$ ,  $\beta$ , and  $\gamma$  (Soret) bands (Fig. 22-20a). The wavelength of the  $\alpha$  peak, which varies characteristically with the particular reduced cytochrome species (it is absent in oxidized cytochromes), is useful for differentiating the various cytochromes. Accordingly, the spectra of mitochondrial membranes (Fig. 22-20b) indicate that they contain three cytochrome types, **cytochromes a, b, and c**.

Within each type of cytochrome, different heme group environments may be characterized by slightly different  $\alpha$  peak wavelengths. For example, Complex III (see below) has two *b*-type hemes: That absorbing maximally at 562 nm is referred to as **heme  $b_{562}$**  or  **$b_H$**  (for *high* potential), whereas that absorbing maximally at 566 nm is referred to as **heme  $b_{566}$**  or  **$b_L$**  (for *low* potential).

Each type of cytochrome contains a differently substituted porphyrin ring (Fig. 22-21a) coordinated with the redox-active iron atom. A *b*-type cytochrome contains **protoporphyrin IX**, which also occurs in hemoglobin and myoglobin (Section 10-1A). The heme group of a *c*-type cytochrome differs from protoporphyrin IX in that its vinyl groups have added the Cys sulfhydryls in the sequence Cys-X-Y-Cys-His across their double bonds to form thioether linkages to the protein (Fig. 9-39). Heme *a* con-

tains a long hydrophobic tail of three isoprene units (a **far-nesyl** group) linked to the porphyrin via a hydroxyethyl group, as well as a formyl group in place of a methyl substituent.

The axial ligands of the heme iron also vary with the cytochrome type. In cytochromes *a* and *b*, both ligands are His residues, whereas in cytochrome *c*, one is the His in the Cys-X-Y-Cys-His sequence and the other is Met (Fig. 22-21b). Note that the designation of a given cytochrome type refers only to the identity of the cytochrome's heme prosthetic group(s); a given cytochrome type may have any of several unrelated protein folds.

### b. Complex II Contains a Linear Chain of Redox Cofactors

Both bacterial and mitochondrial Complex II's consist of four subunits: two water-soluble subunits, a flavoprotein (Fp, ~665 residues) that binds the enzyme's substrate succinate and FAD (which is covalently linked to a specific His side chain via a bond to FAD atom C8a; Section 21-3F), and an iron-sulfur protein (Ip, ~290 residues) that binds the three Fe-S clusters; and two transmembrane subunits, CybL (~170 residues) and CybS (~160 residues) that collectively bind the heme  $b_{560}$  and the CoQ. Fp and Ip are highly conserved, whereas the sequences of CybS and CybL vary among different organisms.

The X-ray structures of porcine, chicken, and *E. coli* Complex II were independently determined by Zihao Rao, Edward Berry, and So Iwata. In all cases, it has the shape of the letter "q," with its top lobe containing Fp and Ip and its tail composed of the transmembrane subunits (Fig. 22-22a). The complex is oriented in the inner mitochondrial membrane such that Fp and Ip extend into the matrix. The

**Figure 22-20** Visible absorption spectra of cytochromes.

(a) Absorption spectrum of reduced cytochrome *c* showing its characteristic  $\alpha$ ,  $\beta$ , and  $\gamma$  (Soret) absorption bands. The absorption maxima for cytochromes *a*, *b*, *c*, and *c*<sub>1</sub> are listed.

(b) The three separate  $\alpha$  bands in the visible absorption

spectrum of beef heart mitochondrial membranes (*below*) indicate the presence of cytochromes *a*, *b*, and *c*. The spectrum of purified cytochrome *c* (*above*) is provided for reference. [After Nicholls, D.G. and Ferguson, S.J., *Bioenergetics* 3, p. 96, Academic Press (2002).]

**Figure 22-21** Porphyrin rings in cytochromes. The (a) chemical structures and (b) axial liganding of the heme groups contained in cytochromes *a*, *b*, and *c* are shown.

**Figure 22-22** X-ray structure of chicken Complex II in complex with its inhibitor oxaloacetate and CoQ. (a) A semitransparent ribbon diagram viewed parallel to the inner mitochondrial membrane with the matrix above and in which the enzyme's four subunits are drawn in different colors. The oxaloacetate (OAA),

FAD, three Fe-S clusters, CoQ, and heme *b* are shown in space-filling form with OAA C magenta, FAD and heme *b* C green, CoQ C cyan, N blue, O red, P orange, S yellow, and Fe red-brown. The inferred position of the inner mitochondrial membrane is indicated. (b) The ligands and redox cofactors viewed and colored as in Part *a* but drawn in stick form. Their closest edge-to-edge distances are indicated. [Based on an X-ray structure by Edward Berry, Lawrence Berkeley National Laboratory, Berkeley, California. PDBid 1YQ3.]

substrate and CoQ binding sites are connected by a nearly linear  $\sim 40$ -Å-long chain of redox centers with the sequence substrate–FAD–[2Fe–2S]–[4Fe–4S]–[3Fe–4S]–CoQ (top to bottom in Fig. 22-22*b*). Thus, despite the measured  $-0.245$  V reduction potential of the [4Fe–4S] cluster (Table 22-1), which would appear to be too low for it to accept electrons from succinate in the succinate  $\rightarrow$  fumarate reaction, the [4Fe–4S] cluster probably participates in the electron-transfer process.

### c. Complex II Suppresses the Formation of Reactive Oxygen Species

The bacterial respiratory complex **quinol–fumarate reductase (QFR)** is a homolog of Complex II that functions in anaerobic organisms that use fumarate as a terminal electron acceptor. There it catalyzes the same reaction as does Complex II but in the opposite direction, that is, it uses a quinol to reduce fumarate to succinate.

Even though QFR and Complex II have similar structures, organisms such as *E. coli* that are capable of both aerobic and anaerobic metabolism employ the two different complexes for these different purposes. This appears to be because under aerobic conditions, QFR produces 25 times as much superoxide radical ( $O_2^{\cdot -}$ ) as does *E. coli* Complex II as well as  $H_2O_2$ , which Complex II does not produce, presumably by leaking electrons to  $O_2$ . As we discuss in Section 22-4Cg, these **reactive oxygen species (ROS)** are highly destructive. Comparison of the X-ray structure of QFR with that of the closely similar *E. coli* Complex II indicates that the electron distributions about their various redox centers greatly favors the ROS-generating side reactions of  $O_2$  with the flavin ring of QFR relative to that of Complex II. Indeed, the heme  $b_{560}$  of Complex II, which QFR lacks and which is not in Complex II's direct electron transfer pathway (Fig. 22-22*b*), appears to fine-tune its electronic properties so as to suppress the side reactions that generate the ROS. This suggests that mutations of the genes encoding human Complex II, which cause a wide variety of disorders including tumor formation, neurological defects, and premature aging, result from ROS generation.

### 3. Complex III (Coenzyme Q–Cytochrome *c* Oxidoreductase or Cytochrome $bc_1$ Complex)

*Complex III passes electrons from reduced CoQ to cytochrome *c*.* It contains four redox cofactors: two *b*-type hemes, a *c*-type heme, and one [2Fe–2S] cluster (Table 22-1).

#### a. X-Ray Structure of the Cytochrome $bc_1$ Complex

All known cytochrome  $bc_1$  complexes contain three common subunits: **cytochrome *b***, which binds both the  $b_H$  and  $b_L$  hemes, **cytochrome  $c_1$** , which contains a single *c*-type heme, and a Rieske iron–sulfur protein (**ISP**), which contains a [2Fe–2S] cluster. The bovine  $bc_1$  complex contains 8 additional subunits for a total of 11 different subunits that combine to form a 2166-residue (243-kD) protomer that dimerizes. Of these, only cytochrome *b* is encoded by a mitochondrial gene.

The X-ray structures of bovine, chicken, and yeast cytochrome  $bc_1$  complexes were independently determined by Johann Deisenhofer, by Iwata and Bing Jap, by Berry, Antony Crofts, and Sung-Hou Kim, and by Hartmut Michel. All of these structures reveal a 2-fold symmetric pear-shaped molecule of maximum diameter  $\sim 130$  Å and height  $\sim 150$  Å, whose wide end extends  $\sim 75$  Å into the matrix space and whose narrow end extends  $\sim 35$  Å into the intermembrane space (Fig. 22-23). Its membrane-spanning region is  $\sim 40$  Å thick and consists of 13 transmembrane helices in each protomer (12 in yeast, which consists of 9 different subunits). Eight of these transmembrane helices are contributed by the cytochrome *b* subunit, which binds both heme  $b_H$  and heme  $b_L$  within its transmembrane region, with heme  $b_L$  being closest to the intermembrane space. One of the remaining transmembrane helices is the membrane anchor of cytochrome  $c_1$ , the rest of which is a globular domain that extends into the intermembrane space. This is the portion of the complex

**Figure 22-23** X-ray structure of the yeast Complex III homodimer in complex with cytochrome *c* and the inhibitor stigmatellin. The view is perpendicular to its 2-fold axis and parallel to the membrane with the matrix below. The nine different subunits in each protomer of Complex III, which collectively have 12 transmembrane helices, are drawn in semitransparent ribbon form and are differently colored with cytochrome *b* pale yellow, cytochrome  $c_1$  light purple, the ISP tan, Core 1 cyan, and Core 2 orange. The bound cytochrome *c* is pink. The four different heme groups, the [2Fe–2S] cluster, and stigmatellin are drawn in space-filling form with heme C green, stigmatellin C magenta, N blue, O red, S yellow, and Fe red-brown. The horizontal lines delineate the inferred position of the membrane. Note that only one cytochrome *c* is bound to the homodimeric Complex III. [Based on an X-ray structure by Carola Hunte, Max Planck Institute for Biophysics, Frankfurt am Main, Germany. PDBid 1KYO.]  See Interactive Exercise 17.

that contains heme  $c_1$  and to which cytochrome  $c$  docks (Figure 22-23). The ISP is likewise anchored by a single transmembrane helix and extends into the intermembrane space. Interestingly, the two ISPs of the dimeric complex are domain swapped (intertwined) such that the  $[2\text{Fe}-2\text{S}]$  cluster-containing domain of one protomer interacts with the cytochrome  $b$  and cytochrome  $c_1$  subunits of the other protomer. The distances between the various metal centers are all quite large, ranging from 21 to 34 Å. The portion of the complex that occupies the matrix, which accounts for more than half the mass of cytochrome  $bc_1$ , consists largely of the structurally homologous **Core 1** and **Core 2** proteins.

The route of electrons through the cytochrome  $bc_1$  complex is discussed in Section 22-3B, together with the mechanism by which the complex preserves the free energy of electron transfer from  $\text{CoQH}_2$  to cytochrome  $c$  for ATP synthesis.

#### 4. Cytochrome $c$

Cytochrome  $c$ , whose evolution we discussed in Section 7-3B, is a peripheral membrane protein of known crystal structure (Figs. 8-42 and 9-41c) that is loosely bound to the outer surface of the inner mitochondrial membrane. It alternately binds to cytochrome  $c_1$  (of Complex III) and to cytochrome  $c$  oxidase (Complex IV) and thereby functions to shuttle electrons between them.

The X-ray structure of yeast cytochrome  $bc_1$  in complex with cytochrome  $c$ , determined by Carola Hunte, reveals, as expected, that cytochrome  $c$  binds to the cytochrome  $c_1$  subunit of cytochrome  $bc_1$  (Fig. 22-23). This association appears to be particularly tenuous because its interfacial area (880 Å<sup>2</sup>) is significantly less than that exhibited by protein-protein complexes known to have low stability (typically <1600 Å<sup>2</sup>). Such a small interface is well suited for fast binding and release. The closest approach between the heme groups of the contacting proteins is 4.1 Å between atoms of their respective thioether-bonded substituents, and their Fe-Fe distance is 17.4 Å. This accounts for the  $8.3 \times 10^6 \text{ s}^{-1}$  rate of electron transfer between these two redox centers (see below).

##### a. Protein Structure Influences the Rate of Electron Transfer

Reduced hemes are highly reactive entities; they can transfer electrons over distances of 10 to 20 Å at physiologically significant rates. Hence cytochromes, in a sense, have the opposite function of enzymes: Instead of persuading unreactive substrates to react, they must prevent their hemes from transferring electrons nonspecifically to other cellular components. This, no doubt, is why these hemes are almost entirely enveloped by protein. However, cytochromes must also provide a path for electron transfer to an appropriate partner.

In proteins, electron transfers occur between redox-active cofactors such as hemes and/or Fe-S clusters. However, a survey of proteins of known structure that function in electron transfer reveals that electrons travel no more

than 14 Å between protein-embedded redox centers and that transfers over longer distances always involve chains of redox-active cofactors (e.g., Figs. 22-19b and 22-22b). Electron transfers occur far more efficiently through bonds than through space via a quantum mechanical process known as **electron tunneling**. Thus, as Harry Gray has experimentally demonstrated, electron tunneling within proteins occurs largely through the polypeptide chains between bound redox-active groups and the rate of electron transfer varies with the structure of the intervening polypeptide. Moreover, tunneling across protein-protein interfaces is largely mediated by van der Waals interactions and water-bridged hydrogen bonds. Nevertheless, Leslie Dutton has shown that the experimentally measured electron transfer rates within proteins vary only with the distance between the electron donor and the electron acceptor and fall off with an ~10-fold decrease in rate for each 1.7 Å increase in this distance.

#### 5. Complex IV (Cytochrome $c$ Oxidase)

*Cytochrome  $c$  oxidase (COX or CcO), the terminal enzyme of the electron-transport chain, catalyzes the one-electron oxidations of four consecutive reduced cytochrome  $c$  molecules and the concomitant four-electron reduction of one  $\text{O}_2$  molecule to yield  $2\text{H}_2\text{O}$ :*

Eukaryotic COX is an ~200-kD transmembrane protein composed of 8 to 13 subunits, whose largest and most hydrophobic chains, Subunits I, II, and III, are encoded by mitochondrial genes, with the remaining subunits encoded by nuclear genes. Eukaryotic COX exists in membranes as a dimer. Subunits I and II of this complex contain all four of its redox-active centers: two  $a$ -type hemes,  $a$  and  $a_3$ , and two Cu-containing centers,  $\text{Cu}_A$  and  $\text{Cu}_B$ . The  $\text{Cu}_A$  center and heme  $a$  are of low potential (0.245 and 0.210 V; Table 22-1), whereas  $\text{Cu}_B$  and heme  $a_3$  are of higher potential (0.340 and 0.385 V). Spectroscopic studies indicate that electrons are passed from cytochrome  $c$  to the  $\text{Cu}_A$  center, then to the heme  $a$ , and finally to a binuclear complex of heme  $a_3$  and  $\text{Cu}_B$ .  $\text{O}_2$  binds to this binuclear complex and is reduced to  $\text{H}_2\text{O}$  in a complex four-electron reaction (see below).

##### a. X-Ray Structures of Cytochrome $c$ Oxidase

The X-ray structures of three species of cytochrome  $c$  oxidase have been determined: two relatively simple forms from the soil bacterium *Paracoccus denitrificans* (1106 residues) by Michel and the purple photosynthetic bacterium *Rhodobacter sphaeroides* by Iwata, and a more complex form from bovine heart (1806 residues) by Shinya Yoshikawa. Each protomer of the 2-fold symmetric dimeric bovine COX has an ellipsoidal (potatolike) shape comprised of a 48-Å-thick transmembrane portion and hydrophilic portions that protrude 32 and 37 Å into the mitochondrial matrix and the intermembrane space,

**Figure 22-24** X-ray structure of the bovine heart cytochrome *c* oxidase homodimer. The view is perpendicular to its 2-fold axis and parallel to the membrane with the matrix below. The 13 subunits in each protomer, which collectively have 28 transmembrane helices, are drawn in semitransparent ribbon form and differently colored according to type with Subunit I pale green, Subunit II pink, and Subunit III pale yellow. The protein's bound heme groups and Cu ions are drawn in space-filling form with C green, N blue, O red, Fe red-brown, and Cu cyan. The horizontal black lines delineate the inferred position of the inner mitochondrial matrix. [Based on an X-ray structure by Shinya Yoshikawa, Himeji Institute of Technology, Hyogo, Japan. PDBid 1V54.]  See Interactive Exercise 18.

respectively (Fig. 22-24). These protomers each consist of 13 different subunits that mainly form 28 transmembrane helices. The protomer surfaces that comprise the dimer interface are concave (Fig. 22-24) and hence their relatively tenuous contacts enclose a lipid-filled cavity. Moreover, mitochondrial COX is active as a monomer. Thus a mechanistic role for dimer formation seems unlikely. The *P. denitrificans* and *Rb. sphaeroides* COXs are monomeric complexes, each of which consists of only 4 subunits that collectively contain 22 transmembrane helices.

The structures of bovine COX Subunits I (12 transmembrane helices) and II (2 transmembrane helices), which bind all of the complex's four redox centers, are closely similar to those of *P. denitrificans* and *Rb. sphaeroides* COXs. These are the subunits that carry out the main functions of the complex: transporting electrons from cytochrome *c* to  $O_2$  to yield water, while pumping protons from inside (as we shall refer to the mitochondrial matrix and the bacterial cytoplasm; also called the **N-side** due to its negative charge) to outside (as we shall refer to the mitochondrial intermembrane space and the bacterial periplasmic space; also called the **P-side** due to its positive charge). Bovine Subunit III (7 transmembrane helices), whose structure also resembles that of its *P. denitrificans* and *Rb. sphaeroides* counterparts, does not appear to directly participate in electron transfer or proton translocation. Indeed, a complex consisting of only *P. denitrificans* Subunits I and II can actively transport electrons and pump protons. Thus the function of Subunit III is unknown,

although there is some evidence that it facilitates the assembly of Subunits I and II to form the active complex. Note, however, that Subunit III does not contact Subunit II. None of the 10 nuclear-encoded subunits of bovine COX resemble Subunit IV of *P. denitrificans* and *Rb. sphaeroides* COXs (1 transmembrane helix). Seven of these bovine subunits each have one transmembrane helix, all oriented with their N-terminal ends on the matrix side of the membrane. These helices are distributed about the periphery of the dimeric core formed by Subunits I, II, and III. The remaining three bovine subunits are globular and associate entirely with the extramembrane portions of the complex. The X-ray structure of bovine COX provides little indication of the function of any of its nuclear-encoded subunits. Perhaps they have regulatory roles.

Subunit I binds heme *a* and the heme  $a_3$ -Cu<sub>B</sub> binuclear center (Fig. 22-25), whose metal ions are all located ~13 Å below the membrane surface on its intermembrane/periplasmic side (Fig. 22-24). The heme  $a_3$  Fe has one axial His ligand, the heme *a* Fe has two axial His ligands

**Figure 22-25** The redox centers in the X-ray structure of bovine heart cytochrome *c* oxidase. The view is similar to that of the left protomer in Fig. 22-24. The Fe and Cu ions are represented by orange and cyan spheres. Their liganding heme and protein groups (from subunit II for the Cu<sub>B</sub> center and subunit I for the others) are drawn in stick form colored according to atom type with heme C magenta, protein C green, N blue, O red, and S yellow. The peroxy group that bridges the Cu<sub>B</sub> and heme  $a_3$  Fe ions is shown in ball-and-stick form in red. Coordination bonds are drawn as thin gray lines. Note that the side chains of His 240 and Tyr 244 are joined by a covalent bond (lower right). [Based on an X-ray structure by Shinya Yoshikawa, Himeji Institute of Technology, Hyogo, Japan. PDBid 2OCC.]

(as in Fig. 22-21*b*, *top*), and the Cu<sub>B</sub> atom has three His ligands, whose coordinating N atoms are arranged in an equilateral triangle that is centered on Cu<sub>B</sub> and is parallel to heme *a*<sub>3</sub>. The X-ray structure of fully oxidized bovine COX reveals a peroxide group (O<sub>2</sub><sup>2-</sup>; Fig. 22-25) that bridges the heme *a*<sub>3</sub> Fe atom and Cu<sub>B</sub> (which are separated by 4.9 Å), thereby liganding Cu<sub>B</sub> via a distorted square-planar arrangement, a stable coordination geometry for Cu(II). However, in the X-ray structure of the fully reduced form of bovine COX (in which the heme *a*<sub>3</sub> Fe—Cu<sub>B</sub> distance is 5.2 Å), this ligand is absent, so that Cu<sub>B</sub> is trigonally liganded, a stable coordination geometry for Cu(I). The closest approach of the two heme groups is 4 Å, and the distance between their Fe atoms is 13.2 Å.

Subunit II, in addition to its two transmembrane helices, has a globular domain on the outside surface that binds the Cu<sub>A</sub> center and largely consists of a 10-stranded β barrel (Fig. 22-24). The Cu<sub>A</sub> center is located ~8 Å above the outside membrane surface. Although the Cu<sub>A</sub> center was, for many years, widely believed to contain only one Cu atom, the X-ray structures of COX clearly indicate that Cu<sub>A</sub> contains two Cu atoms (Fig. 22-25). These are bridged by two Cys S atom ligands and have two additional protein ligands each to form an arrangement similar to that of a [2Fe–2S] cluster (Fig. 22-15*b*) in which the two Cu atoms are 2.4 Å apart. Spectroscopic measurements indicate that in the Cu<sub>A</sub> center's reduced form, both of its Cu atoms are in their Cu(I) states, whereas in its fully oxidized form, an electron appears to be delocalized between the two Cu atoms such that they assume the [Cu<sup>1.5+</sup> ... Cu<sup>1.5+</sup>] state.

### b. Electron and Proton Acquisition

COX's cytochrome *c* binding site is postulated to be in a corner formed by the globular domain of Subunit II and the outside surface of Subunit I, since this region is close to the Cu<sub>A</sub> site and contains 10 acidic side chains that could interact with a ring of Lys side chains that surrounds cytochrome *c*'s heme crevice. Indeed, differential labeling of cytochrome *c* oxidase's carboxyl groups in the presence and absence of cytochrome *c* demonstrated that cytochrome *c* shields the invariant residues Asp 112, Glu 114, and Glu 198 of Subunit II (bovine numbering). Glu 198 is located between the two Cys residues of Subunit II that ligand Cu<sub>A</sub> (Fig. 22-25). This observation supports the spectroscopic evidence that places the cytochrome *c* binding site on Subunit II in close proximity to Cu<sub>A</sub>. Cross-linking studies have additionally shown that the cytochrome *c* surface opposite the electron-transferring site interacts with Subunit III, suggesting that Subunit III also participates in binding cytochrome *c*.

Time-resolved spectroscopic studies indicate that an electron obtained from cytochrome *c* is first acquired by the Cu<sub>A</sub> center and is then transferred to heme *a* rather than heme *a*<sub>3</sub>, probably because the shortest Cu<sub>A</sub> ... heme *a* distance of 11.7 Å is less than the shortest Cu<sub>A</sub> ... heme *a*<sub>3</sub> distance of 14.7 Å. The electron is then rapidly transferred to the heme *a*<sub>3</sub>–Cu<sub>B</sub> binuclear center, where it participates in reducing the bound O<sub>2</sub> to H<sub>2</sub>O. Note that the fifth ligand

**Figure 22-26** Synthetic model of the cytochrome *a*<sub>3</sub>–Cu<sub>B</sub> binuclear complex. This structure efficiently reduces O<sub>2</sub> to H<sub>2</sub>O when attached to an electrode. The pyridine group that axially ligands the Fe ion (*bottom*) can be replaced by an imidazole group.

of heme *a*, His 378, is separated from the fifth ligand of heme *a*<sub>3</sub>, His 376, by only one residue, and hence there is a relatively short through-the-bonds electron transfer pathway between heme *a* and *a*<sub>3</sub> (Fig. 22-25, *lower left*). In addition, the closest approach of the two hemes is 4 Å.

COX must acquire four so-called **chemical** or **scalar protons** from the inside for every molecule of O<sub>2</sub> it reduces to H<sub>2</sub>O. This four-electron process is coupled to the translocation of up to four so-called **pumped** or **vectorial protons** from the inside to the outside, thereby contributing to the proton gradient that powers ATP synthesis (Section 22-3C). Note that for each turnover of the enzyme,

a total of eight positive charges are transported across the membrane, thereby contributing to its membrane potential.

### c. The Reduction of O<sub>2</sub> by Cytochrome *c* Oxidase Occurs in Multiple Steps

The reduction of O<sub>2</sub> to 2H<sub>2</sub>O by cytochrome *c* oxidase takes place on the cytochrome *a*<sub>3</sub>–Cu<sub>B</sub> binuclear complex (Fig. 22-25). Indeed, a synthetic model of this binuclear complex (Fig. 22-26), synthesized by James Collman, efficiently catalyzes the reduction of O<sub>2</sub> to H<sub>2</sub>O when attached to an electrode.

The COX-mediated reduction of O<sub>2</sub> requires, as we shall see, the nearly simultaneous input of four electrons. However, the fully reduced *a*<sub>3</sub><sup>2+</sup>–Cu<sub>B</sub><sup>1+</sup> binuclear complex can readily contribute only three electrons to its bound O<sub>2</sub> in reaching its fully oxidized *a*<sub>3</sub><sup>4+</sup>–Cu<sub>B</sub><sup>2+</sup> state [cytochrome *a*<sub>3</sub> transiently assumes its Fe(IV) or **ferryl** oxidation state during the reduction of O<sub>2</sub>; see below]. What is the source of the fourth electron?

The X-ray structures of both bovine and *P. denitrificans* COX clearly indicate that the His 240 ligand of Cu<sub>B</sub> (bovine numbering) is covalently cross-linked to the side chain of the conserved Tyr 244 (Fig. 22-25, lower right). This places Tyr 244's phenolic —OH group in close proximity to the heme a<sub>3</sub>-ligated O<sub>2</sub> such that Tyr 244 can supply the fourth electron by transiently forming a tyrosyl radical (TyrO•). In fact, adding peroxide to the resting enzyme generates a tyrosyl radical, whereas mutating Tyr 244 to Phe inactivates the enzyme. Moreover, tyrosyl radicals have been implicated in several enzymatically mediated redox processes, including the generation of O<sub>2</sub> from H<sub>2</sub>O in photosynthesis (in a sense, the reverse of the COX reaction; Section 24-2Cd), and in the **ribonucleotide reductase** reaction (which converts NDP to dNDP; Section 28-3Aa). Tyr 244's phenolic —OH group is within hydrogen bonding distance of the COX-bound O<sub>2</sub> and hence is a likely H<sup>+</sup> donor during O—O bond cleavage. The formation of the covalent cross-link is expected to lower both the reduction potential and the p*K* of Tyr 244, thereby facilitating both radical formation and proton donation (the synthetic binuclear complex in Fig. 22-26 can function without an associated tyrosyl radical, presumably because its associated electrode can supply it with electrons much faster than cytochrome *c* can supply them to COX).

The COX reaction, elucidated in large part by Mårten Wikström and Gerald Babcock using a variety of spectroscopic techniques, involves four consecutive one-electron transfers from the Cu<sub>A</sub> and cytochrome *a* sites and occurs as follows (Fig. 22-27):

**1 and 2.** The oxidized binuclear complex [Fe(III)<sub>a3</sub>—OH<sup>−</sup> Cu(II)<sub>B</sub>] is reduced to its [Fe(II)<sub>a3</sub> Cu(I)<sub>B</sub>] state by two con-

secutive one-electron transfers from cytochrome *c* via cytochrome *a* and Cu<sub>A</sub>. A proton from the matrix is concomitantly acquired and an H<sub>2</sub>O is released in this process. Tyr 244 (Y—OH) is in its phenolic state.

**3.** O<sub>2</sub> binds to the reduced binuclear complex so as to ligand its Fe(II)<sub>a3</sub> atom. It binds to the heme with much the same configuration it has in oxymyoglobin (Fig. 10-12).

**4.** Internal electron redistribution rapidly yields the oxyferryl complex [Fe(IV)=O<sup>2−</sup> HO—Cu(II)] in which Tyr 244 has donated an electron and a proton to the complex and thereby assumed its neutral radical state (Y—O•). This is known as compound P because it was originally thought that this spectroscopically identified state was a peroxy complex. However, it has since been shown that a peroxy compound is not on the reaction pathway. The peroxy complex displayed in Fig. 22-25 is a two-electron reduced “mixed valence” state of the enzyme that cannot reduce O<sub>2</sub> past its peroxy form.

**5.** A third one-electron transfer from cytochrome *c* together with the acquisition of two protons reconverts Tyr 244 to its phenolic state, yielding compound F (for ferryl) and releasing an H<sub>2</sub>O.

**6.** A fourth and final electron transfer and proton acquisition yields the oxidized [Fe(III)<sub>a3</sub>—OH<sup>−</sup> Cu(II)<sub>B</sub>] complex, thereby completing the catalytic cycle.

COX typically undergoes 100 to 200 turnovers per second so that one catalytic cycle takes only a few milliseconds. Note that the COX reaction proceeds without the release of the destructive partially reduced reactive oxygen species (ROS) from its active site. The positions in this proposed catalytic cycle at which protons appear to be

**Figure 22-27** Proposed reaction sequence for the reduction of O<sub>2</sub> by the cytochrome a<sub>3</sub>—Cu<sub>B</sub> binuclear complex of cytochrome *c* oxidase. The numbered steps are discussed in the text. The

entire reaction is extremely fast; it goes to completion in ~1 ms at room temperature. [Modified from Babcock, G.T., *Proc. Natl. Acad. Sci.* **96**, 12971 (1999).]

pumped from the matrix (bacterial cytoplasm) to the intermembrane (periplasmic) space are discussed in Section 22-3B. Keep in mind, however, that aspects of this cycle are uncertain and/or disputed and hence it remains under investigation.

#### d. Complexes I, III, and IV Form Supercomplexes

For many years, it had been widely assumed that the complexes of the respiratory chain were laterally mobile within the inner mitochondrial membrane and hence did not associate. However, the development of gentle methods of separating the components of the inner mitochondrial membrane has made it increasingly clear that these already large protein complexes form supercomplexes. In fact, a variety of supercomplexes from several organisms have been characterized, including yeast  $\text{III}_2\text{IV}_2$ , bovine and *Arabidopsis thaliana* (a plant)  $\text{I}_1\text{III}_2$ , and bovine  $\text{I}_1\text{III}_2\text{IV}_1$  (in which, for example,  $\text{IV}_1$  represents a protomer of Complex IV). Electron microscopy-based images such as Fig. 22-28 indicate that Complex IV monomers associate with Complex III dimers, which limits the distance that cytochrome *c* must travel to transport an electron from Complex III to Complex IV to  $<40 \text{ \AA}$ . Similarly, the association of Complex III with Complex I reduces the distance over which  $\text{CoQH}_2$  must diffuse between these two complexes. Apparently, these supermolecular complexes function to increase the efficiency of electron transport via the channeling of their intermediates, a conclusion supported by kinetic measurements. Note that none of these supercomplexes contain Complex II, also in agreement with kinetic measurements.

**Figure 22-28** Electron microscopy-based image of the bovine supercomplex  $\text{I}_1\text{III}_2\text{IV}_1$  at  $32 \text{ \AA}$  resolution. The supercomplex is represented by its semitransparent surface (blue) fitted with the EM-based structure of Complex I (yellow) and the X-ray structures of the Complex III dimer (red) and the Complex IV monomer (green). ### 3 OXIDATIVE PHOSPHORYLATION

The endergonic synthesis of ATP from ADP and  $\text{P}_i$  in mitochondria, which, as we shall see, is catalyzed by **proton-translocating ATP synthase (Complex V)**, is driven by the electron-transport process. Yet, since Complex V is physically distinct from the proteins mediating electron transport (Complexes I–IV), *the free energy released by electron transport must be conserved in a form that ATP synthase can utilize*. Such energy conservation is referred to as **energy coupling or energy transduction**.

The physical characterization of energy coupling proved to be surprisingly elusive; many sensible and often ingenious ideas have failed to withstand the test of experimental scrutiny. In this section we first examine some of the hypotheses that have been formulated to explain the coupling of electron transport and ATP synthesis. We shall then explore the coupling mechanism that has garnered the most experimental support, analyze the mechanism by which ATP is synthesized by ATP synthase, and, finally, discuss how electron transport and ATP synthesis can be uncoupled.

#### A. Energy Coupling Hypotheses

In the more than 70 years that electron transport and oxidative phosphorylation have been studied, numerous mechanisms have been proposed to explain how these processes are coupled. In the following paragraphs, we examine the mechanisms that have received the greatest experimental attention.

**1. The chemical coupling hypothesis.** In 1953, Edward Slater formulated the **chemical coupling hypothesis**, in which he proposed that electron transport yielded reactive intermediates whose subsequent breakdown drove oxidative phosphorylation. We have seen, for example, that such a mechanism is responsible for ATP synthesis in glycolysis (Sections 17-2G and 17-2J). Thus, the exergonic oxidation of glyceraldehyde-3-phosphate by  $\text{NAD}^+$  yields 1,3-bisphosphoglycerate, a reactive (“high-energy”) acyl phosphate whose phosphoryl group is then transferred to ADP to form ATP in the phosphoglycerate kinase reaction. The difficulty with such a mechanism for oxidative phosphorylation, which has caused it to be abandoned, is that despite intensive efforts in numerous laboratories over many years, no appropriate reactive intermediates have been identified.

**2. The conformational coupling hypothesis.** The **conformational coupling hypothesis**, which Paul Boyer formulated in 1964, proposes that electron transport causes proteins of the inner mitochondrial membrane to assume “activated” or “energized” conformational states. These proteins are somehow associated with ATP synthase such that their relaxation back to the deactivated conformation drives ATP synthesis. As with the chemical coupling hypothesis, the conformational coupling hypothesis has found little experimental support. However, conformational coupling of a different sort appears to be involved in ATP synthesis (Section 22-3Cd).

**3. The chemiosmotic hypothesis.** The **chemiosmotic hypothesis**, proposed in 1961 by Peter Mitchell, has spurred considerable controversy, as well as much research, and is now the model most consistent with the experimental evidence. It postulates that *the free energy of electron transport is conserved by pumping  $H^+$  from the mitochondrial matrix to the intermembrane space so as to create an electrochemical  $H^+$  gradient across the inner mitochondrial membrane. The electrochemical potential of this gradient is harnessed to synthesize ATP* (Fig. 22-29).

Several key observations are explained by the chemiosmotic hypothesis:

- Oxidative phosphorylation requires an intact inner mitochondrial membrane.
- The inner mitochondrial membrane is impermeable to ions such as  $H^+$ ,  $OH^-$ ,  $K^+$ , and  $Cl^-$ , whose free diffusion would discharge an electrochemical gradient.
- Electron transport results in the transport of  $H^+$  out of intact mitochondria, thereby creating a measurable electrochemical gradient across the inner mitochondrial membrane.
- Compounds that increase the permeability of the inner mitochondrial membrane to protons, and thereby dissipate the electrochemical gradient, allow electron transport (from NADH and succinate oxidation) to continue but inhibit ATP synthesis; that is, they “uncouple” electron transport from oxidative phosphorylation. Conversely, increasing the acidity outside the inner mitochondrial membrane stimulates ATP synthesis.

In the remainder of this section we examine the mechanisms through which electron transport can result in proton translocation and how an electrochemical gradient can interact with ATP synthase to drive ATP synthesis.

## B. Proton Gradient Generation

Electron transport, as we shall see, causes Complexes I, III, and IV to transport protons across the inner mitochondrial membrane from the matrix, a region of low  $[H^+]$  and negative electrical potential, to the intermembrane space (which is in contact with the cytosol), a region of high  $[H^+]$  and positive electrical potential (Fig. 22-14). The free energy sequestered by the resulting electrochemical gradient [which, in analogy to the term electromotive force (emf), is called **proton-motive force (pmf)**] powers ATP synthesis.

### a. Proton Pumping Is an Endergonic Process

The free energy change of transporting a proton out of the mitochondrion against an electrochemical gradient is expressed by Eq. [20.3], which, in terms of pH, is

$$\Delta G = 2.3 RT[\text{pH}(\text{in}) - \text{pH}(\text{out})] + Z\mathcal{F} \Delta\Psi \quad [22.1]$$

where  $Z$  is the charge on the proton (including sign),  $\mathcal{F}$  is the Faraday constant, and  $\Delta G$  is the membrane potential. The sign convention for  $\Delta G$  is that when a positive ion is transported from negative to positive,  $\Delta G$  is positive. Since  $\text{pH}(\text{out})$  is less than  $\text{pH}(\text{in})$ , the export of protons from the mitochondrial matrix (against the proton gradient) is an endergonic process. In addition, *proton transport out of the matrix makes the inner membrane's internal surface more negative than its external surface*. Outward transport of a positive ion is consequently associated with a positive  $\Delta G$  and an increase in free energy (endergonic process), whereas the outward transport of a negative ion yields the opposite result. Clearly, it is always necessary to describe membrane polarity when specifying a membrane potential.

The measured membrane potential across the inner membrane of a liver mitochondrion, for example, is 0.168 V

**Figure 22-29 Coupling of electron transport (green arrow) and ATP synthesis.**  $H^+$  is pumped out of the mitochondrion by Complexes I, III, and IV of the electron-transport chain (blue arrows), thereby generating an electrochemical gradient across the inner mitochondrial membrane. The exergonic return of these

protons to the matrix powers the synthesis of ATP (red arrow). Note that the outer mitochondrial membrane is permeable to small molecules and ions, including  $H^+$ .  See the Animated Figures

(inside negative; this corresponds to an  $\sim 210,000 \text{ V} \cdot \text{cm}^{-1}$  electric field across its  $\sim 80 \text{ \AA}$  thickness). The pH of the matrix is 0.75 units higher than that of the intermembrane space.  $\Delta G$  for proton transport out of this mitochondrial matrix is therefore  $21.5 \text{ kJ} \cdot \text{mol}^{-1}$ .

### b. The Passage of About Three Protons Is Required to Synthesize One ATP

An ATP molecule's estimated physiological free energy of synthesis, around  $+40$  to  $+50 \text{ kJ} \cdot \text{mol}^{-1}$ , is too large to be driven by the passage of a single proton back into the mitochondrial matrix; at least two protons are required. This number is difficult to measure precisely, in part because transported protons tend to leak back across the mitochondrial membrane. However, most estimates indicate that around three protons are passed per ATP synthesized.

### c. Two Mechanisms of Proton Transport Have Been Proposed

Three of the four electron-transport complexes, Complexes I, III, and IV, are involved in proton translocation. Two mechanisms have been entertained that would couple the free energy of electron transport with the active transport of protons: the **redox loop mechanism** and the **proton pump mechanism**.

### d. The Redox Loop Mechanism

This mechanism, proposed by Mitchell, requires that the redox centers of the respiratory chain (FMN, CoQ, cytochromes, and iron-sulfur clusters) be so arranged in the membrane that reduction would involve a redox center simultaneously accepting  $e^-$  and  $\text{H}^+$  from the matrix side of the membrane. Reoxidation of this redox center by the next center in the chain would involve release of  $\text{H}^+$  on the cytosolic side of the membrane together with the transfer of electrons back to the matrix side (Fig. 22-30). Electron flow from one center to the next would therefore yield net translocation of  $\text{H}^+$  and the creation of an electrochemical gradient ( $\Delta G$  and  $\Delta \text{pH}$ ).

*The redox loop mechanism requires that the first redox carrier contain more hydrogen atoms in its reduced state than in its oxidized state and that the second redox carrier have no difference in its hydrogen atom content between its reduced and oxidized states.* Are these requirements met in the electron-transport chain? Some of the redox carriers, FMN and CoQ, in fact, contain more hydrogen atoms in their reduced state than in their oxidized state and thus can qualify as proton carriers as well as electron carriers. If these centers were spatially alternated with pure electron carriers (cytochromes and iron-sulfur clusters), such a mechanism could well be accommodated.

The main difficulty with the redox loop mechanism involves the deficiency of  $(\text{H}^+ + e^-)$  carriers that can alternate with pure  $e^-$  carriers. Whereas the electron-transport chain has as many as 15 pure  $e^-$  carriers (up to 8 iron-sulfur proteins, 5 cytochromes, and 2 Cu centers), it has only 2

**Figure 22-30** The redox loop mechanism for electron transport-linked  $\text{H}^+$  translocation.  $\text{AH}_2$  represents  $(\text{H}^+ + e^-)$  carriers such as  $\text{FMNH}_2$  and  $\text{CoQH}_2$ , whereas B represents pure  $e^-$  carriers such as iron-sulfur clusters and the cytochromes. These components are so arranged as to require that electron transport be accompanied by  $\text{H}^+$  translocation.

$(\text{H}^+ + e^-)$  carriers. The fact that there are three complexes with standard reduction potential changes large enough to provide free energy for ATP synthesis suggests the need for at least three proton-transport redox carriers. As we shall see, however, there are, in fact, three proton-transport sites but only two proton-transport redox carriers: Both the redox loop mechanism and the proton pump mechanism (discussed below) are employed.

### e. Complex III Pumps Protons via the Q Cycle, a Type of Redox Loop

 **See Guided Exploration 20: The Q cycle** Mitchell postulated that Complex III functions in a way that permits one molecule of  $\text{CoQH}_2$ , the two-electron carrier, to sequentially reduce two molecules of cytochrome  $c$ , a one-electron carrier, while transporting four protons. This occurs via a modified redox loop mechanism involving a remarkable bifurcation of the flow of electrons from  $\text{CoQH}_2$  to cytochrome  $c_1$  and to cytochrome  $b$ . It is through this so-called **Q cycle** that Complex III pumps protons from the matrix to the intermembrane space.

