This book was typeset in 10/12 Times Ten Roman at Aptara®, Inc. and printed and bound by Courier/Kendallville. The cover was printed by Courier/Kendallville.

Founded in 1807, John Wiley & Sons, Inc. has been a valued source of knowledge and understanding for more than 200 years, helping people around the world meet their needs and fulfill their aspirations. Our company is built on a foundation of principles that include responsibility to the communities we serve and where we live and work. In 2008, we launched a Corporate Citizenship Initiative, a global effort to address the environmental, social, economic, and ethical challenges we face in our business. Among the issues we are addressing are carbon impact, paper specifications and procurement, ethical conduct within our business and among our vendors, and community and charitable support. For more information, please visit our website: [www.wiley.com/go/citizenship](http://www.wiley.com/go/citizenship).

The paper in this book was manufactured by a mill whose forest management programs include sustained yield -harvesting of its timberlands. Sustained yield harvesting principles ensure that the number of trees cut each year does not exceed the amount of new growth.

This book is printed on acid-free paper. ∞

## ABOUT THE COVER

---

The cover contains two paintings of horse heart cytochrome *c*. The upper painting, which was drawn by Irving Geis in collaboration with Richard Dickerson, was designed to show the influence of amino acid side chains on the protein's three-dimensional folding pattern. The lower painting, also made by Geis, is of cytochrome *c* illuminated by its single iron atom in which its hydrophobic side chains are drawn in green. These paintings were made in the 1970s,

when only a handful of protein structures were known (around 70,000 are now known) and the personal computers that we presently use to visualize them were many years in the future. It reminds us that biochemistry is a process that is driven by the creativity of the human mind. Our visualization tools have developed from pen, ink, and colored pencils to sophisticated computers and software. Without creativity, however, these tools have little use.

# PREFACE

---

Biochemistry is a field of enormous fascination and utility, arising, no doubt, from our own self-interest. Human welfare, particularly its medical and nutritional aspects, has been vastly improved by our rapidly growing understanding of biochemistry. Indeed, scarcely a day passes without the report of a biomedical discovery that benefits a significant portion of humanity. Further advances in this rapidly expanding field of knowledge will no doubt lead to even more spectacular gains in our ability to understand nature and to control our destinies. It is therefore essential that individuals embarking on a career in biomedical sciences be well versed in biochemistry.

This textbook is a distillation of our experiences in teaching undergraduate and graduate students at the University of Pennsylvania and Swarthmore College and is intended to provide such students with a thorough grounding in biochemistry. We assume that students who use this textbook have had the equivalent of one year of college chemistry and sufficient organic chemistry so that they are familiar with basic principles and nomenclature. We also assume that students have taken a one-year college course in general biology in which elementary biochemical concepts were discussed. Students who lack these prerequisites are advised to consult the appropriate introductory textbooks in those subjects.

## NEW TO THIS EDITION

Since the third edition of *Biochemistry* was published in 2004, the field of biochemistry has continued its phenomenal and rapidly accelerating growth. This remarkable expansion of our knowledge, the work of many thousands of talented and dedicated scientists, has been characterized by numerous new paradigms, as well as an enormous enrichment of almost every aspect of the field. For example, the number of known protein and nucleic acid structures as determined by X-ray and NMR techniques has increased by over 3-fold. Moreover, the quality and complexity of these structures, which include numerous membrane proteins, has significantly improved, thereby providing enormous advances in our understanding of structural biochemistry. Bioinformatics, an only recently coined word, has come to dominate the way that many aspects of biochemistry are conceived and practiced. Since the third edition of *Biochemistry* was published, the number of known genome sequences has increased by over 10-fold and the goal of personalized medicine to determine the genome sequence of each individual seems to be within reach. Likewise, the state of knowledge has exploded in such subdisciplines as eukaryotic and prokaryotic molecular biology, metabolic control, protein folding, electron transport, membrane transport, immunology, signal transduction, etc. New and improved methodologies such as DNA microarrays, rapid DNA sequencing, RNAi, cryoelectron microscopy, mass spectrometry, single molecule techniques,

and robotic devices are now routinely used in the laboratory to answer questions that seemed entirely out of reach a decade ago. Indeed, these advances have affected our everyday lives in that they have changed the way that medicine is practiced, the way that we protect our own health, and the way in which food is produced.

## THEMES

In writing this textbook we have emphasized several themes. First, biochemistry is a body of knowledge compiled by people through experimentation. In presenting what is known, we therefore stress how we have come to know it. The extra effort the student must make in following such a treatment, we believe, is handsomely repaid since it engenders the critical attitudes required for success in any scientific endeavor. Although science is widely portrayed as an impersonal subject, it is, in fact, a discipline shaped through the often idiosyncratic efforts of individual scientists. We therefore identify some of the major contributors to biochemistry (most of whom are still professionally active) and, in many cases, consider the approaches they have taken to solve particular biochemical puzzles. Students should realize, however, that most of the work described could not have been done without the dedicated and often indispensable efforts of numerous co-workers.

The unity of life and its variation through evolution is a second dominant theme running through the text. Certainly one of the most striking characteristics of life on earth is its enormous variety and adaptability. Yet, biochemical research has amply demonstrated that all living things are closely related at the molecular level. As a consequence, the molecular differences among the various species have provided intriguing insights into how organisms have evolved from one another and have helped delineate the functionally significant portions of their molecular machinery.

A third major theme is that biological processes are organized into elaborate and interdependent control networks. Such systems permit organisms to maintain relatively constant internal environments, to respond rapidly to external stimuli, and to grow and differentiate.

A fourth theme is that biochemistry has important medical consequences. We therefore frequently illustrate biochemical principles by examples of normal and abnormal human physiology and discuss the mechanisms of action of a variety of drugs.

## ORGANIZATION AND COVERAGE

As the information explosion in biochemistry has been occurring, teachers have been exploring more active learning methods such as problem-based learning, discovery-based learning, and cooperative learning. These new teaching and

learning techniques involve more interaction among students and teachers and, most importantly, require more in-class time. In writing the fourth edition of this textbook, we have therefore been faced with the dual pressures of increased content and pedagogical innovation. We have responded to this challenge by presenting the subject matter of biochemistry as thoroughly and accurately as we can so as to provide students and instructors alike with this information as they explore various innovative learning strategies. In this way we deal with the widespread concern that these novel methods of stimulating student learning tend to significantly diminish course content. We have thus written a textbook that permits teachers to direct their students to areas of content that can be explored outside of class as well as providing material for in-class discussion.

We have reported many of the advances that have occurred in the last seven years in the fourth edition of *Biochemistry* and have thereby substantially enriched nearly all of its sections. Nevertheless, the basic organization of the fourth edition remains the same as that of the third edition.

The text is organized into five parts:

**I. Introduction and Background:** An introductory chapter followed by chapters that review the properties of aqueous solutions and the elements of thermodynamics.

**II. Biomolecules:** A description of the structures and functions of proteins, nucleic acids, carbohydrates, and lipids.

**III. Mechanisms of Enzyme Action:** An introduction to the properties, reaction kinetics, and catalytic mechanisms of enzymes.

**IV. Metabolism:** A discussion of how living things synthesize and degrade carbohydrates, lipids, amino acids, and nucleotides with emphasis on energy generation and consumption.

**V. Expression and Transmission of Genetic Information:** An expansion of the discussion of nucleic acid structure that is given in Part II followed by an exposition of both prokaryotic and eukaryotic molecular biology.

This organization permits us to cover the major areas of biochemistry in a logical and coherent fashion. Yet, modern biochemistry is a subject of such enormous scope that to maintain a relatively even depth of coverage throughout the text, we include more material than most one-year biochemistry courses will cover in detail. This depth of coverage, we feel, is one of the strengths of this book; it permits the instructor to teach a course of his/her own design and yet provide the student with a resource on biochemical subjects not emphasized in the course.

The order in which the subject matter of the text is presented more or less parallels that of most biochemistry courses. However, several aspects of the textbook's organization deserve comment:

**1.** Chapter 5 (Nucleic Acids, Gene Expression, and Recombinant DNA Technology) introduces molecular biology early in the narrative in response to the central

role that recombinant DNA technology has come to play in modern biochemistry. Likewise, the burgeoning field of bioinformatics is discussed in a separate section of Chapter 7.

**2.** We have split our presentation of thermodynamics between two chapters. Basic thermodynamic principles—enthalpy, entropy, free energy, and equilibrium—are discussed in Chapter 3 because these subjects are prerequisites for understanding structural biochemistry, enzyme mechanisms, and kinetics. Metabolic aspects of thermodynamics—the thermodynamics of phosphate compounds and oxidation–reduction reactions—are presented in Chapter 16 since knowledge of these subjects is not required until the chapters that follow.

**3.** Techniques of protein purification are described in a separate chapter (Chapter 6) that precedes the discussions of protein structure and function. We have chosen this order so that students will not feel that proteins are somehow “pulled out of a hat.” Nevertheless, Chapter 6 has been written as a resource chapter to be consulted repeatedly as the need arises. Techniques of nucleic acid purification are also discussed in that chapter for the above-described reasons.

**4.** Chapter 10 describes the properties of hemoglobin in detail so as to illustrate concretely the preceding discussions of protein structure and function. This chapter introduces allosteric theory to explain the cooperative nature of hemoglobin oxygen binding. The subsequent extension of allosteric theory to enzymology in Chapter 13 is then a straightforward matter.

**5.** Concepts of metabolic control are presented in the chapters on glycolysis (Chapter 17) and glycogen metabolism (Chapter 18) through the consideration of flux generation, allosteric regulation, substrate cycles, covalent enzyme modification, cyclic cascades, and a discussion of metabolic control analysis. We feel that these concepts are best understood when studied in metabolic context rather than as independent topics.

**6.** The rapid growth in our knowledge of biological signal transduction necessitates that this important subject have its own chapter, Chapter 19.

**7.** There is no separate chapter on coenzymes. These substances, we feel, are more logically studied in the context of the enzymatic reactions in which they participate.

**8.** Glycolysis (Chapter 17), glycogen metabolism (Chapter 18), the citric acid cycle (Chapter 21), and electron transport and oxidative phosphorylation (Chapter 22) are detailed as models of general metabolic pathways with emphasis placed on many of the catalytic and control mechanisms of the enzymes involved. The principles illustrated in these chapters are reiterated in somewhat less detail in the other chapters of Part IV.

**9.** Consideration of membrane transport (Chapter 20) precedes that of mitochondrially based metabolic pathways such as the citric acid cycle, electron transport, and oxidative phosphorylation. In this manner, the idea of the compartmentalization of biological processes can be easily assimilated. Chapter 20 also contains a discussion of neurotransmission because it is intimately involved with membrane transport.

**10.** Discussions of both the synthesis and the degradation of lipids have been placed in a single chapter (Chapter 25), as have the analogous discussions of amino acids (Chapter 26) and nucleotides (Chapter 28).

**11.** Energy metabolism is summarized and integrated in terms of organ specialization in Chapter 27, following the descriptions of carbohydrate, lipid, and amino acid metabolism.

**12.** The principles of both prokaryotic and eukaryotic molecular biology are expanded from their introduction in Chapter 5 in sequential chapters on DNA replication, repair and recombination (Chapter 30), transcription (Chapter 31), and translation (Chapter 32). Viruses (Chapter 33) are then considered as paradigms of more complex cellular functions, followed by discussions of eukaryotic gene expression (Chapter 34).

**13.** Chapter 35, the final chapter, is a series of minichapters that describe the biochemistry of a variety of well-characterized human physiological processes: blood clotting, the immune response, and muscle contraction.

**14.** Chapters 33, 34, and 35 are available on the Book Companion Site ([www.wiley.com/college/voet](http://www.wiley.com/college/voet)) with the same appearance and level of detail as the chapters in the printed textbook.

The old adage that you learn a subject best by teaching it simply indicates that learning is an active rather than a passive process. The problems we provide at the end of each chapter are therefore designed to make students think rather than to merely regurgitate poorly assimilated and rapidly forgotten information. Few of the problems are trivial and some of them (particularly those marked with an asterisk) are quite difficult. Yet, successfully working out such problems can be one of the most rewarding aspects of the learning process. Only by thinking long and hard for themselves can students make a body of knowledge truly their own. The answers to the problems are worked out in detail in the *Solutions Manual* for this text. The manual can be an effective learning tool, however, only if the student makes a serious effort to solve a problem before looking up its answer.

We have included lists of references at the end of every chapter to provide students with starting points for independent biochemical explorations. The enormity of the biochemical research literature prevents us from giving all but a few of the most seminal research reports. Rather, we list what we have found to be the most useful reviews and monographs on the various subjects covered in each chapter.

Finally, although we have made every effort to make this text error free, we are under no illusions that we have done so. Thus, we are particularly grateful to the many readers of previous editions, students and faculty alike, who have taken the trouble to write us with suggestions on how to improve the textbook and to point out errors they have found. We earnestly hope that the readers of the fourth edition will continue this practice.

## STUDENT AND INSTRUCTOR RESOURCES

The Book Companion Site for *Biochemistry* ([www.wiley.com/college/voet](http://www.wiley.com/college/voet)) provides online resources for both students and instructors. These online resources are designed to enhance student understanding of biochemistry. They are all keyed to figures or sections in the text and called out in the text with a red mouse icon .

**Bioinformatics Exercises:** A set of exercises cover the contents and uses of databases related to nucleic acids, protein sequences, protein structures, enzyme inhibition, and other topics. These exercises, written by Paul Craig, Rochester Institute of Technology, Rochester, New York, use real data sets, pose specific questions, and prompt students to obtain information from online databases and to access the software tools for analyzing such data.

**Guided Explorations:** 30 self-contained presentations, many with narration, employ extensive animated com-

puter graphics to enhance student understanding of key topics.

**Interactive Exercises:** 58 molecular structures from the text have been rendered in Jmol by Stephen Rouse. Jmol is a browser-independent interface for manipulating structures in three dimensions, and structures are paired with questions designed to facilitate comprehension of concepts. A Tutorial for using Jmol is also provided.

**Kinemages:** A set of 22 exercises comprising 55 three-dimensional images of selected protein and nucleic acids that can be manipulated by users as suggested by accompanying text.

**Animated Figures:** 67 figures from the text, illustrating various concepts, techniques, and processes, are presented as brief animations to facilitate learning.

**Case Studies:** A set of 33 case studies by Kathleen Cornely, Providence College, Providence, Rhode Island, use problem-based learning to promote understanding of biochemical concepts. Each case presents data from the literature and asks questions that require students to apply principles to novel situations often involving topics from multiple chapters in the textbook.

In addition, a printed *Solutions Manual* containing detailed solutions for all of the textbook's end-of-chapter problems is available for purchase.

## FOR INSTRUCTORS

• **PowerPoint Slides** of all the figures and tables in the text are optimized with bold leader lines and large labels for classroom projection. The figures and tables are also

available for importing individually as jpeg files from the *Wiley Image Gallery*.

• **Test Bank** by Marilee Benore, University of Michigan–Dearborn, Dearborn, Michigan, and Robert Kane, Baylor University, Waco, Texas, has over 1000 questions containing a variety of question types (multiple choice, matching, fill in the blank, and short answer). Each question is rated by difficulty.

• **Classroom Response Questions** (“clicker questions”) by Rachel Milner and Adrienne Wright, University of Alberta, Edmonton, Alberta, Canada, are interactive questions for classroom response systems, to facilitate classroom participation and discussion. These questions can also be used by instructors as prelecture questions that help gauge students knowledge of overall concepts while addressing common misconceptions.

## ACKNOWLEDGMENTS

This textbook is the result of the dedicated effort of numerous individuals, many of whom deserve special mention: Laura Ierardi cleverly combined text, figures, and tables in designing each of this textbook's pages. Suzanne Ingrao, our Production Coordinator, skillfully managed the production of the textbook. Madelyn Lesure designed the book's typography and cover. Joan Kalkut, our Editor, skillfully organized and managed the entire project. Hilary Newman and Elyse Rieder acquired many of the photographs in the textbook and kept track of all of them. Connie Parks, our copy editor, put the final polish on the manuscript and eliminated large numbers of grammatical and typographical errors. Special thanks to Alyson Rentrop, our Associate Editor, who coordinated and managed an exceptional supplements package, and to Tom Kulesa, Senior Media Editor, and Marc Wezdecki, Media Editor, who substantially improved and developed the media resources. Much of the art in this fourth edition of *Biochemistry* is the creative legacy of the drawings made for its first and second editions by John and Bette Woolsey and Patrick Lane of J/B Woolsey Associates. The late Irving Geis provided us with his extraordinary molecular art and gave freely of his wise counsel.

The atomic coordinates of most of the proteins and nucleic acids that we have drawn for use in this textbook were obtained from the Protein Data Bank (PDB), which is administered by the Research Collaboratory for Structural Bioinformatics (RCSB). We created these drawings using the molecular graphics programs PyMOL by Warren DeLano; RIBBONS by Mike Carson; and GRASP by Anthony Nicholls, Kim Sharp, and Barry Honig.

The interactive computer graphics diagrams that are presented on the website that accompanies this textbook are either Jmol images or Kinemages. Jmol is a free, open source, interactive, Web browser applet for manipulating molecules in three dimensions. It is based on the program

RasMol by Roger Sayle, which was generously made publicly available. Kinemages are displayed by the program KiNG, which was written and generously provided by David C. Richardson, who also wrote and provided the program PREKIN, which we used to help generate the Kinemages. KiNG (Kinemage, Next Generation) is an interactive system for three-dimensional vector graphics that runs on Windows, Mac OS X, and Linux/Unix systems.

We wish especially to thank those colleagues who reviewed this textbook, in both its current and earlier editions, and provided us with their prudent advice:

## Guide to Media Resources xvi

## PART I

### INTRODUCTION AND BACKGROUND 1

#### CHAPTER 1 Life 3

1. Prokaryotes 3
2. Eukaryotes 6
3. Biochemistry: A Prologue 14
4. Genetics: A Review 19
5. The Origin of Life 28
6. The Biochemical Literature 34

#### CHAPTER 2 Aqueous Solutions 40

1. Properties of Water 40
2. Acids, Bases, and Buffers 45

#### CHAPTER 3 Thermodynamic Principles: A Review 52

1. First Law of Thermodynamics: Energy Is Conserved 52
2. Second Law of Thermodynamics: The Universe Tends Toward Maximum Disorder 54
3. Free Energy: The Indicator of Spontaneity 57
4. Chemical Equilibria 58

APPENDIX: Concentration Dependence of Free Energy 61

## PART II

### BIOMOLECULES 65

#### CHAPTER 4 Amino Acids 67

1. The Amino Acids of Proteins 67
2. Optical Activity 73
3. "Nonstandard" Amino Acids 78

#### CHAPTER 5 Nucleic Acids, Gene Expression, and Recombinant DNA Technology 82

1. Nucleotides and Nucleic Acids 82
2. DNA Is the Carrier of Genetic Information 85
3. Double Helical DNA 88
4. Gene Expression and Replication: An Overview 95
5. Molecular Cloning 104

#### CHAPTER 6 Techniques of Protein and Nucleic Acid Purifications 129

1. Protein Isolation 129
2. Solubilities of Proteins 133
3. Chromatographic Separations 135

4. Electrophoresis 146
5. Ultracentrifugation 152
6. Nucleic Acid Fractionation 156

#### CHAPTER 7 Covalent Structures of Proteins and Nucleic Acids 163

1. Primary Structure Determination of Proteins 164
2. Nucleic Acid Sequencing 176
3. Chemical Evolution 185
4. Bioinformatics: An Introduction 194
5. Chemical Synthesis of Polypeptides 205
6. Chemical Synthesis of Oligonucleotides 209

#### CHAPTER 8 Three-Dimensional Structures of Proteins 221

1. Secondary Structure 221
  2. Fibrous Proteins 232
  3. Globular Proteins 241
  4. Protein Stability 259
  5. Quaternary Structure 266
- APPENDIX: Viewing Stereo Pictures 271

#### CHAPTER 9 Protein Folding, Dynamics, and Structural Evolution 278

1. Protein Folding: Theory and Experiment 278
2. Folding Accessory Proteins 290
3. Protein Structure Prediction and Design 302
4. Protein Dynamics 306
5. Conformational Diseases: Amyloids and Prions 309
6. Structural Evolution 316

#### CHAPTER 10 Hemoglobin: Protein Function in Microcosm 323

1. Hemoglobin and Myoglobin Function 323
  2. Structure and Mechanism 331
  3. Abnormal Hemoglobins 341
  4. Allosteric Regulation 347
- APPENDIX: Derivation of Symmetry Model Equations 354

#### CHAPTER 11 Sugars and Polysaccharides 359

1. Monosaccharides 359
2. Polysaccharides 365
3. Glycoproteins 373

#### CHAPTER 12 Lipids and Membranes 386

1. Lipid Classification 386
2. Properties of Lipid Aggregates 393

- 3. Biological Membranes 399
- 4. Membrane Assembly and Protein Targeting 418
- 5. Lipoproteins 449

### PART III

#### MECHANISMS OF ENZYME ACTION 467

##### CHAPTER 13 Introduction to Enzymes 469

- 1. Historical Perspective 469
- 2. Substrate Specificity 470
- 3. Coenzymes 473
- 4. Regulation of Enzymatic Activity 474
- 5. A Primer of Enzyme Nomenclature 479

##### CHAPTER 14 Rates of Enzymatic Reactions 482

- 1. Chemical Kinetics 482
- 2. Enzyme Kinetics 487
- 3. Inhibition 492
- 4. Effects of pH 496
- 5. Bisubstrate Reactions 497
- APPENDIX: Derivations of Michaelis–Menten Equation Variants 501

##### CHAPTER 15 Enzymatic Catalysis 506

- 1. Catalytic Mechanisms 506
- 2. Lysozyme 517
- 3. Serine Proteases 525
- 4. Drug Design 539

### PART IV

#### METABOLISM 557

##### CHAPTER 16 Introduction to Metabolism 559

- 1. Metabolic Pathways 559
- 2. Organic Reaction Mechanisms 562
- 3. Experimental Approaches to the Study of Metabolism 569
- 4. Thermodynamics of Phosphate Compounds 578
- 5. Oxidation–Reduction Reactions 583
- 6. Thermodynamics of Life 586

##### CHAPTER 17 Glycolysis 593

- 1. The Glycolytic Pathway 593
- 2. The Reactions of Glycolysis 595
- 3. Fermentation: The Anaerobic Fate of Pyruvate 614
- 4. Metabolic Regulation and Control 619
- 5. Metabolism of Hexoses Other than Glucose 630

##### CHAPTER 18 Glycogen Metabolism 638

- 1. Glycogen Breakdown 638
- 2. Glycogen Synthesis 644
- 3. Control of Glycogen Metabolism 647
- 4. Glycogen Storage Diseases 666

##### CHAPTER 19 Signal Transduction 671

- 1. Hormones 671
- 2. Heterotrimeric G Proteins 688
- 3. Tyrosine Kinase–Based Signaling 699
- 4. The Phosphoinositide Cascade 725

##### CHAPTER 20 Transport through Membranes 744

- 1. Thermodynamics of Transport 744
- 2. Kinetics and Mechanisms of Transport 745
- 3. ATP-Driven Active Transport 758
- 4. Ion Gradient–Driven Active Transport 768
- 5. Neurotransmission 771

##### CHAPTER 21 Citric Acid Cycle 789

- 1. Cycle Overview 789
- 2. Metabolic Sources of Acetyl-Coenzyme A 792
- 3. Enzymes of the Citric Acid Cycle 806
- 4. Regulation of the Citric Acid Cycle 815
- 5. The Amphibolic Nature of the Citric Acid Cycle 817

##### CHAPTER 22 Electron Transport and Oxidative Phosphorylation 823

- 1. The Mitochondrion 823
- 2. Electron Transport 828
- 3. Oxidative Phosphorylation 845
- 4. Control of ATP Production 862

##### CHAPTER 23 Other Pathways of Carbohydrate Metabolism 871

- 1. Gluconeogenesis 871
- 2. The Glyoxylate Cycle 880
- 3. Biosynthesis of Oligosaccharides and Glycoproteins 880
- 4. The Pentose Phosphate Pathway 892

##### CHAPTER 24 Photosynthesis 901

- 1. Chloroplasts 901
- 2. Light Reactions 903
- 3. Dark Reactions 926

##### CHAPTER 25 Lipid Metabolism 940

- 1. Lipid Digestion, Absorption, and Transport 940
- 2. Fatty Acid Oxidation 945
- 3. Ketone Bodies 959
- 4. Fatty Acid Biosynthesis 961

5. Regulation of Fatty Acid Metabolism 973
6. Cholesterol Metabolism 975
7. Eicosanoid Metabolism: Prostaglandins, Prostacyclins, Thromboxanes, Leukotrienes, and Lipoxins 993
8. Phospholipid and Glycolipid Metabolism 1004

## CHAPTER 26 Amino Acid Metabolism 1019

1. Amino Acid Deamination 1019
2. The Urea Cycle 1025
3. Metabolic Breakdown of Individual Amino Acids 1029
4. Amino Acids as Biosynthetic Precursors 1047
5. Amino Acid Biosynthesis 1064
6. Nitrogen Fixation 1078

## CHAPTER 27 Energy Metabolism: Integration and Organ Specialization 1088

1. Major Pathways and Strategies of Energy Metabolism: A Summary 1088
2. Organ Specialization 1090
3. Metabolic Homeostasis: Regulation of Appetite, Energy Expenditure, and Body Weight 1095
4. Metabolic Adaptation 1101

## CHAPTER 28 Nucleotide Metabolism 1107

1. Synthesis of Purine Ribonucleotides 1107
2. Synthesis of Pyrimidine Ribonucleotides 1114
3. Formation of Deoxyribonucleotides 1119
4. Nucleotide Degradation 1130
5. Biosynthesis of Nucleotide Coenzymes 1136

## PART V EXPRESSION AND TRANSMISSION OF GENETIC INFORMATION 1143

### CHAPTER 29 Nucleic Acid Structures 1145

1. Double Helical Structures 1145
2. Forces Stabilizing Nucleic Acid Structures 1151
3. Supercoiled DNA 1158

### CHAPTER 30 DNA Replication, Repair, and Recombination 1173

1. DNA Replication: An Overview 1173
2. Enzymes of Replication 1176

3. Prokaryotic Replication 1190
4. Eukaryotic Replication 1201
5. Repair of DNA 1213
6. Recombination and Mobile Genetic Elements 1225
7. DNA Methylation and Trinucleotide Repeat Expansions 1246

### CHAPTER 31 Transcription 1260

1. The Role of RNA in Protein Synthesis 1260
2. RNA Polymerase 1265
3. Control of Transcription in Prokaryotes 1283
4. Post-Transcriptional Processing 1301

### CHAPTER 32 Translation 1338

1. The Genetic Code 1338
2. Transfer RNA and Its Aminoacylation 1345
3. Ribosomes 1362
4. Control of Eukaryotic Translation 1398
5. Post-Translational Modification 1403
6. Protein Degradation 1408

### \*CHAPTER 33 Viruses: Paradigms for Cellular Function W-1

1. Tobacco Mosaic Virus W-3
2. Icosahedral Viruses W-8
3. Bacteriophage  $\lambda$  W-20
4. Influenza Virus W-40

### \*CHAPTER 34 Eukaryotic Gene Expression

1. Chromosome Structure
2. Genomic Organization
3. Control of Expression
4. Cell Differentiation

### \*CHAPTER 35 Molecular Physiology

1. Blood Clotting
2. Immunity
3. Motility: Muscles, Vesicle Transport, Cilia, and Flagella

INDEX I-1

\*Chapters 33, 34, and 35 are available on our book companion website, [www.wiley.com/college/voet](http://www.wiley.com/college/voet).

# GUIDE TO MEDIA RESOURCES

The book website ([www.wiley.com/college/voet](http://www.wiley.com/college/voet)) offers the following resources to enhance student understanding of biochemistry. These are all keyed to figures or sections in the text. They are called out in the text with a red mouse icon or margin note.

Chapter	Media Type	Title	Text Reference	Page
<b>2</b> Acids, Bases, and Buffers	<b>Animated Figure</b>	Acid-base titration curves of 1-L solutions of 1M acetic acid, $\text{H}_2\text{PO}_4^-$ , and $\text{NH}_4^+$ by a strong base	<b>Figure 2-11</b>	<b>47</b>
	<b>Animated Figure</b>	Titration curve of a 1-L solution of 1M $\text{H}_3\text{PO}_4$	<b>Figure 2-13</b>	<b>49</b>
<b>4</b> Amino Acids	<b>Animated Figure</b>	Titration curve of glycine	<b>Figure 4-6</b>	<b>72</b>
<b>5</b> Nucleic Acids, Gene Expression, and Recombinant DNA Technology	<b>Kinimage Exercise</b>	2.1. B-DNA	<b>Figure 5-11</b>	<b>89</b>
	<b>Interactive Exercise</b>	1. B-DNA	<b>Figure 5-11</b>	<b>89</b>
	<b>Kinimage Exercise</b>	2-2, 17-2. The Watson–Crick base pairs	<b>Figure 5-12</b>	<b>89</b>
	<b>Animated Figure</b>	Demonstration of the semiconservative nature of DNA replication in <i>E. coli</i> by density gradient ultracentrifugation	<b>Figure 5-13</b>	<b>91</b>
	<b>Animated Figure</b>	UV absorbance spectra of the nucleic acid bases and DNA	<b>Figure 5-15</b>	<b>92</b>
	<b>Animated Figure</b>	Example of a DNA melting curve	<b>Figure 5-16</b>	<b>93</b>
	<b>Guided Exploration</b>	1: Overview of transcription and translation	<b>Section 5-4</b>	<b>95</b>
	<b>Guided Exploration</b>	2: Regulation of gene expression by the <i>lac</i> repressor system	<b>Figure 5-25</b>	<b>97</b>
	<b>Animated Figure</b>	Construction of a recombinant DNA molecule	<b>Figure 5-44</b>	<b>109</b>
	<b>Animated Figure</b>	Cloning of foreign DNA in $\lambda$ phages	<b>Figure 5-47</b>	<b>111</b>
<b>6</b> Techniques of Protein and Nucleic Acid Purification	<b>Guided Exploration</b>	3: PCR and site-directed mutagenesis	<b>Section 5-5F</b>	<b>114</b>
	<b>Animated Figure</b>	Site-directed mutagenesis	<b>Figure 5-55</b>	<b>119</b>
	<b>Animated Figure</b>	An enzyme-linked immunosorbent assay (ELISA)	<b>Figure 6-1</b>	<b>132</b>
	<b>Animated Figure</b>	Ion exchange chromatography using stepwise elution	<b>Figure 6-6</b>	<b>136</b>
	<b>Animated Figure</b>	Gel filtration chromatography	<b>Figure 6-9</b>	<b>139</b>
	<b>7</b> Covalent Structures of Proteins and Nucleic Acids	<b>Guided Exploration</b>	4: Protein sequence determination	<b>Section 7-1</b>
<b>Animated Figure</b>		The Edman degradation	<b>Figure 7-4</b>	<b>167</b>
<b>Animated Figure</b>		The amino acid sequence of a polypeptide chain is determined by comparing the sequence of two sets of mutually overlapping peptide fragments	<b>Figure 7-6</b>	<b>171</b>
<b>Guided Exploration</b>		5: DNA sequence determination by the chain-terminator method	<b>Section 7-2A</b>	<b>176</b>
<b>Guided Exploration</b>		6: Bioinformatics	<b>Section 7-4</b>	<b>194</b>
<b>8</b> Three-Dimensional Structures of Proteins	<b>Kinimage Exercise</b>	3-1. The peptide group	<b>Figure 8-1, 8-2, 8-4</b>	<b>221, 222, 223</b>
	<b>Guided Exploration</b>	7: Stable helices in proteins: the $\alpha$ helix	<b>Section 8-1B</b>	<b>225</b>
	<b>Kinimage Exercise</b>	3-2. The $\alpha$ helix	<b>Figure 8-11, 8-12</b>	<b>226, 227</b>

Chapter	Media Type	Title	Text Reference	Page
	<b>Animated Figure</b>	The right-handed $\alpha$ helix	<i>Figure 8-11</i>	<b>226</b>
	<b>Guided Exploration</b>	8: Hydrogen bonding in $\beta$ sheets	<i>Section 8-1C</i>	<b>229</b>
	<b>Guided Exploration</b>	9: Secondary structures in proteins	<i>Section 8-1C</i>	<b>229</b>
	<b>Kinemage Exercise</b>	3-3. $\beta$ Pleated sheets	<i>Figure 8-16, 8-17, 8-18</i>	<b>229, 230, 231</b>
	<b>Animated Figure</b>	$\beta$ Pleated sheets	<i>Figure 8-16</i>	<b>229</b>
	<b>Interactive Exercise</b>	2. Triose phosphate isomerase	<i>Figure 8-19</i>	<b>231</b>
	<b>Kinemage Exercise</b>	3-4. Beta bends (reverse turns)	<i>Figure 8-22</i>	<b>233</b>
	<b>Kinemage Exercise</b>	4-1, 4-2. Coiled coils	<i>Figure 8-26</i>	<b>235</b>
	<b>Kinemage Exercise</b>	4-3, 4-4. Collagen	<i>Figure 8-29, 8-30</i>	<b>237</b>
	<b>Kinemage Exercise</b>	6-1. Deoxy myoglobin	<i>Figure 8-39</i>	<b>245</b>
	<b>Interactive Exercise</b>	3. Human carbonic anhydrase	<i>Figure 8-41 (also Figure 15-5)</i>	<b>246 (also 512)</b>
	<b>Interactive Exercise</b>	4. Horse heart cytochrome <i>c</i>	<i>Figure 8-42</i>	<b>247</b>
	<b>Kinemage Exercise</b>	5-1. Cytochromes <i>c</i>	<i>Figure 8-42</i>	<b>247</b>
	<b>Kinemage Exercise</b>	3-2. The $\alpha$ helix	<i>Figure 8-43</i>	<b>248</b>
	<b>Kinemage Exercise</b>	3-3. $\beta$ pleated sheets	<i>Figure 8-44</i>	<b>249</b>
	<b>Interactive Exercise</b>	5. Glyceraldehyde-3-phosphate dehydrogenase	<i>Figure 8-45</i>	<b>249</b>
	<b>Animated Figure</b>	Some possible symmetries of proteins with identical protomers	<i>Figure 8-65</i>	<b>268</b>
<b>9</b> Protein Folding, Dynamics, and Structural Evolution	<b>Animated Figure</b>	Reactions catalyzed by protein disulfide isomerase (PDI)	<i>Figure 9-15</i>	<b>290</b>
	<b>Guided Exploration</b>	10: Protein Evolution	<i>Section 8-6A</i>	<b>316</b>
	<b>Kinemage Exercise</b>	5-1. Cytochromes <i>c</i>	<i>Figure 9-41</i>	<b>317</b>

Chapter	Media Type	Title	Text Reference	Page
<b>10</b> Hemoglobin: Protein Function in Microcosm	<b>Animated Figure</b>	Oxygen-dissociation curves of Mb and of Hb in whole blood	<b>Figure 10-3</b>	<b>326</b>
	<b>Animated Figure</b>	The effects of BPG and CO <sub>2</sub> , both separately and combined, on hemoglobin's O <sub>2</sub> -dissociation curve compared with that of whole blood ( <i>red curve</i> )	<b>Figure 10-8</b>	<b>330</b>
	<b>Kinimage Exercise</b>	6-1. Deoxy myoglobin	<b>Figure 10-11, 10-12</b>	<b>332, 333</b>
	<b>Kinimage Exercise</b>	6-2, 6-3. Hemoglobin and myoglobin	<b>Figure 10-13</b>	<b>334</b>
	<b>Kinimage Exercise</b>	6-4. Hemoglobin structure	<b>Figure 10-15, 10-16</b>	<b>336</b>
	<b>Animated Figure</b>	Triggering mechanism for the T → R transition of Hb	<b>Figure 10-16</b>	<b>336</b>
	<b>Kinimage Exercise</b>	6-5. Conformational changes at hemoglobin's α <sub>1</sub> -β <sub>2</sub> interface	<b>Figure 10-17</b>	<b>337</b>
	<b>Kinimage Exercise</b>	6-3. Binding of BPG to deoxyHb	<b>Figure 10-21</b>	<b>341</b>
<b>11</b> Sugars and Polysaccharides	<b>Kinimage Exercise</b>	7-1. D-Glucopyranose	<b>Figure 11-5, 11-7</b>	<b>362, 363</b>
	<b>Kinimage Exercise</b>	7-2. Sucrose	<b>Figure 11-13</b>	<b>367</b>
	<b>Kinimage Exercise</b>	7-3. Hyaluronic acid	<b>Figure 11-21</b>	<b>371</b>
	<b>Kinimage Exercise</b>	7-4. Structure of a complex carbohydrate	<b>Figure 11-32</b>	<b>379</b>
<b>12</b> Lipids and Membranes	<b>Guided Exploration</b>	11: Membrane structure and the fluid mosaic model	<b>Figures 12-15, 12-16, 12-20</b>	<b>396, 397, 400</b>
	<b>Kinimage Exercise</b>	8-1. Bacteriorhodopsin	<b>Figure 12-25</b>	<b>403</b>
	<b>Kinimage Exercise</b>	8-2. Photosynthetic reaction center	<b>Figure 12-26</b>	<b>404</b>
	<b>Kinimage Exercise</b>	8-3. Porin	<b>Figure 12-27</b>	<b>405</b>
	<b>Animated Figure</b>	The ribosomal synthesis, membrane insertion, and initial glycosylation of an integral protein via the secretory pathway	<b>Figure 12-46</b>	<b>421</b>
	<b>Animated Figure</b>	Model for plasma triacylglycerol and cholesterol transport in humans	<b>Figure 12-86</b>	<b>452</b>

Chapter	Media Type	Title	Text Reference	Page
<b>13</b> Introduction to Enzymes	<b>Animated Figure</b>	The rate of the reaction catalyzed by ATCase as a function of aspartate concentration	<b>Figure 13-5</b>	<b>475</b>
	<b>Kinimage Exercise</b>	11-1. Structure of ATCase	<b>Figure 13-7, 13-9</b>	<b>476, 478</b>
	<b>Kinimage Exercise</b>	11-2. Conformational changes in ATCase	<b>Figure 13-9</b>	<b>478</b>
<b>14</b> Rates of Enzymatic Reactions	<b>Guided Exploration</b>	12: Michaelis–Menten kinetics, Lineweaver–Burk plots, and enzyme inhibition	<b>Section 14-2</b>	<b>487</b>
	<b>Animated Figure</b>	Progress curves for the components of a simple Michaelis–Menten reaction	<b>Figure 14-7</b>	<b>488</b>
	<b>Animated Figure</b>	Plot of the initial velocity $v_0$ of a simple Michaelis–Menten reaction versus the substrate concentration [S]	<b>Figure 14-8</b>	<b>489</b>
	<b>Animated Figure</b>	A double-reciprocal (Lineweaver–Burk) plot	<b>Figure 14-9</b>	<b>490</b>
	<b>Animated Figure</b>	Lineweaver–Burk plot of the competitively inhibited Michaelis–Menten enzyme described by Fig. 14-11	<b>Figure 14-12</b>	<b>494</b>
	<b>Animated Figure</b>	Lineweaver–Burk plot of a simple Michaelis–Menten enzyme in the presence of uncompetitive inhibitor	<b>Figure 14-13</b>	<b>495</b>
	<b>Animated Figure</b>	Lineweaver–Burk plot of a simple Michaelis–Menten enzyme in the presence of a mixed inhibitor	<b>Figure 14-14</b>	<b>496</b>
<b>15</b> Enzymatic Catalysis	<b>Interactive Exercise</b>	3. Human carbonic anhydrase	<b>Figure 15-5</b>	<b>512</b>
	<b>Animated Figure</b>	Reaction coordinate diagrams for a hypothetical enzymatically catalyzed reaction involving a single substrate ( <i>blue</i> ) and the corresponding uncatalyzed reaction ( <i>red</i> )	<b>Figure 15-7</b>	<b>516</b>
	<b>Interactive Exercise</b>	6. HEW lysozyme in complex with (NAG) <sub>6</sub>	<b>Figure 15-10</b>	<b>518</b>
	<b>Kinimage Exercise</b>	9. Lysozyme	<b>Figure 15-10, 15-12, 15-14,</b>	<b>518, 519, 521</b>
	<b>Animated Figure</b>	Chair and half-chair conformations	<b>Figure 15-11</b>	<b>519</b>
	<b>Kinimage Exercise</b>	10-1. Structural overview of a trypsin/inhibitor complex	<b>Figure 15-19</b>	<b>528</b>
	<b>Guided Exploration</b>	12: The catalytic mechanism of serine proteases	<b>Section 15-3C</b>	<b>531</b>
	<b>Kinimage Exercise</b>	10-2. Evolutionary comparison of trypsin, chymotrypsin, and subtilisin	<b>Figure 15-22</b>	<b>531</b>

Chapter	Media Type	Title	Text Reference	Page
	<b>Kinimage Exercise</b>	10-3. A transition state analog bound to chymotrypsin	<i>Figure 15-25</i>	<b>534</b>
	<b>Kinimage Exercise</b>	10-4. Comparison of chymotrypsin with chymotrypsinogen	<i>Figure 15-28</i>	<b>538</b>
	<b>Interactive Exercise</b>	7. HIV-1 protease	<i>Figure 15-38</i>	<b>548</b>
<b>17</b> Glycolysis	<b>Guided Exploration</b>	14: Glycolysis overview	<i>Section 17-2</i>	<b>595</b>
	<b>Animated Figure</b>	Degradation of glucose via the glycolytic pathway	<i>Figure 17-3</i>	<b>596</b>
	<b>Interactive Exercise</b>	8. Conformational changes in yeast hexokinase on binding glucose	<i>Figure 17-5</i>	<b>598</b>
	<b>Animated Figure</b>	Enzymatic mechanism of Class I aldolase	<i>Figure 17-9</i>	<b>602</b>
	<b>Interactive Exercise</b>	2. TIM in complex with its transition state analog 2-phosphoglycolate	<i>Figure 17-11</i>	<b>605</b>
	<b>Kinimage Exercise</b>	12-1, 12-2. Triose phosphate isomerase	<i>Figure 17-11</i>	<b>605</b>
	<b>Animated Figure</b>	Enzymatic mechanism of glyceraldehyde-3-phosphate dehydrogenase	<i>Figure 17-14</i>	<b>608</b>
	<b>Interactive Exercise</b>	9. Pyruvate decarboxylase in complex with its TPP cofactor	<i>Figure 17-28</i>	<b>617</b>
	<b>Kinimage Exercise</b>	13-1, 13-2. Phosphofructokinase	<i>Figure 17-32</i>	<b>626</b>
	<b>Animated Figure</b>	PFK activity versus F6P concentration	<i>Figure 17-33</i>	<b>627</b>
<b>18</b> Glycogen Metabolism	<b>Kinimage Exercise</b>	14-1. Glycogen	<i>Figure 18-2</i>	<b>640</b>
	<b>Kinimage Exercise</b>	14-2, 14-3. Conformational changes in glycogen phosphorylase	<i>Figure 18-11</i>	<b>649</b>
	<b>Guided Exploration</b>	16: Control of glycogen breakdown	<i>Figure 18-14</i>	<b>652</b>
	<b>Animated Figure</b>	Schematic diagram of the major enzymatic modification/demodification systems involved in the control of glycogen metabolism in muscle	<i>Figure 18-14</i>	<b>652</b>
	<b>Interactive Exercise</b>	10. Catalytic (C) subunit of mouse protein kinase A (PKA)	<i>Figure 18-15</i>	<b>654</b>
	<b>Kinimage Exercise</b>	15-1. Protein kinase A (PKA)	<i>Figure 18-15</i>	<b>654</b>
	<b>Kinimage Exercise</b>	16-1. Structure of calmodulin	<i>Figure 18-17, 18-18</i>	<b>656</b>
	<b>Kinimage Exercise</b>	16-2. Calmodulin complex with its target polypeptide	<i>Figure 18-19</i>	<b>657</b>

Chapter	Media Type	Title	Text Reference	Page
<b>19</b> Signal Transduction	<b>Interactive Exercise</b>	11. Human growth hormone (hGH) in complex with two molecules of its receptor's extracellular domain (hGHbp)	<b>Figure 19-10</b>	<b>684</b>
	<b>Guided Exploration</b>	16: Mechanisms of hormone signaling involving the adenylyate cyclase system	<b>Section 19-2A</b>	<b>688</b>
	<b>Interactive Exercise</b>	12. Heterotrimeric G protein	<b>Figure 19-19</b>	<b>694</b>
	<b>Guided Exploration</b>	17. Mechanisms of hormone signaling involving the receptor tyrosine kinase system	<b>Section 19-3</b>	<b>699</b>
	<b>Interactive Exercise</b>	13. The insulin receptor	<b>Figure 19-28</b>	<b>702</b>
	<b>Animated Figure</b>	The Ras-activated MAP kinase cascade	<b>Figure 19-40</b>	<b>712</b>
	<b>Animated Figure</b>	Role of PIP <sub>2</sub> in intracellular signaling	<b>Figure 19-54</b>	<b>726</b>
<b>20</b> Transport through Membranes	<b>Animated Figure</b>	Alternating conformation model for glucose transport	<b>Figure 20-10</b>	<b>751</b>
	<b>Animated Figure</b>	Regulation of glucose uptake in muscle and fat cells	<b>Figure 20-11</b>	<b>751</b>
	<b>Interactive Exercise</b>	14. The KcsA K <sup>+</sup> channel	<b>Figure 20-13</b>	<b>754</b>
<b>21</b> Citric Acid Cycle	<b>Guided Exploration</b>	18: Citric acid cycle overview	<b>Section 21-1</b>	<b>789</b>
	<b>Animated Figure</b>	Regulation of the citric acid cycle	<b>Figure 21-1</b>	<b>790</b>
	<b>Interactive Exercise</b>	15. Conformational changes in citrate synthase	<b>Figure 21-18</b>	<b>806</b>
	<b>Animated Figure</b>	Reactions of the citric acid cycle	<b>Figure 21-25</b>	<b>816</b>
	<b>Animated Figure</b>	Amphibolic functions of the citric acid cycle	<b>Figure 21-26</b>	<b>818</b>
<b>22</b> Electron Transport and Oxidative Phosphorylation	<b>Guided Exploration</b>	19. Electron transport and oxidative phosphorylation overview	<b>Section 22-2B</b>	<b>829</b>
	<b>Animated Figure</b>	The mitochondrial electron-transport chain	<b>Figure 22-14</b>	<b>834</b>
	<b>Interactive Exercise</b>	16. Ferredoxin	<b>Figure 22-16</b>	<b>835</b>
	<b>Interactive Exercise</b>	17. Complex III	<b>Figure 22-23</b>	<b>840</b>
	<b>Interactive Exercise</b>	18. Bovine heart cytochrome <i>c</i> oxidase	<b>Figure 22-24</b>	<b>842</b>
	<b>Animated Figure</b>	Coupling of electron transport ( <i>green arrow</i> ) and ATP synthesis	<b>Figure 22-29</b>	<b>846</b>
	<b>Guided Exploration</b>	20: The Q cycle	<b>Section 22-3Be</b>	<b>847</b>
<b>Guided Exploration</b>	21: F <sub>1</sub> F <sub>0</sub> -ATP synthase and the binding change mechanism	<b>Section 22-3C</b>	<b>852</b>	

Chapter	Media Type	Title	Text Reference	Page
	<b>Interactive Exercise</b>	19. F <sub>1</sub> -ATP synthase	<b>Figure 22-38</b>	<b>854</b>
	<b>Animated Figure</b>	Energy-dependent binding change mechanism for ATP synthesis by proton-translocating ATP synthase	<b>Figure 22-42</b>	<b>857</b>
	<b>Animated Figure</b>	Schematic diagram depicting the coordinated control of glycolysis and the citric acid cycle by ATP, ADP, AMP, P <sub>i</sub> , Ca <sup>2+</sup> , and the [NADH]/[NAD <sup>+</sup> ] ratio (the vertical arrows indicate increases in this ratio)	<b>Figure 22-49</b>	<b>863</b>
<b>23</b> Other Pathways of Carbohydrate Metabolism	<b>Animated Figure</b>	Transport of PEP and oxaloacetate from the mitochondrion to the cytosol	<b>Figure 23-7</b>	<b>877</b>
	<b>Animated Figure</b>	Pathways of gluconeogenesis and glycolysis	<b>Figure 23-8</b>	<b>878</b>
	<b>Animated Figure</b>	The Cori cycle	<b>Figure 23-10</b>	<b>880</b>
	<b>Animated Figure</b>	Pathway of dolichol-PP-oligosaccharide synthesis	<b>Figure 23-16</b>	<b>884</b>
<b>24</b> Photosynthesis	<b>Animated Figure</b>	Energy diagram indicating the electronic states of chlorophyll and their most important modes of interconversion	<b>Figure 24-4</b>	<b>905</b>
	<b>Interactive Exercise</b>	20. Light-harvesting complex LH2	<b>Figure 24-8</b>	<b>907</b>
	<b>Interactive Exercise</b>	21. Photosynthetic reaction center (RC) from <i>Rb. sphaeroides</i>	<b>Figure 24-11</b>	<b>910</b>
	<b>Kinemage Exercise</b>	8-2. Photosynthetic reaction center	<b>Figure 24-11, 24-12</b>	<b>910, 911</b>
	<b>Guided Exploration</b>	22: Two-center photosynthesis (Z-scheme) overview	<b>Section 24-2C</b>	<b>913</b>
	<b>Interactive Exercise</b>	22. Ferredoxin-NADP <sup>+</sup> reductase	<b>Figure 24-28</b>	<b>924</b>
	<b>Animated Figure</b>	The Calvin cycle	<b>Figure 24-31</b>	<b>929</b>
	<b>Animated Figure</b>	Probable mechanism of the carboxylation reaction catalyzed with RuBP carboxylase	<b>Figure 24-34</b>	<b>931</b>
<b>25</b> Lipid Metabolism	<b>Animated Figure</b>	The β-oxidation pathway of fatty acyl-CoA	<b>Figure 25-12</b>	<b>947</b>
	<b>Interactive Exercise</b>	23. Medium-chain acyl-CoA dehydrogenase from pig liver mitochondria in complex with octanoyl-CoA	<b>Figure 25-13</b>	<b>948</b>
	<b>Interactive Exercise</b>	24. Methylmalonyl-CoA mutase	<b>Figure 25-22</b>	<b>955</b>
	<b>Animated Figure</b>	Comparison of fatty acid β oxidation and fatty acid biosynthesis	<b>Figure 25-29</b>	<b>962</b>
	<b>Animated Figure</b>	Reaction cycle for the biosynthesis of fatty acids	<b>Figure 25-32</b>	<b>964</b>

## CHAPTER 1

### 1 Prokaryotes

- A. Form and Function
- B. Prokaryotic Classification

### 2 Eukaryotes

- A. Cellular Architecture
- B. Phylogeny and Differentiation

### 3 Biochemistry: A Prologue

- A. Biological Structures
- B. Metabolic Processes
- C. Expression and Transmission of Genetic Information

### 4 Genetics: A Review

- A. Chromosomes
- B. Mendelian Inheritance
- C. Chromosomal Theory of Inheritance
- D. Bacterial Genetics
- E. Viral Genetics

### 5 The Origin of Life

- A. The Unique Properties of Carbon
- B. Chemical Evolution
- C. The Rise of Living Systems

### 6 The Biochemical Literature

- A. Conducting a Literature Search
- B. Reading a Research Article

It is usually easy to decide whether or not something is alive. This is because living things share many common attributes, such as the capacity to extract energy from nutrients to drive their various functions, the power to actively respond to changes in their environment, and the ability to grow, to differentiate, and—perhaps most telling of all—to reproduce. Of course, a given organism may not have all of these traits. For example, mules, which are obviously alive, rarely reproduce. Conversely, inanimate matter may exhibit some lifelike properties. For instance, crystals may grow larger when immersed in a supersaturated solution of the crystalline material. Therefore, life, as are many other complex phenomena, is perhaps impossible to define in a precise fashion. Norman Horowitz, however, proposed a useful set of criteria for living systems: *Life possesses the properties of replication, catalysis, and mutability.* Much of this text is concerned with the manner in which living organisms exhibit these properties.

*Biochemistry is the study of life on the molecular level.* The significance of such studies is greatly enhanced if they

are related to the biology of the corresponding organisms or even communities of such organisms. This introductory chapter therefore begins with a synopsis of the biological realm. This is followed by an outline of biochemistry, a review of genetics, a discussion of the origin of life, and finally, an introduction to the biochemical literature.

### 1 PROKARYOTES

It has long been recognized that life is based on morphological units known as **cells**. The formulation of this concept is generally attributed to an 1838 paper by Matthias Schleiden and Theodor Schwann, but its origins may be traced to the seventeenth century observations of early microscopists such as Robert Hooke. There are two major classifications of cells: the **eukaryotes** (Greek: *eu*, good or true + *karyon*, kernel or nut), which have a membrane-enclosed **nucleus** encapsulating their **DNA (deoxyribonucleic acid)**; and the **prokaryotes** (Greek: *pro*, before), which lack this organelle. Prokaryotes, which comprise the various types of bacteria, have relatively simple structures and are invariably unicellular (although they may form filaments or colonies of independent cells). They are estimated to represent about half of Earth's biomass. Eukaryotes, which may be multicellular as well as unicellular, are vastly more complex than prokaryotes. (**Viruses**, which are much simpler entities than cells, are not classified as living because they lack the metabolic apparatus to reproduce outside their host cells. They are essentially large molecular aggregates.) This section is a discussion of prokaryotes. Eukaryotes are considered in the following section.

#### A. Form and Function

Prokaryotes are the most numerous and widespread organisms on Earth. This is because their varied and often highly adaptable metabolisms suit them to an enormous variety of habitats. Besides inhabiting our familiar temperate and aerobic environment, certain types of bacteria may thrive in or even require conditions that are hostile to eukaryotes such as unusual chemical environments, high temperatures (as high as 130°C), and lack of oxygen. Moreover, the rapid reproductive rate of prokaryotes (optimally <20 min per cell division for many species) permits them to take advantage of transiently favorable conditions, and

conversely, the ability of many bacteria to form resistant **spores** allows them to survive adverse conditions.

#### a. Prokaryotes Have Relatively Simple Anatomies

Prokaryotes, which were first observed in 1683 by the inventor of the microscope, Antonie van Leeuwenhoek, have sizes that are mostly in the range 1 to 10  $\mu\text{m}$ . They have one of three basic shapes (Fig. 1-1): spheroidal (**cocci**), rodlike (**bacilli**), and helically coiled (**spirilla**), but all have the same general design (Fig. 1-2). They are bounded, as are all cells, by an  $\sim 70\text{-\AA}$ -thick **cell membrane (plasma membrane)**, which consists of a lipid bilayer containing embedded proteins that control the passage of molecules in and out of the cell and catalyze a variety of reactions. The cells of most prokaryotic species are surrounded by a rigid, 30- to 250- $\text{\AA}$ -thick polysaccharide **cell wall** that mainly functions to protect the cell from mechanical injury and to prevent it from bursting in media more osmotically dilute than its contents. Some bacteria further encase themselves in a gelatinous polysaccharide **capsule** that protects them from the defenses of higher organisms. Although prokaryotes lack the membranous subcellular organelles characteristic of eukaryotes (Section 1-2), their plasma membranes may be infolded to form multilayered structures known as **mesosomes**. The mesosomes are thought to serve as the site of DNA replication and other specialized enzymatic reactions.

The prokaryotic **cytoplasm** (cell contents) is by no means a homogeneous soup. Its single **chromosome** (DNA molecule, several copies of which may be present in a rapidly growing cell) is condensed to form a body known as a **nucleoid**. The cytoplasm also contains numerous species of **RNA (ribonucleic acid)**, a variety of soluble **enzymes** (proteins that catalyze specific reactions), and many thousands of 250- $\text{\AA}$ -diameter particles known as **ribosomes**, which are the sites of protein synthesis.

Figure 1-1 Scale drawings of some prokaryotic cells.

Many bacterial cells bear one or more whiplike appendages known as **flagella**, which are used for locomotion (Section 35-3I). Certain bacteria also have filamentous projections named **pili**, some types of which function as conduits for DNA during sexual conjugation (a process in which DNA is transferred from one cell to another; prokaryotes usually reproduce by binary fission) or aid in the attachment of the bacterium to a host organism's cells.

The bacterium *Escherichia coli* (abbreviated *E. coli* and named after its discoverer, Theodor Escherich) is the

Figure 1-2 Schematic diagram of a prokaryotic cell.

(a)

(b)

**Figure 1-3 Electron micrographs of *E. coli* cells.** (a) Stained to show internal structure. (b) Stained to reveal flagella and pili. [a: CNRI/Photo Researchers; b: Courtesy of Howard Berg, Harvard University.]

biologically most well-characterized organism as a result of its intensive biochemical and genetic study over the past 70 years. Indeed, much of the subject matter of this text deals with the biochemistry of *E. coli*. Cells of this normal inhabitant of the higher mammalian colon (Fig. 1-3) are typically 2- $\mu\text{m}$ -long rods that are 1  $\mu\text{m}$  in diameter and weigh  $\sim 2 \times 10^{-12}$  g. Its DNA, which has a molecular mass of  $2.5 \times 10^9$  **daltons (D)**,\* encodes  $\sim 4300$  proteins (of which only  $\sim 60$  to 70% have been identified), although, typically, only  $\sim 2600$  different proteins are present in a cell at any given time. Altogether an *E. coli* cell contains 3 to 6 thousand different types of molecules, including proteins, nucleic acids, polysaccharides, lipids, and various small molecules and ions (Table 1-1).

### b. Prokaryotes Employ a Wide Variety of Metabolic Energy Sources

The nutritional requirements of the prokaryotes are enormously varied. **Autotrophs** (Greek: *autos*, self + *trophikos*, to feed) can synthesize all their cellular constituents from simple molecules such as  $\text{H}_2\text{O}$ ,  $\text{CO}_2$ ,  $\text{NH}_3$ , and  $\text{H}_2\text{S}$ . Of course they need an energy source to do so as well as to power their other functions. **Chemolithotrophs** (Greek: *lithos*, stone) obtain their energy through the oxidation of inorganic compounds such as  $\text{NH}_3$ ,  $\text{H}_2\text{S}$ , or even  $\text{Fe}^{2+}$ :

Indeed, studies have revealed the existence of extensive al-

\*The **molecular mass** of a particle may be expressed in units of daltons, which are defined as 1/12th the mass of a  $^{12}\text{C}$  atom [atomic mass units (amu)]. Alternatively, this quantity may be expressed in terms of **molecular weight**, a dimensionless quantity defined as the ratio of the particle mass to 1/12th the mass of a  $^{12}\text{C}$  atom and symbolized  $M_r$  (for relative molecular mass). In this text, we shall refer to the molecular mass of a particle rather than to its molecular weight.

**Table 1-1 Molecular Composition of *E. coli***

Component	Percentage by Weight

beit extremely slow-growing colonies of chemolithotrophs that live as far as 5 kilometers underground and whose aggregate biomass appears to rival that of surface-dwelling organisms.

**Photoautotrophs** are autotrophs that obtain energy via **photosynthesis** (Chapter 24), a process in which light energy powers the transfer of electrons from inorganic donors to  $\text{CO}_2$  yielding **carbohydrates** [ $(\text{CH}_2\text{O})_n$ ]. In the most widespread form of photosynthesis, the electron donor in the light-driven reaction sequence is  $\text{H}_2\text{O}$ .

This process is carried out by **cyanobacteria** (e.g., the green slimy organisms that grow on the walls of aquariums; cyanobacteria were formerly known as **blue-green algae**), as well as by plants. This form of photosynthesis is thought to have generated the  $\text{O}_2$  in Earth's atmosphere. Some species of cyanobacteria have the ability to convert  $\text{N}_2$  from the atmosphere to organic nitrogen compounds. This **nitrogen fixation** capacity gives them the simplest nutritional

requirements of all organisms: With the exception of their need for small amounts of minerals, they can literally live on sunlight and air.

In a more primitive form of photosynthesis, substances such as  $H_2$ ,  $H_2S$ , thiosulfate, or organic compounds are the electron donors in light-driven reactions such as

The **purple** and the **green photosynthetic bacteria** that carry out these processes occupy such oxygen-free habitats as shallow muddy ponds in which  $H_2S$  is generated by rotting organic matter.

**Heterotrophs** (Greek: *hetero*, other) obtain energy through the oxidation of organic compounds and hence are ultimately dependent on autotrophs for these substances. **Obligate aerobes** (which include animals) must utilize  $O_2$ , whereas **anaerobes** employ oxidizing agents such as sulfate (**sulfate-reducing bacteria**) or nitrate (**denitrifying bacteria**). Many organisms can partially metabolize various organic compounds in intramolecular oxidation–reduction processes known as **fermentation**. **Facultative anaerobes** such as *E. coli* can grow in either the presence or the absence of  $O_2$ . **Obligate anaerobes**, in contrast, are poisoned by the presence of  $O_2$ . Their metabolisms are thought to resemble those of the earliest life-forms (which arose over 3.8 billion years ago when Earth's atmosphere lacked  $O_2$ ; Section 1-5B). At any rate, there are few organic compounds that cannot be metabolized by some prokaryotic organism.

## B. Prokaryotic Classification

The traditional methods of **taxonomy** (the science of biological classification), which are based largely on the anatomical comparisons of both contemporary and fossil organisms, are essentially inapplicable to prokaryotes. This is because the relatively simple cell structures of prokaryotes, including those of ancient bacteria as revealed by their microfossil remnants, provide little indication of their phylogenetic relationships (**phylogenesis**: evolutionary development). Compounding this problem is the observation that prokaryotes exhibit little correlation between form and metabolic function. Moreover, the eukaryotic definition of a species as a population that can interbreed is meaningless for the asexually reproducing prokaryotes. Consequently, the conventional prokaryotic classification schemes are rather arbitrary and lack the implied evolutionary relationships of the eukaryotic classification scheme (Section 1-2B).

In the most widely used prokaryotic classification scheme, the **prokaryotae** (also known as **monera**) have two divisions: the cyanobacteria and the **bacteria**. The latter are further subdivided into 19 parts based on their various distinguishing characteristics, most notably cell structure, metabolic behavior, and staining properties.

A simpler classification scheme, which is based on cell wall properties, distinguishes three major types of prokaryotes: the **mycoplasmas**, the **gram-positive bacteria**, and the

**gram-negative bacteria**. Mycoplasmas lack the rigid cell wall of other prokaryotes. They are the smallest of all living cells (as small as  $0.12 \mu m$  in diameter, Fig. 1-1) and possess ~20% of the DNA of an *E. coli*. Presumably this quantity of genetic information approaches the minimum amount necessary to specify the essential metabolic machinery required for cellular life. Gram-positive and gram-negative bacteria are distinguished according to whether or not they take up **gram stain** (a procedure developed in 1884 by Christian Gram in which heat-fixed cells are successively treated with the dye crystal violet and iodine and then destained with either ethanol or acetone). Gram-negative bacteria possess a complex **outer membrane** that surrounds their cell wall and excludes gram stain, whereas gram-positive bacteria lack such a membrane (Section 11-3B).

The development, in recent decades, of techniques for determining amino acid sequences in proteins (Section 7-1) and base sequences in nucleic acids (Section 7-2A) has provided abundant indications as to the genealogical relationships between organisms. Indeed, these techniques make it possible to place these relationships on a quantitative basis, and thus to construct a phylogenetically based classification system for prokaryotes.

By the analysis of ribosomal RNA sequences, Carl Woese showed that a group of prokaryotes he named the **Archaea** (also known as the **archaeobacteria**) are as distantly related to the other prokaryotes, the **Bacteria** (also called the **eubacteria**), as both of these groups are to the **Eukarya** (the eukaryotes). The Archaea initially appeared to constitute three different kinds of unusual organisms: the **methanogens**, obligate anaerobes that produce methane (marsh gas) by the reduction of  $CO_2$  with  $H_2$ ; the **halobacteria**, which can live only in concentrated brine solutions ( $>2M NaCl$ ); and certain **thermoacidophiles**, organisms that inhabit acidic hot springs ( $\sim 90^\circ C$  and  $pH < 2$ ). However, recent evidence indicates that ~40% of the microorganisms in the oceans are Archaea, and hence they may be the most common form of life on Earth.

On the basis of a number of fundamental biochemical traits that differ among the Archaea, the Bacteria, and the Eukarya, but that are common within each group, Woese proposed that these groups of organisms constitute the three primary **urkingdoms** or **domains** of evolutionary descent (rather than the traditional division into prokaryotes and eukaryotes). However, further sequence determinations have revealed that the Eukarya share sequence similarities with the Archaea that they do not share with the Bacteria. Evidently, the Archaea and the Bacteria diverged from some simple primordial life-form following which the Eukarya diverged from the Archaea, as the **phylogenetic tree** in Fig. 1-4 indicates.