The essence of the Q cycle is that  $\text{CoQH}_2$  undergoes a two-cycle reoxidation in which the semiquinone  $\text{Q}^-$  is a stable intermediate. This involves two independent binding sites for coenzyme Q:  $\text{Q}_o$ , which binds  $\text{CoQH}_2$  and is located between the ISP and heme  $b_L$  in proximity to the intermembrane space (Fig. 22-23); and  $\text{Q}_i$ , which binds both  $\text{Q}^-$  and  $\text{CoQ}$  and is located near heme  $b_H$  in proximity to

the matrix. In the first cycle (Fig. 22-31a), CoQH<sub>2</sub>, which is supplied by Complexes I or II on the matrix side of the inner mitochondrial membrane (1), diffuses through the membrane to its cytoplasmic side, where it binds to the Q<sub>o</sub> site (2). There it transfers one of its electrons to the ISP (3),

**Figure 22-31 The Q cycle.** The Q cycle is an electron-transport cycle in Complex III that accounts for H<sup>+</sup> translocation during the transport of electrons from cytochrome *b* to cytochrome *c*: The overall cycle is actually two cycles, the first (a) requiring reactions 1 through 7 and the second (b) requiring reactions 1 through 6 and 8. (1) Coenzyme QH<sub>2</sub> is supplied by Complex I on the matrix side of the membrane. (2) QH<sub>2</sub> diffuses to the outside of the membrane. (3) QH<sub>2</sub> reduces the Rieske iron–sulfur protein (ISP) forming Q<sup>•</sup> semiquinone and releasing 2H<sup>+</sup>. The ISP goes on to reduce cytochrome *c*<sub>1</sub>. (4) Q<sup>•</sup> reduces heme *b*<sub>L</sub> to form coenzyme Q. (5) Q diffuses to the matrix side. (6) Heme *b*<sub>L</sub> reduces heme *b*<sub>H</sub>. (7, cycle 1 only) Q is reduced to Q<sup>•</sup> by heme *b*<sub>H</sub>. (8, cycle 2 only) Q<sup>•</sup> is reduced to QH<sub>2</sub> by heme *b*<sub>H</sub>. [After Trumpower, B.L., *J. Biol. Chem.* **265**, 11410 (1990).]

releasing its two protons into the intermembrane space and yielding Q<sup>•</sup>. The ISP then reduces cytochrome *c*<sub>1</sub>, whereas the Q<sup>•</sup> transfers its remaining electron to heme *b*<sub>L</sub> (4), yielding fully oxidized CoQ. Heme *b*<sub>L</sub> then reduces heme *b*<sub>H</sub> (6). The CoQ from Step 4 is released from the Q<sub>o</sub> site and diffuses back through the membrane to rebind at the Q<sub>i</sub> site (5), where it picks up the electron from heme *b*<sub>H</sub> (7), reverting to the semiquinone form, Q<sup>•</sup>. Thus, the reaction for this first cycle is

In the second cycle (Fig. 22-31b), another CoQH<sub>2</sub> repeats Steps 1 through 6: One electron reduces the ISP and then cytochrome *c*<sub>1</sub>, and the other electron sequentially reduces heme *b*<sub>L</sub> and then heme *b*<sub>H</sub>. This second electron then reduces the Q<sup>•</sup> at the Q<sub>i</sub> site produced in the first cycle (8), yielding CoQH<sub>2</sub>. The protons taken up in this last step originate in the mitochondrial matrix. The reaction for the second cycle is therefore

For every two CoQH<sub>2</sub> that enter the Q cycle, one CoQH<sub>2</sub> is regenerated. The combination of both cycles, in which two electrons are transferred from CoQH<sub>2</sub> to cytochrome *c*<sub>1</sub>, results in the overall reaction

X-ray studies of Complex III provide direct evidence for the independent existence of the Q<sub>o</sub> and Q<sub>i</sub> sites. The antifungal agents **myxothiazol** and **stigmatellin**,

**Myxothiazol**

**Stigmatellin**

which both block electron flow from  $\text{CoQH}_2$  to the ISP and to heme  $b_L$  (Steps 3 and 4 of both cycles), bind in a pocket within cytochrome  $b$  between the ISP and heme  $b_L$  (Fig. 22-23). Evidently, this binding pocket overlaps the  $Q_o$  site. Similarly, antimycin (Section 22-2Ba), which blocks electron flow from heme  $b_H$  to CoQ and  $Q^-$  (Step 7 of Cycle 1 and Step 8 of Cycle 2), binds in a pocket near heme  $b_H$ , thereby identifying this pocket as site  $Q_i$ .

The circuitous route of electron transfer in Complex III is tied to the ability of coenzyme Q to diffuse within the hydrophobic core of the membrane in order to bind to both the  $Q_o$  and  $Q_i$  sites. This process is facilitated by an indentation in the surface of cytochrome  $b$ 's transmembrane region that contains  $Q_o$  from one protomer and  $Q_i$  from the other. When  $\text{CoQH}_2$  is oxidized, two reduced cytochrome  $c$  molecules and four protons appear on the outer side of the membrane. Proton transport by the Q cycle thus follows the redox loop mechanism of proton transport in which a redox center itself (CoQ) is the proton carrier. As we shall see below, however, Complexes I and IV follow a different mechanism of proton transport, the proton pump mechanism.

#### f. The Bifurcation of the Q Cycle's Electron Flow Occurs via Domain Movement

Why does  $Q_o$ -bound  $Q^-$  exclusively reduce heme  $b_L$  (Step 4 of the Q cycle) rather than the Rieske  $[2\text{Fe}-2\text{S}]$  cluster of the ISP, despite the greater reduction potential difference ( $\Delta\mathcal{E}$ ) favoring the latter reaction (Table 22-1)?

The remarkable answer to this question provides a fascinating insight into the inner workings of Complex III. Although the binding of stigmatellin and myxothiazol to  $Q_o$  are mutually exclusive, these inhibitors affect this site differently: Stigmatellin perturbs the spectrum and redox properties of the ISP's Rieske  $[2\text{Fe}-2\text{S}]$  cluster as well as prevents it from oxidizing cytochrome  $c_1$ , whereas myxothiazol does not interact with the ISP but, instead, shifts the spectrum of heme  $b_L$ . Evidently, stigmatellin is a  $\text{CoQH}_2$  analog and myxothiazol is a  $Q^-$  mimic.

X-ray structures of Complex III reveal that its  $Q_o$  site is a bifurcated pocket in which stigmatellin binds close to the ISP docking interface (see below), whereas myxothiazol binds in the vicinity of heme  $b_L$  (Fig. 22-32; their binding to  $Q_o$  is mutually exclusive because their hydrophobic tails would overlap). Furthermore, the globular Rieske  $[2\text{Fe}-2\text{S}]$  cluster-containing domain of the ISP (Fig. 22-23, top) is conformationally mobile and assumes a conformational state that is controlled by the ligand-binding state of  $Q_o$ : It binds to cytochrome  $b$  near the heme  $b_L$  site when stigmatellin is bound to the  $Q_o$  site, but has swung around by  $\sim 20 \text{ \AA}$  (via an  $\sim 57^\circ$  hinge motion that leaves intact its tertiary structure) to bind to the cytochrome  $c_1$  near its heme  $c$  when myxothiazol is bound to  $Q_o$ . Apparently the globular domain of the ISP functions to shuttle an electron from  $\text{CoQH}_2$ , which is bound to  $Q_o$  near the ISP docking interface, to heme  $c_1$  by mechanically swinging the reduced Rieske  $[2\text{Fe}-2\text{S}]$  cluster between these sites. The resulting  $Q^-$  shifts to the position near heme  $b_L$  (probably via a

(a)

**Figure 22-32** X-ray structures of the  $Q_o$  binding site of the chicken cytochrome  $bc_1$  complex occupied by inhibitors. The structures show (a) its complex with stigmatellin and (b) its complex with myxothiazol. The protein surface (white) has been cut away to show the  $Q_o$  pocket. Heme  $b_L$  (upper right) is shown in ball-and-stick form with C gray, N blue, O red, and Fe tan. In Part a, stigmatellin is drawn as a stick model with C yellow and its volume represented by the dotted surface. The Rieske  $[2\text{Fe}-2\text{S}]$  cluster (lower left) is represented by gold spheres, and the ISP

(b)

domain to which it is bound is drawn as a cyan ribbon. Note that His 161, which is a ligand of the Rieske  $[2\text{Fe}-2\text{S}]$  cluster, forms a hydrogen bond to stigmatellin. In Part b, the myxothiazol is drawn as a stick model with C orange. Note that the semiquinone-mimicking portion of myxothiazol binds to  $Q_o$  in proximity to heme  $b_L$ , whereas its hydrophobic tail occupies the same position as that of stigmatellin. Also note that the  $[2\text{Fe}-2\text{S}]$  cluster-containing ISP domain is not visible in this diagram; it has rotated into proximity with cytochrome  $c_1$ . [Courtesy of Antony Crofts, University of Illinois at Urbana-Champaign, and Edward Berry, University of California at Berkeley. PDBid 3BCC.]

rotation about a bond connecting the semiquinone ring to its nonpolar tail), which it then reduces. Thus,  $Q^-$  is unable to reduce the ISP (after it has reduced cytochrome  $c_1$ ) because it is too far away to do so. This novel mechanism is supported by the observation that mutagenically inserting a disulfide bond either within the hinge of the ISP or between it and cytochrome  $b$  greatly diminishes the activity of Complex III but that its activity is restored on exposure to reducing agents.

### g. The Proton Pump Mechanism

Complex IV (COX) transports four protons from the matrix to the intermembrane space for each  $O_2$  it reduces ( $2H^+$  per electron pair; Fig. 22-14). It contains no ( $H^+ + e^-$ ) carriers and hence cannot do so via a redox loop (Q cycle-like) system. Rather, as we shall see, it does so via the proton pump mechanism (Fig. 22-33), which does not require that the redox centers themselves be  $H^+$  carriers. In this model, *the transfer of electrons results in conformational changes to the complex. The unidirectional translocation of protons occurs as a result of the influence of these conformational changes on the pK's of amino acid side chains and their alternate exposure to the internal and external side of the membrane.* We have previously seen that conformation can influence pK. The Bohr effect in hemoglobin, for example, results from conformational changes induced by  $O_2$  binding, which causes pK changes in protein acid-base groups (Section 10-2E). If such a protein were located in a membrane and if, in addition to pK changes, the conformational changes altered the side of the membrane to which the affected amino acid side chains were exposed, the result would be  $H^+$  transport and the system would be a proton pump.

Keep in mind that protons, being atomic nuclei, must always be associated with molecules or ions. Consequently, a proton cannot be transported across a membrane in the same way that, say, a  $K^+$  ion is. Rather, protons are translocated by hopping along chains of hydrogen bonded groups

**Figure 22-33 Proton pump mechanism of electron transport-linked proton translocation.** At each  $H^+$  translocation site,  $n$  protons bind to amino acid side chains on the matrix side (inside) of the membrane. Reduction causes a conformational change that decreases the pK's of these side chains and exposes them to the cytosolic side (outside) of the membrane, where the protons dissociate. Reoxidation results in a conformational change that restores the pump to its original conformation.

in the transport protein in much the same way that hydronium ions migrate through an aqueous solution (Fig. 2-10), that is, they move along a proton wire (Section 21-2A1). However, unlike a wire in an electrical circuit, all elements of a proton wire need not be connected at the same time and, moreover, internal water molecules, which are not always apparent in protein X-ray structures, are likely to be integral parts of the proton wire. Hence, elucidating the precise pathway of proton transport through a protein is a difficult and uncertain task. Note that proton pumps, like other active transport systems, must be gated to prevent protons from leaking back through the pump and thus short-circuiting the system.

### h. Bacteriorhodopsin Is a Light-Driven Proton Pump

The simplest known and best characterized proton pump is the intrinsic membrane protein **bacteriorhodopsin** of *Halobacterium halobium*. It consists mainly of seven transmembrane helices, A through G, that form a central polar channel (Section 12-3Ab). This channel contains a retinal prosthetic group that is covalently linked, via a protonated Schiff base, to Lys 216, which extends from helix G (Fig. 12-24). The protein obtains the free energy required for unidirectionally pumping protons from the absorption of a photon by the retinal. This initiates a sequence of events in which the protein conformationally adjusts through successive spectroscopically characterized intermediates, designated J, K, L, M, N, and O, as the system decays back to its ground state over a period of  $\sim 10$  ms. The result of this cycle is the net translocation of one proton from the cytoplasm to the extracellular medium, thereby converting light energy to proton-motive force. The as yet incompletely understood mechanism of this process, which was elucidated through detailed structural, mutational, and time-resolved spectroscopic studies carried out in several laboratories, is outlined in Fig. 22-34:

1. On absorbing a photon, the ground state all-*trans*-retinal photoisomerizes to its 13-*cis* form. This is a multi-step process that rapidly passes (in  $\sim 3$  ps) through the J and K states. The free end of the retinal, which is now twisted around the newly *cis* double bond, moves relative to the protein scaffold such that retinal's C13 methyl group and its C14 atom shift toward the inside by 1.3 and 1.7 Å, respectively. This yields the L state.

2. Further conformational adjustments yield the M state. Here the N atom of the Schiff base has rotated and shifted from its ground state position, in which it is hydrogen bonded to an internal water molecule, to one in which it points toward the inside face of the protein in the vicinity of the hydrophobic side chains of Val 49 and Leu 93. This reduces the pK of the protonated Schiff base. In contrast, the pK of Asp 85 increases. This is because, in the ground state, Asp 85 effectively serves as the counterion of the protonated Schiff base and participates in a hydrogen bonded network with three internal water molecules, but in the M state, it is only associated with a single water molecule. Consequently, the Schiff base protonates Asp 85. This process is facilitated by a slight movement of helix C that

**Figure 22-34 Proton pump of bacteriorhodopsin.** See the text for a description of this mechanism. The protein is represented by its seven transmembrane helices, A through G (with helices D and E omitted for clarity in all but the upper left panel), and several mechanistically important side chains. The retinal is drawn with the approximate color of the complex in its various spectroscopically characterized states. Red arrows indicate proton movements, blue arrows indicate the movements of groups of atoms, and the “paddle” attached to helix F represents the bulky side chains that must move aside to open the cytoplasmic channel. [After Kühlbrandt, W., *Nature* **406**, 569 (2000).]

brings Asp 85 closer to the Schiff base N atom. The deprotonated retinal straightens and, in doing so, moves upward (toward the inside) by 0.7 to 1.0 Å. It thereby pushes against the F helix, causing its inside (cytoplasmic) end to tilt outward from the channel by ~3.5 Å and the G helix to partially replace it.

**3.** The movement of the F helix opens up the central channel on the inside of the membrane, admitting several water molecules that form a hydrogen bonded chain between Asp 96 and the Schiff base. One of these water molecules hydrogen bonds with Asp 96 so as to lower its  $pK$ . This permits Asp 96 to protonate the Schiff base via the intermediacy of the chain of hydrogen bonded water molecules, thereby yielding the N state.

**4.** Asp 96 is reprotonated by the cytoplasmic solution. The loops forming bacteriorhodopsin’s inside surface bear numerous charged residues and hence it appears that they function as “antennas” to capture protons from the alkaline cytoplasmic medium. Asp 85 transfers its proton to the extracellular medium via a hydrogen bonded network that includes several bound water molecules. This process is facilitated by a preceding 1.6-Å displacement of the Arg 82 side chain toward a complex of residues that includes Glu 194 and Glu 204, which reduces the  $pK$  of this complex. The retinal then relaxes, via the O state, to its original all-trans form and helices F and G return to their original positions, thereby re-forming the ground state of the protein and completing the catalytic cycle.

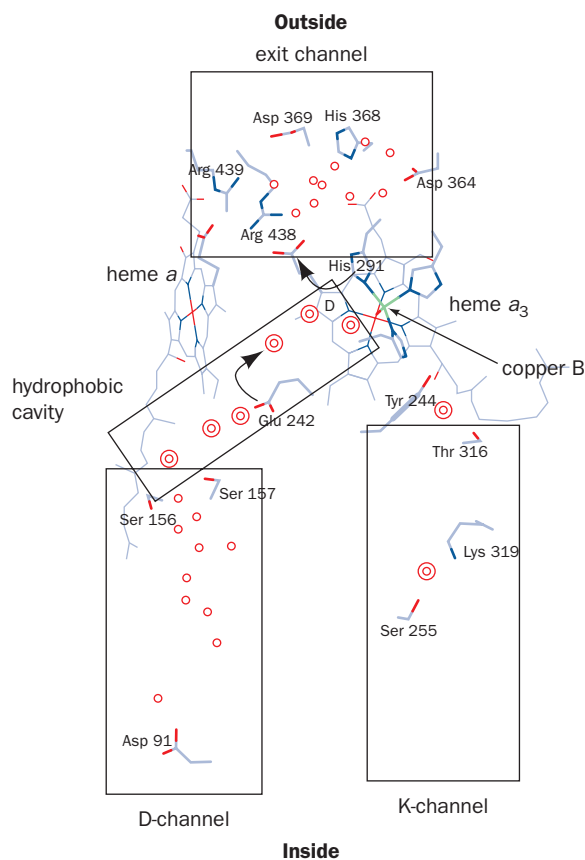

The retinal, which occupies the center of the protein channel, thereby acts as a one-way proton valve. The vectorial nature of this process arises from the unidirectional series of conformational changes made by the photoexcited retinal as it relaxes to its ground state. The protein’s principal proton pumping motions are remarkably small, involving group movements of ~1 Å or less in response to the light-induced flexing of the retinal. These, nevertheless, cause  $pK$  changes in various residues that facilitate proton transfer as well as making and breaking hydrogen bonded networks of protein groups and water molecules in the proper sequence to transport a proton. A similar mechanism is likely to operate in COX, but with its conformational changes motivated by redox reactions rather than by photoexcitation.

#### i. COX Has Two Proton Translocation Channels

Two channels that are candidates for translocating protons from the inside to the vicinity of the  $O_2$ -reducing center have been described in bovine, *P. denitrificans*, and *Rb. sphaeroides* COX (Fig. 22-35). These channels, which are both contained in Subunit I, are named the K- and D-channels after their respective key residues (K319 and D91 in the bovine numbering scheme, which we shall use in the subsequent discussion). Both putative channels are similar in character to that present in bacteriorhodopsin in that they consist of chains of hydrogen bonded and potentially hydrogen bonded protein groups, bound water molecules, and water-filled cavities.

The K-channel leads from K319, which is exposed to the inside, to Y244, the residue that is the proposed substrate electron and proton donor in the reaction forming the P state (Step 4 of Fig. 22-27). The K319M mutant has an extremely low activity (<0.05% of wild type), which is not increased by supplying additional protons from the outside. Hence it appears that the K-channel is not connected to the putative exit channel (Fig. 22-35) that leads to the outside. It therefore seems likely that the K-channel only functions to supply chemical protons to the  $O_2$ -reduction center.

The entrance to the D-channel is within a region on the protein surface that appears likely to act as a proton-gathering antenna. The mutation of D91 to any noncarboxylate residue eliminates proton pumping but reduces the rate of  $O_2$  reduction to only 45% of wild type (in

**Figure 22-35** The proton-translocating channels in bovine COX. The enzyme is viewed parallel to the membrane with the matrix below. The four rectangles delineate the proposed proton entry and exit conduits. Single and double circles, respectively, represent water molecules that are observed in X-ray structures or that theoretical methods suggest are likely to be present. [After a drawing by Mårten Wikström, University of Helsinki, Helsinki, Finland.]

*E. coli*). Evidently, the D-channel, in series with the exit channel, is the proton pumping channel. Moreover, the D-channel, which extends to the vicinity of the heme  $a_3$ -Cu<sub>B</sub> binuclear center, is also the conduit for the chemical protons required for the second part of the reaction cycle (Steps 5 and 6 of Fig. 22-27).

What is the mechanism that couples O<sub>2</sub> reduction to proton pumping in COX? Unfortunately, X-ray crystallography has provided little guidance in answering this question because the X-ray structures of only a few different states of COX have as yet been determined and because the resolution of several of these structures is too low to reliably reveal small structural differences between them. Consequently, the mechanisms that have been proposed to explain how COX pumps protons are largely inferences based on limited structural information, interpretation of site-directed mutagenesis experiments, spectroscopic data, theoretical considerations, and chemical intuition. Several ingenious although largely phenomenological models of how COX pumps protons have been proposed. These mod-

els agree that at least one proton is pumped during each of Steps 5 and 6 in the COX reaction cycle (Fig. 22-27) but disagree as to where in the reaction cycle the remaining two protons are pumped and how the protein actuates this process. Clearly there is still much to learn about how COX carries out its function.

#### j. The Horizontal Helix of Complex I's Peripheral Arm Functions Like a Piston.

Complex I pumps four protons out of the matrix for every electron pair it translocates from NADH to CoQ. One of these protons appears to be transported at the interface between the peripheral and transmembrane arms of Complex I (Fig. 2-18) in a way that presumably is driven by the conformational changes in the peripheral arm as it translocates electrons from NADH to CoQ. But how are these conformational changes coupled to the far more distant antiporter-like subunits, Nqo12, 13, and 14, which presumably pump one proton each out of the matrix? The low resolution of the Complex I X-ray structure (Fig. 22-18) precludes the visualization of the membrane arm's side chains and hence a detailed mechanism for proton transport. However, the unusual 110-Å-long horizontal helix that appears to link the antiporter-like subunits to the conformational changes in the peripheral arm has led Sazanov to postulate that this helix functions like a piston to couple conformational changes in the peripheral arm to those in the antiporter-like channels.

### C. Mechanism of ATP Synthesis

 See Guided Exploration 21: F<sub>1</sub>F<sub>0</sub>-ATP synthase and the binding change mechanism The proton-motive force across the mitochondrial membrane is harnessed in the synthesis of ATP by proton-translocating ATP synthase (also known as F<sub>1</sub>F<sub>0</sub>-ATPase, Complex V, and F-type H<sup>+</sup>-ATPase). In the following subsections we discuss the location and structure of this ATP synthase and the mechanism by which it harnesses proton flux to drive ATP synthesis.

#### a. Proton-Translocating ATP Synthase Is a Multisubunit Transmembrane Protein

Proton-translocating ATP synthase consists of two major substructures comprising 8 to 13 different subunits. Electron micrographs of mitochondria (Fig. 22-36) show lollipop-shaped structures studding the matrix surface of the inner mitochondrial membrane (Fig. 22-36a). Similar entities have been observed lining the inner surface of the bacterial plasma membrane and in chloroplasts (Section 24-2Da). Sonication of the inner mitochondrial membrane yields sealed vesicles, **submitochondrial particles**, from which the “lollipops” project (Fig. 22-36b) and which can carry out ATP synthesis.

Efraim Racker discovered that the proton-translocating ATP synthase from submitochondrial particles comprises two functional units, F<sub>0</sub> and F<sub>1</sub>. F<sub>0</sub> is a water-insoluble transmembrane protein composed of as many as eight different types of subunits (although only three in *E. coli*) that contains a proton translocation channel. F<sub>1</sub> is a water-soluble

**Figure 22-36** Electron micrographs and interpretive drawings of the mitochondrial membrane at various stages of dissection.

peripheral membrane protein, composed of five types of subunits, that is easily dissociated from  $F_0$  by treatment with urea. Solubilized  $F_1$  can hydrolyze ATP but cannot synthesize it (hence the name ATPase). Submitochondrial particles from which  $F_1$  has been removed by urea treatment no longer exhibit the lollipops in their electron micrographs (Fig. 22-36c) and lack the ability to synthesize ATP. If, however,  $F_1$  is added back to these  $F_0$ -containing submitochondrial particles, their ability to synthesize ATP is restored and their electron micrographs again exhibit the

**Figure 22-37** Cryoelectron microscopy-based image of  $F_1F_0$ -ATPase from bovine heart mitochondria. [Courtesy of John Rubinstein, University of Toronto, Canada, and John Walker and Richard Henderson, MRC Laboratory of Molecular Biology, Cambridge, U.K.]

lollipops. Thus *the lollipops are the  $F_1$  particles*. Higher resolution cryoelectron micrograph-based images of the ATP synthase from bovine heart mitochondria reveal that its  $F_1$  and  $F_0$  components are joined by both an  $\sim 50$ -Å-long central stalk and a less substantial peripheral stalk (Fig. 22-37). Certain bacterial  $F_1F_0$ -ATPases translocate  $\text{Na}^+$  ions rather than protons.

**Figure 22-38** X-ray structures of  $F_1$ -ATPase from bovine heart mitochondria. (a)  $F_1$ -ATPase in complex with ADP and ATP drawn as a semitransparent ribbon diagram viewed parallel to the membrane with the matrix above. The  $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ , and  $\epsilon$  subunits are pink, yellow, blue, orange, and green, respectively, and the nucleotides are shown in space-filling form with ATP C green, ADP C cyan, N blue, O red, and P orange. (b) The structure in Part a rotated  $90^\circ$  about the horizontal axis such that the protein is viewed along its pseudo-3-fold axis from the matrix. The  $\delta$  and  $\epsilon$  subunits have been deleted for clarity. Note that although the  $\alpha_{DP}$  and  $\beta_{DP}$  subunits both normally bind ATP, in this structure they have bound ADP. (c) A surface diagram of the inner portion of the  $\alpha_3\beta_3$  assembly through which the C-terminal helix of the  $\gamma$  subunit penetrates as viewed from the matrix. The surface is colored according to its electrical potential, with positive potentials blue, negative potentials red, and neutral white. Note the absence of charge on the inner surface of this sleeve. That part of the  $\gamma$  subunit's C-terminal helix which contacts this sleeve is similarly devoid of charge. [Parts a and b based on an X-ray structure by Andrew Leslie and John Walker, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1E79.  See Interactive Exercise 19

(c)

### b. The X-Ray Structure of $F_1$ Reveals the Basis of Its Lollipoplike Structure

Mitochondrial  $F_1$  is an  $\alpha_3\beta_3\gamma\delta\epsilon$  nonamer in which the  $\beta$  subunits contain the catalytic sites for ATP synthesis and the  $\delta$  subunit is required for binding of  $F_1$  to  $F_0$ . The X-ray structure of  $F_1$  from bovine heart mitochondria, determined by John Walker and Andrew Leslie, reveals that this  $\sim 400$ -kD protein is a  $100$ - $\text{\AA}$ -high and  $100$ - $\text{\AA}$ -wide spheroid

that is mounted on a  $50$ - $\text{\AA}$ -long stem (Fig. 22-38a,b).  $F_1$ 's  $\alpha$  and  $\beta$  subunits (553 and 528 residues), which are 20% identical in sequence and have nearly identical folds, are arranged alternately, like the segments of an orange, about the upper portion of a  $114$ - $\text{\AA}$ -long,  $74$ -residue  $\alpha$  helix formed by the  $\gamma$  subunit (298 residues). The C-terminus of this helix protrudes into a  $15$ - $\text{\AA}$ -deep dimple that is centrally located at the top of the spheroid. The lower half of

**Figure 22-39** X-ray structure of the  $c_{11}$  assembly of the *I. tartaricus*  $\text{Na}^+$ -translocating  $\text{F}_1\text{F}_0$ -ATPase. (a) Ribbon diagram as viewed along the plane of the plasma membrane with the cytosol above. Each subunit is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). Bound  $\text{Na}^+$  ions are represented by purple spheres. The parallel lines delineate the

the helix forms a bent left-handed antiparallel coiled coil with the N-terminal segment of the  $\gamma$  subunit. This coiled coil forms much of the  $\sim 50$ -Å-long central stalk seen in cryoEM-based images of the  $\text{F}_1\text{F}_0$ -ATPase such as Fig. 22-37.

The cyclical arrangement and structural similarities of  $\text{F}_1$ 's  $\alpha$  and  $\beta$  subunits gives it both pseudo-3-fold and pseudo-6-fold rotational symmetry. Nevertheless, the protein is asymmetric. This is in part due to the presence of the  $\gamma$ ,  $\delta$ , and  $\epsilon$  subunits but, more importantly, because each of the  $\alpha$  and  $\beta$  subunits have a somewhat different conformation. Thus, one  $\beta$  subunit (designated  $\beta_{\text{TP}}$ ) normally binds a molecule of ATP, the second ( $\beta_{\text{DP}}$ ) binds ADP, and the third ( $\beta_{\text{E}}$ ) has an empty and distorted binding site. The  $\alpha$  subunits all normally bind ATP, although they also differ conformationally from one another (however,  $\alpha_{\text{TP}}$  and  $\beta_{\text{TP}}$  both bind ADP in Fig. 22-38a,b). The ATP and ADP binding sites each lie at a radius of  $\sim 20$  Å near an interface between adjacent  $\alpha$  and  $\beta$  subunits and, in fact, all incorporate a few residues from the adjacent subunit. The  $\alpha$  and  $\beta$  subunits both contain two sequence motifs, the **Walker A motif** (GXXXXGKT/S, where X is any residue) and the **Walker B motif** (R/KXXXXGXXL/VhhD, where h is a hydrophobic residue), that participate in ATP binding and which occur widely in nucleotide-binding proteins of all descriptions.

The  $\delta$  and  $\epsilon$  subunits (168 and 51 residues) are wrapped about the base of the  $\gamma$  subunit's coiled coil. The X-ray structure of *E. coli*  $\text{F}_1$  resembles its bovine counterpart. Note, however, that in an unfortunate confusion of nomenclature, the *E. coli*  $\epsilon$  subunit is the homolog of the mito-

chondrial  $\delta$  subunit; the *E. coli*  $\delta$  subunit is the counterpart of the mitochondrial **oligomycin-sensitivity conferral protein (OSCP)**; see Problem 11), and the mitochondrial  $\epsilon$  subunit has no counterpart in either bacterial or chloroplast ATP synthases.

### c. The $c$ Subunits of $\text{F}_0$ Form a Transmembrane Ring

The  $\text{F}_0$  component of the  $\text{F}_1\text{F}_0$ -ATPase from *E. coli* consists of three transmembrane subunits,  $a$ ,  $b$ , and  $c$  (271, 161, and 89 residues) that form an  $a_1b_2c_{12}$  complex. However, the number  $c$  subunits per  $\text{F}_0$  assembly varies from 10 to 15, depending on the species. Mitochondrial  $\text{F}_0$  additionally contains one copy each of three different subunits,  $d$ ,  $\text{F}_6$ , and OSCP (256, 108, and 213 residues), as well as several “minor” subunits,  $e$ ,  $f$ ,  $g$ , and A6L, of unknown function. Subunits  $a$  and A6L are encoded by mitochondrial genes. A variety of evidence indicates that the hydrophobic  $c$  subunits associate to form a ring with the  $ab_2$  unit located at its periphery (see below). The sequence of the  $a$  subunit suggests that this highly hydrophobic peptide forms five transmembrane helices.

The X-ray structure of the  $c_{11}$  unit from the  $\text{Na}^+$ -translocating  $\text{F}_1\text{F}_0$ -ATPase of the gram-negative bacterium *Ilyobacter tartaricus*, determined by Peter Dimroth, reveals an 11-fold symmetric cylindrical assembly that is 70 Å high and  $\sim 50$  Å in diameter (Fig. 22-39). Each of its identical, largely hydrophobic subunits consists almost entirely of an inner helix that defines the length of the cylinder and an outer helix that is somewhat shorter. Both helices are bent in the vicinity of the  $\text{Na}^+$  ion-binding

**Figure 22-40** X-ray structure of a portion of the peripheral stalk of bovine  $F_1F_0$ -ATPase. This protein fragment is drawn in ribbon form embedded in its semitransparent molecular surface, with  $b$  (residues 79–183) magenta,  $d$  (residues 3–123) cyan, and  $F_6$  (residues 5–70) orange. The N- and C-termini of each subunit are indicated. [Based on an X-ray structure by Andrew Leslie and John Walker, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 2CLY.]

site, thereby conferring an hourglasslike shape on the  $c_{11}$  assembly (Fig. 22-39a). Each  $Na^+$  ion is liganded by residues from both helices of a given subunit as well as those of the clockwise neighboring outer helix as seen in Fig. 22-29b.

In vertebrates, the peripheral stalk (Fig. 22-37) consists of the OSCP,  $b$ ,  $d$ , and  $F_6$  subunits, whereas in most prokaryotes, it consists of the OSCP homolog  $\delta$  and two copies of  $b$ . The X-ray structure of most of the cytosolic portion of a complex of bovine subunits  $b$ ,  $d$ , and  $F_6$ , constituting 54% of the extramembrane segment of the peripheral stalk, determined by Leslie and Walker, reveals that this  $b$  fragment forms a 160-Å-long and curved  $\alpha$  helix, and that the other subunit fragments are also mainly helical (Fig. 22-40). The curvature of this assembly closely matches that of the peripheral stalk in cryoEM-based images of the  $F_1F_0$ -ATPase (e.g., Fig. 22-37). Such cryoEM-based images, together with the foregoing X-ray structures and the NMR structures of  $\delta$  and the transmembrane segment of  $b$ , both from *E. coli*, has enabled the construction of a composite model of the *E. coli*  $F_1F_0$ -ATPase (Fig. 22-41), which, of course, resembles the mitochondrial assembly. Note the extensive contacts between  $\gamma$  and  $\epsilon$  and the top of the  $c$  cylinder.

#### d. The Binding Change Mechanism: Proton-Translocating ATP Synthase Is Driven by Conformational Changes

The mechanism of ATP synthesis by proton-translocating ATP synthase can be conceptually broken down into three phases:

1. Translocation of protons carried out by  $F_0$ .
2. Catalysis of formation of the phosphoanhydride bond of ATP carried out by  $F_1$ .
3. Coupling of the dissipation of the proton gradient with ATP synthesis, which requires interaction of  $F_1$  and  $F_0$ .

**Figure 22-41** A composite model of the *E. coli*  $F_1F_0$ -ATPase. This model is based on the X-ray structure of the *E. coli*  $F_1$  subunit (PDBid 1JNV), which resembles that of bovine  $F_1$  (Fig. 22-38), the structures displayed in Figs. 22-39 and 22-40, and the NMR structures of  $\delta$  and the transmembrane segment of the  $b$  from *E. coli* (PDBids 2A7U and 1B9U). The structures of  $a$  and the so-called hinge region of  $b$  are unknown. [Courtesy of Peter Dimroth, ETH, Zürich, Switzerland.]

The available evidence supports a mechanism for ATP formation, proposed by Boyer, that resembles the conformational coupling hypothesis of oxidative phosphorylation (Section 22-3A). However, the conformational changes in the ATP synthase that power ATP formation are generated by proton translocation rather than by direct electron transfer, as proposed in the original formulation of the conformational coupling hypothesis.

$F_1$  is proposed to have three interacting catalytic protomers, each in a different conformational state: one that binds substrates and products loosely (L state), one that binds them tightly (T state), and one that does not bind them at all (open or O state). The free energy released on proton translocation is harnessed to interconvert these three states. The phosphoanhydride bond of ATP is synthesized only in the T state and ATP is released only in the O state. The reaction involves three steps (Fig. 22-42):

1. Binding of ADP and  $P_i$  to the “loose” (L) binding site.
2. A free energy-driven conformational change that converts the L site to a “tight” (T) binding site that catalyzes the formation of ATP. This step also involves conformational changes of the other two subunits that convert

**Figure 22-42 Energy-dependent binding change mechanism for ATP synthesis by proton-translocating ATP synthase.**  $F_1$  has three chemically identical but conformationally distinct interacting  $\alpha\beta$  protomers: O, the open conformation, has very low affinity for ligands and is catalytically inactive; L has loose binding for ligands and is catalytically inactive; T has tight binding for ligands and is catalytically active. ATP synthesis occurs in three steps. **(1)** Binding of ADP and  $P_i$  to site L. **(2)** Energy-dependent conformational change converting

binding site L to T, T to O, and O to L. **(3)** Synthesis of ATP at site T and release of ATP from site O. The enzyme returns to its initial state after two more passes of this reaction sequence. The energy that drives the conformational change is apparently transmitted to the catalytic  $\alpha_3\beta_3$  assembly via the rotation of the  $\gamma\epsilon$  assembly (in *E. coli*;  $\gamma\delta\epsilon$  in mitochondria), here represented by the centrally located asymmetric pointer (green). [After Cross, R.L., *Annu. Rev. Biochem.* **50**, 687 (1980).]  See the Animated Figures

the ATP-containing T site to an “open” (O) site and convert the O site to an L site.

**3.** ATP is synthesized at the T site on one subunit while ATP dissociates from the O site on another subunit. On the surface of the active site, the formation of ATP from ADP and  $P_i$  entails little free energy change, that is, the reaction is essentially at equilibrium. Consequently, the free energy supplied by the proton flow primarily facilitates the release of the newly synthesized ATP from the enzyme; that is, it drives the  $T \rightarrow O$  transition, thereby disrupting the enzyme–ATP interactions that had previously promoted the spontaneous formation of ATP from  $ADP + P_i$  in the T site.

How is the free energy of proton transfer coupled to the synthesis of ATP? Boyer proposed that *the binding changes are driven by the rotation of the catalytic assembly,  $\alpha_3\beta_3$ , with respect to other portions of the  $F_1F_0$ -ATPase.* This hypothesis is supported by the X-ray structure of  $F_1$ . Thus, the closely fitting nearly circular arrangement of the  $\alpha$  and  $\beta$  subunits’ inner surface about the  $\gamma$  subunit’s helical C-terminus is reminiscent of a cylindrical bearing rotating in a sleeve (Fig. 22-38c). Indeed, the contacting hydrophobic surfaces in this assembly are devoid of the hydrogen bonding and ionic interactions that would interfere with their free rotation; that is, the bearing and sleeve appear to be “lubricated.” Moreover, the central cavity in the  $\alpha_3\beta_3$  assembly (Fig. 22-38a) would permit the passage of the  $\gamma$  subunit’s N-terminal helix within the core of this particle during rotation. Finally, the conformational differences between  $F_1$ ’s three catalytic sites appear to be correlated with the rotational position of the  $\gamma$  subunit. Apparently the  $\gamma$  subunit, which is thought to rotate within the fixed  $\alpha_3\beta_3$  assembly, acts as a molecular cam shaft in linking the proton-motive force–driven rotational motor to the conformational changes in the catalytic sites of  $F_1$ . This concept is also supported by molecular dynamics simulations (Section 9-4) by Leslie, Walker, and Martin Karplus, which indicate that the conformational changes in the  $\beta$  subunits arise from both steric and electrostatic interactions with the rotating  $\gamma$  subunit.

Rotating assemblies are not unprecedented in biological systems. Bacterial flagella, which function as propellers, had previously been shown to be membrane-mounted rotary engines that are driven by the discharge of a proton gradient (Section 35-3Ib).

#### e. The $F_1F_0$ -ATPase Is a Rotary Engine

In the  $F_1F_0$ -ATPase, the rotor is proposed to be an assembly of the  $c$  ring and its associated  $\gamma$  and (*E. coli*)  $\epsilon$  subunits, whereas the  $ab_2$  unit and the (*E. coli*)  $\delta$  subunit together with the  $\alpha_3\beta_3$  spheroid form the stator (Fig. 22-41). The rotation of the  $c$  ring in the membrane relative to the stationary  $a$  subunit is driven by the migration of protons from the outside to the inside, as we discuss below. The peripheral arm ( $b_2\delta$ ) presumably functions to hold the  $\alpha_3\beta_3$  spheroid in place while the  $\gamma$  subunit rotates inside it.

The rotation of the *E. coli*  $\gamma\epsilon$ - $c$ -ring rotor with respect to the  $ab_2\delta$ - $\alpha_3\beta_3$  stator has been ingeniously demonstrated by Masamitsu Futai using techniques developed by Kazuhiko Kinoshita Jr. and Masasuke Yoshida (Fig. 22-43a). The  $\alpha_3\beta_3$  spheroid of *E. coli*  $F_1F_0$ -ATPase was fixed, head down, to a glass surface as follows: Six consecutive His residues (a so-called **His Tag**; Section 6-3Dg) were mutagenically appended to the N-terminus of the  $\alpha$  subunit, which is located at the top of the  $\alpha_3\beta_3$  spheroid as it is drawn in Fig. 22-38a. The His-tagged assembly was applied to a glass surface coated with horseradish peroxidase (which, like most proteins, sticks to glass) conjugated with  $Ni^{2+}$ -**nitroloacetic acid** [ $N(CH_2COOH)_3$ , which tightly binds His tags], thereby binding the  $F_1F_0$ -ATPase with its  $F_0$  side facing away from the surface. The Glu 2 residues of this assembly’s  $c$  subunits, which are located on the side of the  $c$  ring facing away from  $F_1$ , had been mutagenically replaced by Cys residues, which were then covalently linked to **biotin** (a coenzyme that normally participates in carboxylation reactions; Section 23-1Ab). A fluorescently labeled and biotinylated (at one end) filament of the muscle protein **actin** (Section 35-3Ac) was then attached to the  $c$  subunit through the addition of a bridging molecule of **streptavidin**, a protein that avidly binds biotin to each of four binding sites (Cys 193 of

(a)

(b)

**Figure 22-43** Rotation of the *c* ring in *E. coli*  $F_1F_0$ -ATPase.

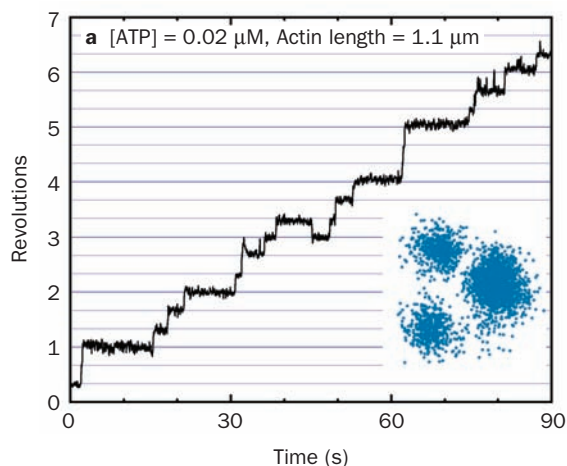

(a) The experimental system used to observe the rotation. See the text for details. The blue arrow indicates the observed direction of rotation of the fluorescently labeled actin filament that was linked to the *c* ring. (b) The rotation of a 3.6- $\mu\text{m}$ -long actin filament in the presence of 5 mM  $\text{MgATP}$  as seen in successive video images taken through a fluorescence microscope. [Courtesy of Masamitsu Futai, Osaka University, Osaka, Japan.]

the  $\gamma$  subunit, the only other Cys residue in the rotor, was mutagenically replaced by Ala to prevent it from being linked to an actin filament).

*E. coli*  $F_1F_0$ -ATPase can work in reverse, that is, it can pump protons from the inside (cytoplasm) to the outside (periplasm) at the expense of ATP hydrolysis (this enables the bacterium to maintain its proton gradient under anaerobic conditions, which it uses to drive various processes such as flagellar rotation). Thus, the foregoing preparation was observed under a fluorescence microscope as a 5 mM  $\text{MgATP}$  solution was infused over it. *Many of the actin filaments were seen to rotate (Fig. 22-43b), and always in a counterclockwise direction when viewed looking down on the glass surface (from the outside).* This would permit the  $\gamma$  subunit to sequentially interact with the  $\beta$  subunits in the direction

(Figs. 22-38b and 22-42), the direction expected for ATP hydrolysis.

**Figure 22-44** Stepwise rotation of the  $\gamma$  subunit of  $F_1$  relative to an immobilized  $\alpha_3\beta_3$  unit at low ATP concentration as observed by fluorescence microscopy.

The graph plots the cumulative number of rotations made by a fluorescently labeled actin filament that was linked at one end to the  $\gamma$  subunit in a preparation similar to that diagrammed in Fig. 22-43a (but lacking  $F_0$ ,  $\delta$ , and  $\epsilon$ ). Note that the actin filament rotates in increments of  $120^\circ$ . This is also evident in the inset, which shows the superposition of the centers of the actin images (the  $\delta_3\beta_3\gamma$  assembly is fixed in the center). [Courtesy of Kazuhiko Kinoshita, Jr., Keio University, Yokohama, Japan.]

In a variation of the above experiment, the  $\gamma$  subunit of the  $\alpha_3\beta_3\gamma$  complex was directly cross-linked, via its Cys 193, to a fluorescently labeled actin filament and, in this case, the  $\beta$  subunits were immobilized by appended His tags. At very low ATP concentrations (e.g., 0.02  $\mu\text{M}$ ), video images (Fig. 22-44) revealed that the fluorescent actin filament rotated counterclockwise in discrete steps of  $120^\circ$ , as the binding change mechanism predicts. Moreover, the calculated frictional work done in each rotational step is very nearly equal to the energy available from the hydrolysis of one ATP molecule, that is, *the  $F_1F_0$ -ATPase converts chemical to mechanical energy with nearly 100% efficiency.*

The foregoing system also works in reverse. An  $\sim 0.7$ - $\mu\text{m}$ -diameter magnetic bead that was coated with streptavidin was attached to the biotinylated  $\gamma$  subunit of an immobilized  $\alpha_3\beta_3\gamma$  complex. When the resulting assembly was placed in a rotating magnetic field in the presence of ADP and  $P_i$ , ATP was produced when the magnetic field rotated in the clockwise direction but hydrolyzed when it rotated in the counterclockwise direction. This further demonstrates that  $F_1$  is a device that interconverts mechanical and chemical energy.

#### f. c-Ring Rotation Is Impelled by $\text{H}^+$ -Induced Conformational Changes

The foregoing structural and biochemical information has led to the model for proton-driven rotation of the  $F_0$  subunit that is diagrammed in Fig. 22-45. Protons from the outside enter a hydrophilic channel between the *a* subunit and the *c* ring, where they bind to a *c* subunit. The *c* ring

**Figure 22-45** Schematic diagram of the action of the *E. coli*  $F_1F_0$ -ATPase. The  $\gamma\epsilon$ - $c_{12}$  ring complex is the rotor and the  $ab_2$ - $\alpha_3\beta_3\delta$  complex is the stator. Rotational motion is imparted to the rotor by the passage of protons from the outside (periplasm) to the inside (cytoplasm). Protons entering from the outside bind to a *c* subunit where it interacts with the *a* subunit, and exit to the inside after the *c* ring has made a nearly full rotation as indicated (black arrows), so that the *c* subunit again contacts the *a* subunit. The  $b_2\delta$  complex presumably functions to prevent the  $\alpha_3\beta_3$  assembly from rotating with the  $\gamma$  subunit. [Courtesy of Richard Cross, State University of New York, Syracuse, New York.]

then rotates nearly a full turn (while protons bind to successive *c* subunits as they pass this input channel) until the subunit reaches a second hydrophilic channel between the *a* subunit and the *c*-ring that opens into the inside. There the proton is released. Thus, *E. coli*  $F_1F_0$ -ATPase, which has 12 *c* subunits in its  $F_0$  assembly and generates 3ATP per turn, ideally forms  $3/12 = 0.25$  ATP for every proton it passes from the periplasmic space (outside) to the cytosol (inside). Organisms with more/less *c* subunits in their *c*-rotor tend to have lesser/greater values of proton-motive force across their membranes and hence have less/more impetus imparted to their *c*-rotor per proton passed. Hence it takes the passage of proportionately more/less protons to generate each ATP, as the first law of thermodynamics requires.

How does the passage of protons through this system induce the rotation of the *c* ring and hence the synthesis of ATP? The mutation of the *c* subunit's conserved Asp 61 to Asn inactivates *E. coli*  $F_1F_0$ -ATPase. The *a* subunit's invariant Arg 210 (*E. coli* numbering) has been similarly impli-

**Figure 22-46** NMR structures of the *c* subunit of *E. coli*  $F_1F_0$ -ATPase. The structures, which closely resemble that in Fig. 22-39, were determined in chloroform-methanol-water (4:4:1) solution at (a) pH 8 (at which D61 is deprotonated) and (b) pH 5 (at which D61 is protonated). Selected side chains are shown to aid in the comparison of the two structures. Note that the C-terminal helix in the pH 8 structure has rotated by  $140^\circ$  clockwise, as viewed from the top of the drawing, relative to that in the pH 5 structure. [Courtesy of Mark Girvin, Albert Einstein College of Medicine. PDBids (a) 1C99 and (b) 1C0V.]

cated in proton translocation. Through the mutagenic conversion of selected residues on the *a* and *c* subunits to Cys, Robert Fillingame has shown that the outer (C-terminal) helix of *E. coli* subunit *c* (Fig. 22-39), which contains Asp 61, can be disulfide-cross-linked to the putative fourth helix of subunit *a*, which contains Arg 210. Evidently, these helices are juxtaposed at some point in the *c* ring's rotation cycle. Thus, it is postulated that the protonation of Asp 61 releases its attraction to Arg 210, thereby permitting the *c* ring to rotate.

Comparison of the NMR structures of subunit *c* at pH 8 and pH 5 (Fig. 22-46), at which Asp 61 is, respectively, deprotonated and protonated, reveals that its main conformational change on protonation is an  $\sim 140^\circ$  clockwise rotation (as viewed from  $F_1$ ) of its Asp 61-containing C-terminal helix with respect to its N-terminal helix. Since the C-terminal helix is the *c* ring's outer helix (Fig. 22-39b), this suggests that, on protonation, the rotation of the C-terminal helix mechanically pushes against the juxtaposed *a* subunit so as to rotate the *c* ring in the direction indicated in Fig. 22-45.

#### D. Uncoupling of Oxidative Phosphorylation

*Electron transport (the oxidation of NADH and FADH<sub>2</sub> by O<sub>2</sub>) and oxidative phosphorylation (the synthesis of ATP) are normally tightly coupled due to the impermeability of the inner mitochondrial membrane to the passage of protons. Thus the only way for H<sup>+</sup> to reenter the matrix is through the F<sub>0</sub> portion of the proton-translocating ATP*

synthase. In the resting state, when oxidative phosphorylation is minimal, the proton-motive force across the inner mitochondrial membrane builds up to the extent that the free energy to pump additional protons is greater than the electron-transport chain can muster, thereby inhibiting further electron transport. However, many compounds, including **2,4-dinitrophenol (DNP)** and **carbonylcyanide-*p*-trifluoromethoxyphenylhydrazone (FCCP)**, have been found to “uncouple” these processes. The chemiosmotic hypothesis has provided a rationale for understanding the mechanism by which these uncouplers act.

The presence in the inner mitochondrial membrane of an agent that renders it permeable to  $H^+$  uncouples oxidative phosphorylation from electron transport by providing a route for the dissipation of the proton-motive force that does not require ATP synthesis. Uncoupling therefore allows electron transport to proceed unchecked even when ATP synthesis is inhibited. DNP and FCCP are lipophilic weak acids that therefore readily pass through membranes. In a pH gradient, they bind protons on the acidic side of the membrane, diffuse through, and release them on the alkaline side, thereby dissipating the gradient (Fig. 22-47). Thus, such uncouplers are proton-transporting ionophores (Section 20-2C).

Even before the mechanism of uncoupling was known, it was recognized that metabolic rates were increased by such compounds. Studies at Stanford University in the

early part of the twentieth century documented an increase in respiration and weight loss caused by DNP. The compound was even used as a “diet pill” for several years. In the words of Efraim Racker (*A New Look at Mechanisms in Bioenergetics*, p. 155):

*In spite of warnings from the Stanford scientists, some enterprising physicians started to administer dinitrophenol to obese patients without proper precautions. The results were striking. Unfortunately in some cases the treatment eliminated not only the fat but also the patients, and several fatalities were reported in the Journal of the American Medical Association in 1929. This discouraged physicians for a while. . .*

#### a. Hormonally Controlled Uncoupling in Brown Adipose Tissue Functions to Generate Heat

The dissipation of an electrochemical  $H^+$  gradient, which is generated by electron transport and uncoupled from ATP synthesis, produces heat. Heat generation is the physiological function of **brown adipose tissue (brown fat)**. This tissue is unlike typical (white) adipose tissue in that, besides containing large amounts of triacylglycerols, it contains numerous mitochondria whose cytochromes color it brown. Newborn mammals that lack fur, such as humans, as well as hibernating mammals, contain brown fat in their neck and upper back that functions in **nonshivering thermogenesis**, that is, as a “biological heating pad.” (The ATP hydrolysis that occurs during the muscle contractions of shivering—or

**Figure 22-47** Uncoupling of oxidative phosphorylation. The proton-transporting ionophores DNP and FCCP uncouple oxidative phosphorylation from electron transport by

discharging the electrochemical proton gradient generated by electron transport.

**Figure 22-48** Mechanism of hormonally induced uncoupling of oxidative phosphorylation in brown fat mitochondria.

**(1)** Norepinephrine binds to a  $\beta_3$ -adrenergic receptor. **(2)** This stimulates the associated heterotrimeric G protein to activate adenylate cyclase (upper green arrow) to synthesize cAMP. **(3)** cAMP binding activates protein kinase A (PKA). **(4)** PKA

phosphorylates hormone-sensitive triacylglycerol lipase, thereby activating it. **(5)** Triacylglycerols are hydrolyzed, yielding free fatty acids. **(6)** Free fatty acids overcome the purine nucleotide block of thermogenin's proton channel (lower green arrow), allowing  $H^+$  to enter the mitochondrion uncoupled from ATP synthesis.

any other movement—also produces heat. Nonshivering thermogenesis through substrate cycling is discussed in Section 17-4Fi.)

The mechanism of heat generation in brown fat involves the regulated uncoupling of oxidative phosphorylation in their mitochondria. These mitochondria contain the protein **thermogenin** [also called **uncoupling protein (UCP)**], a transmembrane homodimer of 307-residue subunits that acts as a channel to control the permeability of the inner mitochondrial membrane to protons. In cold-adapted animals, thermogenin constitutes up to 15% of brown fat inner mitochondrial membrane proteins. The flow of protons through this channel protein is inhibited by physiological concentrations of purine nucleotides (ADP, ATP, GDP, GTP), but this inhibition can be overcome by free fatty acids. The components of this system interact under hormonal control.

*Thermogenesis in brown fat mitochondria is activated by free fatty acids.* These counteract the inhibitory effects of purine nucleotides, thereby stimulating the flux through the proton channel and uncoupling electron transport from oxidative phosphorylation. *The concentration of fatty acids in brown adipose tissue is controlled by the adrenal hormone norepinephrine (noradrenaline; Section 18-3E) with cAMP acting as a second messenger (Section 18-3).* Norepinephrine binds to the  **$\beta_3$ -adrenergic receptor**, a G-protein coupled receptor (GPCR) that, via an associated heterotrimeric G protein, stimulates adenylate cyclase to synthesize cAMP (Fig. 22-48), as described in Section 19-2. The cAMP, in turn, activates protein kinase A (PKA), which activates **hormone-sensitive triacylglycerol lipase** by phosphorylating it (Section 25-5). Finally, the activated lipase hydrolyzes triacylglycerols to yield the free fatty acids that open thermogenin's proton channel. The transcription of

the gene encoding thermogenin is stimulated by the thyroid hormone triiodothyronine (T3; Section 19-1D).

### b. Other Tissues Contain UCP Homologs

Although it originally seemed that only brown fat mitochondria contain an uncoupling protein, it is now apparent that other tissues contain homologs of UCP1. Thus, **UCP2** is expressed in many tissues including white adipose tissue, whereas **UCP3** occurs in both brown and white adipose tissues as well as in muscle. These proteins may help regulate metabolic rates, and variations in UCP levels or activity might explain why some people seem to have a “fast” or “slow” metabolism (Section 27-3E). UCPs are being studied as targets for treating obesity, since increasing the activity of UCPs could uncouple respiration from ATP synthesis, thus permitting stored metabolic fuels (especially fat) to be metabolized. The recent discovery that adult humans have small depots of brown fat that are activated by cold has made this an attractive weight loss strategy, although it is possible that stimulating UCPs will cause a compensatory increase in appetite.

Uncoupling proteins are not limited to animals. Some plants express uncoupling proteins in response to cold stress or to increase flower temperature, possibly to enhance the vaporization of scent to attract pollinators.

## 4 CONTROL OF ATP PRODUCTION

A typical adult woman requires some 1500 to 1800 kcal (6300–7500 kJ) of metabolic energy per day. This corresponds to the free energy of hydrolysis of over 200 mol of ATP to ADP and  $P_i$ . Yet the total amount of ATP present in the body at any one time is  $<0.1$  mol; obviously, this sparse supply of ATP must be continually recycled. As we have seen, when carbohydrates serve as the energy supply and aerobic conditions prevail, this recycling involves glycogenolysis, glycolysis, the citric acid cycle, and oxidative phosphorylation.

Of course the need for ATP is not constant. There is a 100-fold change in ATP utilization between sleep and vigorous activity. *The activities of the pathways that produce ATP are under strict coordinated control so that ATP is never produced more rapidly than necessary.* We have already discussed the control mechanisms of glycolysis, glycogenolysis, and the citric acid cycle (Sections 17-4, 18-3, and 21-4). In this section we discuss the mechanisms through which oxidative phosphorylation is controlled and observe how all four systems are synchronized to produce ATP at precisely the rate required at any particular moment.

### A. Control of Oxidative Phosphorylation

In our discussion of the control of glycolysis, we saw that most of the reactions in a metabolic pathway function close to equilibrium. *The few irreversible reactions constitute the potential control points of the pathway and usually are catalyzed by regulatory enzymes that are under allosteric con-*

*trol.* In the case of oxidative phosphorylation, the pathway from NADH to cytochrome *c* functions near equilibrium ( $\Delta G \approx 0$ ):

for which

$$K_{\text{eq}} = \left( \frac{[\text{NAD}^+]}{[\text{NADH}]} \right)^{1/2} \frac{[\text{ATP}]}{[\text{c}^{3+}][\text{ADP}][P_i]} \quad [22.2]$$

This pathway is therefore readily reversed by the addition of ATP. *In the cytochrome *c* oxidase reaction, however, the terminal step of the electron-transport chain is irreversible and is thus one of the important regulatory sites of the pathway.* Cytochrome *c* oxidase, in contrast to most regulatory enzyme systems, appears to be controlled exclusively by the availability of one of its substrates, reduced cytochrome *c* ( $c^{2+}$ ). Since this substrate is in equilibrium with the rest of the coupled oxidative phosphorylation system (Eq. [22.2]), its concentration ultimately depends on the intramitochondrial  $[\text{NADH}]/[\text{NAD}^+]$  ratio and the **ATP mass action ratio** ( $[\text{ATP}]/[\text{ADP}][P_i]$ ). By rearranging Eq. [22.2], the ratio of reduced to oxidized cytochrome *c* is expressed

$$\frac{[c^{2+}]}{[c^{3+}]} = \left( \frac{[\text{NADH}]}{[\text{NAD}^+]} \right)^{1/2} \left( \frac{[\text{ADP}][P_i]}{[\text{ATP}]} \right) K_{\text{eq}} \quad [22.3]$$

Consequently, the higher the  $[\text{NADH}]/[\text{NAD}^+]$  ratio and the lower the ATP mass action ratio, the higher is the  $[c^{2+}]$  (reduced cytochrome *c*) and thus the higher is the cytochrome *c* oxidase activity.

How is this system affected by changes in physical activity? In an individual at rest, ATP hydrolysis to ADP and  $P_i$  is minimal and the ATP mass action ratio is high; the concentration of reduced cytochrome *c* is therefore low and oxidative phosphorylation is minimal. Increased activity results in hydrolysis of ATP to ADP and  $P_i$ , thereby decreasing the ATP mass action ratio and increasing the concentration of reduced cytochrome *c*. This results in an increase in the electron-transport rate and its coupled phosphorylation. Such control of oxidative phosphorylation by the ATP mass action ratio is called **acceptor control** because the rate of oxidative phosphorylation increases with the concentration of ADP, the phosphoryl group acceptor. In terms of a supply–demand system (Section 17-4D), acceptor control is understood as control by the demand block.

The compartmentalization of the cell into mitochondria, where ATP is synthesized, and cytoplasm, where ATP is utilized, presents an interesting control problem: Is it the ATP mass action ratio in the cytosol or in the mitochondrial matrix that ultimately controls oxidative phosphorylation? Clearly the ATP mass action ratio that exerts direct control must be that of the mitochondrial matrix where ATP is synthesized. However, the inner mitochondrial membrane, which is impermeable to adenine nucleotides and  $P_i$ , depends on specific transport systems to maintain communication between the two compartments (Section 20-4C). This organization makes it possible for the transport

of adenine nucleotides or  $P_i$  to participate in the control of oxidative phosphorylation.

Considerable research effort has been aimed at determining how oxidative phosphorylation is controlled in terms of metabolic control analysis. For example, Hans Westerhoff and Martin Kushmerick employed  $^{31}\text{P}$  NMR to measure the ATP/ADP ratios in human forearm muscle at rest and during twitch contractions caused by external electrical stimulation (the  $^{31}\text{P}$  NMR spectrum of ATP is shown in Fig. 16-15). Under conditions of low to moderate ATP demand, the cytosolic mass action ratio as controlled by the demand block of the system appears to be the major control factor for mitochondrial oxidation. However, as other laboratories have shown, as the demand for ATP increases, the ADP-ATP translocator exerts greater control until finally, when the demand for ATP is high, control shifts to the supply block of the system, oxidative phosphorylation itself.

### B. Coordinated Control of ATP Production

Glycolysis, the citric acid cycle, and oxidative phosphorylation constitute the major pathways for cellular ATP production. Control of oxidative phosphorylation by the ATP mass action ratio depends, of course, on an adequate supply of electrons to fuel the electron-transport chain. This aspect of the system's control is, in turn, dependent on the  $[\text{NADH}]/[\text{NAD}^+]$  ratio (Eq. [22.3]), which is maintained high by the combined action of glycolysis and the citric acid cycle in converting 10 molecules of  $\text{NAD}^+$  to  $\text{NADH}$  per molecule of glucose oxidized (Fig. 22-1). It is clear, therefore, that coordinated control is necessary for the three processes. This is provided by the regulation of each of the control points of glycolysis [hexokinase, phosphofructokinase (PFK), and pyruvate kinase] and the citric acid cycle (pyruvate dehydrogenase, citrate synthase, isocitrate dehydrogenase, and  $\alpha$ -ketoglutarate dehydrogenase) by adenine nucleotides or  $\text{NADH}$  or both as well as by certain metabolites (Fig. 22-49).

#### a. Citrate Inhibits Glycolysis

The main control points of glycolysis and the citric acid cycle are regulated by several effectors besides adenine nucleotides or  $\text{NADH}$  (Fig. 22-49). This is an extremely complex system with complex demands. Its many effectors, which are involved in various aspects of metabolism, increase its regulatory sensitivity. One particularly interesting regulatory effect is the inhibition of PFK by citrate. When demand for ATP decreases,  $[\text{ATP}]$  increases and  $[\text{ADP}]$  decreases. The

**Figure 22-49** Schematic diagram depicting the coordinated control of glycolysis and the citric acid cycle by ATP, ADP, AMP,  $P_i$ ,  $\text{Ca}^{2+}$ , and the  $[\text{NADH}]/[\text{NAD}^+]$  ratio (the vertical arrows indicate increases in this ratio). Here a green dot signifies activation and a red octagon represents inhibition. [After Newsholme, E.A. and Leech, A.R., *Biochemistry for the Medical Sciences*, pp. 316 and 320, Wiley (1983).]  See the Animated Figures

citric acid cycle slows down at its isocitrate dehydrogenase (activated by ADP) and  $\alpha$ -ketoglutarate dehydrogenase (inhibited by ATP) steps, thereby causing the citrate concentration to build up. Citrate can leave the mitochondrion via a specific transport system and, *once in the cytosol, acts to restrain further carbohydrate breakdown by inhibiting PFK.*

#### b. Fatty Acid Oxidation Inhibits Glycolysis

As we shall see in Section 25-2, the oxidation of fatty acids is an aerobic process that produces acetyl-CoA, which enters the citric acid cycle, thereby increasing both the mitochondrial and cytoplasmic concentrations of citrate. The increased [acetyl-CoA] inhibits the pyruvate dehydrogenase complex, whereas the increased [citrate] inhibits phosphofructokinase, leading to a buildup of glucose-6-phosphate, which inhibits hexokinase (Fig. 22-49). This inhibition of glycolysis by fatty acid oxidation is called the **glucose–fatty acid cycle** or **Randle cycle** (after its discoverer, Philip Randle), although it is not, in fact, a cycle. The Randle cycle allows fatty acids to be utilized as the major fuel for oxidative metabolism in heart muscle, while conserving glucose for organs such as the brain, which require it.

### C. Physiological Implications of Aerobic versus Anaerobic Metabolism

In 1861, Louis Pasteur observed that *when yeast are exposed to aerobic conditions, their glucose consumption and ethanol production drop precipitously* (the **Pasteur effect**; alcoholic fermentation in yeast to produce ATP, CO<sub>2</sub>, and ethanol are discussed in Section 17-3B). An analogous effect is observed in mammalian muscle; the concentration of lactic acid, the anaerobic product of muscle glycolysis, drops dramatically when cells switch to aerobic metabolism.

#### a. Hypoxia Causes an Increase in Glycolysis

In the presence of sufficient oxygen, oxidative phosphorylation supplies most of the body's ATP needs. However, during **hypoxia** (when oxygen is limiting), glycolysis must be stimulated (with its inherent increased rate of glucose consumption; the reverse of the Pasteur effect) to supply the necessary ATP. F<sub>2</sub>,6P, the most potent activator of PFK-1, also participates in this process. The concentration of F<sub>2</sub>,6P, as we have seen (Section 18-3Fc), is regulated by the bifunctional enzyme PFK-2/FBPase-2. In its heart isozyme, the PFK-2 activity is stimulated by phosphorylation at its Ser 466. Among the enzymes that do so is **AMP-activated protein kinase** (AMPK; Sections 25-4Ba, 25-5, and 27-1). When oxygen deficiency prevents oxidative phosphorylation from providing sufficient ATP for heart function, as occurs in **ischemia** (insufficient blood flow), the resulting increased [AMP] activates AMPK. The consequent phosphorylation and hence activation of PFK-2 results in an increase of [F<sub>2</sub>,6P], thereby activating PFK-1 and thus glycolysis.

#### b. Aerobic ATP Production Is Far More Efficient than Anaerobic ATP Production

One reason for the decrease in glucose consumption on switching from anaerobic to aerobic metabolism is clear

from an examination of the stoichiometries of anaerobic and aerobic breakdown of glucose (C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>).

#### Anaerobic glycolysis:

#### Aerobic metabolism of glucose:

(2.5 ATP for each of the 10 NADH generated per glucose oxidized, 1.5 ATP for each of the 2 FADH<sub>2</sub> generated, 2 ATP produced in glycolysis, and 2GTP  $\rightleftharpoons$  2ATP produced in the citric acid cycle.) Thus *aerobic metabolism is 16 times more efficient than anaerobic glycolysis in producing ATP.* The switch to aerobic metabolism therefore rapidly increases the ATP mass action ratio. As the ATP mass action ratio increases, the rate of electron transport decreases, which has the effect of increasing the [NADH]/[NAD<sup>+</sup>] ratio. The increases in [ATP] and [NADH] inhibit their target enzymes in the citric acid cycle and in the glycolytic pathway. *The activity of PFK, which is citrate- and adenine nucleotide-regulated and one of the rate-controlling enzymes of glycolysis, decreases manyfold on switching from anaerobic to aerobic metabolism. This accounts for the dramatic decrease in glycolysis.*

#### c. Anaerobic Glycolysis Has Advantages as Well as Limitations

Animals can sustain anaerobic glycolysis for only short periods of time. This is because PFK, which cannot function effectively much below pH 7, is inhibited by the acidification arising from lactic acid production. Despite this limitation and the low efficiency of glycolytic ATP production, *the enzymes of glycolysis are present in such great concentrations that when they are not inhibited, ATP can be produced much more rapidly than through oxidative phosphorylation.*

The different characteristics of aerobic and anaerobic metabolism permit us to understand certain aspects of cancer cell metabolism and cardiovascular disease.

#### d. Cancer Cell Metabolism

As Warburg first noted in 1926, certain cancer cells produce more lactic acid under aerobic conditions than do normal cells. This is because the glycolytic pathway in these cells produces pyruvate more rapidly than the citric acid cycle can accommodate. How can this happen given the interlocking controls on the system? One explanation is that these controls have broken down in cancer cells. Another is that their ATP utilization occurs at rates too rapid to be replenished by oxidative phosphorylation. This would alter the ratios of adenine nucleotides so as to relieve the inhibition of PFK-1. In addition, many cancer cell lines have a much larger [F<sub>2</sub>,6P] than do normal cells. These cells contain an inducible isozyme of PFK-2/FBPase-2 that has an AMPK-phosphorylatable site for activating PFK-2. Consequently, an [AMP] increase in these cells results in an increase in their [F<sub>2</sub>,6P], which further activates PFK-1 and

glycolysis. Efforts to understand the metabolic differences between cancer cells and normal cells may eventually lead to a treatment of certain forms of this devastating disease.

#### e. Cardiovascular Disease

Oxygen deprivation of certain tissues resulting from cardiovascular disease is of major medical concern. For example, two of the most common causes of human death, **myocardial infarction** (heart attack) and **stroke**, are caused by interruption of the blood ( $O_2$ ) supply to a portion of the heart or the brain, respectively. It seems obvious why this should result in a cessation of cellular activity, but why does it cause cell death?

In the absence of  $O_2$ , a cell, which must then rely only on glycolysis for ATP production, rapidly depletes its stores of phosphocreatine (a source of rapid ATP production; Section 16-4Cd) and glycogen. As the rate of ATP production falls below the level required by membrane ion pumps for the maintenance of proper intracellular ionic concentrations, the osmotic balance of the system is disrupted, so that the cell and its membrane-enveloped organelles begin to swell. The resulting overstretched membranes become permeable, thereby leaking their enclosed contents. [In fact, a useful diagnostic criterion for myocardial infarction is the presence in the blood of heart-specific enzymes, such as the H-type isozyme of lactate dehydrogenase (vs the M-type isozyme, which predominates in skeletal muscle; Section 17-3A), which leak out of necrotic (dead) heart tissue.] Moreover, the decreased intracellular pH that accompanies anaerobic glycolysis (because of lactic acid production; Section 17-3A) permits the released lysosomal enzymes (which are active only at acidic pH's) to degrade the cell contents. Thus, the cessation of metabolic activity results in irreversible cell damage. Rapidly respiring tissues, such as those of heart and brain, are particularly susceptible to such damage.

#### f. $IF_1$ Inhibits $F_1F_0$ -ATPase during Hypoxia

Under hypoxic conditions, the proton-motive force across the inner mitochondrial membrane is reduced to the point that  $F_1F_0$ -ATPase would switch from the synthesis of ATP to its hydrolysis, resulting in a catastrophic loss of ATP. This is prevented through the interaction of the  $F_1F_0$ -ATPase with an 84-residue regulatory protein named  **$IF_1$** . Under normal physiological conditions,  $IF_1$  forms inactive tetramers and higher order oligomers. However, when the pH drops below 6.5, which occurs under anaerobic conditions due to lactic acid production,  $IF_1$  forms dimers in which its almost entirely  $\alpha$  helical subunits associate via an antiparallel coiled coil involving its residues 48 to 84. The X-ray structure of  $F_1$  in complex with AMPPNP and  $IF_1$ , determined by Leslie and Walker, reveals that each N-terminal segment of the  $IF_1$  dimer has bound to the  $\alpha_{DP}$ - $\beta_{DP}$  interface (Fig. 22-38b) of a separate  $F_1$ . This traps AMPPNP and presumably ATP in the  $\beta_{DP}$  binding site, which would prevent it from hydrolyzing ATP (which, since AMPPNP rather than ADP is bound to  $\beta_{DP}$ , suggests that this structure is that of a prehydrolysis step in the catalytic reaction). When oxygen becomes available, the cell

re-energizes and its pH increases, thereby causing  $IF_1$  to dissociate from  $F_1F_0$ , which then commences synthesizing ATP.

#### g. Partial Oxygen Reduction Produces Reactive Oxygen Species (ROS)

Although the four-electron reduction of  $O_2$  by cytochrome *c* oxidase normally goes to completion, the enzyme infrequently releases partially reduced reactive oxygen species (ROS) that readily react with a variety of cellular components. The best known ROS is the superoxide radical,  $O_2^-$ . It is also produced by the occasional leakage of electrons from Complexes I and III:

Its production is enhanced under hypoxic conditions.

Superoxide radical is a precursor of other reactive species. Protonation of  $O_2^-$  yields  **$HO_2^\cdot$** , a much stronger oxidant than  $O_2^-$ . The most potent oxygen species in biological systems is probably the **hydroxyl radical**, which forms from the relatively harmless hydrogen peroxide ( $H_2O_2$ ):

The hydroxyl radical also forms through the reaction of superoxide with  $H_2O_2$ :

ROS readily extract electrons from other molecules, converting them to free radicals and thereby initiating a chain reaction.

The random nature of ROS attacks makes it difficult to characterize their reaction products, but all classes of biological molecules are susceptible to oxidative damage caused by free radicals. The oxidation of polyunsaturated lipids in cells may disrupt the structures of membranes, and oxidative damage to DNA may result in point mutations. Enzyme function may also be compromised through radical reactions with amino acid side chains. Because the mitochondrion is the site of the bulk of the cell's oxidative metabolism, its lipids, DNA, and proteins bear the brunt of free radical-related damage.

Several degenerative diseases, including Parkinson's, Alzheimer's, and Huntington's diseases, are associated with oxidative damage to mitochondria. Such observations have led to the free-radical theory of aging, which holds that *free-radical reactions arising during the course of normal oxidative metabolism are at least partially responsible for the aging process*. In fact, individuals with congenital defects in their mitochondrial DNA suffer from a variety of symptoms typical of old age, including neuromotor difficulties, deafness, and dementia. These genetic defects may increase the susceptibility of mitochondria to ROS-generated damage.

#### h. Cells Are Equipped with Antioxidant Mechanisms

Antioxidants eliminate oxidative free radicals such as  $O_2^-$  and  $\cdot OH$ . In 1969, Irwin Fridovich discovered that the

enzyme **superoxide dismutase (SOD)**, which is present in nearly all cells, catalyzes the conversion of  $O_2^-$  to  $H_2O_2$ :

Mitochondrial and bacterial SOD are both  $Mn^{2+}$ -containing tetramers; eukaryotic cytosolic SOD is a dimer that contains both  $Cu^{2+}$  and  $Zn^{2+}$  ions. Although the rate of nonenzymatic superoxide breakdown is  $\sim 2 \times 10^5 M^{-1} \cdot s^{-1}$ , that of the Cu,Zn-SOD-catalyzed reaction is  $\sim 2 \times 10^9 M^{-1} \cdot s^{-1}$ , close to the diffusion-controlled limit (Section 14-2Bb). This is apparently accomplished by electrostatic guidance of the negatively charged superoxide substrate into the enzyme's active site (Fig. 14-10).

$H_2O_2$  is degraded to water and oxygen by enzymes such as **catalase**, which catalyzes the reaction

and **glutathione peroxidase**, which uses glutathione (GSH; Section 21-2Ba) as a reducing agent:

The latter enzyme also catalyzes the breakdown of organic hydroperoxides. Some types of glutathione peroxidase require Se for activity, which is one reason why Se appears to have antioxidant activity.

Other potential antioxidants are plant-derived compounds such as ascorbic acid (vitamin C; Section 11-1Cb) and **vitamin E**, a group of compounds whose most prominent member is  **$\alpha$ -tocopherol**.

**$\alpha$ -Tocopherol (vitamin E)**

These compounds may help protect plants from oxidative damage during photosynthesis, a process in which  $H_2O$  is oxidized to  $O_2$  (Section 24-2). However, clinical trials indicate that their use does not contribute to longevity in humans.

## CHAPTER SUMMARY

**1 The Mitochondrion** Oxidative phosphorylation is the process through which the NADH and  $FADH_2$  produced by nutrient oxidation are oxidized with the concomitant formation of ATP. The process takes place in the mitochondrion, an ellipsoidal organelle that is bounded by a permeable outer membrane and contains an impermeable and highly invaginated inner membrane that encloses the matrix. Enzymes of oxidative phosphorylation are embedded in the inner mitochondrial membrane.  $P_i$  is imported into the mitochondrion by a specific transport protein.  $Ca^{2+}$  import and  $Ca^{2+}$  export proteins operate to maintain a constant cytosolic  $[Ca^{2+}]$ . NADH's electrons are imported into the mitochondrion by shuttle systems such as the glycerophosphate shuttle and the malate-aspartate shuttle.

**2 Electron Transport** The standard free energy change for the oxidation of NADH by  $O_2$  is  $\Delta G^{o'} = -218 \text{ kJ} \cdot \text{mol}^{-1}$ , whereas that for the synthesis of ATP from ADP and  $P_i$  is  $\Delta G^{o'} = 30.5 \text{ kJ} \cdot \text{mol}^{-1}$ . Consequently, the molar free energy of oxidation of NADH by  $O_2$  is sufficient to power the synthesis of several moles of ATP under standard conditions. The electrons generated by oxidation of NADH and  $FADH_2$  pass through four protein complexes, the electron-transport chain, with the coupled synthesis of ATP. Complexes I, III, and IV participate in the oxidation of NADH, producing  $\sim 2.5$  ATPs per NADH, whereas  $FADH_2$  oxidation, which involves Complexes II, III, and IV, produces only  $\sim 1.5$  ATPs per  $FADH_2$ . Thus, the ratio of moles of ATP produced per mole of coenzyme oxidized by  $O_2$ , the P/O ratio, is  $\sim 2.5$  for NADH oxidation and  $\sim 1.5$  for  $FADH_2$  oxidation. The route taken by electrons through the electron-transport chain was elucidated, in part, through the use of electron-transport inhibitors. Rotenone and amylal inhibit Complex I, antimycin inhibits Complex III, and  $CN^-$  inhibits Complex IV. Also involved were measurements of the reduction potentials of the electron-carrying prosthetic groups contained in the electron-transport complexes.

Complex I contains FMN and nine iron-sulfur clusters in a 45-subunit (in mammals) transmembrane protein complex. This L-shaped complex passes electrons from NADH to CoQ, a nonpolar small molecule that diffuses freely within the membrane. Complex II, which is also the citric acid cycle enzyme succinate dehydrogenase, also passes electrons to CoQ, in this case from succinate through FAD and three iron-sulfur clusters. The X-ray structure of Complex II indicates that its redox cofactors are arranged in a linear chain. CoQH<sub>2</sub> passes electrons to Complex III (cytochrome  $bc_1$ ), a homodimeric complex whose protomers each contain two *b*-type hemes bound to a cytochrome *b* subunit, a Rieske iron-sulfur protein (ISP), and a cytochrome  $c_1$ . An electron from cytochrome  $c_1$  of Complex III is passed to the  $Cu_A$  center of Complex IV (cytochrome *c* oxidase) via the peripheral membrane protein cytochrome *c*. This electron is then passed to cytochrome *a*, which, in turn, passes it to a binuclear center composed of heme  $a_3$  and  $Cu_B$ , which reduces  $O_2$  to  $H_2O$ . This process occurs in four 1-electron steps that pump four protons from the mitochondrial matrix/bacterial cytoplasm to the intermembrane space/periplasm. Complexes I, III, and IV form supercomplexes that increase the efficiency of electron transport.

**3 Oxidative Phosphorylation** The mechanism by which the free energy released by the electron-transport chain is stored and utilized in ATP synthesis is described by the chemiosmotic hypothesis. This hypothesis states that the free energy released by electron transport is conserved by the generation of an electrochemical proton gradient across the inner mitochondrial membrane (bacterial cell membrane; outside positive and acidic), which is harnessed to synthesize ATP. The proton gradient is created and maintained by the obligatory outward translocation of  $H^+$  across the inner mitochondrial membrane as electrons travel through Complexes I, III, and IV.

Complex III pumps protons via a redox loop mechanism called the Q cycle, a bifurcated double cycle in which one

molecule of CoQH<sub>2</sub> is oxidized to CoQ and then is rereduced to CoQH<sub>2</sub> by a second molecule of CoQH<sub>2</sub> in a process that collectively transfers four protons from the inside to the outside while oxidizing one molecule of CoQH<sub>2</sub> to CoQ. Electrons are transferred between the two CoQ's, which are bound at different sites, Q<sub>o</sub> and Q<sub>i</sub>, as well as between the CoQH<sub>2</sub> bound at Q<sub>o</sub> and cytochrome *c*<sub>1</sub> via the ISP, which undergoes a conformational change in doing so. Complex IV contains no (H<sup>+</sup> + e<sup>-</sup>) carriers such as CoQH<sub>2</sub> and hence translocates protons via a proton pump mechanism. Bacteriorhodopsin, the best characterized proton pump, translocates protons in a light driven process. This involves a trans to cis isomerization of bacteriorhodopsin's retinal prosthetic group on absorbing a photon, followed by the translocation of a proton through the hydrophilic central channel of this transmembrane protein via a process that involves conformational and p*K* changes of the polar groups lining the channel as the retinal relaxes to its ground state. Complex IV is thought to pump protons via a similar mechanism that is driven by the changes in the redox state of its heme a<sub>3</sub>-Cu<sub>B</sub> binuclear center as it reduces O<sub>2</sub> to H<sub>2</sub>O.

The energy stored in the electrochemical proton gradient is utilized by proton-translocating ATP synthase (Complex V, F<sub>1</sub>F<sub>0</sub>-ATPase) in the synthesis of ATP via the binding change mechanism, by coupling this process to the exergonic transport of H<sup>+</sup> back to the inside. Mitochondrial proton-translocating ATP synthase consists of two oligomeric components: F<sub>1</sub> (α<sub>3</sub>β<sub>3</sub>γδϵ), a peripheral membrane protein that appears as "lollipop" in electron micrographs of the inner mitochondrial membrane, and F<sub>0</sub> (ab<sub>2</sub>c<sub>12</sub> in *E. coli*), an integral membrane

protein that contains the proton channel. The conformational changes that promote the synthesis of ATP from ADP + P<sub>i</sub> arise through the demonstrated rotation of the γ subunit relative to the catalytic α<sub>3</sub>β<sub>3</sub> assembly that contains the enzyme's three active sites. The γ subunit is attached to a ring of *c* subunits in F<sub>0</sub>, whose rotation is driven by the passage of protons between it and the *a* subunit.

Compounds such as 2,4-dinitrophenol are uncouplers of oxidative phosphorylation because they carry H<sup>+</sup> across the mitochondrial membrane, thereby dissipating the proton gradient and allowing electron transport to continue without concomitant ATP synthesis. Brown fat mitochondria contain a regulated uncoupling system that, under hormonal control, generates heat instead of ATP.

**4 Control of ATP Production** Under aerobic conditions, the rate of ATP synthesis by oxidative phosphorylation is regulated, in a phenomenon known as acceptor control, by the ATP mass action ratio. ATP synthesis is tightly coupled to the oxidation of NADH and FADH<sub>2</sub> by the electron-transport chain. Glycolysis and the citric acid cycle are coordinately controlled so as to produce NADH and FADH<sub>2</sub> only at a rate required to meet the system's demand for ATP. IF<sub>1</sub> inhibits the ATP hydrolysis by mitochondrial F<sub>1</sub>F<sub>0</sub>-ATPase that would otherwise occur under hypoxic conditions. Incomplete and side reactions of Complexes I, III, and IV produce damaging reactive oxygen species (ROS) that are largely eliminated through the actions of several cellular enzymes, most notably superoxide dismutase.

## PROBLEMS

- Rank the following redox-active coenzymes and prosthetic groups of the electron-transport chain in order of increasing affinity for electrons: cytochrome *a*, CoQ, FAD, cytochrome *c*, NAD<sup>+</sup>.
- Why is the oxidation of succinate to fumarate only associated with the production of two ATPs during oxidative phosphorylation, whereas the oxidation of malate to oxaloacetate is associated with the production of three ATPs?
- What is the thermodynamic efficiency of oxidizing FADH<sub>2</sub> so as to synthesize two ATPs under standard biochemical conditions?
- Sublethal cyanide poisoning may be reversed by the administration of nitrites. These substances oxidize hemoglobin, which has a relatively low affinity for CN<sup>-</sup>, to methemoglobin, which has a relatively high affinity for CN<sup>-</sup>. Why is this treatment effective?
- Match the compound with its behavior: (1) rotenone, (2) dinitrophenol, and (3) antimycin. (a) Inhibits oxidative phosphorylation when the substrate is pyruvate but not when the substrate is succinate. (b) Inhibits oxidative phosphorylation when the substrate is either pyruvate or succinate. (c) Allows pyruvate to be oxidized by mitochondria even in the absence of ADP.
- Nigericin** is an ionophore (Section 20-2C) that exchanges K<sup>+</sup> for H<sup>+</sup> across membranes. Explain how the treatment of functioning mitochondria with nigericin uncouples electron transport from oxidative phosphorylation. Does valinomycin, an ionophore that transports K<sup>+</sup> but not H<sup>+</sup>, do the same? Explain.
- Why is it possible for electrons in an electron-transfer complex to flow from a redox center to one with a lesser value of  $\mathcal{E}^{\circ}$ ?
- How do the P/O ratios for NADH differ in ATP synthases that contain 10 and 15 *c* subunits?
- The difference in pH between the internal and external surfaces of the inner mitochondrial membrane is 1.4 pH units (external side acidic). If the membrane potential is 0.06 V (inside negative), what is the free energy released on transporting 1 mol of protons back across the membrane? How many protons must be transported to provide enough free energy for the synthesis of 1 mol of ATP (assume standard biochemical conditions)?
- (a) A simplistic interpretation of the Q cycle would predict that the proton pumping efficiency of cytochrome *bc*<sub>1</sub> would be reduced by no more than 50% in the presence of saturating amounts of antimycin. Explain. (b) Indicate why cytochrome *bc*<sub>1</sub> is nearly 100% inhibited by antimycin.