## 2 EUKARYOTES

Eukaryotic cells are generally 10 to  $100 \mu m$  in diameter and thus have a thousand to a million times the volume of typical prokaryotes. It is not size, however, but a profusion of membrane-enclosed organelles, each with a specialized

**Figure 1-4 Phylogenetic tree.** This “family tree” indicates the evolutionary relationships among the three domains of life. The root of the tree represents the last common ancestor of all life on Earth. [After Wheelis, M.L., Kandler, O., and Woese, C.R., *Proc. Natl. Acad. Sci.* **89**, 2931 (1992).]

function, that best characterizes eukaryotic cells (Fig. 1-5). In fact, *eukaryotic structure and function are more complex than those of prokaryotes at all levels of organization, from the molecular level on up.*

Eukaryotes and prokaryotes have developed according to fundamentally different evolutionary strategies.

Prokaryotes have exploited the advantages of simplicity and miniaturization: Their rapid growth rates permit them to occupy ecological niches in which there may be drastic fluctuations of the available nutrients. In contrast, the complexity of eukaryotes, which renders them larger and more slowly growing than prokaryotes, gives them the competitive

**Figure 1-5 Schematic diagram of an animal cell accompanied by electron micrographs of its organelles.** [Nucleus: Tektoff-RM, CNRI/Photo Researchers; rough endoplasmic reticulum: Pietro M. Motta & Tomonori Naguro/Photo Researchers, Inc. and Golgi

**Figure 1-6** [Drawing by T.A. Bramley, in Carlile, M., *Trends Biochem. Sci.* 7, 128 (1982). Copyright © Elsevier Biomedical Press, 1982. Used by permission.]

advantage in stable environments with limited resources (Fig. 1-6). It is therefore erroneous to consider prokaryotes as evolutionarily primitive with respect to eukaryotes. Both types of organisms are well adapted to their respective lifestyles.

The earliest known microfossils of eukaryotes date from ~1.4 billion years ago, some 2.4 billion years after life arose. This observation supports the classical notion that eukaryotes are descended from a highly developed prokaryote, possibly a mycoplasma. The differences between eukaryotes and modern prokaryotes, however, are so profound as to render this hypothesis improbable. Perhaps the early eukaryotes, which according to Woese's evidence evolved from a primordial life-form, were relatively unsuccessful and hence rare. Only after they had developed some of the complex organelles described in the following section did they become common enough to generate significant fossil remains.

### A. Cellular Architecture

Eukaryotic cells, like prokaryotes, are bounded by a plasma membrane. The large size of eukaryotic cells results in their surface-to-volume ratios being much smaller than those of prokaryotes (the surface area of an object increases as the square of its radius, whereas volume does so as the cube). This geometrical constraint, coupled with the fact that many

essential enzymes are membrane associated, partially rationalizes the large amounts of intracellular membranes in eukaryotes (the plasma membrane typically constitutes <10% of the membrane in a eukaryotic cell). Since all the matter that enters or leaves a cell must somehow pass through its plasma membrane, the surface areas of many eukaryotic cells are increased by numerous projections and/or invaginations (Fig. 1-7). Moreover, portions of the plasma membrane often bud inward, in a process known as **endocytosis**, so that the cell surrounds portions of the external medium. Thus eukaryotic cells can engulf and digest food particles such as bacteria, whereas prokaryotes are limited to the absorption of individual nutrient molecules. The reverse of endocytosis, a process termed **exocytosis**, is a common eukaryotic secretory mechanism.

#### a. The Nucleus Contains the Cell's DNA

The nucleus, the eukaryotic cell's most conspicuous organelle, is the repository of its genetic information. This information is encoded in the base sequences of DNA molecules that form the discrete number of chromosomes characteristic of each species. The chromosomes consist of **chromatin**, a complex of DNA and protein. The amount of genetic information carried by eukaryotes is enormous; for example, a human cell has over 700 times the DNA of *E. coli* [in the terms commonly associated with computer memories, the **genome** (genetic complement) in each human

**Figure 1-7** Scanning electron micrograph of a fibroblast. [Courtesy of Guenther Albrecht-Buehler, Northwestern University.]

cell specifies around 800 megabytes of information—about 200 times the information content of this text]. Within the nucleus, the genetic information encoded by the DNA is transcribed into molecules of RNA (Chapter 31), which, after extensive processing, are transported to the cytoplasm (in eukaryotes, the cell contents exclusive of the nucleus), where they direct the ribosomal synthesis of proteins (Chapter 32). The nuclear envelope consists of a double membrane that is perforated by numerous  $\sim 90\text{-\AA}$ -wide pores that regulate the flow of proteins and RNA between the nucleus and the cytoplasm.

The nucleus of most eukaryotic cells contains at least one dark-staining body known as the **nucleolus**, which is the site of ribosomal assembly. It contains chromosomal segments bearing multiple copies of genes specifying ribosomal RNA. These genes are transcribed in the nucleolus, and the resulting RNA is combined with ribosomal proteins that have been imported from their site of synthesis in the **cytosol** (the cytoplasm exclusive of its membrane-bound organelles). The resulting immature ribosomes are then exported to the cytosol, where their assembly is completed. Thus protein synthesis occurs almost entirely in the cytosol.

#### **b. The Endoplasmic Reticulum and the Golgi Apparatus Function to Modify Membrane-Bound and Secretory Proteins**

The most extensive membrane in the cell, which was discovered in 1945 by Keith Porter, forms a labyrinthine compartment named the **endoplasmic reticulum**. A large portion of this organelle, called the **rough endoplasmic reticulum**, is studded with ribosomes that are engaged in the synthesis of proteins that are either membrane-bound or destined for secretion. The **smooth endoplasmic reticulum**, which is devoid of ribosomes, is the site of lipid synthesis. Many of the products synthesized in the endoplasmic reticulum are eventually transported to the **Golgi**

**apparatus** (named after Camillo Golgi, who first described it in 1898), a stack of flattened membranous sacs in which these products are further processed (Section 23-3B).

#### **c. Mitochondria Are the Site of Oxidative Metabolism**

The **mitochondria** (Greek: *mitos*, thread + *chondros*, granule) are the site of cellular **respiration** (aerobic metabolism) in almost all eukaryotes. These cytoplasmic organelles, which are large enough to have been discovered by nineteenth century cytologists, vary in their size and shape but are often ellipsoidal with dimensions of around  $1.0 \times 2.0 \mu\text{m}$ —much like a bacterium. A eukaryotic cell typically contains on the order of 2000 mitochondria, which occupy roughly one-fifth of its total cell volume.

The mitochondrion, as the electron microscopic studies of George Palade and Fritjof Sjöstrand first revealed, has two membranes: a smooth outer membrane and a highly folded inner membrane whose invaginations are termed **cristae** (Latin: crests). Thus the mitochondrion contains two compartments, the **intermembrane space** and the internal **matrix space**. The enzymes that catalyze the reactions of respiration are components of either the gel-like **matrix** or the inner mitochondrial membrane. *These enzymes couple the energy-producing oxidation of nutrients to the energy-requiring synthesis of adenosine triphosphate (ATP; Section 1-3B and Chapter 22).* Adenosine triphosphate, after export to the rest of the cell, fuels its various energy-consuming processes.

Mitochondria are bacteria-like in more than size and shape. Their matrix space contains mitochondrion-specific DNA, RNA, and ribosomes that participate in the synthesis of several mitochondrial components. Moreover, they reproduce by binary fission, and the respiratory processes that they mediate bear a remarkable resemblance to those of modern aerobic bacteria. These observations led to the now widely accepted hypothesis championed by Lynn Margulis that mitochondria evolved from originally free-living gram-negative aerobic bacteria, which formed a symbiotic relationship with a primordial anaerobic eukaryote. The eukaryote-supplied nutrients consumed by the bacteria were presumably repaid severalfold by the highly efficient oxidative metabolism that the bacteria conferred on the eukaryote. This hypothesis is corroborated by the observation that the amoeba *Pelomyxa palustris*, one of the few eukaryotes that lack mitochondria, permanently harbors aerobic bacteria in such a symbiotic relationship.

#### **d. Lysosomes and Peroxisomes Are Containers of Degradative Enzymes**

**Lysosomes**, which were discovered in 1949 by Christian de Duve, are organelles bounded by a single membrane that are of variable size and morphology, although most have diameters in the range 0.1 to 0.8  $\mu\text{m}$ . Lysosomes, which are essentially membranous bags containing a large variety of hydrolytic enzymes, function to digest materials ingested by endocytosis and to recycle cellular components (Section 32-6). Cytological investigations have revealed that lysosomes form by budding from the Golgi apparatus.

**Peroxisomes** (also known as **microbodies**) are membrane-enclosed organelles, typically 0.5  $\mu\text{m}$  in diameter, that contain oxidative enzymes. They are so named because some peroxisomal reactions generate **hydrogen peroxide** ( $\text{H}_2\text{O}_2$ ), a reactive substance that is either utilized in the enzymatic oxidation of other substances or degraded through a disproportionation reaction catalyzed by the enzyme **catalase**:

It is thought that peroxisomes function to protect sensitive cell components from oxidative attack by  $\text{H}_2\text{O}_2$ . Certain plants contain a specialized type of peroxisome, the **glyoxysome**, so named because it is the site of a series of reactions that are collectively termed the **glyoxylate pathway** (Section 23-2).

#### e. The Cytoskeleton Organizes the Cytosol

The cytosol, far from being a homogeneous solution, is a highly organized gel that can vary significantly in its composition throughout the cell. Much of its internal variability arises from the action of the **cytoskeleton**, an extensive array of filaments that gives the cell its shape and the ability to move and is responsible for the arrangement and internal motions of its organelles (Fig. 1-8).

The most conspicuous cytoskeletal components, the **microtubules**, are  $\sim 250\text{-}\text{\AA}$ -diameter tubes that are composed of the protein **tubulin** (Section 35-3G). They form the sup-

portive framework that guides the movements of organelles within a cell. For example, the **mitotic spindle** is an assembly of microtubules and associated proteins that participates in the separation of replicated chromosomes during cell division. Microtubules are also major constituents of **cilia**, the hairlike appendages extending from many cells, whose whiplike motions move the surrounding fluid past the cell or propel single cells through solution. Very long cilia, such as sperm tails, are termed **flagella** (prokaryotic flagella, which are composed of the protein **flagellin**, are quite different from and unrelated to those of eukaryotes).

The **microfilaments** are  $\sim 90\text{-}\text{\AA}$ -diameter fibers that consist of the protein **actin**. Microfilaments, as do microtubules, have a mechanically supportive function. Furthermore, through their interactions with the protein **myosin**, microfilaments form contractile assemblies that are responsible for many types of intracellular movements such as cytoplasmic streaming and the formation of cellular protruberances or invaginations. More conspicuously, however, actin and myosin are the major protein components of muscle (Section 35-3A).

The third major cytoskeletal component, the **intermediate filaments**, are protein fibers that are 100 to 150  $\text{\AA}$  in diameter. Their prominence in parts of the cell that are subject to mechanical stress suggests that they have a load-bearing function. For example, skin in higher animals contains an extensive network of intermediate filaments made of the protein **keratin** (Section 8-2A), which is largely

**Figure 1-8 Immunofluorescence micrographs showing cytoskeletal components.** Cells were treated with antibodies raised against (a) tubulin, (b) actin, (c) keratin, and (d) vimentin (a protein constituent of a type of intermediate filament) and

then stained with fluorescently labeled antibodies that bound to the foregoing antibodies. [a and d: K.G. Murti/Visuals Unlimited; b: M. Schliwa/Visuals Unlimited; c: courtesy of Mary Osborn, Max Planck Institute for Biophysical Chemistry, Göttingen, Germany.]

responsible for the toughness of this protective outer covering. In contrast to the case with microtubules and microfilaments, the proteins forming intermediate filaments vary greatly in size and composition, both among the different cell types within a given organism and among the corresponding cell types in different organisms.

#### f. Plant Cells Are Enclosed by Rigid Cell Walls

Plant cells (Fig. 1-9) contain all of the previously described organelles. They also have several additional features, the most conspicuous of which is a rigid cell wall that lies outside the plasma membrane. These cell walls, whose major component is the fibrous polysaccharide **cellulose** (Section 11-2C), account for the structural strength of plants.

A **vacuole** is a membrane-enclosed space filled with fluid. Although vacuoles occur in animal cells, they are most prominent in plant cells, where they typically occupy 90% of the volume of a mature cell. Vacuoles function as

storage depots for nutrients, wastes, and specialized materials such as pigments. The relatively high concentration of solutes inside a plant vacuole causes it to take up water osmotically, thereby raising its internal pressure. This effect, combined with the cell walls' resistance to bursting, is largely responsible for the turgid rigidity of nonwoody plants.

#### g. Chloroplasts Are the Site of Photosynthesis in Plants

One of the definitive characteristics of plants is their ability to carry out photosynthesis. The site of photosynthesis is an organelle known as the **chloroplast**, which, although generally several times larger than a mitochondrion, resembles it in that both organelles have an inner and an outer membrane. Furthermore, the chloroplast's inner membrane space, the **stroma**, is similar to the mitochondrial matrix in that it contains many soluble enzymes. However, the inner chloroplast membrane is not folded

**Figure 1-9** Drawing of a plant cell accompanied by electron micrographs of its organelles. [Plasmodesma: Courtesy of Hilton Mollenhauer, USDA; nucleus: Courtesy of Myron Ledbetter, Brookhaven National Laboratory; Golgi apparatus: Courtesy of

W. Gordon Whaley, University of Texas; chloroplast: Courtesy of Lewis Shumway, College of Eastern Utah; amyloplast: Biophoto Associates; endoplasmic reticulum: Biophoto Associates/Photo Researchers.]

into cristae. Rather, the stroma encloses a third membrane system that forms interconnected stacks of disklike sacs called **thylakoids**, which contain the photosynthetic pigment **chlorophyll**. The thylakoid uses chlorophyll-trapped light energy to generate ATP, which is used in the stroma to drive biosynthetic reactions forming carbohydrates and other products (Chapter 24).

Chloroplasts, as do mitochondria, contain their own DNA, RNA, and ribosomes, and they reproduce by fission. Apparently chloroplasts, much like mitochondria, evolved from an ancient cyanobacterium that took up symbiotic residence in an ancestral nonphotosynthetic eukaryote. In fact, several modern nonphotosynthetic eukaryotes have just such a symbiotic relationship with authentic cyanobacteria. Hence *most modern eukaryotes are genetic “mongrels” in that they simultaneously have nuclear, mitochondrial, and in the case of plants, chloroplast lines of descent.*

### B. Phylogeny and Differentiation

One of the most remarkable characteristics of eukaryotes is their enormous morphological diversity, on both the cellular and organismal levels. Compare, for example, the architectures of the various human cells drawn in Fig. 1-10. Similarly, recall the great anatomical differences among, say, an amoeba, an oak tree, and a human being.

Taxonomic schemes based on gross morphology as well as on protein and nucleic acid sequences (Sections 7-1 and 7-2) indicate that eukaryotes may be classified into three kingdoms: **Fungi**, **Plantae** (plants), and **Animalia** (animals). The relative structural simplicity of many unicellular eukaryotes, however, makes their classification under this scheme rather arbitrary. Consequently, these organisms are usually assigned a fourth eukaryotic kingdom, the **Protista**. (Note that biological classification schemes are for the convenience of biologists; nature is rarely neatly categorized.) Figure 1-11 is a phylogenetic tree for eukaryotes.

Anatomical comparisons among living and fossil organisms indicate that the various kingdoms of multicellular organisms independently evolved from Protista (Fig. 1-11). The programs of growth, differentiation, and development followed by multicellular animals (the **metazoa**) in their transformation from fertilized ova to adult organisms provide a remarkable indication of this evolutionary history. For example, all vertebrates exhibit gill-like pouches in their early embryonic stages, which presumably reflect their common fish ancestry (Fig. 1-12). Indeed, these early embryos are similar in size and anatomy even though their respective adult forms are vastly different in these characteristics. Such observations led Ernst Haeckel to formulate his famous (although overstated) dictum: *Ontogeny recapitulates phylogeny* (ontogeny: biological development).

**Figure 1-10** Drawings of some human cells. (a) An osteocyte (bone cell), (b) a sperm, (c) a pancreatic acinar cell (which secretes digestive enzymes), and (d) a neuron (nerve cell).

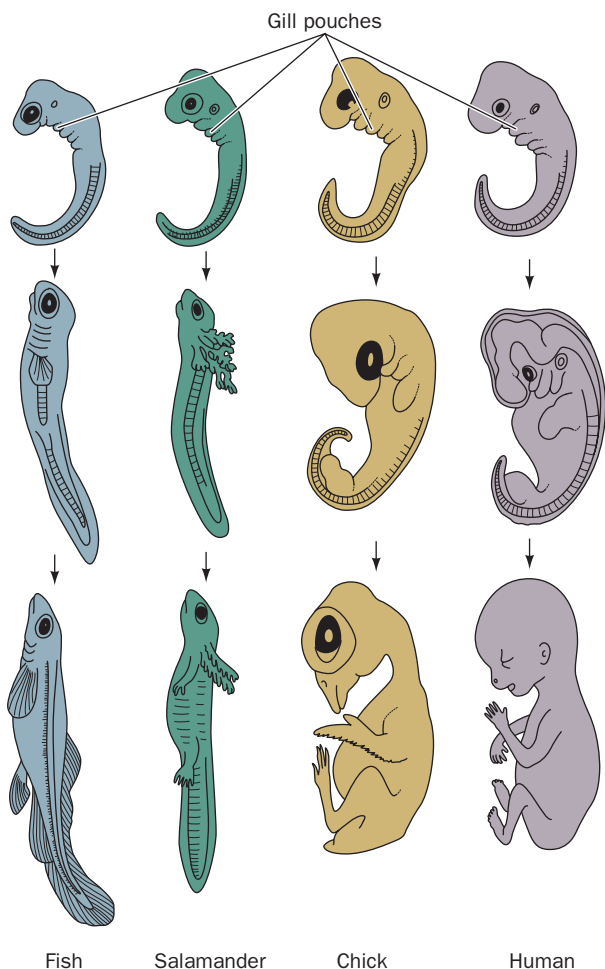

Figure 1-11 Evolutionary tree indicating the lines of descent of cellular life on Earth.

**Figure 1-12 Embryonic development of a fish, an amphibian (salamander), a bird (chick), and a mammal (human).** At early stages they are similar in both size and anatomy (the top drawings have around the same scale), although it is now known that their similarities are not as great as these classic drawings indicate. Later they diverge in both of these properties. [After Haeckel, *E., Anthropogenie oder Entwicklungsgeschichte des Menschen*, Engelmann (1874).]

The elucidation of the mechanism of cellular differentiation in eukaryotes is one of the major long-range goals of modern biochemistry.

### 3 BIOCHEMISTRY: A PROLOGUE

Biochemistry, as the name implies, is the chemistry of life. It therefore bridges the gap between chemistry, the study of the structures and interactions of atoms and molecules, and biology, the study of the structures and interactions of cells and organisms. Since living things are composed of inanimate molecules, *life, at its most basic level, is a biochemical phenomenon.*

Although living organisms, as we have seen, are enormously diverse in their macroscopic properties, there is a

remarkable similarity in their biochemistry that provides a unifying theme with which to study them. For example, hereditary information is encoded and expressed in an almost identical manner in all cellular life. Moreover, the series of biochemical reactions, which are termed **metabolic pathways**, as well as the structures of the enzymes that catalyze them are, for many basic processes, nearly identical from organism to organism. This strongly suggests that all known life-forms are descended from a single primordial ancestor in which these biochemical features first developed.

Although biochemistry is a highly diverse field, it is largely concerned with a limited number of interrelated issues. These are

1. What are the chemical and three-dimensional structures of biological molecules and assemblies, how do they form these structures, and how do their properties vary with them?
2. How do proteins work; that is, what are the molecular mechanisms of enzymatic catalysis, how do receptors recognize and bind specific molecules, and what are the intramolecular and intermolecular mechanisms by which receptors transmit information concerning their binding states?
3. How is genetic information expressed and how is it transmitted to future cell generations?
4. How are biological molecules and assemblies synthesized?
5. What are the control mechanisms that coordinate the myriad biochemical reactions that take place in cells and in organisms?
6. How do cells and organisms grow, differentiate, and reproduce?

These issues are previewed in this section and further illuminated in later chapters. However, as will become obvious as you read further, in all cases, our knowledge, extensive as it is, is dwarfed by our ignorance.

#### A. Biological Structures

Living things are enormously complex. As indicated in Section 1-1A, even the relatively simple *E. coli* cell contains some 3 to 6 thousand different compounds, most of which are unique to *E. coli* (Fig. 1-13). Higher organisms have a correspondingly greater complexity. *Homo sapiens* (human beings), for example, may contain 100,000 different types of molecules, although only a small fraction of them have been characterized. One might therefore suppose that to obtain a coherent biochemical understanding of any organism would be a hopelessly difficult task. This, however, is not the case. *Living things have an underlying regularity that derives from their being constructed in a hierarchical manner.* Anatomical and cytological studies have shown that multicellular organisms are organizations of organs, which are made of tissues consisting of cells, composed of

**Figure 1-13** Simulated cross section of an *E. coli* cell magnified around one millionfold. The right side of the drawing shows the multilayered cell wall and membrane, decorated on its exterior surface with lipopolysaccharides (Section 11-3Bc). A flagellum (lower right) is driven by a motor anchored in the inner membrane (Section 35-31). The cytoplasm, which occupies the middle region of the drawing, is predominantly filled with ribosomes engaged in protein synthesis (Section 32-3). The left side of the drawing

contains a dense tangle of DNA in complex with specific proteins. Only the largest macromolecules and molecular assemblies are shown. In a living cell, the remaining space in the cytoplasm would be crowded with smaller molecules and water (a water molecule would be about the size of the period at the end of this sentence). [After a drawing by David Goodsell, UCLA.]

subcellular organelles (e.g., Fig. 1-14). At this point in our hierarchical descent, we enter the biochemical realm since organelles consist of **supramolecular assemblies**, such as membranes or fibers, that are organized clusters of **macromolecules** (polymeric molecules with molecular masses from thousands of daltons on up).

As Table 1-1 indicates, *E. coli*, and living things in general, contain only a few different types of macromolecules: **proteins** (Greek: *proteios*, of first importance; a term coined in 1838 by Jacob Berzelius), **nucleic acids**, and **polysaccharides** (Greek: *sakcharon*, sugar). *All of these substances have a modular construction; they consist of linked monomeric units that occupy the lowest level of our structural hierarchy.* Thus, as Fig. 1-15 indicates, proteins are polymers of amino acids (Section 4-1B), nucleic acids are polymers of nucleotides (Section 5-1), and polysaccharides are polymers of sugars (Section 11-2). **Lipids** (Greek: *lipos*,

fat), the fourth major class of biological molecules, are too small to be classified as macromolecules but also have a modular construction (Section 12-1).

The task of the biochemist has been vastly simplified by the finding that *there are relatively few species of monomeric units that occur in each class of biological macromolecule.* Proteins are all synthesized from the same 20 species of **amino acids**, nucleic acids are made from 8 types of **nucleotides** (4 each in DNA and RNA), and there are ~8 commonly occurring types of **sugars** in polysaccharides. The great variation in properties observed among macromolecules of each type largely arises from the enormous number of ways its monomeric units can be arranged and, in many cases, derivatized.

One of the central questions in biochemistry is how biological structures are formed. As is explained in later chapters, the monomeric units of macromolecules are either

**Figure 1-14** Example of the hierarchical organization of biological structures.

**Figure 1-15** Polymeric organization of proteins, nucleic acids, and polysaccharides.

directly acquired by the cell as nutrients or enzymatically synthesized from simpler substances. Macromolecules are synthesized from their monomeric precursors in complex enzymatically mediated processes.

Newly synthesized proteins spontaneously fold to assume their native conformations (Section 9-1A); that is, they undergo **self-assembly**. Apparently their amino acid sequences specify their three-dimensional structures. Likewise, the structures of other types of macromolecules are specified by the sequences of their monomeric units. The principle of self-assembly extends at least to the level of supramolecular assemblies. However, the way in which higher levels of biological structures are generated is largely unknown. The elucidation of the mechanisms of cellular and organismal growth and differentiation is a major area of biological research.

## B. Metabolic Processes

There is a bewildering array of chemical reactions that simultaneously occur in any living cell. Yet these reactions follow a pattern that organizes them into the coherent process we refer to as life. For instance, most biological reactions are members of a metabolic pathway; that is, they function as one of a sequence of reactions that produce one or more specific products. Moreover, one of the hallmarks of life is that the rates of its reactions are so tightly regulated that there is rarely an unsatisfied need for a reactant in a metabolic pathway or an unnecessary buildup of some product.

Metabolism has been traditionally (although not necessarily logically) divided into two major categories:

- 1. Catabolism** or degradation, in which nutrients and cell constituents are broken down so as to salvage their components and/or to generate energy.

- 2. Anabolism** or biosynthesis, in which biomolecules are synthesized from simpler components.

The energy required by anabolic processes is provided by catabolic processes largely in the form of **adenosine**

**triphosphate (ATP)**. For instance, such energy-generating processes as photosynthesis and the biological oxidation of nutrients produce ATP from **adenosine diphosphate (ADP)** and a phosphate ion.

Conversely, such energy-consuming processes as biosynthesis, the transport of molecules against a concentration gradient, and muscle contraction are driven by the reverse of this reaction, the hydrolysis of ATP:

Thus, *anabolic and catabolic processes are coupled together through the mediation of the universal biological energy "currency," ATP.*

### C. Expression and Transmission of Genetic Information

Deoxyribonucleic acid (DNA) is the cell's master repository of genetic information. This macromolecule, as is diagrammed in Fig. 1-16, consists of two strands of linked **nucleotides**, each of which is composed of a **deoxyribose** sugar residue, a phosphoryl group, and one of four bases: **adenine (A)**, **thymine (T)**, **guanine (G)**, or **cytosine (C)**. Genetic information is encoded in the sequence of these bases. Each DNA base is hydrogen bonded to a base on the opposite strand to form an entity known as a **base pair**. However, A can only hydrogen bond with T, and G with C,

**Figure 1-16** Double-stranded DNA. The two polynucleotide chains associate through complementary base pairing. A pairs with T, and G pairs with C by forming specific hydrogen bonds.

**Figure 1-17** Schematic diagram of DNA replication. Each strand of parental DNA (*red*) acts as a template for the synthesis of a complementary daughter strand (*green*). Consequently, the resulting double-stranded molecules are identical.

so that the two strands are **complementary**; that is, the sequence of one strand implies the sequence of the other.

The division of a cell must be accompanied by the replication of its DNA. In this enzymatically mediated process, each DNA strand acts as a template for the formation of its complementary strand (Fig. 1-17; Section 5-4C). Consequently, every progeny cell contains a complete DNA molecule (or set of DNA molecules), each of which consists of one parental strand and one daughter strand. Mutations arise when, through rare copying errors or damage to a parental strand, one or more wrong bases are incorporated into a daughter strand. Most mutations are either innocuous or deleterious. Occasionally, however, one results in a new characteristic that confers some sort of selective advantage on its recipient. Individuals with such mutations, according to the tenets of the Darwinian theory of evolution, have an increased probability of

reproducing. New species arise through a progression of such mutations.

The expression of genetic information is a two-stage process. In the first stage, which is termed **transcription**, a DNA strand serves as a template for the synthesis of a complementary strand of ribonucleic acid (RNA; Section 31-2). This nucleic acid, which is generally single stranded, differs chemically from DNA (Fig. 1-16) only in that it has **ribose** sugar residues in place of DNA's deoxyribose and **uracil (U)** replacing DNA's thymine base.

In the second stage of genetic expression, which is known as **translation**, ribosomes enzymatically link together amino acids to form proteins (Section 32-3). The order in which the amino acids are linked together is prescribed by the RNA's sequence of bases. Consequently, since proteins are self-assembling, the genetic information encoded by DNA serves, through the intermediacy of RNA, to specify protein structure and function. Just which genes are expressed in a given cell under a particular set of circumstances is controlled by complex regulatory systems whose workings are understood only in outline.

## 4 GENETICS: A REVIEW

One has only to note the resemblance between parent and child to realize that physical traits are inherited. Yet the mechanism of inheritance was unknown until the mid-twentieth century. The theory of **pangenesis**, which originated with the ancient Greeks, held that semen, which clearly has something to do with procreation, consists of representative particles from all over the body (**pangenes**). This idea was extended in the late eighteenth century by Jean Baptiste de Lamarck, who, in a theory known as **Lamarckism**, hypothesized that an individual's acquired characteristics, such as large muscles resulting from exercise, would be transmitted to his/her offspring. Pangenesis and at least some aspects of Lamarckism were accepted by most nineteenth century biologists, including Charles Darwin.

The realization, in the mid-nineteenth century, that all organisms are derived from single cells set the stage for the development of modern biology. In his **germ plasm theory**, August Weismann pointed out that sperm and ova, the **germ cells** (whose primordia are set aside early in embryonic development), are directly descended from the germ cells of the previous generation and that other cells of the body, the **somatic cells**, although derived from germ cells, do not give rise to them. He refuted the ideas of pangenesis and Lamarckism by demonstrating that the progeny of many successive generations of mice whose tails had been cut off had tails of normal length.

The microtubules forming the mitotic spindle are stained red and the chromosomes are blue. [Courtesy of Andrew S. Bajer, University of Oregon.]

### A. Chromosomes

In the 1860s, eukaryotic cell nuclei were observed to contain linear bodies that were named chromosomes (Greek: *chromos*, color + *soma*, body) because they are strongly stained by certain basic dyes (Fig. 1-18). There are normally two copies of each chromosome (**homologous pairs**) present in every somatic cell. The number of unique chromosomes ( $N$ ) in such a cell is known as its **haploid number**, and the total number of chromosomes ( $2N$ ) is its **diploid number**. Different species differ in their haploid number of chromosomes (Table 1-2).

**Table 1-2 Number of Chromosomes ( $2N$ ) in Some Eukaryotes**

### a. Somatic Cells Divide by Mitosis

The division of somatic cells, a process known as **mitosis** (Fig. 1-19), is preceded by the duplication of each chromosome to form a cell with  $4N$  chromosomes. During cell division, each chromosome attaches by its **centromere** to the **mitotic spindle** such that the members of each duplicate pair line up across the equatorial plane of the cell. The members of each duplicate pair are then pulled to opposite poles of the dividing cell by the action of the spindle to yield diploid daughter cells that each have the same  $2N$  chromosomes as the parent cell.

### b. Germ Cells Are Formed by Meiosis

The formation of germ cells, a process known as **meiosis** (Fig. 1-20), requires two consecutive cell divisions. Before the first meiotic division each chromosome replicates, but the resulting sister **chromatids** remain attached at their centromere. The homologous pairs of the doubled chromosomes then line up across the equatorial plane of the cell in zipperlike fashion, which permits an exchange of the corresponding sections of homologous chromosomes in a process known as **crossing-over**. The spindle then moves the members of each homologous pair to opposite poles of the cell so that, after the first meiotic division, each daughter cell contains  $N$  doubled chromosomes. In the second meiotic division, the sister chromatids separate to form chromosomes and move to opposite poles of the dividing cell to yield a total of four haploid cells that are known as **gametes**. Fertilization consists of the fusion of a male gamete (sperm) with a female gamete (ovum) to yield a diploid cell known as a **zygote** that has received  $N$  chromosomes from each of its parents.

## B. Mendelian Inheritance

The basic laws of inheritance were reported in 1866 by Gregor Mendel. They were elucidated by the analysis of a series of **genetic crosses** between true-breeding strains (producing progeny that have the same characteristics as the parents) of garden peas, *Pisum sativum*, that differ in certain well-defined traits such as seed shape (round vs wrinkled), seed color (yellow vs green), or flower color (purple vs white). Mendel found that in crossing parents ( $P$ ) that differ in a single trait, say seed shape, the progeny ( $F_1$ ; first filial generation) all have the trait of only one of the parents, in this case round seeds (Fig. 1-21). The trait appearing in  $F_1$  is said to be **dominant**, whereas the alternative trait is called **recessive**. In  $F_2$ , the progeny of  $F_1$ , three-quarters have the dominant trait and one-quarter have the recessive trait. Those peas with the recessive trait breed true; that is, self-crossing recessive  $F_2$ 's results in progeny ( $F_3$ ) that also have the recessive trait. The  $F_2$ 's exhibiting the dominant trait, however, fall into two categories: One-third of them breed true, whereas the remainder have progeny with the same 3:1 ratio of dominant to recessive traits as do the members of  $F_2$ .

Mendel accounted for his observations by hypothesizing that *the various pairs of contrasting traits each result from a factor (now called a **gene**) that has alternative forms*

**Figure 1-19** Mitosis, the usual form of cell division in eukaryotes. Mitosis yields two daughter cells, each with the same chromosomal complement as the parental cell.

(**alleles**). Every plant contains a pair of genes governing a particular trait, one inherited from each of its parents. The alleles for seed shape are symbolized *R* for round seeds and *r* for wrinkled seeds (gene symbols are generally given in italics). The pure-breeding plants with round and wrinkled seeds, respectively, have *RR* and *rr* **genotypes** (genetic composition) and are both said to be **homozygous** in seed shape. Plants with the *Rr* genotype are **heterozygous** in seed shape and have the round seed **phenotype** (appearance or character) because *R* is dominant over *r*. The two alleles do not blend or mix in any way in the plant and are independently transmitted through gametes to progeny (Fig. 1-22).

Mendel also found that *different traits are independently inherited*. For example, crossing peas that have round yellow seeds (*RRYY*) with peas that have wrinkled green seeds (*rryy*) results in *F*<sub>1</sub> progeny (*RrYy*) that have round yellow seeds (yellow seeds are dominant over green seeds). The *F*<sub>2</sub> phenotypes appear in the ratio 9 round yellow : 3 round green : 3 wrinkled yellow : 1 wrinkled green. This result indicates that there is no tendency for the genes from

**Figure 1-22 Genotypes and phenotypes.** In a genetic cross between peas with round seeds and peas with wrinkled seeds, the  $F_1$  generation has the round seed phenotype because the round seed genotype is dominant over the wrinkled seed genotype. In the  $F_2$  generation, three-fourths of the seeds are round and one-fourth are wrinkled because the genes for these alleles are independently transmitted by haploid gametes.

any parent to assort together (Fig. 1-23). It was later shown, however, that only genes that occur on different chromosomes exhibit such independence.

The dominance of one trait over another is a common but not universal phenomenon. For example, crossing a pure-breeding red variety of the snapdragon *Antirrhinum* with a pure-breeding white variety results in pink-colored  $F_1$  progeny. The  $F_2$  progeny have red, pink, and white flowers in a 1:2:1 ratio because the flowers of homozygotes for the red color ( $AA$ ) contain more red pigment than do the heterozygotes ( $Aa$ ; Fig. 1-24). The red and white traits are therefore said to be **codominant**. In the case of codominance, the phenotype reveals the genotype.

A given gene may have multiple alleles. A familiar example is the human **ABO blood group system** (Section 12-3E). A person may have type A, type B, type AB, or type O blood depending on whether his/her red blood cells bear A antigens, B antigens, both, or neither. The A and B antigens are specified by the codominant  $I^A$  and  $I^B$  alleles, respectively, and the O phenotype is homozygous for the recessive  $i$  allele.

**C. Chromosomal Theory of Inheritance**

Mendel's theory of inheritance was almost universally ignored by his contemporaries. This was partially because in

**Figure 1-23 Independent assortment.** The genes for round ( $R$ ) versus wrinkled ( $r$ ) and yellow ( $Y$ ) versus green ( $y$ ) pea seeds assort independently. The  $F_2$  progeny consist of nine genotypes comprising the four possible phenotypes.

analyzing his data he used probability theory, an alien subject to most biologists of the time. The major reason his theory was ignored, however, is that it was ahead of its time: Contemporary knowledge of anatomy and physiology provided no basis for its understanding. For instance, mitosis and meiosis had yet to be discovered. Yet, after Mendel's work was rediscovered in 1900, it was shown that his principles explained inheritance in animals as well as in plants. In 1903, as a result of the realization that chromosomes and genes behave in a parallel fashion, Walter Sutton formulated the **chromosomal theory of inheritance** in which he hypothesized that genes are parts of chromosomes.

The first trait to be assigned a chromosomal location was that of sex. In most eukaryotes, the cells of females each contain two copies of the **X chromosome** ( $XX$ ), whereas

**Figure 1-24 Codominance.** In a cross between snapdragons with red (AA) and white (aa) flowers, the F<sub>1</sub> generation is pink (Aa), which demonstrates that the two alleles, A and a, are codominant. The F<sub>2</sub> flowers are red, pink, and white in a 1:2:1 ratio.

male cells contain one copy of X and a morphologically distinct Y chromosome (XY; Fig. 1-25). Ova must therefore contain a single X chromosome, and sperm contain either an X or a Y chromosome (Fig. 1-25). Fertilization by an X-bearing sperm therefore results in a female zygote and fertilization by a Y-bearing sperm yields a male zygote. This explains the observed 1:1 ratio of males to females in most species. The X and Y chromosomes are referred to as **sex chromosomes**; the others are known as **autosomes**.

**a. Fruit Flies Are Favorite Genetic Subjects**

The pace of genetic research greatly accelerated after Thomas Hunt Morgan began using the fruit fly *Drosophila melanogaster* as an experimental subject. This small prolific insect (Fig. 1-26), which is often seen hovering around ripe fruit in summer and fall, is easily maintained in the laboratory, where it produces a new generation every 14 days. With *Drosophila*, the results of genetic crosses can be determined some 25 times faster than they can with peas. *Drosophila* is presently the genetically best characterized higher organism.

The first known mutant strain of *Drosophila* had white eyes rather than the red eyes of the **wild type** (occurring in nature). Through genetic crosses of the white eye strain

**Figure 1-25 Independent segregation.** The independent segregation of the sex chromosomes, X and Y, results in a 1:1 ratio of males to females.

**Figure 1-26 The fruit fly *Drosophila melanogaster*.** The male (left) and the female (right) are shown in their relative sizes; they are actually ~2 mm long and weigh ~1 mg.

with the wild type, Morgan showed that the distribution of the white eye gene (*wh*) parallels that of the X chromosome. This indicates that the *wh* gene is located on the X chromosome and that the Y chromosome does not contain it. The *wh* gene is therefore said to be **sex linked**.

**b. Genetic Maps Can Be Constructed from an Analysis of Crossover Rates**

In succeeding years, the chromosomal locations of many *Drosophila* genes were determined. Those genes that reside on the same chromosome do not assort independently. However, any pair of such **linked** genes **recombine** (exchange relative positions with their allelic counterparts on the homologous chromosome) with a characteristic frequency. The cytological basis of this phenomenon was found to occur at the start of meiosis when the homologous doubled chromosomes line up in parallel (metaphase I; Fig. 1-20). Homologous chromatids then exchange equivalent sections by crossing-over (Fig. 1-27). The chromosomal location of the crossover point varies nearly randomly from event to event. Consequently, *the crossover frequency of a pair of linked genes varies directly with their physical separation along the chromosome*. Morgan and Alfred Sturtevant made use of this phenomenon to **map** (locate) the relative positions of genes on *Drosophila*'s four unique chromosomes. Such studies have demonstrated that *chromosomes are linear unbranched structures*. We now know that such **genetic maps** (Fig. 1-28) parallel the corresponding base sequences of the DNA within the chromosomes.

**c. Nonallelic Genes Complement One Another**

Whether or not two recessive traits that affect similar functions are allelic (different forms of the same gene) can be determined by a **complementation test**. In this test, a homozygote for one of the traits is crossed with a homozygote

for the other. If the two traits are nonallelic, the progeny will have the wild-type phenotype because each of the homologous chromosomes supplies the wild-type function that the other lacks; that is, they complement each other. For example, crossing a *Drosophila* that is homozygous for

(a) **Figure 1-27 Crossing-over.** (a) An electron micrograph, together with an interpretive drawing, of two homologous pairs of chromatids during meiosis in the grasshopper *Chorthippus parallelus*. Nonsister chromatids (*different colors*) may

(b) **Figure 1-27 Crossing-over.** (b) A diagram showing the recombination of pairs of allelic genes (*A, B*) and (*a, b*) during crossover. [Courtesy of Bernard John, The Australian National University.]

an eye color mutation known as purple (*pr*) with a homozygote for another eye color mutation known as brown (*bw*) yields progeny with wild-type eye color, thereby demonstrating that these two genes are not allelic (Fig. 1-29a).

**Figure 1-28** Portion of the genetic map of chromosome 2 of *Drosophila*. The positions of the genes are given in map units. Two genes separated by *m* map units recombine with a frequency of *m*%.

In contrast, in crossing a female *Drosophila* that is homozygous for the sex-linked white eye color allele (*wh*) with a male carrying the sex-linked coffee eye color allele (*cf*), the female progeny do not have wild-type eye color (Fig. 1-29b). The *wh* and *cf* genes must therefore be allelic.

**d. Genes Direct Protein Expression**

The question of how genes control the characteristics of organisms took some time to be answered. Archibald Garrod was the first to suggest a specific connection between genes and enzymes. Individuals with **alkaptonuria** produce urine that darkens alarmingly on exposure to air, a consequence of the oxidation of the **homogentisic acid** they excrete (Section 16-3Ab). In 1902, Garrod showed that this

(a) Nonallelic recessive traits

(b) Allelic recessive traits

**Figure 1-29** The complementation test indicates whether two recessive traits are allelic. Two examples in *Drosophila* are shown. (a) Crossing a homozygote for purple eye color (*pr*) with a homozygote for brown eye color (*bw*) yields progeny with wild-type eye color. This indicates that *pr* and *bw* are nonallelic. Here the superscript “+” indicates the wild-type allele. (b) In crossing a female that is homozygous for the sex-linked white eye color gene *wh* with a male bearing the sex-linked coffee eye color gene *cf*, the female progeny do not have the wild-type eye color. The *wh* and *cf* genes must therefore be allelic.

rather benign metabolic disorder (its only adverse effect is arthritis in later life) results from a recessive trait that is inherited in a Mendelian fashion. He further demonstrated that alkaptonurics are unable to metabolize the homogentisic acid fed to them and therefore concluded that *they lack an enzyme that metabolizes this substance*. Garrod described alkaptonuria and several other inherited human diseases he had studied as **inborn errors of metabolism**.

Beginning in 1940, George Beadle and Edward Tatum, in a series of investigations that mark the beginning of biochemical genetics, showed that *there is a one-to-one correspondence between a mutation and the lack of a specific enzyme*. The wild-type mold *Neurospora* grows on a “minimal medium” in which the only sources of carbon and nitrogen are glucose and  $\text{NH}_3$ . Certain mutant varieties of *Neurospora* that were generated by means of irradiation with X-rays, however, require an additional substance in order to grow. Beadle and Tatum demonstrated, in several cases, that the mutants lack a normally present enzyme that participates in the biosynthesis of the required substance (Section 16-3Ac). This resulted in their famous maxim **one gene—one enzyme**. Today we know this principle to be only partially true since many genes specify proteins that are not enzymes and many proteins consist of several independently specified subunits (Section 8-5). A more accurate dictum might be **one gene—one polypeptide**. Yet even that is not completely correct because RNAs with structural and functional roles are also genetically specified.

#### D. Bacterial Genetics

Bacteria offer several advantages for genetic study. Foremost of these is that *under favorable conditions, many have generation times of under 20 min. Consequently, the results of a genetic experiment with bacteria can be ascertained in a matter of hours rather than the weeks or years required for an analogous study with higher organisms. The tremendous number of bacteria that can be quickly grown ( $\sim 10^{10} \text{ mL}^{-1}$ ) permits the observation of extremely rare biological events*. For example, an event that occurs with a frequency of 1 per million can be readily detected in bacteria with only a few minutes' work. To do so in *Drosophila* would be an enormous and probably futile effort. Moreover, bacteria are usually haploid, so their phenotype indicates their genotype. Nevertheless, the basic principles of genetics were elucidated from the study of higher plants and animals. This is because bacteria do not reproduce sexually in the manner of higher organisms, so the basic technique of classical genetics, the genetic cross, is not normally applicable to bacteria. In fact, before it was shown that DNA is the carrier of hereditary information, it was not altogether clear that bacteria had chromosomes.

The study of bacterial genetics effectively began in the 1940s when procedures were developed for isolating bacterial mutants. Since bacteria have few easily recognized morphological features, *their mutants are usually detected (selected for) by their ability or inability to grow under certain conditions*. For example, wild-type *E. coli* can grow on

**Figure 1-30 Replica plating.** A technique for rapidly and conveniently transferring colonies from a “master” culture plate (Petri dish) to a different medium on another culture plate. Since the colonies on the master plate and on the replicas should have the same spatial distribution, it is easy to identify the desired mutants.

a medium in which glucose is the only carbon source. Mutants that are unable to synthesize the amino acid **leucine**, for instance, require the presence of leucine in their growth media. Mutants that are resistant to an antibiotic, say **ampicillin**, can grow in the presence of that antibiotic, whereas the wild type cannot. Mutants in which an essential protein has become temperature sensitive grow at  $30^\circ\text{C}$  but not at  $42^\circ\text{C}$ , whereas the wild type grows at either temperature. By using a suitable screening protocol, a bacterial colony containing a particular mutation or combination of mutations can be selected. This is conveniently done by the method of **replica plating** (Fig. 1-30).

#### E. Viral Genetics

*Viruses are infectious particles consisting of a nucleic acid molecule enclosed by a protective capsid (coat) that consists largely or entirely of protein. A virus specifically adsorbs to a susceptible cell into which it insinuates its nucleic acid. Over the course of the infection (Fig. 1-31), the viral chromosome redirects the cell's metabolism so as to*

**Figure 1-31** The life cycle of a virus.

produce new viruses. A viral infection usually culminates in the **lysis** (breaking open) of the host cell, thereby releasing large numbers (tens to thousands) of mature virus particles that can each initiate a new round of infection. Viruses, having no metabolism of their own, are the ultimate parasites. They are not living organisms since, in the absence of their host, they are as biologically inert as any other large molecule.

#### a. Viruses Are Subject to Complementation and Recombination

The genetics of viruses can be studied in much the same way as that of cellular organisms. Since viruses have no metabolism, however, their presence is usually detected by their ability to kill their host. The presence of viable **bacteriophages** (viruses infecting bacteria, **phages** for short; Greek: *phagein*, to eat) is conveniently indicated by **plaques** (clear spots) on a “lawn” of bacteria on a culture plate (Fig. 1-32). Plaques mark the spots where single phage particles had multiplied with the resulting lysis of the bacteria in the area. A mutant phage, which can produce progeny under certain **permissive conditions**, is detected by its inability to do so under other **restrictive conditions** in which the wild-type phage is viable. These conditions usually involve differences in the strain of the bacterial host employed or in the temperature.

Viruses are subject to complementation. Simultaneous infection of a bacterium by two different mutant varieties of a phage may yield progeny under conditions in which neither variety by itself can reproduce. If this occurs, then each mutant phage must have supplied a function that could not be supplied by the other. Each such mutation is

**Figure 1-32** Screening for viral mutants. A culture plate covered with a lawn of bacteria on which bacteriophage have formed plaques. [Jack Bostrack/Visuals Unlimited.]

said to belong to a different **complementation group**, a term synonymous for gene.

Viral chromosomes are also subject to recombination. This occurs when a single cell is simultaneously infected by two mutant strains of a virus (Fig. 1-33). The dynamics of viral recombination differ from those in eukaryotes or bacteria because the viral chromosome undergoes recombination throughout the several rounds of DNA replication that occur during the viral life cycle. Recombinant viral

**Figure 1-33 Viral recombination.** Recombination of bacteriophage chromosomes occurs on simultaneous infection of a bacterial host by two phage strains carrying the genes *Ab* and *aB*.

progeny therefore consist of many if not all of the possible recombinant types.

#### b. The Recombinational Unit Is a Base Pair

The enormous rate at which bacteriophages reproduce permits the detection of recombinational events that occur with a frequency of as little as  $1$  in  $10^8$ . In the 1950s, Seymour Benzer carried out high-resolution genetic studies of the *rII* region of the bacteriophage T4 chromosome. This  $\sim 4000$ -base pair (bp) region, which represents  $\sim 2\%$  of the T4 chromosome, consists of two adjacent complementation groups designated *rIIA* and *rIIB*. In a permissive host, *E. coli* B, a mutation that inactivates the product of either gene causes the formation of plaques that are easily identified because they are much larger than those of the wild-type phage (the designation *r* stands for rapid lysis). However, only the wild-type phage will lyse the restrictive host, *E. coli* K12( $\lambda$ ). The presence of plaques in an *E. coli* K12( $\lambda$ ) culture plate that had been simultaneously infected with two different *rII* mutants in the same complementation group demonstrated that recombination can take place within a gene. This refuted a then widely held model of the chromosome in which genes were thought to be discrete entities, rather like beads on a string, such that recombination could take place only between intact genes. The genetic mapping of mutations at over 300 distinguishable sites in the *rIIA* and *rIIB* regions

**Figure 1-34 The cis-trans test.** Consider a chromosome that is present in two copies in which two positions on the same gene, *P* and *Q*, have defective (recessive) mutants, *p* and *q*, respectively. (a) If the two mutations are cis (physically on the same chromosome), one gene will be wild type, so the organism will have a wild-type phenotype. (b) If the mutations are trans (on physically different chromosomes), both genes will be defective and the organism will have a mutant phenotype.

indicated that genes, as are chromosomes, are linear unbranched structures.

Benzer also demonstrated that a complementation test between two mutations in the same complementation group yields progeny in the restrictive host when the two mutations are in the **cis** configuration (on the same chromosome; Fig. 1-34a), but fails to do so when they are in the **trans** configuration (on physically different chromosomes; Fig. 1-34b). This is because only when both mutations physically occur in the same gene will the other gene be functionally intact. The term **cistron** was coined to mean a functional genetic unit defined according to this **cis-trans test**. This word has since become synonymous with gene or complementation group.

The recombination of pairs of *rII* mutants was observed to occur at frequencies as low as 0.01% (although frequencies as low as 0.0001% could, in principle, have been detected). Since a recombination frequency in T4 of 1% corresponds to a 240-bp separation of mutation sites, the unit of recombination can be no larger than  $0.01 \times 240 = 2.4$  bp. For reasons having to do with the mechanism of recombination, this is an upper-limit estimate. On the basis of high-resolution genetic mapping, it was therefore concluded that the unit of recombination is about the size of a single base pair.

## 5 THE ORIGIN OF LIFE

People have always pondered the riddle of their existence. Indeed, all known cultures, past and present, primitive and sophisticated, have some sort of a creation myth that rationalizes how life arose. Only in the modern era, however, has it been possible to consider the origin of life in terms of a scientific framework, that is, in a manner subject to experimental verification. One of the first to do so was Charles

Darwin, the originator of the theory of evolution. In 1871, he wrote in a letter to a colleague:

*It is often said that all the conditions for the first production of a living organism are now present, which could ever have been present. But if (and oh what a big if) we could conceive in some warm little pond, with all sorts of ammonia and phosphoric salts, light, heat, electricity, etc., present, that a protein compound was chemically formed ready to undergo still more complex changes, at the present day such matter would be instantly devoured, or absorbed, which would not have been the case before living creatures were formed.*

Radioactive dating studies indicate that Earth formed ~4.6 billion years ago but, due to the impacts of numerous large objects, its surface remained too hot to support life for several hundred million years thereafter. The earliest evidence of cellular life, microfossils of what appear to be organisms resembling modern cyanobacteria (Fig. 1-35), is ~3.5 billion years old. However, the oldest known sedimentary rocks on Earth, which are ~3.8 billion years old, have been subject to such extensive metamorphic forces (500°C and 5000 atm) that any microfossils they contained would have been obliterated. Nevertheless, geochemical analysis indicates (although not without dispute) that these rocks contain carbonaceous inclusions that are likely to be of biological origin and hence that life must have existed at the time these sedimentary rocks were laid down. If so, life on Earth must have arisen within a window of as little as a hundred million years that opened up ~4 billion years ago.

Since the prebiotic era left no direct record, we cannot hope to determine exactly how life arose. Through laboratory experimentation, however, we can at least demonstrate what sorts of abiotic chemical reactions may have led to the formation of a living system. Moreover, we are not entirely without traces of prebiotic development. The underlying biochemical and genetic unity of modern organisms suggests that life as we know it arose but once (if life arose more than once, the other forms must have rapidly died

**Figure 1-35** Microfossil of what appears to be a cyanobacterium. This fossil, shown with its interpretive drawing, is from ~3.5-billion-year-old rock from western Australia. [Courtesy of J. William Schopf, UCLA.]

out, possibly because they were “eaten” by the present form). Thus, by comparing the corresponding genetic messages of a wide variety of modern organisms it may be possible to derive reasonable models of the primordial messages from which they have descended.

It is generally accepted that the development of life occupied three stages (Fig. 1-36):

1. Chemical evolution, in which simple geologically occurring molecules reacted to form complex organic polymers.
2. The self-organization of collections of these polymers to form replicating entities. At some point in this process, the transition from a lifeless collection of reacting molecules to a living system occurred.
3. Biological evolution to ultimately form the complex web of modern life.

In this section, we outline what has been surmised about these processes. We precede this discussion by a consideration of why only carbon, of all the elements, is suitable as the basis of the complex chemistry required for life.

### A. The Unique Properties of Carbon

Living matter, as Table 1-3 indicates, consists of a relatively small number of elements. C, H, O, N, P, and S, all of which readily form covalent bonds, comprise 92% of the dry weight of living things (most organisms are ~70% water). The balance consists of elements that are mainly present as ions and for the most part occur only in trace quantities (they usually carry out their functions at the active sites of enzymes). Note, however, that there is no known biological requirement for 64 of the 90 naturally occurring elements

**Table 1-3** Elemental Composition of the Human Body

Element	Dry Weight (%) <sup>a</sup>	Elements Present in Trace Amounts
C	61.7	B
N	11.0	F
O	9.3	Si
H	5.7	V

Figure 1-37 Periodic table in which the 26 elements utilized by living systems are highlighted in blue.

(Fig. 1-37). Conversely, with the exceptions of oxygen and calcium, the biologically most abundant elements are but minor constituents of Earth's crust (the most abundant components of which are O, 47%; Si, 28%; Al, 7.9%; Fe, 4.5%; and Ca, 3.5%).

The predominance of carbon in living matter is no doubt a result of its tremendous chemical versatility compared with all the other elements. Carbon has the unique ability to form a virtually infinite number of compounds as a result of its capacity to make as many as four highly stable covalent bonds (including single, double, and triple bonds) combined with its ability to form covalently linked C—C chains of unlimited extent. Thus, of the nearly 40 million chemical compounds that are presently known, ~90% are organic (carbon-containing) substances. Let us examine the other elements in the periodic table to ascertain why they lack these combined properties.

Only five elements, B, C, N, Si, and P, have the capacity to make three or more bonds each and thus to form chains of covalently linked atoms that can also have pendant side chains. The other elements are either metals, which tend to form ions rather than covalent bonds; noble gases, which are essentially chemically inert; or atoms such as H or O that can each make only one or two covalent bonds. However, although B, N, Si, and P can each participate in at least three covalent bonds, they are, for reasons indicated below, unsuitable as the basis of a complex chemistry.

Boron, having fewer valence electrons (3) than valence orbitals (4), is electron deficient. This severely limits the types and stabilities of compounds that B can form. Nitrogen has the opposite problem; its 5 valence electrons make it electron rich. The repulsions between the lone pairs of electrons on covalently bonded N atoms serve to greatly reduce the bond energy of an N—N bond (171 kJ · mol<sup>-1</sup> vs 348 kJ · mol<sup>-1</sup> for a C—C single bond) relative to the unusually stable triple bond of the N<sub>2</sub> molecule (946 kJ · mol<sup>-1</sup>). Even short chains of covalently bonded N atoms therefore tend to decompose, usually violently, to N<sub>2</sub>. Silicon and carbon, being in the same column of the periodic table, might be expected to have similar chemistries. Sili-

con's large atomic radius, however, prevents two Si atoms from approaching each other closely enough to gain much orbital overlap. Consequently Si—Si bonds are weak (177 kJ · mol<sup>-1</sup>) and the corresponding multiple bonds are rarely stable. Si—O bonds, in contrast, are so stable (369 kJ · mol<sup>-1</sup>) that chains of alternating Si and O atoms are essentially inert (silicate minerals, whose frameworks consist of such bonds, form Earth's crust). Science fiction writers have speculated that **silicones**, which are oily or rubbery organosilicon compounds with backbones of linked Si—O units, for example, **methyl silicones**,

could form the chemical basis of extraterrestrial life-forms. Yet the very inertness of the Si—O bond makes this seem unlikely. Phosphorus, being below N in the periodic table, forms even less stable chains of covalently bonded atoms.

The foregoing does not imply that heteronuclear bonds are unstable. On the contrary, proteins contain C—N—C linkages, carbohydrates have C—O—C linkages, and nucleic acids possess C—O—P—O—C linkages. However, *these heteronuclear linkages are less stable than are C—C bonds. Indeed, they usually form the sites of chemical cleavage in the degradation of macromolecules and, conversely, are the bonds formed when monomer units are linked together to form macromolecules.* In the same vein, homonuclear linkages other than C—C bonds are so reactive that they are, with the exception of S—S bonds in proteins, extremely rare in biological systems.

## B. Chemical Evolution

In the remainder of this section, we describe the most widely favored scenario for the origin of life. *Keep in mind, however, that there are valid scientific objections to this scenario as well as to the several others that have been seriously*

entertained, so that we are far from certain as to how life arose.

The solar system is thought to have formed by the gravitationally induced collapse of a large interstellar cloud of dust and gas. The major portion of this cloud, which was composed mostly of hydrogen and helium, condensed to form the sun. The rising temperature and pressure at the center of the protosun eventually ignited the self-sustaining thermonuclear reaction that has since served as the sun's energy source. The planets, which formed from smaller clumps of dust, were not massive enough to support such a process. In fact the smaller planets, including Earth, consist of mostly heavier elements because their masses are too small to gravitationally retain much  $H_2$  and He.

The primordial Earth's atmosphere was quite different from what it is today. It could not have contained signifi-

cant quantities of  $O_2$ , a highly reactive substance. Rather, in addition to the  $H_2O$ ,  $N_2$ , and  $CO_2$  that it presently has, the atmosphere probably contained smaller amounts of  $CO$ ,  $CH_4$ ,  $NH_3$ ,  $SO_2$ , and possibly  $H_2$ , all molecules that have been spectroscopically detected in interstellar space. The chemical properties of such a gas mixture make it a **reducing atmosphere** in contrast to Earth's present atmosphere, which is an **oxidizing atmosphere**.

In the 1920s, Alexander Oparin and J.B.S. Haldane independently suggested that *ultraviolet (UV) radiation from the sun [which is presently largely absorbed by an ozone ( $O_3$ ) layer high in the atmosphere] or lightning discharges caused the molecules of the primordial reducing atmosphere to react to form simple organic compounds such as amino acids, nucleic acid bases, and sugars. That this process is possible was first experimentally demonstrated in 1953 by Stanley Miller and Harold Urey, who, in the apparatus diagrammed in Fig. 1-38, simulated effects of lightning storms in the primordial atmosphere by subjecting a refluxing mixture of  $H_2O$ ,  $CH_4$ ,  $NH_3$ , and  $H_2$  to an electric discharge for about a week. (Although it now appears that Earth's primordial atmosphere did not have the strongly reducing composition assumed by Miller and Urey, localized reducing environments may have existed, particularly near volcanic plumes.) The resulting solution contained significant amounts of water-soluble organic compounds, the most abundant of which are listed in Table 1-4, together with a*

**Figure 1-38** Apparatus for emulating the synthesis of organic compounds on the prebiotic Earth. A mixture of gases thought to resemble the primitive Earth's reducing atmosphere is subjected to an electric discharge, to simulate the effects of lightning, while the water in the flask is refluxed so that the newly formed compounds dissolve in the water and accumulate in the flask. [After Miller, S.L. and Orgel, L.E., *The Origins of Life on Earth*, p. 84, Prentice-Hall (1974).]

substantial quantity of insoluble tar (polymerized material). Several of the soluble compounds are amino acid components of proteins, and many of the others, as we shall see, are also of biochemical significance. Similar experiments in which the reaction conditions, the gas mixture, and/or the energy source were varied have resulted in the synthesis of many other amino acids. This, together with the observation that carbonaceous meteorites contain many of the same amino acids, strongly suggests that these substances were present in significant quantities on the primordial Earth. Indeed, it seems likely that large quantities of organic molecules were delivered to the primordial Earth by the meteorites and dust that so heavily bombarded it.

Nucleic acid bases can also be synthesized under supposed prebiotic conditions. In particular, adenine is formed by the condensation of HCN, a plentiful component of the prebiotic atmosphere, in a reaction catalyzed by  $\text{NH}_3$  [note that the chemical formula of adenine is  $(\text{HCN})_5$ ]. The other bases have been synthesized in similar reactions involving HCN and  $\text{H}_2\text{O}$ . Sugars have been synthesized by the polymerization of formaldehyde ( $\text{CH}_2\text{O}$ ) in reactions catalyzed by divalent cations, alumina, or clays. It is probably no accident that these compounds are the basic components of biological molecules. *They were apparently the most common organic substances in prebiotic times.*

The above described prebiotic reactions probably occurred over a period of hundreds of millions of years. Ultimately, it has been estimated, the oceans attained the organic consistency of a thin bouillon soup. Of course there must have been numerous places, such as tidal pools and shallow lakes, where the prebiotic soup became much more concentrated. In such environments its component organic molecules could have condensed to form, for example, polypeptides and polynucleotides (nucleic acids). Quite possibly these reactions were catalyzed by the adsorption of the reactants on minerals such as clays. If, however, life were to have formed, the rates of synthesis of these complex polymers would have had to be greater than their rates of hydrolysis. Therefore, the “pond” in which life arose may have been cold rather than warm, possibly even below  $0^\circ\text{C}$  (seawater freezes solidly only below  $-21^\circ\text{C}$ ), since hydrolysis reactions are greatly retarded at such low temperatures.

### C. The Rise of Living Systems

Living systems have the ability to replicate themselves. The inherent complexity of such a process is such that no man-made device has even approached having this capacity. Clearly there is but an infinitesimal probability that a collection of molecules can simply gather at random to form a living entity (the likelihood of a living cell forming spontaneously from simple organic molecules has been said to be comparable to that of a modern jet aircraft being assembled by a tornado passing through a junkyard). How then did life arise? The answer, most probably, is that it was guided according to the Darwinian principle of the survival of the fittest as it applies at the molecular level.

#### a. Life Probably Arose Through the Development of Self-Replicating RNA Molecules

*The primordial self-replicating system is widely believed to have been a collection of nucleic acid molecules because such molecules, as we have seen in Section 1-3C, can direct the synthesis of molecules complementary to themselves.* RNA, as does DNA, can direct the synthesis of a complementary strand. In fact, RNA serves as the hereditary material of many viruses (Chapter 33). The polymerization of the progeny molecules would, at first, have been a simple chemical process and hence could hardly be expected to be accurate. The early progeny molecules would therefore have been only approximately complementary to their parents. Nevertheless, repeated cycles of nucleic acid synthesis would eventually exhaust the supply of free nucleotides so that the synthesis rate of new nucleic acid molecules would be ultimately limited by the hydrolytic degradation rate of old ones. Suppose, in this process, a nucleic acid molecule randomly arose that, through folding, was more resistant to degradation than its cousins. The progeny of this molecule, or at least its more faithful copies, could then propagate at the expense of the nonresistant molecules; that is, the resistant molecules would have a Darwinian advantage over their fellows. Theoretical studies suggest that such a system of molecules would evolve so as to optimize its replication efficiency under its inherent physical and chemical limitations.

In the next stage of the evolution of life, it is thought the dominant nucleic acids evolved the capacity to influence the efficiency and accuracy of their own replication. This process occurs in living systems through the nucleic acid-directed ribosomal synthesis of enzymes that catalyze nucleic acid synthesis. How nucleic acid-directed protein synthesis could have occurred before ribosomes arose is unknown because nucleic acids are not known to interact selectively with particular amino acids. This difficulty exemplifies the major problem in tracing the pathway of prebiotic evolution. Suppose some sort of rudimentary nucleic acid-influenced system arose that increased the efficiency of nucleic acid replication. This system must have eventually been replaced, presumably with almost no trace of its existence, by the much more efficient ribosomal system. Our hypothetical nucleic acid synthesis system is therefore analogous to the scaffolding used in the construction of a building. After the building has been erected the scaffolding is removed, leaving no physical evidence that it ever was there. *Most of the statements in this section must therefore be taken as educated guesses.* Without our having witnessed the event, it seems unlikely that we shall ever be certain of how life arose.