## 11. The antibiotic oligomycin B

Oligomycin B

binds to the  $F_0$  subunit of the mitochondrial  $F_1F_0$ -ATPase and thereby prevents it from synthesizing ATP [note that oligomycin-sensitivity conferral protein (OSCF), the mitochondrial counterpart of the *E. coli*  $\delta$  subunit (Fig. 22-41), does not bind oligomycin

B.] Explain why: (a) Submitochondrial particles from which  $F_1$  has been removed are permeable to protons. (b) Addition of oligomycin B to  $F_1$ -depleted submitochondrial particles decreases this permeability severalfold.

12. Oligomycin B (see Problem 11) and cyanide both inhibit oxidative phosphorylation when the substrate is either pyruvate or succinate. Dinitrophenol can be used to distinguish between these inhibitors. Explain.

13. The *E. coli*  $F_1F_0$ -ATPase cannot synthesize ATP when Met 23 of its  $\gamma$  subunit is mutated to Lys. Yet the  $F_1$  component of this complex still exhibits rotation of its  $\gamma$  subunit relative to its  $\alpha_3\beta_3$  spheroid when it is supplied with ATP. Suggest a reason for these effects.

14. For the oxidation of a given amount of glucose, does nonshivering thermogenesis by brown fat or shivering thermogenesis by muscle produce more heat?

15. What is the advantage of hormones activating a lipase to stimulate nonshivering thermogenesis in brown fat rather than activating UCP1 directly?

16. How does atractyloside affect mitochondrial respiration? (*Hint*: See Section 20-4C.)

17. Certain unscrupulous operators offer, for a fee, to freeze recently deceased individuals in liquid nitrogen until medical science can cure the disease from which they died. What is the biochemical fallacy of this procedure?

- B. Isomerization and Epimerization of Ribulose-5-Phosphate
- C. Carbon–Carbon Bond Cleavage and Formation Reactions
- D. Control of the Pentose Phosphate Pathway
- E. Glucose-6-Phosphate Dehydrogenase Deficiency

Heretofore, we have dealt with many aspects of carbohydrate metabolism. We have seen how the free energy of glucose oxidation is sequestered in ATP through glycolysis, the citric acid cycle, and oxidative phosphorylation. We have also studied the mechanism by which glucose is stored as glycogen for future use and how glycogen metabolism is controlled in response to the needs of the organism. In this chapter, we examine several other carbohydrate metabolism pathways of importance:

**1. Gluconeogenesis**, through which noncarbohydrate precursors such as lactate, pyruvate, glycerol, and amino acids are converted to glucose.

**2. The glyoxylate cycle**, through which plants convert acetyl-CoA to glucose.

**3. Oligosaccharide and glycoprotein biosynthesis**, through which oligosaccharides are synthesized and added to specific amino acid residues of proteins.

**4. The pentose phosphate pathway**, an alternate pathway of glucose degradation, which generates **NADPH**, the source of reducing equivalents in reductive biosynthesis, and **ribose-5-phosphate**, the sugar precursor of the nucleic acids.

This chapter completes our study of carbohydrate metabolism in animals; photosynthesis, which occurs only in plants and certain bacteria, is the subject of Chapter 24.

## 1 GLUCONEOGENESIS

Glucose occupies a central role in metabolism, both as a fuel and as a precursor of essential structural carbohydrates and other biomolecules. The brain and red blood cells are almost completely dependent on glucose as an energy source. Yet the liver's capacity to store glycogen is only sufficient to supply the brain with glucose for about half a day under fasting or starvation conditions. Thus, *when fasting, most of the body's glucose needs must be met by gluconeogenesis (literally, new glucose synthesis), the biosynthesis of glucose from noncarbohydrate precursors.* Indeed, isotopic labeling studies determining the source of glucose in the blood during a fast showed that gluconeogenesis is responsible for 64% of total glucose production over the first 22 hours of the fast and accounts for almost all the glucose production by 46 hours. Thus, gluconeogenesis provides a substantial fraction of the glucose produced in fasting humans, even after a few hours' fast. Gluconeogenesis occurs in liver and, to a smaller extent, in kidney.

*The noncarbohydrate precursors that can be converted to glucose include the glycolysis products lactate and pyruvate, citric acid cycle intermediates, and the carbon skeletons of most amino acids. First, however, all these substances must be converted to oxaloacetate, the starting material for gluconeogenesis (Fig. 23-1).* The only amino acids that cannot be converted to oxaloacetate in animals are leucine and lysine because their breakdown yields only acetyl-CoA (Section 26-3F). *There is no pathway in animals for the net conversion of acetyl-CoA to oxaloacetate.* Likewise, fatty acids cannot serve as glucose precursors in animals because most fatty acids are degraded completely to acetyl-CoA (Section 25-2C). Unlike animals, however, plants do contain a pathway for the conversion of acetyl-CoA to oxaloacetate, the **glyoxylate cycle** (Section 23-2), so that fatty acids can serve as a plant cell's only carbon source. Glycerol, a triacylglycerol breakdown product, is converted to glucose via synthesis of the glycolytic intermediate dihydroxyacetone phosphate, as described in Section 25-1.

**Figure 23-1** Pathways converting lactate, pyruvate, and citric acid cycle intermediates to oxaloacetate. The carbon skeletons of

all amino acids but leucine and lysine may be, at least in part, converted to oxaloacetate and thus to glucose by these reactions.

### A. The Gluconeogenesis Pathway

Gluconeogenesis utilizes glycolytic enzymes. Yet three of these enzymes, hexokinase, phosphofruktokinase (PFK), and pyruvate kinase, catalyze reactions with large negative free energy changes in the direction of glycolysis. These reactions must therefore be replaced in gluconeogenesis by reactions that make glucose synthesis thermodynamically favorable. Here, as in glycogen metabolism (Section 18-1D), we see the recurrent theme that *biosynthetic and degradative pathways differ in at least one reaction. This not only permits both directions to be thermodynamically favorable under the same physiological conditions but allows the pathways to be independently controlled so that one direction can be activated while the other is inhibited.*

#### a. Pyruvate Is Converted to Oxaloacetate before Conversion to Phosphoenolpyruvate

The formation of phosphoenolpyruvate (PEP) from pyruvate, the reverse of the pyruvate kinase reaction, is endergonic and therefore requires free energy input. This is accomplished by first converting the pyruvate to oxaloacetate. Oxaloacetate is a “high-energy” intermediate whose exergonic decarboxylation provides the free energy necessary for PEP synthesis. The process requires the participation of two enzymes (Fig. 23-2):

- 1. Pyruvate carboxylase** catalyzes the ATP-driven formation of oxaloacetate from pyruvate and  $\text{HCO}_3^-$ .
- 2. PEP carboxykinase (PEPCK)** converts oxaloacetate

**Figure 23-2** Conversion of pyruvate to oxaloacetate and then to phosphoenolpyruvate. The enzymes involved are (1) pyruvate carboxylase and (2) PEP carboxykinase (PEPCK).

to PEP in a reaction that uses GTP as a phosphorylating agent.

### b. Pyruvate Carboxylase Has a Biotin Prosthetic Group

Pyruvate carboxylase, discovered in 1959 by Merton Utter, is a tetrameric protein of identical ~130-kD subunits, each of which has a **biotin** prosthetic group. *Biotin* (Fig. 23-3a) functions as a  $\text{CO}_2$  carrier by acquiring a carboxyl substituent at its **ureido group** (Fig. 23-3b). Biotin is covalently bound to the enzyme by an amide linkage between the carboxyl group of its valerate side chain and the  $\epsilon$ -amino group of an enzyme Lys residue to form a **biocytin**

**Figure 23-3** Biotin and carboxybiotinyl-enzyme. (a) Biotin consists of an imidazole ring that is cis-fused to a tetrahydrothiophene ring bearing a valerate side chain. The chirality at each of its three asymmetric centers is indicated. Positions 1, 2, and 3 constitute a ureido group. (b) In carboxybiotinyl-enzyme, N1 of the biotin ureido group is the carboxylation site. Biotin is covalently attached to carboxylases by an amide linkage between its valeryl carboxyl group and the  $\epsilon$ -amino group of an enzyme Lys side chain to form biocytin.

(alternatively, **biotinyllysine**) residue (Fig. 23-3b). The biotin ring system is therefore at the end of a 16-Å-long flexible arm, much like that of the lipoic acid prosthetic group in the pyruvate dehydrogenase multienzyme complex (Section 21-2Ac).

Biotin, which was first identified in 1935 as a growth factor in yeast, is an essential human nutrient. Its nutritional deficiency is rare, however, because it occurs in many foods and is synthesized by intestinal bacteria. Human biotin deficiency almost always results from the consumption of large quantities of raw eggs. This is because egg whites contain a protein, **avidin**, that binds biotin so tightly (dissociation constant,  $K = 10^{-15} M$ ) as to prevent its intestinal absorption (cooked eggs do not cause this problem because cooking denatures avidin). The presence of avidin in eggs is thought to inhibit the growth of microorganisms in this highly nutritious environment. The avidin homolog **streptavidin**, which is secreted by *Streptomyces avidinii*, is used as a linking agent in numerous biotechnological applications (e.g., Section 22-3Ce) because of its particularly high affinity for biotin.

### c. The Pyruvate Carboxylase Reaction

The pyruvate carboxylase reaction occurs in two phases (Fig. 23-4):

**Phase I** Biotin is carboxylated at its N1 atom by bicarbonate ion in a three-step reaction in which the hydrolysis of ATP to ADP +  $\text{P}_i$  functions, via the intermediate formation of **carboxyphosphate**, to dehydrate bicarbonate. This yields free  $\text{CO}_2$ , which has sufficient free energy to carboxylate biotin. The resulting carboxyl group is activated relative to bicarbonate ( $\Delta G^\circ$  for its cleavage is  $-19.7 \text{ kJ} \cdot \text{mol}^{-1}$ ) and can therefore be transferred without further free energy input.

**Phase II** The activated carboxyl group is transferred from carboxybiotin to pyruvate in a three-step reaction to form oxaloacetate.

These two reaction phases occur on different active sites of the same enzyme.

### d. Acetyl-CoA Regulates Pyruvate Carboxylase

*Oxaloacetate synthesis is an anaplerotic (filling up) reaction that increases citric acid cycle activity (Section 21-5b).* Accumulation of the citric acid cycle substrate acetyl-CoA is therefore indicative of the need for more oxaloacetate.

## Phase I

## Phase II

**Figure 23-4** Two-phase reaction mechanism of pyruvate carboxylase. **Phase I** is a three-step reaction in which carboxyphosphate is formed from bicarbonate and ATP, followed by the generation of  $CO_2$  on the enzyme, which then carboxylates biotin. **Phase II** is a three-step reaction in which

$CO_2$  is produced at the active site via the elimination of the biotinyl enzyme, which accepts a proton from pyruvate to generate pyruvate enolate. This, in turn, nucleophilically attacks the  $CO_2$ , yielding oxaloacetate. [After Knowles, J.R., *Annu. Rev. Biochem.* **58**, 217 (1989).]

Indeed, acetyl-CoA is a powerful allosteric activator of pyruvate carboxylase; the enzyme is all but inactive without bound acetyl-CoA. If, however, the citric acid cycle is inhibited (by ATP and NADH, whose presence in high concentrations indicates a satisfied demand for oxidative phosphorylation; Section 21-4), oxaloacetate instead undergoes gluconeogenesis.

#### e. X-Ray Structure of Pyruvate Carboxylase Suggests a Mechanism for Carboxyl Group Transfer

The X-ray structure of pyruvate carboxylase from the soil bacterium *Rhizobium etli* in complex with ATP $\gamma$ S and ethyl-CoA (acetyl-CoA with an ethyl group in place of its acetyl group), determined by Ivan Rayment, reveals that each subunit of this homotetrameric, 1154-residue protein consists of four domains (Fig. 23-5a): a biotin carboxylation (BC) domain (residues 1–465) that carries out Phase I of

the pyruvate carboxylase reaction (Fig. 23-4); an allosteric domain (residues 466–510 and 1001–1073) that binds acetyl-CoA; a carboxyltransferase (CT) domain (residues 511–1000) that catalyzes Phase II of the pyruvate carboxylase reaction (Fig. 23-4); and a domain named the biotin carboxyl carrier protein (BCCP; residues 1074–1154) to which the enzyme's biotin prosthetic group is covalently linked via Lys 1119 (Fig. 23-3). The active site of the BC domain is marked by its bound ATP $\gamma$ S, the CT domain is mainly an  $\alpha/\beta$  barrel (viewed from the side in Fig. 23-5a) whose active site is located in the mouth of the barrel and is marked by its bound  $Zn^{2+}$  ion, and the allosteric domain binds the ethyl-CoA, which like acetyl-CoA, activates the enzyme.

The biotin prosthetic group on the BCCP domain is disordered and hence not visible. Nevertheless it is clear that the  $\sim 80\text{-\AA}$  distance between a subunit's active sites is too

**Figure 23-5** X-ray structure of *R. etli* pyruvate carboxylase. (a) Ribbon diagram in which the BC and CT domains are each colored in rainbow order from their N-termini (blue) to their C-termini (red), the allosteric domain is light green, and the BCCP domain is pink. The ATP $\gamma$ S bound at the active site of the BC domain and the ethyl-CoA bound to the allosteric domain (with only its nucleotide portion visible) are drawn in space-filling form with ATP $\gamma$ S C green, ethyl-CoA C cyan, N blue, O red, and P orange. The Zn $^{2+}$  ion bound at the CT domain active site is represented by a purple sphere. (b) Surface representation of the tetramer viewed along its 2-fold axis with the two active subunits closest to the viewer. The BC domain is purple, the allosteric domain is light green, the CT domain is yellow, and the BCCP domain is red. For clarity, one of the subunits is outlined in black. The distance between the ATP $\gamma$ S in the BC active site and the Zn $^{2+}$  ion in the CT active site is 65 Å. (c) View relative to Part b by a 180° rotation about the vertical axis. The top pair of subunits have undergone a conformational change relative to the top pair in Part b such that the ATP $\gamma$ S–Zn $^{2+}$  distance between neighboring subunits is 80 Å. In addition, the BCCP domains in the top pair here are disordered. (d) Model of the tetramer indicating how the BCCP domain transfers a carboxyl group between the BC domain on the same subunit and the CT

domain of its neighboring subunit. The view and domain colors are the same as in Part b. [Part a based on an X-ray structure by and Parts b, c, and d courtesy of Ivan Rayment, University of Wisconsin, Madison, Wisconsin. PDBid 2QF7.]

large to be bridged by the 16-Å-long carboxybiotinyl arm (Fig. 23-3b). However, the BCCP domain is attached to the enzyme by a flexible polypeptide linker that is 34 Å long, much like that linking the lipoyl domain(s) to each dihydrolipoyl transacetylase (E2) subunit of the pyruvate dehydrogenase complex (Section 21-2Ae). Even so, it would require a dramatic movement of the entire BCCP domain to transfer substrate between the two active sites of a single subunit. How, then, does a BCCP domain translocate its carboxybiotin group between the active sites of a BC domain and a CT domain?

Pyruvate carboxylase's homotetrameric structure is required for its enzymatic activity; isolated subunits are catalytically inactive. However, the tetramer has only 2-fold symmetry because the top pair of subunits in Fig. 23-5b differ in conformation from the top pair in Fig. 23-5c by a 40° rotation and a 40-Å translocation of the BC domain relative to the CT domain of the same subunit. Indeed, the BCCP domains in the top pair of subunits in Fig. 23-5c are disordered, probably because the allosteric domains on these subunits do not bind ethyl-CoA. Consequently, the distance between active sites from adjacent subunits is 65 Å for the top pair in Fig. 23-5b, whereas it is 80 Å for the top pair in Fig. 23-5c. This suggests the model drawn in Fig. 23-5d in which each BCCP domain at the top of Fig. 23-5b shuttles CO<sub>2</sub> in the form of carboxybiotin from the active site of the BC domain on the same subunit to the CT domain on the adjacent subunit, whereas the other two subunits are inactive. This is an unusual example of allosteric activation coupled with negative cooperativity. It may permit pyruvate carboxylase to carry out efficient catalysis in association with other metabolic enzymes.

The foregoing model is supported by experiments involving two mutant forms of pyruvate carboxylase: K1119Q, which eliminates the biotinylation of the BC domain; and K718Q, which impairs the Phase II reaction. Tetramers of each of these mutant subunits exhibited 0.1% and 4% of the wild-type enzymatic activity, respectively. However, mixed tetramers exhibit 20% activity, thus indicating the formation of neighboring pairs of functional BC and CT domains.

#### f. PEP Carboxykinase

PEPCK, a monomeric ~630-residue enzyme, catalyzes the GTP-driven decarboxylation of oxaloacetate to form PEP and GDP (Fig. 23-6). Note that the CO<sub>2</sub> that carboxylates pyruvate to yield oxaloacetate is eliminated in the formation of PEP. Oxaloacetate may therefore be considered to be "activated" pyruvate, with CO<sub>2</sub> and biotin facilitating the activation at the expense of ATP hydrolysis. Acetyl-CoA is similarly activated for fatty acid biosynthesis through such a carboxylation decarboxylation process (forming malonyl-CoA; Section 25-4B). In general, β-keto acids may be considered "high-energy" compounds because of the high free energy of decarboxylation of the β-carboxyl group. The enolates they generate are used to form carbon-carbon bonds in fatty acid biosynthesis or phosphoenolpyruvate here in gluconeogenesis.

**Figure 23-6** The PEPCK mechanism. Decarboxylation of oxaloacetate (a β-keto acid) forms a resonance-stabilized enolate anion whose oxygen atom attacks the γ phosphoryl group of GTP forming PEP and GDP.

#### g. Gluconeogenesis Requires Metabolite Transport between Mitochondria and Cytosol

The generation of oxaloacetate from pyruvate or citric acid cycle intermediates occurs only in the mitochondrion, whereas the enzymes that convert PEP to glucose are cytosolic. The cellular location of PEPCK varies with the species. In mouse and rat liver it is located almost exclusively in the cytosol, in pigeon and rabbit liver it is mitochondrial, and in guinea pig and humans it is more or less equally distributed between both compartments. In order for gluconeogenesis to occur, either oxaloacetate must leave the mitochondrion for conversion to PEP or the PEP formed there must enter the cytosol.

PEP is transported across the mitochondrial membrane by specific membrane transport proteins. There is, however, no such transport system for oxaloacetate. It must first be converted either to aspartate (Fig. 23-7, Route 1) or to malate (Fig. 23-7, Route 2), for which mitochondrial transport systems exist (Section 22-1B). The difference between these two routes involves the transport of NADH reducing equivalents. The **malate dehydrogenase** route (Route 2) results in the transport of reducing equivalents from the mitochondrion to the cytosol, since it utilizes mitochondrial NADH and produces cytosolic NADH. The **aspartate aminotransferase** route (Route 1) does not involve NADH. Cytosolic NADH is required for gluconeogenesis so, under most conditions, the route through malate is a necessity. If the gluconeogenic precursor is lactate, however (Section 23-1C), its oxidation to pyruvate generates cytosolic NADH, so that either transport route may then be used. Of course, as we have seen, during oxidative metabolism

**Figure 23-7** Transport of PEP and oxaloacetate from the mitochondrion to the cytosol. PEP is directly transported between these compartments. Oxaloacetate, however, must first be converted to either aspartate through the action of **aspartate aminotransferase** (Route 1) or to malate by malate

dehydrogenase (Route 2). Route 2 involves the mitochondrial oxidation of NADH followed by the cytosolic reduction of  $\text{NAD}^+$  and therefore also transfers NADH reducing equivalents from the mitochondrion to the cytosol. **See the Animated Figures**

the two routes may also alternate (with Route 2 reversed) to form the malate–aspartate shuttle, which transports NADH reducing equivalents into the mitochondrion (Section 22-1Bc).

In the liver, where the urea cycle occurs (Section 26-2), a third route, a modification of Route 1, may be followed for transporting oxaloacetate into the cytosol. The aspartate that enters the cytosol by Route 1 may be converted to fumarate as part of the urea cycle (Fig. 26-8), instead of being transaminated. Fumarate is then hydrated to malate and dehydrogenated to oxaloacetate by cytosolic equivalents of citric acid cycle enzymes. This third route generates cytosolic NADH in the same way as does Route 2.

#### **h. Hydrolytic Reactions Bypass PFK and Hexokinase**

The opposing pathways of gluconeogenesis and glycolysis utilize many of the same enzymes (Fig. 23-8). However, the free energy change is highly unfavorable in the gluconeogenic

direction at two other points in the pathway in addition to the pyruvate kinase reaction: the PFK reaction and the hexokinase reaction. At these points, instead of generating ATP by reversing the glycolytic reactions, FBP and G6P are hydrolyzed, releasing  $\text{P}_i$  in exergonic processes catalyzed by **fructose-1,6-bisphosphatase (FBPase)** and **glucose-6-phosphatase**, respectively. *Glucose-6-phosphatase is unique to liver and kidney, permitting them to supply glucose to other tissues.*

Because of the presence of separate gluconeogenic enzymes at the three irreversible steps in the glycolytic conversion of glucose to pyruvate, both glycolysis and gluconeogenesis are rendered thermodynamically favorable. This is accomplished at the expense of the free energy of hydrolysis of two molecules each of ATP and GTP per molecule of glucose synthesized by gluconeogenesis in addition to that which would be consumed by the direct reversal of glycolysis.

**Glycolysis:****Gluconeogenesis:****Overall:**

Such free energy losses in a cyclic process are thermodynamically inescapable. They are the price that must be paid to maintain independent regulation of the two pathways.

**B. Regulation of Gluconeogenesis**

If both glycolysis and gluconeogenesis were to proceed in an uncontrolled manner, the net effect would be a futile cycle wastefully hydrolyzing ATP and GTP. This does not occur. Rather, *these pathways are reciprocally regulated so as to meet the needs of the organism.* In the fed state, when the blood glucose level is high, the liver is geared toward fuel conservation: Glycogen is synthesized and the glycolytic pathway and pyruvate dehydrogenase are activated, breaking down glucose to acetyl-CoA for fatty acid biosynthesis and fat storage. In the fasted state, however, the liver maintains the blood glucose level both by glycogen breakdown and by reversing the flux through glycolysis toward gluconeogenesis [using mainly protein degradation products via the **glucose-alanine cycle** (Section 26-1Ad) and glycerol from triacylglycerol hydrolysis (Section 25-1e)].

**a. Glycolysis and Gluconeogenesis Are Controlled by Allosteric Interactions and Covalent Modifications**

The rate and direction of glycolysis and gluconeogenesis are controlled at the points in these pathways where the forward and reverse directions can be independently regulated: the reactions catalyzed by (1) hexokinase/glucose-6-phosphatase, (2) PFK/FBPase, and (3) pyruvate kinase/pyruvate carboxylase-PEPCK (Fig. 23-8). Table 23-1 lists these regulatory enzymes and their regulators. The dominant mechanisms are allosteric interactions and cAMP-dependent covalent modifications (phosphorylation/dephosphorylation; Section 18-3). cAMP-dependent covalent modification renders this system sensitive to control by glucagon and other hormones that alter cAMP levels.

One of the most important allosteric effectors involved in the regulation of glycolysis and gluconeogenesis is fructose-2,6-bisphosphate (F2,6P), which activates PFK and inhibits FBPase (Section 18-3F). The concentration of F2,6P is controlled by its rates of synthesis and breakdown by phosphofructokinase-2 (PFK-2) and fructose biphosphatase-2 (FBPase-2), respectively. Control of the activities of PFK-2 and FBPase-2 is therefore an important aspect of gluconeogenic regulation even though these

enzymes do not catalyze reactions of the pathway. PFK-2 and FBPase-2 activities, which occur on separate domains of the same bifunctional enzyme, are subject to allosteric

**Figure 23-8** Pathways of gluconeogenesis and glycolysis. The three numbered steps, which are catalyzed by different enzymes in gluconeogenesis, have red arrows. The  $\Delta G^\circ$ 's for the reactions in the direction of gluconeogenesis under physiological conditions in liver are given in parentheses in  $\text{kJ} \cdot \text{mol}^{-1}$ . [ $\Delta G^\circ$ 's obtained from Newsholme, E.A. and Leech, A.R., *Biochemistry for the Medical Sciences*, p. 448, Wiley (1983).] See the Animated Figures

**Table 23-1** Regulators of Gluconeogenic Enzyme Activity

Enzyme	Allosteric Inhibitors	Allosteric Activators	Enzyme Phosphorylation	Protein Synthesis
PFK	ATP, citrate	AMP, F2,6P		
FBPase	AMP, F2,6P			
Pyruvate kinase	Alanine	F1,6P	Inactivates	
Pyruvate carboxylase		Acetyl-CoA		
PEPCK				Stimulated by glucagon, thyroid hormone, and glucocorticoids, and inhibited by insulin
PFK-2	Citrate	AMP, F6P, P <sub>i</sub>	Inactivates	
FBPase-2	F6P	Glycerol-3-P	Activates	

regulation as well as control by covalent modifications (Table 23-1). Low levels of blood glucose result in hormonal activation of gluconeogenesis through regulation of [F2,6P] (Fig. 23-9).

Activation of gluconeogenesis in liver also involves inhibition of glycolysis at the level of pyruvate kinase. *Liver pyruvate kinase is inhibited both allosterically by alanine (a pyruvate precursor; Section 26-1Ad) and by phosphorylation.* Glycogen breakdown, in contrast, is stimulated by phosphorylation (Section 18-3C). Both pathways then flow toward G6P, which is converted to glucose for export to muscle and brain. Muscle pyruvate kinase, an isozyme of the liver enzyme, is not subject to these controls. Indeed, such controls would be counterproductive in muscle since this tissue lacks glucose-6-phosphatase and thus the ability to synthesize glucose via gluconeogenesis.

**Figure 23-9** Hormonal regulation of [F2,6P]. This process activates gluconeogenesis in liver in response to low blood [glucose].

### b. PEPCK Concentration Is Transcriptionally Controlled

PEPCK is the enzyme that catalyzes the first committed reaction of gluconeogenesis. It is therefore of interest (Table 23-1) that PEPCK's activity is controlled solely through the transcriptional regulation of the gene encoding it (transcriptional regulation is outlined in Section 5-4Aa and discussed in detail in Sections 31-3 and 34-3). In particular, the transcription of the PEPCK gene is stimulated by glucagon, glucocorticoids, and thyroid hormones, and is inhibited by insulin. For instance, the cAMP that is produced in response to stimulation of the liver by glucagon, in addition to its initiation of phosphorylation cascades (Section 18-3), induces the transcription of the PEPCK gene. Richard Hanson has shown that this occurs because the PEPCK gene **promoter** (a control region that precedes the transcriptional initiation site of genes encoding proteins; Section 5-4Aa) contains a specific DNA sequence called the **cAMP response element (CRE)** that is bound by a **transcription factor** named **CRE binding protein (CREB)**, but only when CREB is also binding cAMP (recall that a transcription factor is a protein that binds to a specific segment of its target promoter and, in doing so, activates RNA polymerase to initiate the transcription of the associated gene; Section 5-4Aa). However, the PEPCK gene promoter contains numerous other binding sites for specific transcription factors. Among them are the **thyroid hormone response element (TRE)**, which is bound by thyroid hormone receptor in complex with thyroid hormone (Section 19-1D), and the **glucocorticoid hormone response element (GRE)**, which is bound by the **glucocorticoid receptor** in complex with a glucocorticoid hormone (Sections 19-1G and 34-3Bn). In contrast, PEPCK gene transcription is strongly repressed by protein factors phosphorylated by the PI3K signaling cascade (Section 19-4D) initiated by the binding of insulin to the insulin receptor (these protein factors may repress transcription by interfering with the binding of the above transcription factors; the mechanism of insulin signaling is discussed in Sections 19-3Ac, 19-3Cg, and 19-4F). The rate of PEPCK mRNA production is determined by the integration of these various interactions and hence of the signals that caused them.

**Figure 23-10 The Cori cycle.** Lactate produced by muscle glycolysis is transported by the bloodstream to the liver, where it is converted to glucose by gluconeogenesis. The bloodstream carries the glucose back to the muscles, where it may be stored as glycogen.  See the Animated Figures

### C. The Cori Cycle

Muscle contraction is powered by hydrolysis of ATP, which is then regenerated through oxidative phosphorylation in the mitochondria of slow-twitch (red) muscle fibers and by glycolysis yielding lactate in fast-twitch (white) muscle fibers. Slow-twitch fibers also produce lactate when ATP demand exceeds oxidative flux. The lactate is transferred, via the bloodstream, to the liver, where it is reconverted to pyruvate by lactate dehydrogenase and then to glucose by gluconeogenesis. Thus, through the intermediacy of the bloodstream, liver and muscle participate in a metabolic cycle known as the **Cori cycle** (Fig. 23-10) in honor of Carl and Gerty Cori, who first described it. This is the same ATP-consuming glycolysis/gluconeogenesis “futile cycle” we discussed above. Here, however, instead of occurring in the same cell, the two pathways occur in different organs. Liver ATP is used to resynthesize glucose from lactate produced in muscle. The resynthesized glucose is returned to the muscle, where it is stored as glycogen and used, on demand, to generate ATP for muscle contraction. The ATP utilized by the liver for this process is regenerated by oxidative phosphorylation. After vigorous exertion, it often takes at least 30 min for all of the lactate so produced to be converted to glycogen and the oxygen consumption rate to return to its resting level, a phenomenon known as **oxygen debt**.

## 2 THE GLYOXYLATE CYCLE

Plants, but not animals, possess enzymes that mediate the net conversion of acetyl-CoA to succinate, which is then converted, via malate, to oxaloacetate. This is accomplished via the **glyoxylate cycle** (Fig. 23-11), a pathway involving enzymes of the **glyoxysome** (a membranous plant organelle; Section 1-2Ad). The glyoxylate cycle involves five enzymes, three of which also participate in the citric acid cycle: citrate synthase, aconitase, and malate dehydrogenase.

The two other enzymes, isocitrate lyase and malate synthase, are unique to the cycle.

The glyoxylate cycle consists of five reactions (Fig. 23-11):

**Reactions 1 and 2.** Glyoxysomal oxaloacetate is condensed with acetyl-CoA to form citrate, which is isomerized to isocitrate as in the citric acid cycle. Since the glyoxysome contains no aconitase, Reaction 2 presumably takes place in the cytosol.

**Reaction 3.** Glyoxysomal **isocitrate lyase** cleaves the isocitrate to succinate and **glyoxylate** (hence the cycle’s name).

**Reaction 4. Malate synthase**, a glyoxysomal enzyme, condenses glyoxylate with a second molecule of acetyl-CoA to form malate.

**Reaction 5.** Glyoxysomal malate dehydrogenase catalyzes the oxidation of malate to oxaloacetate by  $\text{NAD}^+$ , thereby completing the cycle.

*The glyoxylate cycle therefore results in the net conversion of two acetyl-CoA to succinate instead of to four molecules of  $\text{CO}_2$ , as would occur in the citric acid cycle.* The succinate produced in Reaction 3 is transported to the mitochondrion, where it enters the citric acid cycle and is converted to malate, which has two alternative fates: (1) It can be converted to oxaloacetate in the mitochondrion, continuing the citric acid cycle and thereby making the glyoxylate pathway an anaplerotic process (Section 21-5b); or (2) it can be transported to the cytosol, where it is converted to oxaloacetate for entry into gluconeogenesis.

The overall reaction of the glyoxylate cycle can be considered to be the formation of oxaloacetate from two molecules of acetyl-CoA.

Isocitrate lyase and malate synthase, the only enzymes of the glyoxylate pathway unique to plants, enable germinating seeds to convert their stored triacylglycerols, through acetyl-CoA, to glucose. It had long been assumed that this was a requirement of germination. However, a mutant of *Arabidopsis thaliana* (an oilseed plant) lacking isocitrate lyase, and hence unable to convert lipids to carbohydrate, nevertheless germinated. This process was only inhibited when the mutant plants were subjected to low light conditions. It therefore appears that the glyoxylate cycle’s importance in seedling growth is its anaplerotic function in providing 4-carbon units to the citric acid cycle, which can then oxidize the triacylglycerol-derived acetyl-CoA.

## 3 BIOSYNTHESIS OF OLIGOSACCHARIDES AND GLYCOPROTEINS

Oligosaccharides consist of monosaccharide units joined together by glycosidic bonds (linkages between C1, the anomeric carbon, of one unit and an OH group of a second

**Figure 23-11** The glyoxylate cycle. The cycle results in the net conversion of two acetyl-CoA to succinate in the glyoxysome, which can be converted to malate in the mitochondrion for use in gluconeogenesis. Isocitrate lyase and malate synthase, enzymes unique to glyoxysomes (which occur only in plants), are boxed in blue. (1) Glyoxysomal citrate synthase catalyzes the condensation of oxaloacetate with acetyl-CoA to form citrate. (2) Cytosolic aconitase catalyzes the conversion of citrate to isocitrate. (3) Isocitrate lyase catalyzes the cleavage of isocitrate to succinate and glyoxylate. (4) Malate synthase catalyzes the

condensation of glyoxylate with acetyl-CoA to form malate. (5) Glyoxysomal malate dehydrogenase catalyzes the oxidation of malate to oxaloacetate, completing the cycle. (6) Succinate is transported to the mitochondrion, where it is converted to malate via the citric acid cycle. (7) Malate is transported to the cytosol, where malate dehydrogenase catalyzes its oxidation to oxaloacetate, which can then be used in gluconeogenesis. (8) Alternatively, malate can continue in the citric acid cycle, making the glyoxylate cycle anaplerotic.

unit; Section 11-1C). About 80 different kinds of naturally occurring glycosidic linkages are known, most of which involve mannose, *N*-acetylglucosamine, *N*-acetylmuramic acid, glucose, galactose, fucose (6-deoxygalactose), *N*-acetylneuraminic acid (sialic acid), and *N*-acetylgalactosamine (Section 11-1C). Glycosidic linkages also occur to lipids (e.g., glycosphingolipids; Section 12-1D) and proteins (glycoproteins; Section 11-3C).

Glycosidic bond formation requires free energy input under physiological conditions ( $\Delta G^{\circ} = 16 \text{ kJ} \cdot \text{mol}^{-1}$ ). This free energy, as we have seen in the case of glycogen synthesis (Section 18-2B), is acquired through the conversion of monosaccharide units to nucleotide sugars. A nucleotide at a sugar's anomeric carbon atom is a good leaving group and thereby facilitates formation of a glycosidic bond to a second sugar unit via reactions catalyzed by **glycosyltransferases**

(Fig. 23-12). The nucleotides that participate in monosaccharide transfers are UDP, GDP, and CMP; a given sugar is associated with only one of these nucleotides (Table 23-2).

### A. Lactose Synthesis

Several disaccharides are synthesized for future use as metabolic fuels. In plants, the major fuel disaccharide is sucrose (Section 11-2B), whose synthesis is discussed in Section 24-3Ad. Typical of mammalian disaccharides is lactose [ $\beta$ -galactosyl-(1  $\rightarrow$  4)-glucose; milk sugar], which is synthesized in the mammary gland by **lactose synthase** (Fig. 23-13). The donor sugar is UDP-galactose, which is formed by epimerization of UDP-glucose (Section 17-5B). The acceptor sugar is glucose.

Lactose synthase consists of two subunits:

**1. Galactosyltransferase**, the catalytic subunit, which occurs in many tissues, where it catalyzes the reaction of UDP-galactose and *N*-acetylglucosamine to yield *N*-acetyllactosamine, a constituent of many complex oligosaccharides (see, e.g., Fig. 23-20, Reaction 6).

**2.  $\alpha$ -Lactalbumin**, a mammary gland protein with no catalytic activity, which alters the specificity of galactosyltransferase such that it utilizes glucose as an acceptor, rather than *N*-acetylglucosamine, to form lactose instead of *N*-acetyllactosamine.

### B. Glycoprotein Synthesis

Eukaryotic proteins destined for secretion, incorporation into membranes, or localization inside membranous organelles contain carbohydrates and are therefore classified as glycoproteins. *Glycosylation and oligosaccharide processing play an indispensable role in the sorting and the distribution of these proteins to their proper cellular destinations.* Their polypeptide components are ribosomally synthesized and processed by addition and modification of oligosaccharides.

The oligosaccharide portions of glycoproteins, as we have seen in Sections 11-3C and 12-3Bc, are classified into three groups:

**1. *N*-Linked oligosaccharides**, which are attached to their polypeptide chain by a  $\beta$ -*N*-glycosidic bond to the side chain N of an Asn residue in the sequence Asn-X-Ser

**Table 23-2 Sugar Nucleotides and Their Corresponding Monosaccharides in Glycosyltransferase Reactions**

or Asn-X-Thr, where X is any amino acid residue except Pro (Fig. 23-14a).

**2. *O*-Linked oligosaccharides**, which are attached to their polypeptide chain through an  $\alpha$ -*O*-glycosidic bond to the side chain O of a Ser or Thr residue (Fig. 23-14b) or, only in collagens (Section 8-2Bb), to that of a 5-hydroxylysine (Hyl) residue (Fig. 23-14c).

**3. Glycosylphosphatidylinositol (GPI) membrane anchors**, which are attached to their polypeptide chain through an amide bond between mannose-6-phosphoethanolamine and the C-terminal carboxyl group (Fig. 23-14d).

We shall consider the synthesis of these three types of oligosaccharides in turn.

#### a. *N*-Linked Glycoproteins Are Synthesized in Four Stages

*N*-Linked glycoproteins are formed in the endoplasmic reticulum and further processed in the Golgi apparatus. Synthesis of their carbohydrate moieties occurs in four stages:

1. Synthesis of a lipid-linked oligosaccharide precursor.
2. Transfer of this precursor to the side chain N of an Asn residue on a growing polypeptide.
3. Removal of some of the precursor's sugar units.
4. Addition of sugar residues to the remaining core oligosaccharide.

**Figure 23-12 Role of nucleotide sugars.** These compounds are the glycosyl donors in oligosaccharide biosynthesis catalyzed by glycosyltransferases.

**Figure 23-13** Lactose synthase. This enzyme catalyzes the formation of lactose from UDP-galactose and glucose.

We shall discuss these stages in order.

### b. N-Linked Oligosaccharides Are Constructed on Dolichol Carriers

*N*-Linked oligosaccharides are initially synthesized as lipid-linked precursors. The lipid component in this process is **dolichol**, a long-chain polyisoprenol of 14 to 24 isoprene units (17–21 units in animals and 14–24 units in fungi and plants; isoprene units are  $C_5$  units with the carbon skeleton of isoprene; Section 25-6A), which is linked to the oligosaccharide precursor via a pyrophosphate bridge (Fig. 23-15). Dolichol apparently anchors the growing oligosaccharide to the endoplasmic reticulum membrane. Involvement of lipid-linked oligosaccharides in *N*-linked glycoprotein synthesis was first demonstrated in 1972 by Armando Parodi and Luis Leloir, who showed that, when a lipid-linked oligosaccharide containing [ $^{14}C$ ]glucose is incubated with rat liver **microsomes** (vesicular fragments of isolated endoplasmic reticulum), the radioactivity becomes associated with protein.

### c. N-Linked Glycoproteins Have a Common Oligosaccharide Core

The pathway of dolichol-PP-oligosaccharide synthesis involves stepwise addition of monosaccharide units to the

**Figure 23-14** Types of saccharide-polypeptide linkages in glycoproteins. (a) An *N*-linked glycosidic bond to an Asn residue in the sequence Asn-X-Ser/Thr. (b) An *O*-linked glycosidic bond to a Ser (or Thr) residue. (c) An *O*-linked glycosidic bond to a 5-hydroxylysine residue in collagen. (d) An amide bond between the C-terminal amino acid of a protein and the phosphoethanolamine bridge to the 6 position of mannose in the glycoposphatidylinositol (GPI) anchor. The X group (green) denotes the rest of the GPI anchor (Fig. 12-30).

**Figure 23-15** Dolichol pyrophosphate glycoside. The carbohydrate precursors of *N*-linked glycosides are synthesized as dolichol pyrophosphate glycosides. Dolichols are long-chain polyisoprenols ( $n = 14\text{--}24$ ) in which the  $\alpha$ -isoprene unit is saturated.

growing glycolipid by specific glycosyltransferases to form a common "core" structure. Each monosaccharide unit is added by a unique glycosyltransferase (Fig. 23-16). For example, in Reaction 2 of Fig. 23-16, five mannosyl units are added through the action of five different mannosyltransferases, each with a different oligosaccharide-acceptor specificity. The oligosaccharide core, the product of Reaction 9 in Fig. 23-16, has the composition (N-acetylglucosamine)<sub>2</sub>(mannose)<sub>9</sub>(glucose)<sub>3</sub>.

Although nucleotide sugars are the most common monosaccharide donors in glycosyltransferase reactions, several mannosyl and glucosyl residues are transferred to

the growing dolichol-PP-oligosaccharide from their corresponding dolichol-P derivatives. This requirement for **dolichol-P-mannose** was discovered by Stuart Kornfeld, who found that mutant mouse lymphoma cells (lymphoma is a type of cancer) that are unable to synthesize normal lipid-linked oligosaccharides formed a defective, smaller glycolipid. These cells contain all the requisite glycosyltransferases but are unable to synthesize dolichol-P-mannose (Reaction 4 in Fig. 23-16 is blocked). When this substance is supplied to the mutant cells, mannosyl units are added to the defective dolichol-PP-oligosaccharide.

**Figure 23-16 Pathway of dolichol-PP-oligosaccharide synthesis.** (1) Addition of N-acetylglucosamine-1-P and a second N-acetylglucosamine to dolichol-P. (2) Addition of five mannosyl residues from GDP-mannose in reactions catalyzed by five different mannosyltransferases. (3) Membrane translocation of dolichol-PP-(N-acetylglucosamine)<sub>2</sub>(mannose)<sub>5</sub> to the lumen of the endoplasmic reticulum (ER). (4) Cytosolic synthesis of dolichol-P-mannose from GDP-mannose and dolichol-P. (5) Membrane translocation of dolichol-P-mannose to the lumen of the ER. (6) Addition of four mannosyl residues from dolichol-P-mannose in reactions catalyzed by four different mannosyltransferases. (7) Cytosolic synthesis of dolichol-P-

glucose from UDP-glucose and dolichol-P. (8) Membrane translocation of dolichol-P-glucose to the lumen of the ER. (9) Addition of three glucosyl residues from dolichol-P-glucose. (10) Transfer of the oligosaccharide from dolichol-PP to the polypeptide chain at an Asn residue in the sequence Asn-X-Ser/Thr, releasing dolichol-PP. (11) Translocation of dolichol-PP to the cytoplasmic surface of the ER membrane. (12) Hydrolysis of dolichol-PP to dolichol-P. (13) Dolichol-P can also be formed by phosphorylation of dolichol by CTP. [Modified from Abeijon, C. and Hirschberg, C.B., *Trends Biochem. Sci.* 17, 34 (1992).]