*A plausible hypothesis for the evolution of self-replicating systems is that they initially consisted entirely of RNA, a scenario known as the “RNA world.”* This idea is based, in part, on the observation that certain species of RNA exhibit enzymelike catalytic properties (Section 31-4A). Moreover, since ribosomes are approximately two-thirds RNA and only one-third protein, it is plausible that the primordial ribosomes were entirely RNA. A cooperative relationship between RNA and protein might have arisen

when these self-replicating protoribosomes evolved the ability to influence the synthesis of proteins that increased the efficiency and/or the accuracy of RNA synthesis. *From this point of view, RNA is the primary substance of life; the participation of DNA and proteins were later refinements that increased the Darwinian fitness of an already established self-replicating system.*

The types of systems that we have so far described were bounded only by the primordial “pond.” A self-replicating system that developed a more efficient component would therefore have to share its benefits with all the “inhabitants” of the “pond,” a situation that minimizes the improvement’s selective advantage. Only through compartmentalization, that is, the generation of cells, could developing biological systems reap the benefits of any improvements that they might have acquired. Of course, cell formation would also hold together and protect any self-replicating system and therefore help it spread beyond its “pond” of origin. Indeed, the importance of compartmentalization is such that it may have preceded the development of self-replicating systems. The erection of cell boundaries is not without its price, however. Cells, as we shall see in later chapters, must expend much of their metabolic effort in selectively transporting substances across their cell membranes. How cell boundaries first arose, or even what they were made from, is presently unknown. However, one plausible theory holds that membranes first arose as empty vesicles whose exteriors could serve as attachment sites for such entities as enzymes and chromosomes in ways that facilitated their function. Evolution then flattened and folded these vesicles so that they enclosed their associated molecular assemblies, thereby defining the primordial cells.

### **b. Competition for Energy Resources Led to the Development of Metabolic Pathways, Photosynthesis, and Respiration**

At this stage in their development, the entities we have been describing already fit Horowitz’s criteria for life (exhibiting replication, catalysis, and mutability). The polymerization reactions through which these primitive organisms replicated were entirely dependent on the environment to supply the necessary monomeric units and the energy-rich compounds such as ATP or, more likely, just polyphosphates, that powered these reactions. As some of the essential components in the prebiotic soup became scarce, organisms developed the enzymatic systems that could synthesize these substances from simpler but more abundant precursors. As a consequence, energy-producing metabolic pathways arose. This latter development only postponed an “energy crisis,” however, because these pathways consumed other preexisting energy-rich substances. The increasing scarcity of all such substances ultimately stimulated the development of photosynthesis to take advantage of a practically inexhaustible energy supply, the sun. Yet this process, as we saw in Section 1-1Ab, consumes reducing agents such as  $\text{H}_2\text{S}$ . The eventual exhaustion of these substances led to the refinement of the photosynthetic process so that it used the ubiquitous  $\text{H}_2\text{O}$  as its re-

ducing agent, thereby yielding  $\text{O}_2$  as a by-product. The discovery, in  $\sim 3.5$ -billion-year-old rocks, of what appears to be fossilized cyanobacteria-like microorganisms (Fig. 1-35) suggests that oxygen-producing photosynthesis developed very early in the history of life.

The development of oxygen-producing photosynthesis led to yet another problem. The accumulation of the highly reactive  $\text{O}_2$ , which over the eons converted the reducing atmosphere of the prebiotic Earth to the modern oxidizing atmosphere (21%  $\text{O}_2$ ), eventually interfered with the existing metabolic apparatus, which had evolved to operate under reducing conditions. The  $\text{O}_2$  accumulation therefore stimulated the development of metabolic refinements that protected organisms from oxidative damage. More importantly, it led to the evolution of a much more efficient form of energy metabolism than had previously been possible, **respiration** (oxidative metabolism), which used the newly available  $\text{O}_2$  as an oxidizing agent. [The availability of atmospheric  $\text{O}_2$  is also responsible for the generation of the stratospheric ozone ( $\text{O}_3$ ) layer that absorbs most of the biologically harmful ultraviolet radiation that strikes Earth.]

As previously outlined, the basic replicative and metabolic apparatus of modern organisms evolved quite early in the history of life on Earth. Indeed, many modern prokaryotes appear to resemble their very ancient ancestors. The rise of eukaryotes, as Section 1-2 indicates, occurred perhaps 2 billion years after prokaryotes had become firmly established. Multicellular organisms are a relatively recent evolutionary innovation, having not appeared, according to the fossil record, until  $\sim 700$  million years ago.

## **6 THE BIOCHEMICAL LITERATURE**

The biochemical literature contains the results of the work of tens of thousands of scientists extending well over a century. Consequently a biochemistry textbook can report only selected highlights of this vast amount of information. Moreover, the tremendous rate at which biochemical knowledge is presently being acquired, which is perhaps greater than that of any other intellectual endeavor, guarantees that there will have been significant biochemical advances even in the year or so that it took to produce this text from its final draft. A serious student of biochemistry must therefore regularly read the biochemical literature to flesh out the details of subjects covered in (or omitted from) this text, as well as to keep abreast of new developments. This section provides a few suggestions on how to do so.

### **A. Conducting a Literature Search**

The primary literature of biochemistry, those publications that report the results of biochemical research, is presently being generated at a rate of tens of thousands of papers per year appearing in over 200 periodicals. An individual can therefore only read this voluminous literature in a highly selective fashion. Indeed, most biochemists tend to “read”

only those publications that are likely to contain reports pertaining to their interests. By “read” it is meant that they scan the tables of contents of these journals for the titles of articles that seem of sufficient interest to warrant further perusal.

It is difficult to learn about a new subject by beginning with its primary literature. Instead, to obtain a general overview of a particular biochemical subject it is best to first peruse appropriate reviews and monographs. These usually present a synopsis of recent (at the time of their writing) developments in the area, often from the authors’ particular point of view. There are more or less two types of reviews: those that are essentially a compilation of facts and those that critically evaluate the data and attempt to place them in some larger context. The latter type of review is of course more valuable, particularly for a novice in the field. Most reviews are published in specialized books and journals, although many journals that publish research reports also occasionally print reviews. Table 1-5 provides a list of many of the important biochemical review publications.

Monographs and reviews relevant to a subject of interest are usually easy to find through the use of a library catalog and the subject indexes of the major review publications (the chapter-end references of this text may also be helpful in this respect). An important part of any review is its reference list. It usually has previous reviews in the same or allied fields as well as indicating the most significant research reports in the area. Note the authors of these articles and the journals in which they tend to publish. When the most current reviews and research articles you have found tend to refer to the same group of earlier articles, you can be reasonably confident that your search for these earlier articles is largely complete. Finally, to familiarize yourself with the latest developments in the field, search the recent primary literature for the work of its most active research groups and visit the websites of these groups.

Academic libraries subscribe to Web-based reference search services such as MedLine, SciFinder Scholar, BIOSIS Previews, and Web of Science. MedLine can also be accessed free of charge through the National Center for Biotechnology Information (NCBI) (<http://www.ncbi.nlm.nih.gov/PubMed>). Google Scholar (<http://scholar.google.com/>) is a freely available search engine that indexes the scholarly literature across many disciplines. When used properly, these bibliographic search services are highly efficient tools for locating specific information. Wikipedia (<http://wikipedia.org/>) is also a valuable and easily available resource.

## B. Reading a Research Article

Research reports more or less all have the same six-part format. They usually have a short abstract or summary located before the main body of the paper. The paper then continues with an introduction, which often contains a short synopsis of the field, the motivation for the research reported, and a preview of its conclusions. The next section contains a description of the methods used to obtain the experimental data. This is followed by a presentation of the results of the

<sup>a</sup>Periodicals that mainly publish research reports.

investigation and then by a discussion section wherein the conclusions of the investigation are set forth and placed in the context of other work in the field. Finally, there is a list of references. Most articles are “full papers,” which may be tens of pages long. However, many journals also contain “communications” or “letters,” which are usually only a few

pages in length and are often published more quickly than are full papers. Many papers have accompanying supplementary material that is available on the journal's website.

It is by no means obvious how to read a scientific paper. Perhaps the worst way to do so is to read it from beginning to end as if it were some kind of a short story. In fact, most practicing scientists only occasionally read a research article in its entirety. It simply takes too long and is rarely productive. Rather, they scan selected parts of a paper and only dig deeper if it appears that to do so will be profitable. The following paragraph describes a reasonably efficient scheme for reading scientific papers. *This should be an active process in which the reader is constantly evaluating what is being read and relating it to his/her previous knowledge.* Moreover, the reader should maintain a healthy skepticism since there is a reasonable probability that any paper, particularly in its interpretation of experimental data and in its speculations, may be erroneous.

If the title of a paper indicates that it may be of interest, then this should be confirmed by a reading of its abstract. For many papers, even those containing useful informa-

tion, it is unnecessary to read further. If you choose to continue, it is probably best to do so by scanning the introduction so as to obtain an overview of the work reported. At this point most experienced scientists scan the conclusions section of the paper to gain a better understanding of what was found. If further effort seems warranted, they scan the results section to ascertain whether the experimental data support the conclusions. The methods section (which in many journals is largely relegated to the supplementary materials) is usually not read in detail because it is often written in a condensed form that is only fully interpretable by an expert in the field. However, for such experts, the methods section may be the most valuable part of the paper. At this point, what to read next, if anything, is largely dictated by the remaining points of confusion. In many cases this confusion can only be eliminated by reading some of the references given in the paper. At any rate, unless you plan to repeat or extend some of the work described, it is rarely necessary to read an article in detail. To do so in a critical manner, you will find, takes several hours for a paper of even moderate size.

## CHAPTER SUMMARY

**1 Prokaryotes** Prokaryotes are single-celled organisms that lack a membrane-enclosed nucleus. Most prokaryotes have similar anatomies: a rigid cell wall surrounding a cell membrane that encloses the cytoplasm. The cell's single chromosome is condensed to form a nucleoid. *Escherichia coli*, the biochemically most well-characterized organism, is a typical prokaryote. Prokaryotes have quite varied nutritional requirements. The chemolithotrophs metabolize inorganic substances. Photolithotrophs, such as cyanobacteria, carry out photosynthesis. Heterotrophs, which live by oxidizing organic substances, are classified as aerobes if they use oxygen in this process and as anaerobes if some other oxidizing agent serves as their terminal electron acceptor. Traditional prokaryotic classification schemes are rather arbitrary because of poor correlation between bacterial form and metabolism. Sequence comparisons of nucleic acids and proteins, however, have established that all life-forms can be classified into three domains of evolutionary descent: the Archaea (archaeobacteria), the Bacteria (eubacteria), and the Eukarya (eukaryotes).

**2 Eukaryotes** Eukaryotic cells, which are far more complex than those of prokaryotes, are characterized by having numerous membrane-enclosed organelles. The most conspicuous of these is the nucleus, which contains the cell's chromosomes, and the nucleolus, where ribosomes are assembled. The endoplasmic reticulum is the site of synthesis of lipids and of proteins that are destined for secretion. Further processing of these products occurs in the Golgi apparatus. The mitochondria, wherein oxidative metabolism occurs, are thought to have evolved from a symbiotic relationship between an aerobic bacterium and a primitive eukaryote. The chloroplast, the site of photosynthesis in plants, similarly evolved from a cyanobacterium. Other eukaryotic organelles include the lysosome, which functions as an intracellular digestive chamber, and the peroxisome, which contains a variety of oxidative en-

zymes including some that generate  $H_2O_2$ . The eukaryotic cytoplasm is pervaded by a cytoskeleton whose components include microtubules, which consist of tubulin; microfilaments, which are composed of actin; and intermediate filaments, which are made of different proteins in different types of cells. Eukaryotes have enormous morphological diversity on the cellular as well as on the organismal level. They have been classified into four kingdoms: Protista, Plantae, Fungi, and Animalia. The pattern of embryonic development in multicellular organisms partially mirrors their evolutionary history.

**3 Biochemistry: A Prologue** Organisms have a hierarchical structure that extends down to the submolecular level. They contain but three basic types of macromolecules: proteins, nucleic acids, and polysaccharides, as well as lipids, each of which are constructed from only a few different species of monomeric units. Macromolecules and supramolecular assemblies form their native biological structures through a process of self-assembly. The assembly mechanisms of higher biological structures are largely unknown. Metabolic processes are organized into a series of tightly regulated pathways. These are classified as catabolic or anabolic depending on whether they participate in degradative or biosynthetic processes. The common energy "currency" in all these processes is ATP, whose synthesis is the product of many catabolic pathways and whose hydrolysis drives most anabolic pathways. DNA, the cell's hereditary molecule, encodes genetic information in its sequence of bases. The complementary base sequences of its two strands permit them to act as templates for their own replication and for the synthesis of complementary strands of RNA. Ribosomes synthesize proteins by linking amino acids together in the order specified by the base sequences of RNAs.

**4 Genetics: A Review** Eukaryotic cells contain a characteristic number of homologous pairs of chromosomes. In mito-

sis each daughter cell receives a copy of each of these chromosomes, but in meiosis each resulting gamete receives only one member of each homologous pair. Fertilization is the fusion of two haploid gametes to form a diploid zygote. The Mendelian laws of inheritance state that alternative forms of true-breeding traits are specified by different alleles of the same gene. Alleles may be dominant, codominant, or recessive depending on the phenotype of the heterozygote. Different genes assort independently unless they are on the same chromosome. The linkage between genes on the same chromosome, however, is never complete because of crossing-over among homologous chromosomes during meiosis. The rate at which genes recombine varies with their physical separation because crossing-over occurs essentially at random. This permits the construction of genetic maps. Whether two recessive traits are allelic may be determined by the complementation test. The nature of genes is largely defined by the dictum “one gene–one polypeptide.” Mutant varieties of bacteriophages are detected by their ability to kill their host under various restrictive conditions. The fine structure analysis of the *rII* region of the bacteriophage T4 chromosome has revealed that recombination may take place within a gene, that genes are linear unbranched structures, and that the unit of mutation is  $\sim 1$  bp.

**5 The Origin of Life** Life is carbon based because only carbon, among all the elements in the periodic table, has a suf-

ficiently complex chemistry together with the ability to form virtually infinite stable chains of covalently bonded atoms. Reactions among the molecules in the reducing atmosphere of the prebiotic Earth are thought to have formed the simple organic precursors from which biological molecules developed. Eventually, in reactions that may have been catalyzed by minerals such as clays, polypeptides and polynucleotides formed. These evolved under the pressure of competition for the available monomeric units. Ultimately, a nucleic acid, most probably RNA, developed the capability of influencing its own replication by directing the synthesis of proteins that catalyze polynucleotide synthesis. This was followed by the development of cell membranes so as to form living entities. Subsequently, metabolic processes evolved to synthesize necessary intermediates from available precursors as well as the high-energy compounds required to power these reactions. Likewise, photosynthesis and respiration arose in response to environmental pressures brought about by the action of living organisms.

**6 The Biochemical Literature** The sheer size and rate of increase of the biochemical literature requires that it be read to attain a thorough understanding of any aspect of biochemistry. The review literature provides an entrée into a given subspecialty. To remain current in any field, however, requires a regular perusal of its primary literature. This should be read in a critical and highly selective fashion.

## PROBLEMS

It is very difficult to learn something well without somehow participating in it. The chapter-end problems are therefore an important part of this book. They contain few problems of the regurgitation type. Rather they are designed to make you think and to offer insights not discussed in the text. Their difficulties range from those that require only a few moments' reflection to those that might take an hour or more of concentrated effort to work out. The more difficult problems are indicated by a leading asterisk (\*). The answers to the problems are worked out in detail in the *Solutions Manual to Accompany Biochemistry* (4th ed.) by Donald Voet and Judith G. Voet. You should, of course, make every effort to work out a problem before consulting the *Solutions Manual*.

**1.** Under optimal conditions for growth, an *E. coli* cell will divide around every 20 min. If no cells died, how long would it take a single *E. coli* cell, under optimal conditions in a 10-L culture flask, to reach its maximum cell density of  $10^{10}$  cells · mL<sup>-1</sup> (a “saturated” culture)? Assuming that optimum conditions could be maintained, how long would it take for the total volume of the cells alone to reach 1 km<sup>3</sup>? (Assume an *E. coli* cell to be a cylinder 2 μm long and 1 μm in diameter.)

**2.** Without looking them up, draw schematic diagrams of a bacterial cell and an animal cell. What are the functions of their various organelles? How many lines of descent might a typical animal cell have?

**3.** Compare the surface-to-volume ratios of a typical *E. coli* cell (its dimensions are given in Problem 1) and a spherical eukaryotic cell that is 20 μm in diameter. How does this difference affect the lifestyles of these two cell types? In order to improve their ability to absorb nutrients, the **brush border cells** of the intestinal epithelium have velvetlike patches of **microvilli** facing into the intestine. How does the surface-to-volume ratio of this eukaryotic cell change if 20% of its surface area is covered with cylindrical microvilli that are 0.1 μm in diameter, 1 μm in length, and occur on a square grid with 0.2-μm center-to-center spacing?

**4.** Many proteins in *E. coli* are normally present at concentrations of two molecules per cell. What is the molar concentration of such a protein? (The dimensions of *E. coli* are given in Problem 1.)

Conversely, how many glucose molecules does an *E. coli* cell contain if it has an internal glucose concentration of 1.0 mM?

**5.** The DNA of an *E. coli* chromosome measures 1.6 mm in length, when extended, and 20 Å in diameter. What fraction of an *E. coli* cell is occupied by its DNA? (The dimensions of *E. coli* are given in Problem 1.) A human cell has some 700 times the DNA of an *E. coli* cell and is typically spherical with a diameter of 20 μm. What fraction of such a human cell is occupied by its DNA?

**\*6.** A new planet has been discovered that has approximately the same orbit about the sun as Earth but is invisible from Earth because it is always on the opposite side of the sun. Interplanetary probes have already established that this planet has a significant atmosphere. The National Aeronautics and Space Administration is preparing to launch a new unmanned probe that will land on the surface of the planet. Outline a simple experiment for this lander that will test for the presence of life on the surface of this planet (assume that the life-forms, if any, on the planet are likely to be microorganisms and therefore unable to walk up to the lander's video cameras and say “Hello”).

**7.** It has been suggested that an all-out nuclear war would so enshroud Earth with clouds of dust and smoke that the entire surface of the planet would be quite dark and therefore intensely cold (well below 0°C) for several years (the so-called nuclear winter). In that case, it is thought, eukaryotic life would die out and bacteria would inherit Earth. Why?

**8.** One method that Mendel used to test his laws is known as a **testcross**. In it, *F*<sub>1</sub> hybrids are crossed with their recessive parent. What is the expected distribution of progeny and what are their phenotypes in a testcross involving peas with different-colored seeds? What is it for snapdragons with different flower colors (use the white parent in this testcross)?

**9.** The disputed paternity of a child can often be decided on the basis of blood tests. The M, N, and MN blood groups (Section 12-3E) result from two alleles, *L*<sup>M</sup> and *L*<sup>N</sup>; the Rh<sup>+</sup> blood group arises from a dominant allele, *R*. Both sets of alleles occur on a different chromosome from each other and from the alleles responsible for the ABO blood groups. The following table gives the

blood types of three children, their mother, and the two possible fathers. Indicate, where possible, each child's paternity and justify your answer.

Child 1	B	M	Rh <sup>-</sup>
Child 2	B	MN	Rh <sup>+</sup>

**10.** The most common form of color blindness, red-green color blindness, afflicts almost only males. What are the genotypes and phenotypes of the children and grandchildren of a red-green color-blind man and a woman with no genetic history of color blindness? Assume the children mate with individuals who also have no history of color blindness.

**11.** Green and purple photosynthetic bacteria are thought to resemble the first organisms that could carry out photosynthesis. Speculate on the composition of Earth's atmosphere when these organisms first arose.

**12.** Explore your local biochemistry library (it may be disguised as a biology, chemistry, or medical library). Locate where the current periodicals, the bound periodicals, and the books are kept. Browse through the contents of a current major biochemistry journal, such as *Biochemistry*, *Cell*, or *Proceedings of the National Academy of Sciences*, and pick a title that interests you. Scan the corresponding paper and note its organization. Likewise, peruse one of the articles in the latest volume of *Annual Review of Biochemistry*.

**13.** Using MedLine, look up the publications over the past 5 years of your favorite biomedical scientist. This person might be a recent Nobel prize winner or someone at your college/university. Note that even if the person you choose has an unusual name, it is likely that publications by other individuals with the same name will be included in your initial list.

# Aqueous Solutions

## CHAPTER 2

### 1 Properties of Water

- A. Structure and Interactions
- B. Water as a Solvent
- C. Proton Mobility

### 2 Acids, Bases, and Buffers

- A. Acid–Base Reactions
- B. Buffers
- C. Polyprotic Acids

*Life, as we know it, occurs in aqueous solution.* Indeed, terrestrial life apparently arose in some primordial sea (Section 1-5B) and, as the fossil record indicates, did not venture onto dry land until comparatively recent times. Yet even those organisms that did develop the capacity to live out of water still carry the ocean with them: The compositions of their intracellular and extracellular fluids are remarkably similar to that of seawater. This is true even of organisms that live in such unusual environments as saturated brine, acidic hot sulfur springs, and petroleum.

Water is so familiar, we generally consider it to be a rather bland fluid of simple character. It is, however, a chemically reactive liquid with such extraordinary physical properties that, if chemists had discovered it in recent times, it would undoubtedly have been classified as an exotic substance.

The properties of water are of profound biological significance. *The structures of the molecules on which life is based—proteins, nucleic acids, lipids, and complex carbohydrates—result directly from their interactions with their aqueous environment. The combination of solvent properties responsible for the intramolecular and intermolecular associations of these substances is peculiar to water; no other solvent even resembles water in this respect.* Although the hypothesis that life could be based on organic polymers other than proteins and nucleic acids seems plausible, it is all but inconceivable that the complex structural organization and chemistry of living systems could exist in other than an aqueous medium. Indeed, direct observations on the surface of Mars, the only other planet in the solar system with temperatures compatible with life, indicate that it is presently devoid of both water and life.

Biological structures and processes can only be understood in terms of the physical and chemical properties of water. We therefore begin this chapter with a discussion of

the molecular and solvent properties of water. In the following section we review its chemical behavior, that is, the nature of aqueous acids and bases.

### 1 PROPERTIES OF WATER

Water's peculiar physical and solvent properties stem largely from its extraordinary internal cohesiveness compared to that of almost any other liquid. In this section, we explore the physical basis of this phenomenon.

#### A. Structure and Interactions

The  $\text{H}_2\text{O}$  molecule has a bent geometry with an O—H bond distance of  $0.958 \text{ \AA}$  and an H—O—H bond angle of  $104.5^\circ$  (Fig. 2-1). The large electronegativity difference between H and O confers a 33% ionic character on the O—H bond as is indicated by water's dipole moment of 1.85 debye units. Water is clearly a highly polar molecule, a phenomenon with enormous implications for living systems.

**Figure 2-1** Structure of the water molecule. The outline represents the van der Waals envelope of the molecule (where the attractive components of the van der Waals interactions balance the repulsive components). The skeletal model of the molecule indicates its covalent bonds.

### a. Water Molecules Associate Through Hydrogen Bonds

The electrostatic attractions between the dipoles of two water molecules tend to orient them such that the O—H bond on one water molecule points toward a lone-pair electron cloud on the oxygen atom of the other water molecule. This results in a directional intermolecular association known as a **hydrogen bond** (Fig. 2-2), an interaction that is crucial both to the properties of water itself and to its role as a biochemical solvent. In general, a *hydrogen bond may be represented as  $D-H\cdots A$* , where  $D-H$  is a weakly acidic “donor group” such as  $N-H$  or  $O-H$ , and  $A$  is a lone-pair-bearing and thus weakly basic “acceptor atom” such as  $N$  or  $O$ . Hence, a hydrogen bond is better represented as  $\delta^-D-H\delta^+\cdots\delta^-A$ , where the charge separation in the  $D-H$  bond arises from the greater electronegativity of  $D$  relative to  $H$ . The peculiar requirement of a central hydrogen atom rather than some other atom in a hydrogen bond stems from the hydrogen atom’s small size: Only a hydrogen nucleus can approach the lone-pair electron cloud of an acceptor atom closely enough to permit an electrostatic association of significant magnitude. Moreover, as X-ray scattering measurements have revealed, hydrogen bonds are partially ( $\sim 10\%$ ) covalent in character.

Hydrogen bonds are structurally characterized by an  $H\cdots A$  distance that is at least  $0.5 \text{ \AA}$  shorter than the calculated van der Waals distance (distance of closest approach between two nonbonded atoms) between the atoms. In water, for example, the  $O\cdots H$  hydrogen bond distance is  $\sim 1.8 \text{ \AA}$  versus  $2.6 \text{ \AA}$  for the corresponding van der Waals distance. The energy of a hydrogen bond ( $\sim 20 \text{ kJ} \cdot \text{mol}^{-1}$  in  $\text{H}_2\text{O}$ ) is small compared to covalent bond energies (for instance,  $460 \text{ kJ} \cdot \text{mol}^{-1}$  for an  $O-H$  covalent bond). Nevertheless, most biological molecules have so many hydrogen bonding groups that hydrogen bonding is of paramount importance in determining their three-dimensional structures and their intermolecular associations. Hydrogen bonding is further discussed in Section 8-4B.

### b. The Physical Properties of Ice and Liquid Water Largely Result from Intermolecular Hydrogen Bonding

The structure of ice provides a striking example of the cumulative strength of many hydrogen bonds. X-ray and neutron diffraction studies have established that water molecules in ice are arranged in an unusually open structure. Each water molecule is tetrahedrally surrounded by four nearest neighbors to which it is hydrogen bonded (Fig. 2-3). In two of these hydrogen bonds the central  $\text{H}_2\text{O}$  molecule is the “donor,” and in the other two it is the “acceptor.” As a consequence of its open structure, water is one of the very few substances that expands on freezing (at  $0^\circ\text{C}$ , liquid water has a density of  $1.00 \text{ g} \cdot \text{mL}^{-1}$ , whereas ice has a density of  $0.92 \text{ g} \cdot \text{mL}^{-1}$ ).

The expansion of water on freezing has overwhelming consequences for life on Earth. Suppose that water contracted on freezing, that is, became more dense rather than less dense. Ice would then sink to the bottoms of lakes and oceans rather than float. This ice would be insulated from the

**Figure 2-2** Hydrogen bond between two water molecules. The strength of this interaction is maximal when the O—H covalent bond points directly along a lone-pair electron cloud of the oxygen atom to which it is hydrogen bonded.

**Figure 2-3** Structure of ice. The tetrahedral arrangement of the water molecules is a consequence of the roughly tetrahedral disposition of each oxygen atom’s  $sp^3$ -hybridized bonding and lone-pair orbitals (Fig. 2-2). Oxygen and hydrogen atoms are represented, respectively, by red and white spheres, and hydrogen bonds are indicated by dashed lines. Note the open structure that gives ice its low density relative to liquid water. [After Pauling, L., *The Nature of the Chemical Bond* (3rd ed.), p. 465, Cornell University Press (1960).]

sun so that oceans, with the exception of a thin surface layer of liquid in warm weather, would be permanently frozen solid (the water at great depths even in tropical oceans is close to  $4^\circ\text{C}$ , its temperature of maximum density). The reflection of sunlight by these frozen oceans and their cooling effect on the atmosphere would ensure that land temperatures would also be much colder than at present; that is, Earth would have a permanent ice age. Furthermore, since life apparently evolved in the ocean, it seems unlikely that life could have developed at all if ice contracted on freezing.

Although the melting of ice is indicative of the cooperative collapse of its hydrogen bonded structure, hydrogen bonds between water molecules persist in the liquid state. The heat of sublimation of ice at  $0^\circ\text{C}$  is  $46.9 \text{ kJ} \cdot \text{mol}^{-1}$ . Yet

only  $\sim 6 \text{ kJ} \cdot \text{mol}^{-1}$  of this quantity can be attributed to the kinetic energy of gaseous water molecules. The remaining  $41 \text{ kJ} \cdot \text{mol}^{-1}$  must therefore represent the energy required to disrupt the hydrogen bonding interactions holding an ice crystal together. The heat of fusion of ice ( $6.0 \text{ kJ} \cdot \text{mol}^{-1}$ ) is  $\sim 15\%$  of the energy required to disrupt the ice structure. *Liquid water is therefore only  $\sim 15\%$  less hydrogen bonded than ice at  $0^\circ\text{C}$ .* Indeed, the boiling point of water is  $264^\circ\text{C}$  higher than that of methane ( $\text{CH}_4$ ), a substance with nearly the same molecular mass as  $\text{H}_2\text{O}$  but which is incapable of hydrogen bonding (in the absence of intermolecular associations, substances with equal molecular masses should have similar boiling points). This reflects the extraordinary internal cohesiveness of liquid water resulting from its intermolecular hydrogen bonding.

### c. Liquid Water Has a Rapidly Fluctuating Structure

X-ray and neutron scattering measurements of liquid water reveal a complex structure. Near  $0^\circ\text{C}$ , water exhibits an average nearest-neighbor  $\text{O} \cdots \text{O}$  distance of  $2.82 \text{ \AA}$ , which is slightly greater than the corresponding  $2.76\text{-}\text{\AA}$  distance in ice despite the greater density of the liquid. The X-ray data further indicate that each water molecule is surrounded by an average of about 4.4 nearest neighbors, which strongly suggests that the short-range structure of liquid water is predominantly tetrahedral in character. This picture is corroborated by the additional intermolecular distances in liquid water of around  $4.5$  and  $7.0 \text{ \AA}$ , which are near the expected second and third nearest-neighbor distances in an icelike tetrahedral structure. Liquid water, however, also exhibits a  $3.5\text{-}\text{\AA}$  intermolecular distance, which cannot be rationalized in terms of an icelike structure. These average distances, moreover, become less sharply defined as the temperature increases into the physiologically significant range, thereby signaling the thermal breakdown of the short-range water structure.

The structure of liquid water is not simply described. This is because each water molecule reorients about once every  $10^{-12} \text{ s}$ , which makes the determination of water's instantaneous structure an experimentally and theoretically difficult problem (very few experimental techniques can make measurements over such short time spans). Indeed, only with the advent of modern computational methods have theoreticians felt that they are beginning to have a reasonable understanding of liquid water at the molecular level.

For the most part, molecules in liquid water are each hydrogen bonded to four nearest neighbors as they are in ice. These hydrogen bonds are distorted, however, so that the networks of linked molecules are irregular and varied, with the number of hydrogen bonds formed by each water molecule ranging from 3 to 6. Thus, for example, 3- to 7-membered rings of hydrogen bonded molecules commonly occur in liquid water (Fig. 2-4), in contrast to the cyclohexane-like 6-membered rings characteristic of ice (Fig. 2-3). Moreover, these networks are continually breaking up and re-forming over time periods on the order of  $2 \times 10^{-11} \text{ s}$ . *Liquid water therefore consists of a rapidly fluctuating, space-filling network of hydrogen bonded  $\text{H}_2\text{O}$  molecules that, over short distances, resembles that of ice.*

**Figure 2-4** Theoretically predicted and spectroscopically confirmed structures of the water trimer, tetramer, and pentamer. Note that these rings are all essentially planar, with each water molecule acting as both a hydrogen bonding donor and acceptor and with the free hydrogens located above and below the planes of the rings. [After Liu, K., Cruzan, J.D., and Saykally, R.J., *Science* **271**, 930 (1996).]

### B. Water as a Solvent

Solubility depends on the ability of a solvent to interact with a solute more strongly than solute particles interact with each other. Water is said to be the “universal solvent.” Although this statement cannot literally be true, water certainly dissolves more types of substances and in greater amounts than any other solvent. In particular, the polar character of water makes it an excellent solvent for polar and ionic materials, which are therefore said to be **hydrophilic** (Greek: *hydor*, water + *philos*, loving). On the other hand, nonpolar substances are virtually insoluble in water (“oil and water don’t mix”) and are consequently described as being **hydrophobic** (Greek: *phobos*, fear). Nonpolar substances, however, are soluble in nonpolar solvents such as  $\text{CCl}_4$  or hexane. This information is summarized by another maxim, “like dissolves like.”

Why do salts dissolve in water? Salts, such as  $\text{NaCl}$  or  $\text{K}_2\text{HPO}_4$ , are held together by ionic forces. The ions of a salt, as do any electrical charges, interact according to **Coulomb’s law**:

$$F = \frac{kq_1q_2}{Dr^2} \quad [2.1]$$

where  $F$  is the force between two electrical charges,  $q_1$  and  $q_2$ , that are separated by the distance  $r$ ,  $D$  is the **dielectric constant** of the medium between them, and  $k$  is a proportionality constant ( $8.99 \times 10^9 \text{ J} \cdot \text{m} \cdot \text{C}^{-2}$ ). Thus, as the dielectric constant of a medium increases, the force between its embedded charges decreases; that is, the dielectric constant

**Table 2-1 Dielectric Constants and Permanent Molecular Dipole Moments of Some Common Solvents**

Substance	Dielectric Constant	Dipole Moment (debye)
Formamide	110.0	3.37
Water	78.5	1.85
Dimethyl sulfoxide	48.9	3.96
Methanol	32.6	1.66
Ethanol	24.3	1.68
Acetone	20.7	2.72
Ammonia	16.9	1.47
Chloroform	4.8	1.15
Diethyl ether	4.3	1.15
Benzene	2.3	0.00
Carbon tetrachloride	2.2	0.00
Hexane	1.9	0.00

of a solvent is a measure of its ability to keep opposite charges apart. In a vacuum,  $D$  is unity and in air, it is only negligibly larger. The dielectric constants of several common solvents, together with their permanent molecular dipole moments, are listed in Table 2-1. Note that these quantities tend to increase together, although not in a regular way.

The dielectric constant of water is among the highest of any pure liquid, whereas those of nonpolar substances, such as hydrocarbons, are relatively small. The force between two ions separated by a given distance in nonpolar liquids such as hexane or benzene is therefore 30 to 40 times greater than that in water. Consequently, in nonpolar solvents (low  $D$ ), ions of opposite charge attract each other so strongly that they coalesce to form a salt, whereas the much weaker forces between ions in water solution (high  $D$ ) permit significant quantities of the ions to remain separated.

An ion immersed in a polar solvent attracts the oppositely charged ends of the solvent dipoles, as is diagrammed in Fig. 2-5 for water. The ion is thereby surrounded by several concentric shells of oriented solvent molecules. Such ions are said to be **solvated** or, if water is the solvent, to be **hydrated**. The electric field produced by the solvent dipoles opposes that of the ion so that, in effect, the ionic charge is

**Figure 2-5 Solvation of ions by oriented water molecules.**

spread over the volume of the solvated complex. This arrangement greatly attenuates the coulombic forces between ions, which is why polar solvents have such high dielectric constants.

The orienting effect of ionic charges on dipolar molecules is opposed by thermal motions, which continually tend to randomly reorient all molecules. The dipoles in a solvated complex are therefore only partially oriented. The reason why the dielectric constant of water is so much greater than that of other liquids with comparable dipole moments is that liquid water's hydrogen bonded structure permits it to form oriented structures that resist thermal randomization, thereby more effectively distributing ionic charges. Indeed, ice under high pressure has a measured dielectric constant of 3 because its water molecules cannot reorient in response to an external electric field.

The bond dipoles of uncharged polar molecules make them soluble in aqueous solutions for the same reasons that ionic substances are water soluble. The solubilities of polar and ionic substances are enhanced if they carry functional groups, such as hydroxyl ( $-\text{OH}$ ), keto ( $-\text{C}=\text{O}$ ), carboxyl ( $-\text{CO}_2\text{H}$  or  $-\text{COOH}$ ), or amino ( $-\text{NH}_2$ ) groups, that can form hydrogen bonds with water, as is illustrated in Fig. 2-6. Indeed, water-soluble biomolecules such as proteins, nucleic acids, and carbohydrates bristle with just such groups. Nonpolar substances, in contrast, lack both hydrogen bonding donor and acceptor groups.

#### a. Amphiphiles Form Micelles and Bilayers

Most biological molecules have both polar (or ionically charged) and nonpolar segments and are therefore simultaneously hydrophilic and hydrophobic. Such molecules, for

**Figure 2-6 Hydrogen bonding by functional groups.** Hydrogen bonds form between water and (a) hydroxyl groups, (b) keto groups, (c) carboxyl groups, and (d) amino groups.

**Table 2.2** Ionic Mobilities<sup>a</sup> in H<sub>2</sub>O at 25°C

Ion	Mobility × 10 <sup>-5</sup> (cm <sup>2</sup> · V <sup>-1</sup> · s <sup>-1</sup> )

Ca <sup>2+</sup>	61.6
OH <sup>-</sup>	197.6
Cl <sup>-</sup>	76.3
Br <sup>-</sup>	78.3
CH <sub>3</sub> COO <sup>-</sup>	40.9
SO <sub>4</sub> <sup>2-</sup>	79.8

<sup>a</sup>Ionic mobility is the distance an ion moves in 1 s under the influence of an electric field of 1 V · cm<sup>-1</sup>.

Source: Brey, W.S., *Physical Chemistry and Its Biological Applications*, p. 172, Academic Press (1978).

OH<sup>-</sup> are anomalously large compared to those of other ions. For H<sub>3</sub>O<sup>+</sup> (the **hydronium ion**, which is abbreviated H<sup>+</sup>; a bare proton has no stable existence in aqueous solution), this high migration rate results from the ability of protons to jump rapidly from one water molecule to another, as is diagrammed in Fig. 2-10. Although a given hydronium ion can physically migrate through solution in the manner of, say, an Na<sup>+</sup> ion, the rapidity of the proton-jump mechanism makes the H<sub>3</sub>O<sup>+</sup> ion's effective ionic mobility much greater than it otherwise would be (the mean lifetime of a given H<sub>3</sub>O<sup>+</sup> ion is 10<sup>-12</sup> s at 25°C). The anomalously high ionic mobility of the OH<sup>-</sup> ion is likewise accounted for by the proton-jump mechanism but, in this case, the apparent direction of ionic migration is opposite

**Figure 2-10** Mechanism of hydronium ion migration in aqueous solution via proton jumps. Proton jumps, which mostly occur at random, take place rapidly compared with direct molecular migration, thereby accounting for the observed high ionic mobilities of hydronium and hydroxyl ions in aqueous solutions.

to the direction of proton jumping. Proton jumping is also responsible for the observation that *acid–base reactions are among the fastest reactions that take place in aqueous solutions*, and as we shall see (Section 23-3B), is of importance in biological proton-transfer reactions.

## 2 ACIDS, BASES, AND BUFFERS

Biological molecules, such as proteins and nucleic acids, bear numerous functional groups, such as carboxyl and amino groups, that can undergo acid–base reactions. Many properties of these molecules therefore vary with the acidities of the solutions in which they are immersed. In this section we discuss the nature of acid–base reactions and how acidities are controlled, both physiologically and in the laboratory.

### A. Acid–Base Reactions

**Acids** and **bases**, in a definition coined in the 1880s by Svante Arrhenius, are, respectively, substances capable of donating protons and hydroxide ions. This definition is rather limited, because, for example, it does not account for the observation that NH<sub>3</sub>, which lacks an OH<sup>-</sup> group, exhibits basic properties. In a more general definition, which was formulated in 1923 by Johannes Brønsted and Thomas Lowry, *an acid is a substance that can donate protons (as in the Arrhenius definition) and a base is a substance that can accept protons*. Under this definition, in every acid–base reaction,

a **Brønsted acid** (here HA) reacts with a **Brønsted base** (here H<sub>2</sub>O) to form the **conjugate base** of the acid (A<sup>-</sup>) and the **conjugate acid** of the base (H<sub>3</sub>O<sup>+</sup>) (this reaction is usually abbreviated HA ⇌ H<sup>+</sup> + A<sup>-</sup> with the participation of H<sub>2</sub>O implied). Accordingly, the acetate ion (CH<sub>3</sub>COO<sup>-</sup>) is the conjugate base of acetic acid (CH<sub>3</sub>COOH) and the ammonium ion (NH<sub>4</sub><sup>+</sup>) is the conjugate acid of ammonia (NH<sub>3</sub>). (In a yet more general definition of acids and bases, Gilbert Lewis described a **Lewis acid** as a substance that can accept an electron pair and a **Lewis base** as a substance that can donate an electron pair. This definition, which is applicable to both aqueous and nonaqueous systems, is unnecessarily broad for describing most biochemical phenomena.)

#### a. The Strength of an Acid Is Specified by Its Dissociation Constant

The above acid dissociation reaction is characterized by its **equilibrium constant**, which, for acid–base reactions, is known as a **dissociation constant**,

$$K = \frac{[\text{H}_3\text{O}^+][\text{A}^-]}{[\text{HA}][\text{H}_2\text{O}]} \quad [2.2]$$

a quantity that is a measure of the relative proton affinities of the HA/A<sup>-</sup> and H<sub>3</sub>O<sup>+</sup>/H<sub>2</sub>O conjugate acid–base pairs. Here, as throughout the text, quantities in square brackets symbolize the molar concentrations of the

enclosed substances. Since in dilute aqueous solutions the water concentration is essentially constant with  $[\text{H}_2\text{O}] = 1000 \text{ g} \cdot \text{L}^{-1} / 18.015 \text{ g} \cdot \text{mol}^{-1} = 55.5 \text{ M}$ , this term is customarily combined with the dissociation constant, which then takes the form

$$K_a = K[\text{H}_2\text{O}] = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]} \quad [2.3]$$

For brevity, however, we shall henceforth omit the subscript “a.” The dissociation constants for acids useful in preparing biochemical solutions are listed in Table 2-3.

Acids may be classified according to their relative strengths, that is, according to their abilities to transfer a

proton to water. Acids with dissociation constants smaller than that of  $\text{H}_3\text{O}^+$  (which, by definition, is unity in aqueous solutions) are only partially ionized in aqueous solutions and are known as **weak acids** ( $K < 1$ ). Conversely, **strong acids** have dissociation constants larger than that of  $\text{H}_3\text{O}^+$  so that they are almost completely ionized in aqueous solutions ( $K > 1$ ). The acids listed in Table 2-3 are all weak acids. However, many of the so-called mineral acids, such as  $\text{HClO}_4$ ,  $\text{HNO}_3$ ,  $\text{HCl}$ , and  $\text{H}_2\text{SO}_4$  (for its first ionization), are strong acids. Since strong acids rapidly transfer all their protons to  $\text{H}_2\text{O}$ , the strongest acid that can stably exist in aqueous solutions is  $\text{H}_3\text{O}^+$ . Likewise, there can be no stronger base in aqueous solutions than  $\text{OH}^-$ .

**Table 2-3** Dissociation Constants and pK's at 25°C of Some Acids in Common Laboratory Use as Biochemical Buffers

Acid	$K$ (M)	pK
Oxalic acid	$5.37 \times 10^{-2}$	1.27 (pK <sub>1</sub> )
$\text{H}_3\text{PO}_4$	$7.08 \times 10^{-3}$	2.15 (pK <sub>1</sub> )

$\text{HCO}_3^-$	$4.68 \times 10^{-11}$	10.33 (pK <sub>2</sub> )
Piperidine	$7.58 \times 10^{-12}$	11.12
$\text{HPO}_4^{2-}$	$4.17 \times 10^{-13}$	12.38 (pK <sub>3</sub> )

Source: Mostly Dawson, R.M.C., Elliott, D.C., Elliott, W.H., and Jones, K.M., *Data for Biochemical Research* (3rd ed.), pp. 424–425, Oxford Science Publications (1986); and Good, N.E., Winget, G.D., Winter, W., Connolly, T.N., Izawa, S., and Singh, R.M.M., *Biochemistry* 5, 467 (1966).

Water, being an acid, has a dissociation constant:

$$K = \frac{[\text{H}^+][\text{OH}^-]}{[\text{H}_2\text{O}]}$$

As above, the constant  $[\text{H}_2\text{O}] = 55.5M$  can be incorporated into the dissociation constant to yield the expression for the ionization constant of water,

$$K_w = [\text{H}^+][\text{OH}^-] \quad [2.4]$$

The value of  $K_w$  at  $25^\circ\text{C}$  is  $10^{-14} M^2$ . Pure water must contain equimolar amounts of  $\text{H}^+$  and  $\text{OH}^-$  so that  $[\text{H}^+] = [\text{OH}^-] = (K_w)^{1/2} = 10^{-7} M$ . Since  $[\text{H}^+]$  and  $[\text{OH}^-]$  are reciprocally related by Eq. [2.4], if  $[\text{H}^+]$  is greater than this value,  $[\text{OH}^-]$  must be correspondingly less and vice versa. Solutions with  $[\text{H}^+] = 10^{-7} M$  are said to be **neutral**, those with  $[\text{H}^+] > 10^{-7} M$  are said to be **acidic**, and those with  $[\text{H}^+] < 10^{-7} M$  are said to be **basic**. Most physiological solutions have hydrogen ion concentrations near neutrality. For example, human blood is normally slightly basic, with  $[\text{H}^+] = 4.0 \times 10^{-8} M$ .

The values of  $[\text{H}^+]$  for most solutions are inconveniently small and difficult to compare. A more practical quantity, which was devised in 1909 by Søren Sørensen, is known as the **pH**:

$$\text{pH} = -\log[\text{H}^+] \quad [2.5]$$

The pH of pure water is 7.0, whereas acidic solutions have  $\text{pH} < 7.0$  and basic solutions have  $\text{pH} > 7.0$ . For a 1M solution of a strong acid,  $\text{pH} = 0$  and for a 1M solution of a strong base,  $\text{pH} = 14$ . Note that if two solutions differ in pH by one unit, they differ in  $[\text{H}^+]$  by a factor of 10. The pH of a solution may be accurately and easily determined through electrochemical measurements with a device known as a **pH meter**.

### b. The pH of a Solution Is Determined by the Relative Concentrations of Acids and Bases

The relationship between the pH of a solution and the concentrations of an acid and its conjugate base can be easily derived by rearranging Eq. [2.3]

$$[\text{H}^+] = K \left( \frac{[\text{HA}]}{[\text{A}^-]} \right)$$

and substituting it into Eq. [2.5]

$$\text{pH} = -\log K + \log \left( \frac{[\text{A}^-]}{[\text{HA}]} \right)$$

Defining  $\text{p}K = -\log K$  in analogy with Eq. [2.5], we obtain the **Henderson-Hasselbalch equation**:

$$\text{pH} = \text{p}K + \log \left( \frac{[\text{A}^-]}{[\text{HA}]} \right) \quad [2.6]$$

This equation indicates that *the pK of an acid is numerically equal to the pH of the solution when the molar concentrations of the acid and its conjugate base are equal*. Table 2-3 lists the pK values of several acids.

## B. Buffers

A 0.01-mL droplet of 1M HCl added to 1 L of pure water changes the water's pH from 7 to 5, which represents a 100-fold increase in  $[\text{H}^+]$ . Yet, since the properties of biological substances vary significantly with small changes in pH, they require environments in which the pH is insensitive to additions of acids or bases. To understand how this is possible, let us consider the titration of a weak acid with a strong base.

Figure 2-11 shows how the pH values of 1-L solutions of 1M acetic acid,  $\text{H}_2\text{PO}_4^-$ , and ammonium ion ( $\text{NH}_4^+$ ), vary with the quantity of  $\text{OH}^-$  added. Titration curves such as those in Fig. 2-11, as well as distribution curves such as those

**Figure 2-11** Acid-base titration curves of 1-L solutions of 1M acetic acid,  $\text{H}_2\text{PO}_4^-$ , and  $\text{NH}_4^+$  by a strong base. At the starting point of each titration, the acid form of the conjugate acid-base pair overwhelmingly predominates. At the midpoint of the titration, where  $\text{pH} = \text{p}K$ , the concentration of the acid is equal to that of its conjugate base. Finally, at the end point of the titration, where the equivalents of strong base added equal the equivalents of acid at the starting point, the conjugate base is in great excess over acid. The shaded bands indicate the pH ranges over which the corresponding solution can function effectively as a buffer. See the Animated Figures.

**Figure 2-12** Distribution curves for acetic acid and acetate ion.

The fraction of species present is given as the ratio of the concentration of  $\text{CH}_3\text{COOH}$  or  $\text{CH}_3\text{COO}^-$  to the total concentrations of these two species. The customarily accepted useful buffer range of  $\text{pK} \pm 1$  is indicated by the shaded region.

in Fig. 2-12, may be calculated using the Henderson–Hasselbalch equation. Near the beginning of the titration, a significant fraction of the  $\text{A}^-$  present arises from the dissociation of HA. Similarly, near the end point, much of the HA derives from the reaction of  $\text{A}^-$  with  $\text{H}_2\text{O}$ . Throughout most of the titration, however, the  $\text{OH}^-$  added reacts essentially completely with the HA to form  $\text{A}^-$  so that

$$[\text{A}^-] = \frac{x}{V} \quad [2.7]$$

where  $x$  represents the equivalents of  $\text{OH}^-$  added and  $V$  is the volume of the solution. Then, letting  $c_0$  represent the equivalents of HA initially present,

$$[\text{HA}] = \frac{c_0 - x}{V} \quad [2.8]$$

Incorporating these relationships into Eq. [2.6] yields

$$\text{pH} = \text{pK} + \log\left(\frac{x}{c_0 - x}\right) \quad [2.9]$$

which accurately describes a titration curve except near its wings (these regions require more exact treatments that take into account the ionizations of water).

Several details about the titration curves in Fig. 2-11 should be noted:

1. The curves have similar shapes but are shifted vertically along the pH axis.

2. The pH at the **equivalence point** of each titration (where the equivalents of  $\text{OH}^-$  added equal the equiva-

lents of HA initially present) is  $>7$  because of the reaction of  $\text{A}^-$  with  $\text{H}_2\text{O}$  to form  $\text{HA} + \text{OH}^-$ ; similarly, each initial pH is  $<7$ .

3. The pH at the midpoint of each titration is numerically equal to the pK of its corresponding acid; here, according to the Henderson–Hasselbalch equation,  $[\text{HA}] = [\text{A}^-]$ .

4. The slope of each titration curve is much less near its midpoint than it is near its wings. This indicates that *when  $[\text{HA}] \approx [\text{A}^-]$ , the pH of the solution is relatively insensitive to the addition of strong base or strong acid. Such a solution, which is known as an **acid–base buffer**, is resistant to pH changes because small amounts of added  $\text{H}^+$  or  $\text{OH}^-$ , respectively, react with the  $\text{A}^-$  or HA present without greatly changing the value of  $\log([\text{A}^-]/[\text{HA}])$ .*

#### a. Buffers Stabilize a Solution's pH

The ability of a buffer to resist pH changes with added acid or base is directly proportional to the total concentration of the conjugate acid–base pair,  $[\text{HA}] + [\text{A}^-]$ . It is maximal when  $\text{pH} = \text{pK}$  and decreases rapidly with a change in pH from that point. A good rule of thumb is that *a weak acid is in its useful buffer range within 1 pH unit of its pK* (the shaded regions of Figs. 2-11 and 2-12). Above this range, where the ratio  $[\text{A}^-]/[\text{HA}] > 10$ , the pH of the solution changes rapidly with added strong base. A buffer is similarly impotent with addition of strong acid when its pK exceeds the pH by more than a unit.

Biological fluids, both those found intracellularly and extracellularly, are heavily buffered. For example, the pH of the blood in healthy individuals is closely controlled at pH 7.4. The phosphate and carbonate ions that are components of most biological fluids are important in this respect because they have pK's in this range (Table 2-3). Moreover, many biological molecules, such as proteins, nucleic acids, and lipids, as well as numerous small organic molecules, bear multiple acid–base groups that are effective as buffer components in the physiological pH range.

The concept that the properties of biological molecules vary with the acidity of the solution in which they are dissolved was not fully appreciated before the beginning of the twentieth century so that the acidities of biochemical preparations made before that time were rarely controlled. Consequently these early biochemical experiments yielded poorly reproducible results. More recently, biochemical preparations have been routinely buffered to simulate the properties of naturally occurring biological fluids. Many of the weak acids listed in Table 2-3 are commonly used as buffers in biochemical preparations. In practice, the chosen weak acid and one of its soluble salts are dissolved in the (nearly equal) mole ratio necessary to provide the desired pH and, with the aid of a pH meter, the resulting solution is fine-tuned by titration with strong acid or base.

### C. Polyprotic Acids

Substances that bear more than one acid–base group, such as  $\text{H}_3\text{PO}_4$  or  $\text{H}_2\text{CO}_3$ , as well as most biomolecules, are known as **polyprotic acids**. The titration curves of such sub-

**Figure 2-13** Titration curve of a 1-L solution of 1M  $\text{H}_3\text{PO}_4$ . The two intermediate equivalence points occur at the steepest parts of the curve. Note the flatness of the curve near its starting points and end points in comparison with the curved ends of the titration curves in Fig. 2-11. This indicates that  $\text{H}_3\text{PO}_4$  ( $\text{p}K_1 = 2.15$ ) is verging on being a strong acid and  $\text{PO}_4^{3-}$  ( $\text{p}K_3 = 12.38$ ) is verging on being a strong base.  See the Animated Figures.

stances, as is illustrated in Fig. 2-13 for  $\text{H}_3\text{PO}_4$ , are characterized by multiple  $\text{p}K$ 's, one for each ionization step. Exact calculations of the concentrations of the various ionic species present at a given pH is clearly a more complex task than for a **monoprotic acid**.

The  $\text{p}K$ 's of two closely associated acid–base groups are *not independent*. The ionic charge resulting from a proton dissociation electrostatically inhibits further proton dissociation from the same molecule, thereby increasing the values of the corresponding  $\text{p}K$ 's. This effect, according to Coulomb's law, decreases as the distance between the ionizing groups increases. For example, the  $\text{p}K$ 's of **oxalic acid's** two adjacent carboxyl groups differ by 3 pH units (Table 2-3), whereas those of **succinic acid**, in which the carboxyl groups are separated by two methylene groups, differ by 1.4 units.

Likewise, successive ionizations from the same center, such as in  $\text{H}_3\text{PO}_4$  or  $\text{H}_2\text{CO}_3$ , have  $\text{p}K$ 's that differ by 4 to 5 pH units. If the  $\text{p}K$ 's for successive ionizations of a polyprotic acid differ by at least 3 pH units, it can be accurately assumed that, at a given pH, only the members of the conjugate acid–base pair characterized by the nearest  $\text{p}K$  are present in significant concentrations. This, of course, greatly simplifies the calculations for determining the concentrations of the various ionic species present.

#### a. Polyprotic Acids with Closely Spaced $\text{p}K$ 's Have Molecular Ionization Constants

If the  $\text{p}K$ 's of a polyprotic acid differ by less than  $\sim 2$  pH units, as is true in perhaps the majority of biomolecules, the ionization constants measured by titration are not true group ionization constants but, rather, reflect the average ionization of the groups involved. The resulting ionization constants are therefore known as **molecular ionization constants**.

Consider the acid–base equilibria shown in Fig. 2-14 in which there are two nonequivalent protonation sites. Here, the quantities  $K_A$ ,  $K_B$ ,  $K_C$ , and  $K_D$ , the ionization constants for each group, are alternatively called **microscopic ionization constants**. The molecular ionization constant for the removal of the first proton from HAH is

$$K_1 = \frac{[\text{H}^+](\text{[AH}^-] + \text{[HA}^-])}{\text{[HAH]}} = K_A + K_B \quad [2.10]$$

**Figure 2-14** Ionization of an acid that has two nonequivalent protonation sites.

Similarly, the molecular ionization constant  $K_2$  for the removal of the second proton is

$$K_2 = \frac{[\text{H}^+][\text{A}^{2-}]}{[\text{AH}^-] + [\text{HA}^-]} = \frac{1}{(1/K_C) + (1/K_D)} \\ = \frac{K_C K_D}{K_C + K_D} \quad [2.11]$$

If  $K_A \gg K_B$ , then  $K_1 \approx K_A$ ; that is, the first molecular ionization constant is equal to the microscopic ionization constant of the more acidic group. Likewise, if  $K_D \gg K_C$ , then  $K_2 \approx K_C$ , so that the second molecular ionization constant is the microscopic ionization constant of the less acidic group. If the ionization steps differ sufficiently in their  $pK$ 's, the molecular ionization constants, as expected, become identical to the microscopic ionization constants.

## CHAPTER SUMMARY

**1 Properties of Water** Water is an extraordinary substance, the properties of which are of great biological importance. A water molecule can simultaneously participate in as many as four hydrogen bonds: two as a donor and two as an acceptor. These hydrogen bonds are responsible for the open, low-density structure of ice. Much of this hydrogen bonded structure exists in the liquid phase, as is evidenced by the high boiling point of water compared to those of other substances of similar molecular masses. Physical and theoretical evidence indicates that liquid water maintains a rapidly fluctuating, hydrogen bonded molecular structure that, over short ranges, resembles that of ice. The unique solvent properties of water derive from its polarity as well as its hydrogen bonding properties. In aqueous solutions, ionic and polar substances are surrounded by multiple concentric hydration shells of oriented water dipoles that act to attenuate the electrostatic interactions between the charges in the solution. The thermal randomization of the oriented water molecules is resisted by their hydrogen bonding associations, thereby accounting for the high dielectric constant of water. Nonpolar substances are essentially insoluble in water. However, amphipathic substances aggregate in aqueous solutions to form micelles and bilayers due to the combination of hydrophobic interactions among the nonpolar portions of these molecules and the hydrophilic interactions of their polar groups with the aqueous solvent. The  $\text{H}_3\text{O}^+$  and  $\text{OH}^-$  ions have anomalously large ionic mobilities in aqueous solutions because the migration of these ions through solution occurs largely via proton jumping from one  $\text{H}_2\text{O}$  molecule to another.

**2 Acids, Bases, and Buffers** A Brønsted acid is a sub-

stance that can donate protons, whereas a Brønsted base can accept protons. On losing a proton, a Brønsted acid becomes its conjugate base. In an acid–base reaction, an acid donates its proton to a base. Water can react as an acid to form hydroxide ion,  $\text{OH}^-$ , or as a base to form hydronium ion,  $\text{H}_3\text{O}^+$ . The strength of an acid is indicated by the magnitude of its dissociation constant,  $K$ . Weak acids, which have a dissociation constant less than that of  $\text{H}_3\text{O}^+$ , are only partially dissociated in aqueous solution. Water has the dissociation constant  $10^{-14}$  at  $25^\circ\text{C}$ . A practical quantity for expressing the acidity of a solution is  $\text{pH} = -\log[\text{H}^+]$ . The relationship between  $\text{pH}$ ,  $\text{p}K$ , and the concentrations of the members of its conjugate acid–base pair is expressed by the Henderson–Hasselbalch equation. An acid–base buffer is a mixture of a weak acid with its conjugate base in a solution that has a  $\text{pH}$  near the  $\text{p}K$  of the acid. The ratio  $[\text{A}^-]/[\text{HA}]$  in a buffer is not very sensitive to the addition of strong acids or bases, so that the  $\text{pH}$  of a buffer is not greatly affected by these substances. Buffers are operationally effective only in the  $\text{pH}$  range of  $\text{p}K \pm 1$ . Outside of this range, the  $\text{pH}$  of the solution changes rapidly with the addition of strong acid or base. Buffer capacity also depends on the total concentration of the conjugate acid–base pair. Biological fluids are generally buffered near neutrality. Many acids are polyprotic. However, unless the  $\text{p}K$ 's of their various ionizations differ by less than 2 or 3  $\text{pH}$  units,  $\text{pH}$  calculations can effectively treat them as if they were a mixture of separate weak acids. For polyprotic acids with  $\text{p}K$ 's that differ by less than this amount, the observed molecular ionization constants are simply related to the microscopic ionization constants of the individual dissociating groups.

## PROBLEMS

1. Draw the hydrogen bonding pattern that water forms with acetamide ( $\text{CH}_3\text{CONH}_2$ ) and with pyridine (benzene with a CH group replaced by N).

2. Explain why the dielectric constants of the following pairs of liquids have the order given in Table 2-1: (a) carbon tetrachloride and chloroform; (b) ethanol and methanol; and (c) acetone and formamide.

3. “Inverted” micelles are made by dispersing amphipathic molecules in a nonpolar solvent, such as benzene, together with a small amount of water (counterions are also provided if the head groups are ionic). Draw the structure of an inverted micelle and describe the forces that stabilize it.

\*4. Amphipathic molecules in aqueous solutions tend to concentrate at surfaces such as liquid–solid or liquid–gas interfaces. They are therefore said to be **surface-active molecules** or **surfactants**. Rationalize this behavior in terms of the properties of the amphiphiles and indicate the effect that surface-active molecules have on the surface tension of water (surface tension is a measure of the internal cohesion of a liquid as manifested by the force necessary to increase its surface area). Explain why surfactants such as soaps and detergents are effective in dispersing oily substances and oily dirt in aqueous solutions. Why do aqueous solutions of surfactants foam and why does the presence of oily substances reduce this foaming?

5. Indicate how hydrogen bonding forces and hydrophobic forces vary with the dielectric constant of the medium.

6. Using the data in Table 2-2, indicate the times it would take a  $\text{K}^+$  and an  $\text{H}^+$  ion to each move 1 cm in an electric field of  $100 \text{ V} \cdot \text{cm}^{-1}$ .

7. Explain why the mobility of  $\text{H}^+$  in ice is only about an order of magnitude less than that in liquid water, whereas the mobility of  $\text{Na}^+$  in solid NaCl is zero.

8. Calculate the pH of: (a)  $0.1M$  HCl; (b)  $0.1M$  NaOH; (c)  $3 \times 10^{-5} M$   $\text{HNO}_3$ ; (d)  $5 \times 10^{-10} M$   $\text{HClO}_4$ ; and (e)  $2 \times 10^{-8} M$  KOH.

9. The volume of a typical bacterial cell is on the order of  $1.0 \mu\text{m}^3$ . At pH 7, how many hydrogen ions are contained inside a bacterial cell? A bacterial cell contains thousands of macromolecules, such as proteins and nucleic acids, that each bear multiple ionizable groups. What does your result indicate about the common notion that ionizable groups are continuously bathed with  $\text{H}^+$  and  $\text{OH}^-$  ions?

10. Using the data in Table 2-3, calculate the concentrations of all molecular and ionic species and the pH in aqueous solutions that have the following formal compositions: (a)  $0.01M$  acetic acid; (b)  $0.25M$  ammonium chloride; (c)  $0.05M$  acetic acid +

$0.10M$  sodium acetate; and (d)  $0.20M$  boric acid [ $\text{B}(\text{OH})_3$ ] +  $0.05M$  sodium borate [ $\text{NaB}(\text{OH})_4$ ].

11. **Acid–base indicators** are weak acids that change color on changing ionization states. When a small amount of an appropriately chosen indicator is added to a solution of an acid or base being titrated, the color change “indicates” the **end point** of the titration. **Phenolphthalein** is a commonly used acid–base indicator that, in aqueous solutions, changes from colorless to red-violet in the pH range between 8.2 and 10.0. Referring to Figs. 2-11 and 2-13, describe the effectiveness of phenolphthalein for accurately detecting the end point of a titration with strong base of: (a) acetic acid; (b)  $\text{NH}_4\text{Cl}$ ; and (c)  $\text{H}_3\text{PO}_4$  (at each of its three equivalence points).

\*12. The formal composition of an aqueous solution is  $0.12M$   $\text{K}_2\text{HPO}_4$  +  $0.08M$   $\text{KH}_2\text{PO}_4$ . Using the data in Table 2-3, calculate the concentrations of all ionic and molecular species in the solution and the pH of the solution.

13. Distilled water in equilibrium with air contains dissolved carbon dioxide at a concentration of  $1.0 \times 10^{-5} M$ . Using the data in Table 2-3, calculate the pH of such a solution.

14. Calculate the formal concentrations of acetic acid and sodium acetate necessary to prepare a buffer solution of pH 5 that is  $0.20M$  in total acetate. The  $pK$  of acetic acid is given in Table 2-3.

15. In order to purify a certain protein, you require  $0.1M$  glycine buffer at pH 9.4. Unfortunately, your stockroom has run out of glycine. However, you manage to find two  $0.1M$  glycine buffer solutions, one at pH 9.0 and the other at pH 10.0. What volumes of these two solutions must you mix in order to obtain 200 mL of your required buffer?

16. An enzymatic reaction takes place in 10 mL of a solution that has a total citrate concentration of 120 mM and an initial pH of 7.00. During the reaction (which does not involve citrate), 0.2 milliequivalents of acid are produced. Using the data in Table 2-3, calculate the final pH of the solution. What would the final pH of the solution be in the absence of the citrate buffer assuming that the other components of the solution have no significant buffering capacity and that the solution is initially at pH 7?

\*17. A solution’s **buffer capacity**  $\beta$  is defined as the ratio of an incremental amount of base added, in equivalents, to the corresponding pH change. This is the reciprocal of the slope of the titration curve, Eq. [2.9]. Derive the equation for  $\beta$  and show that it is maximal at  $\text{pH} = pK$ .

18. Using the data in Table 2-3, calculate the microscopic ionization constants for oxalic acid and for succinic acid. How do these values compare with their corresponding molecular ionization constants?

- C. Coupled Reactions

### Appendix: Concentration Dependence of Free Energy

You can't win.

*First law of thermodynamics*

You can't even break even.

*Second law of thermodynamics*

You can't stay out of the game.

*Third law of thermodynamics*

Living things require a continuous throughput of energy. For example, through photosynthesis, plants convert radiant energy from the sun, the primary energy source for life on Earth, to the chemical energy of carbohydrates and other organic substances. The plants, or the animals that eat them, then metabolize these substances to power such functions as the synthesis of biomolecules, the maintenance of concentration gradients, and the movement of muscles. These processes ultimately transform the energy to heat, which is dissipated to the environment. A considerable portion of the cellular biochemical apparatus must therefore be devoted to the acquisition and utilization of energy.

**Thermodynamics** (Greek: *therme*, heat + *dynamis*, power) is a marvelously elegant description of the relationships among the various forms of energy and how energy affects matter on the macroscopic as opposed to the molecular level; that is, it deals with amounts of matter large enough for their average properties, such as temperature

and pressure, to be well defined. Indeed, the basic principles of thermodynamics were developed in the nineteenth century before the atomic theory of matter had been generally accepted.

*With a knowledge of thermodynamics we can determine whether a physical process is possible.* Thermodynamics is therefore essential for understanding why macromolecules fold to their native conformations, how metabolic pathways are designed, why molecules cross biological membranes, how muscles generate mechanical force, and so on. The list is endless. Yet the reader should be cautioned that thermodynamics does not indicate the rates at which possible processes actually occur. For instance, although thermodynamics tells us that glucose and oxygen react with the release of copious amounts of energy, it does not indicate that this mixture is indefinitely stable at room temperature in the absence of the appropriate enzymes. The prediction of reaction rates requires, as we shall see in Section 14-1C, a mechanistic description of molecular processes. Yet thermodynamics is also an indispensable guide in formulating such mechanistic models because such models must conform to thermodynamic principles.

Thermodynamics, as it applies to biochemistry, is most frequently concerned with describing the conditions under which processes occur *spontaneously* (by themselves). We shall consequently review the elements of thermodynamics that enable us to predict chemical and biochemical spontaneity: the first and second laws of thermodynamics, the concept of free energy, and the nature of processes at equilibrium. Familiarity with these principles is indispensable for understanding many of the succeeding discussions in this text. We shall, however, postpone consideration of the thermodynamic aspects of metabolism until Sections 16-4 through 16-6.

### 1 FIRST LAW OF THERMODYNAMICS: ENERGY IS CONSERVED

In thermodynamics, a **system** is defined as that part of the universe that is of interest, such as a reaction vessel or an organism; the rest of the universe is known as the **surroundings**. A system is said to be **open**, **closed**, or **isolated** according to whether or not it can exchange matter and energy with its surroundings, only energy, or neither matter nor energy. Living organisms, which take up nutrients, re-

lease waste products, and generate work and heat, are examples of open systems; if an organism were sealed inside an uninsulated box, it would, together with the box, constitute a closed system, whereas if the box were perfectly insulated, the system would be isolated.

### A. Energy

The **first law of thermodynamics** is a mathematical statement of the law of conservation of energy: *Energy can be neither created nor destroyed.*

$$\Delta U = U_{\text{final}} - U_{\text{initial}} = q + w \quad [3.1]$$

Here  $U$  is energy,  $q$  represents the **heat** absorbed by the system from the surroundings, and  $w$  is the **work** done on the system by the surroundings. Heat is a reflection of random molecular motion, whereas work, which is defined as force times the distance moved under its influence, is associated with organized motion. Force may assume many different forms, including the gravitational force exerted by one mass on another, the expansional force exerted by a gas, the tensional force exerted by a spring or muscle fiber, the electrical force of one charge on another, or the dissipative forces of friction and viscosity. Processes in which the system releases heat, which by convention are assigned a negative  $q$ , are known as **exothermic processes** (Greek: *exo*, out of); those in which the system gains heat (positive  $q$ ) are known as **endothermic processes** (Greek: *endon*, within). Under this convention, work done by the system against an external force is defined as a negative quantity.

The SI unit of energy, the **joule (J)**, is steadily replacing the **calorie (cal)** in modern scientific usage. The **large calorie (Cal)**, with a capital C is a unit favored by nutritionists. The relationships among these quantities and other units, as well as the values of constants that will be useful throughout this chapter, are collected in Table 3-1.

#### a. State Functions Are Independent of the Path a System Follows

Experiments have invariably demonstrated that the energy of a system depends only on its current properties or **state**, not on how it reached that state. For example, the state of a system composed of a particular gas sample is completely described by its pressure and temperature. The energy of this gas sample is a function only of these so-called **state functions** (quantities that depend only on the state of the system) and is therefore a state function itself. Consequently, there is no net change in energy ( $\Delta U = 0$ ) for any process in which the system returns to its initial state (a **cyclic process**).

Neither heat nor work is separately a state function because each is dependent on the **path** followed by a system in changing from one state to another. For example, in the process of changing from an initial to a final state, a gas may do work by expanding against an external force, or do no work by following a path in which it encounters no external resistance. If Eq. [3.1] is to be obeyed, heat must also be path dependent. It is therefore meaningless to refer to

**Table 3-1** Thermodynamic Units and Constants

the heat or work content of a system (in the same way that it is meaningless to refer to the number of one dollar bills and ten dollar bills in a bank account containing \$85.00). To indicate this property, the heat or work produced during a change of state is never referred to as  $\Delta q$  or  $\Delta w$  but rather as just  $q$  or  $w$ .

### B. Enthalpy

Any combination of only state functions must also be a state function. One such combination, which is known as **enthalpy** (Greek: *enthalpein*, to warm in), is defined

$$H = U + PV \quad [3.2]$$

where  $V$  is the volume of the system and  $P$  is its pressure. Enthalpy is a particularly convenient quantity with which to describe biological systems because *under constant pressure, a condition typical of most biochemical processes, the enthalpy change between the initial and final states of a process,  $\Delta H$ , is the easily measured heat that it generates or absorbs.* To show this, let us divide work into two categories: pressure–volume ( $P$ – $V$ ) work, which is work performed by expansion against an external pressure ( $-P \Delta V$ ), and all other work ( $w'$ ):

$$w = -P \Delta V + w' \quad [3.3]$$

Then, by combining Eqs. [3.1], [3.2], and [3.3], we see that

$$\Delta H = \Delta U + P \Delta V = q_P + w + P \Delta V = q_P + w' \quad [3.4]$$

where  $q_p$  is the heat transferred at constant pressure. Thus if  $w' = 0$ , as is often true of chemical reactions,  $\Delta H = q_p$ . Moreover, the volume changes in most biochemical processes are negligible, so that the differences between their  $\Delta U$  and  $\Delta H$  values are usually insignificant.

We are now in a position to understand the utility of state functions. For instance, suppose we wished to determine the enthalpy change resulting from the complete oxidation of 1 g of glucose to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  by muscle tissue. To make such a measurement directly would present enormous experimental difficulties. For one thing, the enthalpy changes resulting from the numerous metabolic reactions not involving glucose oxidation that normally occur in living muscle tissue would greatly interfere with our enthalpy measurement. Since enthalpy is a state function, however, we can measure glucose's enthalpy of combustion in any apparatus of our choosing, say, a constant pressure calorimeter rather than a muscle, and still obtain the same value. This, of course, is true whether or not we know the mechanism through which muscle converts glucose to  $\text{CO}_2$  and  $\text{H}_2\text{O}$  as long as we can establish that these substances actually are the final metabolic products. *In general, the change of enthalpy in any hypothetical reaction pathway can be determined from the enthalpy change in any other reaction pathway between the same reactants and products.*

We stated earlier in the chapter that thermodynamics serves to indicate whether a particular process occurs spontaneously. Yet the first law of thermodynamics cannot, by itself, provide the basis for such an indication, as the following example demonstrates. If two objects at different temperatures are brought into contact, we know that heat spontaneously flows from the hotter object to the colder one, never vice versa. Yet either process is consistent with the first law of thermodynamics since the aggregate energy of the two objects is independent of their temperature distribution. Consequently, we must seek a criterion of spontaneity other than only conformity to the first law of thermodynamics.

## 2 SECOND LAW OF THERMODYNAMICS: THE UNIVERSE TENDS TOWARD MAXIMUM DISORDER

When a swimmer falls into the water (a spontaneous process), the energy of the coherent motion of his body is converted to that of the chaotic thermal motion of the surrounding water molecules. The reverse process, the swimmer being ejected from still water by the sudden coherent motion of the surrounding water molecules, has never been witnessed even though such a phenomenon violates neither the first law of thermodynamics nor Newton's laws of motion. This is because *spontaneous processes are characterized by the conversion of order (in this case the coherent motion of the swimmer's body) to chaos (here the random thermal motion of the water molecules).* The **second law of thermodynamics**, which expresses this phenomenon, therefore provides a criterion for determining whether a process is spontaneous. Note that thermodynamics says nothing about the rate of a process; that is the purview of **chemical**

**kinetics** (Chapter 14). Thus a spontaneous process might proceed at only an infinitesimal rate.

### A. Spontaneity and Disorder

The second law of thermodynamics states, in accordance with all experience, that *spontaneous processes occur in directions that increase the overall disorder of the universe*, that is, of the system and its surroundings. Disorder, in this context, is defined as the number of equivalent ways,  $W$ , of arranging the components of the universe. To illustrate this point, let us consider an isolated system consisting of two bulbs of equal volume containing a total of  $N$  identical molecules of ideal gas (Fig. 3-1). When the stopcock connecting the bulbs is open, there is an equal probability that a given molecule will occupy either bulb, so there are a total of  $2^N$  equally probable ways that the  $N$  molecules may be distributed among the two bulbs. Since the gas molecules are indistinguishable from one another, there are only  $(N + 1)$  different states of the system: those with 0, 1, 2, . . . ,  $(N - 1)$ , or  $N$  molecules in the left bulb. Probability theory indicates that the number of (indistinguishable) ways,  $W_L$ , of placing  $L$  of the  $N$  molecules in the left bulb is

$$W_L = \frac{N!}{L!(N - L)!}$$

The probability of such a state occurring is its fraction of the total number of possible states:  $W_L/2^N$ .

For any value of  $N$ , the state that is most probable, that is, the one with the highest value of  $W_L$ , is the one with half of the molecules in one bulb ( $L = N/2$  for  $N$  even). As  $N$  becomes large, the probability that  $L$  is nearly equal to  $N/2$  approaches unity: For instance, when  $N = 10$  the probability that  $L$  is within 20% of  $N/2$  (that is, 4, 5, or 6) is 0.66, whereas for  $N = 50$  this probability (that  $L$  is in the range 20–30) is 0.88. For a chemically significant number of molecules, say

**Figure 3-1** Two bulbs of equal volumes connected by a stopcock.

In (a), a gas occupies the left bulb, the right bulb is evacuated, and the stopcock is closed. When the stopcock is opened (b), the gas molecules diffuse back and forth between the bulbs and eventually become distributed so that half of them occupy each bulb.

**Figure 3-2 The improbability of even a small amount of order.**

Consider a simple “universe” consisting of a square array of 9 positions that collectively contain 4 identical “molecules” (*red dots*). If the 4 molecules are arranged in a square, we call the arrangement a “crystal”; otherwise we call it a “gas.” The total number of distinguishable arrangements of our 4 molecules in 9 positions is given by

$$W = \frac{9 \cdot 8 \cdot 7 \cdot 6}{4 \cdot 3 \cdot 2 \cdot 1} = 126$$

Here, the numerator indicates that the first molecule may occupy any of the universe’s 9 positions, the second molecule may occupy any of the 8 remaining unoccupied positions, and so on, whereas the denominator corrects for the number of indistinguishable arrangements of the 4 identical molecules. Of the 126 arrangements this universe can have, only 4 are crystals (*black squares*). Thus, even in this simple universe, there is a more than 30-fold greater probability that it will contain a disordered gas, when arranged at random, than an ordered crystal. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

$N = 10^{23}$ , the probability that the number of molecules in the left bulb differs from those in the right by as insignificant a ratio as 1 molecule in every 10 billion is  $10^{-434}$ , which, for all intents and purposes, is zero. Therefore, the reason the number of molecules in each bulb of the system in Fig. 3-1b is always observed to be equal is not because of any law of motion; the energy of the system is the same for any arrangement of the molecules. *It is because the aggregate probability of all other states is so utterly insignificant* (Fig. 3-2). By the same token, the reason that our swimmer is never thrown out of the water or even noticeably disturbed by the chance coherent motion of the surrounding water molecules is that the probability of such an event is nil.

**B. Entropy**

In chemical systems,  $W$ , the number of equivalent ways of arranging a system in a particular state, is usually inconveniently immense. For example, when the above twin-bulb system contains  $N$  gas molecules, so  $W_{N/2} \approx 10^{N \ln 2}$  so that for  $N = 10^{23}$ ,  $W_{5 \times 10^{22}} \approx 10^{7 \times 10^{22}}$ . In order to be able to deal with  $W$  more easily, we define, as did Ludwig Boltzmann in 1877, a quantity known as **entropy** (Greek: *en*, in + *trope*, turning):

$$S = k_B \ln W \quad [3.5]$$

that increases with  $W$  but in a more manageable way. Here  $k_B$  is the **Boltzmann constant** (Table 3-1). For our twin-bulb system,  $S = k_B N \ln 2$ , so the entropy of the system in its most probable state is proportional to the number of gas molecules it contains. Note that *entropy is a state function because it depends only on the parameters that describe a state.*

*The laws of random chance cause any system of reasonable size to spontaneously adopt its most probable arrangement, the one in which entropy is a maximum, simply because this state is so overwhelmingly probable.* For example, assume that all  $N$  molecules of our twin-bulb system are

initially placed in the left bulb (Fig. 3-1a;  $W_N = 1$  and  $S = 0$  since there is only one way of doing this). After the stopcock is opened, the molecules will randomly diffuse in and out of the right bulb until eventually they achieve their most probable (maximum entropy) state, that with half of the molecules in each bulb. The gas molecules will subsequently continue to diffuse back and forth between the bulbs, but there will be no further macroscopic (net) change in the system. The system is therefore said to have reached **equilibrium**.

According to Eq. [3.5], the foregoing spontaneous expansion process causes the system's entropy to increase. In general, for any constant energy process ( $\Delta U = 0$ ), a spontaneous process is characterized by  $\Delta S > 0$ . Since the energy of the universe is constant (energy can assume different forms but can be neither created nor destroyed), any spontaneous process must cause the entropy of the universe to increase:

$$\Delta S_{\text{system}} + \Delta S_{\text{surroundings}} = \Delta S_{\text{universe}} > 0 \quad [3.6]$$

Equation [3.6] is the usual expression for the second law of thermodynamics. It is a statement of the general tendency of all spontaneous processes to disorder the universe; that is, the entropy of the universe tends toward a maximum.

The conclusions based on our twin-bulb apparatus may be applied to explain, for instance, why blood transports  $O_2$  and  $CO_2$  between the lungs and the tissues. Solutes in solution behave analogously to gases in that they tend to maintain a uniform concentration throughout their occupied volume because this is their most probable arrangement. In the lungs, where the concentration of  $O_2$  is higher than that in the venous blood passing through them, more  $O_2$  enters the blood than leaves it. On the other hand, in the tissues, where the  $O_2$  concentration is lower than that in the arterial blood, there is net diffusion of  $O_2$  from the blood to the tissues. The reverse situation holds for  $CO_2$  transport since the  $CO_2$  concentration is low in the lungs but high in the tissues. Keep in mind, however, that thermodynamics says nothing about the rates at which  $O_2$  and  $CO_2$  are transported to and from the tissues. The rates of these processes depend on the physicochemical properties of the blood, the lungs, and the cardiovascular system.

Equation [3.6] does not imply that a particular system cannot increase its degree of order. As is explained in Section 3-3, however, a system can only be ordered at the expense of disordering its surroundings to an even greater extent by the application of energy to the system. For example, living organisms, which are organized from the molecular

level upward and are therefore particularly well ordered, achieve this order at the expense of disordering the nutrients they consume. Thus, eating is as much a way of acquiring order as it is of gaining energy.

A state of a system may constitute a distribution of more complicated quantities than those of gas molecules in a bulb or simple solute molecules in a solvent. For example, if our system consists of a protein molecule in aqueous solution, its various states differ, as we shall see, in the conformations of the protein's amino acid residues and in the distributions and orientations of its associated water molecules. The second law of thermodynamics applies here because a protein molecule in aqueous solution assumes its native conformation largely in response to the tendency of its surrounding water structure to be maximally disordered (Section 8-4C).

### C. Measurement of Entropy

In chemical and biological systems, it is impractical, if not impossible, to determine the entropy of a system by counting the number of ways,  $W$ , it can assume its most probable state. An equivalent and more practical definition of entropy was proposed in 1864 by Rudolf Clausius: For spontaneous processes

$$\Delta S \geq \int_{\text{initial}}^{\text{final}} \frac{dq}{T} \quad [3.7]$$

where  $T$  is the absolute temperature at which the change in heat occurs. The proof of the equivalence of our two definitions of entropy, which requires an elementary knowledge of statistical mechanics, can be found in many physical chemistry textbooks. It is evident, however, that any system becomes progressively disordered (its entropy increases) as its temperature rises (e.g., Fig. 3-3). The equality in Eq. [3.7] holds only for processes in which the system remains in equilibrium throughout the change; these are known as **reversible processes**.

**Figure 3-3** Relationship of entropy and temperature. The structure of water, or any other substance, becomes increasingly disordered, that is, its entropy increases, as its temperature rises.

For the constant temperature conditions typical of biological processes, Eq. [3.7] reduces to

$$\Delta S \geq \frac{q}{T} \quad [3.8]$$

Thus the entropy change of a reversible process at constant temperature can be determined straightforwardly from measurements of the heat transferred and the temperature at which this occurs. However, since a process at equilibrium can only change at an infinitesimal rate (equilibrium processes are, by definition, unchanging), real processes can approach, but can never quite attain, reversibility. Consequently, *the universe's entropy change in any real process is always greater than its ideal (reversible) value.* This means that when a system departs from and then returns to its initial state via a real process, the entropy of the universe must increase even though the entropy of the system (a state function) does not change.

### 3 FREE ENERGY: THE INDICATOR OF SPONTANEITY

The disordering of the universe by spontaneous processes is an impractical criterion for spontaneity because it is rarely possible to monitor the entropy of the entire universe. Yet the spontaneity of a process cannot be predicted from a knowledge of the system's entropy change alone. This is because exothermic processes ( $\Delta H_{\text{system}} < 0$ ) may be spontaneous even though they are characterized by  $\Delta S_{\text{system}} < 0$ . For example, 2 mol of  $\text{H}_2$  and 1 mol of  $\text{O}_2$ , when sparked, react in a decidedly exothermic reaction to form 2 mol of  $\text{H}_2\text{O}$ . Yet two water molecules, each of whose three atoms are constrained to stay together, are more ordered than are the three diatomic molecules from which they formed. Similarly, under appropriate conditions, many **denatured** (unfolded) proteins will spontaneously fold to assume their highly ordered **native** (normally folded) conformations (Section 9-1A). What we really want, therefore, is a state function that predicts whether or not a given process is spontaneous. In this section, we consider such a function.

#### A. Gibbs Free Energy

The **Gibbs free energy**,

$$G = H - TS \quad [3.9]$$

which was formulated by J. Willard Gibbs in 1878, is the required indicator of spontaneity for constant temperature and pressure processes. For systems that can only do pressure-volume work ( $w' = 0$ ), combining Eqs. [3.4] and [3.9] while holding  $T$  and  $P$  constant yields

$$\Delta G = \Delta H - T \Delta S = q_P - T \Delta S \quad [3.10]$$

But Eq. [3.8] indicates that  $T \Delta S \geq q$  for spontaneous processes at constant  $T$ . Consequently,  $\Delta G \leq 0$  is the *criterion of spontaneity we seek* for the constant  $T$  and  $P$  conditions that are typical of biochemical processes.

**Table 3-2** Variation of Reaction Spontaneity (Sign of  $\Delta G$ ) with the Signs of  $\Delta H$  and  $\Delta S$

$\Delta H$	$\Delta S$	$\Delta G = \Delta H - T \Delta S$
–	+	The reaction is both enthalpically favored (exothermic) and entropically favored. It is spontaneous (exergonic) at all temperatures.
–	–	The reaction is enthalpically favored but entropically opposed. It is spontaneous only at temperatures <i>below</i> $T = \Delta H/\Delta S$ .
+	+	The reaction is enthalpically opposed (endothermic) but entropically favored. It is spontaneous only at temperatures <i>above</i> $T = \Delta H/\Delta S$ .
+	–	The reaction is both enthalpically and entropically opposed. It is <i>unspontaneous</i> (endergonic) at all temperatures.

Spontaneous processes, that is, those with negative  $\Delta G$  values, are said to be **exergonic** (Greek: *ergon*, work); they can be utilized to do work. Processes that are not spontaneous, those with positive  $\Delta G$  values, are termed **endergonic**; they must be driven by the input of free energy (through mechanisms discussed in Section 3-4C). Processes at equilibrium, those in which the forward and backward reactions are exactly balanced, are characterized by  $\Delta G = 0$ . Note that the value of  $\Delta G$  varies directly with temperature. This is why, for instance, the native structure of a protein, whose formation from its denatured form has both  $\Delta H < 0$  and  $\Delta S < 0$ , predominates below the temperature at which  $\Delta H = T \Delta S$  (the **denaturation temperature**), whereas the denatured protein predominates above this temperature. The variation of the spontaneity of a process with the signs of  $\Delta H$  and  $\Delta S$  is summarized in Table 3-2.

#### B. Free Energy and Work

When a system at constant temperature and pressure does non- $P$ - $V$  work, Eq. [3.10] must be expanded to

$$\Delta G = q_P - T \Delta S + w' \quad [3.11]$$

or, because  $T \Delta S \geq q_P$  (Eq. [3.8]),

$$\Delta G \leq w'$$

so that

$$\Delta G \geq -w' \quad [3.12]$$

Since  $P$ - $V$  work is unimportant in biological systems,  $\Delta G$  for a biological process represents its maximum recoverable work. The  $\Delta G$  of a process is therefore indicative of the maximum charge separation it can establish, the maximum concentration gradient it can generate (Section 3-4A), the maximum muscular activity it can produce, and so on. In fact, for real processes, which can only approach reversibility, the inequality in Eq. [3.12] holds, so that *the work put*

into any system can never be fully recovered. This is indicative of the inherent dissipative character of nature. Indeed, as we have seen, it is precisely this dissipative character that provides the overall driving force for any change.

It is important to reiterate that a large negative value of  $\Delta G$  does not ensure a chemical reaction will proceed at a measurable rate. This depends on the detailed mechanism of the reaction, which is independent of  $\Delta G$ . For instance, most biological molecules, including proteins, nucleic acids, carbohydrates, and lipids, are thermodynamically unstable to hydrolysis but, nevertheless, spontaneously hydrolyze at biologically insignificant rates. Only with the introduction of the proper enzymes will the hydrolysis of these molecules proceed at a reasonable pace. Yet a catalyst, which by definition is unchanged by a reaction, cannot affect the  $\Delta G$  of a reaction. Consequently, *an enzyme can only accelerate the attainment of thermodynamic equilibrium; it cannot, for example, promote a reaction that has a positive  $\Delta G$ .*

## 4 CHEMICAL EQUILIBRIA

The entropy (disorder) of a substance increases with its volume. For example, as we have seen for our twin-bulb apparatus (Fig. 3-1), a collection of gas molecules, in occupying all of the volume available to it, maximizes its entropy. Similarly, dissolved molecules become uniformly distributed throughout their solution volume. Entropy is therefore a function of concentration.

If entropy varies with concentration, so must free energy. Thus, as is shown in this section, the free energy change of a chemical reaction depends on the concentrations of both its reactants and its products. This phenomenon is of great biochemical significance because enzymatic reactions can proceed in either direction depending on the relative concentrations of their reactants and products. Indeed, the directions of many enzymatically catalyzed reactions depend on the availability of their **substrates** (reactants) and on the metabolic demand for their products (although most metabolic pathways operate unidirectionally; Section 16-6C).

### A. Equilibrium Constants

The relationship between the concentration and the free energy of a substance A, which is derived in the appendix to this chapter, is approximately

$$\bar{G}_A - \bar{G}_A^\circ = RT \ln [A] \quad [3.13]$$

where  $\bar{G}_A$  is known equivalently as the **partial molar free energy** or the **chemical potential** of A (the bar indicates the quantity per mole),  $\bar{G}_A^\circ$  is the partial molar free energy of A in its **standard state** (see Section 3-4B),  $R$  is the gas constant (Table 3-1), and  $[A]$  is the molar concentration of A. Thus for the general reaction,

since free energies are additive and the free energy change

of a reaction is the sum of the free energies of the products less those of the reactants, the free energy change for this reaction is

$$\Delta G = c\bar{G}_C + d\bar{G}_D - a\bar{G}_A - b\bar{G}_B \quad [3.14]$$

Substituting this relationship into Eq. [3.13] yields

$$\Delta G = \Delta G^\circ + RT \ln \left( \frac{[C]^c [D]^d}{[A]^a [B]^b} \right) \quad [3.15]$$

where  $\Delta G^\circ$  is the free energy change of the reaction when all of its reactants and products are in their standard states. Thus the expression for the free energy change of a reaction consists of two parts: (1) a constant term whose value depends only on the reaction taking place, and (2) a variable term that depends on the concentrations of the reactants and the products, the stoichiometry of the reaction, and the temperature.

For a reaction at equilibrium, there is no *net* change because the free energy of the forward reaction exactly balances that of the backward reaction. Consequently,  $\Delta G = 0$ , so that Eq. [3.15] becomes

$$\Delta G^\circ = -RT \ln K_{\text{eq}} \quad [3.16]$$

where  $K_{\text{eq}}$  is the familiar **equilibrium constant** of the reaction:

$$K_{\text{eq}} = \frac{[C]_{\text{eq}}^c [D]_{\text{eq}}^d}{[A]_{\text{eq}}^a [B]_{\text{eq}}^b} = e^{-\Delta G^\circ/RT} \quad [3.17]$$

and the subscript “eq” in the concentration terms indicates their equilibrium values. (The equilibrium condition is usually clear from the context of the situation, so that equilibrium concentrations are often expressed without this subscript.) *The equilibrium constant of a reaction may therefore be calculated from standard free energy data and vice versa.* Table 3-3 indicates the numerical relationship between  $\Delta G^\circ$  and  $K_{\text{eq}}$ . Note that a 10-fold variation of  $K_{\text{eq}}$  at 25°C corresponds to a 5.7 kJ · mol<sup>-1</sup> change in  $\Delta G^\circ$ , which is less than half of the free energy of even a weak hydrogen bond.

Equations [3.15] through [3.17] indicate that when the reactants in a process are in excess of their equilibrium

**Table 3-3** Variation of  $K_{\text{eq}}$  with  $\Delta G^\circ$  at 25°C

$K_{\text{eq}}$	$\Delta G^\circ$ (kJ · mol <sup>-1</sup> )
10 <sup>6</sup>	-34.3
10 <sup>4</sup>	-22.8
10 <sup>2</sup>	-11.4
10 <sup>1</sup>	-5.7
10 <sup>0</sup>	0.0
10 <sup>-1</sup>	5.7
10 <sup>-2</sup>	11.4
10 <sup>-4</sup>	22.8
10 <sup>-6</sup>	34.3

concentrations, the net reaction will proceed in the forward direction until the excess reactants have been converted to products and equilibrium is attained. Conversely, when products are in excess, the net reaction proceeds in the reverse direction so as to convert products to reactants until the equilibrium concentration ratio is likewise achieved. Thus, as **Le Châtelier's principle** states, *any deviation from equilibrium stimulates a process that tends to restore the system to equilibrium. All isolated systems must therefore inevitably reach equilibrium.* Living systems escape this thermodynamic cul-de-sac by being open systems (Section 16-6A).

The manner in which the equilibrium constant varies with temperature is seen by substituting Eq. [3.10] into Eq. [3.16] and rearranging:

$$\ln K_{\text{eq}} = \frac{-\Delta H^\circ}{R} \left( \frac{1}{T} \right) + \frac{\Delta S^\circ}{R} \quad [3.18]$$

where  $H^\circ$  and  $S^\circ$  represent enthalpy and entropy in the standard state. If  $\Delta H^\circ$  and  $\Delta S^\circ$  are independent of temperature, as they often are to a reasonable approximation, a plot of  $\ln K_{\text{eq}}$  versus  $1/T$ , known as a **van't Hoff plot**, yields a straight line of slope  $-\Delta H^\circ/R$  and intercept  $\Delta S^\circ/R$ . This relationship permits the values of  $\Delta H^\circ$  and  $\Delta S^\circ$  to be determined from measurements of  $K_{\text{eq}}$  at two (or more) different temperatures. Calorimetric data, which until recent decades were quite difficult to measure for biochemical processes, are therefore not required to obtain the values of  $\Delta H^\circ$  and  $\Delta S^\circ$ . Consequently, most biochemical thermodynamic data have been obtained through the application of Eq. [3.18]. However, the development of the **scanning microcalorimeter** has made the direct measurement of  $\Delta H (q_p)$  for biochemical processes a practical alternative. Indeed, a discrepancy between the values of  $\Delta H^\circ$  for a reaction as determined calorimetrically and from a van't Hoff plot suggests that the reaction occurs via one or more intermediate states in addition to the initial and final states implicit in the formulation of Eq. [3.18].

### B. Standard Free Energy Changes

Since only free energy differences,  $\Delta G$ , can be measured, not free energies themselves, it is necessary to refer these differences to some standard state in order to compare the free energies of different substances (likewise, we refer the elevations of geographic locations to sea level, which is arbitrarily assigned the height of zero). By convention, the free energy of all pure elements in their standard state of 25°C, 1 atm, and in their most stable form (e.g.,  $\text{O}_2$  not  $\text{O}_3$ ), is defined to be zero. The **free energy of formation** of any nonelemental substance,  $\Delta G_f^\circ$ , is then defined as the change in free energy accompanying the formation of 1 mol of that substance, in its standard state, from its component elements in their standard states. The standard free energy change for any reaction can be calculated according to

$$\Delta G^\circ = \sum \Delta G_f^\circ(\text{products}) - \sum \Delta G_f^\circ(\text{reactants}) \quad [3.19]$$

**Table 3-4 Free Energies of Formation of Some Compounds of Biochemical Interest**

Compound	$-\Delta G_f^\circ$ (kJ · mol <sup>-1</sup> )

Table 3-4 provides a list of standard free energies of formation,  $\Delta G_f^\circ$ , for a selection of substances of biochemical significance.

#### a. Standard State Conventions in Biochemistry

The standard state convention commonly used in physical chemistry defines the standard state of a solute as that with unit **activity** at 25°C and 1 atm (activity is concentration corrected for nonideal behavior, as is explained in the appendix to this chapter; for the dilute solutions typical of biochemical reactions in the laboratory, such corrections are small, so activities can be replaced by concentrations).

However, because biochemical reactions usually occur in dilute aqueous solutions near neutral pH, a somewhat different standard state convention for biological systems has been adopted:

- Water's standard state is defined as that of the pure liquid, so that the activity of pure water is taken to be unity despite the fact that its concentration is  $55.5M$ . In essence, the  $[H_2O]$  term is incorporated into the value of the equilibrium constant. This procedure simplifies the free energy expressions for reactions in dilute aqueous solutions involving water as a reactant or product because the  $[H_2O]$  term can then be ignored.

- The hydrogen ion activity is defined as unity at the physiologically relevant pH of 7 rather than at the physical chemical standard state of pH 0, where many biological substances are unstable.

- The standard state of a substance that can undergo an acid–base reaction is defined in terms of the total concentration of its naturally occurring ion mixture at pH 7. In contrast, the physical chemistry convention refers to a pure species whether or not it actually exists at pH 0. The advantage of the biochemistry convention is that the total concentration of a substance with multiple ionization states, such as most biological molecules, is usually easier to measure than the concentration of one of its ionic species. Since the ionic composition of an acid or base varies with pH, however, the standard free energies calculated according to the biochemistry convention are valid only at pH 7.

Under the biochemistry convention, the standard free energy changes of substances are customarily symbolized by  $\Delta G^{\circ'}$  in order to distinguish them from physical chemistry standard free energy changes,  $\Delta G^\circ$  (note that the value of  $\Delta G$  for any process, being experimentally measurable, is independent of the chosen standard state; i.e.,  $\Delta G = \Delta G'$ ). Likewise, the biochemical equilibrium constant, which is defined by using  $\Delta G^{\circ'}$  in place of  $\Delta G^\circ$  in Eq. [3.17], is represented by  $K'_{\text{eq}}$ .

The relationship between  $\Delta G^{\circ'}$  and  $\Delta G^\circ$  is often a simple one. There are three general situations:

1. If the reacting species include neither  $H_2O$  nor  $H^+$ , the expressions for  $\Delta G^{\circ'}$  and  $\Delta G^\circ$  coincide.

2. For a reaction in dilute aqueous solution that yields  $n H_2O$  molecules:

Eqs. [3.16] and [3.17] indicate that

$$\Delta G^\circ = -RT \ln K_{\text{eq}} = -RT \ln \left( \frac{[C][D][H_2O]^n}{[A][B]} \right)$$

Under the biochemistry convention, which defines the activity of pure water as unity,

$$\Delta G^{\circ'} = -RT \ln K'_{\text{eq}} = -RT \ln \left( \frac{[C][D]}{[A][B]} \right)$$

Therefore

$$\Delta G^{\circ'} = \Delta G^\circ + nRT \ln [H_2O] \quad [3.20]$$

where  $[H_2O] = 55.5M$  (the concentration of water in aqueous solution), so that for a reaction at  $25^\circ\text{C}$  which yields 1 mol of  $H_2O$ ,  $\Delta G^{\circ'} = \Delta G^\circ + 9.96 \text{ kJ} \cdot \text{mol}^{-1}$ .

3. For a reaction involving hydrogen ions, such as

where

$$K = \left( \frac{[H^+][D^-]}{[HD]} \right)$$

manipulations similar to those above lead to the relationship

$$\Delta G^{\circ'} = \Delta G^\circ - RT \ln(1 + K/[H^+]_0) + RT \ln [H^+]_0 \quad [3.21]$$

where  $[H^+]_0 = 10^{-7}M$ , the only value of  $[H^+]$  for which this equation is valid. Of course, if more than one ionizable species participates in the reaction and/or if any of them are polyprotic, Eq. [3.21] is correspondingly more complicated.

### C. Coupled Reactions

The additivity of free energy changes allows an endergonic reaction to be driven by an exergonic reaction under the proper conditions. This phenomenon is the thermodynamic basis for the operation of metabolic pathways, since most of these reaction sequences comprise endergonic as well as exergonic reactions. Consider the following two-step reaction process:

If  $\Delta G_1 \geq 0$ , Reaction (1) will not occur spontaneously. However, if  $\Delta G_2$  is sufficiently exergonic so that  $\Delta G_1 + \Delta G_2 < 0$ , then although the equilibrium concentration of D in Reaction (1) will be relatively small, it will be larger than that in Reaction (2). As Reaction (2) converts D to products, Reaction (1) will operate in the forward direction to replenish the equilibrium concentration of D. The highly exergonic Reaction (2) therefore *drives* the endergonic Reaction (1), and the two reactions are said to be **coupled** through their common intermediate, D. That these coupled reactions proceed spontaneously (although not necessarily at a finite rate) can also be seen by summing Reactions (1) and (2) to yield the overall reaction

Where  $\Delta G_3 = \Delta G_1 + \Delta G_2 < 0$ . As long as the overall pathway (reaction sequence) is exergonic, it will operate in the

forward direction. Thus, the free energy of ATP hydrolysis, a highly exergonic process, is harnessed to drive many oth-

erwise endergonic biological processes to completion (Section 16-4C).

## APPENDIX Concentration Dependence of Free Energy

To establish that the free energy of a substance is a function of its concentration, consider the free energy change of an ideal gas during a reversible pressure change at constant temperature ( $w' = 0$ , since an ideal gas is incapable of doing non- $P$ - $V$  work). Substituting Eqs. [3.1] and [3.2] into Eq. [3.9] and differentiating the result yields

$$dG = dq + dw + P dV + V dP - T dS \quad [3.A1]$$

On substitution of the differentiated forms of Eqs. [3.3] and [3.8] into this expression, it reduces to

$$dG = V dP \quad [3.A2]$$

The ideal gas equation is  $PV = nRT$ , where  $n$  is the number of moles of gas. Therefore

$$dG = nRT \frac{dP}{P} = nRT d \ln P \quad [3.A3]$$

This gas phase result can be extended to the more biochemically relevant area of solution chemistry by application of **Henry's law** for a solution containing the volatile solute A in equilibrium with the gas phase:

$$P_A = K_A X_A \quad [3.A4]$$

Here  $P_A$  is the partial pressure of A when its mole fraction in the solution is  $X_A$ , and  $K_A$  is the **Henry's law constant** of A in the solvent being used. It is generally more convenient, however, to express the concentrations of the relatively dilute solutions of chemical and biological systems in terms of molarity rather than mole fractions. For a dilute solution

$$X_A \approx \frac{n_A}{n_{\text{solvent}}} = \frac{[A]}{[\text{solvent}]} \quad [3.A5]$$

where the solvent concentration,  $[\text{solvent}]$ , is approximately constant. Thus

$$P_A \approx K'_A [A] \quad [3.A6]$$

where  $K'_A = K_A/[\text{solvent}]$ . Substituting this expression into Eq. [3.A3] yields

$$dG_A = n_A RT d(\ln K'_A + \ln [A]) = n_A RT d \ln [A] \quad [3.A7]$$

Free energy, as are energy and enthalpy, is a relative quantity that can only be defined with respect to some arbitrary standard state. The standard state is customarily taken to be 25°C, 1 atm pressure, and, for the sake of mathematical simplicity,  $[A] = 1$ . The integration of Eq. [3.A7] from the standard state,  $[A] = 1$ , to the final state,  $[A] = [A]$ , results in

$$G_A - G_A^\circ = n_A RT \ln [A] \quad [3.A8]$$

where  $G_A^\circ$  is the free energy of A in the standard state and  $[A]$  really represents the concentration ratio  $[A]/1$ . Since Henry's law is valid for real solutions only in the limit of infinite dilution, however, the standard state is defined as the entirely hypothetical state of 1M solute with the properties that it has at infinite dilution.

The free energy terms in Eq. [3.A8] may be converted from **extensive quantities** (those dependent on the amount of material) to **intensive quantities** (those independent of the amount of material) by dividing both sides of the equation by  $n_A$ . This yields

$$\bar{G}_A - \bar{G}_A^\circ = RT \ln [A] \quad [3.A9]$$

Equation [3.A9] has the limitation that it refers to solutions that exactly follow Henry's law, although real solutions only do so in the limit of infinite dilution if the solute is, in fact, volatile. These difficulties can all be eliminated by replacing  $[A]$  in Eq. [3.A9] by a quantity,  $a_A$ , known as the **activity** of A. This is defined

$$a_A = \gamma_A [A] \quad [3.A10]$$

where  $\gamma_A$  is the **activity coefficient** of A. Equation [3.A9] thereby takes the form

$$\bar{G}_A - \bar{G}_A^\circ = RT \ln a_A \quad [3.A11]$$

in which all departures from ideal behavior, including the provision that the system may perform non- $P$ - $V$  work, are incorporated into the activity coefficient, which is an experimentally measurable quantity. Ideal behavior is only approached at infinite dilution; that is,  $\gamma_A \rightarrow 1$  as  $[A] \rightarrow 0$ . The standard state in Eq. [3.A11] is redefined as that of unit activity.

The concentrations of reactants and products in most laboratory biochemical reactions are usually so low (on the order of millimolar or less) that the activity coefficients of these various species are nearly unity. Consequently, the activities of most biochemical species under laboratory conditions can be satisfactorily approximated by their molar concentrations:

$$\bar{G}_A - \bar{G}_A^\circ = RT \ln [A] \quad [3.13]$$

However, the activity coefficient of a particular species varies with the total concentration of all other species present as well as with its own concentration. Thus, despite the low concentrations of most biochemical species in the cell, their extraordinarily high combined concentrations (e.g., see Fig. 1-13) make the activity coefficients of the individual species deviate significantly from unity. Unfortunately, it is difficult to determine the values of these quantities in a cellular compartment (where it is likewise difficult to determine the concentration of any given species).

## CHAPTER SUMMARY

**1 First Law of Thermodynamics: Energy Is Conserved**

The first law of thermodynamics,

$$\Delta U = q + w \quad [3.1]$$

where  $q$  is heat and  $w$  is work, is a statement of the law of conservation of energy. Energy is a state function because the energy of a system depends only on the state of the system. Entropy,

$$H = U + PV \quad [3.2]$$

where  $P$  is pressure and  $V$  is volume, is a closely related state function that represents the heat at constant pressure under conditions where only pressure–volume work is possible.

**2 Second Law of Thermodynamics: The Universe Tends Toward Maximum Disorder** Entropy, which is also a state function, is defined

$$S = k_B \ln W \quad [3.5]$$

where  $W$ , the disorder, is the number of equivalent ways the system can be arranged under the conditions governing it and  $k_B$  is the Boltzmann constant. The second law of thermodynamics states that the universe tends toward maximum disorder and hence  $\Delta S_{\text{universe}} > 0$  for any real process.

**3 Free Energy: The Indicator of Spontaneity** The Gibbs free energy of a system

$$G = H - TS \quad [3.9]$$

decreases in a spontaneous, constant pressure process. In a process at equilibrium, the system suffers no net change, so that  $\Delta G = 0$ . An ideal process, in which the system is always at equilibrium, is said to be reversible. All real processes are irreversible since processes at equilibrium can only occur at an infinitesimal rate.

**4 Chemical Equilibria** For a chemical reaction

the change in the Gibbs free energy is expressed

$$\Delta G = \Delta G^\circ + RT \ln \left( \frac{[C]^c [D]^d}{[A]^a [B]^b} \right) \quad [3.15]$$

where  $\Delta G^\circ$ , the standard free energy change, is the free energy change at 25°C, 1 atm pressure, and unit activities of reactants and products. The biochemical standard state,  $\Delta G^{\circ'}$ , is similarly defined but in dilute aqueous solution at pH 7 in which the activities of water and  $H^+$  are both defined as unity. At equilibrium

$$\Delta G^{\circ'} = -RT \ln K'_{\text{eq}} = -RT \ln \left( \frac{[C]_{\text{eq}}^c [D]_{\text{eq}}^d}{[A]_{\text{eq}}^a [B]_{\text{eq}}^b} \right)$$

where  $K'_{\text{eq}}$  is the equilibrium constant under the biochemical convention. An endergonic reaction ( $\Delta G > 0$ ) may be driven by an exergonic reaction ( $\Delta G < 0$ ) if they are coupled and if the overall reaction is exergonic.

## PROBLEMS

**1.** A common funeral litany is the Biblical verse: “Ashes to ashes, dust to dust.” Why might a bereaved family of thermodynamicists be equally comforted by a recitation of the second law of thermodynamics?

**2.** How many 4-m-high flights of stairs must an overweight person weighing 75 kg climb to atone for the indiscretion of eating a 500-Cal hamburger? Assume that there is a 20% efficiency in converting nutritional energy to mechanical energy. The gravitational force of an object of mass  $m$  kg is  $F = mg$ , where the gravitational constant  $g$  is  $9.8 \text{ m} \cdot \text{s}^{-2}$ .

**3.** In terms of thermodynamic concepts, why is it more difficult to park a car in a small space than it is to drive it out from such a space?

**4.** It has been said that an army of dedicated monkeys, typing at random, would eventually produce all of Shakespeare’s works. How long, on average, would it take 1 million monkeys, each typing on a 46-key keyboard (space included but no shift key) at the rate of 1 keystroke per second, to type the phrase “to be or not to be”? How long, on average, would it take one monkey to do so at a computer if the computer would only accept the correct letter in

the phrase and then would shift to its next letter (i.e., the computer knew what it wanted)? What do these results indicate about the probability of order randomly arising from disorder versus order arising through a process of evolution?

**5.** Show that the transfer of heat from an object of higher temperature to one of lower temperature, but not the reverse process, obeys the second law of thermodynamics.

**6.** Carbon monoxide crystallizes with its CO molecules arranged in parallel rows. Since CO is a very nearly ellipsoidal molecule, in the absence of polarity effects, adjacent CO molecules could equally well line up in a head-to-tail or a head-to-head fashion. In a crystal consisting of  $10^{23}$  CO molecules, what is the entropy of all the CO molecules being aligned head to tail?

**7.** The U.S. Patent Office has received, and continues to receive, numerous applications for perpetual motion machines. Perpetual motion machines have been classified as those of the first kind, which violate the first law of thermodynamics, and those of the second kind, which violate the second law of thermodynamics. The fallacy in a perpetual motion machine of the first kind is generally easy to detect. An example would be a motor-driven electrical generator that produces energy in excess of that input by the motor. The fallacy in a perpetual motion machine of the second type, however, is usually more subtle. Take, for example, a ship that uses heat energy extracted from the sea by a heat pump to boil water so as to power a steam engine that drives the ship as well as the heat pump. Show, in general terms, that such a propulsion system would violate the second law of thermodynamics.

**8.** Using the data in Table 3-4, calculate the values of  $\Delta G^\circ$  at  $25^\circ\text{C}$  for the following metabolic reactions:

- (a)  $\text{C}_6\text{H}_{12}\text{O}_6 + 6 \text{O}_2 \rightleftharpoons 6 \text{CO}_2(aq) + 6 \text{H}_2\text{O}(\ell)$   
**Glucose**
- (b)  $\text{C}_6\text{H}_{12}\text{O}_6 \rightleftharpoons 2 \text{CH}_3\text{CH}_2\text{OH} + 2 \text{CO}_2(aq)$   
**Glucose            Ethanol**
- (c)  $\text{C}_6\text{H}_{12}\text{O}_6 \rightleftharpoons 2 \text{CH}_3\text{CHOHCOO}^- + 2\text{H}^+$   
**Glucose            Lactate**

[These reactions, respectively, constitute oxidative metabolism, alcoholic fermentation in yeast deprived of oxygen, and homolactic fermentation in skeletal muscle requiring energy faster than oxidative metabolism can supply it (Section 17-3B).]

**\*9.** The native and denatured forms of a protein are generally in equilibrium as follows:

For a certain solution of the protein **ribonuclease A**, in which the total protein concentration is  $2.0 \times 10^{-3} M$ , the concentrations of the denatured and native proteins at both  $50$  and  $100^\circ\text{C}$  are given in the following table:

Temperature ( $^\circ\text{C}$ )	[Ribonuclease A (denatured)] ( $M$ )	[Ribonuclease A (native)] ( $M$ )
50	$5.1 \times 10^{-6}$	$2.0 \times 10^{-3}$
100	$2.8 \times 10^{-4}$	$1.7 \times 10^{-3}$

(a) Determine  $\Delta H^\circ$  and  $\Delta S^\circ$  for the folding reaction assuming that these quantities are independent of temperature. (b) Calculate  $\Delta G^\circ$  for ribonuclease A folding at  $25^\circ\text{C}$ . Is this process spontaneous under standard state conditions at this temperature? (c) What is the denaturation temperature of ribonuclease A under standard state conditions?

**\*10.** Using the data in Table 3-4, calculate  $\Delta G_i^{\circ'}$  for the following compounds at  $25^\circ\text{C}$ : (a)  $\text{H}_2\text{O}(\ell)$ ; (b) sucrose (sucrose +  $\text{H}_2\text{O} \rightleftharpoons$  glucose + fructose:  $\Delta G^{\circ'} = -29.3 \text{ kJ} \cdot \text{mol}^{-1}$ ); and (c) ethyl acetate (ethyl acetate +  $\text{H}_2\text{O} \rightleftharpoons$  ethanol + acetate $^-$  +  $\text{H}^+$ :  $\Delta G^{\circ'} = -19.7 \text{ kJ} \cdot \text{mol}^{-1}$ ; the  $\text{p}K$  of acetic acid is 4.76).

**11.** Calculate the equilibrium constants for the hydrolysis of the following compounds at  $\text{pH } 7$  and  $25^\circ\text{C}$ : (a) phosphoenolpyruvate ( $\Delta G^{\circ'} = -61.9 \text{ kJ} \cdot \text{mol}^{-1}$ ); (b) pyrophosphate ( $\Delta G^{\circ'} = -33.5 \text{ kJ} \cdot \text{mol}^{-1}$ ); and (c) glucose-1-phosphate ( $\Delta G^{\circ'} = -20.9 \text{ kJ} \cdot \text{mol}^{-1}$ ).

**12.**  $\Delta G^{\circ'}$  for the isomerization reaction

is  $-7.1 \text{ kJ} \cdot \text{mol}^{-1}$ . Calculate the equilibrium ratio of [G1P] to [G6P] at  $25^\circ\text{C}$ .

**13.** For the reaction  $\text{A} \rightarrow \text{B}$  at  $298 \text{ K}$ , the change in enthalpy is  $-7 \text{ kJ} \cdot \text{mol}^{-1}$  and the change in entropy is  $-25 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ . Is the reaction spontaneous? If not, should the temperature be increased or decreased to make the reaction spontaneous?

**14.** Two biochemical reactions have the same  $K_{\text{eq}} = 5 \times 10^{-8}$  at temperature  $T_1 = 298 \text{ K}$ . However, reaction 1 has  $\Delta H^\circ = -28 \text{ kJ} \cdot \text{mol}^{-1}$  and Reaction 2 has  $\Delta H^\circ = +28 \text{ kJ} \cdot \text{mol}^{-1}$ . The two reactions utilize the same reactants. Your lab partner has proposed that you can get more of the reactants to proceed via Reaction 2 rather than Reaction 1 by lowering the temperature of the reaction. Will this strategy work? Why or why not? How much would the temperature have to be raised or lowered to change the value of  $K_2/K_1$  from 1 to 10?

## CHAPTER 4

### 1 The Amino Acids of Proteins

- A. General Properties
- B. Peptide Bonds
- C. Classification and Characteristics
- D. Acid–Base Properties
- E. A Few Words on Nomenclature

### 2 Optical Activity

- A. An Operational Classification
- B. The Fischer Convention
- C. The Cahn–Ingold–Prelog System
- D. Chirality and Biochemistry

### 3 “Nonstandard” Amino Acids

- A. Amino Acid Derivatives in Proteins
- B. Specialized Roles of Amino Acids

It is hardly surprising that much of the early biochemical research was concerned with the study of proteins. Proteins form the class of biological macromolecules that have the most well-defined physicochemical properties, and consequently they were generally easier to isolate and characterize than nucleic acids, polysaccharides, or lipids. Furthermore, proteins, particularly in the form of enzymes, have obvious biochemical functions. The central role that proteins play in biological processes has therefore been recognized since the earliest days of biochemistry. In contrast, the task of nucleic acids in the transmission and expression of genetic information was not realized until the late 1940s and their catalytic function only began to come to light in the 1980s, the role of lipids in biological membranes was not appreciated until the 1960s, and the biological functions of polysaccharides are still somewhat mysterious.

In this chapter we study the structures and properties of the monomeric units of proteins, the **amino acids**. It is from these substances that proteins are synthesized through processes that we discuss in Chapter 32. Amino acids are

**Figure 4-1** General structural formula for  $\alpha$ -amino acids. There are 20 different R groups in the commonly occurring amino acids (Table 4-1).

also energy metabolites and, in animals, many of them are essential nutrients (Chapter 26). In addition, as we shall see, many amino acids and their derivatives are of biochemical importance in their own right (Section 4-3B).

### 1 THE AMINO ACIDS OF PROTEINS

The analyses of a vast number of proteins from almost every conceivable source have shown that *all proteins are composed of the 20 “standard” amino acids listed in Table 4-1*. These substances are known as  **$\alpha$ -amino acids** because, with the exception of **proline**, they have a primary amino group and a carboxylic acid group substituent on the same carbon atom (Fig. 4-1; proline has a secondary amino group).

#### A. General Properties

The  $pK$  values of the 20 “standard”  $\alpha$ -amino acids of proteins are tabulated in Table 4-1. Here  $pK_1$  and  $pK_2$ , respectively, refer to the  $\alpha$ -carboxylic acid and  $\alpha$ -amino groups, and  $pK_R$  refers to the side groups with acid–base properties. Table 4-1 indicates that the  $pK$  values of the  $\alpha$ -carboxylic acid groups lie in a small range around 2.2 so that above pH 3.5 these groups are almost entirely in their carboxylate forms. The  $\alpha$ -amino groups all have  $pK$  values near 9.4 and are therefore almost entirely in their ammonium ion forms below pH 8.0. This leads to an important structural point: *In the physiological pH range, both the carboxylic acid and the amino groups of  $\alpha$ -amino acids are completely ionized* (Fig. 4-2). An amino acid can therefore act as either an acid or a base. Substances with this property are said to be **amphoteric** and are referred to as **ampholytes** (*amphoteric electrolytes*). In Section 4-1D, we shall delve a bit deeper into the acid–base properties of the amino acids.

**Figure 4-2** Zwitterionic form of the  $\alpha$ -amino acids that occurs at physiological pH values.

**Table 4-1** Covalent Structures and Abbreviations of the “Standard” Amino Acids of Proteins, Their Occurrence, and the p*K* Values of Their Ionizable Groups

<sup>e</sup>Both the neutral and protonated forms of histidine are present at pH 7.0 because its p*K*<sub>R</sub> is close to 7.0. The imidazole ring of histidine is numbered here according to the biochemistry convention. In the IUPAC convention, N3 of the biochemistry convention is designated N1 and the numbering increases clockwise around the ring.

<sup>f</sup>The three- and one-letter symbols for asparagine *or* aspartic acid are Asx and B, whereas for glutamine *or* glutamic acid they are Glx and Z. The one-letter symbol for an undetermined *or* “nonstandard” amino acid is X.

Molecules that bear charged groups of opposite polarity are known as **zwitterions** (German: *zwitter*, hybrid) or **dipolar ions**. The zwitterionic character of the  $\alpha$ -amino acids has been established by several methods including spectroscopic measurements and X-ray crystal structure determinations (in the solid state the  $\alpha$ -amino acids are zwitterionic because the basic amine group abstracts a proton from the nearby acidic carboxylic acid group). Because amino acids are zwitterions, their physical properties are characteristic of ionic compounds. For instance, most  $\alpha$ -amino acids have melting points near  $300^\circ\text{C}$ , whereas their nonionic derivatives usually melt around  $100^\circ\text{C}$ . Furthermore, amino acids, like other ionic compounds, are more soluble in polar solvents than in nonpolar solvents. Indeed, most  $\alpha$ -amino acids are very soluble in water but are largely insoluble in most organic solvents.

### B. Peptide Bonds

The  $\alpha$ -amino acids polymerize, at least conceptually, through the elimination of a water molecule as is indicated in Fig. 4-3. The resulting CO—NH linkage, which was independently characterized in 1902 by Emil Fischer and Franz Hofmeister, is known as a **peptide bond**. Polymers composed of two, three, a few (3–10), and many **amino acid residues** (alternatively called **peptide units**) are known, respectively, as **dipeptides**, **tripeptides**, **oligopeptides**, and **polypeptides**. These substances, however, are often referred to simply as “peptides.” *Proteins are molecules that consist of one or more polypeptide chains.* These polypeptides range in length from  $\sim 40$  to  $\sim 34,000$  amino acid residues (although few have more than 1500 residues) and, since the average mass of an amino acid residue is  $\sim 110$  D, have molecular masses that range from  $\sim 40$  to over  $\sim 3700$  kD.

*Polypeptides are linear polymers;* that is, each amino acid residue is linked to its neighbors in a head-to-tail fashion rather than forming branched chains. This observation reflects the underlying elegant simplicity of the way living systems construct these macromolecules for, as we shall see, the nucleic acids that encode the amino acid sequences

**Figure 4-3** Condensation of two  $\alpha$ -amino acids to form a dipeptide. The peptide bond is shown in red.

of polypeptides are also linear polymers. This permits the direct correspondence between the monomer (nucleotide) sequence of a nucleic acid and the monomer (amino acid) sequence of the corresponding polypeptide without the added complication of specifying the positions and sequences of any branching chains.

With 20 different choices available for each amino acid residue in a polypeptide chain, it is easy to see that a huge number of different protein molecules can exist. For example, for dipeptides, each of the 20 different choices for the first amino acid residue can have 20 different choices for the second amino acid residue, for a total of  $20^2 = 400$  distinct dipeptides. Similarly, for tripeptides, there are 20 possibilities for each of the 400 choices of dipeptides to yield a total of  $20^3 = 8000$  different tripeptides. A relatively small protein molecule consists of a single polypeptide chain of 100 residues. There are  $20^{100} = 1.27 \times 10^{130}$  possible unique polypeptide chains of this length, a quantity vastly greater than the estimated number of atoms in the universe ( $9 \times 10^{78}$ ). Clearly, nature can have made only a tiny fraction of the possible different protein molecules. Nevertheless, *the various organisms on Earth collectively synthesize an enormous number of different protein molecules whose great range of physicochemical characteristics stem largely from the varied properties of the 20 “standard” amino acids.*

### C. Classification and Characteristics

The most common and perhaps the most useful way of classifying the 20 “standard” amino acids is according to the polarities of their side chains (**R groups**). This is because proteins fold to their native conformations largely in response to the tendency to remove their hydrophobic side chains from contact with water and to solvate their hydrophilic side chains (Chapters 8 and 9). According to this classification scheme, there are three major types of amino acids: (1) those with nonpolar R groups, (2) those with uncharged polar R groups, and (3) those with charged polar R groups.

#### a. The Nonpolar Amino Acid Side Chains Have a Variety of Shapes and Sizes

Nine amino acids are classified as having nonpolar side chains. **Glycine** (which, when it was found to be a component of gelatin in 1820, was the first amino acid to be identified in protein hydrolyzates) has the smallest possible side chain, an H atom. **Alanine** (Fig. 4-4), **valine**, **leucine**, and **isoleucine** have aliphatic hydrocarbon side chains ranging in size from a methyl group for alanine to isomeric butyl groups for leucine and isoleucine. **Methionine** has a thiol ether side chain that resembles an *n*-butyl group in many of its physical properties (C and S have nearly equal electronegativities and S is about the size of a methylene group). **Proline**, a cyclic secondary amino acid, has conformational constraints imposed by the cyclic nature of its pyrrolidine side chain, which is unique among the “standard” 20 amino acids. **Phenylalanine**, with its phenyl moiety (Fig. 4-4), and **tryptophan**, with its indole group, contain

**Figure 4-4** Structures of the  $\alpha$ -amino acids alanine, glutamine, and phenylalanine. The amino acids are shown as ball-and-stick models embedded in their transparent space-filling models. The

atoms are colored according to type with C green, H white, N blue, and O red.

aromatic side chains, which are characterized by bulk as well as nonpolarity.

#### b. Uncharged Polar Side Chains Have Hydroxyl, Amide, or Thiol Groups

Six amino acids are commonly classified as having uncharged polar side chains. **Serine** and **threonine** bear hydroxylic R groups of different sizes. **Asparagine** and **glutamine** (Fig. 4-4) have amide-bearing side chains of different sizes. **Tyrosine** has a phenolic group, which, together with the aromatic groups of phenylalanine and tryptophan, accounts for most of the UV absorbance and fluorescence exhibited by proteins (Section 9-1Cb). **Cysteine** has a thiol group that is unique among the 20 amino acids in that it often forms a disulfide bond to another cysteine residue through the oxidation of their thiol groups (Fig. 4-5). This disulfide bond has great importance in protein structure: *It can join separate polypeptide chains or cross-link two cysteines in the same chain.* Two disulfide-linked cysteines are referred to in the older biochemical literature as the amino

acid **cystine** because they were originally thought to form a unique amino acid. However, the discovery that cystine residues arise through the cross-linking of two cysteine residues after polypeptide biosynthesis has occurred has caused the name cystine to become less commonly used.

#### c. Charged Polar Side Chains May Be Positively or Negatively Charged

Five amino acids have charged side chains. The basic amino acids are positively charged at physiological pH values; they are **lysine**, which has a butylammonium side chain, **arginine**, which bears a guanidino group, and **histidine**, which carries an imidazolium moiety. Of the 20  $\alpha$ -amino acids, only histidine, with  $pK_R = 6.0$ , ionizes within the physiological pH range. At pH 6.0, its imidazole side group is only 50% charged so that histidine is neutral at the basic end of the physiological pH range. As a consequence, histidine side chains often participate in the catalytic reactions of enzymes. The acidic amino acids, **aspartic acid** and **glutamic acid**, are negatively charged above pH 3; in their ionized state, they are often referred to as **aspartate** and **glutamate**. Asparagine and glutamine are, respectively, the amides of aspartic acid and glutamic acid.

The allocation of the 20 amino acids among the three different groups is, of course, somewhat arbitrary. For example, glycine and alanine, the smallest of the amino acids, and tryptophan, with its heterocyclic ring, might just as well be classified as uncharged polar amino acids. Similarly, tyrosine and cysteine, with their ionizable side chains, might also be thought of as charged polar amino acids, particularly at higher pH's, whereas asparagine and glutamine are nearly as polar as their corresponding carboxylates, aspartate and glutamate.

*The 20 amino acids vary considerably in their physicochemical properties such as polarity, acidity, basicity, aromaticity, bulk, conformational flexibility, ability to cross-link, ability to hydrogen bond, and chemical reactivity. These several characteristics, many of which are interrelated, are largely responsible for proteins' great range of properties.*

**Figure 4-5** The reaction linking two cysteine residues by a disulfide bond.

### D. Acid–Base Properties

Amino acids and proteins have conspicuous acid–base properties. The  $\alpha$ -amino acids have two or, for those with ionizable side groups, three acid–base groups. The titration curve of glycine, the simplest amino acid, is shown in Fig. 4-6. At low pH values, both acid–base groups of glycine are fully protonated so that it assumes the cationic form  $^+\text{H}_3\text{NCH}_2\text{COOH}$ . In the course of the titration with a strong base, such as NaOH, glycine loses two protons in the stepwise fashion characteristic of a polyprotic acid.

The  $pK$  values of glycine's two ionizable groups are sufficiently different so that the Henderson–Hasselbalch equation:

$$\text{pH} = \text{p}K + \log\left(\frac{[\text{A}^-]}{[\text{HA}]}\right) \quad [2.6]$$

closely approximates each leg of its titration curve. Consequently, the  $pK$  for each ionization step is that of the midpoint of its corresponding leg of the titration curve (Sections 2-2A & 2-2C): At pH 2.35 the concentrations of the cationic form,  $^+\text{H}_3\text{NCH}_2\text{COOH}$ , and the zwitterionic form,  $^+\text{H}_3\text{NCH}_2\text{COO}^-$ , are equal; similarly, at pH 9.78 the concentrations of the zwitterionic form and the anionic form,  $\text{H}_2\text{NCH}_2\text{COO}^-$ , are equal. Note that *amino acids never assume the neutral form in aqueous solution*.

The pH at which a molecule carries no net electric charge is known as its **isoelectric point,  $pI$** . For the  $\alpha$ -amino acids, the application of the Henderson–Hasselbalch equation indicates that, to a high degree of precision,

$$pI = \frac{1}{2} (\text{p}K_i + \text{p}K_j) \quad [4.1]$$

**Figure 4-6** Titration curve of glycine. Other monoamino, monocarboxylic acids ionize in a similar fashion. [After Meister, A., *Biochemistry of the Amino Acids* (2nd ed.), Vol. 1, p. 30, Academic Press (1965).]  See the Animated Figures

where  $K_i$  and  $K_j$  are the dissociation constants of the two ionizations involving the neutral species. For monoamino, monocarboxylic acids such as glycine,  $K_i$  and  $K_j$  represent  $K_1$  and  $K_2$ . However, for aspartic and glutamic acids,  $K_i$  and  $K_j$  are  $K_1$  and  $K_R$ , whereas for arginine, histidine, and lysine, these quantities are  $K_R$  and  $K_2$ .

Acetic acid's  $pK$  (4.76), which is typical of aliphatic monocarboxylic acids, is  $\sim 2.4$  pH units higher than the  $pK_1$  of its  $\alpha$ -amino derivative glycine. This large difference in  $pK$  values of the same functional group is caused, as is discussed in Section 2-2C, by the electrostatic influence of glycine's positively charged ammonium group; that is, its  $-\text{NH}_3^+$  group helps repel the proton from its COOH group. Conversely, glycine's carboxylate group increases the basicity of its amino group ( $pK_2 = 9.78$ ) with respect to that of glycine methyl ester ( $pK = 7.75$ ). However, the  $-\text{NH}_3^+$  groups of glycine and its esters are significantly more acidic than are aliphatic amines ( $pK \approx 10.7$ ) because of the electron-withdrawing character of the carboxyl group.

The electronic influence of one functional group on another is rapidly attenuated as the distance between the groups increases. Hence, the  $pK$  values of the  $\alpha$ -carboxylate groups of amino acids and the side chain carboxylates of aspartic and glutamic acids form a series that is progressively closer in value to the  $pK$  of an aliphatic monocarboxylic acid. Likewise, the ionization constant of lysine's side chain amino group is indistinguishable from that of an aliphatic amine.