 See the Animated Figures

#### d. Dolichol-PP-Oligosaccharide Synthesis Involves Topological Changes of the Intermediates

Reactions 1, 2, 4, and 7 of Fig. 23-16 all occur on the cytoplasmic side of the endoplasmic reticulum (ER) membrane. This was determined by using “right-side-out” rough ER vesicles and showing that various membrane-impermeant reagents can disrupt one or another of these reactions. Reactions 6, 9, and 10 occur in the lumen of the ER as judged by the inability of concanavalin A, a **lectin** (carbohydrate-binding protein), to bind to the products of these reactions until the membrane is permeabilized. The (mannose)<sub>5</sub> (*N*-acetylglucosamine)<sub>2</sub>-PP-dolichol product of Reaction 2, the dolichol-P-mannose product of Reaction 4, and the dolichol-P-glucose product of Reaction 7 must therefore be translocated across the ER membrane (Reactions 3, 5, and 8) such that they extend from its luminal surface in order for the synthesis of *N*-linked oligosaccharides to continue. The translocations are mediated by specific ATP-independent flippases.

#### e. *N*-Linked Oligosaccharides Are Cotranslationally Added to Proteins

**Vesicular stomatitis virus (VSV)**, which infects cattle, producing influenza-like symptoms, provides an excellent model system for studying *N*-linked glycoprotein processing. The VSV coat consists of host-cell membrane in which a single

viral glycoprotein, the **VSV G-protein** (not to be confused with the GTPases involved in signal transduction; Chapter 19), is embedded. Since a viral infection almost totally usurps an infected cell’s protein synthesizing machinery, a VSV-infected cell’s Golgi apparatus, which normally contains hundreds of different types of glycoproteins, contains virtually no other glycoprotein but G-protein. Consequently, the maturation of the G-protein is relatively easy to follow.

Of the Asn-X-Ser/Thr sites in mature eukaryotic proteins, 70 to 90% are *N*-glycosylated. Studies of VSV-infected cells indicate that the *transfer of the lipid-linked oligosaccharide to a polypeptide chain occurs while the polypeptide chain is still being synthesized*. Structural predictions (Section 9-3A), together with glycosylation studies of model polypeptides, suggest that the amino acid sequences flanking known *N*-glycosylation sites occur at  $\beta$  turns or loops in which Asn’s backbone N—H group is hydrogen bonded to the Ser/Thr hydroxyl O atom (Fig. 23-17a). This explains why Pro cannot occupy the X position; it would prevent Asn-X-Ser/Thr from assuming the putative required hydrogen bonded conformation.

VSV G-protein is *N*-glycosylated by **oligosaccharyltransferase (OST)**, a membrane-bound, ~300-kD, 8-subunit enzyme that recognizes the amino acid sequence Asn-X-Ser/Thr (Fig. 23-16, Reaction 10). Ernst Bause has proposed a catalytic mechanism for OST in which an enzyme base

**Figure 23-17 The oligosaccharyltransferase (OST) reaction.** (a) The Asn-X-Thr component of a hexapeptide model substrate forms a ring that is closed by a hydrogen bond from the Asn amide group to the Thr hydroxyl group. A base on the enzyme facilitates the nucleophilic displacement of dolichol pyrophosphate from the oligosaccharide (Sac) by the amide nitrogen. (b) The inactivation of the OST by reacting it with a hexapeptide containing Asn-Gly-epoxyethylGly in the presence of dolichol-PP-oligosaccharide. This chemically labels the base with the oligopeptide to which the oligosaccharide has become covalently linked.

abstracts a proton from the Ser/Thr hydroxyl group, which in turn abstracts a proton from the Asn NH<sub>2</sub> group, thereby promoting its nucleophilic attack on the oligosaccharide (Sac), which then displaces the dolichol pyrophosphate (Fig. 23-17a). This mechanism is supported by the observation that reacting the OST with dolichol-PP-oligosaccharide and a hexapeptide model substrate containing the sequence Asn-X-epoxyethylGly (rather than Asn-X-Ser/Thr) irreversibly inactivates the enzyme by covalently linking it to the now glycosylated hexapeptide (Fig. 23-17b).

#### f. The Calnexin/Calreticulin Cycle Facilitates Glycoprotein Folding

The processing of an N-linked core oligosaccharide begins in the endoplasmic reticulum by the enzymatic trimming (removal) of its three glucose residues (Fig. 23-18, Reactions 2 and 3) and one of its mannose residues (Fig. 23-18, Reaction 4) before the protein has folded to its native conformation. This is not a straightforward process, however, because **UDP-glucose:glycoprotein glucosyltransferase (GT)**, a 1513-residue soluble protein, reglucosylates the oligosaccharides of partially folded glycoproteins, a reaction that reverses the removal of the last of the three glucose residues by **glucosidase II** (Fig. 23-18, Reaction 3). This futile cycle (most glycoproteins undergo reglucosylation at least

once) is part of a chaperone-mediated glycoprotein folding process called the **calnexin/calreticulin cycle**. **Calnexin (CNX; ~570 residues)**, which is membrane bound, and **calreticulin (CRT; ~400 residues)**, its soluble homolog, are ER-resident lectins that bind partially folded glycoproteins bearing a monoglucosylated oligosaccharide in a way that protects the glycoprotein from degradation and premature transfer to the Golgi apparatus. If the glycoprotein is released and deglucosylated before it has correctly folded, GT, which recognizes only non-native glycoproteins, reglucosylates it so that the CNX/CRT cycle can repeat. CNX and CRT both also bind **ERp57**, a 481-residue thiol oxidoreductase homologous to protein disulfide isomerase (PDI; Section 9-2A). While the partially folded glycoprotein is bound to the complex, ERp57 catalyzes disulfide interchange reactions to facilitate the formation of the correctly paired disulfide bonds. The CNX/ERp57 and CRT/ERp57 complexes are therefore responsible for the correct folding and disulfide bond formation of the glycoproteins in the ER. The importance of this process is demonstrated by the observation that knockout mice lacking the gene for CRT die *in utero*.

The X-ray structure of the luminal domain of calnexin (residues 61–458), determined by Miroslaw Cygler, reveals a most unusual structure (Fig. 23-19): a compact globular domain (residues 61–262 and 415–458) from which extends

**Figure 23-18** The calnexin/calreticulin cycle for glycoprotein folding in the endoplasmic reticulum. The reactions are catalyzed by: (1) oligosaccharyltransferase (OST); (2)  $\alpha$ -glucosidase I; (3)  $\alpha$ -glucosidase II, UDP-glucose:glycoprotein glucosyltransferase

(GT), calreticulin (CRT), calnexin (CNX), and the thiol oxidoreductase ERp57; and (4) ER  $\alpha$ -1,2-mannosidase. [After Helenius, A. and Aebi, M., *Science* **291**, 2367 (2001).]

a 145-Å-long arm (residues 270–414). The globular domain forms a sandwich of a 6-stranded and a 7-stranded antiparallel  $\beta$  sheet that binds a  $\text{Ca}^{2+}$  ion and which resembles legume lectins such as concanavalin A (Fig. 8-40). This domain binds glucose on its concave (blue) surface, which is lined by hydrogen bonding groups that model building suggests binds the (glucose)<sub>1</sub>(mannose)<sub>3</sub> portion of calnexin's natural (glucose)<sub>1</sub>(mannose)<sub>9</sub> substrate. The long arm, which consists of an extended hairpin, is known as the P domain because it has four copies each of two different Pro-rich motifs arranged in the sequence 11112222, with each ~18-residue motif 1 in antiparallel association with an ~14-residue motif 2 on the opposite strand of the hairpin. Each of these motif pairs has a similar structure, with its conserved residues maintaining identical interactions in each pair. The P domain has been shown to form the binding site for ERp57 in both calnexin and calreticulin.

### g. Glycoprotein Processing is Completed in the Golgi Apparatus

Once a glycoprotein has folded to its native conformation and ER  $\alpha$ -1,2-mannosidase has removed one of its

**Figure 23-19** X-ray structure of the luminal portion of canine calnexin. The protein is drawn in ribbon form embedded in its semitransparent molecular surface. The 6- and 7-stranded antiparallel  $\beta$  sheets of its globular domain are colored orange and blue, with its remaining portions gray and its bound  $\text{Ca}^{2+}$  ion represented by a blue-green sphere. In the P domain, motifs 1 are alternately colored green and yellow and motifs 2 are alternately colored magenta and cyan. [Based on an X-ray structure by Mirosław Cygler, Biotechnology Research Institute, NRC, Montreal, Quebec, Canada. PDBid 1JHN.]

mannosyl residues (Fig. 23-18, Step 4), the glycoprotein is transported, in membranous vesicles, to the Golgi apparatus, where it is further processed (Fig. 23-20). The Golgi apparatus (Fig. 12-58), as we discussed in Section 12-4C, consists of, from opposite the ER outward, the cis Golgi

**Figure 23-20** Oligosaccharide processing of VSV G-protein in the Golgi network. The reactions are catalyzed by: (1) Golgi  $\alpha$ -mannosidase I, (2) *N*-acetylglucosaminyltransferase I, (3) Golgi  $\alpha$ -mannosidase II, (4) *N*-acetylglucosaminyltransferase II, (5) fucosyltransferase, (6) galactosyltransferase, and (7) sialyltransferase. Lysosomal proteins are modified by: (I) *N*-acetylglucosaminyl phosphotransferase and (II) *N*-acetylglucosamine-1-phosphodiester  $\alpha$ -*N*-acetylglucosaminidase. [Modified from Kornfeld, R. and Kornfeld, S., *Annu. Rev. Biochem.* 54, 640 (1985).]

network, through which glycoproteins enter the Golgi apparatus; a stack of at least three different types of sacs, the cis, medial, and trans cisternae; and the trans Golgi network, through which proteins exit the Golgi apparatus. Glycoproteins traverse the Golgi stack, from the cis to the medial to the trans cisternae, each of which, as shown by James Rothman and Kornfeld, contains different sets of glycoprotein processing enzymes. As this occurs, mannose residues are trimmed from each oligosaccharide group and *N*-acetylglucosamine, galactose, fucose, and/or sialic acid residues are added to complete the processing of the glycoprotein (Fig. 23-20; Reactions 1–7). The glycoproteins are then sorted in the trans Golgi network for transport to their respective cellular destinations via membranous vesicles (Sections 12-4C and 12-4D).

There is enormous diversity among the different oligosaccharides of *N*-linked glycoproteins, as is indicated, for example, in Fig. 11-32c. Indeed, *even glycoproteins with a given polypeptide chain exhibit considerable microheterogeneity* (Section 11-3C), presumably as a consequence of incomplete glycosylation and lack of absolute specificity on the part of glycosyltransferases and glycosylases.

The processing of all *N*-linked oligosaccharides is identical through Reaction 4 of Fig. 23-18, so that all of them have a common (*N*-acetylglucosamine)<sub>2</sub>(mannose)<sub>3</sub> core (five “noncore” mannose residues are subsequently trimmed from VSV G-protein; Fig. 23-20, Reactions 1 and 3). The diversity of the *N*-linked oligosaccharides therefore arises through divergence from this sequence after Fig. 23-20, Reaction 3. The resulting oligosaccharides are classified into three groups:

**1. High-mannose oligosaccharides** (Fig. 23-21a), which contain 2 to 9 mannose residues appended to the common pentasaccharide core (red residues in Fig. 23-21).

**2. Complex oligosaccharides** (Fig. 23-21b), which contain variable numbers of *N*-acetylglucosamine units as well as sialic acid and/or fucose residues linked to the core.

**3. Hybrid oligosaccharides** (Fig. 23-21c), which contain elements of both high-mannose and complex chains.

It is unclear how different types of oligosaccharides are related to the functions and/or final cellular locations of their glycoproteins. Lysosomal glycoproteins, however, appear to be of the high-mannose variety.

#### h. Inhibitors Have Aided the Study of *N*-Linked Glycosylation

Elucidation of the events in the glycosylation process has been greatly facilitated through the use of inhibitors that block specific glycosylation enzymes. Two of the most useful are the antibiotics **tunicamycin** (Fig. 23-22a), a hydrophobic analog of UDP-*N*-acetylglucosamine, and **bacitracin** (Fig. 23-23), a cyclic polypeptide. Both were discovered because of their ability to inhibit bacterial cell wall biosynthesis, a process that also involves the participation of lipid-linked oligosaccharides. Tunicamycin blocks the formation of dolichol-PP-oligosaccharides by inhibiting the synthesis of dolichol-PP-*N*-acetylglucosamine from dolichol-P and UDP-*N*-acetylglucosamine (Fig. 23-16, Reaction 1). Tunicamycin resembles an adduct of these reactants (Fig. 23-22b) and, in fact, binds to the enzyme with a dissociation constant of  $7 \times 10^{-9} M$ .

**Figure 23-21** Types of *N*-linked oligosaccharides. Typical primary structures of (a) high-mannose, (b) complex, and (c) hybrid *N*-linked oligosaccharides. The pentasaccharide core

common to all *N*-linked oligosaccharides is indicated in red. [After Kornfeld, R. and Kornfeld, S., *Annu. Rev. Biochem.* **54**, 633 (1985).]

**Figure 23-22** Chemical structure of tunicamycin. The structure of (a) the glycosylation inhibitor tunicamycin is compared to that of (b) dolichol-P + UDP-*N*-acetylglucosamine.

Bacitracin forms a complex with dolichol-PP that inhibits its dephosphorylation (Fig. 23-16, Reaction 12), thereby preventing glycoprotein synthesis from lipid-linked oligosaccharide precursors. Bacitracin is clinically

useful because it destroys bacterial cell walls but does not affect animal cells because it cannot cross cell membranes (bacterial cell wall biosynthesis is an extracellular process).

**Figure 23-23** Chemical structure of bacitracin. Note that this dodecapeptide has four D-amino acid residues and two unusual

intrachain linkages. “Orn” represents the nonstandard amino acid residue ornithine (Fig. 26-7).

### i. O-Linked Oligosaccharides Are Post-Translationally Formed

The study of the biosynthesis of **mucin**, an *O*-linked glycoprotein secreted by the submaxillary salivary gland, indicates that *O*-linked oligosaccharides are synthesized in the Golgi apparatus by serial addition of monosaccharide units to a completed polypeptide chain (Fig. 23-24). Synthesis starts with the transfer of *N*-acetylgalactosamine (GalNAc) from UDP-GalNAc to a Ser or Thr residue on the polypeptide by **GalNAc transferase**. In contrast to *N*-linked oligosaccharides, which are transferred to an Asn in a specific amino acid sequence, the *O*-glycosylated Ser and Thr residues are not members of any common sequence. Rather, it appears that the location of glycosylation sites is specified only by the secondary or tertiary structure of the polypeptide. Glycosylation continues with stepwise addition of galactose, sialic acid, *N*-acetylglucosamine, and/or fucose by the corresponding glycosyltransferases.

### j. Oligosaccharides on Glycoproteins Act as Recognition Sites

Glycoproteins that are synthesized in the endoplasmic reticulum and processed in the Golgi apparatus are targeted for secretion, insertion into cell membranes, or incorporation into cellular organelles such as lysosomes. This suggests that *oligosaccharides serve as recognition markers for this sorting process*. For example, the study of I-cell disease (Section 12-4Cg) demonstrated that in glycoprotein enzymes destined for the lysosome, a mannose residue is converted to mannose-6-phosphate (M6P) in the cis cisternae of the Golgi. The process involves two enzymes (Fig. 23-20, Reactions I and II), which are thought to recognize lysosomal protein precursors by certain structural features on these proteins rather than a specific amino acid sequence. In the trans Golgi network, M6P-bearing glycoproteins are sorted into lysosome-bound coated vesicles through their specific binding to one of two M6P receptors, one of which is a 275-kD membrane glycoprotein called the **M6P/IGF-II receptor** (because it has been found that this M6P receptor and the **insulinlike growth factor II receptor** are the same protein). Individuals with I-cell disease lack the enzyme catalyzing mannose phosphorylation (Fig. 23-20, Reaction I), resulting in the secretion of the normally lysosome-resident enzymes.

ABO blood group antigens (Section 12-3E) are *O*-linked glycoproteins. Their characteristic oligosaccharides are components of both cell-surface lipids and of proteins that occur in various secretions such as saliva. These oligosaccharides form antibody recognition sites.

*Glycoproteins are believed to mediate cell-cell recognition*. For example, an *O*-linked oligosaccharide on a glycoprotein that coats the mouse ovum surface (*zona pellucida*) acts as the sperm receptor. Even when this oligosaccharide is separated from its protein, it retains the ability to bind mouse sperm.

### k. GPI-Linked Proteins

**Glycosylphosphatidylinositol (GPI)** groups function to anchor a wide variety of proteins to the exterior surface of the eukaryotic plasma membrane, thus providing an alternative to transmembrane polypeptide domains (Section

**Figure 23-24** Proposed synthesis pathway for the carbohydrate moiety of an *O*-linked oligosaccharide chain of canine submaxillary mucin. SA and Fuc represent sialic acid and fucose.

12-3Bc; Fig. 12-30). This anchoring results from transamidation of a preformed GPI glycolipid within 1 min of the synthesis and transfer of a target protein to the ER. Biosynthesis of the GPI core structure (Fig. 23-25a) begins on the cytoplasmic side of the ER with the transfer of

**Figure 23-25** GPI anchors. (Opposite) (a) The pathway of synthesis of the tetrasaccharide core of glycosylphosphatidylinositol (GPI). The following enzymes and steps are involved: (1) UDP-GlcNAc:PI  $\alpha 1 \rightarrow 6$  *N*-acetylglucosaminyltransferase complex, (2) GlcNAc-PI de-*N*-acetylase, (3) inositol acyltransferase, (4) Dol-P-Man:GlcN-PI/GlcN-(acyl)PI  $\alpha 1 \rightarrow 4$  mannosyltransferase (MT-I), (5) an ethanolamine phosphotransferase, (6) Dol-P-Man:Man<sub>1</sub>GlcN-(acyl)PI  $\alpha 1 \rightarrow 6$  mannosyltransferase (MT-II), (7) Dol-P-Man:Man<sub>2</sub>GlcN-(acyl)PI  $\alpha 1 \rightarrow 2$  mannosyltransferase (MT-III), (8) lipid remodeling (replacement of the fatty acyl groups on PI), and (9) transfer of phosphoethanolamine from phosphatidylethanolamine to the 6-hydroxyl group of the terminal mannose residue of the core tetrasaccharide by an ethanolamine phosphotransferase. (b) Transamidation of the target protein, resulting in a C-terminal amide link to the GPI anchor.

(a)

(b)

*N*-acetylglucosamine from UDP-*N*-acetylglucosamine (UDP-GlcNAc) to the 6 hydroxyl of the inositol of phosphatidylinositol, followed by the removal of the acetyl group. The mammalian pathway then continues with the 2-acylation of inositol, translocation to the luminal side of the ER membrane, and the addition of mannose from dolichol-P-mannose (Dol-P-Man; Fig. 23-16) and phosphoethanolamine from phosphatidylethanolamine (Table 12-2), as indicated in Fig. 23-25*a*. This core is modified with a variety of additional sugar residues, depending on the species and the protein to which it is attached. There is considerable diversity in the fatty acid residues of GPI anchors due to the extensive lipid remodeling that occurs during anchor synthesis. Target proteins become anchored to the membrane surface when the amino group of the GPI phosphoethanolamine nucleophilically attacks a specific amino acyl group of the protein near its C-terminus, resulting in a transamidation that releases a 20- to 30-residue hydrophobic C-terminal signal peptide (Fig. 23-25*b*). Since GPI groups are appended to proteins on the luminal surface of the RER, GPI-anchored proteins occur on the exterior surface of the plasma membrane (Fig. 12-60). However, they are distributed unevenly in the outer leaflet of the plasma membrane because they prefer to associate with sphingolipid-cholesterol rafts (Section 12-3Cb).

The core GPI structure is evolutionarily conserved among all eukaryotes, although there are differences between species in its synthesis. For example, the cell surface of the trypanosomes that cause African sleeping sickness (a debilitating and often fatal disease that afflicts millions of people in sub-Saharan Africa) has a dense coating of **variant surface glycoprotein (VSG)** that is GPI-anchored to its plasma membrane. The VSG coating conceals the trypanosome's plasma membrane from the host's immune system although it recognizes and attacks the VSG itself. The parasite is nevertheless able to evade the host's immunological defenses because it has a genetic repertoire of about a thousand immunologically distinct VSGs. An individual trypanosome expresses only one of its VSG genes and hence the host can mount an effective immunological attack against the prevailing population of VSGs, a process that takes around 1 week (Section 35-2A). However, by switching VSG genes, a new population of trypanosomes arises that replicates unchecked until the host can mount a new immune response, a cycle that repeats until the death of the host. The comparison of the GPI biosynthetic pathway in trypanosomes with that in mammalian systems has revealed several differences in the pathway order. For example, Steps 3 and 4 of Fig. 23-25*a* are reversed in trypanosomes. This and other differences in the substrate specificities of the enzymes catalyzing this pathway have brought to light several promising drug targets for the treatment of African sleeping sickness.

#### 4 THE PENTOSE PHOSPHATE PATHWAY

ATP is the cell's "energy currency"; its exergonic hydrolysis is coupled to many otherwise endergonic cell functions. *Cells have a second currency, reducing power.* Many endergonic reactions, notably the reductive biosynthesis of fatty acids

(Section 25-4) and cholesterol (Section 25-6A), as well as photosynthesis (Section 24-3A), require NADPH in addition to ATP. Despite their close chemical resemblance, *NADPH* and *NADH* are not metabolically interchangeable (recall that these coenzymes differ only by a phosphate group at the 2'-OH group of NADPH's adenosine moiety; Fig. 13-2). Whereas NADH participates in utilizing the free energy of metabolite oxidation to synthesize ATP (oxidative phosphorylation), *NADPH is involved in utilizing the free energy of metabolite oxidation for otherwise endergonic reductive biosynthesis.* This differentiation is possible because the dehydrogenase enzymes involved in oxidative and reductive metabolism exhibit a high degree of specificity toward their respective coenzymes. Indeed, cells normally maintain their  $[NAD^+]/[NADH]$  ratio near 1000, which favors metabolite oxidation, while keeping their  $[NADP^+]/[NADPH]$  ratio near 0.01, which favors metabolite reduction.

*NADPH is generated by the oxidation of G6P via an alternative pathway to glycolysis, the **pentose phosphate pathway** [also called the **hexose monophosphate (HMP) shunt** and the **phosphogluconate pathway**; Fig. 23-26]. The pathway also produces ribose-5-phosphate (R5P), an essential precursor in nucleotide biosynthesis (Sections 28-1, 28-2, and 28-5).* The first evidence of this pathway's existence was obtained in the 1930s by Otto Warburg, who discovered  $NADP^+$  through his studies on the oxidation of G6P to 6-phosphogluconate. Further indications came from the observation that tissues continue to respire in the presence of high concentrations of fluoride ion, which, it will be recalled, blocks glycolysis by inhibiting enolase (Section 17-21). It was not until the 1950s, however, that the pentose phosphate pathway was elucidated by Frank Dickens, Bernard Horecker, Fritz Lipmann, and Efraim Racker. Tissues most heavily involved in fatty acid and cholesterol biosynthesis (liver, mammary gland, adipose tissue, and adrenal cortex) are rich in pentose phosphate pathway enzymes. Indeed, some 30% of the glucose oxidation in liver occurs via the pentose phosphate pathway.

The overall reaction of the pentose phosphate pathway is

$$3G6P + 6NADP^+ + 3H_2O \rightleftharpoons$$

However, the pathway may be considered to have three stages:

1. Oxidative reactions (Fig. 23-26, Reactions 1–3), which yield NADPH and **ribulose-5-phosphate (Ru5P)**.

2. Isomerization and epimerization reactions (Fig. 23-26, Reactions 4 and 5), which transform Ru5P either to **ribose-5-phosphate (R5P)** or to **xylulose-5-phosphate (Xu5P)**.

3. A series of C—C bond cleavage and formation reactions (Fig. 23-26, Reactions 6–8) that convert two molecules of Xu5P and one molecule of R5P to two molecules

**Figure 23-26 The pentose phosphate pathway.** The number of lines in an arrow represents the number of molecules reacting in one turn of the pathway so as to convert three G6P to three CO<sub>2</sub>, two F6P, and one GAP. For the sake of clarity, sugars from Reaction 3 onward are shown in their linear forms. The carbon

skeleton of R5P and the atoms derived from it are drawn in red and those from Xu5P are drawn in green. The C<sub>2</sub> units transferred by transketolase are shaded in green and the C<sub>3</sub> units transferred by transaldolase are shaded in blue. Double-headed arrows indicate reversible reactions.

of fructose-6-phosphate (F6P) and one of glyceraldehyde-3-phosphate (GAP).

The reactions of Stages 2 and 3 are freely reversible so that the products of the pathway vary with the needs of the cell.

For example, when R5P is required for nucleotide biosynthesis, Stage 3 works in reverse, producing R5P from F6P and GAP nonoxidatively. In this section, we discuss the three stages of the pentose phosphate pathway and how this pathway is controlled. We close by considering the consequences of one of its abnormalities.

**Figure 23-27** The glucose-6-phosphate dehydrogenase reaction.

### A. Oxidative Reactions of NADPH Production

Only the first three reactions of the pentose phosphate pathway are involved in NADPH production.

**1. Glucose-6-phosphate dehydrogenase (G6PD)** catalyzes net transfer of a hydride ion to  $\text{NADP}^+$  from C1 of G6P to form **6-phosphoglucono- $\delta$ -lactone** (Fig. 23-27). G6P, a cyclic hemiacetal with C1 in the aldehyde oxidation state, is thereby oxidized to a cyclic ester (lactone). The enzyme is specific for  $\text{NADP}^+$  and is strongly inhibited by NADPH.

**2. 6-Phosphogluconolactonase** increases the rate of hydrolysis of 6-phosphoglucono- $\delta$ -lactone to **6-phosphogluconate** (the nonenzymatic reaction occurs at a significant rate), the substrate of the next oxidative enzyme in the pathway.

**3. 6-Phosphogluconate dehydrogenase** catalyzes the oxidative decarboxylation of 6-phosphogluconate, a  $\beta$ -hydroxy acid, to Ru5P and  $\text{CO}_2$  (Fig. 23-28). The reaction is similar to that catalyzed by the citric acid cycle enzyme isocitrate dehydrogenase (Section 21-3C).

Formation of Ru5P completes the oxidative portion of the pentose phosphate pathway. *It generates two molecules of NADPH for each molecule of G6P that enters the pathway.* The product Ru5P must subsequently be converted to R5P or Xu5P for further use.

### B. Isomerization and Epimerization of Ribulose-5-Phosphate

Ru5P is converted to R5P by **ribulose-5-phosphate isomerase** (Fig. 23-26, Reaction 4) and to Xu5P by **ribulose-**

**5-phosphate epimerase** (Fig. 23-26, Reaction 5). These isomerization and epimerization reactions, as discussed in Section 16-2Db, are both thought to occur via enediolate intermediates (Fig. 23-29).

R5P is an essential precursor in the biosynthesis of nucleotides (Sections 28-1, 28-2, and 28-5). If, however, more R5P is formed than the cell needs, the excess, along with Xu5P, is converted to the glycolytic intermediates F6P and GAP as described below.

### C. Carbon–Carbon Bond Cleavage and Formation Reactions

The conversion of three  $\text{C}_5$  sugars to two  $\text{C}_6$  sugars and one  $\text{C}_3$  sugar involves a remarkable “juggling act” catalyzed by two enzymes, **transaldolase** and **transketolase**. As we discussed in Section 16-2E, enzymatic reactions that make or break carbon–carbon bonds usually have mechanisms that involve generation of a stabilized carbanion and its addition to an electrophilic center such as an aldehyde. This is the dominant theme of both the transaldolase and the transketolase reactions.

#### a. Transketolase Catalyzes the Transfer of $\text{C}_2$ Units

Transketolase, which has a thiamine pyrophosphate cofactor (TPP; Section 17-3Ba), catalyzes the transfer of a  $\text{C}_2$  unit from Xu5P to R5P, yielding GAP and **sedoheptulose-7-phosphate (S7P)** (Fig. 23-26, Reaction 6). The reaction involves the intermediate formation of a covalent adduct between Xu5P and TPP (Fig. 23-30). The X-ray structure of this homodimeric enzyme shows that the TPP binds in a deep cleft between the subunits such that residues from both

**Figure 23-28** The phosphogluconate dehydrogenase reaction. Oxidation of the OH group forms an easily decarboxylated

$\beta$ -keto acid (although the proposed intermediate has not been isolated).

**Figure 23-29** Ribulose-5-phosphate isomerase and ribulose-5-phosphate epimerase. The reactions catalyzed by both these enzymes involve enediolate intermediates. In the isomerase reaction (*right*), a base on the enzyme removes a proton from C1 of Ru5P to form a 1,2-enediolate and then adds a proton at C2 to form R5P. In the epimerase reaction (*left*), a base on the enzyme removes a C3 proton to form a 2,3-enediolate. A proton is then added to the same carbon atom but with inversion of configuration to yield Xu5P.

**Figure 23-30** Mechanism of transketolase. Transketolase utilizes the coenzyme thiamine pyrophosphate to stabilize the carbanion formed on cleavage of the C2—C3 bond of Xu5P. The reaction occurs as follows: **(1)** The TPP ylid attacks the carbonyl group of Xu5P. **(2)** C2—C3 bond cleavage yields GAP and enzyme-bound 2-(1,2-dihydroxyethyl)-TPP, a resonance-stabilized carbanion. **(3)** The C2 carbanion attacks the aldehyde carbon of R5P forming an S7P—TPP adduct. **(4)** TPP is eliminated yielding S7P and the regenerated TPP—enzyme.

subunits participate in its binding, just as in pyruvate decarboxylase (another TPP-requiring enzyme; Figure 17-28). In fact the structures are so similar that it is likely that they diverged from a common ancestor.

### b. Transaldolase Catalyzes the Transfer of C<sub>3</sub> Units

Transaldolase catalyzes the transfer of a C<sub>3</sub> unit from S7P to GAP, yielding **erythrose-4-phosphate (E4P)** and F6P (Fig. 23-26, Reaction 7). The reaction occurs by aldol cleavage, which begins with the formation of a Schiff base between an ε-amino group of an essential enzyme Lys residue and the carbonyl group of S7P (Fig. 23-31). Transaldolase and Class I aldolase (Section 17-2Da) share a common reaction mechanism and may also share a common ancestor, despite their lack of significant sequence identity. Both are α/β barrel proteins (Section 8-3Bh), but while the Schiff base-forming Lys is on β4 (the fourth β strand from the N-terminus) of transaldolase, it is on β6 of Class I aldolase. Superimposing the barrel structures of these two enzymes while maintaining the alignment of the β strands bearing the Schiff base-forming Lys residues results in a significantly better fit than doing so while maintaining the alignment of their entire α/β barrels. Moreover, five of the pairs of matched active site residues in the former superposition are identical. This suggests that, during evolution, the DNA sequence for two α/β units was transferred from the N-terminus to the C-terminus of the evolving Class I aldolase, moving the active site Lys from β6 to β4. Such a circular permutation of an α/β barrel's structural elements does not greatly change its structure.

### c. A Second Transketolase Reaction Yields GAP and a Second F6P Molecule

In a second transketolase reaction, a C<sub>2</sub> unit is transferred from a second molecule of Xu5P to E4P to form GAP and another molecule of F6P (Fig. 23-26, Reaction 8). The third phase of the pentose phosphate pathway thus transforms two molecules of Xu5P and one of R5P to two molecules of F6P and one molecule of GAP. These carbon skeleton transformations (Fig. 23-26, Reactions 6–8) are summarized in Fig. 23-32.

### D. Control of the Pentose Phosphate Pathway

The principal products of the pentose phosphate pathway are R5P and NADPH. The transaldolase and transketolase reactions serve to convert excess R5P to glycolytic intermediates

**Figure 23-31 Mechanism of transaldolase.** Transaldolase contains an essential Lys residue that forms a Schiff base with S7P to facilitate an aldol cleavage reaction. The reaction occurs as follows: **(1)** The ε-amino group of an essential Lys residue forms a Schiff base with the carbonyl group of S7P. **(2)** A Schiff base-stabilized C3 carbanion is formed in an aldol cleavage reaction between C3 and C4 that eliminates E4P. **(3)** The enzyme-bound resonance-stabilized carbanion adds to the carbonyl C atom of GAP, forming F6P linked to the enzyme via a Schiff base. **(4)** The Schiff base hydrolyzes, regenerating active enzyme and releasing F6P.

**Figure 23-32 Summary of carbon skeleton rearrangements in the pentose phosphate pathway.** A series of carbon-carbon bond formations and cleavages convert three  $C_5$  sugars to two  $C_6$  and one  $C_3$  sugar. The number to the left of each reaction is keyed to the corresponding reaction in Fig. 23-26.

when the metabolic need for NADPH exceeds that of R5P in nucleotide biosynthesis. The resulting GAP and F6P can be consumed through glycolysis and oxidative phosphorylation or recycled by gluconeogenesis to form G6P. *In the latter case, 1 molecule of G6P can be converted, via six cycles of the pentose phosphate pathway and gluconeogenesis, to 6  $CO_2$  molecules with the concomitant generation of 12 NADPH molecules.* When the need for R5P outstrips that for NADPH, F6P and GAP can be diverted from the glycolytic pathway for use in the synthesis of R5P by reversal of the transaldolase and transketolase reactions. In fact, mass spectral analysis of the  $^{13}C$ -labeled carbons from  $[1,2-^{13}C]$ glucose incorporated into RNA in rapidly proliferating cancer cells has shown that more than ~70% of the *de novo* ribose synthesis arises through this nonoxidative reversal of the pentose phosphate pathway (rather than its forward direction).

*Flux through the oxidative pentose phosphate pathway and thus the rate of NADPH production is controlled by the rate of the glucose-6-phosphate dehydrogenase reaction (Fig. 23-26, Reaction 1).* The activity of this enzyme, which catalyzes the pentose phosphate pathway's first committed step ( $\Delta G = -17.6 \text{ kJ} \cdot \text{mol}^{-1}$  in liver), is regulated by the  $NADP^+$  concentration (substrate availability). When the cell consumes NADPH, the  $NADP^+$  concentration rises, increasing the rate of the glucose-6-phosphate dehydrogenase reaction, thereby stimulating NADPH regeneration.

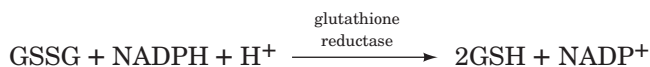

### E. Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH is required for several reductive processes in addition to biosynthesis. For example, erythrocyte membrane integrity requires a plentiful supply of reduced glutathione (GSH), a Cys-containing tripeptide (Sections 21-2Ba and 26-4C). A major function of GSH in the erythrocyte is to eliminate  $H_2O_2$  and organic hydroperoxides.  $H_2O_2$ , a toxic product of various oxidative processes (Section 22-4Cg), reacts with double bonds in the fatty acid residues of the erythrocyte cell membrane to form organic hydroperoxides. These, in turn, react to cleave fatty acid C—C bonds, thereby damaging the membrane. In erythrocytes, the unchecked buildup of peroxides results in premature cell lysis. Peroxides are eliminated through the action of **glutathione peroxidase**, one of the handful of

enzymes with a selenium cofactor, yielding glutathione disulfide (GSSG).

GSH is subsequently regenerated by the NADPH reduction of GSSG catalyzed by glutathione reductase (Section 21-2Ba).

A steady supply of NADPH is therefore vital for erythrocyte integrity.

#### a. Primaquine Causes Hemolytic Anemia in Glucose-6-Phosphate Dehydrogenase Mutants

A genetic defect, common in African, Asian, and Mediterranean populations, results in severe hemolytic anemia on infection or on the administration of certain drugs including the antimalarial agent **primaquine**.

Similar effects, which go by the name of **favism**, occur when individuals bearing this trait eat **fava beans (broad beans, *Vicia faba*)**, a staple Middle Eastern vegetable that contains small quantities of toxic glycosides (the Greek philosopher and mathematician Pythagoras, who lived in the sixth century BCE, forbade his followers from eating fava beans, possibly because of their deleterious effects). This trait has been traced to an altered gene for glucose-6-phosphate dehydrogenase (G6PD). Under most conditions, mutant erythrocytes have sufficient enzyme activity for normal function. Agents such as primaquine and fava beans, however, stimulate peroxide formation, thereby increasing the demand for NADPH to a level that mutant cells cannot meet.

The major reason for low enzymatic activity in affected cells appears to be an accelerated rate of breakdown of the mutant enzyme (protein degradation is discussed in Section 32-6). This explains why patients with G6PD deficiency react to primaquine with hemolytic anemia but recover within a week despite continued primaquine treatment. Mature erythrocytes lack a nucleus and protein synthesizing machinery and therefore cannot synthesize new enzyme molecules to replace degraded ones (they likewise cannot synthesize new membrane components, which is why they are so sensitive to membrane damage in the first place). The initial primaquine treatments result in

the lysis of old red blood cells whose defective G6PD has been largely degraded. Lysis products stimulate the release of young cells that contain more enzyme and are therefore better able to cope with primaquine stress.

It is estimated that over 400 million people are deficient in G6PD, which makes this condition the most common human enzymopathy. Indeed, ~400 G6PD variants have been reported and at least 140 of them have been characterized at the molecular level. G6PD is active in a dimer–tetramer equilibrium. Many of the mutation sites in individuals with the most severe G6PD deficiency are at the dimer interface, shifting the equilibrium toward the inactive and unstable monomer.

Several G6PD variants occur with high incidence. For example, the so-called type A<sup>-</sup> deficiency, which exhibits ~10% of the normal G6PD activity, has an incidence of 11% among African Americans. This variant is also the most common form of G6PD deficiency in sub-Saharan Africa. The variant “Mediterranean” is found throughout the Mediterranean and Middle East regions, and occurs in

65% of Kurdish Jews, the population with the highest known incidence of this trait. The high prevalence of defective G6PD in malarial areas of the world suggests that such mutations confer resistance to the malarial parasite, *Plasmodium falciparum* (as we likewise saw to be the case for the sickle-cell trait; Section 7-3Ab). Indeed, two epidemiological studies involving over 2000 African children with A<sup>-</sup> G6PD deficiency indicate that this form is associated with an ~50% reduction in the risk of severe malaria for both female heterozygotes and male hemizygotes (G6PD deficiency is an X-linked trait).

*In vitro* studies indicate that erythrocytes with G6PD deficiency are less suitable hosts for plasmodia than are normal cells. This is presumably because the parasite requires the products of the pentose phosphate pathway and/or because the erythrocyte is lysed before the parasite has had a chance to mature. Thus, like the sickle-cell trait, *a defective G6PD confers a selective advantage on individuals living where malaria is endemic.*

## CHAPTER SUMMARY

**1 Gluconeogenesis** Lactate, pyruvate, citric acid cycle intermediates, and many amino acids may be converted, by gluconeogenesis, to glucose via the formation of oxaloacetate. For this to occur, the three irreversible steps of glycolysis must be bypassed. The pyruvate kinase reaction is bypassed by converting pyruvate to oxaloacetate in an ATP-driven reaction catalyzed by the biotinyl-containing enzyme pyruvate carboxylase. The two phases of the pyruvate decarboxylase reaction are catalyzed on different active sites of the homotetrameric enzyme, which translocates its covalently linked carboxybiotinyl group from its BC domain to the CT domain of a neighboring subunit. The oxaloacetate is subsequently decarboxylated and phosphorylated by GTP to form PEP in a reaction catalyzed by PEPCK. For this to happen in species in which PEPCK is a cytosolic enzyme, the oxaloacetate must be transported from the mitochondrion to the cytosol via its interim conversion to either malate or aspartate. Conversion to malate concomitantly transports reducing equivalents to the cytosol in the form of NADH. The two other irreversible steps of glycolysis, the PFK reaction and the hexokinase reaction, are bypassed by simply hydrolyzing their products, FBP and G6P, by FBPase and glucose-6-phosphatase, respectively. A glucose molecule may therefore be synthesized from pyruvate at the expense of four ATPs more than are generated by the reverse process.

Glycolysis and gluconeogenesis are reciprocally regulated so as to consume glucose when the demand for ATP is high and synthesize it when the demand is low. The control points in these processes are at pyruvate kinase/pyruvate carboxylase–PEPCK, PFK/FBPase, and hexokinase/glucose-6-phosphatase. Regulation of these enzymes is exerted largely through allosteric interactions, cAMP-dependent enzyme modifications, and, for PEPCK, gene expression. Muscle, which is incapable of gluconeogenesis, transfers much of the lactate it produces to the liver via the blood for conversion to glucose and return to the muscle. This Cori cycle shifts the metabolic burden of oxidative ATP generation for gluconeogenesis from muscle to liver.

**2 The Glyoxylate Cycle** Animals cannot convert fatty acids to glucose because they lack the enzymes necessary to synthesize oxaloacetate from acetyl-CoA. Plants, however, can do so via the glyoxylate cycle, a glyoxysomal process that converts two molecules of acetyl-CoA to one molecule of succinate via the intermediate formation of glyoxylate. Succinate is converted to oxaloacetate for use in gluconeogenesis or the citric acid cycle.

**3 Biosynthesis of Oligosaccharides and Glycoproteins** Glycosidic bonds are formed by transfer of the monosaccharide unit of a sugar nucleotide to a second sugar unit. Such reactions occur in the synthesis of disaccharides such as lactose and in the synthesis of the carbohydrate components of glycoproteins. In *N*-linked glycoproteins, the carbohydrate component is attached to the protein via an *N*-glycosidic bond to an Asn residue in the sequence Asn-X-Ser/Thr. In *O*-linked glycoproteins, the carbohydrate attachment is an *O*-glycosidic bond to Ser or Thr or, in collagens, to 5-hydroxylysine. In GPI-anchored proteins a glycosylphosphatidylinositol group is linked to the protein through an intermediary phosphoethanolamine bridge, which forms an amide bond to the protein's C-terminal amino acid residue.