#### a. Proteins Have Complex Titration Curves

The titration curves of the  $\alpha$ -amino acids with ionizable side chains, such as that of glutamic acid, exhibit the expected three  $pK$  values. However, the titration curves of polypeptides and proteins, an example of which is shown in Fig. 4-7, rarely provide any indication of individual  $pK$  values because of the large numbers of ionizable groups they represent (typically 30% of a protein's amino acid side chains are ionizable; Table 4-1). Furthermore, the covalent and three-dimensional structure of a protein may cause the  $pK$  of each ionizable group to shift by as much as several pH units from its value in the free  $\alpha$ -amino acid as a result of the electrostatic influence of nearby charged groups, medium effects arising from the proximity of groups of low dielectric constant, and the effects of hydrogen bonding associations. The titration curve of a protein is also a function of the salt concentration, as is shown in Fig. 4-7, because the salt ions act electrostatically to shield the side chain charges from one another, thereby attenuating these charge–charge interactions.

#### E. A Few Words on Nomenclature

The three-letter abbreviations for the 20 amino acid residues are given in Table 4-1. It is worthwhile memorizing these symbols because they are widely used throughout the biochemical literature, including this text. These abbreviations are, in most cases, taken from the first three letters of the corresponding amino acid's name; they are conversationally pronounced as read.

**Figure 4-7** Titration curves of the enzyme ribonuclease A at 25°C. The concentration of KCl is 0.01M for the blue curve, 0.03M for the red curve, and 0.15M for the green curve. [After Tanford, C. and Hauenstein, J.D., *J. Am. Chem. Soc.* **78**, 5287 (1956).]

The symbol **Glx** means Glu or Gln and, similarly, **Asx** means Asp or Asn. These ambiguous symbols stem from laboratory experience: Asn and Gln are easily hydrolyzed to aspartic acid and glutamic acid, respectively, under the acidic or basic conditions that are usually used to excise them from proteins. Therefore, without special precautions, we cannot determine whether a detected Glu was originally Glu or Gln, and likewise for Asp and Asn.

The one-letter symbols for the amino acids are also given in Table 4-1. This more compact code is often used when comparing the amino acid sequences of several similar proteins and hence should also be memorized. Note that the one-letter symbols are usually the first letter of the amino acid residue's name. However, for those sets of residues that have the same first letter, this is only true of the most abundant residue of the set.

Amino acid residues in polypeptides are named by dropping the suffix **-ine** in the name of the amino acid and replacing it by **-yl**. Polypeptide chains are described by starting at the amino terminus (known as the **N-terminus**) and sequentially naming each residue until the carboxyl terminus (the **C-terminus**) is reached. The amino acid at the C-terminus is given the name of its parent amino acid. Thus the compound shown in Fig. 4-8 is alanyltyrosylaspartylglycine. Of course such names for polypeptide chains of more than a few residues are extremely cumbersome. The use of abbreviations for amino acid residues partially relieves this problem. Thus the foregoing tetrapeptide is Ala-Tyr-Asp-Gly using the three-letter abbreviations and AYDG using the one-letter symbols. Note that these ab-

**Figure 4-8** The tetrapeptide Ala-Tyr-Asp-Gly.

brevisions are always written so that the N-terminus of the polypeptide chain is to the left and the C-terminus is to the right.

The various nonhydrogen atoms of the amino acid side chains are often named in sequence with the Greek alphabet ( $\alpha$ ,  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\epsilon$ ,  $\zeta$ ,  $\eta$ , ...) starting at the carbon atom adjacent to the peptide carbonyl group (the  $C_\alpha$  atom). Therefore, as Fig. 4-9 indicates, Glu has a  $\gamma$ -carboxyl group and Lys has a  $\zeta$ -amino group (alternatively known as an  $\epsilon$ -amino group because the N atom is substituent to  $C_\epsilon$ ). Unfortunately, this labeling system is ambiguous for several amino acids. Consequently, standard numbering schemes for organic molecules are also employed. These are indicated in Table 4-1 for the heterocyclic side chains.

## 2 OPTICAL ACTIVITY

The amino acids as isolated by the mild hydrolysis of proteins are, with the exception of glycine, all **optically active**; that is, they rotate the plane of plane-polarized light (see below).

*Optically active molecules have an asymmetry such that they are not superimposable on their mirror image in the same way that a left hand is not superimposable on its mirror image, a right hand.* This situation is characteristic of substances that contain tetrahedral carbon atoms that have four different substituents. The two such molecules

**Figure 4-9** Greek lettering scheme used to identify the atoms in the glutamyl and lysyl R groups.

**Figure 4-10** The two enantiomers of fluorochlorobromomethane. The four substituents are tetrahedrally arranged about the central atom with the dotted lines indicating that a substituent lies behind the plane of the paper, a triangular line indicating that it lies above the plane of the paper, and a thin line indicating that it lies in the plane of the paper. The mirror plane relating the enantiomers is represented by a vertical dashed line.

depicted in Fig. 4-10 are not superimposable since they are mirror images. The central atoms in such atomic constellations are known as **asymmetric centers** or **chiral centers** and are said to have the property of **chirality** (Greek: *cheir*, hand). The  $C_\alpha$  atoms of all the amino acids, with the exception of glycine, are asymmetric centers. Glycine, which has two H atoms substituent to its  $C_\alpha$  atom, is superimposable on its mirror image and is therefore not optically active.

Molecules that are nonsuperimposable mirror images are known as **enantiomers** of one another. Enantiomeric molecules are physically and chemically indistinguishable by most techniques. *Only when probed asymmetrically, for example, by plane-polarized light or by reactants that also contain chiral centers, can they be distinguished and/or differentially manipulated.*

There are three commonly used systems of nomenclature whereby a particular stereoisomer of an optically active molecule can be classified. These are explained in the following sections.

### A. An Operational Classification

Molecules are classified as **dextrorotatory** (Greek: *dexter*, right) or **levorotatory** (Greek: *laevus*, left) depending on

whether they rotate the plane of plane-polarized light clockwise or counterclockwise from the point of view of the observer. This can be determined by an instrument known as a **polarimeter** (Fig. 4-11). A quantitative measure of the optical activity of the molecule is known as its **specific rotation**:

$$[\alpha]_D^{25} = \frac{\text{observed rotation (degrees)}}{\text{optical path length (dm)} \times \text{concentration (g} \cdot \text{cm}^{-3})} \quad [4.2]$$

where the superscript 25 refers to the temperature at which polarimeter measurements are customarily made ( $25^\circ\text{C}$ ) and the subscript D indicates the monochromatic light that is traditionally employed in polarimetry, the so-called D-line in the spectrum of sodium (589.3 nm). Dextrorotatory and levorotatory molecules are assigned positive and negative values of  $[\alpha]_D^{25}$ . Dextrorotatory molecules are therefore designated by the prefix (+) and their levorotatory enantiomers have the prefix (-). In an equivalent but archaic nomenclature, the lowercase letters *d* (*dextro*) and *l* (*levo*) are used.

The sign and magnitude of a molecule's specific rotation depend on the structure of the molecule in a complicated and poorly understood manner. It is not yet possible to predict reliably the magnitude or even the sign of a given molecule's specific rotation. For example, proline, leucine, and arginine, which are isolated from proteins, have specific rotations in pure aqueous solutions of  $-86.2^\circ$ ,  $-10.4^\circ$ , and  $+12.5^\circ$ , respectively. Their enantiomers exhibit values of  $[\alpha]_D^{25}$  of the same magnitude but of opposite signs. As might be expected from the acid-base nature of the amino acids, these quantities vary with the solution pH.

A problem with this operational classification system for optical isomers is that it provides no presently interpretable indication of the **absolute configuration** (spatial arrangement) of the chemical groups about a chiral center. Furthermore, a molecule with more than one asymmetric center may have an optical rotation that is not obviously

**Figure 4-11** Schematic diagram of a polarimeter. This device is used to measure optical rotation.

related to the rotatory powers of the individual asymmetric centers. For this reason, the following relative classification scheme is more useful.

### B. The Fischer Convention

In this system, the configuration of the groups about an asymmetric center is related to that of **glyceraldehyde**, a molecule with one asymmetric center. By a convention introduced by Fischer in 1891, the (+) and (−) stereoisomers of glyceraldehyde are designated **D-glyceraldehyde** and **L-glyceraldehyde**, respectively (note the use of small uppercase letters). With the realization that there was only a 50% chance that he was correct, Fischer assumed that the configurations of these molecules were those shown in Fig. 4-12. Fischer also proposed a convenient shorthand notation for these molecules, known as **Fischer projections**, which are also given in Fig. 4-12. In the Fischer convention, horizontal bonds extend above the plane of the paper and vertical bonds extend below the plane of the paper as is explicitly indicated by the accompanying geometrical formulas.

The configuration of groups about a chiral center can be related to that of glyceraldehyde by chemically converting these groups to those of glyceraldehyde using reactions of known stereochemistry. For  $\alpha$ -amino acids, the arrangement of the amino, carboxyl, R, and H groups about the  $C_\alpha$  atom is related to that of the hydroxyl, aldehyde,  $CH_2OH$ , and H groups, respectively, of glyceraldehyde. In this way, L-glyceraldehyde and L- $\alpha$ -amino acids are said to have the same relative configurations (Fig. 4-13). Through the use of this method, the configurations of the

**Figure 4-12** Fischer convention configurations for naming the enantiomers of glyceraldehyde. Glyceraldehyde enantiomers are represented by geometric formulas (*top*) and their corresponding Fischer projection formulas (*bottom*). Note that in Fischer projections, all horizontal bonds point above the page and all vertical bonds point below the page. The mirror planes relating the enantiomers are represented by a vertical dashed line. (Fischer projection formulas, as traditionally presented, omit the central C symbolizing the chiral carbon atom. The Fischer projection formulas in this text, however, will generally have a central C.)

**Figure 4-13** Configurations of L-glyceraldehyde and L- $\alpha$ -amino acids.

$\alpha$ -amino acids can be described without reference to their specific rotations.

All  $\alpha$ -amino acids derived from proteins have the L stereochemical configuration; that is, they all have the same relative configuration about their  $C_\alpha$  atoms. In 1949, it was demonstrated by a then new technique in X-ray crystallography that Fischer's arbitrary choice was correct: The designation of the relative configuration of chiral centers is the same as their absolute configuration. The absolute configuration of L- $\alpha$ -amino acid residues may be easily remembered through the use of the "CORN crib" mnemonic that is diagrammed in Fig. 4-14.

#### a. Diastereomers Are Chemically and Physically Distinguishable

A molecule may have multiple asymmetric centers. For such molecules, the terms **stereoisomers** and **optical isomers** refer to molecules with different configurations about at least one of their chiral centers, but that are otherwise identical. The term enantiomer still refers to a molecule that is the mirror image of the one under consideration, that is, different in all its chiral centers. Since each asymmetric center in a chiral molecule can have two possible configurations, a molecule with  $n$  chiral centers has  $2^n$  different possible stereoisomers and  $2^{n-1}$  enantiomeric pairs. Threonine and isoleucine each have two chiral centers and hence  $2^2 = 4$  possible stereoisomers. The forms of threonine and isoleucine that are isolated from proteins, which are by convention called the L forms, are indicated in Table 4-1. The mirror images of the L forms are the D forms. Their other two optical isomers are said to be **diastereomers** (or **allo** forms) of the enantiomeric D and L forms. The relative

**Figure 4-14** "CORN crib" mnemonic for the hand of L-amino acids. Looking at the  $C_\alpha$  atom from its H atom substituent, its other substituents should read CO—R—N in the clockwise direction as shown. Here CO, R, and N, respectively, represent the carbonyl group, side chain, and main chain nitrogen atom. [After Richardson, J.S., *Adv. Protein Chem.* **34**, 171 (1981).]

**Figure 4-15** Fischer projections of threonine's four stereoisomers. The D and L forms are mirror images as are the D-allo and L-allo forms. D- and L-threonine are each diastereomers of both D-allo- and L-allo-threonine.

configurations of all four stereoisomers of threonine are given in Fig. 4-15. Note the following points:

1. The D-allo and L-allo forms are mirror images of each other, as are the D and L forms. Neither allo form is symmetrically related to either of the D or L forms.

2. In contrast to the case for enantiomeric pairs, diastereomers are physically and chemically distinguishable from one another by ordinary means such as melting points, spectra, and chemical reactivity; that is, they are really different compounds in the usual sense.

A special case of diastereoisomerism occurs when the two asymmetric centers are chemically identical. Two of the four Fischer projections of the sort shown in Fig. 4-15 then represent the same molecule. This is because the two asymmetric centers in this molecule are mirror images of each other. Such a molecule is superimposable on its mirror image and is therefore optically inactive. This so-called **meso** form is said to be **internally compensated**. The three optical isomers of cystine are shown in Fig. 4-16, where it can be seen that the D and L isomers are mirror images of each other as before. Only L-cystine occurs in proteins.

**Figure 4-16** The three stereoisomers of cystine. The D and L forms are related by mirror symmetry, whereas the meso form has internal mirror symmetry and therefore lacks optical activity.

### C. The Cahn-Ingold-Prelog System

Despite its usefulness, the Fischer scheme is awkward and often ambiguous for molecules with more than one asymmetric center. For this reason, the following absolute nomenclature scheme was formulated in 1956 by Robert Cahn, Christopher Ingold, and Vladimir Prelog. In this system, the four groups surrounding a chiral center are ranked according to a specific although arbitrary priority scheme: *Atoms of higher atomic number bonded to a chiral center are ranked above those of lower atomic number*. For example, the oxygen atom of an OH group takes precedence over the carbon atom of a CH<sub>3</sub> group that is bonded to the same chiral C atom. If any of the first substituent atoms are of the same element, the priority of these groups is established from the atomic numbers of the second, third, etc., atoms outward from the asymmetric center. Hence a CH<sub>2</sub>OH group takes precedence over a CH<sub>3</sub> group. There are other rules (given in the references and in many organic chemistry textbooks) for assigning priority ratings to substituents with multiple bonds or differing isotopes. The order of priority of some common functional groups is

Note that each of the groups substituent to a chiral center must have a different priority rating; otherwise the center could not be asymmetric.

The prioritized groups are assigned the letters W, X, Y, Z such that their order of priority rating is  $W > X > Y > Z$ . To establish the configuration of the chiral center, it is viewed from the asymmetric center toward the Z group (lowest priority). *If the order of the groups  $W \rightarrow X \rightarrow Y$  as seen from this direction is clockwise, then the configuration of the asymmetric center is designated (R)* (Latin: *rectus*, right). *If the order of  $W \rightarrow X \rightarrow Y$  is counterclockwise, the asymmetric center is designated (S)* (Latin: *sinister*, left). L-Glyceraldehyde is therefore designated (*S*)-glyceraldehyde (Fig. 4-17) and, similarly, L-alanine is (*S*)-alanine (Fig. 4-18). In fact, all the L-amino acids from proteins are (*S*)-amino acids, with the exception of L-cysteine, which is (*R*)-cysteine.

A major advantage of this so-called **Cahn-Ingold-Prelog** or (**RS**) system is that the chiralities of compounds with multiple asymmetric centers can be unambiguously described. Thus, in the (*RS*) system, L-threonine is (*2S,3R*)-threonine, whereas L-isoleucine is (*2S,3S*)-isoleucine (Fig. 4-19).

L-Glyceraldehyde (S)-Glyceraldehyde

**Figure 4-17** The structural formula of L-glyceraldehyde. Its equivalent (*RS*) system representation indicates that it is (*S*)-glyceraldehyde. In the latter drawing, the chiral C atom is represented by the large circle, and the H atom, which is located behind the plane of the paper, is represented by the smaller concentric dashed circle.

L-Alanine (S)-Alanine

**Figure 4-18** The structural formula of L-alanine. Its equivalent (*RS*) system representation indicates that it is (*S*)-alanine.

**Figure 4-19** Newman projection diagrams of the stereoisomers of threonine and isoleucine derived from proteins. Here the  $C_\alpha-C_\beta$  bond is viewed end on. The nearer atom,  $C_\alpha$ , is represented by the confluence of the three bonds to its substituents, whereas the more distant atom,  $C_\beta$ , is represented by a circle from which its three substituents project.

### a. Prochiral Centers Have Distinguishable Substituents

Two chemically identical substituents to an otherwise chiral tetrahedral center are geometrically distinct; that is, the center has no rotational symmetry so that it can be unambiguously assigned left and right sides. Consider, for example, the substituents to the C1 atom of ethanol (the  $\text{CH}_2$  group; Fig. 4-20a). If one of the H atoms were converted to another group (not  $\text{CH}_3$  or  $\text{OH}$ ), C1 would be a chiral center. The two H atoms are therefore said to be **prochiral**. If we arbitrarily assign the H atoms the subscripts *a* and *b* (Fig. 4-20), then  $\text{H}_b$  is said to be **pro-*R*** because in sighting from C1 toward  $\text{H}_a$  (as if it were the *Z* group of a chiral center), the order of priority of the other substituents de-

**Figure 4-20** Views of ethanol. (a) Note that  $\text{H}_a$  and  $\text{H}_b$ , although chemically identical, are distinguishable: Rotating the molecule by  $180^\circ$  about the vertical axis so as to interchange these two hydrogen atoms does not yield an indistinguishable view of the molecule because the rotation also interchanges the chemically different  $\text{OH}$  and  $\text{CH}_3$  groups. (b) Looking from C1 to  $\text{H}_a$ , the *pro-S* hydrogen atom (the dotted circle). (c) Looking from C1 to  $\text{H}_b$ , the *pro-R* hydrogen atom.

creases in a clockwise direction (Fig. 4-20b). Similarly,  $\text{H}_a$  is said to be **pro-*S*** (Fig. 4-20c).

Planar objects with no rotational symmetry also have the property of prochirality. For example, in many enzymatic reactions, stereospecific addition to a trigonal carbon atom occurs from a particular side of that carbon atom to yield a chiral center (Section 13-2A). If a trigonal carbon is facing the viewer such that the order of priority of its substituents decreases in a clockwise manner (Fig. 4-21a), that face is designated as the **re face** (after *rectus*). The opposite face is designated as the **si face** (after *sinister*) since the priorities of its substituents decrease in the counterclockwise direction (Fig. 4-21b). Comparison of Figs. 4-20b and 4-21a indicates that an H atom adding to the *re* side of acetaldehyde atom C1 occupies the *pro-R* position of the resulting tetrahedral center. Conversely, a *pro-S* H atom is generated by *si* side addition to this trigonal center (Figs. 4-20c and 4-21b).

Closely related compounds that have the same configurational representation under the Fischer DL convention may have different representations under the (*RS*) system. Consequently, we shall use the Fischer convention in most cases. The (*RS*) system, however, is indispensable for describing prochirality and stereospecific reactions, so we shall find it invaluable for describing enzymatic reactions.

**Figure 4-21** Views of acetaldehyde. (a) Its *re* face and (b) its *si* face.

### D. Chirality and Biochemistry

The ordinary chemical synthesis of chiral molecules produces **racemic** mixtures of these molecules (equal amounts of each member of an enantiomeric pair) because ordinary chemical and physical processes have no stereochemical bias. Consequently, there are equal probabilities for an asymmetric center of either hand to be produced in any such process. In order to obtain a product with net optical activity, a chiral process must be employed. This usually takes the form of using chiral reagents, although, at least in principle, the use of any asymmetric influence such as light that is plane polarized in one direction can produce a net asymmetry in a reaction product.

One of the most striking characteristics of life is its production of optically active molecules. *The biosynthesis of a substance possessing asymmetric centers almost invariably produces a pure stereoisomer.* The fact that the amino acid residues of proteins all have the L configuration is just one example of this phenomenon. This observation has prompted the suggestion that a simple diagnostic test for the past or present existence of extraterrestrial life, be it on moon rocks or in meteorites that have fallen to Earth, would be the detection of net optical activity in these materials. Any such finding would suggest that the asymmetric molecules thereby detected had been biosynthetically produced. Thus, even though  $\alpha$ -amino acids have been extracted from carbonaceous meteorites, the observation that they come in racemic mixtures suggests that they are of chemical rather than biological origin.

One of the enigmas of the origin of life is why terrestrial life is based on certain chiral molecules rather than their enantiomers, that is, on L-amino acids, for example, rather than D-amino acids. Arguments that physical effects such as polarized light might have promoted significant net asymmetry in prebiotically synthesized molecules (Section 1-5B) have not been convincing. Perhaps L-amino acid-based life-forms arose at random and simply “ate” any D-amino acid-based life-forms.

The importance of stereochemistry in living systems is also a concern of the pharmaceutical industry. *Many drugs are chemically synthesized as racemic mixtures, although only one enantiomer has biological activity.* In most cases, the opposite enantiomer is biologically inert and is therefore packaged along with its active counterpart. This is true, for example, of the widely used anti-inflammatory agent **ibuprofen**, only one enantiomer of which is physiologically active (Fig. 4-22). Occasionally, the inactive enan-

**Figure 4-22** **Ibuprofen.** Only the enantiomer shown has anti-inflammatory action. The chiral carbon is red.

**Thalidomide**

**Figure 4-23** **Thalidomide.** This drug was widely used in Europe as a mild sedative in the early 1960s. Its inactive enantiomer (not shown), which was present in equal amounts in the formulations used, causes severe birth defects in humans when taken during the first trimester of pregnancy. Thalidomide was often prescribed to alleviate the nausea (morning sickness) that is common during this period.

tiomer of a useful drug produces harmful effects and must therefore be eliminated from the racemic mixture. The most striking example of this is the drug **thalidomide** (Fig. 4-23), a mild sedative whose “inactive” enantiomer causes severe birth defects. Partly because of the unanticipated problems caused by “inactive” drug enantiomers, **chiral organic synthesis** has become an active area of medicinal chemistry.

### 3 “NONSTANDARD” AMINO ACIDS

The 20 common amino acids are by no means the only amino acids that occur in biological systems. “Nonstandard” amino acid residues are often important constituents of proteins and biologically active polypeptides. Many amino acids, however, are not constituents of proteins. Together with their derivatives, they play a variety of biologically important roles.

#### A. Amino Acid Derivatives in Proteins

The “universal” genetic code, which is nearly identical in all known life-forms (Section 5-4Bb), specifies only the 20 “standard” amino acids of Table 4-1. Nevertheless, many other amino acids, a selection of which is given in Fig. 4-24, are components of certain proteins. *In all known cases but two (Section 32-2De), however, these unusual amino acids result from the specific modification of an amino acid residue after the polypeptide chain has been synthesized.* Among the most prominent of these modified amino acid residues are **4-hydroxyproline** and **5-hydroxylysine**. Both of these amino acid residues are important structural constituents of the fibrous protein **collagen**, the most abundant protein in mammals (Section 8-2B). Amino acids of proteins that form complexes with nucleic acids are often modified. For example, the chromosomal proteins known as **histones** may be specifically methylated, acetylated, and/or phosphorylated at specific Lys, Arg, and Ser residues (Section 34-3Baa). Several of these derivatized

**Figure 4-24** Some uncommon amino acid residues that are components of certain proteins. All of these residues are modified from one of the 20 "standard" amino acids after polypeptide chain

biosynthesis. Those amino acid residues that are derivatized at their N<sub>α</sub> position occur at the N-termini of proteins.

amino acid residues are presented in Fig. 4-24. **N-Formylmethionine** is initially the N-terminal residue of all prokaryotic proteins, but is usually removed as part of the protein maturation process (Section 32-3Ca). **γ-Carboxyglutamic acid** is a constituent of several proteins involved in blood clotting (Section 35-1Ba). Note that in most cases, these modifications are important, if not essential, for the function of the protein.

D-Amino acid residues are components of many of the relatively short (<20 residues) bacterial polypeptides that are enzymatically rather than ribosomally synthesized. These polypeptides are perhaps most widely distributed as constituents of bacterial cell walls (Section 11-3Ba), which D-amino acids render less susceptible to attack by the **peptidases** (enzymes that hydrolyze peptide bonds) that many organisms employ to digest bacterial cell walls. Likewise, D-amino acids are components of many bacterially produced peptide antibiotics including **valinomycin**, **gramicidin A** (Section 20-2C), and **actinomycin D** (Section 31-2Cc).

D-Amino acid residues are also functionally essential components of several ribosomally synthesized polypeptides of eukaryotic as well as prokaryotic origin. These D-amino acid residues are posttranslationally formed, most probably through the enzymatically mediated inversion of the preexisting L-amino acid residues.

### B. Specialized Roles of Amino Acids

Besides their role in proteins, amino acids and their derivatives have many biologically important functions. A few examples of these substances are shown in Fig. 4-25. This alternative use of amino acids is an example of the biological opportunism that we shall repeatedly encounter: *Nature tends to adapt materials and processes that are already present to new functions.*

Amino acids and their derivatives often function as chemical messengers in the communications between cells. For example, glycine, **γ-aminobutyric acid (GABA)**; a glutamate

**Figure 4-25** Some biologically produced derivatives of “standard” amino acids and amino acids that are not components of proteins.

decarboxylation product), and **dopamine** (a tyrosine derivative) are neurotransmitters (substances released by nerve cells to alter the behavior of their neighbors; Section 20-5C); **histamine** (the decarboxylation product of histidine) is a potent local mediator of allergic reactions; and **thyroxine** (a tyrosine derivative) is an iodine-containing thyroid hormone that generally stimulates vertebrate metabolism (Section 19-1D).

*Certain amino acids are important intermediates in various metabolic processes.* Among them are **citrulline** and **ornithine**, intermediates in urea biosynthesis (Section 26-2B); **homocysteine**, an intermediate in amino acid metabolism

(Section 26-3Ea); and **S-adenosylmethionine**, a biological methylating reagent (Section 26-3Ea).

Nature’s diversity is remarkable. Over 700 different amino acids have been found in various plants, fungi, and bacteria, most of which are  $\alpha$ -amino acids. For the most part, their biological roles are obscure although the fact that many are toxic suggests that they have a protective function. Indeed, some of them, such as **azaserine**, are medically useful antibiotics. Many of these amino acids are simple derivatives of the 20 “standard” amino acids although some of them, including **azaserine** and  **$\beta$ -cyanoalanine** (Fig. 4-25), have unusual structures.

## CHAPTER SUMMARY

**1 The Amino Acids of Proteins** Proteins are linear polymers that are synthesized from the same 20 “standard”  $\alpha$ -amino acids through their condensation to form peptide bonds. These amino acids all have a carboxyl group with a  $pK$  near 2.2 and an amino substituent with a  $pK$  near 9.4 attached to the same carbon atom, the  $C_\alpha$  atom. The  $\alpha$ -amino acids are zwitterionic compounds,  $^+H_3N-CHR-COO^-$ , in the physiological pH range. The various amino acids are usually classified according to the polarities of their side chains, R, which are substituent to the  $C_\alpha$  atom. Glycine, alanine, valine, leucine, isoleucine, methionine, proline (which is really a secondary amino acid), phenylalanine, and tryptophan are nonpolar amino acids; serine, threonine, asparagine, glutamine, tyrosine, and cysteine are uncharged and polar; and lysine, arginine, histidine, aspartic acid, and glutamic acid are charged and polar. The side chains of many of these amino acids bear acid-base groups, and hence the properties of the proteins containing them are pH dependent.

**2 Optical Activity** The  $C_\alpha$  atoms of all  $\alpha$ -amino acids ex-

cept glycine each bear four different substituents and are therefore chiral centers. According to the Fischer convention, which relates the configuration of D- or L-glyceraldehyde to that of the asymmetric center of interest, all the amino acids of proteins have the L configuration; that is, they all have the same absolute configuration about their  $C_\alpha$  atom. According to the Cahn–Ingold–Prelog (*RS*) system of chirality nomenclature, they are, with the exception of cysteine, all (*S*)-amino acids. The side chains of threonine and isoleucine also contain chiral centers. A prochiral center has no rotational symmetry, and hence its substituents, in the case of a central atom, or its faces, in the case of a planar molecule, are distinguishable.

**3 “Nonstandard” Amino Acids** Amino acid residues other than the 20 from which proteins are synthesized also have important biological functions. These “nonstandard” residues result from the specific chemical modifications of amino acid residues in preexisting proteins. Amino acids and their derivatives also have independent biological roles such as neurotransmitters, metabolic intermediates, and poisons.

## PROBLEMS

- Name the 20 standard amino acids without looking them up. Give their three-letter and one-letter symbols. Identify the two standard amino acids that are isomers and the two others that, although not isomeric, have essentially the same molecular mass for the neutral molecules.
- Draw the following oligopeptides in their predominant ionic forms at pH 7: (a) Phe-Met-Arg, (b) tryptophanyllysylaspartic acid, and (c) Gln-Ile-His-Thr.
- How many different pentapeptides are there that contain one residue each of Gly, Asp, Tyr, Cys, and Leu?
- Draw the structures of the following two oligopeptides with their cysteine residues cross-linked by a disulfide bond: Val-Cys, Ser-Cys-Pro.
- What are the concentrations of the various ionic species in a 0.1M solution of lysine at pH 4, 7, and 10?
- Derive Eq. [4.1] for a monoamino, monocarboxylic acid (use the Henderson–Hasselbalch equation).
- The **isoionic point** of a compound is defined as the pH of a pure water solution of the compound. What is the isoionic point of a 0.1M solution of glycine?
- Normal human hemoglobin has an isoelectric point of 6.87. A mutant variety of hemoglobin, known as **sickle-cell hemoglobin**, has an isoelectric point of 7.09. The titration curve of hemoglobin indicates that, in this pH range, 13 groups change ionization states per unit change in pH. Calculate the difference in

ionic charge between molecules of normal and sickle-cell hemoglobin.

**9.** Indicate whether the following familiar objects are chiral, prochiral, or nonchiral.

- |                             |                               |
|-----------------------------|-------------------------------|
| (a) A glove                 | (g) A snowflake               |
| (b) A tennis ball           | (h) A spiral staircase        |
| (c) A good pair of scissors | (i) A flight of normal stairs |
| (d) A screw                 | (j) A paper clip              |
| (e) This page               | (k) A shoe                    |
| (f) A toilet paper roll     | (l) A pair of glasses         |

**10.** Draw four equivalent Fischer projection formulas for L-alanine (see Figs. 4-12 and 4-13).

**\*11.** (a) Draw the structural formula and the Fischer projection formula of (*S*)-3-methylhexane. (b) Draw all the stereoisomers of 2,3-dichlorobutane. Name them according to the (*RS*) system and indicate which of them has the meso form.

**12.** Identify and name the prochiral centers or faces of the following molecules:

- |             |                      |
|-------------|----------------------|
| (a) Acetone | (d) Alanine          |
| (b) Propene | (e) Lysine           |
| (c) Glycine | (f) 3-Methylpyridine |

**13.** Write out the dominant structural formula, at pH 12.0, of the pentapeptide Thr-Tyr-His-Cys-Lys. Indicate the positions of its chiral centers and its prochiral centers. Assume that the *pK*'s of its ionizable groups are the same as those in the corresponding free amino acid.

- I. Social, Ethical, and Legal Considerations

Knowledge of how genes are expressed and how they can be manipulated is becoming increasingly important for understanding nearly every aspect of biochemistry. Consequently, although we do not undertake a detailed discussion of these processes until Part V of this textbook, we outline their general principles in this chapter. We do so by describing the chemical structures of nucleic acids, how we have come to know that DNA is the carrier of genetic information, the structure of the major form of DNA, and the general principles of how the information in genes directs the synthesis of RNA and proteins (how genes are expressed) and how DNA is replicated. The chapter ends with a discussion of how DNA is experimentally manipulated and expressed, processes that are collectively referred to as genetic engineering. These processes have revolutionized the practice of biochemistry.

### 1 NUCLEOTIDES AND NUCLEIC ACIDS

**Nucleotides** and their derivatives are biologically ubiquitous substances that participate in nearly all biochemical processes:

1. They form the monomeric units of nucleic acids and thereby play central roles in both the storage and the expression of genetic information.

2. **Nucleoside triphosphates**, most conspicuously ATP (Section 1-3B), are the “energy-rich” end products of the majority of energy-releasing pathways and the substances whose utilization drives most energy-requiring processes.

3. Most metabolic pathways are regulated, at least in part, by the levels of nucleotides such as ATP and ADP. Moreover, certain nucleotides, as we shall see, function as intracellular signals that regulate the activities of numerous metabolic processes.

4. Nucleotide derivatives, such as **nicotinamide adenine dinucleotide** (Section 13-2A), **flavin adenine dinucleotide** (Section 16-2C), and **coenzyme A** (Section 21-2), are required participants in many enzymatic reactions.

5. As components of the enzymelike nucleic acids known as **ribozymes**, nucleotides have important catalytic activities themselves.

#### A. Nucleotides, Nucleosides, and Bases

*Nucleotides are phosphate esters of a five-carbon sugar (which is therefore known as a **pentose**; Section 11-1A) in which a nitrogenous base is covalently linked to C1' of the sugar residue. In **ribonucleotides** (Fig. 5-1a), the monomeric units of RNA, the pentose is **D-ribose**, whereas in **deoxyribonucleotides** (or just **deoxynucleotides**; Fig. 5-1b),*

**Figure 5-1** Chemical structures of (a) ribonucleotides and (b) deoxyribonucleotides.

the monomeric units of DNA, the pentose is **2'-deoxy-D-ribose** (note that the “primed” numbers refer to the atoms of the ribose residue; “unprimed” numbers refer to atoms of the nitrogenous base). The phosphate group may be bonded to C5' of the pentose to form a **5'-nucleotide** (Fig. 5-1) or to its C3' to form a **3'-nucleotide**. If the phosphate group is absent, the compound is known as a **nucleoside**. A 5'-nucleotide, for example, may therefore be referred to as a **nucleoside-5'-phosphate**. In all naturally occurring nucleotides and nucleosides, the bond linking the nitrogenous base to the pentose C1' atom (which is called a glycosidic bond; Section 11-1Ca) extends from the same side of the ribose ring as does the C4'—C5' bond (the so-called  $\beta$  configuration; Section 11-1Ba) rather than from the opposite side (the  $\alpha$  configuration). Note that nucleotide phosphate groups are doubly ionized at physiological pH's; that is, *nucleotides are moderately strong acids*.

The nitrogenous bases are planar, aromatic, heterocyclic molecules which, for the most part, are derivatives of either **purine** or **pyrimidine**.

Purine

Pyrimidine

The structures, names, and abbreviations of the common bases, nucleosides, and nucleotides are given in Table 5-1. The major purine components of nucleic acids are **adenine** and **guanine** residues; the major pyrimidine residues are those of **cytosine**, **uracil** (which occurs mainly in RNA), and **thymine** (5-methyluracil, which occurs mainly in DNA). The purines form glycosidic bonds to ribose via

**Table 5-1** Names and Abbreviations of Nucleic Acid Bases, Nucleosides, and Nucleotides

Base Formula	Base (X = H)	Nucleoside (X = ribose <sup>a</sup> )	Nucleotide <sup>b</sup> (X = ribose phosphate <sup>a</sup> )
	Adenine Ade A	Adenosine Ado A	Adenylic acid Adenosine monophosphate AMP
	Guanine Gua G	Guanosine Guo G	Guanylic acid Guanosine monophosphate GMP
	Cytosine Cyt C	Cytidine Cyd C	Cytidylic acid Cytidine monophosphate CMP
	Uracil Ura U	Uridine Urd U	Uridylic acid Uridine monophosphate UMP
	Thymine Thy T	Deoxythymidine dThd dT	Deoxythymidylic acid Deoxythymidine monophosphate dTMP

<sup>a</sup>The presence of a 2'-deoxyribose unit in place of ribose, as occurs in DNA, is implied by the prefixes “deoxy” or “d.” For example, the deoxynucleoside of adenine is deoxyadenosine or dA. However, for thymine-containing residues, which rarely occur in RNA, the prefix is redundant and may be dropped. The presence of a ribose unit may be explicitly implied by the prefixes “ribo” or “r.” Thus the ribonucleotide of thymine is ribothymidine or rT.

<sup>b</sup>The position of the phosphate group in a nucleotide may be explicitly specified as in, for example, 3'-AMP and 5'-GMP.

their N9 atoms, whereas pyrimidines do so through their N1 atoms (note that purines and pyrimidines have dissimilar atom numbering schemes).

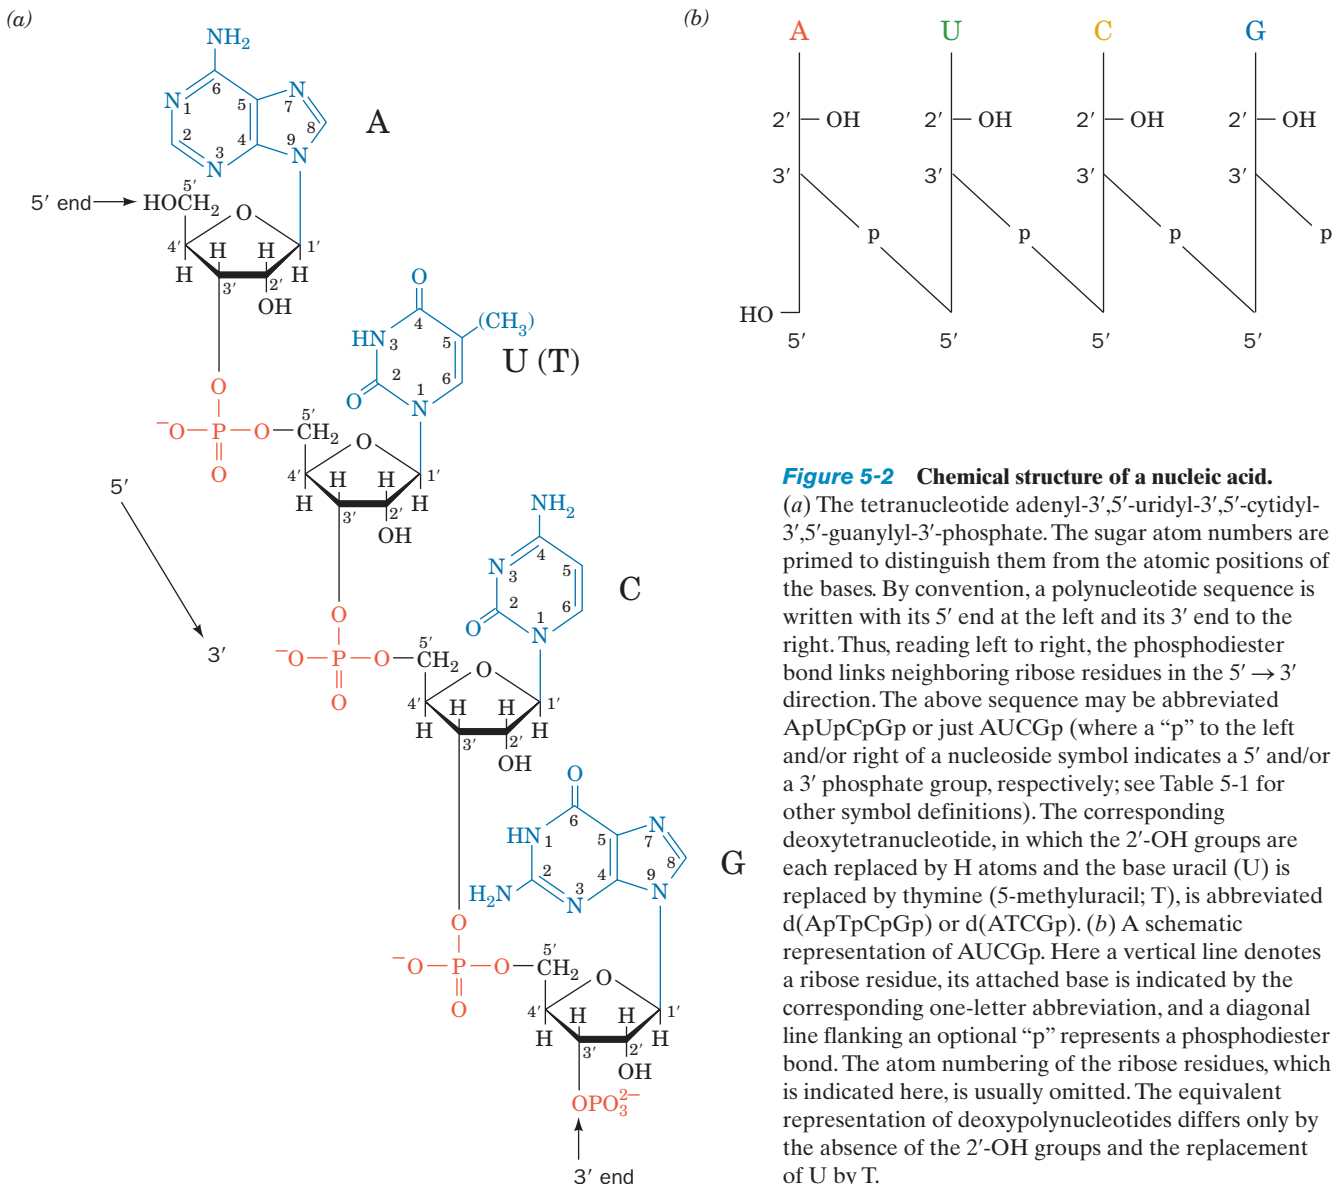

### B. The Chemical Structures of DNA and RNA

The chemical structures of the nucleic acids were elucidated by the early 1950s largely through the efforts of Phoebus Levene, followed by the work of Alexander Todd. *Nucleic acids are, with few exceptions, linear polymers of nucleotides whose phosphate groups bridge the 3' and 5' positions of successive sugar residues (e.g., Fig. 5-2).* The phosphates of these **polynucleotides**, the **phosphodiester** groups, are acidic, so that, *at physiological pH's, nucleic acids are polyanions.* Polynucleotides have directionality, that is, each has a **3' end** (the end whose C3' atom is not linked to a neighboring nucleotide) and a **5' end** (the end whose C5' atom is not linked to a neighboring nucleotide).

#### a. DNA's Base Composition Is Governed by Chargaff's Rules

*DNA has equal numbers of adenine and thymine residues ( $A = T$ ) and equal numbers of guanine and cytosine residues ( $G = C$ ).* These relationships, known as **Chargaff's rules**, were discovered in the late 1940s by Erwin Chargaff, who first devised reliable quantitative methods for the separation and analysis of DNA hydrolysates. Chargaff also found that the base composition of DNA from a given organism is characteristic of that organism; that is, it is independent of the tissue from which the DNA is taken as well as the organism's age, its nutritional state, or any other environmental factor. The structural basis for Chargaff's rules is that in double-stranded DNA, G is always hydrogen bonded (forms a **base pair**) with C, whereas A always forms a base pair with T (Fig. 1-16).

DNA's base composition varies widely among different organisms. It ranges from ~25% to 75% G + C in different

species of bacteria. It is, however, more or less constant among related species; for example, in mammals G + C ranges from 39% to 46%.

RNA, which usually occurs as single-stranded molecules, has no apparent constraints on its base composition. However, double-stranded RNA, which comprises the genetic material of certain viruses, also obeys Chargaff's rules (here A base pairs with U in the same way it does with T in DNA; Fig. 1-16). Conversely, single-stranded DNA, which occurs in certain viruses, does not obey Chargaff's rules. On entering its host organism, however, such DNA is replicated to form a double-stranded molecule, which then obeys Chargaff's rules.

### b. Nucleic Acid Bases May Be Modified

Some DNAs contain bases that are chemical derivatives of the standard set. For example, dA and dC in the DNAs of many organisms are partially replaced by *N*<sup>6</sup>-methyl-dA and 5-methyl-dC, respectively.

The altered bases are generated by the sequence-specific enzymatic modification of normal DNA (Sections 5-5A and 30-7). The modified DNAs obey Chargaff's rules if the derivatized bases are taken as equivalent to their parent bases. Likewise, many bases in RNAs and, in particular, those in transfer RNAs (tRNAs; Section 32-2Aa) are derivatized.

### c. RNA but Not DNA Is Susceptible to Base-Catalyzed Hydrolysis

RNA is highly susceptible to base-catalyzed hydrolysis by the reaction mechanism diagrammed in Fig. 5-3 so as to yield a mixture of 2' and 3' nucleotides. In contrast, DNA, which lacks 2'-OH groups, is resistant to base-catalyzed hydrolysis and is therefore much more chemically stable than RNA. This is probably why DNA rather than RNA evolved to be the cellular genetic archive.

## 2 DNA IS THE CARRIER OF GENETIC INFORMATION

Nucleic acids were first isolated in 1869 by Friedrich Miescher and so named because he found them in the nuclei of **leukocytes** (pus cells) from discarded surgical bandages. The presence of nucleic acids in other cells was demonstrated within a few years, but it was not until some 75 years after their discovery that their biological function was elucidated. Indeed, in the 1930s and 1940s it was widely held, in what was termed the **tetranucleotide hypothesis**, that nucleic acids have a monotonously repeating sequence of all four bases, so that they were not suspected of having a

**Figure 5-3** Mechanism of base-catalyzed RNA hydrolysis. The base-induced deprotonation of the 2'-OH group facilitates its nucleophilic attack on the adjacent phosphorus atom, thereby cleaving the RNA backbone. The resultant 2',3'-cyclic phosphate group subsequently hydrolyzes to either the 2' or the 3' phosphate.

genetic function. Rather, it was generally assumed that genes were proteins since proteins were the only biochemical entities that, at that time, seemed capable of the required specificity. In this section, we outline the experiments that established DNA's genetic role.

### A. Transforming Principle Is DNA

The virulent (capable of causing disease) form of pneumococcus (*Diplococcus pneumoniae*), a bacterium that causes pneumonia, is encapsulated by a gelatinous polysaccharide coating that contains the binding sites (known as **O-antigens**; Section 11-3Bc) through which it recognizes the cells it infects. Mutant pneumococci that lack this coating, because of a defect in an enzyme involved in its formation, are not pathogenic (capable of causing disease). The virulent and

**Figure 5-4 Pneumococci.** The large glistening colonies are virulent S-type pneumococci that resulted from the transformation of nonpathogenic R-type pneumococci (smaller colonies) by DNA from heat-killed S pneumococci. [From Avery, O.T., MacLeod, C.M., and McCarty, M., *J. Exp. Med.* **79**, 153 (1944). Copyright © 1944 by Rockefeller University Press.]

nonpathogenic pneumococci are known as the S and R forms, respectively, because of the smooth and rough appearances of their colonies in culture (Fig. 5-4).

In 1928, Frederick Griffith made a startling discovery. He injected mice with a mixture of live R and heat-killed S pneumococci. This experiment resulted in the death of most of the mice. More surprising yet was that the blood of the dead mice contained live S pneumococci. The dead S pneumococci initially injected into the mice had somehow **transformed** the otherwise innocuous R pneumococci to the virulent S form. Furthermore, the progeny of the transformed pneumococci were also S; the transformation was permanent. Eventually, it was shown that the transformation could also be made *in vitro* (outside a living organism; literally “in glass”) by mixing R cells with a cell-free extract of S cells. The question remained: What is the nature of the **transforming principle**?

In 1944, Oswald Avery, Colin MacLeod, and Maclyn McCarty, after a 10-year investigation, reported that *transforming principle is DNA*. The conclusion was based on the observations that the laboriously purified (few modern fractionation techniques were then available) transforming principle had all the physical and chemical properties of DNA, contained no detectable protein, was unaffected by enzymes that catalyze the hydrolysis of proteins and RNA, and was totally inactivated by treatment with an enzyme that catalyzes the hydrolysis of DNA. *DNA must therefore be the carrier of genetic information.*

Avery’s discovery was another idea whose time had not yet come. This seminal advance was initially greeted with skepticism and then largely ignored. Indeed, even Avery did not directly state that DNA is the hereditary material but merely that it has “biological specificity.” His work, however, influenced several biochemists, including Erwin Chargaff, whose subsequent accurate determination of DNA base ratios refuted the tetranucleotide hypothesis and thereby indicated that DNA could be a complex molecule.

It was eventually demonstrated that eukaryotes are also subject to transformation by DNA. Thus DNA, which cyto-

**Figure 5-5 Transgenic mouse.** The gigantic mouse (*left*) grew from a fertilized ovum that had been microinjected with DNA bearing the rat growth hormone gene. His normal-sized littermate (*right*) is shown for comparison. [Courtesy of Ralph Brinster, University of Pennsylvania.]

logical studies had shown resides in the chromosomes, must also be the hereditary material of eukaryotes. In a spectacular demonstration of eukaryotic transformation, Ralph Brinster, in 1982, microinjected DNA bearing the gene for rat **growth hormone** (a polypeptide) into the nuclei of fertilized mouse eggs (a technique discussed in Section 5-5H) and implanted these eggs into the uteri of foster mothers. The resulting “supermice” (Fig. 5-5), which had high levels of rat growth hormone in their serum, grew to nearly twice the weight of their normal littermates. Such genetically altered animals are said to be **transgenic**.

### B. The Hereditary Molecule of Many Bacteriophages Is DNA

Electron micrographs of bacteria infected with bacteriophages show empty-headed phage “ghosts” attached to the bacterial surface (Fig. 5-6). This observation led Roger Herriott to suggest that “the virus may act like a little hypodermic needle full of transforming principle,” which it in-

**Figure 5-6 Bacteriophages attached to the surface of a bacterium.** This early electron micrograph shows an *E. coli* cell to which **bacteriophage T5** are adsorbed by their tails. [Courtesy of Thomas F. Anderson, Fox Chase Cancer Center.]

**Figure 5-7** Diagram of T2 bacteriophage injecting its DNA into an *E. coli* cell.

jects into the bacterial host (Fig. 5-7). This proposal was tested in 1952 by Alfred Hershey and Martha Chase as is diagrammed in Fig. 5-8. **Bacteriophage T2** was grown on *E. coli* in a medium containing the radioactive isotopes  $^{32}\text{P}$  and  $^{35}\text{S}$ . This labeled the phage capsid, which contains no P, with  $^{35}\text{S}$ , and its DNA, which contains no S, with  $^{32}\text{P}$ . These phages were added to an unlabeled culture of *E. coli* and, after sufficient time was allowed for the phages to infect the bacterial cells, the culture was agitated in a kitchen blender so as to shear the phage ghosts from the bacterial cells. This rough treatment neither injured the bacteria nor altered the course of the phage infection. When the phage ghosts were separated from the bacteria (by centrifugation; Section 6-5), the ghosts were found to contain most of the  $^{35}\text{S}$ , whereas the bacteria contained most of the  $^{32}\text{P}$ . Furthermore, 30% of the  $^{32}\text{P}$  appeared in the progeny phages but only 1% of the  $^{35}\text{S}$  did so. Hershey and Chase therefore concluded that only the phage DNA was essential for the production of progeny. *DNA therefore must be the hereditary material.* In later years it was shown that, in a process known as **transfection**, purified phage DNA can, by itself, induce a normal phage infection of a properly treated bacterial host (transfection differs from transformation in that the latter results from the recombination of the bacterial chromosome with a fragment of homologous DNA).

In 1952, the state of knowledge of biochemistry was such that Hershey's discovery was much more readily accepted than Avery's identification of the transforming principle had been some 8 years earlier. Within a few months, the first speculations arose as to the nature of the **genetic**

**Figure 5-8** The Hershey–Chase experiment. This experiment demonstrated that only the nucleic acid component of bacteriophages enters the bacterial host during phage infection.

**code** (the correspondence between the base sequence of a gene and the amino acid sequence of a protein, Section 5-4Bb), and James Watson and Francis Crick were inspired to investigate the structure of DNA. In 1955, it was shown that the somatic cells of eukaryotes have twice the DNA of the corresponding germ cells. When this observation was proposed to be a further indicator of DNA's genetic role, there was little comment even though the same could be said of any other chromosomal component.

### 3 DOUBLE HELICAL DNA

The determination of the structure of DNA by Watson and Crick in 1953 is often said to mark the birth of modern molecular biology. The **Watson–Crick structure** of DNA is of such importance because, in addition to providing the structure of what is arguably the central molecule of life, it suggested the molecular mechanism of heredity. Watson and Crick's accomplishment, which is ranked as one of science's major intellectual achievements, tied together the less than universally accepted results of several diverse studies:

1. **Chargaff's rules.** At the time, the relationships  $A = T$  and  $G = C$  were quite obscure because their significance was not apparent. In fact, even Chargaff did not emphasize them.

2. **Correct tautomeric forms of the bases.** X-ray, nuclear magnetic resonance (NMR), and spectroscopic investigations have firmly established that the nucleic acid bases are overwhelmingly in the keto tautomeric forms shown in Table 5-1. In 1953, however, this was not generally appreciated. Indeed, guanine and thymine were widely believed to be in their enol forms (Fig. 5-9) because it was thought that the resonance stability of these aromatic molecules would thereby be maximized. Knowledge of the dominant tautomeric forms, which

**Figure 5-9** Some possible tautomeric conversions for bases. (a) Thymine and (b) guanine residues. Cytosine and adenine residues can undergo similar proton shifts.

was prerequisite for the prediction of the correct hydrogen bonding associations of the bases, was provided by Jerry Donohue, an office mate of Watson and Crick and an expert on the X-ray structures of small organic molecules.

3. **Information that DNA is a helical molecule.** This was provided by an X-ray diffraction photograph of a DNA fiber taken by Rosalind Franklin (Fig. 5-10; DNA, being a thread-like molecule, does not crystallize but, rather, can be drawn out in fibers consisting of parallel bundles of molecules). This photograph enabled Crick, an X-ray crystallographer by training who had earlier derived the equations describing diffraction by helical molecules, to deduce (a) that DNA is a helical molecule and (b) that its planar aromatic bases form a stack of parallel rings which is parallel to the fiber axis.

This information only provided a few crude landmarks that guided the elucidation of the DNA structure. It mostly sprang from Watson and Crick's imaginations through model building studies. Once the Watson–Crick model had been published, however, its basic simplicity combined with its obvious biological relevance led to its rapid acceptance. Later investigations have confirmed the essential correctness of the Watson–Crick model, although its details have been modified.

#### A. The Watson–Crick Structure: B-DNA

Fibers of DNA assume the so-called B conformation, as indicated by their X-ray diffraction patterns, when the counterion is an alkali metal such as  $\text{Na}^+$  and the relative humidity is  $>92\%$ . **B-DNA** is regarded as the *native* (biologically functional) form of DNA because, for example, its X-ray pattern resembles that of the DNA in intact sperm heads.

**Figure 5-10** X-ray diffraction photograph of a vertically oriented  $\text{Na}^+$  DNA fiber in the B conformation taken by Rosalind Franklin. This is the photograph that provided key information for the elucidation of the Watson–Crick structure. The central X-shaped pattern of spots is indicative of a helix, whereas the heavy black arcs on the top and bottom of the diffraction pattern correspond to a distance of  $3.4 \text{ \AA}$  and indicate that the DNA structure largely repeats every  $3.4 \text{ \AA}$  along the fiber axis. [Courtesy of Maurice Wilkins, King's College, London.]

The Watson–Crick structure of B-DNA has the following major features:

1. It consists of two polynucleotide strands that wind about a common axis with a right-handed twist to form an  $\sim 20\text{-\AA}$ -diameter double helix (Fig. 5-11). The two strands are antiparallel (run in opposite directions) and wrap around each other such that they cannot be separated without unwinding the helix. The bases occupy the core of the helix and the sugar–phosphate chains are coiled about its periphery, thereby minimizing the repulsions between charged phosphate groups.

2. The planes of the bases are nearly perpendicular to the helix axis. Each base is hydrogen bonded to a base on the opposite strand to form a planar base pair (Fig. 5-11). It is these hydrogen bonding interactions, a phenomenon

known as **complementary base pairing**, that result in the specific association of the two chains of the double helix.

3. The “ideal” B-DNA helix has 10 base pairs (**bp**) per turn (a helical twist of  $36^\circ$  per bp) and, since the aromatic bases have van der Waals thicknesses of  $3.4\text{ \AA}$  and are partially stacked on each other (**base stacking**, Fig. 5-11), the helix has a **pitch** (rise per turn) of  $34\text{ \AA}$ .

The most remarkable feature of the Watson–Crick structure is that it can accommodate only two types of base pairs: Each adenine residue must pair with a thymine residue and vice versa, and each guanine residue must pair with a cytosine residue and vice versa. The geometries of these A · T and G · C base pairs, the so-called **Watson–Crick base pairs**, are shown in Fig. 5-12. It can be seen that both of these base pairs are interchangeable in that they can replace each other in the double helix without altering the positions of the sugar–phosphate backbone’s

**Figure 5-11** Three-dimensional structure of B-DNA. The repeating helix in this ball-and-stick drawing is based on the X-ray structure of the self-complementary dodecamer d(CGCGAATTCGCG) determined by Richard Dickerson and Horace Drew. The view is perpendicular to the helix axis. The sugar–phosphate backbones (blue with blue-green ribbon outlines) wind about the periphery of the molecule in opposite directions. The bases (red), which occupy its core, form hydrogen bonded base pairs. H atoms have been omitted for clarity. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

See Interactive Exercise 1 and Kinemage 2-1

**Figure 5-12** Watson–Crick base pairs. The line joining the C1' atoms is the same length in both base pairs and makes equal angles with the glycosidic bonds to the bases. This gives DNA a series of pseudo-twofold symmetry axes (often referred to as **dyad axes**) that pass through the center of each base pair (red line) and are perpendicular to the helix axis. Note that A · T base pairs associate via two hydrogen bonds, whereas C · G base pairs are joined by three hydrogen bonds. [After Arnott, S., Dover, S.D., and Wonacott, A.J., *Acta Cryst.* **B25**, 2192 (1969).] See Kinemages 2-2 and 17-2

*C1'* atoms. Likewise, the double helix is undisturbed by exchanging the partners of a Watson–Crick base pair, that is, by changing a  $G \cdot C$  to a  $C \cdot G$  or an  $A \cdot T$  to a  $T \cdot A$ . In contrast, any other combination of bases (e.g.,  $A \cdot G$  or  $A \cdot C$ ) would significantly distort the double helix since the formation of a non-Watson–Crick base pair would require considerable reorientation of the sugar–phosphate chain.

B-DNA has two deep exterior grooves that wind between its sugar–phosphate chains as a consequence of the helix axis passing through the approximate center of each base pair. However, the grooves are of unequal size (Fig. 5-11) because (1) the top edge of each base pair, as drawn in Fig. 5-12, is structurally distinct from the bottom edge; and (2) the deoxyribose residues are asymmetric. The **minor groove** exposes that edge of a base pair from which its  $C1'$  atoms extend (opening toward the bottom in Fig. 5-12), whereas the **major groove** exposes the opposite edge of each base pair (the top of Fig. 5-12).

Although B-DNA is, by far, the most prevalent form of DNA in the cell, double helical DNAs and RNAs can assume several distinct structures. The structures of these other double helical nucleic acids are discussed in Section 29-1B.

### B. DNA Is Semiconservatively Replicated

The Watson–Crick structure can accommodate any sequence of bases on one polynucleotide strand if the opposite strand has the complementary base sequence. This immediately accounts for Chargaff's rules. More importantly, it suggests that hereditary information is encoded in the sequence of bases on either strand. Furthermore, each polynucleotide strand can act as a template for the formation of its complementary strand through base pairing interactions (Fig. 1-17). The two strands of the parent molecule must therefore separate so that a complementary daughter strand may be enzymatically synthesized on the surface of each parent strand. This results in two molecules of **duplex** (double-stranded) DNA, each consisting of one polynucleotide strand from the parent molecule and a newly synthesized complementary strand. Such a mode of replication is termed **semiconservative** in contrast with **conservative** replication, which, if it occurred, would result in a newly synthesized duplex copy of the original DNA molecule with the parent DNA molecule remaining intact. The mechanism of DNA replication is the main subject of Chapter 30.

The semiconservative nature of DNA replication was elegantly demonstrated in 1958 by Matthew Meselson and Franklin Stahl. The density of DNA was increased by labeling it with  $^{15}\text{N}$ , a heavy isotope of nitrogen ( $^{14}\text{N}$  is the naturally abundant isotope). This was accomplished by growing *E. coli* for 14 generations in a medium that contained  $^{15}\text{NH}_4\text{Cl}$  as the only nitrogen source. The labeled bacteria were then abruptly transferred to an  $^{14}\text{N}$ -containing medium, and the density of their DNA was monitored as a function of bacterial growth by **equilibrium density gradi-**

**ent ultracentrifugation** (a technique for separating macromolecules according to their densities, which Meselson, Stahl, and Jerome Vinograd had developed for the purpose of distinguishing  $^{15}\text{N}$ -labeled DNA from unlabeled DNA; Section 6-5Bb).

The results of the Meselson–Stahl experiment are displayed in Fig. 5-13. After one generation (doubling of the cell population), all of the DNA had a density exactly halfway between the densities of fully  $^{15}\text{N}$ -labeled DNA and unlabeled DNA. This DNA must therefore contain equal amounts of  $^{14}\text{N}$  and  $^{15}\text{N}$ , as is expected after one generation of semiconservative replication. Conservative DNA replication, in contrast, would result in the preservation of the parental DNA, so that it maintained its original density, and the generation of an equal amount of unlabeled DNA. After two generations, half of the DNA molecules were unlabeled and the remainder were  $^{14}\text{N}$ – $^{15}\text{N}$  hybrids. This is also in accord with the predictions of the semiconservative replication model and in disagreement with the conservative replication model. In succeeding generations, the amount of unlabeled DNA increased relative to the amount of hybrid DNA, although the hybrid never totally disappeared. This is again in harmony with semiconservative replication but at odds with conservative replication, which predicts that the fully labeled parental DNA will always be present and that hybrid DNA never forms.

### C. Denaturation and Renaturation

When a solution of duplex DNA is heated above a characteristic temperature, its native structure collapses and its two complementary strands separate and assume a flexible and rapidly fluctuating conformational state known as a **random coil** (Fig. 5-14). This **denaturation** process is accompanied by a qualitative change in the DNA's physical properties. For instance, the characteristic high viscosity of native DNA solutions, which arises from the resistance to deformation of its rigid and rodlike duplex molecules, drastically decreases when the duplex DNA decomposes (denatures) to two relatively freely jointed single strands.

#### a. DNA Denaturation Is a Cooperative Process

The most convenient way of monitoring the amount of nucleic acid present is by its ultraviolet (UV) absorbance spectrum. A solution containing a solute that absorbs light does so according to the **Beer–Lambert law**,

$$A = -\log\left(\frac{I}{I_0}\right) = \epsilon cl \quad [5.1]$$

where  $A$  is the solute's **absorbance** (alternatively, its **optical density**),  $I_0$  is the incident intensity of light at a given wavelength  $\lambda$ ,  $I$  is its transmitted intensity at  $\lambda$ ,  $\epsilon$  is the **molar extinction coefficient** of the solute at  $\lambda$ ,  $c$  is its molar concentration, and  $l$  is the length of the light path in centimeters. The value of  $\epsilon$  varies with  $\lambda$ ; a plot of  $\epsilon$  versus  $\lambda$  for the

**Figure 5-13** Demonstration of the semiconservative nature of DNA replication in *E. coli* by density gradient ultracentrifugation. The DNA was dissolved in an aqueous CsCl solution of density  $1.71 \text{ g} \cdot \text{cm}^{-3}$  and was subjected to an acceleration of 140,000 times that of gravity in an analytical ultracentrifuge (a device in which the rapidly spinning sample can be optically observed). This enormous acceleration induced the CsCl to redistribute in the solution such that its concentration increased with its radius in the ultracentrifuge. Consequently, the DNA migrated within the resulting density gradient to its position of buoyant density. The left panels are ultraviolet absorption photographs of ultracentrifuge cells (DNA strongly absorbs ultraviolet light) and are arranged such that regions of equal density have the same horizontal positions. The middle panels

are microdensitometer traces of the corresponding photographs in which the vertical displacement is proportional to the DNA concentration. The buoyant density of DNA increases with its  $^{15}\text{N}$  content. The bands farthest to the right (of greatest radius and density) arise from DNA that is fully  $^{15}\text{N}$  labeled, whereas unlabeled DNA, which is  $0.014 \text{ g} \cdot \text{cm}^{-3}$  less dense, forms the leftmost bands. The bands in the intermediate position result from duplex DNA in which one strand is  $^{15}\text{N}$ -labeled and the other strand is unlabeled. The accompanying interpretive drawings (right) indicate the relative numbers of DNA strands at each generation donated by the original parents (blue,  $^{15}\text{N}$  labeled) and synthesized by succeeding generations (red, unlabeled). [From Meselson, M. and Stahl, F.W., *Proc. Natl. Acad. Sci.* **44**, 671 (1958).]  See the Animated Figures

**Figure 5-14** Schematic representation of the strand separation in duplex DNA resulting from its heat denaturation.

solute is called its **absorbance spectrum**. The absorbance spectra of the five nucleic acid bases are shown in Fig. 5-15a. The spectra of the corresponding nucleosides and nucleotides are closely similar above 190 nm because, in this wavelength range, the molar extinction coefficients of ribose and phosphate groups are vanishingly small relative to those of the aromatic bases. As expected, the spectrum of native DNA (Fig. 5-15b) resembles that of its component bases in shape.