Synthesis of *N*-linked oligosaccharides begins in the endoplasmic reticulum with the multistep formation of a lipid-linked precursor consisting of dolichol pyrophosphate bonded to a common 14-residue core oligosaccharide. The carbohydrate is then transferred to an Asn residue of a growing polypeptide chain. The correct folding of the immature *N*-linked glycoprotein is assisted via the calnexin/calreticulin cycle and it is subsequently transferred, via a membranous vesicle, to the cis Golgi network of the Golgi apparatus. Processing is completed by the trimming of mannose residues followed by attachment of a variety of other monosaccharides as catalyzed by specific enzymes in the cis, medial, and trans Golgi cisternae. Completed *N*-linked glycoproteins are sorted in the trans Golgi network according to the identities of their carbohydrate components for transport, via membranous vesicles, to their final cellular destinations. Three

major types of *N*-linked oligosaccharides have been identified, high mannose, complex, and hybrid oligosaccharides, all of which contain a common pentasaccharide core. Studies of glycoprotein formation have been facilitated by the use of antibiotics, such as tunicamycin and bacitracin, which inhibit specific enzymes involved in the synthesis of these oligosaccharides.

*O*-Linked oligosaccharides are synthesized in the Golgi apparatus by sequential attachments of specific monosaccharide units to certain Ser or Thr residues. Carbohydrate components of glycoproteins are thought to act as recognition markers for the transport of glycoproteins to their proper cellular destinations and for cell–cell and antibody recognition. The GPI membrane anchor is appended to proteins on the luminal surface of the endoplasmic reticulum, thereby targeting GPI-anchored proteins to the external surface of the plasma membrane.

**4 The Pentose Phosphate Pathway** The cell uses NAD<sup>+</sup> in oxidative reactions and employs NADPH in reductive biosynthesis. NADPH is synthesized by the pentose phosphate pathway, an alternate mode of glucose oxidation. This pathway also synthesizes R5P for use in nucleotide biosynthesis. The first three reactions of the pentose phosphate pathway

involve oxidation of G6P to Ru5P with release of CO<sub>2</sub> and formation of two NADPH molecules. This is followed by reactions that either isomerize Ru5P to R5P or epimerize it to Xu5P. Each molecule of R5P not required for nucleotide biosynthesis, together with two Xu5P, is converted to two molecules of F6P and one molecule of GAP via the sequential actions of transketolase, transaldolase, and, again, transketolase. The products of the pentose phosphate pathway depend on the needs of the cell. The F6P and GAP may be metabolized through glycolysis and the citric acid cycle or recycled via gluconeogenesis. If NADPH is in excess, the latter portion of the pentose phosphate pathway may be reversed to synthesize R5P from glycolytic intermediates. The pentose phosphate pathway is controlled at its first committed step, the glucose-6-phosphate dehydrogenase reaction, by the NADP<sup>+</sup> concentration. A genetic deficiency in glucose-6-phosphate dehydrogenase leads to hemolytic anemia on administration of the antimalarial drug primaquine. This X-linked deficiency, which results from the accelerated degradation of the mutant enzyme, provides resistance against severe malaria to female heterozygotes and male hemizygotes for this sex-linked trait.

## PROBLEMS

- Compare the relative energetic efficiencies, in ATPs per mole of glucose oxidized, of glucose oxidation via glycolysis + the citric acid cycle versus glucose oxidation via the pentose phosphate pathway + gluconeogenesis. Assume that NADH and NADPH are each energetically equivalent to 2.5 ATP.
- Although animals cannot synthesize glucose from acetyl-CoA, if a rat is fed <sup>14</sup>C-labeled acetate, some of the label will appear in the glycogen extracted from its muscles. Explain.
- Substances that inhibit specific trimming steps in the processing of *N*-linked glycoproteins have been useful tools in elucidating the pathway of this process. Explain.
- Through clever genetic engineering you have developed an unregulatable enzyme that can interchangeably use NAD<sup>+</sup> or NADP<sup>+</sup> in a redox reaction. What would be the physiological consequence(s) on an organism of having such an enzyme?
- What is the free energy change of the reaction
 
$$\text{NADH} + \text{NADP}^+ \rightleftharpoons \text{NAD}^+ + \text{NADPH}$$
 under physiological conditions? Assume that  $\Delta G^\circ = 0$  for this reaction and that  $T = 37^\circ\text{C}$ .
- If G6P is <sup>14</sup>C-labeled at its C2 position, what is the distribution of the radioactive label in the products of the pentose phosphate pathway after one turnover of the pathway? What is the distribution of the label after passage of these products through gluconeogenesis followed by a second round of the pentose phosphate pathway?
- After feeding rapidly growing and proliferating cells [<sup>1,2-<sup>13</sup>C</sup>]glucose and isolating the RNA, you find that both the C1 and C2 atoms of the ribosyl units are labeled. Show, using chemical structures and the appropriate enzymes, how the pentose phosphate pathway can yield this distribution of the label.
- The relative metabolic activities in an organism of glycolysis + the citric acid cycle versus the pentose phosphate pathway + gluconeogenesis can be measured by comparing the rates of <sup>14</sup>CO<sub>2</sub> generation on administration of glucose labeled with <sup>14</sup>C at C1 with that of glucose labeled at C6. Explain.
- (a) Describe the lengths of the products of the transketolase reaction when the two substrates are both five-carbon sugars. (b) Describe the products of the reaction when the substrates are a five-carbon aldose and a six-carbon ketose. Does it matter which of the substrates binds to the enzyme first?
- In light of the finding that an otherwise benign or even advantageous mutation leads to abnormal primaquine sensitivity combined with the fact that human beings have enormous genetic complexity, comment on the possibility of developing drugs that exhibit no atypical side effects in any individual.
- Glucose-6-phosphatase is located inside the endoplasmic reticulum. Describe the probable symptoms of a defect in G6P transport across the endoplasmic reticulum membrane.

- D. Photophosphorylation

#### 3 Dark Reactions

- A. The Calvin Cycle
- B. Control of the Calvin Cycle
- C. Photorespiration and the C<sub>4</sub> Cycle

Life on Earth depends on the sun. *Plants and cyanobacteria chemically sequester light energy through photosynthesis, a light-driven process in which CO<sub>2</sub> is “fixed” to yield carbohydrates (CH<sub>2</sub>O).*

This process, in which CO<sub>2</sub> is reduced and H<sub>2</sub>O is oxidized to yield carbohydrates and O<sub>2</sub>, is essentially the reverse of oxidative carbohydrate metabolism. Photosynthetically produced carbohydrates therefore serve as an energy source for the organism that produced them as well as for nonphotosynthetic organisms that directly or indirectly consume photosynthetic organisms. In fact, even modern industry is highly dependent on the products of photosynthesis because coal, oil, and gas (the so-called fossil fuels) are thought to be the remains of ancient organisms. It is estimated that photosynthesis annually fixes ~10<sup>11</sup> tons of carbon, which represents the storage of over 10<sup>18</sup> kJ of energy. Moreover, photosynthesis, over the eons, has produced the O<sub>2</sub> in Earth's atmosphere (Section 1-5Cb).

The notion that plants obtain nourishment from such insubstantial things as light and air took nearly two centuries to develop. In 1648, the Flemish physician Jean Baptiste van Helmont reported that growing a potted willow tree from a shoot caused an insignificant change in the weight of the soil in which the tree had been rooted. Although another century was to pass before the law of conservation of matter was formulated, van Helmont attributed the tree's weight gain to the water it had taken up. This idea was extended in 1727 by Stephen Hales, who proposed that plants extract some of their matter from the air.

The first indication that plants produce oxygen was found by the English clergyman and pioneering chemist Joseph Priestley, who reported:

*Finding that candles burn very well in air in which plants had grown a long time, and having some reason to think, that there was something attending vegetation, which restored air that had been injured by respiration, I thought it was possible that the same process might also restore the air that had been injured by the burning of candles. Accordingly, on the 17th of August, 1771, I put a sprig of mint into a quantity of air, in which a wax candle had burned out, and found that, on the 27th of the same month, another candle burned perfectly well in it.*

Although Priestley later discovered oxygen, which he named “dephlogisticated air,” it was Antoine Lavoisier who elucidated its role in combustion and respiration. Nevertheless, Priestley's work inspired the Dutch physician Jan Ingenhousz, who in 1779 demonstrated that the “purifying” power of plants resides in the influence of sunlight on their green parts. In 1782, the Swiss pastor Jean Senebier showed that CO<sub>2</sub>, which he called “fixed air,” is taken up during photosynthesis. His compatriot Nicolas-Théodore de Saussure found, in 1804, that the combined weights of the organic matter produced by plants and the oxygen they evolve is greater than the weight of the CO<sub>2</sub> they consume. He therefore concluded that water, the only other substance he added to his system, was also necessary for photosynthesis. The final ingredient in the overall photosynthetic recipe was established in 1842 by the German physiologist Robert Mayer, one of the formulators of the first law of thermodynamics, who concluded that plants convert light energy to chemical energy.

### 1 CHLOROPLASTS

*The site of photosynthesis in eukaryotes (algae and higher plants) is the **chloroplast** (Section 1-2Ag), a member of the membranous subcellular organelles peculiar to plants known as **plastids**. The first indication that chloroplasts have a photosynthetic function was Theodor Englemann's observation, in 1882, that small, motile, O<sub>2</sub>-seeking bacteria congregate at the surface of the alga *Spirogyra*, overlying its single chloroplast, but only while the chloroplast is illuminated. Chloroplasts must therefore be the site of light-induced O<sub>2</sub> evolution, that is, photosynthesis. Chloroplasts, of which there are 1 to 1000 per cell, vary considerably in size and*

eukaryote; Section 1-2Ag). In eukaryotes, the dark reactions occur in the stroma through a cyclic series of enzyme-catalyzed reactions. In the following sections, we consider the light and dark reactions in detail.

## 2 LIGHT REACTIONS

In the first decades of the twentieth century, it was generally assumed that light, as absorbed by photosynthetic pigments, directly reduced  $\text{CO}_2$ , which, in turn, combined with water to form carbohydrate. In this view,  $\text{CO}_2$  is the source of the  $\text{O}_2$  generated by photosynthesis. In 1931, however, Cornelis van Niel showed that green photosynthetic bacteria, anaerobes that use  $\text{H}_2\text{S}$  in photosynthesis, generate sulfur:

The chemical similarity between  $\text{H}_2\text{S}$  and  $\text{H}_2\text{O}$  led van Niel to propose that the general photosynthetic reaction is

where  $\text{H}_2\text{A}$  is  $\text{H}_2\text{O}$  in green plants and cyanobacteria and  $\text{H}_2\text{S}$  in photosynthetic sulfur bacteria. This suggests that photosynthesis is a two-stage process in which light energy is harnessed to oxidize  $\text{H}_2\text{A}$  (the light reactions):

and the resulting reducing agent  $[\text{H}]$  subsequently reduces  $\text{CO}_2$  (the dark reactions):

Thus, in aerobic photosynthesis,  $\text{H}_2\text{O}$ , not  $\text{CO}_2$ , is photolyzed (split by light).

The validity of van Niel's hypothesis was established unequivocally by two experiments. In 1937, Robert Hill discovered that when isolated chloroplasts that lack  $\text{CO}_2$  are illuminated in the presence of an artificial electron acceptor such as ferricyanide  $[\text{Fe}(\text{CN})_6^{3-}]$ ,  $\text{O}_2$  is evolved with concomitant reduction of the acceptor [to ferrocyanide,  $\text{Fe}(\text{CN})_6^{4-}$ , in our example]. This so-called **Hill reaction** demonstrates that  $\text{CO}_2$  does not participate directly in the  $\text{O}_2$ -producing reaction. It was discovered eventually that the natural photosynthetic electron acceptor is  $\text{NADP}^+$  (Fig. 13-2), whose reduction product,  $\text{NADPH}$ , is utilized in the dark reactions to reduce  $\text{CO}_2$  to carbohydrate (Section 24-3A). In 1941, when the oxygen isotope  $^{18}\text{O}$  became available, Samuel Ruben and Martin Kamen directly demonstrated that the source of the  $\text{O}_2$  formed in photosynthesis is  $\text{H}_2\text{O}$ :

This section discusses the major aspects of the light reactions.

### A. Absorption of Light

The principal photoreceptor in photosynthesis is **chlorophyll**. This cyclic tetrapyrrole, like the heme group of globins and cytochromes (Sections 10-1A and 22-2C), is derived biosynthetically from protoporphyrin IX. Chlorophyll, however, differs from heme in four major respects (Fig. 24-3):

1. Its central metal ion is  $\text{Mg}^{2+}$  rather than  $\text{Fe(II)}$  or  $\text{Fe(III)}$ .

2. It has a cyclopentenone ring, Ring V, fused to pyrrole Ring III.

3. Pyrrole Ring IV is partially reduced in **chlorophyll a (Chl a)** and **chlorophyll b (Chl b)**, the two major chlorophyll varieties in eukaryotes and cyanobacteria, whereas in **bacteriochlorophyll a (BChl a)** and **bacteriochlorophyll b (BChl b)**, the principal chlorophylls of photosynthetic bacteria, Rings II and IV are partially reduced.

4. The propionyl side chain of Ring IV is esterified to a tetraisoprenoid alcohol. In **Chl a** and **b** as well as in **BChl b** it is **phytol** but in **BChl a** it is either phytol or **geranylgeraniol**, depending on the bacterial species.

In addition, **Chl b** has a formyl group in place of the methyl substituent to atom C3 of Ring II of **Chl a**. Similarly, **BChl a** and **BChl b** have different substituents to atom C4.

#### a. Light and Matter Interact in Complex Ways

As photosynthesis is a light-driven process, it is worthwhile reviewing how light and matter interact. Electromagnetic radiation is propagated as discrete **quanta (photons)** whose energy  $E$  is given by **Planck's law**:

$$E = h\nu = \frac{hc}{\lambda} \quad [24.1]$$

where  $h$  is **Planck's constant** ( $6.626 \times 10^{-34} \text{ J} \cdot \text{s}$ ),  $c$  is the speed of light ( $2.998 \times 10^8 \text{ m} \cdot \text{s}^{-1}$  in a vacuum),  $\nu$  is the frequency of the radiation, and  $\lambda$  is its wavelength (visible light ranges in wavelength from 400 to 700 nm). Thus red light with  $\lambda = 680 \text{ nm}$  has an energy of  $176 \text{ kJ} \cdot \text{einstein}^{-1}$  (an **einstein** is a mole of photons).

Molecules, like atoms, have numerous electronic quantum states of differing energies. Moreover, because molecules contain more than one nucleus, each of their electronic states has an associated series of vibrational and rotational substates that are closely spaced in energy (Fig. 24-4). Absorption of light by a molecule usually occurs through the promotion of an electron from its ground (lowest energy) state molecular orbital to one of higher energy. However, *a given molecule can only absorb photons of certain wavelengths because, as is required by the law of conservation of energy, the energy difference between the two states must exactly match the energy of the absorbed photon.*

	$R_1$	$R_2$	$R_3$	$R_4$
Chlorophyll <i>a</i>	$-\text{CH}=\text{CH}_2$	$-\text{CH}_3$	$-\text{CH}_2-\text{CH}_3$	P
Chlorophyll <i>b</i>	$-\text{CH}=\text{CH}_2$	$-\overset{\text{O}}{\parallel}{\text{C}}-\text{H}$	$-\text{CH}_2-\text{CH}_3$	P
Bacteriochlorophyll <i>a</i>	$-\overset{\text{O}}{\parallel}{\text{C}}-\text{CH}_3$	$-\text{CH}_3^a$	$-\text{CH}_2-\text{CH}_3^a$	P or G
Bacteriochlorophyll <i>b</i>	$-\overset{\text{O}}{\parallel}{\text{C}}-\text{CH}_3$	$-\text{CH}_3^a$	$=\text{CH}-\text{CH}_3^a$	P

<sup>a</sup> No double bond between positions C3 and C4.

**Figure 24-3 Chlorophyll structures.** The molecular formulas of chlorophylls *a* and *b* and bacteriochlorophylls *a* and *b* are compared to that of iron protoporphyrin IX (heme). The starred atom has the opposite stereochemistry in **chlorophyll *a'* (Chl *a'*)**. The isoprenoid phytol and geranylgeranyl tails presumably increase the chlorophylls' solubility in nonpolar media.

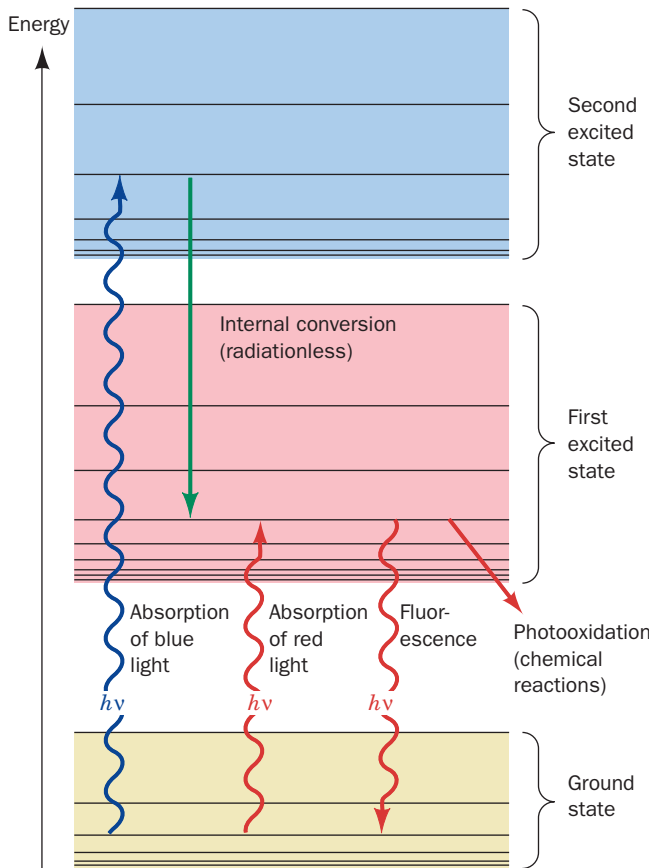

The various chlorophylls are highly conjugated molecules (Fig. 24-3). It is just such molecules that strongly absorb visible light (the spectral band in which the solar radiation reaching Earth's surface is of peak intensity). In fact, the peak molar extinction coefficients of the various chlorophylls,  $>10^5 \text{ M}^{-1} \cdot \text{cm}^{-1}$ , are among the highest known for organic molecules (Fig. 24-5; absorbance spectra are discussed in Section 5-3Ca). Yet the relatively small chemical differences among the various chlorophylls greatly affect their absorption spectra. These spectral differences, as we shall see, are functionally significant.

An electronically excited molecule can dissipate its excitation energy in many ways. Those modes with the greatest photosynthetic significance are as follows (Fig. 24-4):

**1. Internal conversion**, a common mode of decay in which electronic energy is converted to the kinetic energy of molecular motion, that is, to heat. This process occurs

very rapidly, being complete in  $<10^{-11}$  s. Many molecules relax in this manner to their ground states. Chlorophyll molecules, however, usually relax only to their lowest excited states. Therefore, *the photosynthetically applicable excitation energy of a chlorophyll molecule that has absorbed a photon in its short-wavelength band, which corresponds to its second excited state, is no different than if it had absorbed a photon in its less energetic long-wavelength band.*

**2. Fluorescence**, in which an electronically excited molecule decays to its ground state by emitting a photon. Such a process requires  $\sim 10^{-8}$  s, so it occurs much more slowly than internal conversion. Consequently, a fluorescently emitted photon generally has a longer wavelength (lower energy) than that initially absorbed. Fluorescence accounts for the dissipation of only 3 to 6% of the light energy absorbed by living plants. However, chlorophyll in solution,

**Figure 24-4** Energy diagram indicating the electronic states of chlorophyll and their most important modes of interconversion. The thin black lines denote different vibrational and rotational substates of each electronic state. The wiggly arrows represent the absorption of photons or their fluorescent emission. Excitation energy may also be dissipated in radiationless processes such as internal conversion (heat production) or chemical reactions.

See the Animated Figures

where of course the photosynthetic uptake of this energy cannot occur, has an intense red fluorescence.

**3. Exciton transfer** (also known as **resonance energy transfer**), in which an excited molecule directly transfers its excitation energy to nearby unexcited molecules with similar electronic properties (the basis of FRET; Section 9-1Cd). This process occurs through interactions between the molecular orbitals of the participating molecules in a manner analogous to the interactions between mechanically coupled pendulums of similar frequencies. An exciton (excitation) may be serially transferred between members of a group of molecules or, if their electronic coupling is strong enough, the entire group may act as a single excited “supermolecule.” We shall see that *exciton transfer is of particular importance in funneling light energy to photosynthetic reaction centers.*

**4. Photooxidation**, in which a light-excited donor molecule is oxidized by transferring an electron to an acceptor molecule, which is thereby reduced. This process occurs because the transferred electron is less tightly bound to the donor in its excited state than it is in the ground state. In photosynthesis, excited chlorophyll ( $\text{Chl}^*$ ) is such a donor. *The energy of the absorbed photon is thereby chemically transferred to the photosynthetic reaction system.* Photooxidized chlorophyll,  $\text{Chl}^+$ , a cationic free radical, eventually returns to its ground state by oxidizing some other molecule.

#### b. Light Absorbed by Antenna Chlorophylls Is Transferred to Photosynthetic Reaction Centers

The primary reactions of photosynthesis, as is explained in Sections 24-2B and 24-2C, take place at **photosynthetic reaction centers (RCs)**. Yet *photosynthetic organelles contain far more chlorophyll molecules than RCs.* This was

**Figure 24-5** Absorption spectra of various photosynthetic pigments. The chlorophylls each have two absorption bands, one in the red and one in the blue. Phycocerythrin absorbs blue and

green light, whereas phycocyanin absorbs yellow light. Together, these pigments absorb most of the visible light in the solar spectrum. [After a drawing by Govindjee, University of Illinois.]

**Figure 24-6** The amount of  $O_2$  evolved by *Chlorella* algae versus the intensity of light flashes. Flashes are separated by dark intervals of  $>20$  ms.

demonstrated in 1932 by Robert Emerson and William Arnold in their studies of  $O_2$  production by the green alga *Chlorella* (a favorite experimental subject), which had been exposed to repeated brief (10- $\mu$ s) flashes of light. The amount of  $O_2$  generated per flash was maximal when the interval between flashes was at least 20 ms. Evidently, this is the time required for a single turnover of the photosynthetic reaction cycle. Emerson and Arnold then measured the variation of  $O_2$  yield with flash intensity when the flash interval was the optimal 20 ms. With weak flashes, the  $O_2$  increased linearly with flash intensity such that about one molecule of  $O_2$  was generated per eight photons absorbed (Fig. 24-6). With increasing flash intensity the efficiency of this process fell off, no doubt because the number of pho-

**Figure 24-7** Flow of energy through a photosynthetic antenna complex. (a) The excitation resulting from photon absorption randomly migrates by exciton transfer among the molecules of the antenna complex (light green circles) until it is either trapped

tons began to approach the number of photochemical units. What was unanticipated, however, was that each flash of saturating intensity produced only one molecule of  $O_2$  per  $\sim 2400$  molecules of chlorophyll present. Since at least eight photons must be sequentially absorbed to liberate one  $O_2$  molecule (Section 24-2C), these results suggest that the photosynthetic apparatus contains  $\sim 2400/8 = 300$  chlorophyll molecules per RC.

With such a great excess of chlorophyll molecules per RC, it seems unlikely that all participate directly in photochemical reactions. Rather, as subsequent experiments have shown, *most chlorophylls function to gather light; that is, they act as light-harvesting antennas*. These **antenna chlorophylls** pass the energy of an absorbed photon, by exciton transfer, from molecule to molecule until the excitation reaches an RC (Fig. 24-7a). There, the excitation is trapped because RC chlorophylls, although chemically identical to antenna chlorophylls, have slightly lower excited state energies because of their different environments (Fig. 24-7b).

Transfer of energy from the antenna system to an RC occurs in  $<10^{-10}$  s with an efficiency of  $>90\%$ . This high efficiency depends on the chlorophyll molecules having appropriate spacings and relative orientations. Even in bright sunlight, an RC intercepts only  $\sim 1$  photon per second, a metabolically insignificant rate, and hence, these **light-harvesting complexes (LHCs)** serve an essential function.

### c. The LHCs of Purple Photosynthetic Bacteria Contain Multiple Symmetrically Arranged Light-Absorbing Molecules

Most **purple photosynthetic bacteria**, which are among the simplest photosynthetic organisms, have two types of LHCs, **LH1** and **LH2**, that are transmembrane proteins but have different spectral and biochemical properties. LH2, which absorbs light at shorter wavelengths than LH1, rapidly passes the energy from the photons it absorbs to

by an RC chlorophyll (dark green circles) or, less frequently, fluorescently reemitted. (b) The excitation is trapped by the RC chlorophyll because its lowest excited state has a lower energy than those of the antenna pigment molecules.

LH1, which, in turn, passes it to the RC. The X-ray structure of LH2 from the purple photosynthetic bacterium *Rhodospirillum (Rs.) molischianum* (Fig. 24-8), determined by Hartmut Michel, reveals that this protein is an 8-fold rotationally symmetric  $\alpha_8\beta_8$  16-mer that binds 24 bacteriochlorophyll *a* (BChl *a*) molecules and 8 lycopene molecules (a **carotenoid**; see below):

**Lycopene**

The  $\alpha$  and  $\beta$  subunits (56 and 45 residues, respectively) both consist largely of single helices that are aligned nearly perpendicularly to the plane of the membrane in which they are embedded. The eight  $\alpha$  subunits pack side by side to form a hollow cylinder of diameter  $\sim 31$  Å (as measured between helix axes). Each of the eight  $\beta$  subunits occupies a position radially outward from an  $\alpha$  subunit to form a concentric cylinder of diameter  $\sim 62$  Å. Sixteen of the BChl *a* molecules are packed between these rings of helices in an arrangement resembling a 16-bladed turbine: Successive nearly parallel BChl *a* ring systems are in partial van der Waals contact (their  $\text{Mg}^{2+}$  ions are  $\sim 9$  Å apart) with their planes perpendicular to the plane of the membrane. Their  $\text{Mg}^{2+}$  atoms are each singly axially liganded by His side

chains [much like the Fe(II) in deoxyhemoglobin] that alternately extend from an  $\alpha$  and a  $\beta$  subunit around the lower end of the cylinder. The remaining eight BChl *a* molecules, which are each singly axially liganded by a side chain of Asp 6 $\alpha$  near the upper end of the cylinder, are arranged in an 8-fold symmetric ring between successive  $\beta$  subunit helices and are oriented with the planes of their ring systems tilted by  $\sim 35^\circ$  relative to the plane of the membrane. The eight lycopene molecules are sandwiched between the  $\alpha$  and  $\beta$  subunits and extend along much of their lengths, thereby contacting both sets of BChl *a* molecules. The LH2 from *Rhodospseudomonas (Rps.) acidophila*, another purple photosynthetic bacterium, is an  $\alpha_9\beta_9$  18-mer but otherwise has a similar structure in its transmembrane region to that of *Rs. molischianum*, even though their  $\alpha$  and  $\beta$  subunits are only 26 and 31% identical.

Spectroscopic measurements indicate that an LH2's His-liganded and closely associated BChl *a* molecules maximally absorb radiation at a wavelength of 850 nm (and hence are called B850) and are strongly coupled, that is, they absorb radiation almost as a unit. The other, more loosely associated BChl *a* molecules (B800) maximally absorb radiation at 800 nm, largely as individual molecules (BChl *a*'s local environment in the protein alters its spectrum from that in solution; Fig. 24-5). When a B800 BChl *a* absorbs a photon, the excitation is rapidly [in  $\sim 700$  femtoseconds (fs);  $1 \text{ fs} = 10^{-15} \text{ s}$ ] transferred to a lower energy B850 BChl *a* (which may independently absorb a photon),

(a)

(b)

#### Exercise 20

**Figure 24-9** Model of the light-absorbing antenna system of purple photosynthetic bacteria. Several LH2s associate with each other and with LH1, which surrounds the photosynthetic reaction center (RC). The BChl *a*'s of LH2 B850 and LH1 are green, those of LH2 B800 are purple, and the light-absorbing pigments of the RC (see below) are red and black. Light absorbed by the Bchl *a* and lycopene molecules of an LH2 is rapidly transferred (curved arrows), often via other contacting LH2s, to LH1, which, in turn, transfers the excitation to its enclosed RC. [From Bhattacharjee, Y., *Nature* **412**, 474 (2001).]

which even more rapidly (in  $\sim 100$  fs) exchanges the excitation among the other B850 BChl *a* molecules. Hence, the B850 system acts as a kind of energy storage ring that delocalizes the excitation over a large region. The carotenoid molecules in this system absorb visible light ( $< 800$  nm) and may also facilitate the transmission of excitation between the rather distantly separated ( $19 \text{ \AA}$  between Mg atoms) nearest-neighbor B850 and B800 BChl *a* molecules.

LH1, like LH2, has  $\alpha$  and  $\beta$  subunits of  $\sim 50$  residues each. The low ( $8.5\text{-\AA}$ ) resolution structure of LH1 from *Rs. rubrum*, as determined by electron crystallography, reveals that it resembles LH2 but with 16-fold rotational symmetry, and forms a  $116\text{-\AA}$ -diameter cylinder with a  $68\text{-\AA}$ -diameter hole down its center. This hole is of sufficient size to contain an RC (see below), as electron microscopy studies indicate is, in fact, the case (Fig. 24-9). LH1's BChl *a* molecules absorb radiation at a longer wavelength than those of LH2 and consequently, when these two assemblies are in contact, excitation is rapidly [in  $1\text{--}5$  picoseconds (ps);  $1 \text{ ps} = 10^{-12} \text{ s}$ ] transferred from LH2 to LH1 and then (in  $20\text{--}40$  ps) to LH1's enclosed RC. Excitations may also be rapidly exchanged between contacting LH2s. Thus, this antenna system transfers virtually all of the radiation energy it absorbs to the RC in far less than the few nanoseconds (ns;  $1 \text{ ns} = 10^{-9} \text{ s}$ ) over which these excitations would otherwise decay. It should be noted that this complicated arrangement of **chromophores** (light-absorbing molecules) is among the simplest known; those of the light-harvesting systems of plants are even more elaborate (see below).

#### d. LHCs Contain Accessory Pigments

Most LHCs contain organized arrays of other light-absorbing substances in addition to chlorophyll. These **accessory pigments** function to fill in the absorption spectra of the antenna complexes in spectral regions where chlorophylls do not absorb strongly (Fig. 24-5). **Carotenoids**, which are  $C_{40}$ , largely linear polyenes such as lycopene and  $\beta$ -carotene,

$\beta$ -Carotene

are components of all green plants and many photosynthetic bacteria and are therefore the most common accessory pigments. They are largely responsible for the brilliant fall colors of deciduous trees as well as for the orange color of carrots (after which carotenoids are named).

[Ross M. Horowitz/The Image Bank/Getty Images.]

The light-harvesting protein **LHC-II** of green plants comprises  $\sim 30\%$  of the protein in chloroplast membranes, which makes it the most abundant membrane protein in nature. Each subunit of this highly conserved, 232-residue, trimeric protein binds eight Chl *a*'s, six Chl *b*'s, and four carotenoids (Fig. 24-10), thereby accounting for around half the chlorophyll in the biosphere. The orientations of the 42 chlorophylls in each LHC-II trimer evenly sample nearly all directions in space, thus maximizing the efficiency of light harvesting.

Carotenoids serve an additional function besides that of light-gathering antennas: Through electronic interactions, they prevent their associated light-excited chlorophyll molecules from transferring this excitation to  $O_2$ , which would otherwise yield highly destructive reactive oxygen species (ROS; Section 22-4Cg). This is particularly important under full sunlight, when the rate that light energy is absorbed exceeds the rate that it can be used in photosynthesis. Then, the excess energy is dissipated as heat through internal

**Figure 24-10** X-ray structure of the homotrimeric protein **LHC-II** from pea chloroplasts. The protein is drawn in ribbon form (gray) viewed (a) perpendicular to the thylakoid membrane from the stroma and along its 3-fold axis; and (b) parallel to the membrane (gray band) with the stroma above. Its bound carotenoids and chlorophylls are drawn in stick form with Chl *a* cyan, Chl *b* green, carotenoids orange, and lipids magenta.  $Mg^{2+}$  ions are represented by light pink spheres. Each subunit has three transmembrane helices oriented with its N-terminus on the stromal surface. Note the unusually high density of cofactors: Nearly 40% of this protein's nonhydrogen atoms comprise its chlorophylls and carotenoids. [Courtesy of Werner Kühlbrandt, Max Planck Institute of Biophysics, Frankfurt, Germany. PDBid 2BHW.]

conversion by carotenoids, thereby minimizing the irreversible damage to the photosynthetic system that would otherwise occur. In fact, the acidification of the thylakoid lumen resulting from high photosynthetic activity (see below) induces a conformational change in LHC-II. This converts it to a dissipative state by twisting one of its carotenoids and hence changing its electronic properties.

Aquatic photosynthetic organisms, which are responsible for nearly half of the photosynthesis on Earth, additionally contain other types of accessory pigments. This is because light outside the wavelengths 450 to 550 nm (blue and green light) is absorbed almost completely by passage through more than 10 m of water. In red algae and cyanobacteria, Chl *a* is therefore replaced as an antenna pigment by a

series of linear tetrapyrroles, notably the red **phycoerythrobilin** and the blue **phycocyanobilin**:

#### Peptide-linked phycoerythrobilin and phycocyanobilin

The lowest excited states of these so-called **bilins** have higher energies than those of the chlorophylls, thereby facilitating energy transfer to the RC. The bilins are covalently linked via Cys S atoms to **phycobiliproteins** to form **phycoerythrin** and **phycocyanin** (spectra in Fig. 24-5). These, in turn, are organized in high molecular mass particles called **phycobilisomes** that are bound to the outer faces of photosynthetic membranes so as to funnel excitation energy to RCs over long distances with >90% efficiency.

### B. Electron Transport in Purple Photosynthetic Bacteria

Photosynthesis is a process in which electrons from excited chlorophyll molecules are passed through a series of acceptors that convert electronic energy to chemical energy. Thus two questions arise: (1) What is the mechanism of energy transduction; and (2) how do photooxidized chlorophyll molecules regain their lost electrons? We shall see that photosynthetic bacteria solve these problems somewhat differently from cyanobacteria and plants. We first discuss these mechanisms in photosynthetic bacteria, where they are simpler and better understood. Electron transport in cyanobacteria and plants is the subject of Section 24-2C.

#### a. The Photosynthetic Reaction Center Is a Transmembrane Protein Containing a Variety of Chromophores

The first indication that chlorophyll undergoes direct photooxidation during photosynthesis was obtained by Louis Duysens in 1952. He observed that illumination of membrane preparations from the purple photosynthetic bacterium *Rs. rubrum* caused a slight (~2%) bleaching of their absorbance at 870 nm, which returned to their original levels in the dark. Duysens suggested that this bleaching is caused by photooxidation of a bacteriochlorophyll complex that he named **P870** (P for pigment and 870 nm for the position of the major long-wavelength absorption band of BChl *a*; photosynthetic bacteria tend to inhabit murky stagnant ponds, so that they require an infrared-absorbing species of chlorophyll). The ability to detect the presence of P870 eventually led to the purification and characterization of the RC to which it is bound.

RC particles from several species of purple photosynthetic bacteria (**PbRCs**) have similar compositions. That from *Rps. viridis* consists of three hydrophobic subunits: H (258 residues), L (273 residues), and M (323 residues). The L and M subunits of this membrane-spanning protein collectively bind four molecules of BChl *b* (which maximally absorbs light at 960 nm), two molecules of **bacteriopheophytin *b*** (**BPheo *b***; BChl *b* in which the  $\text{Mg}^{2+}$  is replaced by two protons), one nonheme/non-Fe-S Fe(II) ion, one molecule of the redox coenzyme ubiquinone (Fig. 22-17b), and one molecule of the related **menaquinone**

**Menaquinone**

(**vitamin K<sub>2</sub>**, a substance required for proper blood clotting; Section 35-1Ba). In many PbRCs, however, the BChl *b*, BPheo *b*, and menaquinone are replaced by BChl *a*, BPheo *a*, and a second ubiquinone, respectively.

The RC of *Rps. viridis*, whose X-ray structure was determined by Johann Deisenhofer, Robert Huber, and Hartmut Michel in 1984, was the first transmembrane protein to be described in atomic detail (Fig. 12-26). The protein's transmembrane portion consists of 11  $\alpha$  helices that form a 45-Å-long flattened cylinder with the expected hydrophobic surface. A c-type cytochrome containing four hemes, which is an integral constituent of the PbRC complex in only some photosynthetic bacteria, binds to the PbRC on the external side of the plasma membrane. In fact, the PbRC from another bacterial species, *Rhodobacter (Rb.) sphaeroides*, whose X-ray structure (Fig. 24-11) was independently determined by Marianne Schiffer and by Douglas Rees and George Feher, is nearly identical to that of *Rps. viridis* but lacks such a bound cytochrome.

#### b. Two BChl Molecules Form a "Special Pair"

The most striking aspect of the PbRC is that its chromophoric prosthetic groups are arranged with nearly perfect 2-fold symmetry (Fig. 24-12a). This symmetry arises because the L and M subunits, with which these prosthetic groups are exclusively associated, have homologous sequences and similar folds. Two of the BChl *b* molecules in the *Rps. viridis* PbRC, the so-called **special pair**, are closely associated; they are nearly parallel and have an Mg—Mg distance of  $\sim 7$  Å. The special pair occupies a predominantly hydrophobic region of the protein and each of its  $\text{Mg}^{2+}$  ions has a His side chain as a fifth ligand. Each member of the special pair is in contact with another His-ligated BChl *b* molecule, which, in turn, is associated with a BPheo *b* molecule. The menaquinone is in close association with the L subunit BPheo *b* (Fig. 24-12a, right), whereas the ubiquinone, which is but loosely bound to the protein,

(a)

(b)

**Figure 24-11** A ribbon diagram of the photosynthetic reaction center (RC) from *Rb. sphaeroides*. (a) The H, M, and L subunits, as viewed from within the plane of the plasma membrane with the cytoplasm below, are magenta, cyan, and orange, respectively. The prosthetic groups are drawn in stick form with C green, N blue, and O red. The Fe(II) atom is represented by a yellow sphere. The 11 largely vertical helices that form the central portion of the protein constitute its transmembrane region. Compare this structure with that of the RC from *Rps. viridis* (Fig. 12-26), whose H, M, and L subunits are 39, 50, and 59% identical to those of *Rb. sphaeroides*. Note that the *Rb. sphaeroides* protein lacks the four-heme c-type cytochrome (green in Fig. 12-26) on its periplasmic surface and that the  $\text{Q}_A$  prosthetic group, whose quinone ring lies to the right of the Fe(II), is ubiquinone in *Rb. sphaeroides* but menaquinone in *Rps. viridis*. (b) View from the extracellular side of the membrane. Note how the transmembrane portions of the M and L subunits are related by a pseudo-2-fold axis passing through the Fe(II) ion and that the prosthetic groups are sandwiched between these two subunits. [Based on an X-ray structure by Marianne Schiffer, Argonne National Laboratory. PDBid 2RCR.] See **Interactive Exercise 21** and **Kinemage Exercise 8-2**

associates with the M subunit BPheo *b* (Fig. 24-12*a*, left). These various chromophores are closely associated with a number of protein aromatic rings, which are therefore also thought to participate in the electron-transfer process

**Figure 24-12** Sequence of excitations in the bacterial RC of *Rps. viridis*. The RC chromophores are shown in the same view as in Fig. 12-26*a*, which resembles that in Fig. 24-11*a*. Note that their rings, but not their aliphatic side chains, are arranged with close to 2-fold symmetry. (a) At zero time, a photon is absorbed by the “special pair” of BChl *b* molecules, thereby collectively raising them to an excited state [in each step, the excited molecule(s) is shown in red]. (b) Within 3 ps, an excited electron has passed to the BPheo *b* of the L subunit (right arm of the system) without becoming closely associated with the accessory BChl *b*. The special pair is thereby left with a positive charge. (c) Some 200 ps later, the excited electron has transferred to the menaquinone ( $Q_A$ , which is ubiquinone in *Rb. sphaeroides*). (d) Within the next 100  $\mu$ s, the special pair has been reduced (via an electron-transport chain discussed in the text), thereby eliminating its positive charge, while the excited electron migrates to the ubiquinone ( $Q_B$ ). After a second such electron has been transferred to  $Q_B$ , it picks up two protons from solution and exchanges with the membrane-bound ubiquinone pool.

See Kinemage Exercise 8-2

described below. The Fe(II) is positioned between the menaquinone and ubiquinone rings and is octahedrally liganded by four His side chains and the two carboxyl oxygen atoms of a Glu side chain. Curiously, the two symmetry related groups of chromophores are not functionally equivalent; electrons, as we shall see, are almost exclusively transferred through the L subunit (the right sides of Figs. 24-11 and 24-12). This effect is generally attributed to subtle structural and electronic differences between the L and M subunits.

### c. The Electronic States of Molecules Undergoing Fast Reactions Can Be Monitored by EPR and Laser Spectroscopy Techniques

The turnover time of a photosynthetic reaction cycle, as we have seen, is only a few milliseconds. Its sequence of reactions can therefore only be traced by measurements that can follow extremely rapid electronic changes in molecules. Two techniques are well suited to this task:

**1. Electron paramagnetic resonance (EPR) spectroscopy** [also called **electron spin resonance (ESR) spectroscopy**], which detects the spins of unpaired electrons in a manner analogous to the detection of nuclear spins in NMR spectroscopy. A molecular species with unpaired electrons, such as an organic radical or a transition metal ion, has a characteristic EPR spectrum because its unpaired electrons interact with the magnetic fields generated by the nuclei and the other electrons of the molecule. Paramagnetic species as short lived as 10 ps can exhibit definitive EPR spectra.

**2. Optical spectroscopy using pulsed lasers.** Laser flashes as brief as 20 attoseconds (as;  $1 \text{ as} = 10^{-18} \text{ s}$ ) have been generated. By monitoring the bleaching (disappearance) of certain absorption bands and the emergence of others, laser spectroscopy can track the time course of a fast reaction process.