When DNA denatures, its UV absorbance increases by ~40% at all wavelengths (Fig. 5-15b). This phenomenon, which is known as the **hyperchromic effect** (Greek: *hyper*, above + *chroma*, color), results from the disruption of the electronic interactions among nearby bases. DNA's hyperchromic shift, as monitored at a particular wavelength (usually 260 nm), occurs over a narrow temperature range (Fig. 5-16). This indicates that the collapse of one part of the duplex DNA's structure destabilizes the remainder, a phenomenon known as a **cooperative process**. The denaturation of DNA may be described as the melting of a one-

**Figure 5-15** UV absorbance spectra of the nucleic acid bases and DNA. (a) Spectra of adenine, guanine, cytosine, thymine, and uracil near pH 7. (b) Spectra of native and heat-denatured *E. coli* DNA. Note that denaturation does not change the general shape of the absorbance spectrum but increases its absorbance at all wavelengths. [After Voet, D., Gratzer, W.B., Cox, R.A., and Doty, P., *Biopolymers* **1**, 193 (1963).]  See the Animated Figures

**Figure 5-16** Example of a DNA melting curve. The relative absorbance is the ratio of the absorbance (customarily measured at 260 nm) at the indicated temperature to that at 25°C. The melting temperature,  $T_m$ , is defined as the temperature at which half of the maximum absorbance increase is attained.  See the Animated Figures

dimensional solid, so Fig. 5-16 is referred to as a **melting curve** and the temperature at its midpoint is known as the **melting temperature,  $T_m$** .

The stability of the DNA double helix, and hence its  $T_m$ , depends on several factors, including the nature of the solvent, the identities and concentrations of the ions in solution, and the pH. For example, duplex DNA denatures (its  $T_m$  decreases) under alkaline conditions that cause some of the bases to ionize and thereby disrupt their base pairing interactions. The  $T_m$  increases linearly with the mole fraction of G · C base pairs (Fig. 5-17), which indicates that triply hydrogen bonded G · C base pairs are more stable than doubly hydrogen bonded A · T base pairs.

#### b. Denatured DNA Can Be Renatured

If a solution of denatured DNA is rapidly cooled to well below its  $T_m$ , the resulting DNA will be only partially base paired (Fig. 5-18) because its complementary strands will not have had sufficient time to find each other before the partially base paired structures become effectively “frozen in.” If, however, the temperature is maintained  $\sim 25^\circ\text{C}$  below the  $T_m$ , enough thermal energy is available for short base paired regions to rearrange by melting and reforming but not enough to melt out long complementary stretches. Under such **annealing conditions**, as Julius Marmur discovered in 1960, denatured DNA eventually

**Figure 5-17** Variation of the melting temperatures,  $T_m$ , of DNA with its G + C content. The DNAs were dissolved in a solution containing 0.15M NaCl and 0.015M sodium citrate. [After Marmur, J. and Doty, P., *J. Mol. Biol.* **5**, 113 (1962).]

completely renatures. Likewise, complementary strands of RNA and DNA, in a process known as **hybridization**, form RNA–DNA hybrid double helices that are only slightly less stable than the corresponding DNA double helices.

**Figure 5-18** Partially renatured DNA. A schematic representation showing the imperfectly base paired structures assumed by DNA that has been heat denatured and then rapidly cooled to well below its  $T_m$ . Note that both intramolecular and intermolecular aggregation may occur.

### D. The Size of DNA

DNA molecules are generally enormous (Fig. 5-19). The molecular mass of DNA has been determined by a variety of techniques including ultracentrifugation (Section 6-5A) and through length measurements by electron microscopy [a base pair of Na<sup>+</sup> B-DNA has an average molecular mass of 660 D and a length (thickness) of 3.4 Å] and **autoradiography** (a technique in which the position of a radioactive substance in a sample is recorded by the blackening of a photographic emulsion that the sample is laid over or embedded in; Fig. 5-20). The number of base pairs and the **contour lengths** (the end-to-end lengths of the stretched-out native molecules) of the DNAs from a selection of organisms of increasing complexity are listed in Table 5-2. Not surprisingly, an organism's haploid quantity (unique amount) of DNA varies more or less with its complexity (although there are notable exceptions to this generalization, such as the last entry in Table 5-2).

The visualization of DNAs from prokaryotes has demonstrated that their entire **genome** (complement of genetic information) is contained on a single, often circular, length of DNA. Similarly, Bruno Zimm demonstrated that the *largest chromosome of the fruit fly *Drosophila melanogaster* contains a single molecule of DNA* by comparing the molecular mass of this DNA with the cytologically measured length of DNA contained in the chromosome. Likewise, other eukaryotic chromosomes contain only single molecules of DNA.

The highly elongated shape of duplex DNA (recall B-DNA is only 20 Å in diameter), together with its stiffness, make it extremely susceptible to mechanical damage outside the cell's protective environment (for instance, if the *Drosophila* DNA of Fig. 5-20 were enlarged by a factor of 500,000, it would have the shape and some of the mechanical properties of a 6-km-long strand of uncooked spaghetti). The hydrodynamic shearing forces generated by such ordinary

**Figure 5-19** Electron micrograph of a T2 bacteriophage and its DNA. The phage has been osmotically lysed (broken open) in distilled water so that its DNA spilled out. Without special treatment, duplex DNA, which is only 20 Å in diameter, is difficult to visualize in the electron microscope. In the **Kleinschmidt procedure** used here, DNA is fattened to ~200 Å in diameter by coating it with a denatured basic protein. [From Kleinschmidt, A.K., Lang, D., Jacherts, D., and Zahn, R.K., *Biochim. Biophys. Acta* **61**, 857 (1962).]

laboratory manipulations as stirring, shaking, and pipetting break DNA into relatively small pieces so that the isolation of an intact molecule of DNA requires extremely gentle

**Table 5-2** Sizes of Some DNA Molecules

handling. Before 1960, when this was first realized, the measured molecular masses of DNA were no higher than ~10 million D (~15 kb, where 1 kb = 1 kilobase pair = 1000 bp). DNA fragments of uniform molecular mass and as small as a few hundred base pairs may be generated by **shear degrading** DNA in a controlled manner; for instance, by forcing the DNA solution through a small orifice or by **sonication** (exposure to intense high-frequency sound waves).

#### 4 GENE EXPRESSION AND REPLICATION: AN OVERVIEW

 **See Guided Exploration 1: Overview of transcription and translation**  
 How do genes function, that is, how do they direct the synthesis of RNA and proteins, and how are they replicated? The answers to these questions form the multifaceted discipline known as **molecular biology**. In 1958, Crick neatly encapsulated the broad outlines of this process in a flow scheme he called the **central dogma of molecular biology**: *DNA directs its own replication and its transcription to yield RNA which, in turn, directs its translation to form proteins* (Fig. 5-21). Here the term “transcription” indicates that in transferring

**Figure 5-21** **The central dogma of molecular biology.** Solid arrows indicate the types of genetic information transfers that occur in all cells. Special transfers are indicated by the dashed arrows: **RNA-directed RNA polymerase** is expressed both by certain RNA viruses and by some plants; **RNA-directed DNA polymerase (reverse transcriptase)** is expressed by other RNA viruses; and DNA directly specifying a protein is unknown but does not seem beyond the realm of possibility. However, the missing arrows are information transfers the central dogma postulates never occur: protein specifying either DNA, RNA, or protein. In other words, *proteins can only be the recipients of genetic information*. [After Crick, F., *Nature* **227**, 561 (1970).]

information from DNA to RNA, the “language” encoding the information remains the same, that of base sequences, whereas the term “translation” indicates that in transferring information from RNA to proteins, the “language” changes from that of base sequences to that of amino acid sequences (Fig. 5-22). The machinery required to carry out the complex tasks of gene expression and DNA replication in an organized manner and with high fidelity occupies a major portion of every cell. In this section we summarize how gene expression and replication occur to provide the background for understanding the techniques of recombinant DNA technology (Section 5-5). This subject matter is explored in considerably greater detail in Chapters 29 to 34.

##### A. RNA Synthesis: Transcription

The enzyme that synthesizes RNA is named **RNA polymerase**. It catalyzes the DNA-directed coupling of the **nucleoside triphosphates (NTPs) adenosine triphosphate**

**Figure 5-22** **Gene expression.** One strand of DNA directs the synthesis of RNA, a process known as transcription. The base sequence of the transcribed RNA is complementary to that of the DNA strand. The RNAs known as **messenger RNAs (mRNAs)** are translated when molecules of **transfer RNA (tRNA)** align with the mRNA via complementary base pairing between segments of three consecutive nucleotides known as codons. Each type of tRNA carries a specific amino acid. These amino acids are covalently joined by the ribosome to form a polypeptide. Thus, the sequence of bases in DNA specifies the sequence of amino acids in a protein.

**Figure 5-23 Action of RNA polymerases.**

These enzymes assemble incoming ribonucleoside triphosphates on templates consisting of single-stranded segments of DNA such that the growing strand is elongated in the 5' to 3' direction.

(ATP), cytidine triphosphate (CTP), guanosine triphosphate (GTP), and uridine triphosphate (UTP) in a reaction that releases pyrophosphate ion (P<sub>2</sub>O<sub>4</sub><sup>4-</sup>):

RNA synthesis proceeds in a stepwise manner in the 5' → 3' direction, that is, the incoming nucleotide is appended to the free 3'—OH group of the growing RNA chain (Fig. 5-23). RNA polymerase selects the nucleotide it incorporates into the nascent (growing) RNA chain through the requirement that it form a Watson–Crick base pair with the DNA strand that is being transcribed, the **template strand** (only one of duplex DNA's two strands is transcribed at a time). This is possible because, as the RNA polymerase moves along the duplex DNA it is transcribing, it separates a short (~14 bp) segment of its two strands to form a so-called **transcription bubble**, thereby permitting this portion of the template strand to transiently form a short DNA–RNA hybrid helix with the newly synthesized RNA (Fig. 5-24). Like duplex DNA, a DNA–RNA hybrid helix consists of antiparallel strands, and hence the DNA's template strand is read in its 3' → 5' direction.

All cells contain RNA polymerase. In bacteria, one species of this enzyme synthesizes nearly all of the cell's RNA. Certain viruses generate RNA polymerases that syn-

thesize only virus-specific RNAs. Eukaryotic cells contain four or five different types of RNA polymerases that each synthesize a different class of RNA.

#### a. Transcriptional Initiation Is a Precisely Controlled Process

The DNA template strand contains control sites consisting of specific base sequences that specify both the site at which RNA polymerase initiates transcription (the site on the DNA at which the RNA's first two nucleotides are joined) and the rate at which RNA polymerase initiates transcription at this site. Specific proteins known in prokaryotes as **activators** and **repressors** and in eukaryotes as **transcription factors** bind to these control sites or to other such proteins that do so and thereby stimulate or inhibit transcriptional initiation by RNA polymerase. For the RNAs that encode proteins, which are named **messenger RNAs (mRNAs)**, these control sites precede the initiation site (that is, they are “upstream” of the initiation site relative to the RNA polymerase's direction of travel).

*The rate at which a cell synthesizes a given protein, or even whether the protein is synthesized at all, is mainly governed by the rate at which the synthesis of the corresponding mRNA is initiated.* The way that prokaryotes regulate the rate at which many genes undergo transcriptional initiation

**Figure 5-24 Function of the transcription bubble.** RNA polymerase unwinds the DNA double helix by about a turn in the region being transcribed, thereby permitting the DNA's template strand to form a short segment of DNA–RNA hybrid double helix with the RNA's newly synthesized 3' end. As the

RNA polymerase advances along the DNA template (here to the right), the DNA unwinds ahead of the RNA's growing 3' end and rewinds behind it, thereby stripping the newly synthesized RNA from the template strand.

can be relatively simple. For example, the transcriptional initiation of numerous prokaryotic genes requires only that RNA polymerase bind to a control sequence, known as a **promoter**, that precedes the transcriptional initiation site. However, not all promoters are created equal: RNA polymerase initiates transcription more often at so-called efficient promoters than at those with even slightly different sequences. Thus the rate at which a gene is transcribed is governed by the sequence of its associated promoter.

A more complex way in which prokaryotes control the rate of transcriptional initiation is exemplified by the *E. coli lac operon*, a cluster of three consecutive genes (*Z*, *Y*, and *A*) encoding proteins that the bacterium requires to metabolize the sugar **lactose** (Section 11-2B). In the absence of lactose, a protein named the **lac repressor** specifically binds to a control site in the *lac* operon known as an **operator** (Section 31-3B). This prevents RNA polymerase from initiating the transcription of *lac* operon genes (Fig. 5-25a), thereby halting the synthesis of unneeded proteins. However, when lactose is available, the bacterium meta-

**Figure 5-25** Control of transcription of the *E. coli lac* operon.

(a) In the absence of an inducer such as allolactose, the *lac* repressor binds to the operator (*O*), thereby preventing RNA polymerase from transcribing the *Z*, *Y*, and *A* genes of the *lac* operon. (b) On binding inducer, the *lac* repressor dissociates from the operator, which permits RNA polymerase to bind to the promoter (*P*) and transcribe the *Z*, *Y*, and *A* genes. See **Guided Exploration 2: Regulation of gene expression by the *lac* repressor system**

bologically modifies a small amount of it to form the related sugar **allolactose**. This so-called **inducer** specifically binds to the *lac* repressor, thereby causing it to dissociate from the operator DNA so that RNA polymerase can initiate the transcription of the *lac* operon genes (Fig. 5-25b).

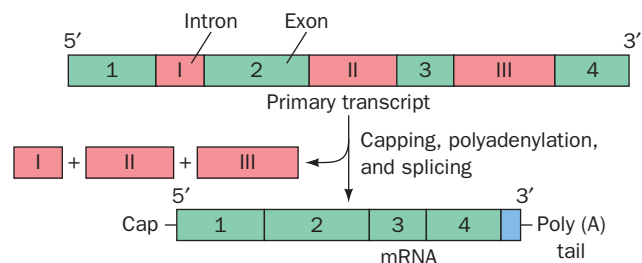

In eukaryotes, the control sites regulating transcriptional initiation can be quite extensive and surprisingly distant from the transcriptional initiation site (by as much as several tens of thousands of base pairs; Section 34-3). Moreover, the eukaryotic transcriptional machinery that binds to these sites and thereby induces RNA polymerase to commence transcription can be enormously complex (consisting of up to 50 or more proteins; Section 34-3).

### b. Transcriptional Termination Is a Relatively Simple Process

The site on the template strand at which RNA polymerase terminates transcription and releases the completed RNA is governed by the base sequence in this region. However, the control of transcriptional termination is rarely involved in the regulation of gene expression. In keeping with this, the cellular machinery that mediates transcriptional termination is relatively simple compared with that involved in transcriptional initiation (Section 31-2D).

### c. Eukaryotic RNA Undergoes Post-Transcriptional Modifications

Most prokaryotic mRNA transcripts participate in translation without further alteration. However, most primary transcripts in eukaryotes require extensive **post-transcriptional modifications** to become functional. For mRNAs, these modifications include the addition of a 7-methylguanosine-containing “cap” that is enzymatically appended to the transcript’s 5’ end and ~250-nucleotide **polyadenylic acid [poly(A)]** “tail” that is enzymatically appended to its 3’ end. However, the most striking modification that most eukaryotic transcripts undergo is a process called **gene splicing** in which one or more often lengthy RNA segments known as **introns** (for “intervening sequences”) are precisely excised from the RNA and the remaining **exons** (for “expressed sequences”) are rejoined in their original order to form the mature mRNA (Fig. 5-26; Section 31-4A). Different mRNAs can be generated from

**Figure 5-26** Post-transcriptional processing of eukaryotic mRNAs. Most primary transcripts require further covalent modification to become functional, including the addition of a 5’ cap and a 3’ poly(A) tail, and splicing to excise its introns from between its exons.

the same gene through the selection of alternate transcriptional initiation sites and/or alternative splice sites, leading to the production of somewhat different proteins, usually in a tissue-specific manner (Section 34-3C).

### B. Protein Synthesis: Translation

Polypeptides are synthesized under the direction of the corresponding mRNA by **ribosomes**, numerous cytosolic organelles that consist of about two-thirds RNA and one-third protein and have molecular masses of  $\sim 2500$  kD in prokaryotes and  $\sim 4200$  kD in eukaryotes. Ribosomal RNAs (**rRNAs**), of which there are several kinds, are transcribed from DNA templates, as are all other kinds of RNA.

#### a. Transfer RNAs Deliver Amino Acids to the Ribosome

mRNAs are essentially a series of consecutive 3-nucleotide segments known as **codons**, each of which specifies a particular amino acid. However, codons do not bind amino acids. Rather, on the ribosome, they specifically bind molecules of **transfer RNA (tRNA)** that are each covalently linked to the corresponding amino acid (Fig. 5-27). A tRNA typically consists of  $\sim 76$  nucleotides (which makes it comparable in mass and structural complexity to a medium-sized protein) and contains a trinucleotide sequence, its **anticodon**, which is complementary to the codon(s) specifying its appended amino acid (see below). An amino acid is covalently linked to the 3' end of its corresponding tRNA to form an **aminoacyl-tRNA** (a process called “charging”) through the action of an enzyme that specifically recognizes both the tRNA and the amino acid (see below). During

**Figure 5-27** Transfer RNA (tRNA) drawn in its “cloverleaf” form. Its covalently linked amino acid residue forms an aminoacyl-tRNA (*top*), and its anticodon (*bottom*), a trinucleotide segment, base pairs with the complementary codon on mRNA during translation.

translation, the mRNA is passed through the ribosome such that each codon, in turn, binds its corresponding aminoacyl-tRNA (Fig. 5-28). As this occurs, the ribosome transfers the amino acid residue on the tRNA to the C-terminal end of

**Figure 5-28** Schematic diagram of translation. The ribosome binds an mRNA and two tRNAs and facilitates their specific association through consecutive codon–anticodon interactions. The ribosomal binding site closer to the 5' end of the mRNA binds a **peptidyl-tRNA** (*left*, a tRNA to which the growing polypeptide chain is covalently linked) and is therefore known as the **P site**, whereas the ribosomal site closer to the 3' end of the mRNA binds an aminoacyl-tRNA (*right*) and is hence called the **A site**.

The ribosome catalyzes the transfer of the polypeptide from the peptidyl-tRNA to the aminoacyl-tRNA, thereby forming a new peptidyl-tRNA whose polypeptide chain has increased in length by one residue at its C-terminus. The discharged tRNA in the P site is then ejected, and the peptidyl-tRNA, together with its bound mRNA, is shifted from the A site to the P site, thereby permitting the next codon to bind its corresponding aminoacyl-tRNA in the ribosomal A site.

**Figure 5-29** The ribosomal reaction forming a peptide bond. The amino group of the aminoacyl-tRNA in the ribosomal A site nucleophilically displaces the tRNA of the peptidyl-tRNA ester

the growing polypeptide chain (Fig. 5-29). Hence, *the polypeptide grows from its N-terminus to its C-terminus*.

### b. The Genetic Code

The correspondence between the sequence of bases in a codon and the amino acid residue it specifies is known as the **genetic code** (Table 5-3). Its near universality among all forms of life is compelling evidence that life on Earth arose from a common ancestor and makes it possible, for example, to express human genes in *E. coli* (Section 5-5Ga). There are four possible bases (U, C, A, and G) that can occupy each of the three positions in a codon, and hence there are  $4^3 = 64$  possible codons. Of these codons, 61 specify amino acids (of which there are only 20) and the remaining three, UAA, UAG, and UGA, are **Stop codons** that instruct the ribosome to cease polypeptide synthesis and release the resulting transcript. All but two amino acids (Met and Trp) are specified by more than one codon and three (Leu, Ser, and Arg) are specified by six codons. Consequently, in a term borrowed from mathematics, the genetic code is said to be **degenerate** (taking on several discrete values).

Note that the arrangement of the genetic code is non-random: Most codons that specify a given amino acid, which are known as **synonyms**, occupy the same box in Table 5-3, that is, they differ in sequence only in their third (3') nucleotide. Moreover, most codons specifying non-polar amino acid residues have a G in their first position and/or a U in their second position (Table 5-3).

A tRNA may recognize as many as three synonymous codons because the 5' base of a codon and the 3' base of a

in the ribosomal P site, thereby forming a new peptide bond and transferring the growing polypeptide to the A site tRNA.

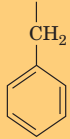

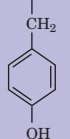

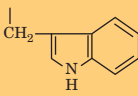

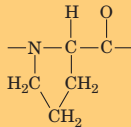

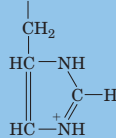

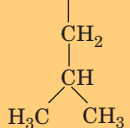

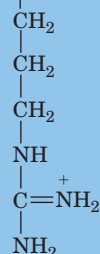

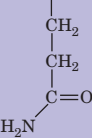

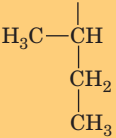

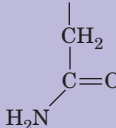

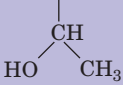

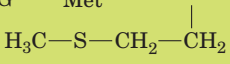

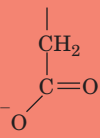

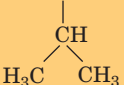

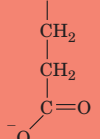

corresponding anticodon do not necessarily interact via a Watson-Crick base pair (Section 32-2D; keep in mind that the codon and the anticodon associate in an antiparallel fashion to form a short segment of an RNA double helix). Thus, cells can have far fewer than the 61 tRNAs that would be required for a 1:1 match with the 61 amino acid-specifying codons, although, in fact, some eukaryotic cells contain over 500 different tRNAs.

### c. tRNAs Acquire Amino Acids Through the Actions of Aminoacyl-tRNA Synthetases

In synthesizing a polypeptide, a ribosome does not recognize the amino acid appended to a tRNA but only whether its anticodon binds to the mRNA's codon (the anticodon and the amino acid on a charged tRNA are actually quite distant from one another, as Fig. 5-27 suggests). Thus, *the charging of a tRNA with the proper amino acid is as critical a step for accurate translation as is the proper recognition of a codon by its corresponding anticodon*. The enzymes that catalyze these additions are known as **aminoacyl-tRNA synthetases (aaRSs)**. Cells typically contain 20 aaRSs, one for each amino acid, and therefore a given aaRS will charge all the tRNAs that bear codons specifying its corresponding amino acid. Consequently, each aaRS must somehow differentiate its cognate (corresponding) tRNAs from among the many other types of structurally and physically quite similar tRNAs that each cell contains. Although many aaRSs recognize the anticodons of their cognate tRNAs, not all of them do so. Rather, they recognize other sites on their cognate tRNAs.

<sup>a</sup>Nonpolar residues are tan, basic residues are blue, acidic residues are red, and polar uncharged residues are purple.

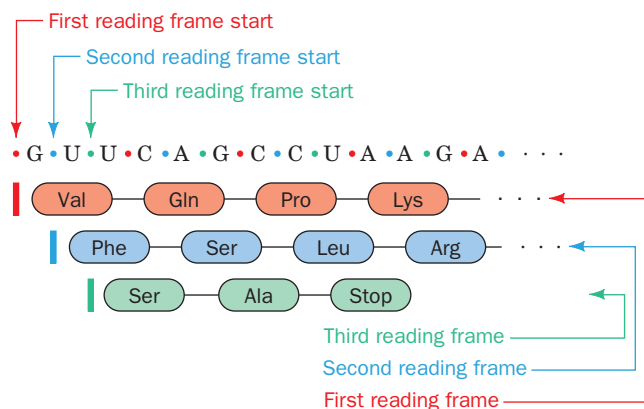

<sup>b</sup>AUG forms part of the initiation signal as well as coding for internal Met residues.

**d. Translation Is Initiated at Specific AUG Codons**

Ribosomes read mRNAs in their 5' to 3' direction (from “upstream” to “downstream”). The initiating codon is AUG, which specifies a Met residue. However, the tRNA that recognizes this initiation codon differs from the tRNA

that delivers a polypeptide’s internal Met residues to the ribosome, although both types of tRNA are charged by the same **methionyl-tRNA synthetase (MetRS)**.

If a polypeptide is to be synthesized with the correct amino acid sequence, it is essential that the ribosome main-

**Figure 5-30** Nucleotide reading frames. An mRNA might be read in any of three different reading frames, each of which yields a different polypeptide.

tain the proper register between the mRNA and the incoming tRNAs, that is, that the ribosome maintain the correct **reading frame**. As is illustrated in Fig. 5-30, a shift of even one nucleotide along an mRNA will lead to the synthesis of an entirely different polypeptide from the point of the shift onward. Thus, the AUG codon that initiates polypeptide synthesis also sets the polypeptide's reading frame. Yet AUG also specifies a polypeptide's internal Met residues, and an mRNA is likely to contain numerous AUGs in different reading frames. How then does the ribosome select the initiation codon from among the many AUGs in an mRNA? In prokaryotes, the answer is that each mRNA contains a sequence on the upstream (5') side of the initiating codon (a region that does not encode polypeptide chain) through which the ribosome identifies this codon. In eukaryotes, the answer is simpler; the initiating codon is usually the first AUG that is downstream of the mRNA's 5' cap.

#### e. Prokaryotic mRNAs Have Short Lifetimes

In prokaryotes, transcription and translation both take place in the same cellular compartment, the cytosol (Figs. 1-2 and 1-13). Consequently ribosomes often attach to the 5' end of an mRNA before its synthesis is complete and commence synthesizing the corresponding polypeptide. This is essential because, since the mRNAs in prokaryotes have average lifetimes of only 1 to 3 minutes before being hydrolytically degraded by enzymes known as **nucleases**, the 5' end of an mRNA may be degraded before its 3' end is synthesized. This rapid turnover of its mRNAs permits a prokaryote to respond quickly to changes in its environment by synthesizing the proteins appropriate for its new situation within minutes of the change (recall that prokaryotes are adapted to live in environments in which there are rapid fluctuations in the available nutrients; Section 1-2).

Eukaryotic cells, in contrast, mostly lead a more sedentary existence. Their RNAs are transcribed and post-transcriptionally modified in the nucleus, whereas ribosomes occupy the cytosol where translation takes place (Fig. 1-5). Hence, mature mRNAs must be transported from the nucleus to the cytosol in order to participate in translation.

Eukaryotic mRNAs therefore tend to have lifetimes on the order of several days.

#### f. Proteins Are Subject to Post-Translational Modifications and Degradation

Newly synthesized polypeptides often require post-translational modifications to become functional. In many proteins, the leading (N-terminal) Met residue that was specified by its mRNA's initiating codon is excised by a specific **protease** (an enzyme that hydrolytically cleaves peptide bonds). Proteins are then subject to numerous other chemical modifications at specific residues, including specific proteolytic cleavages, acylation, hydroxylation, methylation, and phosphorylation (Section 4-3A). In addition, eukaryotic proteins, but not prokaryotic proteins, are subject to **glycosylation** (the addition of polysaccharides) at specific sites (Sections 11-3C and 23-3B). Indeed, **glycoproteins** (proteins that have been glycosylated) are the most common type of eukaryotic protein and can consist of up to 90% or more by mass of polysaccharide groups.

All cells have several mechanisms for degrading proteins to their component amino acids. This enables cells to eliminate damaged or abnormal proteins, destroy proteins that are no longer needed, and utilize proteins as nutrients. The lifetime of a protein in a cell can be surprisingly short, as little as a fraction of a minute, although many proteins in eukaryotes have lifetimes of days or weeks. Thus cells are dynamic entities that are constantly turning over most of their components, in particular their RNA and proteins.

### C. DNA Replication

The chemical reaction by which DNA is replicated (Fig. 5-31) is nearly identical to that synthesizing RNA (Fig. 5-23), but with two major differences: (1) deoxynucleoside triphosphates (**dNTPs**) rather than nucleoside triphosphates are the reactants and (2) the enzyme that catalyzes the reaction is **DNA polymerase** rather than RNA polymerase. The properties of DNA polymerase result in a third major difference between RNA and DNA synthesis: Whereas RNA polymerase can link together two nucleotides on a DNA template, *DNA polymerase can only extend (in the 5' to 3' direction) an existing polynucleotide that is base paired to the DNA's template strand*. Thus, whereas RNA polymerase can initiate RNA synthesis *de novo* (from the beginning), *DNA polymerase requires an oligonucleotide primer, which it lengthens*.

#### a. Primers Are RNA

If DNA polymerase cannot synthesize DNA *de novo*, where do primers come from? It turns out that they are not DNA, as might be expected, but rather RNA. In *E. coli*, these RNA primers are synthesized by both RNA polymerase (the same enzyme that synthesizes all other RNAs) and by a special RNA polymerase known as **primase**. DNA polymerase then extends this RNA primer, which is eventually excised and replaced by DNA, as is explained below. This extra complexity in DNA synthesis increases the fidelity of DNA replication. Whereas a cell makes many copies of an RNA and

**Figure 5-31** Action of DNA polymerases. DNA polymerases assemble incoming deoxynucleoside triphosphates on single-

stranded DNA templates such that the growing strand is elongated in the 5' to 3' direction.

hence can tolerate an occasional mistake in its synthesis, a mistake (mutation) in the synthesis of DNA, the archive of genetic information, may be passed on to all of the cell's descendants. Since a Watson–Crick base pair is partially stabilized by its neighboring base pairs (a cooperative interaction), the first few base pairs that are formed in a newly synthesized polynucleotide will initially be less stable than the base pairs that are formed later. Consequently, these first few bases are more likely to be erroneously incorporated due to mispairing than those at the end of a longer chain. If a primer were DNA, there would be no way to differentiate it from other DNA so as to selectively replace it with more accurately synthesized DNA. Since the primer is RNA, however, it is readily identified and replaced.

**b. DNA's Two Strands Are Replicated in Different Ways**

A fourth major difference between RNA and DNA synthesis is that, whereas only one DNA strand at a time is transcribed, in most cases both of its strands are simultaneously replicated. This takes place at a **replication fork**, the junction where the two strands of the parental DNA are pried apart and where the two daughter strands are synthesized (Fig. 1-17), each by a different molecule of DNA polymerase. One of these DNA polymerase molecules continuously copies the parental strand that extends in its 3' to 5' direction from the replication fork, thereby synthesizing the resulting daughter strand, which is known as the **leading strand**, in its 5' to 3' direction. However, since the second

**Figure 5-32** Replication of duplex DNA in *E. coli*. (a) Since the two DNA polymerase molecules at the replication fork are linked together and DNA polymerase can only synthesize DNA in its 5' to 3' direction, the leading strand can be synthesized continuously but the lagging strand must be synthesized discontinuously, that is, in segments. (b) This is because the lagging strand template can only be copied if it loops around so as to feed through the DNA polymerase in its 3' to 5' direction. Consequently, when the DNA polymerase that is synthesizing the lagging strand encounters the previously synthesized lagging strand segment, it releases the lagging strand template and rebinds to it farther upstream so as to extend the next RNA primer to be synthesized.

**Figure 5-33** The 5' → 3' exonuclease function of DNA polymerase I. This enzymatic activity excises up to 10 nucleotides from the 5' end of a single-strand nick. The nucleotide immediately past the nick (X) may or may not be base paired.

DNA polymerase at the replication fork also synthesizes DNA in the 5' to 3' direction and yet must travel with the replication fork, how does it copy the parental strand that extends from the replication fork in its 5' to 3' direction? The answer is that it synthesizes the so-called **lagging strand discontinuously**, that is, in pieces (Fig. 5-32a, opposite). It does so by binding the looped-around lagging strand template so as to extend its newly synthesized RNA primer in its 5' to 3' direction (Fig. 5-32b; in effect, reversing its direction of travel) until it encounters the previously synthesized primer. The DNA polymerase then disengages from the lagging strand template and rebinds to it upstream of its previous position, where it then extends the next RNA primer to be synthesized. Thus the lagging strand is synthesized discontinuously, whereas the leading strand is synthesized continuously. The synthesis of lagging strand primers in *E. coli* is catalyzed by primase, which accompanies the replication fork (Fig. 5-32b), whereas the synthesis of leading strand primers, a much rarer event, occurs most efficiently when both primase and RNA polymerase are present.

**Figure 5-34** Replacement of RNA primers by DNA in lagging strand synthesis. In *E. coli*, the RNA primer on the 5' end of a newly synthesized DNA segment is excised through the action of DNA polymerase I's 5' → 3' exonuclease activity and is simultaneously replaced by DNA as catalyzed by the enzyme's DNA polymerase activity.

### c. Lagging Strand Synthesis Requires Several Enzymes

*Escherichia coli* contains two species of DNA polymerase that are essential for its survival. Of these, **DNA polymerase III (Pol III)** is the DNA replicase, that is, it synthesizes the leading strand and most of the lagging strand. **DNA polymerase I (Pol I)** has a different function, that of removing the RNA primers and replacing them with DNA. Pol I can do so because it has a second enzymatic activity besides that of a DNA polymerase; it is also a **5' → 3' exonuclease** (an exonuclease hydrolytically removes one or more nucleotides from the end of a polynucleotide rather than cleaving it at an internal position). The 5' → 3' exonuclease function binds to single-strand nicks (places where successive nucleotides are not covalently linked such as on the 5' side of an RNA primer after the succeeding lagging strand segment has been synthesized). It then excises a 1- to 10-nucleotide segment of the nicked strand in the 5' to 3' (5' → 3') direction past the nick (Fig. 5-33). Pol I's 5' → 3' exonuclease and DNA polymerase activities work in concert, so as Pol I's 5' → 3' exonuclease removes the primer, its DNA polymerase activity replaces this RNA with DNA (Fig. 5-34).

The synthesis of the leading strand is completed by the replacement of its single RNA primer with DNA. However, the completion of lagging strand synthesis requires that the nicks between its multiple discontinuously synthesized segments be sealed. This is the job of an independent enzyme named **DNA ligase** that covalently links adjacent 3'-OH and 5'-phosphate groups (Fig. 5-35).

### d. Errors in DNA Sequences Are Subject to Correction

In *E. coli*, RNA polymerase has an error rate of ~1 wrong base for every  $10^4$  nucleotides it transcribes. In contrast, newly replicated DNA contains only ~1 error per  $10^8$  to  $10^{10}$  base pairs. We have already seen that the use of RNA primers increases the fidelity of lagging strand synthesis. However, the main reason for the enormous fidelity of DNA replication is that both Pol I and Pol III have **3' → 5' exonuclease** activities. The 3' → 5' exonuclease

**Figure 5-35** Function of DNA ligase. DNA ligase seals single-strand nicks in duplex DNA. It does so in a reaction that is powered by the hydrolysis of ATP or a similar compound.

**Figure 5-36** The 3' → 5' exonuclease function of DNA polymerase I and DNA polymerase III. In *E. coli*, this enzymatic activity excises mispaired nucleotides from the 3' end of a growing DNA strand.

degrades the newly synthesized 3' end of a daughter strand one nucleotide at a time (Fig. 5-36), thereby annulling the polymerase reaction. This enzymatic function is activated by non-Watson–Crick base pairing and consequently acts to edit out the occasional mistakes made by the polymerase function, thereby greatly increasing the fidelity of replication. However, in addition to this proofreading function on both Pol I and Pol III, all cells contain batteries of enzymes that detect and correct residual errors in replication as well as damage which DNA incurs through the action of such agents as UV radiation and **mutagens** (substances that damage DNA by chemically reacting with it) as well as by spontaneous hydrolysis (Section 30-5). In *E. coli*, Pol I also functions to replace the damaged DNA segments that these enzymes have excised.

## 5 MOLECULAR CLONING

A major problem in almost every area of biochemical research is obtaining sufficient quantities of the substance of interest. For example, a 10-L culture of *E. coli* grown to its maximum titer of  $\sim 10^{10}$  cells  $\cdot$  mL<sup>-1</sup> contains, at most, 7 mg of DNA polymerase I, and many of its proteins are present in far lesser amounts. Yet it is rare that even as much as half of any protein originally present in an organism can be recovered in pure form (Chapter 6). Eukaryotic proteins may be even more difficult to obtain because many eukaryotic tissues, whether acquired from an intact organism or grown in tissue culture, are available only in small quantities. As far as the amount of DNA is concerned, our 10-L *E. coli* culture would contain  $\sim 0.1$  mg of any 1000-bp length of chromosomal DNA (a length sufficient to contain most prokaryotic genes), but its purification in the presence of the rest of the chromosomal DNA (which consists of 4.6 million bp) would be an all but impossible task. These difficulties have been largely eliminated through the development of **molecular cloning** techniques (a **clone** is a collection of identical organisms that are derived from a single ancestor). These methods, which are also referred to as **genetic engineering** and **recombinant DNA** technology, deserve much of the credit for

the enormous progress in biochemistry and the dramatic rise of the biotechnology industry since the late 1970s.

The main idea of molecular cloning is to insert a DNA segment of interest into an autonomously replicating DNA molecule, a so-called **cloning vector** or **vehicle**, so that the DNA segment is replicated with the vector. Cloning such a **chimeric vector** (*chimera*: a monster in Greek mythology that has a lion's head, a goat's body, and a serpent's tail) in a suitable **host organism** such as *E. coli* or yeast results in the production of large amounts of the inserted DNA segment. If a cloned gene is flanked by the properly positioned control sequences for transcription and translation, the host may also produce large quantities of the RNA and protein specified by that gene. The techniques of genetic engineering, whose understanding is prerequisite to understanding many of the experiments discussed in this textbook, are outlined in this section.

### A. Restriction Endonucleases

In order to effectively carry out molecular cloning, it is necessary to be able to manipulate precisely sequence-defined DNA fragments. This is done through the use of enzymes known as **restriction endonucleases**.

Bacteriophages that propagate efficiently on one bacterial strain, such as *E. coli* K12, have a very low rate of infection ( $\sim 0.001\%$ ) in a related bacterial strain such as *E. coli* B. However, the few viral progeny of this latter infection propagate efficiently in the new host but only poorly in the original host. Evidently, the new host modifies these bacteriophages in some way. What is the molecular basis of this **host-specific modification**? Werner Arber showed that it results from a **restriction–modification system** in the bacterial host, which consists of a restriction endonuclease (alternatively, **restriction enzyme**; endonucleases are enzymes that hydrolytically cleave polynucleotides at internal sites) and a matched **DNA methyltransferase**. *Restriction endonucleases recognize a specific base sequence of four to eight bases in double-stranded DNA and cleave both strands of the duplex*. DNA methyltransferases methylate a specific base (at the amino group of an adenine or either the 5 position or the amino group of a cytosine) in the same base sequence recognized by the matched restriction enzyme.

A restriction enzyme does not cleave its corresponding methylated DNA. A newly replicated strand of bacterial DNA, which is protected from degradation by the methylated parent strand with which it forms a duplex, is methylated before the next cycle of replication. A restriction–modification system therefore protects the bacterium against invasion by foreign (usually viral) DNAs which, once they have been cleaved by a restriction endonuclease, are further degraded by bacterial exonucleases. Invading DNAs are only rarely methylated before being attacked by restriction enzymes. Yet if a viral DNA does become methylated, it is able to reproduce in its new host. Its progeny, however, are no longer methylated in the way that permits them to propagate in the original host (which has different restriction–modification systems).

There are four types of restriction endonucleases, Types I, II, III, and IV. **Type I** and **Type III** restriction enzymes

**Table 5-4** Recognition and Cleavage Sites of Some Type II Restriction Enzymes

Enzyme	Recognition Sequence <sup>a</sup>	Microorganism
AluI	AG↓C*T	<i>Arthrobacter luteus</i>

XhoI	C↓TCGAG	<i>Xanthomonas holcicola</i>

<sup>a</sup>The recognition sequence is abbreviated so that only one strand, reading 5' to 3', is given. The cleavage site is represented by an arrow (↓) and the modified base, where it is known, is indicated by a following asterisk (A\* is N<sup>6</sup>-methyladenine and C\* is 5-methylcytosine). R, Y, and N represent purine nucleotide, pyrimidine nucleotide, and any nucleotide, respectively.

Source: REBASE. The restriction enzyme database (<http://rebase.neb.com>).

each carry both the endonuclease and the DNA methyltransferase activity on a single protein molecule. **Type I** restriction enzymes cleave the DNA at a possibly random site located at least 1000 bp from the recognition sequence, **Type III** enzymes do so 24 to 26 bp distant from the recognition sequence, and **Type IV** enzymes cleave methylated DNA. **Type II** restriction enzymes, which were discovered and characterized by Hamilton Smith and Daniel Nathans in the late 1960s, are separate entities from their corresponding DNA methyltransferases. They cleave DNAs at specific sites within or near the recognition sequence, a property that makes Type II restriction enzymes indispensable biochemical tools for DNA manipulation. In what follows, we discuss only Type II restriction enzymes.

Nearly 4000 species of Type II restriction enzymes from a variety of bacteria that have over 270 different sequence specificities have been characterized. Several of the more widely used species are listed in Table 5-4. A restriction endonuclease is named by the first letter of the genus of the bacterium that produced it and the first two letters of its species, followed by its serotype or strain designation, if any, and a roman numeral if the bacterium expresses more than one type of restriction enzyme. For example, **EcoRI** is produced by *E. coli* strain RY13.

### a. Most Restriction Endonucleases Recognize Palindromic DNA Sequences

Most Type II restriction enzyme recognition sites possess exact twofold rotational symmetry, as is diagrammed in Fig. 5-37. Such sequences are known as **palindromes** (a palindrome is a word, verse, or sentence that reads the

same backward and forward; two examples are “Madam, I’m Adam” and “Sex at noon taxes”). Many restriction enzymes, such as EcoRI (Fig. 5-37a), catalyze cleavage of the two DNA strands at positions that are symmetrically staggered about the center of the palindromic recognition sequence. This yields restriction fragments with complementary single-stranded ends that are from one to four nucleotides in length. Restriction fragments with such **cohesive** or **sticky ends** can associate by complementary base pairing with other restriction fragments generated by the same restriction enzyme. Some restriction cuts, such as that of EcoRV (Fig. 5-37b), pass through the twofold axis of the

**Figure 5-37** Restriction sites. The recognition sequences of the restriction endonucleases (a) EcoRI and (b) EcoRV have twofold (palindromic) symmetry (red symbol). The cleavage sites are indicated (arrows). Note that EcoRI generates DNA fragments with sticky ends, whereas EcoRV generates blunt-ended fragments.

palindrome to yield restriction fragments with fully base paired **blunt ends**. Since a given base has a one-fourth probability of occurring at any nucleotide position (assuming the DNA has equal proportions of all bases), a restriction enzyme with an  $n$ -base pair recognition site produces restriction fragments that are, on average,  $4^n$  base pairs long. Thus AluI (4-bp recognition sequence) and EcoRI (6-bp recognition sequence) restriction fragments should average  $4^4 = 256$  and  $4^6 = 4096$  bp in length, respectively.

**Figure 5-38** Agarose gel electrophoretogram of restriction digests. The *Agrobacterium radiobacter* plasmid pAgK84 was digested with (A) BamHI, (B) PstI, (C) BglII, (D) HaeIII, (E) HincII, (F) SacI, (G) XbaI, and (H) HpaI. Lane I contains  $\lambda$  phage DNA digested with HindIII as standards since these fragments have known sizes. The DNA fragments in the electrophoretogram are made visible by fluorescence against a black background. [From Slota, J.E. and Farrand, S.F., *Plasmid* 8, 180 (1982). ### b. Restriction-Fragment Length Polymorphisms Provide Markers for Characterizing Genes

The treatment of a DNA molecule with a restriction endonuclease produces a series of precisely defined fragments that can be separated according to size by **gel electrophoresis** (Fig. 5-38). (In gel electrophoresis, charged molecules are applied to one end of a thin slab of polyacrylamide or agarose gel and are separated through the application of an electric field. Under the conditions used to separate DNA fragments, the molecules move according to size, with the smallest fragments moving fastest. Gel electrophoresis is further discussed in Section 6-4B.) Complementary single strands can be separated either by melting the DNA and subjecting it to gel electrophoresis, or by using density gradient ultracentrifugation in alkaline CsCl solution (recall that DNA is denatured under alkaline conditions).

Individuality in humans and other species derives from their genetic polymorphism; homologous human chromosomes differ in sequence, on average, every  $\sim 1250$  bp. These genetic differences create and eliminate restriction sites (Fig. 5-39). Restriction enzyme digests of the corresponding segments from homologous chromosomes therefore contain fragments with different lengths; that is, these DNAs have **restriction-fragment length polymorphisms (RFLPs)**; Fig. 5-40). Since, with the exception of identical twins, each individual has a unique set of RFLPs (its **haplotype**), RFLPs can be used for purposes of identification.

### B. Cloning Vectors

Plasmids, viruses, and artificial chromosomes are used as cloning vectors in genetic engineering.

#### a. Plasmid-Based Cloning Vectors

**Plasmids** are circular DNA duplexes of 1 to 200 kb that contain the requisite genetic machinery, such as a **replication origin** (a site at which DNA replication is initiated; Section 30-3Ca), to permit their autonomous propagation in a bacterial host or in yeast. Plasmids may be considered molecular parasites but in many instances they benefit

**Figure 5-39** Restriction-fragment length polymorphisms. A mutational change that affects a restriction site in a DNA segment alters the number and sizes of its restriction fragments.

**Figure 5-40** Inheritance of RFLPs according to the rules of Mendelian genetics. Four alleles of a particular gene, each characterized by different restriction markers, can occur in all possible pairwise combinations and segregate independently in each generation (circles in the upper panel represent females and squares represent males). In the  $P$  (parental) generation, two individuals have heterozygous haplotypes (CD and BD) and the other two have homozygous haplotypes (AA and BB). Their children, the  $F_1$  generation, have the haplotypes AC or BB. Consequently, every individual in the  $F_2$  generation (grandchildren) inherited either an A or a C from their mother and a B from their father. The lower panel shows a gel electrophoretogram of these restriction fragments run in parallel lanes. [Courtesy of Ray White, University of Utah Medical School.]

their host by providing functions, such as resistance to antibiotics, that the host lacks. Indeed, the widespread and alarming appearance, since antibiotics came into use, of an-

tibiotic-resistant pathogens is partially the result of the rapid proliferation among these organisms of plasmids containing genes that confer resistance to antibiotics.

Some types of plasmids, which are present in one or a few copies per cell, replicate once per cell division as does the bacterial chromosome; their replication is said to be under **stringent control**. Most plasmids used in molecular cloning, however, are under **relaxed control**; they are normally present in 10 to as many as 700 copies per cell. Moreover, if protein synthesis in the bacterial host is inhibited, for example, by the antibiotic **chloramphenicol** (Section 32-3Gb), thereby preventing cell division, these plasmids continue to replicate until 2 or 3 thousand copies have accumulated per cell (which represents about half of the cell's total DNA). The plasmids that have been constructed (by genetic engineering techniques; Section 5-5C) for use in molecular cloning are relatively small, replicate under relaxed control, carry genes specifying resistance to one or more antibiotics, and contain a number of conveniently located restriction endonuclease sites into which the DNA to be cloned may be inserted. Indeed, many plasmid vectors contain a strategically located short (<100 bp) segment of DNA known as a **polylinker** that has been synthesized to contain a variety of restriction sites that are not present elsewhere in the plasmid. The *E. coli* plasmid designated **pUC18** (Fig. 5-41) is representative of the cloning vectors presently in use ("pUC" stands for "plasmid-Universal Cloning").

The expression of a chimeric plasmid in a bacterial host was first demonstrated in 1973 by Herbert Boyer and Stanley Cohen. The host bacterium takes up a plasmid when the two are mixed together in a process that is greatly enhanced by the presence of divalent cations such as  $\text{Ca}^{2+}$

**Figure 5-41** The pUC18 cloning vector. A restriction map of the plasmid pUC18 indicates the positions of its  $\text{amp}^R$ ,  $\text{lacZ}'$ , and  $\text{lacI}$  genes. The  $\text{amp}^R$  gene confers resistance to the antibiotic **ampicillin** (a penicillin derivative; Section 11-3Bb);  $\text{lacZ}'$  is a modified form of the  $\text{lacZ}$  gene, which encodes the enzyme  **$\beta$ -galactosidase** (Section 11-2B); and  $\text{lacI}$  encodes the  $\text{lac}$  repressor, a protein that controls the transcription of  $\text{lacZ}$  (Section 5-4Aa). The polylinker, which encodes an 18-residue polypeptide segment inserted near the N-terminus of  $\beta$ -galactosidase, incorporates 13 different restriction sites that do not occur elsewhere in the plasmid.

and brief heating to  $\sim 42^{\circ}\text{C}$  (which increases cell membrane permeability to DNA; such cells are said to be **transformation competent**). Nevertheless, an absorbed plasmid vector becomes permanently established in its bacterial host (transformation) with an efficiency of only  $\sim 0.1\%$ .

Plasmid vectors cannot be used to clone DNAs of more than  $\sim 10$  kb. This is because the time required for plasmid replication increases with plasmid size. Hence intact plasmids with large, unessential (to them) inserts are lost through the faster proliferation of plasmids that have eliminated these inserts by random deletions.

### b. Virus-Based Cloning Vectors

**Bacteriophage  $\lambda$**  (Fig. 5-42) is an alternative cloning vehicle that can be used to clone DNAs of up to 16 kb. The central third of this virus's 48.5-kb genome is not required for phage infection (Section 33-3Aa) and can therefore be replaced by foreign DNAs of up to slightly greater size using techniques discussed in Section 5-5C. The chimeric phage DNA can then be introduced into the host cells by infecting them with phages formed from the DNA by an *in vitro* packaging system (Section 33-3Bc). The use of phages as cloning vectors has the additional advantage that the chimeric DNA is produced in large amounts and in easily purified form.

**Figure 5-42** Electron micrograph of bacteriophage  $\lambda$ . Bacteriophage  $\lambda$  reproduces in certain strains of *E. coli*. On binding to a susceptible *E. coli*, the DNA contained in the “head” of the phage particle is injected, through its “tail,” into the bacterial cell, where it is replicated  $\sim 100$  times and packaged to form progeny phage (Section 33-3). [Courtesy of A.F. Howatson. From Lewin, B., *Gene Expression*, Vol. 3, Fig. 5.23, Wiley (1977).]

$\lambda$  Phages can be used to clone even longer DNA inserts. The viral apparatus that packages DNA into phage heads requires only that the DNA have a specific 16-bp sequence known as a **cos site** located at each end and that these ends be 36 to 51 kb apart (Section 33-3Bc). Placing two *cos* sites the proper distance apart on a plasmid vector yields, via an *in vitro* packaging system, a so-called **cosmid** vector, which can contain foreign DNA of up to  $\sim 49$  kb. Cosmids have no phage genes and hence, on introduction into a host cell via phage infection, reproduce as plasmids.

The **filamentous bacteriophage M13** (Fig. 5-43) is also a useful cloning vector. It has a single-stranded circular DNA that is contained in a protein tube composed of  $\sim 2700$  helically arranged identical protein subunits. This number is controlled, however, by the length of the phage DNA being coated; insertion of foreign DNA in a nonessential region of the M13 chromosome results in the production of longer phage particles. Although M13 cloning vectors cannot stably maintain DNA inserts of  $>1$  kb, they are widely used in the production of DNA for sequence analysis (Section 7-2Ba) because these phages directly produce the single-stranded DNA that the technique requires.

**Baculoviruses** are a large and diverse group of pathogenic viruses that infect mainly insects (but not vertebrates, so that they are safe for laboratory use) and hence can be grown in cultures of insect cells. A segment of the double-stranded DNA that forms the genome of some of these viruses is unnecessary for viral replication in tissue cultures of insect cells and hence can be replaced by a foreign DNA of up to 15 kb.

### c. YAC and BAC Vectors

DNA segments larger than those that can be carried by cosmids may be cloned in **yeast artificial chromosomes (YACs)** and in **bacterial artificial chromosomes (BACs)**. YACs are linear DNA segments that contain all the molecular paraphernalia required for replication in yeast: a replication

**Figure 5-43** Electron micrograph of the filamentous bacteriophage M13. Note that some filaments appear to be pointed at one end (arrows). [Courtesy of Robley Williams, Stanford University, and Harold Fisher, University of Rhode Island.]

**Figure 5-44 Construction of a recombinant DNA molecule.** A restriction fragment is inserted in a cloning vector's corresponding restriction cut. The sticky ends of the vector and the foreign

DNA anneal and are subsequently covalently joined by DNA ligase to yield a chimeric DNA.  See the Animated Figures

origin [known as an **autonomously replicating sequence (ARS)**], a **centromere** (the chromosomal segment that attaches to the spindle during mitosis and meiosis), and **telomeres** (the ends of linear chromosomes that permit their replication; Section 30-4D). BACs, which replicate in *E. coli*, are derived from circular plasmids that normally replicate long regions of DNA and are maintained at a level of approximately one copy per cell (properties similar to those of actual chromosomes). These vectors contain the minimal sequences required for autonomous replication, copy-number control, and proper partitioning of the plasmid during cell division. YACs and BACs containing inserts of several hundred kilobase pairs have been successfully cloned.

### C. Gene Manipulation

A DNA to be cloned is, in many cases, obtained as a sequence-defined fragment through the application of restriction endonucleases (for M13 vectors, the restriction enzymes' requirement of duplex DNA necessitates converting this phage DNA to its double-stranded form through the use of DNA polymerase I). Recall that most restriction endonucleases cleave duplex DNA at specific palindromic sites so as to yield single-stranded ends that are complementary to each other (cohesive or sticky ends; Section 5-5Aa). Therefore, as Janet Mertz and Ron Davis first demonstrated in 1972, a restriction fragment may be inserted into a cut made in a cloning vector by the same restriction enzyme (Fig. 5-44). The complementary (cohesive) ends of the two DNAs specifically associate under annealing conditions and are covalently joined (spliced) through the action of DNA ligase (Fig. 5-35; the DNA ligase produced by **bacteriophage T4** must be used for blunt-ended restriction cuts such as those generated by AluI, EcoRV, and HaeIII; Table 5-4). A great advantage of using a restriction enzyme to construct a chimeric vector is that the DNA insert can be precisely excised from the cloned vector by cleaving it with the same restriction enzyme.

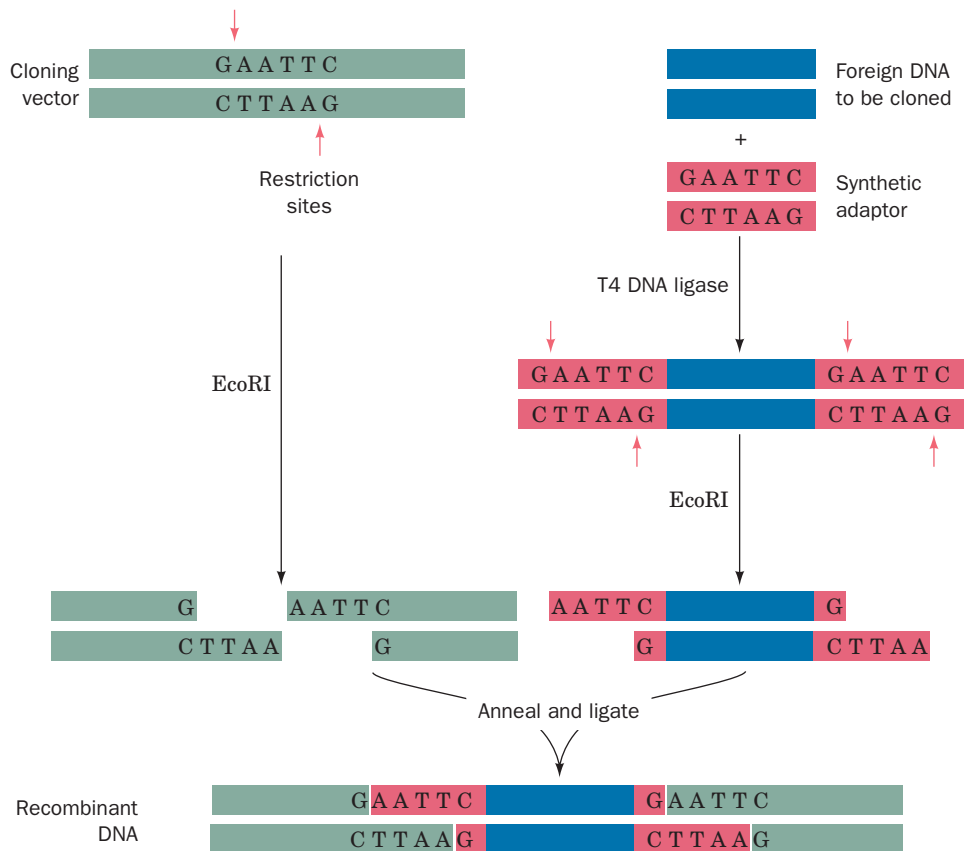

If the foreign DNA and cloning vector have no common restriction sites at innocuous positions, they may still be spliced, using a procedure pioneered by Dale Kaiser and Paul Berg, through the use of **terminal deoxynucleotidyl trans-**

**ferase (terminal transferase)**. This mammalian enzyme adds nucleotides to the 3'-terminal OH group of a DNA chain; it is the only known DNA polymerase that does not require a template. Terminal transferase and dTTP, for example, can build up poly(dT) tails of ~100 residues on the 3' ends of the DNA segment to be cloned (Fig. 5-45). The cloning vector is enzymatically cleaved at a specific site and the 3' ends of the cleavage site are similarly extended with poly(dA) tails. The complementary homopolymer tails are annealed, any gaps resulting from differences in their lengths filled in by DNA polymerase I, and the strands joined by DNA ligase.

A disadvantage of the above technique is that it eliminates the restriction sites that were used to generate the foreign DNA insert and to cleave the vector. It may therefore be difficult to recover the insert from the cloned vector. This difficulty is circumvented by a technique in which a chemically synthesized palindromic "linker" having a restriction site matching that of the cloning vector is appended to both ends of the foreign DNA (the chemical

**Figure 5-45 Splicing DNA using terminal transferase.** Two DNA fragments may be joined through the generation of complementary homopolymer tails via the action of the enzyme terminal transferase. The poly(dA) and poly(dT) tails shown in this example may be replaced by poly(dC) and poly(dG) tails.

**Figure 5-46** Construction of a recombinant DNA molecule through the use of synthetic oligonucleotide adaptors. In this ex-

ample, the adaptor and the cloning vector have EcoRI restriction sites (red arrows).

synthesis of oligonucleotides is discussed in Section 7-6A). The linker is attached to the foreign DNA by blunt end ligation with T4 DNA ligase and then cleaved with the appropriate restriction enzyme to yield the correct cohesive ends for ligation to the vector (Fig. 5-46).

**a. Properly Transformed Cells Must Be Selected**

Both transformation and the proper construction of chimeric vectors occur with low efficiency. How can one select only those host organisms that have been transformed by the properly constructed vector? In the case of plasmid transformation, this is usually done through a double screen using antibiotics and/or **chromogenic** (color-producing) substrates. For example, the pUC18 plasmid contains the *lacZ'* gene (Fig. 5-41; a modified form of the *lac* operon's *Z* gene; Fig. 5-25). The *lacZ'* gene encodes the enzyme  $\beta$ -galactosidase, which catalyzes the hydrolysis of the bond from O1 of the sugar  $\beta$ -D-galactose to a substituent.

Thus, when grown in the presence of **5-bromo-4-chloro-3-indolyl- $\beta$ -D-galactoside** (commonly known as **X-gal**), a colorless substance which when hydrolyzed by  $\beta$ -galactosidase yields a blue product,

**5-Bromo-4-chloro-3-indolyl- $\beta$ -D-galactoside (X-gal)**  
(colorless)

**Figure 5-47 Cloning of foreign DNA in  $\lambda$  phages.** A nonessential portion of the phage genome can be replaced by a foreign DNA and packaged to form an infectious phage particle only if

the foreign DNA is approximately the same size as the DNA segment it replaced.  See the Animated Figures

*E. coli* transformed by an unmodified pUC18 plasmid form blue colonies. However, *E. coli* transformed by a pUC18 plasmid containing a foreign DNA insert in its polylinker region form colorless colonies because the insert interrupts the protein-encoding sequence of the *lacZ'* gene and hence they lack  $\beta$ -galactosidase activity. Bacteria that have failed to take up any plasmid, which would otherwise also form colorless colonies in the presence of X-gal, are excluded by adding the antibiotic **ampicillin** (Fig. 11-25) to the growth medium. Bacteria that do not contain the plasmid are sensitive to ampicillin, whereas bacteria containing the plasmid will grow, because the plasmid's intact *amp<sup>R</sup>* gene confers ampicillin resistance. Genes such as *amp<sup>R</sup>* are therefore known as **selectable markers**.

Genetically engineered  $\lambda$  phage variants contain restriction sites that flank the dispensable central third of the phage genome (Section 5-5Bb). This segment may therefore be replaced, as is described above, by a foreign DNA insert (Fig. 5-47). DNA is only packaged in  $\lambda$  phage heads if its length is from 75 to 105% of the 48.5-kb wild-type  $\lambda$  genome. Consequently,  $\lambda$  phage vectors that have failed to acquire a foreign DNA insert are unable to propagate because they are too short to form infectious phage particles. Cosmid vectors are subject to the same limitation. Moreover, cloned cosmids are harvested by repackaging them into phage particles. Hence, any cosmids that have lost sufficient DNA through random deletion to make them shorter than the above limit are not recovered. This is why cosmids can support the proliferation of large DNA inserts, whereas most other types of plasmids cannot.

#### **D. The Identification of Specific DNA Sequences: Southern Blotting**

DNA with a specific base sequence may be identified through a procedure developed by Edwin Southern known

as the **Southern transfer technique** or, more colloquially, as **Southern blotting** (Fig. 5-48). This procedure takes advantage of the valuable property of nitrocellulose that it tenaciously binds single-stranded (but not duplex) DNA [**nylon** and **polyvinylidene fluoride (PVDF)** membranes also have this property]. Following the gel electrophoresis of double-stranded DNA, the gel is soaked in 0.5M NaOH solution, which converts the DNA to its single-stranded form. The gel is then overlaid by a sheet of nitrocellulose paper which, in turn, is covered by a thick layer of paper towels, and the entire assembly is compressed by a heavy plate. The liquid in the gel is thereby forced (blotted) through the nitrocellulose so that the single-stranded DNA binds to it at the same position it had in the gel (the transfer to nitrocellulose can alternatively be accomplished by an electrophoretic process called **electroblotting**). After vacuum drying the nitrocellulose at  $\sim 80^\circ\text{C}$ , which permanently fixes the DNA in place, the nitrocellulose sheet is moistened with a minimal quantity of solution containing  $^{32}\text{P}$ -labeled single-stranded DNA or RNA (the "probe") that is complementary in sequence to the DNA of interest. The moistened sheet is held at a suitable renaturation temperature for several hours to permit the probe to anneal to its target sequence(s), washed to remove the unbound radioactive probe, dried, and then autoradiographed by placing it for a time (hours to days) over a sheet of X-ray film. The positions of the molecules that are complementary to the radioactive sequences are indicated by a blackening of the developed film. Alternatively, a **phosphorimager**, essentially "electronic film" that detects radioactivity with tenfold greater sensitivity than X-ray film, can be used.

A DNA segment containing a particular base sequence (e.g., an RFLP) may, in this manner, be detected and isolated. The radioactive probe used in this procedure can be the corresponding mRNA if it is produced in sufficient quantity to be isolated [e.g., **reticulocytes** (immature red

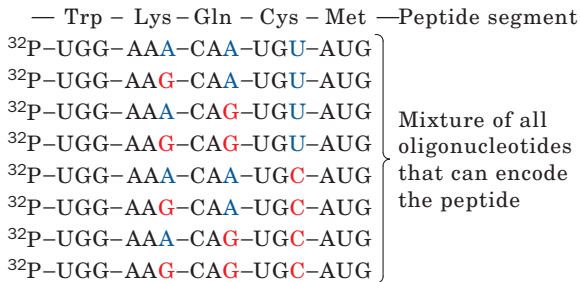

**Figure 5-48** Detection of DNAs containing specific base sequences by the Southern transfer technique.

blood cells), which produce little protein besides **hemoglobin** (the red protein that transports  $\text{O}_2$  in the blood), are rich in the mRNAs that specify hemoglobin]. Alternatively, the gene specifying a protein of known amino acid sequence may be found by synthesizing a probe that is a mixture of all oligonucleotides, which, according to the genetic code (Table 5-3), can specify a segment of the gene that has low degeneracy (Fig. 5-49).

*Southern blotting may be used for the diagnosis and prenatal detection of genetic diseases. These diseases often result from a specific change in a single gene such as a base substitution, deletion, or insertion.* The temperature at which probe hybridization is carried out may be adjusted so that only an oligonucleotide that is perfectly complementary to

a length of DNA will hybridize to it. Even a single base mismatch, under appropriate conditions, will result in a failure to hybridize. For example, the genetic disease **sickle-cell anemia** arises from a single  $\text{A} \rightarrow \text{T}$  base change in the gene specifying the  $\beta$  subunit of hemoglobin, which causes the amino acid substitution  $\text{Glu } \beta 6 \rightarrow \text{Val}$  (Section 7-3Aa). A 19-residue oligonucleotide that is complementary to the sickle-cell gene's mutated segment hybridizes, at the proper temperature, to DNA from homozygotes for the sickle-cell gene but not to DNA from normal individuals. An oligonucleotide that is complementary to the gene encoding the  $\beta$  subunit for normal hemoglobin yields opposite results. DNA from sickle-cell heterozygotes (who have one hemoglobin  $\beta$  gene bearing the sickle-cell anemia mu-

**Figure 5-49 A degenerate oligonucleotide probe.** Such a probe is a mixture of all oligonucleotides that can encode a polypeptide segment of known sequence. In practice, such a segment is chosen to contain a high proportion of residues specified by low-degeneracy codons. In the pentapeptide segment shown here, Trp and Met are each specified by only one codon and Lys, Gln, and Cys are each specified by two codons that differ in only their third positions (*blue and red*; Table 5-3) for a total of  $1 \times 2 \times 2 \times 2 \times 1 = 8$  oligonucleotides. The oligonucleotides are <sup>32</sup>P-labeled for use in Southern blotting.

tation and one that is normal) hybridizes to both probes but in reduced amounts relative to the DNAs from homozygotes. The oligonucleotide probes may consequently be used in the prenatal diagnosis of sickle-cell anemia. (Note that the availability of fetal genetic testing has actually increased the number of births because many couples who knew they had a high risk of conceiving a genetically defective child previously chose not to have children.) The use of DNA probes is also rapidly replacing the much slower and less accurate culturing techniques for the identification of pathogenic bacteria.

In a variation of the Southern blotting procedure, specific DNAs may be detected by linking the probe to an enzyme that generates a colored or fluorescent deposit on the blot when exposed to the proper reagents. Alternatively, a probe that is covalently linked to a dye that fluoresces when stimulated by a laser may be used. Such nonradioactive detection techniques are desirable in a clinical setting because of the health hazards, disposal problems, and more cumbersome nature of radiographic methods. Specific RNA sequences may be detected through a different variation of the Southern transfer, punningly named a **North-ern transfer (Northern blot)**, in which the RNA is immobilized on nitrocellulose paper and detected through the use of complementary RNA or DNA probes.

### E. Genomic Libraries

In order to clone a particular DNA fragment, it must first be obtained in relatively pure form. The magnitude of this task may be appreciated when it is realized that, for example, a 1-kb fragment of human DNA represents only 0.000033% of the 3 billion-bp human genome. A DNA fragment may be identified by Southern blotting of a restriction digest of the genomic DNA under investigation. In practice, however, it is usually more difficult to identify a particular gene from an organism and then clone it than

it is to clone the organism's entire genome as DNA fragments and then identify the clone(s) containing the sequence(s) of interest. Such a set of cloned fragments is known as a **genomic library**. A genomic library of a particular organism need only be made once since it can be perpetuated for use whenever a new probe becomes available.

Genomic libraries are generated according to a procedure known as **shotgun cloning**. The chromosomal DNA of the organism of interest is isolated, cleaved to fragments of clonable size, and inserted in a cloning vector by the methods described in Section 5-5B. The DNA is fragmented by partial rather than exhaustive restriction digestion (permitting the restriction enzyme to act for only a short time) so that the genomic library contains intact representatives of all the organism's genes, including those whose sequences contain restriction sites. Shear fragmentation by rapid stirring of a DNA solution or by sonication is also used but requires further treatment of the fragments to insert them into cloning vectors. Genomic libraries have been established for numerous organisms including yeast, *Drosophila*, mice, and humans.

#### a. Many Clones Must Be Screened to Obtain a Gene of Interest

The number of random cleavage fragments that must be cloned to ensure a high probability that a given sequence is represented at least once in the genomic library is calculated as follows: The probability  $P$  that a set of  $N$  clones contains a fragment that constitutes a fraction  $f$ , in bp, of the organism's genome is

$$P = 1 - (1 - f)^N \quad [5.2]$$

Consequently,

$$N = \log(1 - P)/\log(1 - f) \quad [5.3]$$

Thus, to have  $P = 0.99$  with fragments averaging 10 kb in length, for the 4639-kb *E. coli* chromosome ( $f = 0.00216$ ),  $N = 2134$  clones, whereas for the 180,000-kb *Drosophila* genome ( $f = 0.0000566$ ),  $N = 83,000$ . The use of YAC- or BAC-based genomic libraries therefore greatly reduces the effort necessary to obtain a given gene segment from a large genome.

Since a genomic library lacks an index, it must be screened for the presence of a particular gene. This is done by a process known as **colony** or **in situ hybridization** (Fig. 5-50; Latin: *in situ*, in position). The cloned yeast colonies, bacterial colonies, or phage plaques to be tested are transferred, by replica plating (Fig. 1-30), from a master plate to a nitrocellulose filter. The filter is treated with NaOH, which lyses the cells or phages and denatures the DNA so that it binds to the nitrocellulose (recall that single-stranded DNA is preferentially bound to nitrocellulose). The filter is then dried to fix the DNA in place, treated under annealing conditions with a radioactive probe for the gene of interest, washed, and autoradiographed. *Only those colonies or plaques containing the sought-after gene will bind the probe and thereby blacken the film.* The corresponding clones can then be retrieved from the master plate.

**Figure 5-50** Colony (*in situ*) hybridization. This technique identifies the clones containing a DNA of interest.

Using this technique, even an  $\sim 1$  million clone human genomic library can be readily screened for the presence of one particular DNA segment.

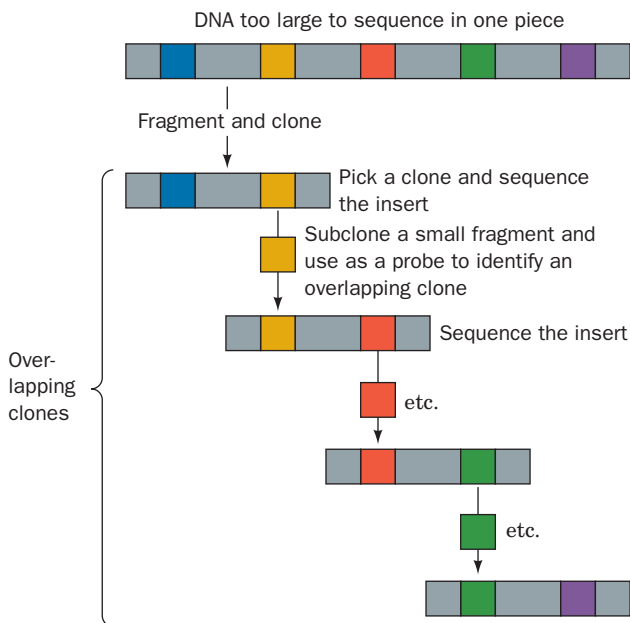

Many eukaryotic genes and gene clusters span enormous tracts of DNA (Section 34-2); some consist of  $>1000$  kb. With the use of plasmid-, phage-, or cosmid-based genomic libraries, such long DNAs can only be obtained as a series of overlapping fragments (Fig. 5-51). Each gene frag-

ment that has been isolated is, in turn, used as a probe to identify a successive but partially overlapping fragment of that gene, a process called **chromosome walking**. The use of YACs and BACs, however, greatly reduces the need for this laborious and error-prone process.

## F. The Polymerase Chain Reaction

 See Guided Exploration 3: PCR and site-directed mutagenesis Although molecular cloning techniques are indispensable to modern biochemical research, the use of the **polymerase chain reaction (PCR)** offers a faster and more convenient method of amplifying a specific DNA segment of up to 6 kb. In this technique (Fig. 5-52), which was formulated in 1985 by Kary Mullis, a heat denatured (strand-separated) DNA sample is incubated with DNA polymerase, dNTPs, and two oligonucleotide primers whose sequences flank the DNA segment of interest so that they direct the DNA polymerase to synthesize new complementary strands. Multiple cycles of this process, each doubling the amount of DNA present, geometrically amplify the DNA starting from as little as a single gene copy. In each cycle, the two strands of the duplex DNA are separated by heat denaturation at  $95^{\circ}\text{C}$ , the temperature is then lowered to permit the primers to anneal to their complementary segments on the DNA, and the DNA polymerase directs the synthesis of the complementary strands (Section 5-4C). The use of a heat-stable DNA polymerase, such as those from the thermophilic bacteria *Thermus aquaticus* (**Taq DNA polymerase**) or *Pyrococcus furiosus* (**Pfu DNA polymerase**), both of which are stable at  $95^{\circ}\text{C}$ , eliminates the need to add fresh enzyme after each heat denaturation step. Hence, in the presence of sufficient quantities of primers and dNTPs, the PCR is carried out simply by cyclically varying the temperature in an automatic device called a **thermocycler**.

Twenty cycles of PCR amplification theoretically increase the amount of the target sequence by  $2^{20} \approx 10^6$ -fold with high specificity (in practice, the number of copies of target sequence largely doubles with each PCR cycle until

**Figure 5-51** Chromosome walking. A DNA segment too large to sequence in one piece is fragmented and cloned. A clone is picked and the DNA insert it contains is sequenced. A small fragment of the insert near one end is subcloned (cloned from a clone) and used as a probe to select a clone containing an overlapping insert, which, in turn, is sequenced. The process is repeated so as to "walk" down the chromosome. Chromosome walking can, of course, extend in both directions.

**Figure 5-52 The polymerase chain reaction (PCR).** In each cycle of the reaction, the strands of the duplex DNA are separated by heat denaturation, the preparation is cooled such that synthetic DNA primers anneal to a complementary segment on each strand, and the primers are extended by DNA polymerase. The process is then repeated for numerous cycles. The number of “unit-length” strands doubles with every cycle after the second cycle.

more primer–template complex accumulates than the DNA polymerase can extend during a cycle, whereon the rate of increase of target DNA becomes linear rather than geometric; the actual yield is typically ~20% of the theoretical yield). Indeed, the method has been shown to amplify a target DNA present only once in a sample of  $10^5$  cells, thereby demonstrating that the method can be used without prior DNA purification (although, as a consequence of this enormous amplification, particular care must be taken that the DNA sample of interest is not contaminated by extraneous DNA that is similar in sequence to that under investigation). The amplified DNA can be characterized by a variety of techniques including RFLP analysis, Southern blotting, and direct sequencing (Section 7-2A). PCR amplification is therefore a form of “cell-free molecular cloning” that can accomplish in an automated *in vitro* procedure requiring as little as 30 minutes what would otherwise take days or weeks via the cloning techniques discussed above.

#### a. PCR Has Many Uses

*PCR amplification has become an indispensable tool in a great variety of applications.* Clinically, it is used for the rapid diagnosis of infectious diseases and the detection of rare pathological events such as mutations leading to cancer (Section 19-3Ba). Forensically, the DNA from a single hair, sperm, or drop of blood can be used to identify the donor. This is most commonly done through the analysis of **short tandem repeats (STRs)**, segments of DNA that contain repeating sequences of 2 to 7 bp such as  $(CA)_n$  and  $(ATGC)_n$  and that are scattered throughout the genome [e.g., the human genome contains ~100,000  $(CA)_n$  STRs]. The number of tandem repeats,  $n$ , in many STRs is genetically variable [ $n$  varies from 1 to 40 for particular  $(CA)_n$  STRs] and hence such repeats are markers of individuality (much as are RFLPs). The DNA of a particular STR can be PCR-amplified through the use of primers that are complementary to the unique (nonrepeating) sequences flanking the STR. The number of tandem repeats in that STR from a particular individual can then be determined, either by the measurement of its molecular mass through polyacrylamide gel electrophoresis (Section 6-6C) or by direct sequencing (Section 7-2A). The determination of this number for several well-characterized STRs (those whose numbers of repeats have been determined in numerous individuals of multiple ethnicities), that is, the DNA’s haplotype, can unambiguously identify the DNA’s donor.

STRs are also widely used to prove or disprove familial relationships. For example, oral tradition suggests that

Thomas Jefferson, the third American president, fathered a son, Eston Hemings (born in 1808), with his slave Sally Hemings (Eston Hemings was said to bear a striking physical resemblance to Jefferson). Only the tips of the Y chromosome undergo recombination (with the X chromosome) and the rest of it is passed unchanged from father to son (except for occasional mutations). The finding that the Y chromosomes of male-line descendants of both Eston Hemings and Jefferson's father's brother (Jefferson had no surviving legitimate sons) had identical STR-based haplotypes indicates that Thomas Jefferson was probably Eston Hemings' father (although this could also be true of any of Jefferson's contemporary male-line relatives).

RNA may also be amplified via PCR by first reverse-transcribing it into a complementary strand of DNA (**cdDNA**) through the action of an enzyme named **RNA-directed DNA polymerase** (commonly known as **reverse transcriptase**). This enzyme, which is produced by certain RNA-containing viruses known as **retroviruses** (Section 30-4C), uses an RNA template but is otherwise similar in the reaction it catalyzes to DNA polymerase I.

Variations on the theme of PCR have found numerous applications. For instance, single-stranded DNA (which is required for DNA sequencing; Section 7-2A) can be rapidly generated via **asymmetric PCR**, in which such a small amount of one primer is used that it is exhausted after several PCR cycles. In subsequent cycles, only the strand extended from the other primer, which is present in excess, is synthesized (note that PCR amplification becomes linear rather than geometric after one primer is used up). In cases that primers may anneal to more than one site in the target DNA, **nested primers** can be used to ensure that only the target sequence is amplified. In this technique, PCR amplification is normally carried out using one pair of primers. The products of this amplification are then further amplified through the use of a second pair of primers that anneal to the target DNA within its amplified region. It is highly unlikely that both pairs of primers will incorrectly anneal in a nested fashion to a nontarget DNA, and hence only the target DNA will be amplified.

### b. Neanderthals Are Not Ancestors of Modern Humans

PCR is also largely responsible for the budding science of molecular archeology. For example, PCR-based techniques have been used by Svante Pääbo to determine whether or not Neanderthals form a different species from modern human beings. Neanderthals (*Homo neandertalensis*; also called Neandertals) are extinct hominids that were about 30% larger than are modern humans, apparently had great muscular strength, and had low foreheads and protruding brows. According to the radiodated fossil record, they became extinct ~28,000 years ago after having inhabited Europe and western Asia for over 300,000 years. During the latter part of this period they coexisted with our direct ancestors (who might well have been responsible for their demise). Thus, an important anthropological issue is whether Neanderthals constituted an ancient race of *Homo sapiens* ancestral to modern humans or were a sep-

arate species. The morphological evidence has been cited as supporting both possibilities. A convincing way to settle this dispute would be by the comparison of the DNA sequences of modern humans with those of Neanderthals.

The DNA was extracted from a 0.4-g sample of a Neanderthal bone, and its mitochondrial DNA (**mtDNA**) was amplified by PCR (mtDNA rather than nuclear DNA was amplified because cells contain numerous mitochondria and hence an mtDNA sequence is 100- to 1000-fold more abundant than is any particular sequence of nuclear DNA). The sequence of the Neanderthal mtDNA was compared to those of 986 modern human lineages of a wide variety of ethnicities and 16 common lineages of chimpanzees (the closest living relatives of modern humans). A phylogenetic tree based on their sequence differences indicates that humans and chimpanzees diverged (had their last common ancestor) about 4 million years ago, humans and Neanderthals diverged around 660,000 years ago, and modern humans diverged from one another about 150,000 years ago. These sequence comparisons indicate that Neanderthals did not contribute significant genetic information to modern humans during their many thousand-year coexistence and hence that *Homo neandertalensis* and *Homo sapiens* are separate species. This conclusion was confirmed by similar analyses of eleven Neanderthal samples from diverse locations throughout Europe.

### c. DNA Decays Quickly on the Geological Time Scale

There have been reports in the literature of DNAs that were PCR-amplified from fossils that were several million years old and from amber-entombed insects (amber is fossilized tree resin) that were as old as 135 million years (a phenomenon that formed the "basis" for the novel and movie *Jurassic Park*). Yet, over geological time spans, DNA decomposes, mostly through hydrolysis of the sugar-phosphate backbone and oxidative damage to the bases. How old can a fossil become before its DNA has decayed beyond recognition?

The amino acid residues in hydrated proteins racemize at a rate similar to the rate at which DNA decomposes. Since proteins in organisms are far more abundant than are specific DNA sequences, the enantiomeric (D/L) ratios of an amino acid residue can be determined directly (rather than requiring some sort of amplification, as in the case of DNA). The determination, in a variety of archeological specimens whose age could be authenticated, of the enantiomeric ratio of Asp (the fastest racemizing amino acid residue) revealed that DNA sequences can only be retrieved from samples in which the Asp D/L ratio is less than 0.08. These studies indicate that the survival of recognizable DNA sequences is limited to a few thousand years in warm regions such as Egypt and to as much as 100,000 years in cold regions such as Siberia. It therefore appears that the putatively very ancient DNAs, in reality, resulted from the artifactual amplification of contaminating modern DNAs, particularly those from the human operators carrying out the PCR amplifications. Indeed, the DNA in the above Neanderthal fossil had decomposed to the point that it appeared unlikely that its nuclear DNA could have

been successfully sequenced, which is why its mtDNA was amplified instead [although with contemporary methods of DNA sequencing (Section 7-2C) this has now become possible].

Despite the foregoing, there is credible evidence that certain bacterial spores can remain viable almost indefinitely. Bacterial spores, which several bacterial groups including bacilli form under adverse conditions, function to permit the bacterium's survival until conditions become favorable for growth. Bacterial spores have thick protective protein coats, their cytoplasm is partially dehydrated and mineralized, and their DNA is specifically stabilized by specialized proteins (Section 29-1Ba). Thus, a bacillus was cultured from a 25- to 40-million-year-old (Myr) amber-entombed bee after the surface of the amber had been chemically sterilized. Similarly, a halophilic (salt-loving) bacillus was cultured from a tiny ( $\sim 9 \mu\text{L}$ ) brine-filled inclusion in a surface-sterilized salt crystal from a 250-Myr salt deposit.

### G. Production of Proteins

One of the most important uses of recombinant DNA technology is the production of large quantities of scarce and/or novel proteins. This is a relatively straightforward procedure for bacterial proteins: A cloned **structural gene** (a gene that encodes a protein) is inserted into an **expression vector**, a plasmid or virus that contains the properly positioned transcriptional and translational control sequences for the protein's expression. With the use of a relaxed control plasmid and an efficient promoter, the production of a protein of interest may reach 30% of the host bacterium's total cellular protein. Such genetically engineered organisms are called **overproducers**.

Bacterial cells often sequester such large amounts of useless (to the bacterium) protein as insoluble and denatured **inclusion bodies** (Fig. 5-53). A protein extracted from such inclusion bodies must therefore be renatured, usually by dissolving it in a solution of **urea** or **guanidinium ion** (substances that induce proteins to denature)

and then slowly removing the denaturant via a membrane through which the denaturant but not the protein can pass [**dialysis** or **ultrafiltration** (Section 6-3Bc); protein denaturation and renaturation are discussed in Section 9-1A].

A strategy for avoiding the foregoing difficulty is to engineer the gene for the protein of interest so that is preceded with a bacterial **signal sequence** that directs the protein synthesizing machinery of gram-negative bacteria such as *E. coli* to secrete the protein to their **periplasmic space** (the compartment between their plasma membrane and cell wall; signal sequences are discussed in Section 12-4Ba). The signal sequence is then removed by a specific bacterial protease. Secreted proteins, which are relatively few in number, can be released into the medium by the osmotic disruption (Section 6-1B) of the bacterial outer membrane

**Figure 5-53** Electron micrograph of an inclusion body of the protein prochymosin in an *E. coli* cell. [Courtesy of Teruhiko Beppu, Nikon University, Japan.]

(Section 1-1B; the bacterial cell wall is porous), so their purification is greatly simplified relative to that of intracellular proteins.

Another problem encountered when producing a foreign protein is that the protein may be toxic to the host cell (e.g., producing a protease may destroy the cell's proteins), thus killing the bacterial culture before sufficient amounts of the protein can be generated. One way to circumvent this problem is to place the gene encoding the toxic protein under the control of an inducible promoter, for example, the *lac* promoter in a plasmid that also includes the gene for the *lac* repressor (Section 5-4Aa). Then, the binding of the *lac* repressor to the *lac* promoter will prevent the expression of the foreign protein in the same way that it prevents the expression of the *lac* operon genes (Fig. 5-25a). However, after the cells have grown to a high concentration, an inducer is added that releases the repressor from the promoter and permits the expression of the foreign protein (Fig. 5-25b). The cells are thereby killed but not before they have produced large amounts of the foreign protein. For the *lac* repressor, the inducer of choice is **isopropylthiogalactoside (IPTG)**; (Section 31-1Aa), a synthetic, nonmetabolizable analog of the *lac* repressor's natural inducer, allolactose.

A problem associated with inserting a DNA segment into a vector, as is indicated in Fig. 5-44, is that any pair of sticky ends that have been made by a given restriction enzyme can be ligated together. Consequently, the products of a ligation reaction will include tandemly (one-after-the-other) linked vectors, inserts, and their various combinations in both linear and circular arrangements. Moreover, in the case of expression systems, 50% of the structural genes that are inserted into circular expression vectors will be installed backward with respect to the expression vector's

transcriptional and translational control sequences and hence will not be properly expressed. The efficiency of the ligation process can be greatly enhanced through the use of **directional cloning** (Fig. 5-54). In this process, two different restriction enzymes are employed to generate two different types of sticky ends on both the insert and the vector. In expression systems, these are arranged such that the structural gene can only be inserted into the expression vector in the correct orientation for expression.

**Figure 5-54 Construction of a recombinant DNA molecule by directional cloning.** Two restriction enzymes, which yield different sticky ends, are used so that the foreign DNA fragment can only be inserted into the cloning vector in one orientation.

### a. Eukaryotic Proteins Can Be Produced in Bacteria and in Eukaryotic Cells

The synthesis of a eukaryotic protein in a prokaryotic host presents several problems not encountered with prokaryotic proteins:

1. The eukaryotic control elements for RNA and protein synthesis are not recognized by bacterial hosts.
2. Bacteria lack the cellular machinery to excise the introns that are present in most eukaryotic transcripts, that is, bacteria cannot carry out gene splicing (Section 5-4Ac).
3. Bacteria lack the enzyme systems to carry out the specific post-translational processing that many eukaryotic proteins require for biological activity (Section 32-5). Most conspicuously, bacteria do not glycosylate proteins (although, in many cases, glycosylation does not seem to affect protein function).
4. Eukaryotic proteins may be preferentially degraded by bacterial proteases (Section 32-6A).

The problem of nonrecognition of eukaryotic control elements can be eliminated by inserting the protein-encoding portion of a eukaryotic gene into a vector containing correctly placed bacterial control elements. The need to excise introns can be circumvented by cloning the cDNA of the protein's mature mRNA. Alternatively, genes encoding small proteins of known sequence can be chemically synthesized (Section 7-6A). Neither of these strategies is universally applicable, however, because few mRNAs are sufficiently abundant to be isolated and the genes encoding many eukaryotic proteins are much larger than can presently be reliably synthesized. Likewise, no general approach has been developed for the post-translational modification of eukaryotic proteins.

The preferential bacterial proteolysis of certain eukaryotic proteins may be prevented by inserting the eukaryotic gene after a bacterial gene such that both have the same reading frame. The resulting **hybrid** or **fusion protein** has an N-terminal polypeptide of bacterial origin that, in some cases, prevents bacterial proteases from recognizing the eukaryotic segment as being foreign. The purification of a fusion protein may be greatly facilitated by the specific binding properties of its N-terminal portion via a process known as **affinity chromatography** (Section 6-3C). Moreover, the formation of a fusion protein may render soluble its otherwise insoluble C-terminal portion. The two polypeptide segments can later be separated by treatment with a protease that specifically cleaves a susceptible site that had been engineered into the boundary between the segments (see below).

The development of cloning vectors that propagate in eukaryotic hosts, such as yeast or cultured animal cells, has led to the elimination of many of the above problems (although post-translational processing, and in particular glycosylation, may vary among different eukaryotes). Baculovirus-based vectors, which replicate in cultured insect cells, have been particularly successful in this regard. Moreover, **shuttle vectors** are available that can propagate in both yeast and *E. coli* and thus transfer (shuttle) genes between these two types of cells.

### b. Recombinant Protein Production Has Important Practical Consequences

The ability to synthesize a given protein in large quantities has had an enormous medical, agricultural, and industrial impact. Those that are in routine clinical use include **human insulin** (a polypeptide hormone that regulates fuel metabolism and whose administration is required for survival by certain types of diabetics; Section 27-3B), human growth hormone [**somatotropin**, which induces the proliferation of muscle, bone, and cartilage and is used to stimulate growth in children of abnormally short stature (Section 19-1J); before the advent of recombinant DNA techniques, somatotropin was only available in small quantities from the pituitaries of cadavers], **erythropoietin** (a protein growth factor secreted by the kidney that stimulates the production of red blood cells and is used in the treatment of anemia arising from kidney disease), several types of **colony-stimulating factors** (which stimulate the production and activation of white blood cells and are used clinically to counter the white cell-killing effects of chemotherapy and to facilitate bone marrow transplantation), and **tissue-type plasminogen activator (t-PA)**, which is used to promote the dissolution of the blood clots responsible for heart attacks and stroke; Section 35-1F). Synthetic vaccines consisting of harmless but immunogenic components of pathogens, for example, **hepatitis B** vaccine, are eliminating the risks attendant in using killed or attenuated viruses or bacteria in vaccines as well as making possible new strategies of vaccine development. The use of recombinant **blood clotting factors** in treating individuals with the inherited disease **hemophilia** (in which these factors are defective; Section 35-1Da) has replaced the need to extract these scarce proteins from large quantities of human blood and has thereby eliminated the high risk that hemophiliacs previously faced of contracting such blood-borne diseases as hepatitis and AIDS. Bovine somatotropin (**bST**) has long been known to stimulate milk production in dairy cows by ~15%. Its use has been made cost-effective, however, by the advent of recombinant DNA technology since bST could previously only be obtained in small quantities from cow pituitaries. Recombinant porcine somatotropin (**pST**), which is administered to growing pigs, induces ~15% greater growth on ~20% less feed while producing leaner meat.

### c. Site-Directed and Cassette Mutagenesis Generate Proteins with Specific Sequence Changes

Of equal importance to protein production is the ability to tailor proteins to specific applications by altering their amino acid sequences at specific sites. This is frequently done via a method pioneered by Michael Smith known as **site-directed mutagenesis**. In this technique, an oligonucleotide containing a short gene segment with the desired altered base sequence corresponding to the new amino acid sequence (and synthesized by techniques discussed in Section 7-6Aa) is used as a primer in the DNA polymerase I-mediated replication of the gene of interest. Such a primer can be made to hybridize to the corresponding wild-type sequence if there are only a few mismatched base

**Figure 5-55 Site-directed mutagenesis.** A chemically synthesized oligonucleotide incorporating the desired base changes is hybridized to the DNA encoding the gene to be altered (*green strand*). The mismatched primer is then extended by DNA polymerase I, thereby generating the mutated gene (*blue strand*). The mutated gene can subsequently be inserted into a suitable host organism so as to yield the mutant DNA, or its corresponding RNA, in quantity, produce a specifically altered protein, and/or generate a mutant organism.  See the Animated Figures

pairs, and its extension, by DNA polymerase I, yields the desired altered gene (Fig. 5-55). The altered gene can then be inserted in a suitable organism via techniques discussed in Section 5-5C and grown (cloned) in quantity. Similarly, PCR may be used as a vehicle for site-directed mutagenesis simply by using a mutagenized primer in amplifying a gene of interest so that the resulting DNA contains the altered sequence.

Using site-directed mutagenesis, the development of a variant form of the bacterial protease **subtilisin** (Section 15-3Bb) in which Met 222 has been changed to Ala (Met 222 → Ala or M222A) has permitted its use in laundry detergent that contains bleach (which largely inactivates wild-type subtilisin by oxidizing Met 222). **Monoclonal antibodies** (a single species of antibody produced by a clone of an antibody-producing cell; Sections 6-1Da and 35-2Bd) can be targeted against specific proteins and hence are used as antitumor agents. However, since monoclonal antibodies, as usually made, are mouse proteins, they are ineffective as therapeutic agents in humans because humans mount an immune response against mouse proteins. This difficulty has been rectified by “humanizing” monoclonal antibodies by replacing their mouse-specific sequences with those of humans (which the human immune system ignores) through site-directed mutagenesis. Thus the monoclonal antibody known as **trastuzumab** (trade name **Herceptin**), which binds specifically to the growth factor receptor **HER2** that is overexpressed in ~25% of breast

cancers, blocks HER2's growth-signaling activity, thereby causing the tumor to stop growing or even regress.

In an alternative mutagenesis technique called **cassette mutagenesis**, complementary oligonucleotides containing the mutation(s) of interest are chemically synthesized (Section 7-6Aa) and annealed to create a duplex "cassette." The cassette is then ligated into the target gene, which must therefore contain an appropriately placed unique restriction site (which can be introduced through site-directed mutagenesis; the cassette must, of course, have the corresponding sticky ends) or, if the cassette is to replace an existing segment of the target gene, two possibly different restriction sites flanking the replaceable segment. Cassette mutagenesis is particularly useful for the insertion of short peptide sequences into a protein of interest (e.g., for the introduction of a proteolytic target site for the cleavage of a fusion protein), when a specific region of the protein is to be subjected to extensive and/or repeated mutagenesis, and for the generation of proteins containing all possible sequences in a short segment (by synthesizing a mixture of cassettes containing all possible variants of the corresponding codons; Section 7-6C).

We will see numerous instances throughout this textbook of protein function being mutagenically character-

**Figure 5-56 Use of green fluorescent protein (GFP) as a reporter gene.** The gene for GFP was placed under the control of the *Drosophila per* gene promoter and transformed into *Drosophila*. The *per* gene encodes a so-called clock protein that is involved in controlling the fruit fly's circadian (daily) rhythm. The intensity of the green fluorescence of the isolated fly head seen here, which also occurs in other body parts, follows a daily oscillation that can be reset by light. These observations indicate that individual cells in *Drosophila* have photoreceptors and suggest that each of these cells possesses an independent clock. Evidently the head, which was previously thought to be the fly's master oscillator, does not coordinate all of its rhythms. [Courtesy of Steve A. Kay, The Scripps Research Institute, La Jolla, California.]

ized through the replacement of a specific residue(s) or a polypeptide segment suspected of having an important mechanistic or structural role. Indeed, mutagenesis has become an indispensable tool in the practice of enzymology.

#### d. Reporter Genes Can Be Used to Monitor Transcriptional Activity

The rate at which a structural gene is expressed depends on its upstream control sequences. Consequently, the rate of expression of a gene can be monitored by replacing its protein-encoding portion with or fusing it in frame to a gene expressing a protein whose presence can be easily determined. An already familiar example of such a **reporter gene** is the *lacZ* gene in the presence of X-gal (Section 5-5Ca) because its level of expression is readily quantitated by the intensity of the blue color that is generated. Although numerous reporter genes have been developed, that which has gained the greatest use encodes **green fluorescent protein (GFP)**. GFP, a product of the bioluminescent jellyfish *Aequorea victoria*, fluoresces with a peak wavelength of 508 nm (green light) when irradiated by UV or blue light (optimally 400 nm). This nontoxic protein, whose use was pioneered by Osamu Shimomura and Martin Chalfie, is intrinsically fluorescent; its light-emitting group is the product of the spontaneous cyclization and oxidation by O<sub>2</sub> of three consecutive residues, Ser-Tyr-Gly, to yield a conjugated system of double bonds that gives the protein its fluorescent properties.

Hence GFP requires no substrate or small molecule cofactor to fluoresce as do other highly fluorescent proteins. Its presence can therefore be monitored through the use of UV light or a fluorometer, and its cellular location can be determined through fluorescence microscopy (Fig. 5-56). Consequently, when the GFP gene is placed under control of the gene expressing a particular protein (GFP's fluorescence

**Figure 5-57** Fluorescence of solutions of GFP and ten of its variants. Note that each of these proteins fluoresces with a different color. [Courtesy of Roger Tsien, University of California at San Diego.]

is unaffected by the formation of a fusion protein), the protein's expressional activity can be readily determined. In fact, a number of GFP variants with distinct sets of excitation and emission wavelengths were developed by Roger Tsien through genetic engineering (Fig. 5-57) and hence the expressional activities of several different genes can be monitored simultaneously. Moreover, the development of pH-sensitive GFP variants permits the monitoring of the pH in subcellular compartments.

#### H. Transgenic Organisms and Gene Therapy

For many purposes it is preferable to tailor an intact organism rather than just a protein—true genetic engineering. Multicellular organisms expressing a foreign (from another organism) gene are said to be **transgenic** and their transplanted foreign genes are often referred to as **transgenes**. For the change to be permanent, that is, heritable, a transgene must be stably integrated into the organism's germ cells. For mice, in techniques pioneered by Mario Capecchi, Martin Evans, and Oliver Smithies, this is accomplished by microinjecting (transfecting) DNA encoding the desired altered characteristics into a **pronucleus** of a fertilized ovum (Fig. 5-58; a fertilized ovum contains two pronuclei,

**Figure 5-58** Microinjection of DNA into the pronucleus of a fertilized mouse ovum. The ovum is being held in place by gentle suction from the pipette on the left. [Science Vu/Visuals Unlimited.]

one from the sperm and the other from the ovum, which eventually fuse to form the nucleus of the one-celled embryo) and implanting it into the uterus of a foster mother. The DNA integrates at a random position in the genome of the pronucleus through a poorly understood mechanism. Alternatively, an **embryonic stem cell** (an undifferentiated embryonic cell that can give rise, *in utero*, to an entire organism) may be transfected with an altered gene, which occasionally replaces its normal counterpart via recombination. A normal gene may, in this manner, be “knocked out” (permanently inactivated) by transfection with a defective version of the gene. With either method, mating heterozygotes for the altered gene yields progeny that are homozygotes for the altered gene. The use of transgenic mice, and in particular **knockout mice**, has greatly enhanced our understanding of vertebrate gene expression (Section 34-3).

#### a. Transgenic Organisms Have Many Uses

Procedures are being developed to generate transgenic farm animals such as cows, goats, pigs, and sheep. Animals may thus be induced to grow larger on lesser amounts of feed and/or to be resistant to particular diseases, although this will require a greater understanding of the genes involved than is presently available. An intriguing application of transgenic farm animals is for them to secrete pharmaceutically useful proteins, such as human growth hormone and blood clotting factors, into their milk. Such a transgenic cow, it is expected, will yield several grams of a foreign protein per liter of milk (tens of kilograms per year), which can thereby be produced far more economically than it can by bacteria. A small herd of such “pharm animals” could satisfy the world's need for a particular medicinally useful protein.

The transplantation between humans of organs such as hearts, lungs, livers, and kidneys (a process known as **allo-transplantation**; Greek: *allos*, other) has saved tens of thousands of lives since the late 1960s. However, the demand for transplantable organs has so outstripped the supply that as little as 5% of the organs needed in the United States become available. This organ shortage could be entirely eliminated if organs from human-sized animals such as pigs could be transplanted into humans (a process known as **xenotransplantation**; Greek: *xenos*, strange or foreign). However, the xenotransplantation of a pig organ into a human results in the destruction of that organ in as little as a six minutes through a series of **complement system**-mediated reactions that are triggered by the foreign antigens lining the blood vessels of the xenograft (the complement system constitutes the body's first line of immunological defenses; Section 35-2F). This **hyperacute rejection** occurs because the porcine tissue lacks the human proteins that inhibit the human complement system. However, when the organs from pigs that were made transgenic in these human inhibitory proteins were transplanted into baboons, the hyperacute rejection of these organs did not occur. Thus, although not all the problems of xenotransplantation have been eliminated (baboons with transplanted pig hearts have survived as long as six months), it now seems likely that genetic engineering techniques will eventually

make xenotransplantation a practical alternative to allotransplantation.

Transgenic plants are becoming increasingly available, promising a significant extension of the “green revolution” that has changed the face of agriculture throughout the world since the 1950s. For example, during sporulation, various strains of the soil microbe *Bacillus thuringiensis* (**Bt**) express proteins that specifically bind to the intestinal cells of certain insects in a manner that lyses these cells, thereby killing the insect through starvation and infection. These so-called  **$\delta$ -endotoxins** (also known as **crystal proteins** because Bt spores contain them in microcrystalline form) are innocuous to vertebrates and, hence, Bt spores have been used to control such pests as the **gypsy moth**. Unfortunately, Bt decays after a short time. However, the gene for a  $\delta$ -endotoxin has been cloned into corn, where, for example, it confers protection against the **European corn borer** (a commercially significant pest that, for much of its life cycle, lives inside the corn plant, where it is largely inaccessible to chemical insecticides). The use of such **Bt corn**, which is now widely planted in the United States, has greatly reduced the need for chemical insecticides.  $\delta$ -Endotoxin genes have likewise been successfully cloned into a variety of agriculturally significant plants including potatoes, soybeans, and cotton.

Among the properties of crop plants that have been generated through genetic engineering are increased herbicide resistance (which permits the more selective use of herbicides to control weeds); resistance to viruses, bacteria, and fungi; control of ripening (to permit a crop to be brought to market at the optimum time); altered plant architecture such as height (which can improve crop productivity); increased tolerance to environmental stresses such as cold, heat, drought and salinity; and modified or additional vitamins, starch, proteins, and oils (for improved nutritional properties and the production of sustainable supplies of raw materials). For example, a strain of rice has been developed that contains the foreign genes encoding the enzymes that synthesize  **$\beta$ -carotene** (Section 24-2Ad), an orange pigment that is a precursor of **vitamin A**. This genetically modified rice, which is named golden rice (Fig. 5-59), could help alleviate vitamin A deficiency, which afflicts ~400 million people and causes an estimated 1.5 million deaths and 400,000 cases of irreversible blindness per year, mainly in children. Unfortunately, the irrational fear of genetically modified organisms fostered by certain environmental and antiglobalization organizations has led to a thicket of regulations on transgenic crops that, as yet, has prevented golden rice from being made available to farmers in the poor countries where vitamin A deficiency is widespread.

#### b. Gene Therapy Has Enormous Medical Potential

**Gene therapy**, the transfer of new genetic material to the cells of an individual resulting in therapeutic benefit to that individual, has been under clinical investigation since 1990, when W. French Anderson and Michael Blaese employed this technology with two children (Section 28-4A) in an effort to alleviate their **severe combined immunodeficiency disease (SCID)**; any of several genetic diseases that

**Figure 5-59 Golden rice.** The rice grains on the left are the wild type. The grains on the right have been engineered to synthesize  $\beta$ -carotene, which gives them their yellow color. [Courtesy of Golden Rice Humanitarian Board, <http://www.goldenrice.org>.]

so impair the immune system that a victim must be kept in a sterile environment in order to survive). Around 4000 genetic diseases are presently known and are therefore potential targets of gene therapy.

Hundreds of gene-transfer protocols are currently under development for use in gene therapy. Ideally, these would deliver the gene(s) of interest to only their target cells such that the gene is permanently installed in these cells in a way that it undergoes sustained expression at the proper level and without causing any adverse side effects. Both nonviral and viral vectors are under development. Nonviral vectors deliver naked DNA to target cells, for example, by direct injection and via **liposomes** (membrane enveloped vesicles that are designed to be taken up by specific cells; Section 12-2B). A large variety of viral vectors are under investigation including those whose genetic material is DNA and those in which it is RNA. These viral vectors have been engineered so as to replace the genes encoding essential viral proteins with therapeutic genes. Hence, cells that have been “infected” by these “viruses” contain the therapeutic genes in their chromosomes but they lack the genetic information to replicate the virus.

There are three categories of gene therapy:

1. In the *ex vivo* (out of the body) approach, cells are removed from the body, incubated with a vector, and then returned to the body. This procedure is usually done with bone marrow cells, which are blood cell precursors.

2. In the *in situ* approach, the vector is applied directly to affected tissues. Such methods are being developed, for example, to treat tumors by injecting into the tumor a vector bearing the gene for a toxin or a gene that would make the tumor susceptible to a chemotherapeutic agent or to attack by the immune system; and to treat **cystic fibrosis**, by inhaling an aerosol containing a vector encoding the normal protein. (Cystic fibrosis, one of the most common genetic diseases, is caused by a defect in a protein involved in the secretion of chloride ion in the lungs and other tissues. This causes the secretion of abnormally thick mucus, which

results in recurrent and often damaging lung infections leading to early death.)

3. In the *in vivo* (in the body) approach, the vector would be injected directly into the bloodstream. There are, as yet, no clinical examples of this approach, although vectors to do so must ultimately be developed if gene therapy is to fulfill its promise.

In the first well-documented clinical success of gene therapy, Alain Fischer reported that several infants appear to have been cured, via the *ex vivo* treatment of their bone marrow cells, of a form of SCID called **SCID-X1** (which is caused by a mutation in the gene encoding the  $\gamma$  **cytokine receptor**, a receptor for certain protein growth factors, whose proper function is essential for the differentiation, growth, and survival of the white blood cells known as **T cells**; Section 35-2A). However, because the viral vector containing the  $\gamma$  cytokine receptor gene integrates into the genome at random, the location of the transgene may affect the expression of other genes, triggering cancer (Section 34-4Ca). In fact, two children have developed leukemia (a white blood cell cancer) as a result of gene therapy for SCID-X1.

Recently, several patients with the rare inherited blinding disease **Leber's congenital amaurosis 2 (LCA2)**; which results in degeneration of the retina) have shown improved vision without significant adverse side effects, after the subretinal injection of a viral vector bearing a normal copy of the defective gene responsible for LCA2. This gene, named **RPE65**, encodes an enzyme that helps convert vitamin A to **retinal** (Section 12-3Ab), the light-sensing pigment of the eye. Evidently, steady progress is being made in our understanding of the requirements for the construction and administration of effective gene therapy vectors. It therefore seems likely that, over the next few decades, gene therapy will revolutionize the practice of medicine.

### I. Social, Ethical, and Legal Considerations

In the early 1970s, when strategies for genetic engineering were first being discussed, it was realized that little was known about the safety of the proposed experiments. Certainly it would be foolhardy to attempt experiments such as introducing the gene for **diphtheria toxin** (Section 32-3Ge) into *E. coli* so as to convert this human symbiont into a deadly pathogen. But what biological hazards would result, for example, from cloning tumor virus genes in *E. coli* (a useful technique for analyzing these viruses)? Consequently, in 1975, molecular biologists declared a voluntary moratorium on molecular cloning experiments until these risks could be assessed. There ensued a spirited debate, at first among molecular biologists and later in the public arena, between two camps: those who thought that the enormous potential benefits of recombinant DNA research warranted its continuation once adequate safety precautions had been instituted, and those who felt that its potential dangers were so great that it should not be pursued under any circumstances.

The former viewpoint eventually prevailed with the promulgation, in 1976, of a set of U.S. government regula-

tions for recombinant DNA research. Experiments that are obviously dangerous were forbidden. In other experiments, the escape of laboratory organisms was to be prevented by both physical and biological containment. By biological containment it is meant that vectors will only be cloned in host organisms with biological defects that prevent their survival outside the laboratory. For example,  $\chi$ 1776, the first approved "safe" strain of *E. coli*, has among its several defects the requirement for diaminopimelic acid, an intermediate in lysine biosynthesis (Section 26-5Ba), which is neither present in human intestines nor commonly available in the environment.

As experience with recombinant DNA research accumulated, it became evident that the foregoing reservations were largely groundless. *No genetically altered organism yet reported has caused an unexpected health hazard*. Indeed, recombinant DNA techniques have, in many cases, eliminated the health hazards of studying dangerous pathogens such as the virus causing **acquired immune deficiency syndrome (AIDS)**. Consequently, since 1979, the regulations governing recombinant DNA research have been gradually relaxed.

There are other social, ethical, and legal considerations that will have to be faced as new genetic engineering techniques become available (Fig. 5-60). Recombinant erythropoietin is now routinely prescribed to treat the effects of certain types of kidney disease. However, should athletes be permitted to use this protein, as many reportedly have, to increase the number of red cells in their blood and hence its oxygen-carrying capacity (a dangerous procedure if uncontrolled since the increased number of cells in the blood can put a great strain on the heart)? Few would dispute the use of gene therapy, if it can be developed, to cure such devastating genetic defects as **sickle-cell anemia** (a painful and debilitating condition caused by deformed red blood cells that often results in early death; Section 10-3B) and **Tay-Sachs disease** (which is caused by the absence of the lysosomal enzyme **hexosaminidase A** and results in progressive neuronal dysfunction that is invariably fatal by around age 3; Section 25-8Ce). If, however, it becomes possible to alter complex (i.e., multigene) traits such as athletic ability or intelligence, which changes would be considered desirable, under what circumstances would they be made, and who would decide whether to make them? Should gene therapy be used on individuals with inherited diseases only to correct defects in their somatic cells or should it also be used to alter genes in their germ cells, which could then be transmitted to succeeding generations? Animals such as sheep, cows, dogs, and mice have already been cloned. Should humans with particularly desirable traits, either naturally occurring or generated through genetic engineering, be cloned? When it becomes easy to determine an individual's genetic makeup, should this information be used, for example, in evaluating applications for educational and employment opportunities, or in assessing a person's eligibility for health insurance (which has recently been made illegal in the United States)? These conundrums have led to the advent of a branch of philosophy named **bioethics** designed to deal with them.

## CHAPTER SUMMARY

**1 Nucleotides and Nucleic Acids** A nucleotide consists of either a ribose or a 2'-deoxyribose residue whose C1' atom forms a glycosidic bond with a nitrogenous base and whose 3' or 5' position is esterified to a phosphate group. Nucleosides lack the phosphate groups of nucleotides. The nitrogenous bases in the great majority of nucleotides are the purines adenine and guanine and the pyrimidines cytosine and either thymine in DNA or uracil in RNA. Nucleic acids are linear polymers of nucleotides containing either ribose residues in RNA or deoxyribose residues in DNA and whose 3' and 5' positions are linked by phosphate groups. In double helical DNAs and RNAs, the base compositions obey Chargaff's rules:  $A = T(U)$  and  $G = C$ . RNA, but not DNA, is susceptible to base-catalyzed hydrolysis.

**2 DNA Is the Carrier of Genetic Information** Extracts of virulent S-type pneumococci transform nonpathogenic R-type pneumococci to the S form. The transforming principle is DNA. Similarly, radioactive labeling has demonstrated that the genetically active substance of bacteriophage T2 is its DNA. The viral capsid serves only to protect its enclosed DNA and to inject it into the bacterial host. This establishes that DNA is the hereditary molecule.

**3 Double Helical DNA** B-DNA consists of a right-handed double helix of antiparallel sugar-phosphate chains with  $\sim 10$  bp per turn of  $34 \text{ \AA}$  and with its bases nearly perpendicular to the helix axis. Bases on opposite strands hydrogen bond in a geometrically complementary manner to form  $A \cdot T$  and  $G \cdot C$  Watson-Crick base pairs. DNA replicates in a semi-conservative manner, as has been demonstrated by the Meselson-Stahl experiment. When heated past its melting temperature,  $T_m$ , DNA denatures and undergoes strand separation. This process may be monitored by the hyperchromism of the DNA's UV spectrum. Denatured DNA can be renatured by maintaining it at  $\sim 25^\circ\text{C}$  below its  $T_m$ . DNA occurs in nature as molecules of enormous lengths which, because they are also quite stiff, are easily mechanically cleaved by laboratory manipulations.

**4 Gene Expression and Replication: An Overview** Genes are expressed according to the central dogma of molecular biology: DNA directs its own replication and its transcription to yield RNA, which, in turn, directs its translation to form proteins. RNA is synthesized from ribonucleoside triphosphates on DNA templates by RNA polymerase, a process in which the DNA template strand is read in its 3' to 5' direction and the

RNA is synthesized in its 5' to 3' direction. The rate at which a particular gene is transcribed is governed by control sites, which, for mRNAs, are located upstream of the transcriptional initiation site and can be quite extensive, particularly in eukaryotes. Eukaryotic mRNAs often require substantial post-transcriptional modifications, including gene splicing (the excision of introns and the rejoining of their flanking exons), to become functional.

mRNAs direct the ribosomal synthesis of polypeptides. In this process, ribosomes facilitate the binding of the mRNA's codons to the anticodons of tRNAs bearing their cognate amino acids, and the ribosomes then catalyze the formation of peptide bonds between successive amino acids. The correspondence between codons and the amino acid carried by the tRNAs that bind to them is called the genetic code. Enzymes known as aminoacyl-tRNA synthetases covalently link their corresponding tRNAs to their cognate amino acids. The selection of the correct initiation site on the mRNA also sets the reading frame for the polypeptide being synthesized. Newly synthesized proteins often require post-translational modifications to be functional, including specific proteolytic cleavages and, in eukaryotes only, glycosylation. The lifetime of a protein in a cell varies from fractions of a minute to days or weeks.

DNA is synthesized from deoxynucleoside triphosphates by DNA polymerase, an enzyme that can only extend existing polynucleotides bound to the template DNA and hence requires a primer. In cells, primers are RNA, which are synthesized on DNA templates by an RNA polymerase. The replication of both strands of duplex DNA takes place at a replication fork. In *E. coli*, duplex DNA replication is carried out by two molecules of DNA polymerase III, one of which synthesizes the leading strand and the other of which synthesizes the lagging strand. The leading strand is synthesized continuously. However, since all DNA polymerases can only extend DNA in its 5' to 3' direction, the lagging strand template must loop around to be read in its 3' to 5' direction, which requires that the lagging strand be synthesized discontinuously. The RNA primers for the lagging strand are synthesized by primase, and once a lagging strand segment has been synthesized, its primer is replaced through the combined actions of DNA polymerase I's 5' → 3' exonuclease and DNA polymerase activities. The single-strand nicks between successive

lagging strand segments are then sealed by DNA ligase. Both DNA polymerase I and DNA polymerase III also have 3' → 5' exonuclease activities that function to proofread the newly synthesized DNA for mispairing errors and excise the mispaired nucleotides.

**5 Molecular Cloning** Molecular cloning techniques have revolutionized the practice of biochemistry. Defined DNA fragments are generated through the use of Type II restriction endonucleases (restriction enzymes), which cleave DNA at specific and usually palindromic sequences of four to six bases. Restriction-fragment length polymorphisms (RFLPs) provide markers for identifying chromosomal differences and hence are useful in identity tests and in establishing familial relationships. A DNA fragment may be produced in large quantities by inserting it, using recombinant DNA techniques, into a suitable cloning vector. These may be genetically engineered plasmids, viruses, cosmids, yeast artificial chromosomes (YACs), or bacterial artificial chromosomes (BACs). The DNA to be cloned is usually obtained as a restriction fragment so that it can be specifically ligated into a corresponding restriction cut in the cloning vector. Gene splicing may also occur through the generation of complementary homopolymer tails on the DNA fragment and the cloning vector or through the use of synthetic palindromic linkers containing restriction sequences. The introduction of a recombinant cloning vector into a suitable host organism permits the foreign DNA segment to be produced in nearly unlimited quantities. Those cells that have been properly transformed by a vector can be chosen through the use of selectable markers and chromogenic substrates. Specific base sequences may be detected in DNA by Southern blotting and in RNA by the similar Northern blotting. A particular gene may be isolated through the screening of a genomic library of the organism producing the gene. The polymerase chain reaction (PCR) is a particularly fast and convenient method of identifying and obtaining specific sequences of DNA. Genetic engineering techniques may be used to produce otherwise scarce or specifically altered proteins in large quantities and to monitor gene expression through the use of reporter genes such as green fluorescent protein. They are also used to produce transgenic plants and animals and in gene therapy. The development of recombinant DNA techniques has generated numerous social, ethical, and legal issues whose resolution will govern how biotechnology is used.

### Chapter 5

#### Electrophoresis

- One-Dimensional Electrophoresis.** Perform an SDS-PAGE electrophoresis simulation with known and unknown proteins.
- Two-Dimensional Electrophoresis.** Explore the predicted and observed electrophoretic parameters ( $pI$ , molecular mass, and fragmentation pattern) for a known protein.

## PROBLEMS

1. The base sequence of one of the strands of a 20-bp duplex DNA is

What is the base sequence of its complementary strand?

2. Non-Watson–Crick base pairs are of biological importance. For example: (a) **Hypoxanthine** (6-oxopurine) is often one of the bases of the anticodon of tRNA. With what base on mRNA is hypoxanthine likely to pair? Draw the structure of this base pair. (b) The third position of the codon–anticodon interaction between tRNA and mRNA is often a G · U base pair. Draw a plausible structure for such a base pair. (c) Many species of tRNA contain a hydrogen bonded U · A · U assembly. Draw two plausible structures for this assembly in which each U forms at least two hydrogen bonds with the A. (d) Mutations may arise during DNA replication when mispairing occurs as a result of the transient formation of a rare tautomeric form of a base. Draw the structure of a base pair with proper Watson–Crick geometry that contains a tautomeric form of adenine. What base sequence change would be caused by such mispairing?

3. (a) What is the molecular mass and contour length of a segment of B-DNA that specifies a 40-kD protein? (b) How many helical turns does this DNA have and what is its axial ratio (length to width ratio)?

\*4. The antiparallel orientation of complementary strands in duplex DNA was elegantly demonstrated in 1960 by Arthur Kornberg by **nearest-neighbor analysis**. In this technique, DNA is synthesized by DNA polymerase I from one deoxynucleoside triphosphate whose  $\alpha$ -phosphate group is radioactively labeled with  $^{32}\text{P}$  and three unlabeled deoxynucleoside triphosphates. The resulting product is treated with an enzyme, DNase I, that catalyzes the hydrolysis of the phosphodiester bonds on the 3' sides of all deoxynucleotides.

In this example, the relative frequencies of occurrence of ApA, CpA, GpA, and TpA in the DNA can be determined by measuring the relative amounts of Ap\*, Cp\*, Gp\*, and Tp\*, respectively, in the product (where p\* represents a  $^{32}\text{P}$ -labeled phosphate group). The relative frequencies with which the other 12 dinucleotides occur may likewise be determined by labeling, in turn, the other 3 nucleoside triphosphates in the above reactions. There are equivalencies between the amounts of certain pairs of dinucleotides. However, the identities of these equivalencies depend on whether the DNA consists of parallel or antiparallel strands. What are these equivalencies in both cases?

5. What would be the effect of the following treatments on the melting curve of B-DNA dissolved in 0.5M NaCl solution? Explain. (a) Decreasing the NaCl concentration. (b) Squirting the DNA solution, at high pressure, through a narrow orifice.

(c) Bringing the solution to 0.1M adenine. (d) Heating the solution to 25°C above the DNA's melting point and then rapidly cooling it to 35°C below the DNA's melting point.

6. What is the mechanism of alkaline denaturation of duplex DNA? [Hint: Some of the bases are relatively acidic.]

7. The following duplex DNA is transcribed from right to left as is printed here.

(a) Identify the template strand. (b) What is the amino acid sequence of the polypeptide that this DNA sequence encodes? Assume that translation starts at the first initiation codon. (c) Why doesn't the UGA sequence in the mRNA transcript cause transcription to terminate?

8. After undergoing splicing, a mature mRNA has the following sequence, where the vertical line indicates the position of the splice junction (the nucleotides from between which an intron had been removed).

(a) What is the sequence of the polypeptide specified by this mRNA? Assume that translation starts at the first initiation codon. (b) What would the polypeptide sequence be if the splicing system had erroneously deleted the GU on the 3' side of the splice junction? (c) What would the polypeptide sequence be if the splicing system had erroneously failed to excise a G at the splice junction? (d) Is there any relationship between the polypeptides specified in b and c and, if so, why?

9. Explain why the charging of a tRNA with the correct amino acid is equally as important for accurate translation as is the correct recognition of a codon by its corresponding aminoacyl-tRNA.

10. Describe how to select recombinant clones if a foreign DNA is inserted into the polylinker site of pUC18 and then introduced into *E. coli* cells.

11. Describe the possible outcome of a PCR experiment in which (a) one of the primers is inadvertently omitted from the reaction mixture; (b) one of the primers is complementary to several sites in the starting DNA sample; (c) there is a single-stranded break in the target DNA sequence, which is present in only one copy in the starting sample; (d) there is a double-stranded break in the target DNA sequence, which is present in only one copy in the starting sample.

12. In DNA replication, the leading strand and lagging strand are so named because any particular portion of the lagging strand is always synthesized after the corresponding portion of the leading strand has been synthesized. Explain why this must be the case.

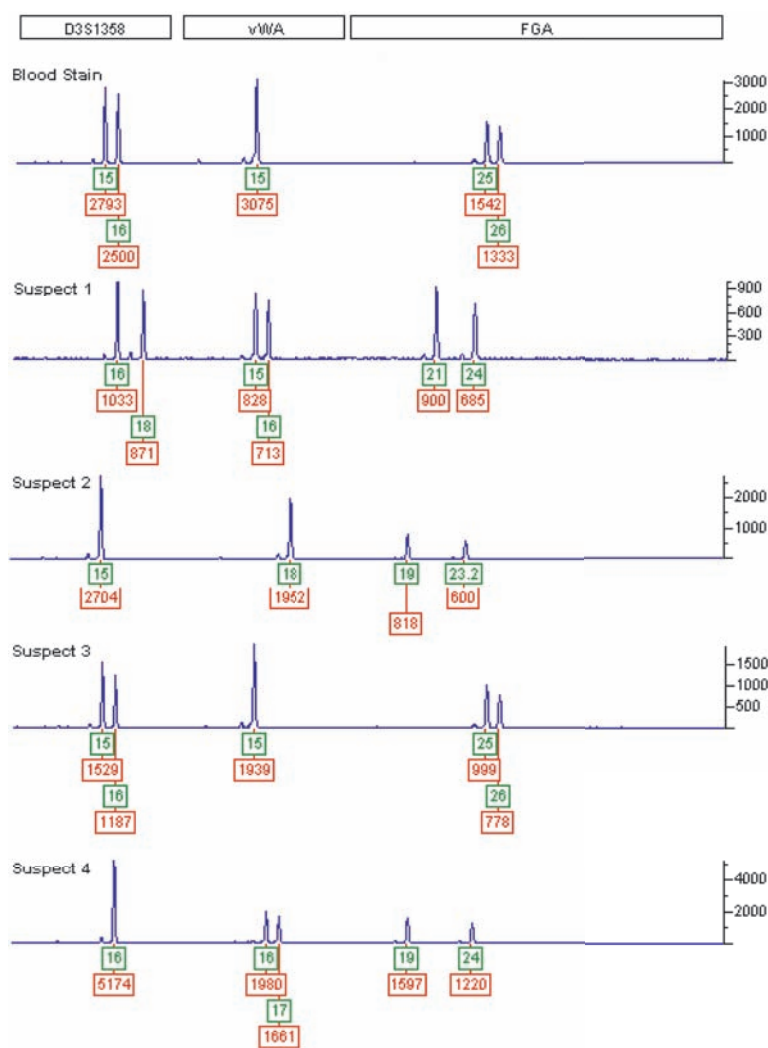

13. SV40 DNA is a circular molecule of 5243 bp that is 40% G + C. In the absence of sequence information, how many restriction cuts would TaqI, EcoRII, PstI, and HaeII be expected to make, on average, in SV40 DNA?

14. Which of the restriction endonucleases listed in Table 5-4 produce blunt ends? Which sets of them are **isoschizomers** (enzymes

that have the same recognition sequence but do not necessarily cleave at the same sites; Greek: *isos*, equal + *schizein*, to cut); which of them are **isocaudamers** (enzymes that produce identical sticky ends; Latin: *cauda*, tail)?

**15.** The plasmid pBR322 contains the *amp<sup>R</sup>* and *tet<sup>R</sup>* genes, which respectively confer resistance to the antibiotics ampicillin and **tetracycline** (Section 32-3Gd). The *tet<sup>R</sup>* gene contains a cleavage site for the restriction enzyme Sall, the only such site in the entire plasmid. Describe how one can select for *E. coli* that had been transformed by pBR322 that contains a foreign DNA insert in its Sall site.

**16.** A blood stain from a crime scene and blood samples from four suspects were analyzed by PCR using fluorescent primers associated with three STR loci (positions): D3S1358, vWA, and FGA. The resulting electrophoretograms are shown below. The numbers beneath each peak identify the allele (*green box*) and the height of the peak in relative fluorescence units (*red box*). (a) Since everyone has two copies of each chromosome and therefore two copies of each gene, what accounts for the appearance of only one allele at some loci? (b) Which suspect, if any, is a possible source of the blood? (c) Could the suspect be identified using just one of the three STR loci? (d) What can you conclude about the amount of DNA obtained from Suspect 1 compared to Suspect 4?

**17.** How many yeast DNA fragments of average length 5 kb must be cloned in order to be 90%, 99%, and 99.9% certain that a genomic library contains a particular segment? The yeast genome consists of 12,100 kb.

**18.** Many of the routine operations in genetic engineering are carried out using commercially available “kits.” Genbux Inc., a prospective manufacturer of such kits, has asked your advice on the feasibility of supplying a kit of intact  $\lambda$  phage cloning vectors with the nonessential central section of their DNA already removed. Presumably a “gene jockey” could then grow the required amount of phage, isolate its DNA, and restriction cleave it without having to go to the effort of separating out the central section. What advice would you give the company?

**19.** Indicate the sequences of the two 10-residue primers that could be used to amplify the central 40-nucleotide region of the following 50-nucleotide single-stranded DNA by PCR.

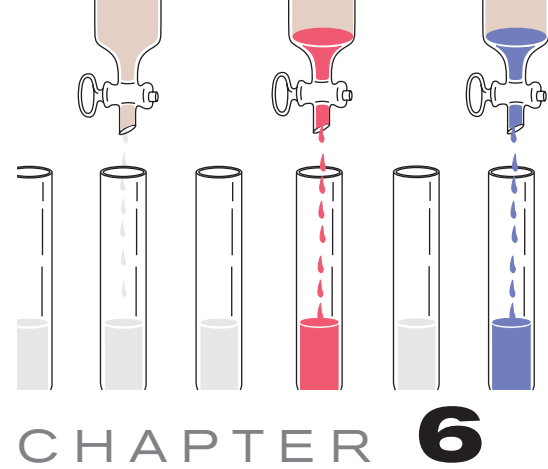

5'-AGCTGGACCACTGATCATTGACTGCTAGCGTCA  
GTCTAGTAGACTGACG-3'

**20.** A protein segment of sequence -Phe-Cys-Gly-Val-Leu-His-Lys-Met-Glu-Thr- is encoded by the following DNA segment:

5'-TTCTGCGGAGTCCTACACAAGATGGAGACA-3'

Design an 18-base oligonucleotide that could be used to change the protein's Leu-His segment to Ile-Pro via site-directed mutagenesis.

A major portion of most biochemical investigations involves the purification of the materials under consideration because these substances must be relatively free of contaminants if they are to be properly characterized. This can be a formidable task because a typical cell contains thousands of different substances, many of which closely resemble other cellular constituents in their physical and chemical properties. Furthermore, the material of interest may be unstable and exist in vanishingly small amounts. Typically, a substance that comprises  $<0.1\%$  of a tissue's dry weight must be brought to  $\sim 98\%$  purity. Purification problems of this magnitude would be considered unreasonably difficult by most synthetic chemists. It is therefore

hardly surprising that our understanding of biochemical processes has by and large paralleled our ability to purify biological materials.

This chapter presents an overview of the most commonly used techniques for the isolation, the purification, and, to some extent, the characterization of proteins and nucleic acids, as well as other types of biological molecules. These methods are the basic tools of biochemistry whose operation dominates the day-to-day efforts of the practicing biochemist. Furthermore, many of these techniques are routinely used in clinical applications. Indeed, *a basic comprehension of the methods described here is necessary for an appreciation of the significance and the limitations of much of the information presented in this text.* This chapter should therefore be taken as reference material to be consulted repeatedly as the need arises while reading other chapters. Many of the techniques used for protein and nucleic acid fractionation are similar. Consequently, we shall first focus on how proteins are purified and only then concentrate on how these techniques are used in nucleic acid fractionation.

## 1 PROTEIN ISOLATION

Proteins constitute a major fraction of the mass of all organisms. A particular protein, such as **hemoglobin** in red blood cells, may be the dominant substance present in a tissue. Alternatively, a protein such as the **lac repressor** of *E. coli* (Section 31-3B) may normally have a population of only a few molecules per cell. Similar techniques are used for the isolation and purification of both proteins, although, in general, the lower the initial concentration of a substance, the more effort is required to isolate it in pure form.

In this section we discuss the care and handling of proteins and outline the general strategy for their purification. For many proteins, the isolation and purification procedure is an exacting task requiring days of effort to obtain only a few milligrams or less of the desired product. However, as we shall see, modern analytical techniques have achieved such a high degree of sensitivity that this small amount of material is often sufficient to characterize a protein extensively. You should note that the techniques described in this chapter are applicable to the separations of most types of biological molecules.