#### d. Photon Absorption Rapidly Photooxidizes the Special Pair

The sequence of photochemical events mediated by the photosynthetic reaction center is diagrammed in Fig. 24-12:

(a) The primary photochemical event of bacterial photosynthesis is absorption of a photon by the special pair (P870 or **P960** depending on whether it consists of BChl *a* or *b*; here, for argument's sake, we assume it to be P960). This event is nearly instantaneous; it occupies the  $\sim 3$ -fs oscillation time of a light wave. EPR measurements established that P960 is, in fact, a pair of BChl *b* molecules and indicated that the excited electron is delocalized over both of them.

(b) P960\*, the excited state of P960, has but a fleeting existence. Laser spectroscopy has demonstrated that within  $\sim 3$  ps after its formation, P960\* has transferred an electron to the BPheo *b* on the right in Fig. 24-12*b* to yield P960<sup>+</sup> BPheo *b*<sup>-</sup>. In forming this radical pair, the transferred electron must pass near but seems not to reduce the intervening BChl *b* (which is therefore termed an accessory chlorophyll), although its position strongly suggests that it has an important role in conveying electrons.

(c) By some 200 ps later, the electron has further migrated to the menaquinone (or, in many species, the second ubiquinone), designated Q<sub>A</sub>, to form the anionic semiquinone radical Q<sub>A</sub><sup>-</sup>. All these electron transfers, as diagrammed in Fig. 24-13, are to progressively lower energy states, which makes this process all but irreversible.

Rapid removal of the excited electron from the vicinity of P960<sup>+</sup> is an essential feature of the PbRC; this prevents back reactions that would return the electron to P960<sup>+</sup> so as to provide the time required for the wasteful internal conversion of its excitation energy to heat. In fact, *this sequence of electron transfers is so efficient that its overall quantum yield (ratio of molecules reacted to photons absorbed) is virtually 100%*. No man-made device has yet approached this level of efficiency.

#### e. Electrons Are Returned to the Photooxidized Special Pair via an Electron-Transport Chain

The remainder of the photosynthetic electron-transport process occurs on a much slower timescale. Within  $\sim 100$   $\mu$ s after its formation, Q<sub>A</sub><sup>-</sup>, which occupies a hydrophobic pocket in the protein, transfers its excited electron to the more solvent-exposed ubiquinone, Q<sub>B</sub>, to form Q<sub>B</sub><sup>-</sup> (Fig. 24-12*d*). The nonheme Fe(II) is not reduced in this process and, in fact, its removal only slightly affects the electron transfer rate, so that the Fe(II) probably functions to fine-tune the PbRC's electronic character. Q<sub>A</sub> never becomes fully reduced; it shuttles between its oxidized and semiquinone forms. Moreover, the lifetime of Q<sub>A</sub><sup>-</sup> is so short that it never becomes protonated. In contrast, once the PbRC again becomes excited, it transfers a second electron to Q<sub>B</sub><sup>-</sup> to form the fully reduced Q<sub>B</sub><sup>2-</sup>. This anionic quinol takes up two protons from the solution on the cytoplasmic side of the plasma membrane to form Q<sub>B</sub>H<sub>2</sub>. Thus Q<sub>B</sub> is a molecular transducer that converts two

light-driven one-electron excitations to a two-electron chemical reduction.

The electrons taken up by Q<sub>B</sub>H<sub>2</sub> are eventually returned to P960<sup>+</sup> via a complex electron-transport chain (Fig. 24-13). The details of this process are more species dependent than the preceding and are not so well understood. The available redox carriers include a membrane-bound pool of ubiquinone molecules, **cytochrome *bc*<sub>1</sub>**, and **cytochrome *c*<sub>2</sub>**. Cytochrome *bc*<sub>1</sub> is a transmembrane protein complex composed of a [2Fe-2S] cluster-containing subunit; a heme *c*-containing cytochrome *c*<sub>1</sub>; a cytochrome *b* that contains two functionally inequivalent heme *b*'s, *b*<sub>H</sub> and *b*<sub>L</sub> (H and L for high and low potential); and, in some species, a fourth subunit. Note that cytochrome *bc*<sub>1</sub> is strikingly similar to the proton-translocating Complex III of mitochondria (Section 22-2C3a), which is also called cytochrome *bc*<sub>1</sub>. The electron-transport pathway leads from Q<sub>B</sub>H<sub>2</sub> on the cytoplasmic side of the plasma membrane, through the ubiquinone pool, with which Q<sub>B</sub>H<sub>2</sub> exchanges, to cytochrome *bc*<sub>1</sub>, and then to cytochrome *c*<sub>2</sub> on the external (periplasmic) side of the plasma membrane. The reduced cytochrome *c*<sub>2</sub>, which, as its name implies, closely resembles mitochondrial cytochrome *c*, diffuses along the external membrane surface until it reacts with the membrane-spanning PbRC to transfer an electron to P960<sup>+</sup> (the structures of several *c*-type cytochromes, including that of cytochrome *c*<sub>2</sub> from *Rs. rubrum*, are diagrammed in Fig. 9-41). In *Rps. viridis*, the four-heme *c*-type cytochrome bound to the PbRC complex on the external side of the plasma membrane (Fig. 12-26) is interposed between cytochrome *c*<sub>2</sub> and P960<sup>+</sup>. Note that one of this *c*-type cytochrome's hemes is positioned to reduce the photooxidized special pair. The PbRC is thereby prepared to absorb another photon.

#### f. Photosynthetic Electron Transport Drives the Formation of a Proton Gradient

Since electron transport in PbRCs is a cyclic process (Fig. 24-13), it results in no net oxidation-reduction. Rather, it functions to translocate the cytoplasmic protons acquired by Q<sub>B</sub>H<sub>2</sub> across the plasma membrane, thereby making the cell alkaline relative to its environment. The mechanism of this process is essentially identical to that of proton transport in mitochondrial Complex III (Section 22-3Be); that is, in addition to the translocation of the two H<sup>+</sup> resulting from the two-electron reduction of Q<sub>B</sub> to QH<sub>2</sub>, a Q cycle mediated by cytochrome *bc*<sub>1</sub> translocates two H<sup>+</sup> for a total of four H<sup>+</sup> translocated per two photons absorbed (Fig. 24-13*a*; also see Fig. 22-31). *Synthesis of ATP, a process known as photophosphorylation, is driven by the dissipation of the resulting pH gradient in a manner that closely resembles ATP synthesis in oxidative phosphorylation (Section 22-3C)*. We further discuss the mechanism of photophosphorylation in Section 24-2D.

Photosynthetic bacteria use photophosphorylation-generated ATP to drive their various endergonic processes. However, unlike cyanobacteria and plants, which generate their required reducing equivalents by the light-driven oxidation of H<sub>2</sub>O (see below), photosynthetic bacteria must obtain their reducing equivalents from the environment.

**Figure 24-13** Photosynthetic electron-transport system of purple photosynthetic bacteria. (a) Schematic diagram indicating the arrangement of the system components in the bacterial plasma membrane and the flows of electrons (black arrows) and protons (blue arrows) that photon ( $h\nu$ ) absorption promotes through them. The system contains two protein complexes, the RC and cytochrome  $bc_1$ . Two electrons liberated from the special pair, here P870 (as in *Rb. sphaeroides*), by the consecutive absorption of two photons are taken up by ubiquinone ( $Q_B$ ) together with two protons from the cytoplasm to yield ubiquinol ( $QH_2$ ). The  $QH_2$  is released from the RC and diffuses (dotted arrows) through the membrane to cytochrome  $bc_1$ , which, in a two-electron reaction, oxidizes it to ubiquinone with the concomitant liberation of its two protons to the external medium. One of the two electrons is passed, via the  $[2Fe-2S]$  cluster and cytochrome  $c_1$ , to cytochrome  $c_2$ , a peripheral membrane protein that then diffuses across the external surface of the membrane so as to return the electron to P870 of the RC. The second electron from  $QH_2$  passes, via a Q cycle, through hemes  $b_L$  and  $b_H$  of cytochrome  $bc_1$  and then contributes to the reduction of a molecule of ubiquinone (Q) with the concomitant uptake of two more cytoplasmic protons (two rounds of a Q cycle are required for the reduction of one molecule of Q to  $QH_2$ ; Fig. 22-31). The resulting  $QH_2$  diffuses back to cytochrome  $bc_1$ . There it is again oxidized, with the liberation of its two protons to the exterior and the return of one of its two electrons, via cytochrome  $c_2$ , to P870, thereby completing the electrical circuit. Note that in every turn of a Q cycle, half the electrons liberated by the oxidation of

$QH_2$  to Q are used to reduce Q to  $QH_2$ , so that, after a large number of turns, an electron that enters the Q cycle, on average, passes through it twice before being returned to P870. Thus, the net result of the absorption of two photons by the RC is the translocation of four  $H^+$  from the cytoplasm to the external medium. (b) The approximate standard reduction potentials of the photosynthetic electron-transport system's various components. The overall process is essentially irreversible because electrons are transferred to progressively lower energy states (more positive standard reduction potentials).

Various substances, such as  $H_2S$ , S,  $S_2O_3^{2-}$ ,  $H_2$ , and many organic compounds, function in this capacity depending on the bacterial species.

Modern photosynthetic bacteria are thought to resemble the original photosynthetic organisms. These presumably arose very early in the history of cellular life when environmentally supplied sources of "high-energy" compounds were dwindling but reducing agents were still plentiful (Section 1-5Cb). During this era, photosynthetic bacteria were no doubt the dominant form of life. However, their very success eventually caused them to exhaust the available reductive resources. The ancestors of modern cyanobacteria adapted to this situation by evolving a photosynthetic sys-

tem with sufficient electromotive force to abstract electrons from  $H_2O$ . The gradual accumulation of the resulting toxic waste product,  $O_2$ , forced photosynthetic bacteria, which cannot photosynthesize in the presence of  $O_2$  (although some species have evolved the ability to respire), into the narrow ecological niches to which they are presently confined (Section 1-1Ab).

### C. Two-Center Electron Transport

 See Guided Exploration 22: Two-center photosynthesis (Z-scheme) overview Plants and cyanobacteria use the reducing power generated by the light-driven oxidation of  $H_2O$  to produce

*NADPH*. The component half-reactions of this process, together with their standard reduction potentials, are

and

Hence, the overall four-electron reaction and its standard redox potential is

This latter quantity corresponds (Eq. [16.5]) to a standard free energy change of  $\Delta G^{\circ'} = 438 \text{ kJ} \cdot \text{mol}^{-1}$ , which Eq. [24.1] indicates is the energy of one einstein of 223-nm photons (UV light). Clearly, *even if photosynthesis were 100% efficient, which it is not, it would require more than one photon of visible light to generate a molecule of O<sub>2</sub>. In fact, experimental measurements indicate that algae minimally require 8 to 10 photons of visible light to produce one molecule of O<sub>2</sub>.* In the following subsections, we discuss how plants and cyanobacteria manage this multiphoton process.

### a. Photosynthetic O<sub>2</sub> Production Requires Two Sequential Photosystems

Two seminal observations led to the elucidation of the basic mechanism of photosynthesis in plants:

1. The quantum yield for O<sub>2</sub> evolution by *Chlorella pyrenoidosa* varies little with the wavelength of the illuminating light between 400 and 675 nm, but decreases precipitously above 680 nm (Fig. 24-14, *lower curve*). This phenomenon, the “red drop,” was unexpected because Chl *a* absorbs such far-red light (Fig. 24-5).

2. Shorter wavelength light, such as yellow-green light, enhances the photosynthetic efficiency of 700-nm light well in excess of the energy content of the shorter wavelength light; that is, *the rate of O<sub>2</sub> evolution by both lights is greater than the sum of the rates for each light acting alone* (Fig. 24-14, *upper curve*). Moreover, this enhancement still occurs if the yellow-green light is switched off several seconds before the red light is turned on and vice versa.

These observations clearly indicate that two processes are involved. They are explained by a mechanistic model, the **Z-scheme**, which postulates that *O<sub>2</sub>-producing photosynthesis occurs through the actions of two photosynthetic RCs that are connected essentially in series* (Fig. 24-15).

1. **Photosystem I (PSI)** generates a strong reductant capable of reducing NADP<sup>+</sup> and, concomitantly, a weak oxidant.

2. **Photosystem II (PSII)** generates a strong oxidant capable of oxidizing H<sub>2</sub>O and, concomitantly, a weak reductant.

**Figure 24-14** Quantum yield for O<sub>2</sub> production by *Chlorella* algae as a function of the wavelength of the incident light. The experiment was conducted in the absence (*lower curve*) and the presence (*upper curve*) of supplementary yellow-green light. The upper curve has been corrected for the amount of O<sub>2</sub> production stimulated by the supplementary light alone. Note that the lower curve falls off precipitously above 680 nm (the red drop). However, the supplementary light greatly increases the quantum yield in the wavelength range above 680 nm (far-red) in which the algae absorb light. [After Emerson, R., Chalmers, R., and Cederstrand, C., *Proc. Natl. Acad. Sci.* **49**, 137 (1957).]

The weak reductant reduces the weak oxidant, so that *PSI and PSII form a two-stage electron “energizer.” Both photosystems must therefore function for photosynthesis (electron transfer from H<sub>2</sub>O to NADP<sup>+</sup>, forming O<sub>2</sub> and NADPH) to occur.*

The red drop is explained in terms of the Z-scheme by the observation that PSII is only poorly activated by 680-nm light. In the presence of only this far-red light, PSI is activated but is unable to obtain more than a few of the electrons it is capable of energizing. Yellow-green light, however, efficiently stimulates PSII to supply these electrons. The observation that the far-red and yellow-green lights can be alternated indicates that both photosystems remain activated for a time after the light is switched off.

The validity of the Z-scheme was established as follows. The oxidation state of **cytochrome *f***, a *c*-type cytochrome of the electron-transport chain connecting PSI and PSII (see below), can be spectroscopically monitored. Illumination of algae with 680-nm (far-red) light results in the oxidation of cytochrome *f* (Fig. 24-16). However, the additional imposition of a 562-nm (yellow-green) light results in this

**Figure 24-15** The Z-scheme for photosynthesis in plants and cyanobacteria. Two photosystems, PSI and PSII, function to drive electrons from  $H_2O$  to NADPH. The reduction potential increases downward so that electron flow occurs spontaneously in this direction. The herbicide DCMU (see text) blocks photosynthetic electron transport from PSII to cytochrome *f*.

protein's partial re-reduction. In the presence of the herbicide **3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU)**,

**3-(3,4-Dichlorophenyl)-1,1-dimethylurea (DCMU)**

which abolishes photosynthetic oxygen production, 680-nm light still oxidizes cytochrome *f* but simultaneous 562-nm light only oxidizes it further. The explanation for these effects is that 680-nm light, which efficiently activates only PSI, causes it to withdraw electrons from (oxidize) cytochrome *f*. The 562-nm light also activates PSII, which thereby transfers electrons to (reduces) cytochrome *f*. DCMU blocks electron flow from PSII to cytochrome *f* (Fig. 24-15), so an increased intensity of light, whatever its wavelength, only serves to activate PSI further.

**b. O<sub>2</sub>-Producing Photosynthesis Is Mediated by Three Transmembrane Protein Complexes Linked by Mobile Electron Carriers**

The components of the Z-scheme, which mediate electron transport from  $H_2O$  to NADPH, are largely organized into three thylakoid membrane-bound particles (Fig. 24-17): (1)

**Figure 24-16** The oxidation state of cytochrome *f* in *Porphyridium cruentum* algae as monitored by a weak beam of 420-nm (blue-violet) light. An increase in the transmitted light signals the oxidation of cytochrome *f*. In the upper curve, strong light at 680 nm (far-red) causes the oxidation of the cytochrome *f* but the superposition of 562-nm (yellow-green) light causes its partial re-reduction. In the lower curve, the presence of the herbicide DCMU, which inhibits photosynthetic electron transport, causes 562-nm light to further oxidize, rather than reduce, the cytochrome *f*.

PSII, (2) the **cytochrome *b<sub>6</sub>f* complex**, and (3) PSI. As in oxidative phosphorylation, electrons are transferred between these complexes via mobile electron carriers. The ubiquinone analog **plastoquinone (Q)**, via its reduction to **plastoquinol (QH<sub>2</sub>)**,

**Figure 24-17** Schematic representation of the thylakoid membrane showing the components of its electron-transport chain. The system consists of three protein complexes: PSII, the cytochrome  $b_6f$  complex, and PSI, which are electrically “connected” by the diffusion of the electron carriers plastoquinol (Q) and plastocyanin (PC). Light-driven transport of electrons (black arrows) from  $\text{H}_2\text{O}$  to  $\text{NADP}^+$  forming NADPH motivates the transport of protons (red arrows) into the thylakoid space (Fd is ferredoxin). Additional protons are split off from water by

the oxygen-evolving complex (OEC), yielding  $\text{O}_2$ . The resulting proton gradient powers the synthesis of ATP by the  $\text{CF}_1\text{CF}_0$  proton-translocating ATP synthase [ $\text{CF}_1$  and  $\text{CF}_0$  are chloroplast (C) analogs of mitochondrial  $\text{F}_1$  and  $\text{F}_0$ ]. The membrane also contains light-harvesting complexes whose component chlorophylls and other chromophores transfer their excitations to PSI and PSII. [After Ort, D.R. and Good, N.E., *Trends Biochem. Sci.* **13**, 469 (1988).]

links PSII to the cytochrome  $b_6f$  complex, which, in turn, interacts with PSI through the mobile Cu-containing redox protein **plastocyanin (PC)**. In what follows, we trace the electron pathway through this chloroplast system from  $\text{H}_2\text{O}$  to  $\text{NADP}^+$  (Fig. 24-18).

### c. PSII Resembles the PbRC

PSII from the thermophilic cyanobacterium *Thermosynechococcus elongatus* consists of 20 subunits, 14 of which occupy the photosynthetic membrane. These transmembrane subunits include the reaction center proteins **D1 (PsbA)** and **D2 (PsbD)**, the chlorophyll-containing inner-antenna subunits **CP43 (PsbC)** and **CP47 (PsbB)**, and **cytochrome  $b_{559}$** . The X-ray structure of this PSII (Fig. 24-19), independently determined by James Barber and So Iwata and by Wolfram Saenger, reveals that this ~340-kD protein is a symmetric dimer, whose protomeric units each contain 35 transmembrane helices. Each protomer, which has pseudo-2-fold symmetry, binds 36 Chl  $a$ 's, 2 **pheophytin  $a$ 's (Pheo  $a$ 's)**; Chl  $a$  with its  $\text{Mg}^{2+}$  replaced by two protons), one heme  $b$ , one heme  $c$ , 2 plastoquinones, one nonheme

Fe, 12 all-trans carotenoids presumed to be  $\beta$ -carotene, one  $\text{HCO}_3^-$  ion, and one  $\text{Mn}_4\text{CaO}_4$  complex known as the **oxygen-evolving center [OEC; alternatively, the water-oxidizing complex (WOC)]**. In higher plants, the PSII protomer contains ~25 subunits and forms an ~1000-kD transmembrane supercomplex with several antenna proteins. The arrangement of the 5 transmembrane helices in both D1 and D2 resembles that in the L and M subunits of the PbRC (Fig. 24-11). Indeed, these two sets of subunits have similar sequences, thereby indicating that they arose from a common ancestor.

The cofactors of PSII's RC (Fig. 24-20) are organized similarly to those of the bacterial system (Fig. 24-12): They have essentially the same components (with Chl  $a$ , Pheo  $a$ , and plastoquinone replacing BChl  $b$ , BPheo  $b$ , and menaquinone, respectively) and are symmetrically organized along the complex's pseudo-2-fold axis. The two Chl  $a$  rings labeled  $\text{P}_{\text{D1}}$  and  $\text{P}_{\text{D2}}$  in Fig. 24-20 are positioned analogously to the BChl  $b$ 's of P960's “special pair” and are therefore presumed to form PSII's primary electron donor, **P680** (named after the wavelength at which its absorbance

**Figure 24-18 Detailed diagram of the Z-scheme of photosynthesis.** Electrons ejected from P680 by the absorption of photons are replaced with electrons abstracted from  $\text{H}_2\text{O}$  by an Mn complex (OEC), thereby forming  $\text{O}_2$  and four  $\text{H}^+$ . Each ejected electron is passed through a chain of electron carriers to a pool of plastoquinone molecules (Q). The resulting plastoquinol, in turn, reduces the cytochrome  $b_6f$  particle (yellow box) that transfers electrons with the concomitant translocation of protons, via a Q cycle, into the thylakoid lumen. Cytochrome

$b_6f$  then transfers the electrons to plastocyanin (PC). The plastocyanin regenerates photooxidized P700. The electron ejected from P700, through the intermediacy of a chain of electron carriers ( $A_0$ ,  $A_1$ ,  $F_x$ ,  $F_A$ ,  $F_B$ , and Fd), reduces  $\text{NADP}^+$  to  $\text{NADPH}$  in noncyclic electron transport. Alternatively, the electron may be returned to the cytochrome  $b_6f$  complex in a cyclic process that only translocates protons into the thylakoid lumen.

maximally decreases on photooxidation). The electron ejected from P680 follows a similar asymmetric course as that in the PbRC even though the two systems operate over different ranges of reduction potential (compare Figs. 24-13b and 24-18). As indicated in the central part of Fig. 24-18, the electron is transferred to a molecule of Pheo  $a$  (Pheo $_{D1}$  in Fig. 24-20), probably via a Chl  $a$  molecule (Chl $_{D1}$ ), and then to a bound plastoquinone ( $Q_A$ ). The electron is subsequently transferred to a second plastoquinone molecule,  $Q_B$ , which after it receives a second electron in a like manner, takes up two protons at the stromal (cytosolic in cyanobacteria) surface of the thylakoid membrane. The resulting plastoquinol,  $Q_B\text{H}_2$ , then exchanges with a membrane-bound pool of plastoquinone molecules. DCMU as well as many other commonly used herbicides compete with plastoquinone for the  $Q_B$ -binding site on PSII, which explains how they inhibit photosynthesis.

Two “extra” Chl  $a$  molecules, Chl $_{ZD1}$  and Chl $_{ZD2}$ , lie on the periphery of the RC, where they are postulated to func-

tion in the transfer of excitation from the antenna systems to P680. Cytochrome  $b_{559}$ , whose function is unclear, breaks the pseudosymmetry of the PSII protomer as does the Mn cluster, whose function we now discuss.

#### d. $\text{O}_2$ Is Generated in a Five-Stage Water-Splitting Reaction Mediated by an Mn-Containing Protein Complex

The oxidation by the OEC of two molecules of  $\text{H}_2\text{O}$  to form one molecule of  $\text{O}_2$  requires four electrons. Since transfer of a single electron from  $\text{H}_2\text{O}$  to  $\text{NADP}^+$  requires two photochemical events, this accounts for the observed minimum of 8 to 10 photons absorbed per molecule of  $\text{O}_2$  produced.

Must the four electrons necessary to produce a given  $\text{O}_2$  molecule be removed by a single photosystem or can they be extracted by several different photosystems? Pierre Joliet and Bessel Kok answered this question by analyzing the rate at which dark-adapted chloroplasts produce  $\text{O}_2$

(a)

(b)

**Figure 24-19** X-ray structure of PSII from *T. elongatus*.

(a) The PSII dimer is viewed from within the plane of the membrane with the stroma above. Its transmembrane subunits include D1 (yellow), D2 (orange), CP47 (red), CP43 (green), and cytochrome  $b_{559}$  (magenta). Other transmembrane subunits are colored light blue and blue-gray. Its membrane-extrinsic proteins are PsbO (dark blue), PsbU (purple), and PsbV (light green). The various cofactors are drawn in stick form with the chlorophylls of the D1/D2 reaction center light green, those of the antenna complexes dark green, pheophytins dark blue, hemes red,  $\beta$ -carotenes orange,  $Q_A$  and  $Q_B$  purple, and the nonheme Fe represented by a red sphere. The inferred position of the membrane is indicated by the light blue band. (b) View of a PSII protomer perpendicular to the membrane from the thylakoid lumen showing only the transmembrane portions of the complex and colored as in Part a. A portion of the other protomer in the PSII dimer is shown in muted colors with the dashed line indicating the region of monomer–monomer interactions and the black ellipse indicating the position of the 2-fold axis. The pseudo-2-fold axis, which is perpendicular to the membrane and passes through the nonheme Fe, relates the transmembrane helices of the D1/D2 heterodimer, CP43 and CP47, and PsbI and PsbX as emphasized by the black lines encircling these subunits. [Courtesy of James Barber and So Iwata, Imperial College London, U.K. PDBid 1S5L.]

when exposed to a series of short flashes.  $O_2$  was evolved with a peculiar oscillatory pattern (Fig. 24-21). There is virtually no  $O_2$  evolved by the first two flashes. The third flash results in the maximal  $O_2$  yield. Thereafter, the amount of  $O_2$  produced peaks with every fourth flash until the oscillations damp out to a steady state. This periodicity indicates that each OEC cycles through five different states,  $S_0$  through  $S_4$  (Fig. 24-22). Each of the transitions between  $S_0$  and  $S_4$  is a photon-driven redox reaction; that from  $S_4$  to  $S_0$

results in the release of  $O_2$ . Thus, *each  $O_2$  molecule must be produced by a single photosystem*. The observation that  $O_2$  evolution peaks at the third rather than the fourth flash indicates that the OEC's resting state is predominantly  $S_1$  rather than  $S_0$ . The oscillations gradually damp out because a small fraction of the RCs fail to be excited or become doubly excited by a given flash of light, so that they eventually lose synchrony. The five reaction steps release a total of four water-derived protons into the inner thylakoid space

**Figure 24-20** The arrangement of electron-transfer cofactors in PSII from *T. elongatus*. The complex is viewed along the membrane plane with the thylakoid lumen below. The cofactors are colored as in Fig. 24-19 but with  $Mg^{2+}$  yellow, N blue, and O red. The phytol tails of the chlorophylls and pheophytins have been removed for clarity. The side chain C atoms of Tyr<sub>Z</sub> (D1 Tyr 161) and D1 His 190 are yellow, and those of Tyr<sub>D</sub> (D2 Tyr 160)

and D2 His 189 are orange. The OEC is drawn in space-filling form with Mn purple,  $Ca^{2+}$  cyan, and O red. The numbers indicate the center-to-center distances, in angstroms, between the cofactors spanned by the accompanying thin black lines. Compare this figure to Fig. 24-12 (which is drawn upside down relative to this figure). [Courtesy of James Barber and So Iwata, Imperial College London, U.K. PDBid 1S5L.]

(lumen) in a stepwise manner (Fig. 24-22). These protons contribute to the transmembrane proton gradient.

Since the OEC abstracts electrons from  $H_2O$ , its five states must have extraordinarily high reduction potentials (recall from Table 22-1 that the  $O_2/H_2O$  half-reaction has a standard reduction potential of 0.815 V). PSII must also stabilize the highly reactive intermediates for extended periods (as much as minutes) in close proximity to water.

**Figure 24-21** The  $O_2$  yield per flash in dark-adapted spinach chloroplasts. Note that the yield peaks on the third flash and then on every fourth flash thereafter until the curve eventually damps out to its average value. [After Forbush, B., Kok, B., and McGloin, M.P., *Photochem. Photobiol.* **14**, 309 (1971).]

The OEC, which is located at the luminal surface of the D1 subunit (Fig. 24-20), is a  $Mn_4CaO_4$  or  $Mn_4CaO_5$  complex in which the O atoms bridge neighboring Mn atoms. The structure of the OEC remains elusive due to PSII's relatively poorly resolved X-ray structures and the observation

**Figure 24-22** Schematic mechanism of  $O_2$  generation in chloroplasts. Four electrons are stripped, one at a time in light-driven reactions ( $S_0 \rightarrow S_4$ ), from two bound  $H_2O$  molecules. In the recovery step ( $S_4 \rightarrow S_0$ ), which is light independent,  $O_2$  is released and two more  $H_2O$  molecules are bound. Three of these five steps release protons into the thylakoid lumen.

**Figure 24-23** A model of the OEC. This  $\text{Mn}_4\text{CaO}_5$  complex is shown in ball-and-stick form with Mn ions purple, the  $\text{Ca}^{2+}$  ion cyan, and O red. The bonds between the Ca and Mn ions are drawn in gray to indicate that the position of the Ca ion is relatively poorly defined. Presumably, numerous protein side chains and water molecules ligand the Ca and Mn ions. Several related models are also compatible with the structural data. [Based on a model by Vittal Yachandra, Lawrence Berkeley National Laboratory, Berkeley, California.]

that the OEC decomposes when illuminated with X-rays at the intensities used in X-ray structure determinations. However, the use of X-ray spectroscopy techniques of lower intensity that are sensitive to bond lengths have led to the formulation of several related models for the OEC that are compatible with the X-ray structure of PSII. One of these models is shown in Fig. 24-23.

The water-splitting reaction is driven by the excitation of the PSII RC. A variety of evidence indicates that the Mn ions in the OEC's various  $S$  states (Fig. 24-22) cycle through specific combinations of Mn(II), Mn(III), Mn(IV), and Mn(V) while abstracting protons and electrons from two  $\text{H}_2\text{O}$  molecules to yield  $\text{O}_2$ , which is released into the thylakoid lumen. However, the mechanism whereby this occurs, that is, the nature of the five  $S$  states, remains unknown due to the lack of structural information concerning these states.

The next link in the PSII electron transport chain is an entity, originally named Z (Fig. 24-18), which relays electrons from the OEC to P680. The existence of Z is signaled by a transient EPR spectrum of illuminated chloroplasts that parallels the  $S$ -state transitions. The change in this spectrum on supplying deuterated tyrosine to cyanobacteria indicates that  $Z^+$  is a tyrosyl radical ( $\text{TyrO}\cdot$ ; EPR spectra reflect the nuclear spins of the atoms with which the unpaired electrons interact). It has been identified as  $\text{Tyr}_Z$  in PSII (Fig. 24-20) due to its position between the Mn cluster and P680's chlorophyll  $\text{P}_{\text{D1}}$ . Recall that a tyrosyl radical has also been implicated in the reduction of  $\text{O}_2$  to  $2 \text{H}_2\text{O}$  by cytochrome  $c$  oxidase (Complex IV) in the respiratory electron-transport chain (Section 22-2C5c).

### e. Electron Transport through the Cytochrome $b_6f$ Complex Generates a Proton Gradient

From the plastoquinone pool, electrons pass through the cytochrome  $b_6f$  complex. This integral membrane assembly resembles cytochrome  $bc_1$ , its purple bacterial counterpart (Section 24-2Be), as well as Complex III of the mitochondrial electron-transport chain (also called cytochrome  $bc_1$ ; Section 22-2C3a). Electron flow through the cytochrome  $b_6f$  complex occurs through a Q cycle (Fig. 22-31) in which plastoquinone is the ( $\text{H}^+ + e^-$ ) carrier. Accordingly, two protons are translocated across the thylakoid membrane for every electron transported. The four electrons abstracted from  $2 \text{H}_2\text{O}$  by the OEC therefore lead to the translocation of eight  $\text{H}^+$  from the stroma to the thylakoid lumen. *Electron transport via the cytochrome  $b_6f$  complex generates much of the electrochemical proton gradient that drives the synthesis of ATP in chloroplasts.*

The X-ray structure of cytochrome  $b_6f$  (Fig. 24-24) was independently determined by Janet Smith and William Cramer and by Jean-Luc Popot and Daniel Picot. Cytochrome  $b_6f$  is a dimer of  $\sim 109$ -kD protomers, each containing four large subunits (18–32 kD) that have counterparts in cytochrome  $bc_1$ : **cytochrome  $b_6$** , a homolog of the N-terminal half of cytochrome  $b$ ; **subunit IV**, a homolog of the C-terminal half of cytochrome  $b$ ; a Rieske iron–sulfur protein (ISP), which is also present in cytochrome  $bc_1$ ; and **cytochrome  $f$**  ( $f$  for *feuille*, French for leaf), a  $c$ -type cytochrome that is a functional analog of cytochrome  $c_1$ , although the two are unrelated in structure or sequence. In fact, cytochrome  $f$  is an elongated, two-domain protein that is dominated by  $\beta$  sheets and hence has an entirely different fold from those of other  $c$ -type cytochromes of known structure. Cytochrome  $f$ 's single heme  $c$  is, nevertheless, covalently linked to the protein's larger domain via the two Cys residues in a Cys-X-Y-Cys-His sequence that is characteristic of  $c$ -type cytochromes (Fig. 9-41) and whose His residue forms one of the Fe ion's two axial ligands (Fig. 22-21). Intriguingly, however, the second axial ligand is not a Met S atom, as occurs in most  $c$ -type cytochromes, but instead is the protein's N-terminal amino group, a group that had previously not been observed to be a heme ligand.

In addition, cytochrome  $b_6f$  has four small hydrophobic subunits that have no equivalents in cytochrome  $bc_1$ . Each protomer contains 13 transmembrane helices, four in cytochrome  $b_6$ , three in subunit IV, and one each in the remaining subunits. Cytochrome  $b_6f$  binds cofactors that are the equivalents of all of those in cytochrome  $bc_1$ : **heme  $f$** , a  $c$ -type heme bound by cytochrome  $f$ ; a  $[\text{2Fe}-\text{2S}]$  cluster bound by the ISP; hemes  $b_{\text{H}}$  and  $b_{\text{L}}$ ; a plastoquinone molecule that occupies either the  $\text{Q}_i$  site (the quinone-binding site at which fully reduced quinone is regenerated during the Q cycle; Section 22-3Be) or the  $\text{Q}_o$  site. In addition, cytochrome  $b_6f$  binds several cofactors that have no counterparts in cytochrome  $bc_1$ : a Chl  $a$ , a  $\beta$ -carotene, and, unexpectedly, a novel heme named **heme  $x$**  (alternatively, **heme  $c_i$** ), which is covalently linked to the protein via a single thioether bond to Cys 35 of cytochrome  $b_6$ , and whose only axial ligand is a water molecule (compare with hemes  $a$ ,  $b$ , and  $c$ ; Fig. 22-21).

**Figure 24-24** X-ray structure of the cytochrome  $b_6/f$  complex from the thermophilic cyanobacterium *Mastigocladus laminosus*. A ribbon diagram of the dimeric complex is drawn on the left with cytochrome  $b_6$  blue, subunit IV purple, cytochrome  $f$  red, the iron-sulfur protein (ISP) yellow, and the other subunits green. The inferred position of the lipid bilayer is

indicated by a yellow band. Compare this figure to Fig. 22-23 (which is upside down relative to this figure). The paths of electron and proton transfer through the complex and the distances, in angstroms, between redox centers are shown on the right. [Modified from a drawing by William A. Cramer and Janet Smith, Purdue University. PDBid 1UM3.]

#### f. Plastocyanin Transports Electrons from Cytochrome $b_6/f$ to PSI

Electron transfer between cytochrome  $f$ , the terminal electron carrier of the cytochrome  $b_6/f$  complex, and PSI is mediated by **plastocyanin (PC)**, a 99-residue, monomeric, Cu-containing, peripheral membrane protein located on the thylakoid luminal surface (Fig. 24-17). Thus PC is the functional analog of cytochrome  $c$ , which transfers electrons from Complex III to Complex IV in the mitochondrial electron-transport chain (Section 22-2C4).

PC's redox center cycles between its Cu(I) and Cu(II) oxidation states. The X-ray structure of PC from poplar leaves, determined by Hans Freeman, shows that its single

Cu atom is coordinated with distorted tetrahedral geometry by a Cys, a Met, and two His residues (Fig. 24-25). Cu(II) complexes with four ligands normally adopt a square planar coordination geometry, whereas those of Cu(I) are generally tetrahedral. Evidently, the strain of Cu(II)'s protein-imposed tetrahedral coordination in PC promotes its

**Figure 24-25** X-ray structure of plastocyanin (PC) from poplar leaves. This 99-residue monomeric protein, a member of the family of **blue copper proteins** (as is the globular domain of Complex IV's Subunit II, which binds the  $\text{Cu}_A$  center; Section 22-2C5a), folds into a  $\beta$  sandwich. Its Cu atom (*orange sphere*), which alternates between its Cu(I) and Cu(II) oxidation states, is tetrahedrally coordinated by the side chains of His 37, Cys 84, His 87, and Met 92, which are shown in stick form with their C, N, and S atoms green, blue, and yellow. Seven conserved Asp and Glu residues (*red*) form a negatively charged patch on the surface of PC that has been implicated in electrostatically binding to a positively charged patch on the surface of cytochrome  $f$  formed by five Lys and Arg residues. [Based on an X-ray structure by Mitchell Guss and Hans Freeman, University of Sydney, Australia. PDBid 1PLC.]

reduction to Cu(I). This hypothesis accounts for PC's high standard reduction potential (0.370 V) compared to that of the normal Cu(II)/Cu(I) half-reaction (0.158 V). This is an example of how proteins modulate the reduction potentials of their redox centers so as to match them to their function—in the case of plastocyanin, the efficient transfer of electrons from the cytochrome *b<sub>6</sub>f* complex to PSI.

### g. PSI Resembles Both PSII and the PbRC

Cyanobacterial PSIs are trimers of protomers that each consist of at least 11 different protein subunits coordinating >100 cofactors. The X-ray structure of PSI from *T. elongatus* (Fig. 24-26), determined at 2.5-Å resolution by Norbert Krauss, Saenger, and Petra Fromme, reveals that each of its 356-kD protomers contains nine transmembrane subunits (**PsaA, PsaB, PsaF, PsaI–M, and PsaX**) and three stromal (cytoplasmic) subunits (**PsaC–E**), which collectively bind 127 cofactors that comprise 30% of PSI's mass. The cofactors forming the PSI RC are all bound by the homologous subunits PsaA (755 residues) and PsaB (740 residues), whose 11 transmembrane helices each are arranged in a manner resembling those in the L and M subunits of the PbRC (Fig. 24-11) and the D1 and D2 subunits of PSII (Fig. 24-19), thus supporting the hypothesis that all

RCs arose from a common ancestor. PsaA and PsaB, together with other transmembrane subunits, also bind the cofactors of the core antenna system (see below).

Figure 24-27 indicates that PSI's RC consists of six molecules of chlorophyll and two molecules of **phyloquinone (vitamin K)**; note that it has the same phytol side chain as chlorophylls; Fig. 24-3),

all arranged in two pseudosymmetrically related branches, followed by three [4Fe–4S] clusters. The primary electron donor of this system, **P700**, consists of a Chl *a'* (Fig. 24-3) and a Chl *a* (A1 and B1, respectively), whose rings are

**Figure 24-26** X-ray structure of PSI from *T. elongatus*.

(a) View of the trimer perpendicular to the membrane from its stromal side. The stromal subunits have been removed for clarity. PSI's 3-fold axis of symmetry is represented by the small black triangle. Different structural elements are shown for each of the three protomers (I, II, and III). I shows the arrangement of transmembrane helices (*cylinders*), which are differently colored for each subunit. The transmembrane helices of both PsaA (*blue*) and PsaB (*red*) are named a through k from their N- to C-termini. The six helices in extramembranous loop regions are drawn as spirals. II shows the transmembrane helices as cylinders with the stromal and luminal loop regions drawn in ribbon form. III shows the transmembrane helices as cylinders together with

all cofactors. The RC Chl *a*'s and quinones, drawn in stick form, are purple, the Fe and S atoms of the [4Fe–4S] clusters are drawn as orange and yellow spheres, the antenna system Chl *a*'s (whose side chains have been removed for clarity) are yellow, the carotenoids are black, and the bound lipids are light green. (b) One protomer as viewed parallel to the membrane along the arrow in Part a with the stroma above. The transmembrane subunits are colored as in Part a with the stromal subunits PsaC, PsaD, and PsaE pink, cyan, and light green. The vertical line and triangle mark the trimer's 3-fold axis of symmetry. [Courtesy of Wolfram Saenger, Freie Universität Berlin, Germany. PDBid 1JB0.]

**Figure 24-27** Cofactors of the PSI RC and PsaC. The structure is viewed parallel to the membrane plane with the stroma above. The Chl *a* and phylloquinone molecules are arranged in two branches that are related by PSI's 2-fold axis of pseudosymmetry, which is vertical in this drawing. The Chl *a*'s are labeled A or B to indicate that their Mg<sup>2+</sup> ions are liganded by the side chains of PsaA or PsaB, respectively, and, from the luminal side upward, by different colors and numbers, 1 to 3. The phylloquinones are named Q<sub>K</sub>-A and Q<sub>K</sub>-B. PsaC is shown in ribbon form with those portions resembling segments in bacterial 2[4Fe-4S] ferredoxins pink and with insertions and extensions green. The three [4Fe-4S] clusters are shown in ball-and-stick form and labeled according to their spectroscopic identities F<sub>X</sub>, F<sub>A</sub>, and F<sub>B</sub>. The center-to-center distances between cofactors (*vertical black lines*) are given in angstroms. Compare this figure with Figs. 24-20 and 24-12. [Courtesy of Wolfram Saenger, Freie Universität Berlin, Germany. PDBid 1JB0.]

parallel and whose Mg<sup>2+</sup> ions are separated by 6.3 Å. Thus P700 resembles the special pair in the PbRC. However, EPR studies indicate that ~80% of the unpaired electron associated with photooxidized P700<sup>+</sup> resides on Chl *a* B1. A1 is followed in the left branch of Fig. 24-27 by two more Chl *a* rings, B2 and A3, and B1 is followed by A2 and B3 in the right branch. One or both of the third pair of Chl *a* molecules, A3 and B3, probably form the spectroscopically identified primary electron acceptor A<sub>0</sub> (right side of Fig. 24-18). The Mg<sup>2+</sup> ions of A3 and B3 are each axially liganded by the S atom of a Met residue rather than by a His side chain (thereby forming the only known biological examples of Mg<sup>2+</sup>-S coordination). All of the residues involved in Mg<sup>2+</sup> coordination and hydrogen bonding to these second and third Chl *a*'s are strictly conserved in PSI's, from cyanobacteria to higher plants, thereby suggesting that all of these interactions are important for fine-tuning their redox potentials. Electrons are passed from A3 and B3 to the phylloquinones, Q<sub>K</sub>-A and Q<sub>K</sub>-B, which almost certainly correspond to the spectroscopically identified electron acceptor A<sub>1</sub>. Spectroscopically based kinetic investigations indicate that, in contrast to the case for the PbRC, electrons pass through both branches of the PSI

RC, although at different rates:  $35 \times 10^6 \text{ s}^{-1}$  for the branch ending in Q<sub>K</sub>-B and  $4.4 \times 10^6 \text{ s}^{-1}$  for that ending in Q<sub>K</sub>-A. Indeed, the PSI RC is most closely related to the RC of **green sulfur bacteria** (a second class of photosynthetic bacteria), which is a true homodimer.

Up until this point, PSI's RC resembles those of PSII and purple photosynthetic bacteria. However, rather than the reduced forms of either Q<sub>K</sub>-A or Q<sub>K</sub>-B dissociating from PSI, both of these quinones directly pass their photoexcited electron to a chain of three spectroscopically identified [4Fe-4S] clusters designated F<sub>X</sub>, F<sub>A</sub>, and F<sub>B</sub> (right side of Fig. 24-18). F<sub>X</sub>, which lies on the pseudo-2-fold axis relating PsaA and PsaB, is coordinated by two Cys residues from each of these subunits. F<sub>A</sub> and F<sub>B</sub> are bound to the stromal subunit PsaC, which structurally resembles bacterial 2[4Fe-4S] ferredoxins (e.g., Fig. 22-16). Mutational studies on the Cys residues of PsaC that coordinate its two [4Fe-4S] clusters indicate that the cluster that lies closer to F<sub>X</sub> is F<sub>A</sub> and the more distant cluster is F<sub>B</sub> (Fig. 24-27). The observation that both branches of PSI's electron-transfer pathways are active, in contrast to only one active branch in PSII and the PbRC, is rationalized by the fact that the two quinones at the ends of each branch are functionally equivalent in PSI but functionally different in PSII and the PbRC.

PSI's core antenna system consists of 90 Chl *a* molecules and 22 carotenoids (Fig. 24-26a). The Mg<sup>2+</sup> ions of 79 of these Chl *a* molecules are axially liganded by residues of PsaA and PsaB (mostly His side chains or protein-bound water molecules), whereas the remaining 11 are so liganded by the smaller subunits PsaJ through M and PsaX. The spatial distribution of these antenna Chl *a*'s resembles that in the core antenna subunits CP43 and CP47 of PSII. Indeed, the N-terminal domains of PsaA and PsaB are similar in sequence to those of CP43 and CP47 and fold into similar structures containing six transmembrane helices each. The carotenoids, which are mostly β-carotenes, are deeply buried in the membrane, where they are in van der Waals contact with Chl *a* rings. This permits efficient energy transfer from photoexcited carotenoids to Chl *a* as well as protects PSI from photooxidative damage. PSI also tightly binds four lipid molecules such that their fatty acyl groups are embedded among the complex's transmembrane helices. This strongly suggests that these lipids have specific structural and/or functional roles rather than being artifacts of preparation. Indeed, the head group of one of them, a phospholipid, coordinates the Mg<sup>2+</sup> of an antenna Chl *a*, an unprecedented interaction.

PSIs from higher plants are monomers rather than trimers as are cyanobacterial PSIs. Nevertheless, the X-ray structure of PSI from peas, determined by Nathan Nelson, reveals that the positions and orientations of the chlorophylls in both species of PSIs are nearly identical, a remarkable finding considering the >1 billion years since chloroplasts diverged from their cyanobacterial ancestors. However, pea PSI has four antenna proteins not present in cyanobacterial PSI that are arranged in a crescent-shaped transmembrane belt around one side of its RC and which collectively bind 56 chlorophyll molecules.

### h. PSI-Activated Electrons May Reduce $\text{NADP}^+$ or Motivate Proton Gradient Formation

Electrons ejected from  $F_B$  in PSI may follow either of two alternative pathways (Fig. 24-18):

1. Most electrons follow a noncyclic pathway by passing to an  $\sim 100$ -residue, single  $[2\text{Fe}-2\text{S}]$ -containing, soluble ferredoxin (**Fd**) that is located in the stroma. Reduced Fd, in turn, reduces  $\text{NADP}^+$  in a reaction mediated by the  $\sim 310$ -residue, monomeric, FAD-containing **ferredoxin-NADP<sup>+</sup> reductase (FNR)**, (Fig. 24-28a), to yield the final product of the chloroplast light reaction, NADPH. Two reduced Fd molecules successively deliver one electron each to the FAD of FNR, which thereby sequentially assumes the neutral semiquinone and fully reduced states before transferring the two electrons and a proton to the  $\text{NADP}^+$  via what is formally a hydride ion transfer. The X-ray structure of the complex between Fd and FNR from maize leaf (Fig. 24-28b), determined by Genji Kurisu, reveals that the shortest interatomic approach between Fd's  $[2\text{Fe}-2\text{S}]$  cluster and FNR's FAD is the 6.0 Å between an Fe atom and FAD atom C8a (the methyl C closest to its ribitol residue; Fig. 16-8). This is

sufficiently close for direct electron transfer through space between these prosthetic groups. The complex is stabilized by five salt bridges, as similarly appears to be the case for the interaction between cytochrome *f* and PC.

2. Some electrons are returned from PSI, via cytochrome  $b_6$ , to the plastoquinone pool, thereby traversing a cyclic pathway that translocates protons across the thylakoid membrane. A mechanism that has been proposed for this process is that Fd transfers an electron to heme *x* of cytochrome  $b_6$  (Fig. 24-24) rather than to FNR. Since heme *x* contacts heme  $b_L$  at the periphery of cytochrome  $b_6/f$ 's  $Q_1$  site, an electron injected into heme *x* would be expected to reduce plastoquinone via a Q cycle-like mechanism (Fig. 22-31). Note that the cyclic pathway is independent of the action of PSII and hence does not result in the evolution of  $\text{O}_2$ . This accounts for the observation that chloroplasts absorb more than eight photons per  $\text{O}_2$  molecule evolved.

The cyclic electron flow presumably functions to increase the amount of ATP produced relative to that of

**Figure 24-28 Ferredoxin-NADP<sup>+</sup> reductase.** (a) The X-ray structure of the Y308S mutant form of pea ferredoxin-NADP<sup>+</sup> reductase (FNR) in complex with FAD and NADP<sup>+</sup>. This 308-residue protein has two domains: The N-terminal domain (*gold*), which forms the FAD binding site, folds into an antiparallel  $\beta$  barrel, whereas the C-terminal domain (*magenta*), which provides the NADP<sup>+</sup> binding site, forms a dinucleotide-binding fold (Section 8-3Bi). The FAD and NADP<sup>+</sup> are shown in stick form with NADP<sup>+</sup> C green, FAD C cyan, N blue, O red, and P yellow. The flavin and nicotinamide rings are in opposition with C4 of the nicotinamide ring and C5 of the flavin ring 3.0 Å apart, an arrangement that is consistent with direct hydride transfer as also occurs in glutathione reductase and dihydrolipoyl dehydrogenase (Section 21-2Ba). However, in contrast to these

latter enzymes, whose bound flavin and nicotinamide rings are parallel, those in FNR are inclined by  $\sim 30^\circ$ , a heretofore unobserved binding mode. [Based on an X-ray structure by Andrew Karplus, Cornell University, PDBid 1QFY.] (b) The X-ray structure of the complex between Fd (*red*) and FNR (*blue*) from maize leaf with both proteins drawn in ribbon form embedded in their transparent solvent-accessible surfaces. The  $[2\text{Fe}-2\text{S}]$  cluster of Fd (*green*) and the FAD of FNR (*yellow*) are drawn in ball-and-stick form. The Fd binds in a hollow between FNR's two domains (Part a) such that the line joining the two Fe's of the  $[2\text{Fe}-2\text{S}]$  cluster lies roughly in the plane of the flavin ring. [Courtesy of Genji Kurisu, Osaka University, Osaka, Japan. PDBid 1GAQ.]  See Interactive Exercise 22

NADPH and thus permits the cell to adjust the relative amounts of these two substances produced according to its needs. However, the mechanism that apports electrons between the cyclic and noncyclic pathways is unknown.

### i. PSI and PSII Occupy Different Parts of the Thylakoid Membrane

Freeze-fracture electron microscopy (Section 12-3Ca) revealed that the protein complexes of the thylakoid membrane have characteristic distributions (Fig. 24-29):

1. PSI occurs mainly in the unstacked stroma lamellae, in contact with the stroma, where it has access to  $\text{NADP}^+$ .
2. PSII is located almost exclusively between the closely stacked grana, out of direct contact with the stroma.
3. Cytochrome  $b_6f$  is uniformly distributed throughout the membrane.

The high mobilities of plastoquinone and plastocyanin, the electron carriers that shuttle electrons between these complexes, permits photosynthesis to proceed at a reasonable rate.

What function is served by the segregation of PSI and PSII, which are typically present in chloroplasts in equimolar amounts? If these two photosystems were in close proximity, the higher excitation energy of PSII (P680 vs P700) would cause it to pass a large fraction of its absorbed photons to PSI via exciton transfer; that is, PSII would act as a light-harvesting antenna for PSI (Fig. 24-7b). The separation of these particles by around 100 Å eliminates this difficulty.

The physical separation of PSI and PSII also permits the chloroplast to respond to changes in illumination. The relative amounts of light absorbed by the two photosystems vary with how the light-harvesting complexes (LHCs) are distributed between the stacked and un-

stacked portions of the thylakoid membrane. Under high illumination (normally direct sunlight, which contains a high proportion of short-wavelength blue light), all else being equal, PSII absorbs more light than PSI. PSI is then unable to take up electrons as fast as PSII can supply them, so the plastoquinone is predominantly in its reduced state. The reduced plastoquinone activates a protein kinase to phosphorylate specific Thr residues of the LHCs, which, in response, migrate to the unstacked regions of the thylakoid membrane, where they bind to PSI. A greater fraction of the incident light is thereby funneled to PSI. Under low illumination (normally shady light, which contains a high proportion of long-wavelength red light), PSI takes up electrons faster than PSII can provide them so that plastoquinone predominantly assumes its oxidized form. The LHCs are consequently dephosphorylated and migrate to the stacked portions of the thylakoid membrane, where they drive PSII. The chloroplast therefore maintains the balance between its two photosystems by a light-activated feedback mechanism.

### D. Photophosphorylation

*Chloroplasts generate ATP in much the same way as mitochondria, that is, by coupling the dissipation of a proton gradient to the enzymatic synthesis of ATP (Section 22-3C).* This was clearly demonstrated by the imposition of an artificially produced pH gradient across the thylakoid membrane. Chloroplasts were soaked, in the dark, for several hours in a succinic acid solution at pH 4 so as to bring the thylakoid lumen to this pH (the thylakoid membrane is permeable to unionized succinic acid). The abrupt transfer of these chloroplasts to an  $\text{ADP} + \text{P}_i$ -containing buffer at pH 8 resulted in an impressive burst of ATP synthesis: About 100 ATPs were synthesized per molecule of cytochrome  $f$  present. Moreover, the amount of ATP

**Figure 24-29 Segregation of PSI and PSII.** The distribution of photosynthetic protein complexes between the stacked (grana) and the unstacked (stroma exposed) regions of the thylakoid

membrane is shown. [After Anderson, J.M. and Anderson, B., *Trends Biochem. Sci.* **7**, 291 (1982).]

synthesized was unaffected by the presence of electron-transport inhibitors such as DCMU. This, together with the observations that photophosphorylation requires an intact thylakoid membrane and that proton translocators such as 2,4-dinitrophenol (Section 22-3D) uncouple photophosphorylation from light-driven electron transport, provides convincing evidence favoring the chemiosmotic hypothesis (Section 22-3A).

#### a. Chloroplast Proton-Translocating ATP Synthase Resembles That of Mitochondria

Electron micrographs of thylakoid membrane stromal surfaces and bacterial plasma membrane inner surfaces reveal lollipop-shaped structures (Fig. 24-30). These closely resemble the  $F_1$  units of the proton-translocating ATP synthase studding the matrix surfaces of inner mitochondrial membranes (Fig. 22-36a). In fact, the chloroplast ATP synthase, which is termed the  **$CF_1CF_0$  complex** (C for chloroplast), has remarkably similar properties to the mitochondrial  $F_1F_0$  complex (Section 22-3C). For example,

1. Both  $F_0$  and  $CF_0$  units are hydrophobic transmembrane proteins that contain a proton-translocating channel.
2. Both  $F_1$  and  $CF_1$  are hydrophilic peripheral membrane proteins of subunit composition  $\alpha_3\beta_3\gamma\delta\epsilon$ , of which  $\beta$  is a reversible ATPase.
3. Both ATP synthases are inhibited by oligomycin.
4. Chloroplast ATP synthase translocates protons out of the thylakoid lumen into the stroma (Fig. 24-17), and mitochondrial ATP synthase conducts them into the matrix space (the mitochondrial equivalent of the stroma) from the intermembrane space (Section 22-3A).

**Figure 24-30** Electron micrograph of thylakoids. The  $CF_1$  “lollipops” of their ATP synthases project from their stromal surfaces. Compare this with Fig. 22-36a. [Courtesy of Peter Hinkle, Cornell University.]

Clearly, proton-translocating ATP synthases must have evolved very early in the history of cellular life. Chloroplast ATP synthase is located in the unstacked portions of the thylakoid membrane, in contact with the stroma, where there is room for the bulky  $CF_1$  globule and access to ADP (Fig. 24-29).

#### b. Photosynthesis with Noncyclic Electron Transport Produces Around 1.25 ATP Equivalents per Absorbed Photon

At saturating light intensities, chloroplasts generate proton gradients of  $\sim 3.5$  pH units across their thylakoid membranes. This, as we have seen (Figs. 24-17 and 24-18), arises from two sources:

1. The evolution of a molecule of  $O_2$  from two  $H_2O$  molecules releases four protons into the thylakoid lumen. These protons should be considered as being supplied from the stroma by the protons and H atoms taken up in the synthesis of NADPH.
2. The transport of the liberated four electrons through the cytochrome  $b_6f$  complex occurs with the translocation of what is estimated to be eight protons from the stroma to the thylakoid lumen.

*Altogether  $\sim 12$  protons are translocated per molecule of  $O_2$  produced by noncyclic electron transport.*

The thylakoid membrane, in contrast to the inner mitochondrial membrane, is permeable to ions such as  $Mg^{2+}$  and  $Cl^-$ . Translocation of protons and electrons across the thylakoid membrane is consequently accompanied by the passage of these ions so as to maintain electrical neutrality ( $Mg^{2+}$  out and  $Cl^-$  in). This all but eliminates the membrane potential,  $\Delta\Psi$  (Eq. [22.1]). *The electrochemical gradient in chloroplasts is therefore almost entirely a result of the pH gradient.*

Chloroplast ATP synthase, according to most estimates, produces one ATP for every three protons it transports out of the thylakoid lumen. Noncyclic electron transport in chloroplasts therefore results in the production of  $\sim 12/3 = 4$  molecules of ATP per molecule of  $O_2$  evolved (although this quantity is subject to revision) or around half an ATP per photon absorbed. Cyclic electron transport is a more productive ATP generator since it yields two-thirds of an ATP (two protons transported) per absorbed photon. The noncyclic process, of course, also yields NADPH, each molecule of which has the free energy to produce three ATPs (Section 22-2A; although this does not normally occur), for a total of six more ATP equivalents per  $O_2$  produced. Consequently, the energetic efficiency of the noncyclic process is  $4/8 + 6/8 = 1.25$  ATP equivalents per absorbed photon.

### 3 DARK REACTIONS

In the previous section we saw how light energy is harnessed to generate ATP and NADPH. In this section we discuss how these products are used to synthesize carbohydrates and other substances from  $CO_2$ .

### A. The Calvin Cycle

The metabolic pathway by which plants incorporate  $\text{CO}_2$  into carbohydrates was elucidated between 1946 and 1953 by Melvin Calvin, James Bassham, and Andrew Benson. They did so by tracing the metabolic fate of the radioactive label from  $^{14}\text{CO}_2$  as it passed through a series of photosynthetic intermediates. The basic experimental strategy they used was to expose growing cultures of algae, such as *Chlorella*, to  $^{14}\text{CO}_2$  for varying times and under differing illumination conditions and then to drop the cells into boiling alcohol so as to disrupt them while preserving their labeling pattern. The radioactive products were subsequently separated and identified (an often difficult task) through the use of the then recently developed technique of two-dimensional paper chromatography (Section 6-3Dc) coupled with autoradiography. The overall pathway, diagrammed in Fig. 24-31, is known as the **Calvin cycle** or the **reductive pentose phosphate cycle**.

Some of Calvin's earliest experiments indicated that algae exposed to  $^{14}\text{CO}_2$  for a minute or more had synthesized a complex mixture of labeled metabolic products, including sugars and amino acids. By inactivating the algae within 5 s of their exposure to  $^{14}\text{CO}_2$ , however, it was shown that *the first stable radioactively labeled compound formed is 3-phosphoglycerate (3PG), which is initially labeled only in its carboxyl group*. This result immediately suggested, in analogy with most biochemical experience, that the 3PG was formed by the carboxylation of a  $\text{C}_2$  compound. Yet the failure to find any such precursor eventually forced this hypothesis to be abandoned. The actual carboxylation reaction was discovered through an experiment in which illuminated algae had been exposed to  $^{14}\text{CO}_2$  for  $\sim 10$  min so that the levels of their labeled photosynthetic intermediates had reached a steady state. The  $\text{CO}_2$  was then withdrawn. As expected, the carboxylation product, 3PG, decreased in concentration (Fig. 24-32) because it was depleted by reactions farther along the pathway. The concentration of **ribulose-5-phosphate (Ru5P)**,

**Ribulose-5-phosphate (Ru5P)**

however, simultaneously increased. Evidently, Ru5P is the Calvin cycle's carboxylation substrate. If so, the resulting  $\text{C}_6$  carboxylation product must split into two  $\text{C}_3$  compounds, one of which is 3PG (Fig. 24-31, Reaction 2). A consideration of the oxidation states of Ru5P and  $\text{CO}_2$  indicates that, in fact, both  $\text{C}_3$  compounds must be 3PG and that the carboxylation reaction requires no external redox source.

While the search for the carboxylation substrate was going on, several other photosynthetic intermediates had

been identified and, through chemical degradation studies, their labeling patterns had been elucidated. For example, the hexose fructose-1,6-bisphosphate (FBP) is initially labeled only at its C3 and C4 positions (Fig. 24-31) but later becomes labeled to a lesser degree at its other atoms. Similarly, a series of tetrose, pentose, hexose, and heptose phosphates were isolated that had the identities and initial labeling patterns indicated in Fig. 24-31. A consideration of the flow of the labeled atoms through these various intermediates led, in what was a milestone of metabolic biochemistry, to the deduction of the Calvin cycle as is diagrammed in Fig. 24-31. The existence of many of its postulated reactions was eventually confirmed by *in vitro* studies using purified enzymes.

#### a. The Calvin Cycle Generates GAP from $\text{CO}_2$ via a Two-Stage Process

The Calvin cycle may be considered to have two stages:

**Stage 1** The production phase (top line of Fig. 24-31), in which three molecules of Ru5P react with three molecules of  $\text{CO}_2$  to yield six molecules of glyceraldehyde-3-phosphate (GAP) at the expense of nine ATP and six NADPH molecules. *The cyclic nature of the pathway makes this process equivalent to the synthesis of one GAP from three  $\text{CO}_2$  molecules*. Indeed, at this point, one GAP can be bled off from the cycle for use in biosynthesis (see Stage 2).

**Stage 2** The recovery phase (bottom lines of Fig. 24-31), in which the carbon atoms of the remaining five GAPs are shuffled in a remarkable series of reactions, similar to those of the pentose phosphate pathway (Section 23-4), to reform the three Ru5Ps with which the cycle began. Indeed, the elucidation of the pentose phosphate pathway at about the same time that the Calvin cycle was being worked out provided much of the biochemical evidence in support of the Calvin cycle. This stage can be conceptually decomposed into four sets of reactions (with the numbers keyed to the corresponding reactions in Fig. 24-31):

6.  $\text{C}_3 + \text{C}_3 \longrightarrow \text{C}_6$
8.  $\text{C}_3 + \text{C}_6 \longrightarrow \text{C}_4 + \text{C}_5$
9.  $\text{C}_3 + \text{C}_4 \longrightarrow \text{C}_7$
11.  $\text{C}_3 + \text{C}_7 \longrightarrow \text{C}_5 + \text{C}_5$

The overall stoichiometry for this process is therefore

Note that this stage of the Calvin cycle occurs without further input of free energy (ATP) or reducing power (NADPH).

#### b. Most Calvin Cycle Reactions Also Occur in Other Metabolic Pathways

The types of reactions in the Calvin cycle are all familiar (Section 23-4), with the exception of the carboxylation reaction. This first stage of the Calvin cycle begins with the phosphorylation of Ru5P by **phosphoribulokinase** to form **ribulose-1, 5-bisphosphate (RuBP)**. Following the

**Figure 24-31 The Calvin cycle.** (Opposite) The number of lines in an arrow indicates the number of molecules reacting in that step for a single turn of the cycle that converts three CO<sub>2</sub> molecules to one GAP molecule. For the sake of clarity, the sugars are all shown in their linear forms, although the hexoses and heptoses predominantly exist in their cyclic forms (Section 11-1B). The <sup>14</sup>C-labeling patterns generated in one turn of the cycle through the use of <sup>14</sup>CO<sub>2</sub> are indicated in red. Note that two of the Ru5Ps are labeled only at C3, whereas the third Ru5P is equally labeled at C1, C2, and C3.  See the Animated Figures

carboxylation step, which is discussed below, the resulting 3PG is converted first to 1,3-bisphosphoglycerate (BPG) and then to GAP. This latter sequence is the reverse of two consecutive glycolytic reactions (Sections 17-2G and 17-2F) except that the Calvin cycle reaction involves NADPH rather than NADH.

The second stage of the Calvin cycle begins with the reverse of a familiar glycolytic reaction, the isomerization of GAP to dihydroxyacetone phosphate (DHAP) by triose phosphate isomerase (Section 17-2E). Following this, DHAP is directed along two analogous paths (Fig. 24-31): Reactions 6–8 or Reactions 9–11. Reactions 6 and 9 are

aldolase-catalyzed aldol condensations in which DHAP is linked to an aldehyde (aldolase is specific for DHAP but accepts a variety of aldehydes). Reaction 6 is also the reverse of a glycolytic reaction (Section 17-2D). Reactions 7 and 10 are phosphate hydrolysis reactions that are catalyzed, respectively, by fructose biphosphatase (FBPase, which we previously encountered in our discussion of glycolytic substrate cycles and gluconeogenesis; Sections 17-4Ff and 23-1Ah) and **sedoheptulose biphosphatase (SBPase)**. The remaining Calvin cycle reactions are catalyzed by enzymes that also participate in the pentose phosphate pathway. In Reactions 8 and 11, both catalyzed by **transketolase**, a C<sub>2</sub> keto unit (shaded in green in Fig. 24-31) is transferred from a ketose to GAP to form **xylulose-5-phosphate (Xu5P)** and leave the aldoses **erythrose-4-phosphate (E4P)** in Reaction 8 and **ribose-5-phosphate (R5P)** in Reaction 11. The E4P produced by Reaction 8 feeds into Reaction 9. The Xu5Ps produced by Reactions 8 and 11 are converted to Ru5P by **phosphopentose epimerase** in Reaction 12. The R5P from Reaction 11 is also converted to Ru5P by **ribose phosphate isomerase** in Reaction 13, thereby completing a turn of the Calvin cycle. Thus only 3 of the 11 Calvin cycle enzymes, phosphoribulokinase, the carboxylation enzyme **ribulose biphosphate carboxylase**, and SBPase, have no equivalents in animal tissues.

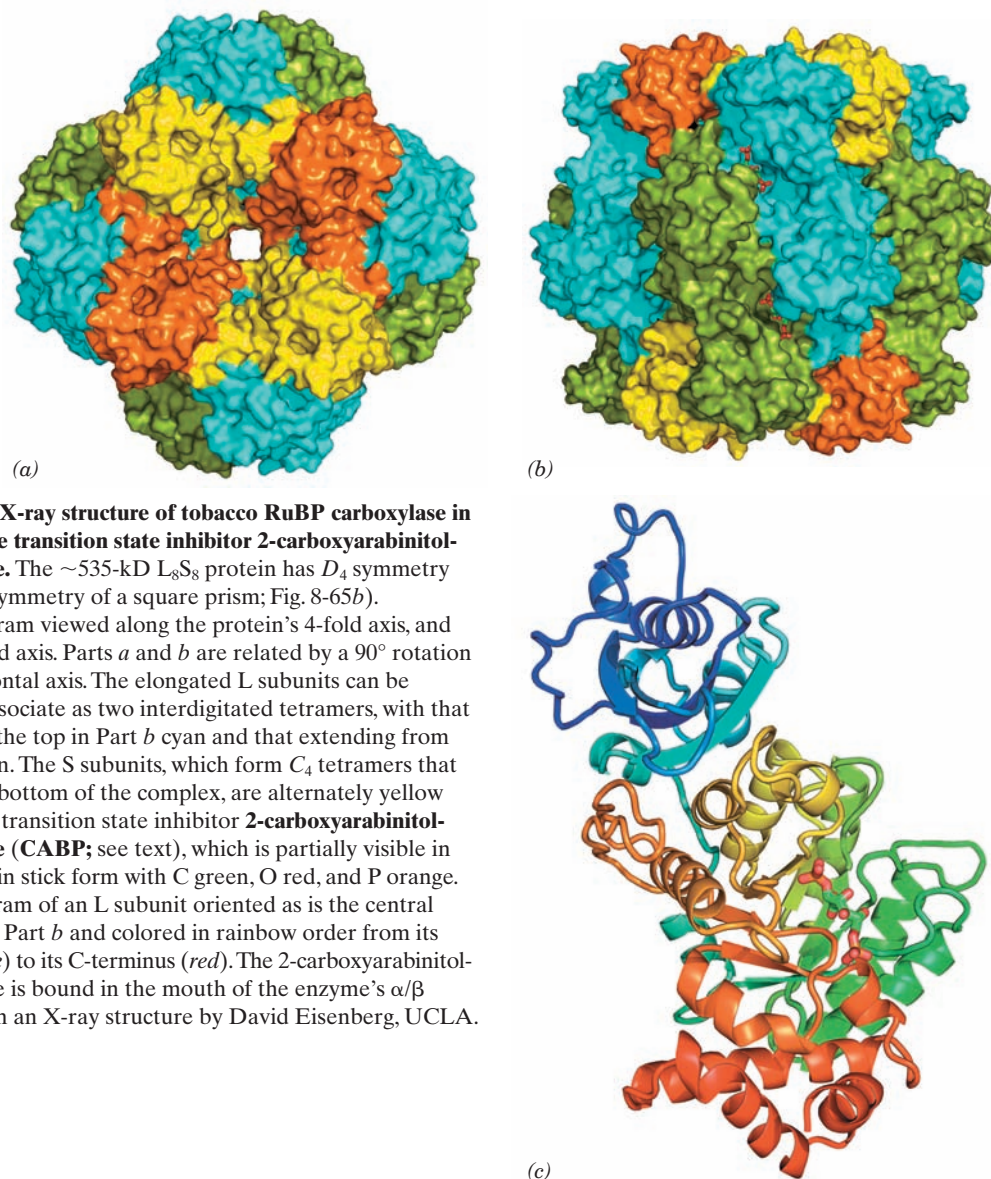

### c. RuBP Carboxylase Catalyzes CO<sub>2</sub> Fixation in an Exergonic Process

The enzyme that catalyzes CO<sub>2</sub> fixation, ribulose biphosphate carboxylase (**RuBP carboxylase**), is arguably the world's most important enzyme, since nearly all life on Earth ultimately depends on its action. This protein, presumably as a consequence of its particularly low catalytic efficiency ( $k_{\text{cat}} = \sim 3 \text{ s}^{-1}$ ), comprises up to 50% of leaf proteins and is therefore the most abundant protein in the biosphere (it is estimated to be synthesized at the rate of  $\sim 4 \times 10^9$  tons/year, which fixes  $\sim 10^{11}$  tons of CO<sub>2</sub>/year; in comparison crude oil is consumed at the rate of  $\sim 3 \times 10^9$  tons/year). RuBP carboxylase from higher plants and most photosynthetic microorganisms consists of eight large (L) subunits (477 residues in tobacco leaves) encoded by chloroplast DNA and eight small (S) subunits (123 residues) specified by a nuclear gene (the RuBP carboxylase from certain photosynthetic bacteria is an L<sub>2</sub> dimer whose L subunit has 28% sequence identity with and is structurally similar to that of the L<sub>8</sub>S<sub>8</sub> enzyme). X-ray studies by Carl-Ivar Brändén and by David Eisenberg demonstrated that the L<sub>8</sub>S<sub>8</sub> enzyme has the D<sub>4</sub> symmetry of a square prism (Fig. 24-33a,b). The L subunit contains the enzyme's catalytic site, as is demonstrated by its enzymatic activity in the absence of the S subunit. It consists of two domains (Fig. 24-33c): Residues 1 to 150 form a mixed five-stranded  $\beta$  sheet and residues 151 to 477 fold into an  $\alpha/\beta$  barrel (Fig. 8-19b,c) which, as do nearly all known  $\alpha/\beta$  barrel enzymes (Section 8-3Bh), contains the enzyme's active site at the mouth of the barrel near the C-terminus of its  $\beta$  strands. The function of the S subunit is unknown; attempts to show that it has a regulatory role, in analogy with other enzymes, have been unsuccessful.

**Figure 24-32 Algal 3PG and RuBP levels on removal of CO<sub>2</sub>.** The time course of the levels of 3PG (purple curve) and RuBP (green curve) in steady-state <sup>14</sup>CO<sub>2</sub>-labeled, illuminated algae is shown during a period in which the CO<sub>2</sub> (orange curve) is abruptly withdrawn. In the absence of CO<sub>2</sub>, the 3PG concentration rapidly decreases because it is taken up by the reactions of the Calvin cycle but cannot be replenished by them. Conversely, the RuBP concentration transiently increases as it is synthesized from the residual pool of Calvin cycle intermediates but, in the absence of CO<sub>2</sub>, cannot be used for their regeneration.

**Figure 24-33** X-ray structure of tobacco RuBP carboxylase in complex with the transition state inhibitor 2-carboxyarabinitol-1,5-bisphosphate. The ~535-kD  $L_8S_8$  protein has  $D_4$  symmetry (the rotational symmetry of a square prism; Fig. 8-65*b*). (a) Surface diagram viewed along the protein's 4-fold axis, and (b) along a 2-fold axis. Parts *a* and *b* are related by a  $90^\circ$  rotation about the horizontal axis. The elongated L subunits can be considered to associate as two interdigitated tetramers, with that extending from the top in Part *b* cyan and that extending from the bottom green. The S subunits, which form  $C_4$  tetramers that cap the top and bottom of the complex, are alternately yellow and orange. The transition state inhibitor 2-carboxyarabinitol-1,5-bisphosphate (CABP; see text), which is partially visible in Part *b*, is drawn in stick form with C green, O red, and P orange. (c) Ribbon diagram of an L subunit oriented as is the central green subunit in Part *b* and colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The 2-carboxyarabinitol-1,5-bisphosphate is bound in the mouth of the enzyme's  $\alpha/\beta$  barrel. [Based on an X-ray structure by David Eisenberg, UCLA. PDBid 1RLC.]

The accepted mechanism of RuBP carboxylase, which was largely formulated by Calvin, is indicated in Fig. 24-34. Abstraction of the C3 proton of RuBP, the reaction's rate-determining step, generates an enediolate that nucleophilically attacks  $CO_2$  (not  $HCO_3^-$ ). The resulting  $\beta$ -keto acid is rapidly attacked at its C3 position by  $H_2O$  to yield an adduct that splits, by a reaction similar to aldol cleavage, to yield the two product 3PG molecules. The following evidence favors this mechanism:

1. The C3 proton of enzyme-bound RuBP exchanges with solvent, an observation compatible with the existence of the enediolate intermediate.

2. The C2 and C3 oxygen atoms remain attached to their respective C atoms, which eliminates mechanisms involving a covalent adduct such as a Schiff base between RuBP and the enzyme.

3. The trapping of the proposed  $\beta$ -keto acid intermediate by borohydride reduction and the tight enzymatic binding of its analogs, such as **2-carboxyarabinitol-1-phosphate**

(CA1P) and **2-carboxyarabinitol-1,5-bisphosphate** (CABP),

**2-Carboxyarabinitol-1-phosphate**  
(CA1P)

**2-Carboxyarabinitol-1,5-bisphosphate**  
(CABP)

provide strong evidence for the existence of this intermediate.

The driving force for the overall reaction, which is highly exergonic ( $\Delta G^{\circ} = -35.1 \text{ kJ} \cdot \text{mol}^{-1}$ ), is provided by the

**Figure 24-34** Probable mechanism of the carboxylation reaction catalyzed by RuBP carboxylase. The reaction proceeds via an enediolate intermediate that nucleophilically attacks  $\text{CO}_2$

to form a  $\beta$ -keto acid. This intermediate reacts with water to yield two molecules of 3PG.  See the Animated Figures

cleavage of the  $\beta$ -keto acid intermediate to yield an additional resonance-stabilized carboxylate group.

RuBP carboxylase activity requires a bound divalent metal ion, physiologically  $\text{Mg}^{2+}$ , which acts to stabilize the developing negative charges during catalysis. The  $\text{Mg}^{2+}$  is, in part, bound to the enzyme by a catalytically essential carbamate group that is generated by the reaction of a non-substrate  $\text{CO}_2$  with the  $\epsilon$ -amino group of Lys 201 ( $\text{R}-\text{NH}_2 + \text{CO}_2 \rightarrow \text{R}-\text{NH}-\text{COO}^- + \text{H}^+$ ). Although the *in vitro* activation reaction occurs spontaneously in the presence of  $\text{Mg}^{2+}$  and  $\text{HCO}_3^-$ , it is blocked *in vivo* by the particularly tight binding of RuBP to active sites lacking carbamate. This inhibition is relieved, however, by the release of RuBP in an ATP-driven process catalyzed by **RuBP carboxylase activase**.

#### d. Calvin Cycle Products Are Converted to Starch, Sucrose, and Cellulose

The overall stoichiometry of the Calvin cycle is

GAP, the primary product of photosynthesis, is used in a variety of biosynthetic pathways, both inside and outside the chloroplast. For example, fatty acids and amino acids are synthesized from GAP as is described, respectively, in Sections 25-4 and 26-5. GAP can also be converted to fructose-

6-phosphate by the further action of Calvin cycle enzymes and then to glucose-1-phosphate (G1P) by phosphoglucose isomerase (Section 17-2B) and phosphoglucomutase (Section 18-1B). *G1P is the precursor of the higher carbohydrates characteristic of plants.*

The polysaccharide  $\alpha$ -amylose, a major component of starch (Section 11-2D), is synthesized in the chloroplast stroma as a temporary storage depot for glucose units. It is also synthesized as a long-term storage molecule elsewhere in the plant, including leaves, seeds, and roots. G1P is first activated by its reaction with ATP to form ADP-glucose as catalyzed by **ADP-glucose pyrophosphorylase**. **Starch synthase** then transfers the glucose residue to a nonreducing end of an  $\alpha$ -amylose or amylopectin molecule, forming a new glycosidic linkage (Fig. 24-35). The overall reaction is driven by the exergonic hydrolysis of the  $\text{PP}_i$  released in the formation of ADP-glucose. A similar reaction sequence occurs in glycogen synthesis, which uses UDP-glucose (Section 18-2A). The  $\alpha(1 \rightarrow 6)$  branches of amylopectin (Section 11-2D) are made by **starch-branching enzyme**, which functions similarly to glycogen branching enzyme (Section 18-2C).

Sucrose, a disaccharide of glucose and fructose (Section 11-2B), is the major transport sugar for delivering carbohydrates to nonphotosynthesizing cells and hence is the major photosynthetic product of green leaves. Since sucrose is synthesized in the cytosol, either glyceraldehyde-3-phosphate

**Figure 24-35** Starch synthesis. ADP-glucose is formed from G1P and ATP in a phosphoanhydride exchange reaction (1). The PP<sub>i</sub> product is rapidly hydrolyzed. ADP-glucose is the substrate for starch synthase (2), which adds the glucose residue to a nonreducing end of an existing polysaccharide, releasing ADP.

or dihydroxyacetone phosphate is transported out of the chloroplast by an antiporter that exchanges phosphate for a triose phosphate. Two trioses combine to form fructose-6-phosphate (F6P) and subsequently glucose-1-phosphate (G1P), which is then activated by UTP to form UDP-glucose. Next, sucrose-6-phosphate is produced in a reaction catalyzed by **sucrose-phosphate synthase**. Finally, sucrose-6-phosphate is hydrolyzed by **sucrose-phosphate phosphatase** to yield sucrose (Fig. 24-36), which is then exported to other plant tissues.

Cellulose, which consists of long chains of  $\beta(1 \rightarrow 4)$ -linked glucose units and is the major polysaccharide of plants, is also synthesized from UDP-glucose. Plant cell walls consist of almost crystalline cables containing 36 par-

**Figure 24-36** The synthesis of sucrose.

allel cellulose chains, each of 500 to 15,000 glucose units, all embedded in an amorphous matrix of other polysaccharides and lignin (Section 11-2C). Unlike starch in plants or glycogen in mammals, cellulose is synthesized by multisubunit enzyme complexes in the plant plasma membrane and extruded into the extracellular space.

## B. Control of the Calvin Cycle

During the day, plants satisfy their energy needs via the light and dark reactions of photosynthesis. At night, however, like other organisms, they must use their nutritional reserves to generate their required ATP and NADPH through glycolysis, oxidative phosphorylation, and the pentose phosphate pathway. Since the stroma contains the enzymes of glycolysis and the pentose phosphate pathway as well as those of the Calvin cycle, *plants must have a light-sensitive control mechanism to prevent the Calvin cycle from consuming this catabolically produced ATP and NADPH in a wasteful futile cycle.*

As we saw in Section 17-4F, the control of flux in a metabolic pathway occurs at enzymatic steps that are far from equilibrium; that is, those that have a large negative value of  $\Delta G$ . Inspection of Table 24-1 indicates that the four best candidates for flux control in the Calvin cycle are the reactions catalyzed by phosphoribulokinase, RuBP carboxylase, FBPase, and SBPase (Reactions 1, 2, 7, and 10, Fig. 24-31). In fact, the catalytic efficiencies of these four enzymes all vary, *in vivo*, with the level of illumination.

**Table 24-1** Standard and Physiological Free Energy Changes for the Reactions of the Calvin Cycle

Step <sup>a</sup>	Enzyme	$\Delta G^{\circ\prime}$ (kJ · mol <sup>-1</sup> )	$\Delta G$ (kJ · mol <sup>-1</sup> )
1	Phosphoribulokinase	-21.8	-15.9
2	Ribulose biphosphate carboxylase	-35.1	-41.0
3 + 4	Phosphoglycerate kinase + glyceraldehyde-3-phosphate dehydrogenase	+18.0	-6.7
5	Triose phosphate isomerase	-7.5	-0.8
6	Aldolase	-21.8	-1.7
7	Fructose biphosphatase	-14.2	-27.2
8	Transketolase	+6.3	-3.8
9	Aldolase	-23.4	-0.8
10	Sedoheptulose biphosphatase	-14.2	-29.7
11	Transketolase	+0.4	-5.9
12	Phosphopentose epimerase	+0.8	-0.4
13	Ribose phosphate isomerase	+2.1	-0.4

The activity of RuBP carboxylase responds to three light-dependent factors:

1. It varies with pH. On illumination, the pH of the stroma increases from around 7.0 to about 8.0 as protons are pumped from the stroma into the thylakoid lumen. RuBP carboxylase has a sharp pH optimum near pH 8.0.

2. It is stimulated by Mg<sup>2+</sup>. Recall that the light-induced influx of protons to the thylakoid lumen is accompanied by the efflux of Mg<sup>2+</sup> to the stroma (Section 24-2Db).

3. It is strongly inhibited by its transition state analog 2-carboxyarabinitol-1-phosphate (CA1P; Section 24-3Ac), which many plants synthesize only in the dark. RuBP carboxylase activase (Section 24-3Ac) also facilitates the release of the tight-binding CA1P from RuBP carboxylase.

FBPase and SBPase are also activated by increased pH and Mg<sup>2+</sup>, and by NADPH as well. The action of these factors is complemented by a second regulatory system that responds to the redox potential of the stroma. **Thioredoxin (Trx)**, an ~105-residue protein that occurs in many types of cells, contains a redox-active disulfide group. Reduced Trx activates five Calvin cycle enzymes by disulfide interchange reactions (Fig. 24-37): phosphoribulokinase, glyceraldehyde-3-phosphate dehydrogenase, FBPase, SBPase, and RuBP carboxylase activase. This explains why these enzymes are activated by reduced disulfide reagents such as dithiothreitol. The redox level of Trx is maintained by **ferredoxin-thioredoxin reductase (FTR)**, which contains a redox-active disul-

fide that is closely associated with a [4Fe-4S] cluster through which the protein directly responds to the redox state of soluble ferredoxin (Fd) in the stroma. This, as we have seen (Section 24-2Ch), varies with the illumination level.

**Figure 24-37** Light-activation mechanism of chloroplast enzymes.

Photoactivated PSI reduces soluble ferredoxin (Fd), which reduces ferredoxin-thioredoxin reductase, which, in turn, reduces the disulfide linkage of thioredoxin. Reduced thioredoxin reacts with its target enzymes by disulfide interchange, thereby activating or deactivating these enzymes. In the dark, these processes are quickly reversed by reaction with oxygen.

**Figure 24-38** X-ray structure of a Fd-FTR-Trx complex. The subunits are drawn in ribbon form with Fd green, the catalytic subunit of FTR blue, its variable subunit cyan, and Trx magenta. The [2Fe-2S] cluster of Fd and the [4Fe-4S] cluster of FTR are drawn in space-filling form with S yellow and Fe red-brown. The two Cys side chains forming the disulfide bond between FTR and Trx are shown in stick form with C green and S yellow. [Based on an X-ray structure by Hans Eklund, Swedish University of Agricultural Sciences, Uppsala, Sweden. PDBid 2PVO.]

The X-ray structure of a Fd-FTR-Trx complex (Fig. 24-38), determined by Hans Eklund, reveals that redox-active Cys residues of FTR and thioredoxin have formed a disulfide bond. Moreover, the distance between this disulfide bond and the [2Fe-2S] cluster of Fd is only ~20 Å as a consequence of the remarkably thin disklike catalytic subunit of FTR, and that the [4Fe-4S] cluster of FTR lies on a straight line between these two redox centers. This maximizes the efficiency of electron transfer from the [2Fe-2S] cluster of Fd to the redox active disulfide of Trx.