### A. Selection of a Protein Source

Proteins with identical functions generally occur in a variety of organisms. For example, most of the enzymes that mediate basic metabolic processes or that are involved in the expression and transmission of genetic information are common to all cellular life. Of course, there is usually considerable variation in the properties of a particular protein from various sources. In fact, different variants of a given protein may occur in different tissues from the same organism or even in different compartments in the same cell. Therefore, if flexibility of choice is possible, the isolation of a protein may be greatly simplified by a judicious choice of the protein source. This choice should be based on such criteria as the ease of obtaining sufficient quantities of the tissue from which the protein is to be isolated, the amount of the chosen protein in that tissue, and any properties peculiar to the specific protein chosen that would aid in its stabilization and isolation. Tissues from domesticated animals such as chickens, cows, pigs, or rats are often chosen. Alternative sources might be easily obtainable microorganisms such as *E. coli* or **baker's yeast** (*Saccharomyces cerevisiae*). We shall see, however, that proteins from a vast variety of organisms have been studied.

Molecular cloning methods (Section 5-5) have rapidly become equally if not more important protein production techniques. Almost any protein-encoding gene can be isolated from its parent organism, specifically altered (genetically engineered) if desired, and expressed at high levels (overproduced) in a conveniently grown organism such as *E. coli* or yeast, where it may constitute up to 30% of the overproducer's total cell protein. This high level of protein production generally renders the cloned protein far easier to isolate than it would be from its parent organism (in which it may normally occur in vanishingly small amounts).

### B. Methods of Solubilization

The first step in the isolation of a protein, or any other biological molecule, is to get it into solution. In some cases, such as with blood serum proteins, nature has already done so. However, a protein must usually be liberated from the cells that contain it. The method of choice for this procedure depends on the mechanical characteristics of the source tissue as well as on the location of the required protein in the cell.

If the protein of interest is located in the cytosol of the cell, its liberation requires only the breaking open (**lysis**) of the cell. In the simplest and gentlest method of doing so, which is known as **osmotic lysis**, the cells are suspended in a **hypotonic solution**; that is, a solution in which the total molar concentration of solutes is less than that inside the cell in its normal physiological state. Under the influence of osmotic forces, water diffuses into the more concentrated intracellular solution, thereby causing the cells to swell and burst. This method works well with animal cells, but with cells that have a cell wall, such as bacteria or plant cells, it is usually ineffective. The use of an enzyme, such as **lysozyme**, which chemically degrades bacterial cell walls (Section 15-2),

is sometimes effective with such cells. Detergents or organic solvents such as acetone or toluene are also useful in lysing cells, but care must be exercised in their use as they may denature the protein of interest (Section 8-4E).

Many cells require some sort of mechanical disruption process to break them open. This may include several cycles of freezing and thawing, grinding with sand, alumina, or glass beads, or the use of a high-speed blender (similar to the familiar kitchen appliance), a **homogenizer** (an implement for crushing tissue between a closely fitting piston and sleeve that may be manually or mechanically driven), a **French press** (a device that shears open cells by squirting them at high pressure through a small orifice), or a **sonicator** (which breaks open cells through ultrasonic vibrations). Once the cells have been broken open, the crude **lysate** may be filtered or centrifuged to remove the particulate cell debris, thereby leaving the protein of interest in the supernatant solution.

If the required protein is a component of subcellular assemblies such as membranes or mitochondria, a considerable purification of the protein can be effected by first separating the subcellular assembly from the rest of the cellular material. This is usually accomplished by **differential centrifugation**, a process in which the cell lysate is centrifuged at a speed that removes only the cell components denser than the desired organelle followed by centrifugation at a speed that spins down the component of interest. The required protein is then usually separated from the purified subcellular component by extraction with concentrated salt solutions or, in the case of proteins tightly bound to membranes, with the use of detergent solutions or organic solvents, such as butanol, that solubilize lipids.

### C. Stabilization of Proteins

Once a protein has been removed from its natural environment, it becomes exposed to many agents that can irreversibly damage it. These influences must be carefully controlled at all stages of a purification process or the yield of the desired protein may be greatly reduced or even eliminated.

The structural integrity of many proteins is sensitive to pH as a consequence of their numerous acid-base groups. To prevent damage to biological materials due to variations in pH, they are routinely dissolved in buffer solutions effective in the pH range over which the material is stable.

Proteins are easily denatured by high temperatures. Although the thermal stabilities of proteins vary widely, many of them slowly denature above 25°C. Therefore, the purification of proteins is normally carried out at temperatures near 0°C. However, there are numerous proteins that require lower temperatures, some even lower than -100°C, for stability. Conversely, some **cold-labile** proteins become unstable below characteristic temperatures.

The thermal stability characteristics of a protein can sometimes be used to advantage in its purification. A heat-stable protein in a crude mixture can be greatly purified by briefly heating the mixture so as to denature and precipitate most of the contaminating proteins without affecting the desired protein.

Cells contain **proteases** (enzymes that catalyze the hydrolytic cleavage of peptide bonds) and other degradative enzymes that, on cell lysis, are liberated into solution along with the protein of interest. Care must be taken that the protein is not damaged by these enzymes. Degradative enzymes may often be rendered inactive at pH's and temperatures that are not harmful to the protein of interest. Alternatively, these enzymes can often be specifically inhibited by chemical agents without affecting the desired protein. Of course, as the purification of a protein progresses, more and more of these degradative enzymes are eliminated.

Some proteins are more resistant than others to proteolytic degradation. The purification of a protein that is particularly resistant to proteases may be effected by maintaining conditions in a crude protein mixture under which the proteolytic enzymes present are active. This so-called **autolysis** technique simplifies the purification of the resistant protein because it is generally far easier to remove selectively the degradation products of contaminating proteins than it is the intact proteins.

Many proteins are denatured by contact with the air–water interface, and, at low concentrations, a significant fraction of the protein present may be lost by adsorption to surfaces. Hence, a protein solution should be handled so as to minimize frothing and should be kept relatively concentrated. There are, of course, other factors to which a protein may be sensitive, including the oxidation of cysteine residues to form disulfide bonds; heavy metal contaminants, which may irreversibly bind to the protein; and the salt concentration and polarity of the solution, which must be kept within the stability range of the protein. Finally, many microorganisms consider proteins to be delicious, so protein solutions should be stored under conditions that inhibit the growth of microorganisms [e.g., in a refrigerator and/or with small amounts of a toxic substance that does not react with proteins, such as **sodium azide** ( $\text{NaN}_3$ )].

#### D. Assay of Proteins

To purify any substance, some means must be found for quantitatively detecting its presence. A particular protein rarely comprises more than a few percent by weight of its tissue of origin and is usually present in much smaller amounts. Yet much of the material from which it is being extricated closely resembles the protein of interest. Accordingly, an assay must be specific for the protein being purified and highly sensitive to its presence. Furthermore, the assay must be convenient to use because it may be done repeatedly, often at every stage of the purification process.

Among the most straightforward of protein assays are those for enzymes that catalyze reactions with readily detectable products. Perhaps such a product has a characteristic spectroscopic absorption or fluorescence that can be monitored. Alternatively, the enzymatic reaction may consume or generate acid so that the enzyme can be assayed by acid–base titrations. If an enzymatic reaction product is not easily quantitated, its presence may still be revealed by further chemical treatment to yield a more readily observable product. Often, this takes the form of a **coupled enzymatic**

**reaction**, in which the product of the enzyme being assayed is converted, by an added enzyme, to an observable substance.

Proteins that are not enzymes may be assayed through their ability to bind specific substances or through observation of their biological effects. For example, receptor proteins are often assayed by incubating them with a radioactive molecule that they specifically bind, passing the mixture through a protein-retaining filter, and then measuring the amount of radioactivity bound to the filter. The presence of a hormone may be revealed by its effect on some standard tissue sample or on a whole organism. The latter type of assays are usually rather lengthy procedures because the response elicited by the assay may take days to develop. In addition, their reproducibility is often less than satisfactory because of the complex behavior of living systems. Such assays are therefore used only when no alternative procedure is available.

##### a. Immunochemical Techniques Can Readily Detect Small Quantities of Specific Proteins

**Immunochemical** procedures provide protein assay techniques of high sensitivity and discrimination. These methods employ **antibodies**, proteins that are produced by an animal's immune system in response to the introduction of a foreign protein and that specifically bind to the foreign protein (antibodies and the immune system are discussed in Section 35-2).

Antibodies extracted from the blood serum of an animal that has been immunized against a particular protein are the products of many different antibody-producing cells. They therefore form a heterogeneous mixture of molecules, which vary in their exact specificities and binding affinities for their target protein. Antibody-producing cells normally die after a few cell divisions, so one of them cannot be cloned to produce a single species of antibody in useful quantities. Such **monoclonal antibodies** may be obtained, however, by fusing a cell producing the desired antibody with a cell of an immune system cancer known as a **myeloma** (Section 35-2Bd). The resulting **hybridoma** cell has an unlimited capacity to divide and, when raised in cell culture, produces large quantities of the monoclonal antibody.

A protein can be directly detected, or even isolated, through its precipitation by its corresponding antibodies. Alternatively, in a so-called **radioimmunoassay**, a protein can be indirectly detected by determining the degree with which it competes with a radioactively labeled standard for binding to the antibody (Section 19-1Aa). In an **enzyme-linked immunosorbent assay (ELISA; Fig. 6-1)**:

1. An antibody against the protein of interest is immobilized on an inert solid such as polystyrene.
2. The solution being assayed for the protein is applied to the antibody-coated surface under conditions in which the antibody binds the protein. The unbound protein is then washed away.
3. The resulting protein–antibody complex is further reacted with a second protein-specific antibody to which an easily assayed enzyme has been covalently linked.

**Figure 6-1** An enzyme-linked immunosorbent assay (ELISA).  
 See the Animated Figures

4. After washing away any unbound antibody-linked enzyme, the enzyme in the immobilized antibody–protein–antibody–enzyme complex is assayed, thereby indicating the amount of the protein present.

Both radioimmunoassays and ELISAs are widely used to detect small amounts of specific proteins and other biological substances in both laboratory and clinical applications. For example, a commonly available pregnancy test, which is reliably positive within a few days post conception, uses an ELISA to detect the placental hormone **chorionic gonadotropin** (Section 19-11) in the mother’s urine.

### E. General Strategy of Protein Purification

The fact that proteins are well-defined substances was not widely accepted until after 1926, when James Sumner first crystallized an enzyme, jack bean **urease**. Before that, it was thought that the high molecular masses of proteins resulted from a colloidal aggregation of rather ill-defined and mysterious substances of lower molecular mass. Once it was realized that it was possible, in principle, to purify proteins, work to do so began in earnest.

In the first half of the twentieth century, the protein purification methods available were extremely crude by today’s standards. Protein purification was an arduous task that was as much an art as a science. Usually, the development of a satisfactory purification procedure for a given protein was a matter of years of labor ultimately involving huge quantities of starting material. Nevertheless, by 1940, ~20 enzymes had been obtained in pure form.

Since then, tens of thousands of proteins have been purified and characterized to varying extents. Modern techniques of separation have such a high degree of discrimination that one can now obtain, in quantity, a series of proteins with such similar properties that only a few years ago their mixture was thought to be a pure substance. Nevertheless, the development of an efficient procedure for the purification of a given protein may still be an intellectually challenging and time-consuming task.

*Proteins are purified by fractionation procedures.* In a series of independent steps, the various physicochemical properties of the protein of interest are utilized to separate it progressively from other substances. The idea here is not necessarily to minimize the loss of the desired protein, but to eliminate selectively the other components of the mixture so that only the required substance remains.

It may not be philosophically possible to prove that a substance is pure. However, *the operational criterion for establishing purity takes the form of the method of exhaustion: the demonstration, by all available methods, that the sample of interest consists of only one component.* Therefore, as new separation techniques are devised, standards of purity may have to be revised. Experience has shown that when a sample of material previously thought to be a pure substance is subjected to a new separation technique, it occasionally proves to be a mixture of several components.

The characteristics of proteins and other biomolecules that are utilized in the various separation procedures are solubility, ionic charge, polarity, molecular size, and binding specificity for other biological molecules. Some of the procedures we shall discuss and the protein characteristics they depend on are as follows:

Characteristic	Procedure
<b>Solubility</b>	1. Salting in 2. Salting out
<b>Ionic Charge</b>	1. Ion exchange chromatography 2. Electrophoresis 3. Isoelectric focusing
<b>Polarity</b>	1. Adsorption chromatography 2. Paper chromatography 3. Reverse-phase chromatography 4. Hydrophobic interaction chromatography
<b>Molecular Size</b>	1. Dialysis and ultrafiltration 2. Gel electrophoresis 3. Gel filtration chromatography 4. Ultracentrifugation
<b>Binding Specificity</b>	1. Affinity chromatography

In the remainder of this chapter, we discuss these separation procedures.

## 2 SOLUBILITIES OF PROTEINS

A protein's multiple acid–base groups make its solubility properties dependent on the concentrations of dissolved salts, the polarity of the solvent, the pH, and the temperature.

**Figure 6-2** Solubilities of several proteins in ammonium sulfate solutions. [After Cohn, E.J. and Edsall, J.T., *Proteins, Amino Acids and Peptides*, p. 602, Academic Press (1943).]

**Figure 6-3** Solubility of carboxy-hemoglobin at its isoelectric point as a function of ionic strength and ion type. Here  $S$  and  $S'$  are, respectively, the solubilities of the protein in the salt solution and in pure water. The logarithm of their ratios is plotted so that the solubility curves can be placed on a common scale. [After Green, A.A., *J. Biol. Chem.* **95**, 47 (1932).]

Different proteins vary greatly in their solubilities under a given set of conditions: Certain proteins precipitate from solution under conditions in which others remain quite soluble. This effect is routinely used as a basis for protein purification.

### A. Effects of Salt Concentrations

The solubility of a protein in aqueous solution is a sensitive function of the concentrations of dissolved salts (Figs. 6-2 through 6-4). The salt concentration in Figs. 6-2 and 6-3 is expressed in terms of the **ionic strength**,  $I$ , which is defined

$$I = \frac{1}{2} \sum c_i Z_i^2 \quad [6.1]$$

where  $c_i$  is the molar concentration of the  $i$ th ionic species and  $Z_i$  is its ionic charge. The use of this parameter to account for the effects of ionic charges results from theoretical considerations of ionic solutions. However, as Fig. 6-3 indicates, a protein's solubility at a given ionic strength varies with the types of ions in solution. The order of effectiveness of these various ions in influencing protein solubility is quite similar for different proteins and is apparently mainly due to the ions' size and hydration.

The solubility of a protein at low ionic strength generally increases with the salt concentration (left side of Fig. 6-3 and the different curves of Fig. 6-4). The explanation of this **salting in** phenomenon is that as the salt concentration of the protein solution increases, the additional counterions more effectively shield the protein molecules' multiple ionic charges and thereby increase the protein's solubility.

**Figure 6-4** Solubility of  $\beta$ -lactoglobulin as a function of pH at several NaCl concentrations. [After Fox, S. and Foster, J.S., *Introduction to Protein Chemistry*, p. 242, Wiley (1975).]

At high ionic strengths, the solubilities of proteins, as well as those of most other substances, decrease. This effect, known as **salting out**, is primarily a result of the competition between the added salt ions and the other dissolved solutes for molecules of solvation. At high salt concentrations, so many of the added ions are solvated that the amount of bulk solvent available becomes insufficient to dissolve other solutes. In thermodynamic terms, the solvent's activity (effective concentration; Appendix to Chapter 3) is decreased. Hence, solute–solute interactions become stronger than solute–solvent interactions and the solute precipitates.

*Salting out is the basis of one of the most commonly used protein purification procedures.* Figure 6-2 shows that the solubilities of different proteins vary widely as a function of salt concentration. For example, at an ionic strength of 3, fibrinogen is much less soluble than the other proteins in Fig. 6-2. *By adjusting the salt concentration in a solution containing a mixture of proteins to just below the precipitation point of the protein to be purified, many unwanted proteins can be eliminated from the solution. Then, after the precipitate is removed by filtration or centrifugation, the salt concentration of the remaining solution is increased so as to precipitate the desired protein.* In this manner, a significant purification and concentration of large quantities of protein can be conveniently effected. Consequently, salting out is often the initial step in protein purification procedures. Ammonium sulfate is the most commonly used reagent for salting out proteins because its high solubility (3.9M in water at 0°C) permits the achievement of solutions with high ionic strengths (up to 23.4 in water at 0°C).

Certain ions, notably  $I^-$ ,  $ClO_4^-$ ,  $SCN^-$ ,  $Li^+$ ,  $Mg^{2+}$ ,  $Ca^{2+}$ , and  $Ba^{2+}$ , increase the solubilities of proteins rather than salting them out. These ions also tend to denature proteins (Section 8-4E). Conversely, ions that decrease the solubilities of proteins stabilize their native structures, so that proteins which have been salted out are not denatured.

**Table 6-1 Isoelectric Points of Several Common Proteins**

Protein	Isoelectric pH
Pepsin	<1.0
Ovalbumin (hen)	4.6
Serum albumin (human)	4.9
Tropomyosin	5.1
Insulin (bovine)	5.4
Fibrinogen (human)	5.8
$\gamma$ -Globulin (human)	6.6
Collagen	6.6
Myoglobin (horse)	7.0
Hemoglobin (human)	7.1
Ribonuclease A (bovine)	7.8
Cytochrome <i>c</i> (horse)	10.6
Histone (bovine)	10.8
Lysozyme (hen)	11.0
Salmine (salmon)	12.1

## B. Effects of Organic Solvents

Water-miscible organic solvents, such as acetone and ethanol, are generally good protein precipitants because their low dielectric constants reduce the solvating power of their aqueous solutions for dissolved ions such as proteins. The different solubilities of proteins in these mixed solvents form the basis of a useful fractionation technique. This procedure is normally used near 0°C or less because, at higher temperatures, organic solvents tend to denature proteins. The lowering of the dielectric constant by organic solvents also magnifies the differences in the salting out behavior of proteins, so that these two techniques can be effectively combined. Some water-miscible organic solvents, however, such as dimethyl sulfoxide (DMSO) or *N,N*-dimethylformamide (DMF), are rather good protein solvents because of their relatively high dielectric constants.

## C. Effects of pH

Proteins generally bear numerous ionizable groups that have a variety of  $pK$ 's. At a pH characteristic for each protein, the positive charges on the molecule exactly balance its negative charges. At this pH, the protein's isoelectric point,  $pI$  (Section 4-1D), the protein molecule carries no net charge and is therefore immobile in an electric field.

Figure 6-4 indicates that the solubility of the protein  $\beta$ -lactoglobulin is a minimum near its  $pI$  of 5.2 in dilute NaCl solutions and increases more or less symmetrically about the  $pI$  with changes in pH. This solubility behavior, which is shared by most proteins, is easily explained. Physicochemical considerations suggest that the solubility properties of uncharged molecules are insensitive to the salt concentration. To a first approximation, therefore, a protein at its isoelectric point should not be subject to salting in. Conversely, as the pH is varied from a protein's  $pI$ , that is, as the protein's net charge increases, it should be increasingly subject to salting in because the electrostatic interactions between neighboring molecules that promote aggregation and precipitation should likewise increase. Hence, *in solutions of moderate salt concentrations, the solubility of a protein as a function of pH is expected to be at a minimum at the protein's  $pI$  and to increase about this point with respect to pH.*

Proteins vary in their amino acid compositions and therefore, as Table 6-1 indicates, in their  $pI$ 's. This phenomenon is the basis of a protein purification procedure known as **isoelectric precipitation** in which the pH of a protein mixture is adjusted to the  $pI$  of the protein to be isolated so as to selectively minimize its solubility. In practice, this technique is combined with salting out so that the protein being purified is usually salted out near its  $pI$ .

## D. Crystallization

Once a protein has been brought to a reasonable state of purity, it may be possible to crystallize it. This is usually

**Figure 6-5 Protein crystals.** (a) Azurin from *Pseudomonas aeruginosa*, (b) flavodoxin from *Desulfovibrio vulgaris*, (c) rubredoxin from *Clostridium pasteurianum*, (d) azidomet myohemerythrin from the marine worm *Siphonosoma funafuti*, (e) lamprey hemoglobin, and (f) bacteriochlorophyll *a* protein from *Prosthecochloris aestuarii*. These proteins are colored because of their associated chromophores (light-absorbing groups); proteins are colorless in the absence of such bound groups. [Parts a–c courtesy of Larry Sieker, University of Washington; Parts d and e courtesy of Wayne Hendrickson, Columbia University; and Part f courtesy of John Olsen, Brookhaven National Laboratories, and Brian Matthews, University of Oregon.]

done by bringing the protein solution just past its saturation point with the types of precipitating agents discussed above. On standing for a time (as little as a few minutes, as much as several months), often while the concentration of the precipitating agent is being slowly increased, the protein may precipitate from the solution in crystalline form. It may be necessary to attempt the crystallization under different solution conditions and with various precipitating agents before crystals are obtained. The crystals may range in size from microscopic to 1 mm or more across. Crystals of the latter size, which generally require great care to grow, may be suitable for X-ray crystallographic analysis (Section 8-3A). Several such crystals are shown in Fig. 6-5.

### 3 CHROMATOGRAPHIC SEPARATIONS

In 1903, the Russian botanist Mikhail Tswett described the separation of plant leaf pigments in solution through the use of solid adsorbents. He named this process **chromatography** (Greek: *chroma*, color + *graphein*, to write), presumably because of the colored bands that formed in the adsorbents as the components of the pigment mixtures separated from one another (and possibly because Tswett means “color” in Russian).

Modern separation methods rely heavily on chromatographic procedures. In all of them, a mixture of substances

to be fractionated is dissolved in a liquid or gaseous fluid known as the **mobile phase**. The resultant solution is percolated through a column consisting of a porous solid matrix known as the **stationary phase**, which in certain types of chromatography may be associated with a bound liquid. The interactions of the individual solutes with the stationary phase act to retard their progress through the matrix in a manner that varies with the properties of each solute. If the mixture being fractionated starts its journey through the column in a narrow band, the different retarding forces on each component that cause them to migrate at different rates will eventually cause the mixture to separate into bands of pure substances.

The power of chromatography derives from the continuous nature of the separation processes. A single purification step (or “theoretical plate” as it is often termed in analogy with distillation processes) may have very little tendency to separate a mixture into its components. However, since this process is applied in a continuous fashion so that it is, in effect, repeated hundreds or even thousands of times, the segregation of the mixture into its components ultimately occurs. The separated components can then be collected into separate fractions for analysis and/or further fractionation.

The various chromatographic methods are classified according to their mobile and stationary phases. For example, in gas–liquid chromatography the mobile and stationary phases are gaseous and liquid, respectively, whereas in liquid–liquid chromatography they are immiscible liquids, one of which is bound to an inert solid support. Chromatographic methods may be further classified according to the nature of the dominant interaction between the stationary phase and the substances being separated. For example, if the retarding force is ionic in character, the separation technique is referred to as **ion exchange chromatography**, whereas if it is a result of the adsorption of the solutes onto a solid stationary phase, it is known as **adsorption chromatography**.

As has been previously mentioned, a cell contains huge numbers of different components, many of which closely resemble one another in their various properties. Therefore, the isolation procedures for most biological substances incorporate a number of independent chromatographic steps in order to purify the substance of interest according to several criteria. In this section, the most commonly used of these chromatographic procedures are described.

#### A. Ion Exchange Chromatography

*In the process of ion exchange, ions that are electrostatically bound to an insoluble and chemically inert matrix are reversibly replaced by ions in solution.*

Here,  $R^+A^-$  is an **anion exchanger** in the  $A^-$  form and  $B^-$  represents anions in solution. **Cation exchangers** similarly bear negatively charged groups that reversibly bind

**Figure 6-6 Ion exchange chromatography using stepwise elution.** Here the tan region of the column represents the ion exchanger and the colored bands represent the various proteins. (a) The protein mixture is bound to the topmost portion of the ion exchanger in the chromatography column. (b) As the elution progresses, the various proteins separate into discrete bands as a consequence of their different affinities for the ion exchanger

under the prevailing solution conditions. Here the first band of protein (*red*) has passed through the column and is being isolated as a separate fraction, whereas the other, less mobile, bands remain near the top of the column. (c) The salt concentration in the elution buffer is increased to increase the mobility of and thus elute the remaining bands. (d) The elution diagram of the protein mixture from the column.  See the Animated Figures

cations. Polyanions and polycations therefore bind to anion and cation exchangers, respectively. However, proteins and other **polyelectrolytes** (polyionic polymers) that bear both positive and negative charges can bind to both cation and anion exchangers depending on their net charge. *The affinity with which a particular polyelectrolyte binds to a given ion exchanger depends on the identities and concentrations of the other ions in solution because of the competition among these various ions for the binding sites on the ion exchanger. The binding affinities of polyelectrolytes bearing acid–base groups are also highly pH dependent because of the variation of their net charges with pH.* These principles are used to great advantage in isolating biological molecules by **ion exchange chromatography** (Fig. 6-6), as described below.

In purifying a given protein (or some other polyelectrolyte), the pH and the salt concentration of the buffer solution in which the protein is dissolved are chosen so that the desired protein is strongly bound to the selected ion ex-

changer. A small volume of the impure protein solution is applied to the top of a column in which the ion exchanger has been packed, and the column is washed with this buffer solution.

Various proteins bind to the ion exchanger with different affinities. As the column is washed with the buffer, a process known as **elution**, those proteins with relatively low affinities for the ion exchanger move through the column faster than the proteins that bind to the ion exchanger with higher affinities. This occurs because the progress of a given protein through the column is retarded relative to that of the solvent due to interactions between the protein molecules and the ion exchanger.

The greater the binding affinity of a protein for the ion exchanger, the more it will be retarded. Thus, proteins that bind tightly to the ion exchanger can be eluted by changing the elution buffer to one with a higher salt concentration (and/or a different pH), a process called **stepwise elution**.

With the use of a fraction collector, purification of a substance can be effected by selecting only those fractions of the column effluent that contain it. Chromatographically separated materials may be detected in a variety of ways. The contents of the column effluent may be directly monitored through column-mounted detectors according to its UV absorbance at a specific wavelength [often 280 nm for proteins (because the aromatic side chains of Phe, Trp, and Tyr have strong absorbances at this wavelength; Section 9-1Cb) and 260 nm for nucleic acids (their absorption maximum; Fig. 5-15b)], its fluorescence, its radioactivity, its refractive index, its pH, or its electrical conductivity. These properties may also be measured for the individual column fractions after the chromatographic run has been completed. In addition, biomolecules may be detected through their enzymatic and biological activities, as is discussed in Section 6-1D.

#### a. Gradient Elution Improves Chromatographic Separations

The purification process can be further improved by washing the protein-loaded column using the method of **gradient elution**. Here the salt concentration and/or pH is continuously varied as the column is eluted so as to release sequentially the various proteins that are bound to the ion exchanger. This procedure generally leads to a better separation of proteins than does elution of the column by a single solution or stepwise elution.

Many different types of elution gradients have been successfully employed in purifying biological molecules. The most widely used of these is the **linear gradient**, in which the concentration of the eluant solution varies linearly with the volume of solution passed. A simple device for generating such a gradient is illustrated in Fig. 6-7. Here the solute concentration,  $c$ , in the solution being withdrawn from the mixing chamber, is expressed by

$$c = c_2 - (c_2 - c_1)f \quad [6.2]$$

where  $c_1$  is the solution's initial concentration in the mixing chamber,  $c_2$  is its concentration in the reservoir chamber, and  $f$  is the remaining fraction of the combined volumes of the solutions initially present in both reservoirs. Linear gradients of increasing salt concentration are probably more commonly used than all other means of column elution. However, gradients of different shapes can be generated by using two or more chambers of different cross-sectional areas or programmed mixing devices.

**Figure 6-7** Device for generating a linear concentration gradient. Two connected open chambers, which have identical cross-sectional areas, are initially filled with equal volumes of solutions of different concentrations. As the solution of concentration  $c_1$  drains out of the mixing chamber, it is partially replaced by a solution of concentration  $c_2$  from the reservoir chamber. The concentration of the solution in the mixing chamber varies linearly from its initial concentration,  $c_1$ , to the final concentration,  $c_2$ , as is expressed by Eq. [6.2].

#### b. Several Types of Ion Exchangers Are Available

Ion exchangers consist of charged groups covalently attached to a support matrix. The chemical nature of the charged groups determines the types of ions that bind to the ion exchanger and the strength with which they bind. The chemical and mechanical properties of the support matrix govern the flow characteristics, ion accessibility, and stability of the ion exchanger.

Several classes of materials, colloquially referred to as **resins**, are in general use as support matrices for ion exchangers in protein purification, including cellulose (Fig. 6-8), polystyrene, agarose gels, and cross-linked dextran gels (Section 6-3Bb). Table 6-2 contains descriptions of some commercially available ion exchangers in common use.

Cellulosic ion exchangers are among the materials most commonly employed to separate biological molecules. The cellulose, which is derived from wood or cotton, is lightly derivatized with ionic groups to form the ion exchanger. The most often used cellulosic anion exchanger is **diethylaminoethyl (DEAE)-cellulose**, whereas **carboxymethyl (CM)-cellulose**

**Figure 6-8** Molecular formulas of cellulose-based ion exchangers.

**Table 6-2** Some Biochemically Useful Ion Exchangers

Name <sup>a</sup>	Type	Ionizable Group	Remarks
DEAE-cellulose	Weakly basic	Diethylaminoethyl —CH <sub>2</sub> CH <sub>2</sub> N(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub>	Used to separate acidic and neutral proteins
CM-cellulose	Weakly acidic	Carboxymethyl —CH <sub>2</sub> COOH	Used to separate basic and neutral proteins
P-cellulose	Strongly and weakly acidic	Phosphate —OPO <sub>3</sub> H <sub>2</sub>	Dibasic; binds basic proteins strongly
Bio-Rex 70	Weakly acidic, polystyrene-based	Carboxylic acid —COOH	Used to separate basic proteins and amines
DEAE-Sephadex	Weakly basic cross-linked dextran gel	Diethylaminoethyl —CH <sub>2</sub> CH <sub>2</sub> N(C <sub>2</sub> H <sub>5</sub> ) <sub>2</sub>	Combined chromatography and gel filtration of acidic and neutral proteins
SP-Sephacrose	Strongly acidic cross-linked agarose gel	Methyl sulfonate —CH <sub>2</sub> SO <sub>3</sub> H	Combined chromatography and gel filtration of basic proteins

<sup>a</sup>Sephadex and Sepharose are products of GE Healthcare; Bio-Rex resins are products of BioRad Laboratories.

**(CM)-cellulose** is the most popular cellulosic cation exchanger (Fig. 6-8).

Gel-type ion exchangers can have the same sorts of charged groups as do cellulosic ion exchangers. The advantage of gel-type ion exchangers is that they combine the separation properties of gel filtration (Section 6-3B) with those of ion exchange. Because of their high degree of substitution of charged groups, which results from their porous structures, these gels have a higher loading capacity than do cellulosic ion exchangers.

One disadvantage of cellulosic and gel-type matrices is that they are easily compressed (usually by the high pressures resulting from attempts to increase the eluant flow rate), thereby greatly reducing eluant flow. This problem has been alleviated by the fabrication of noncompressible matrices such as derivatized **silica**

or coated glass beads. Such materials allow very high flow rates and pressures, even when they are very finely powdered, and hence permit more effective chromatographic separations (see HPLC in Section 6-3Dh).

### B. Gel Filtration Chromatography

In **gel filtration chromatography**, which is also called **size exclusion** and **molecular sieve chromatography**, molecules are separated according to their size and shape. The stationary phase in this technique consists of beads of a hydrated, spongelike material containing pores that span a relatively narrow size range of molecular dimensions. If an aqueous

solution containing molecules of various sizes is passed through a column containing such “molecular sieves,” the molecules that are too large to pass through the pores are excluded from the solvent volume inside the gel beads. These larger molecules therefore traverse the column more rapidly, that is, in a smaller eluant volume, than the molecules that pass through the pores (Fig. 6-9).

The molecular mass of the smallest molecule unable to penetrate the pores of a given gel is said to be the gel’s **exclusion limit**. This quantity is to some extent a function of molecular shape because elongated molecules, as a consequence of their higher radius of hydration, are less likely to penetrate a given gel pore than spherical molecules of the same molecular volume.

The behavior of a molecule on a particular gel column can be quantitatively characterized. If  $V_x$  is the volume occupied by the gel beads and  $V_0$ , the **void volume**, is the volume of the solvent space surrounding the beads, then  $V_t$ , the total **bed volume** of the column, is simply their sum:

$$V_t = V_x + V_0 \quad [6.3]$$

$V_0$  is typically ~35% of  $V_t$ .

The **elution volume** of a given solute,  $V_e$ , is the volume of solvent required to elute the solute from the column after it has first contacted the gel. The void volume of a column is easily measured as the elution volume of a solute whose molecular mass is larger than the exclusion limit of the gel. The behavior of a particular solute on a given gel is therefore characterized by the ratio  $V_e/V_0$ , the **relative elution volume**, a quantity that is independent of the size of the particular column used.

Molecules with molecular masses ranging below the exclusion limit of a gel will elute from the gel in the order of their molecular masses, with the largest eluting first. This is because the pore sizes in any gel vary over a limited range, so that larger molecules have less of the gel’s interior volume available to them than do smaller molecules. This effect is the basis of gel filtration chromatography.

**Figure 6-9** Gel filtration chromatography. (a) A gel bead, whose periphery is represented by a dashed line, consists of a gel matrix (wavy solid lines) that encloses an internal solvent space. Smaller molecules (red dots) can freely enter the internal solvent space of the gel bead from the external solvent space. However, larger molecules (blue dots) are too large to penetrate the gel pores. (b) The sample solution begins to enter the gel column (in which the gel beads are now represented by brown spheres).

(c) The smaller molecules can penetrate the gel and consequently migrate through the column more slowly than the larger molecules that are excluded from the gel. (d) The larger molecules emerge from the column to be collected separately from the smaller molecules, which require additional solvent for elution from the column. (e) The elution diagram of the chromatogram indicating the complete separation of the two components, with the larger component eluting first.  See the Animated Figures

### a. Gel Filtration Chromatography Can Be Used to Estimate Molecular Masses

There is a linear relationship between the relative elution volume of a substance and the logarithm of its molecular mass over a considerable molecular mass range (Fig. 6-10). If a plot such as Fig. 6-10 is made for a particular gel filtration column using macromolecules of known molecular masses, the molecular mass of an unknown substance can be estimated from its position on the plot. The precision of this technique is limited by the accuracy of the underlying assumption that the known and unknown macromolecules have identical shapes. Nevertheless, gel filtration chromatography is often used to estimate molecular masses because it can be applied to quite impure samples (providing that the molecule of interest can be identified) and because it can be rapidly carried out using simple equipment.

### b. Most Gels Are Made from Dextran, Agarose, or Polyacrylamide

The most commonly used materials for making chromatographic gels are **dextran** (a high molecular mass polymer of

glucose produced by the bacterium *Leuconostoc mesenteroides*), **agarose** (a linear polymer of alternating D-galactose and 3,6-anhydro-L-galactose from red algae), and **polyacrylamide** (Section 6-4B). The properties of several gels that are commonly employed in separating biological molecules are listed in Table 6-3. The porosity of dextran-based gels, sold under the trade name Sephadex, is controlled by the molecular mass of the dextran used and the introduction of glyceryl ether units that cross-link the hydroxyl groups of the polyglucose chains. The several classes of Sephadex that are available have exclusion limits between 0.7 and 600 kD. The pore size in polyacrylamide gels is similarly controlled by the extent of cross-linking of neighboring polyacrylamide molecules (Section 6-4B). They are commercially available under the trade name of Bio-Gel P and have exclusion limits between 0.2 and 400 kD. Very large molecules and supramolecular assemblies can be separated using agarose gels, sold under the trade names Sepharose and Bio-Gel A, which have exclusion limits ranging up to 150,000 kD.

Gel filtration is often used to “desalt” a protein solution. For example, an ammonium sulfate-precipitated protein

**Figure 6-10** Molecular mass determination by gel filtration chromatography. The graph shows the relative elution volume versus the logarithm of molecular mass for a variety of proteins on a cross-linked dextran column (Sephadex G-200) at pH 7.5.

Orange bars represent glycoproteins (proteins with attached carbohydrate groups). [After Andrews, P., *Biochem. J.* **96**, 597 (1965).]

**Table 6-3** Some Commonly Used Gel Filtration Materials

Name <sup>a</sup>	Type	Fractionation Range (kD)
Sephadex G-10	Dextran	0.05–0.7
Sephadex G-25	Dextran	1–5
Sephadex G-50	Dextran	1–30
Sephadex G-100	Dextran	4–150
Sephadex G-200	Dextran	5–600
Sephacryl S-100	Dextran, cross-linked	1–100
Sephacryl S-200	Dextran, cross-linked	5–250
Sephacryl S-300	Dextran, cross-linked	4–150
Sephacryl S-400	Dextran, cross-linked	20–8000
Bio-Gel P-2	Polyacrylamide	0.1–1.8
Bio-Gel P-6	Polyacrylamide	1–6
Bio-Gel P-10	Polyacrylamide	1.5–20
Bio-Gel P-30	Polyacrylamide	2.5–40
Bio-Gel P-100	Polyacrylamide	5–100
Sepharose 6B	Agarose	10–4,000
Sepharose 4B	Agarose	60–20,000
Sepharose 2B	Agarose	70–40,000

<sup>a</sup>Sephadex, Sephacryl, and Sepharose are products of GE Healthcare; Bio-Gel gels are products of BioRad Laboratories.

can be easily freed of ammonium sulfate by dissolving the protein precipitate in a minimum volume of suitable buffer and applying this solution to a column of gel with an exclusion limit less than the molecular mass of the protein. On elution of the column with buffer, the protein will precede the ammonium sulfate through the column.

Dextran and agarose gels can be derivatized with ionizable groups such as DEAE and CM to form ion exchange gels (Section 6-3Ab). Substances that are chromatographed on these gels are therefore subject to separation according to their ionic charges as well as their sizes and shapes.

### C. Dialysis Is a Form of Molecular Filtration

**Dialysis** is a process that separates molecules according to size through the use of semipermeable membranes containing pores of less than macromolecular dimensions. These pores allow small molecules, such as those of solvents, salts, and small metabolites, to diffuse across the membrane but block the passage of larger molecules. **Cellophane** (cellulose acetate) is the most commonly used dialysis material, although several other substances such as cellulose and **collodion** are similarly employed. These are available in a wide variety of **molecular weight cutoff** values (the size of the smallest particle that cannot penetrate the membrane) that range from 0.1 to 500 kD.

Dialysis (which is not considered to be a form of chromatography) is used to change the solvent in which macromolecules are dissolved. A macromolecular solution is sealed inside a dialysis bag (usually made by knotting dialysis membrane tubing at both ends), which is immersed in a relatively large volume of the new solvent (Fig. 6-11a). After several hours of stirring, the solutions will have equilibrated, but with the macromolecules remaining inside the dialysis bag (Fig. 6-11b). The process can be repeated several times to replace one solvent system completely by another.

**Figure 6-11** Use of dialysis to separate small and large molecules. (a) Only small molecules can diffuse through the pores in the bag, which is shown here as a tube knotted at both ends. (b) At equilibrium, the concentrations of small molecules are nearly the same inside and outside the bag, whereas the macromolecules remain in the bag.

Dialysis has been largely supplanted by a related technique known as **ultrafiltration** in which a macromolecular solution is forced, under pressure or by centrifugation, through a semipermeable membranous disk, which can be made from a variety of materials including cellulose acetate, nylon, and polyvinylidene fluoride (PVDF). Solvent and small solutes pass through the membrane, leaving behind a more concentrated macromolecular solution. Ultrafiltration can thus be used to desalt a macromolecular solution. Since ultrafiltration membranes with different pore sizes are available, ultrafiltration can also be used to separate different-sized macromolecules.

Solvent may also be removed from a sample solution through **lyophilization** (freeze-drying), a process in which the solution is frozen and the solvent sublimed away under vacuum. Lyophilization is usually used to prepare biological materials for long-term storage or transport.

### C. Affinity Chromatography

A striking characteristic of many proteins is their ability to bind specific molecules tightly but noncovalently. This property can be used to purify such proteins by **affinity chromatography** (Fig. 6-12). In this technique, a molecule,

**Figure 6-12** Affinity chromatography. A ligand (yellow) is covalently anchored to a porous matrix. The sample mixture (whose ligand-binding sites are represented by the cutout squares, semicircles, and triangles) is passed through the column. Only certain molecules (represented by orange circles) specifically bind to the ligand; the others are washed through the column.

known as a **ligand** (in analogy with the ligands of coordination compounds), which specifically binds to the protein of interest, is covalently attached to an inert and porous matrix. When an impure protein solution is passed through this chromatographic material, the desired protein binds to the immobilized ligand, whereas other substances are washed through the column with the buffer. The desired protein can then be recovered in highly purified form by changing the elution conditions such that the protein is released from the chromatographic matrix. The great advantage of affinity chromatography is its ability to exploit the desired protein's unique biochemical properties rather than the small differences in physicochemical properties between proteins that other chromatographic methods must utilize.

The chromatographic matrix in affinity chromatography must be chemically inert, have high porosity, and have large numbers of functional groups capable of forming covalent linkages to ligands. Of the few materials available that meet these criteria, agarose, which has numerous free hydroxyl groups, is by far the most widely used. If the ligand has a primary amino group that is not essential for its binding to the protein of interest, the ligand can be covalently linked to the agarose in a two-step process (Fig. 6-13):

**Figure 6-13** Covalent linking of ligand to agarose. The formation of cyanogen bromide-activated agarose (top) and its reaction with a primary amine to form a covalently attached ligand for affinity chromatography (bottom).

1. Agarose is reacted with **cyanogen bromide** to form an “activated” but stable intermediate (which is commercially available).

2. Ligand reacts with the activated agarose to form covalently bound product.

Many proteins are unable to bind their cyanogen bromide-coupled ligands due to steric interference with the agarose matrix. This problem is alleviated by attaching the ligand to the agarose by a flexible “spacer” group. This is conveniently done through the use of commercially available activated resins. One such resin is “epoxy-activated” agarose, in which a spacer group (containing, e.g., a chain of 12 atoms) links the resin to a reactive epoxy group. The epoxy group can react with many of the nucleophilic groups on ligands, thereby permitting the ligand of choice to be covalently linked to the agarose via a tether of defined length (Fig. 6-14).

The ligand used in the affinity chromatography isolation of a particular protein must have an affinity for the protein high enough to immobilize it on the agarose gel but not so high as to prevent its subsequent release. If the ligand is a substrate for an enzyme being isolated, the chromatography conditions must be such that the enzyme does not function catalytically or the ligand will be destroyed.

After a protein has been bound to an affinity chromatography column and washed free of impurities, it must be released from the column. One method of doing so is to elute the column with a solution of a compound that has higher affinity for the protein-binding site than the bound ligand. Another is to alter the solution conditions such that the protein–ligand complex is no longer stable, for example, by changes in pH, ionic strength, and/or temperature. However, care must be taken that the solution conditions are not so inhospitable to the protein being isolated that it is irreversibly damaged. An example of protein purification by affinity chromatography is shown in Fig. 6-15.

Affinity chromatography has been used to isolate such substances as enzymes, antibodies, transport proteins, hormone receptors, membranes, and even whole cells. For instance, the protein hormone **insulin** (Section 7-1) has been covalently attached to agarose and used to isolate **insulin receptor** (Section 19-3Ac), a cell-surface protein whose other properties were previously unknown and which is present in tissues in only very small amounts. Genetic engineering techniques (Section 5-5G) have permitted the affinity purification of proteins for which there is no useful ligand by forming a fusion protein with (linking them to) a protein for which a useful ligand is available. For example, fusion proteins whose N-terminal portions consist of the enzyme **glutathione-S-transferase (GST)** (Section 25-7Cb) tightly bind the tripeptide **glutathione** (Section 21-2Ba) and hence are readily purified by affinity chromatography on glutathione–agarose.

The separation power of affinity chromatography for a specific protein is often far greater than that of other chromatographic techniques. Indeed, the replacement of many chromatographic steps in a tried-and-true protein isolation

**Figure 6-14** Derivatization of epoxy-activated agarose. Various types of nucleophilic groups can be covalently attached to epoxy-activated agarose via reaction with its epoxide groups.

protocol by a single affinity chromatographic step often results in purer protein in higher yield.

#### a. Immunoaffinity Chromatography Employs the Binding Specificity of Monoclonal Antibodies

A melding of immunochemistry with affinity chromatography has generated a powerful method for purifying biological molecules. Cross-linking monoclonal antibodies (Section 6-1Da) to a suitable column material yields a substance that will bind only the protein against which the antibody has been raised. Such **immunoaffinity chromatography** can achieve a 10,000-fold purification in a single step. Disadvantages of immunoaffinity chroma-

tography include the technical difficulty of producing monoclonal antibodies and the harsh conditions that are often required to elute the bound protein.

#### D. Other Chromatographic Techniques

A number of other chromatographic techniques are of biochemical value. These are briefly discussed below.

##### a. Adsorption Chromatography Separates Nonpolar Substances

In **adsorption chromatography** (the original chromatographic method), molecules are physically adsorbed on the

**Figure 6-15** (a) The purification of **staphylococcal nuclease** (a DNA-hydrolyzing enzyme) by affinity chromatography. The compound shown in Part b, whose bisphosphothymidine moiety specifically binds to the enzyme, was covalently linked to cyanogen bromide-activated agarose. The column was equilibrated with 0.05M borate buffer, pH 8.0, containing 0.01M  $\text{CaCl}_2$ , and approximately 40 mg of partially purified material was applied to the column. After 50 mL of buffer had been passed through the column to wash away the unbound material, 0.1M acetic acid was added to elute the enzyme. All of the original enzymatic activity, comprising 8.2 mg of pure nuclease, was recovered. [After Cuatrecasas, P., Wilchek, M., and Anfinsen, C.B., *Proc. Natl. Acad. Sci.* **61**, 636 (1968).]

surface of an insoluble substance such as **alumina** ( $\text{Al}_2\text{O}_3$ ), charcoal, **diatomaceous earth** (also called **kieselguhr**, the siliceous fossils of unicellular organisms known as diatoms), finely powdered sucrose, or **silica gel** (silicic acid), through van der Waals and hydrogen bonding associations. The molecules are then eluted from the column by a pure solvent such as chloroform, hexane, or ethyl ether or by a mixture of such solvents. The separation process is based on the partition of the various substances between the polar column material and the nonpolar solvent. This procedure is most often used to separate nonpolar molecules rather than proteins.

### b. Hydroxyapatite Chromatography Separates Proteins

Proteins are adsorbed by gels of crystalline **hydroxyapatite**, an insoluble form of calcium phosphate with empirical formula  $\text{Ca}_5(\text{PO}_4)_3\text{OH}$ . The separation of the proteins occurs on gradient elution of the column with phosphate buffer (the presence of other anions is unimportant). The physicochemical basis of this fractionation procedure is not fully understood but apparently involves the adsorption of anions to the  $\text{Ca}^{2+}$  sites and cations to the  $\text{PO}_4^{3-}$  sites of the hydroxyapatite crystalline lattice.

### c. Paper Chromatography Separates Small Polar Molecules

**Paper chromatography**, developed in 1941 by Archer Martin and Richard Synge, played an indispensable role in biochemical analysis due to its ability to efficiently separate small molecules such as amino acids, oligopeptides, nucleotides, and oligonucleotides and its requirement for only the simplest of equipment. Although paper chromatography has been supplanted by the more modern techniques discussed in this chapter, we briefly describe it here because of its historical importance and because many of its principles and ancillary techniques are directly applicable to the more modern techniques.

In paper chromatography (Fig. 6-16), a few drops of solution containing a mixture of the components to be separated are applied (spotted) ~2 cm above one end of a strip of filter paper. After drying, that end of the paper is dipped into a solvent mixture consisting of aqueous and organic components; for example, water/butanol/acetic acid in a 4:5:1 ratio, 77% aqueous ethanol, or 6:7:7 water/*t*-amyl alcohol/pyridine. The paper should also be in contact with the equilibrium vapors of the solvent. The solvent soaks into the paper by capillary action because of the fibrous nature of the paper. The aqueous component of the solvent binds to the cellulose of the paper and thereby forms a stationary gel-like phase with it. The organic component of the solvent continues migrating, thus forming the mobile phase.

The rates of migration of the various substances being separated are governed by their relative solubilities in the polar stationary phase and the nonpolar mobile phase. In a single step of the separation process, a given solute is distributed between the mobile and stationary phases accord-

**Figure 6-16** Experimental arrangement for paper chromatography.

ing to its **partition coefficient**, an equilibrium constant defined as

$$K_p = \frac{\text{concentration in stationary phase}}{\text{concentration in mobile phase}} \quad [6.4]$$

The molecules are therefore separated according to their polarities, with nonpolar molecules moving faster than polar ones.

After the solvent front has migrated an appropriate distance, the **chromatogram** is removed from the solvent and dried. The separated materials, if not colored, may be detected by such means as their radioactivity, their fluorescence or ability to quench the normal fluorescence of paper under UV light, or by spraying the chromatogram with a solution of a substance that forms a colored product on reaction with the substance(s) under investigation.

The migration rate of a substance may be expressed according to the ratio

$$R_f = \frac{\text{distance traveled by substance}}{\text{distance traveled by solvent front}} \quad [6.5]$$

For a given solvent system and paper type, each substance has a characteristic  $R_f$  value.

A complex mixture that is incompletely separated in a single paper chromatogram can often be fully resolved by **two-dimensional paper chromatography** (Fig. 6-17). In this technique, a chromatogram is made as previously described except that the sample is spotted onto one corner of a sheet of filter paper and the chromatogram is run parallel to an edge of the paper. After the chromatography has been completed and the paper dried, the chromatogram is

**Figure 6-17** Two-dimensional paper chromatography.

rotated 90° and is chromatographed parallel to the second edge using another solvent system. Since each compound migrates at a characteristic rate in a given solvent system, the second chromatographic step should greatly enhance the separation of the mixture into its components.

#### d. Thin Layer Chromatography Is Used to Separate Organic Molecules

In **thin layer chromatography (TLC)**, a thin (~0.25 mm) coating of a solid material spread on a glass or plastic plate is utilized in a manner similar to that of the paper in paper chromatography. In the case of TLC, however, the chromatographic material can be a variety of substances such as ion exchangers, gel filtration agents, and physical adsorbents. According to the choice of solvent for the mobile phase, the separation may be based on adsorption, partition, gel filtration, ion exchange processes, or some combination of these. The advantages of thin layer chromatography in convenience, rapidity, and high resolution have led to its routine use in the analysis of organic molecules.

#### e. Reverse-Phase Chromatography Separates Nonpolar Substances Including Denatured Proteins

**Reverse-phase chromatography (RPC)** is a form of liquid-liquid partition chromatography in which the polar character of the phases is reversed relative to that of paper chromatography: The stationary phase typically consists of a nonpolar liquid immobilized on silica substituted with *n*-alkyl chains such as C<sub>8</sub> and C<sub>18</sub>, and the mobile phase is a more polar liquid. Reverse-phase chromatography was first developed to separate mixtures of nonpolar substances such as lipids but has also been found to be effective in separating polar substances such as oligonucleotides and proteins, provided that they have exposed nonpolar areas. Although nonpolar side chains tend to inhabit the water-free interiors of native proteins (Section 8-3Bb),

denaturation results in the exposure of these side chains to the solvent. Even when the protein is still in the native state, a significant fraction of these hydrophobic groups are at least partially exposed to the solvent at the protein surface. Consequently, under suitable conditions, proteins hydrophobically interact with the nonpolar groups on an immobilized matrix. The hydrophobic interactions in RPC are strong, so the eluting mobile phase must be highly nonpolar (containing high concentrations of organic solvents such as acetonitrile) to dislodge adsorbed substances from the stationary phase. RPC therefore usually denatures proteins.

#### f. Hydrophobic Interaction Chromatography Separates Native Proteins on the Basis of Surface Hydrophobicity

Hydrophobic interactions form the basis not only of RPC but of **hydrophobic interaction chromatography (HIC)**. However, whereas the stationary phase in RPC is strongly hydrophobic in character, often resulting in protein denaturation, in HIC it is a hydrophilic substance, such as an agarose gel, that is only lightly substituted with hydrophobic groups, usually octyl or phenyl residues. The resulting hydrophobic interactions in HIC are therefore relatively weak, so proteins maintain their native structures. The eluants in HIC, whose gradients must progressively reduce these weak hydrophobic interactions, are aqueous buffers with, for example, decreasing salt concentrations (hydrophobic interactions are strengthened by increased ionic strength; Section 6-2A), increasing concentrations of detergents, or increasing pH. Thus, HIC separates native proteins according to their degree of surface hydrophobicity, a criterion that differs from those on which other types of chromatography are based.

#### g. Metal Chelation Affinity Chromatography Separates Proteins with Metal-Chelating Groups

In **metal chelation affinity chromatography**, a divalent metal ion such as Mn<sup>2+</sup>, Zn<sup>2+</sup>, or Ni<sup>2+</sup> is attached to a chromatographic matrix such as agarose beads covalently linked to metal-chelating groups under conditions that proteins bearing metal-chelating groups (e.g., multiple His or Cys side chains) are retained. Recombinant DNA techniques (Section 5-5G) can be used to append a segment of six consecutive His residues, known as a **His Tag**, to the N- or C-terminus of the polypeptide to be isolated. This creates a metal ion-binding site that allows the recombinant protein to be purified by metal chelation affinity chromatography. After the protein has been eluted, usually by altering the pH, the His-Tag can be removed by the action of a specific protease whose recognition sequence cleaves the (His)<sub>6</sub> sequence from the rest of the protein.

#### h. HPLC Has Permitted Greatly Improved Separations

In **high-performance liquid chromatography (HPLC)**, a separation may be based on adsorption, ion exchange, size exclusion, HIC, or RPC as previously described. The separa-

rations are greatly improved, however, through the use of high-resolution columns, and the column retention times are much reduced. The narrow and relatively long columns are packed with a noncompressible matrix of fine (1–10  $\mu\text{m}$  in diameter) silica beads, whose available hydroxyl groups can be derivatized with many of the commonly used functional groups of ion exchange chromatography, RPC, HIC, or affinity chromatography. Alternatively, glass or plastic beads may be coated with a thin layer of the stationary phase. The mobile phase is one of the solvent systems previously discussed, including gradient elutions with binary or even ternary mixtures. In the case of HPLC, however, the mobile phase is forced through the tightly packed column at pressures of up to 15,000 psi (pounds per square inch), leading to greatly reduced analysis times. The elutants are detected as they leave the column according to their UV absorption, refractive index, or fluorescence.

The advantages of HPLC are

1. Its high resolution, which permits the routine purification of mixtures that have defied separation by other techniques.
2. Its speed, which permits separations to be accomplished in as little as a few minutes.
3. Its high sensitivity, which, in favorable cases, permits the quantitative estimation of less than picomole quantities of materials.
4. Its capacity for automation.

Thus, few biochemistry laboratories now function without access to at least one HPLC system. HPLC is also often utilized in the clinical analyses of body fluids because it can rapidly, routinely, and automatically yield reliable quantitative estimates of nanogram quantities of biological materials such as vitamins, steroids, lipids, and drug metabolites.

## 4 ELECTROPHORESIS

**Electrophoresis**, the migration of ions in an electric field, is widely used for the analytical separation of biological molecules. The laws of electrostatics state that the electrical force,  $F_{\text{electric}}$ , on an ion with charge  $q$  in an electric field of strength  $E$  is expressed by

$$F_{\text{electric}} = qE \quad [6.6]$$

The resulting electrophoretic migration of the ion through the solution is opposed by a frictional force

$$F_{\text{friction}} = vf \quad [6.7]$$

where  $v$  is the rate of migration (velocity) of the ion and  $f$  is its **frictional coefficient**. *The frictional coefficient is a measure of the drag that the solution exerts on the moving ion and is dependent on the size, shape, and state of solvation of the ion as well as on the viscosity of the solution (Section 6-5A).* In a constant electric field, the forces on the ion balance each other:

$$qE = vf \quad [6.8]$$

so that each ion moves with a constant characteristic velocity. An ion's **electrophoretic mobility**,  $\mu$ , is defined

$$\mu = \frac{v}{E} = \frac{q}{f} \quad [6.9]$$

The electrophoretic (ionic) mobilities of several common small ions in  $\text{H}_2\text{O}$  at  $25^\circ\text{C}$  are listed in Table 2-2.

Equation [6.9] really applies only to ions at infinite dilution in a nonconducting solvent. In aqueous solutions, polyelectrolytes such as proteins are surrounded by a cloud of counterions, which impose an additional electric field of such magnitude that Eq. [6.9] is, at best, a poor approximation of reality. Unfortunately, the complexities of ionic solutions have, so far, precluded the development of a theory that can accurately predict the mobilities of polyelectrolytes. Equation [6.9], however, correctly indicates that molecules at their isoelectric points,  $pI$ , have zero electrophoretic mobility. Furthermore, for proteins and other polyelectrolytes that have acid–base properties, the ionic charge, and hence the electrophoretic mobility, is a function of pH.

The use of electrophoresis to separate proteins was first reported in 1937 by the Swedish biochemist Arne Tiselius. The technique he introduced, **moving boundary electrophoresis**, was one of the few powerful analytical techniques available in the early years of protein chemistry. However, since this method takes place entirely in solution, preventing the convective mixing of the migrating proteins necessitates a cumbersome apparatus that requires very large samples. Moving boundary electrophoresis has therefore been supplanted by **zone electrophoresis**, a technique in which the sample is constrained to move in a solid support such as filter paper, cellulose acetate, or, most commonly, a gel. This largely eliminates the convective mixing of the sample that limits the resolution achievable by moving boundary electrophoresis. Moreover, in zone electrophoresis, the various sample components migrate as discrete bands (zones) and hence only small quantities of materials are required.

### A. Paper Electrophoresis

In **paper electrophoresis**, the sample is applied to a point on a strip of filter paper or cellulose acetate moistened with buffer solution. The ends of the strip are immersed in separate reservoirs of buffer in which the electrodes are placed (Fig. 6-18). On application of a direct current (often of  $\sim 20 \text{ V} \cdot \text{cm}^{-1}$ ), the ions of the sample migrate toward the electrodes of opposite polarity at characteristic rates to eventually form discrete bands. An ion's migration rate is influenced, to some extent, by its interaction with the support matrix but is largely a function of its charge. On completion of the electrophoretogram (which usually takes several hours), the strip is dried and the sample components are located using the same detection methods employed in paper chromatography (Section 6-3D).

Paper electrophoresis and paper chromatography are superficially similar. However, *paper electrophoresis separates*

ions largely on the basis of their ionic charges, whereas paper chromatography separates molecules on the basis of their polarities. The two methods can be combined in a two-

**Figure 6-18 Paper electrophoresis.** (a) A diagram of the apparatus used. The sample is applied to a point on the buffer-moistened paper. The ends of the paper are dipped into reservoirs of buffer in which the electrodes are immersed, and an electric field is applied. (b) The completed paper electrophoretogram. Note that positive ions (cations) have migrated toward the cathode and negative ions (anions) have migrated toward the anode. Uncharged molecules remain at the point of sample application.

dimensional technique called **fingerprinting** in which a sample is first treated as in two-dimensional paper chromatography (Section 6-3D) but is subjected to electrophoresis in place of the second chromatographic step. Molecules are thereby separated according to both their charge and their polarity.

## B. Gel Electrophoresis

**Gel electrophoresis**, which is among the most powerful and yet conveniently used methods of macromolecular separation, has supplanted paper electrophoresis. The gels in common use, polyacrylamide and agarose, have pores of molecular dimensions whose sizes can be specified. *The molecular separations are therefore based on gel filtration as well as the electrophoretic mobilities of the molecules being separated.* The gels in gel electrophoresis, however, retard large molecules relative to smaller ones, the reverse of what occurs in gel filtration chromatography, because there is no solvent space in gel electrophoresis analogous to that between the gel beads in gel filtration chromatography (electrophoretic gels are often directly cast in the electrophoresis device, although precast gels are also widely used). Since the molecules in a sample cannot leave the gel, the electrophoretic movement of larger molecules is impeded relative to that of smaller molecules.

In **polyacrylamide gel electrophoresis (PAGE)**, gels are made by the free radical-induced polymerization of **acrylamide** and ***N,N'*-methylenebisacrylamide** in the buffer of choice (Fig. 6-19). The gel is usually cast as a thin rectangular slab in which several samples can be simultaneously

**Figure 6-19 Polymerization of acrylamide and *N,N'*-methylenebisacrylamide to form a cross-linked polyacrylamide gel.** The polymerization is induced by free radicals resulting from the chemical decomposition of **ammonium persulfate** ( $\text{S}_2\text{O}_8^{2-} \rightarrow 2\text{SO}_4^{\cdot -}$ ) or the photodecomposition of riboflavin in the presence of traces of  $\text{O}_2$ . In either case, ***N,N,N',N'*-tetramethylethylenediamine (TEMED)**, a free

radical stabilizer, is usually added to the gel mixture. The physical properties of the gel and its pore size are controlled by the proportion of polyacrylamide in the gel and its degree of cross-linking. The most commonly used polyacrylamide concentrations are in the range 3–15%, with the amount of *N,N'*-methylenebisacrylamide usually fixed at 5% of the total acrylamide present.

**Figure 6-20** Apparatus for slab gel electrophoresis. Samples, applied in slots that have been cast in the top of the gel, are electrophoresed in parallel lanes.

analyzed in parallel lanes (Fig. 6-20), a good way of comparing similar samples. The buffer, which is the same in both reservoirs and the gel, has a pH (usually  $\sim 9$  for proteins) such that the macromolecules have net negative charges and hence migrate to the anode in the lower reservoir. Each sample, which can contain as little as  $10 \mu\text{g}$  of macromolecular material, is dissolved in a minimal amount of a relatively dense glycerol or sucrose solution to prevent it from mixing with the buffer in the upper reservoir and is applied in preformed slots at the top of the gel (Fig. 6-20). Alternatively, the sample may be contained in a short length of “sample gel,” whose pores are too large to impede macromolecular migration. A direct current of  $\sim 300 \text{ V}$  is passed through the gel for a time sufficient to separate the macromolecular components into a series of discrete bands (30–90 min), the gel is removed from its holder, and the bands are visualized by an appropriate method (see below). Using this technique, a protein mixture of 0.1 to 0.2 mg can be resolved into as many as 20 discrete bands.

#### a. Disc Electrophoresis Has Improved Resolution

The narrowness of the bands in the foregoing method, and therefore the resolution of the separations, is limited by the length of the sample column as it enters the gel. The bands are greatly sharpened by an ingenious technique known as **discontinuous pH** or **disc electrophoresis**, which requires a two-gel system and several different buffers (Fig. 6-21). The “running gel,” in which the separation takes place, is prepared as described previously and then overlaid by a short (1 cm), large-pored “stacking” or “spacer gel.” The buffer in the lower reservoir and in the running gel is as described before, while that in the sample solution (or gel) and in the stacking gel has a pH about two units less than that of the lower reservoir. The pH of the buffer in the upper reservoir, which must contain a weak acid (usu-

ally glycine,  $\text{p}K_2 = 9.78$ ), is adjusted to a pH near that of the lower reservoir.

When the current is switched on, the buffer ions from the upper reservoir migrate into the stacking gel as the stacking gel buffer ions migrate ahead of them. As this occurs, the upper reservoir buffer ions encounter a pH that is much lower than their  $\text{p}K$ . They therefore assume their uncharged (or, in the case of glycine, zwitterionic) form and become electrophoretically immobile. This causes a deficiency of charge carriers, that is, a high electrical resistance  $R$ , in this region which, because of the requirement of a constant current,  $I$ , throughout the electrical circuit, results, according to Ohm's law ( $E = IR$ ), in a highly localized increase in the electric field,  $E$ . In response to this increased field, the macromolecular anions migrate rapidly until they reach the region containing the stacking gel buffer ions, where they slow down because at that point there is no ion deficiency. This effect causes the macromolecular ions to approach the running gel as stacks of very narrow ( $\sim 0.01 \text{ mm}$  thick) bands or disks that are ordered according to their mobilities and lie between the migrating ions of the upper reservoir and those of the stacking gel. As the macromolecular ions enter the running gel, they slow down as a result of gel filtration effects. This permits the upper reservoir buffer ions to overtake the macromolecular bands and, because of the running gel's higher pH, assume their fully charged form as they too enter the gel. The charge carrier deficiency therefore disappears and from this point on the electrophoretic separation proceeds normally. However, the compactness of the macromolecular bands entering the running gel greatly increases the resolution of the macromolecular separations (e.g., Fig. 6-22).

#### b. Agarose Gels Are Used to Separate Large Molecules Electrophoretically

The very large pores needed for the PAGE of large molecular mass compounds ( $>200 \text{ kD}$ ) requires gels with such low polyacrylamide concentrations ( $<2.5\%$ ) that they are too soft to be usable. This difficulty is circumvented by using agarose (Fig. 6-13). For example, a 0.8% agarose gel is

**Figure 6-21** Diagram of a disc electrophoresis apparatus.

**Figure 6-22** Disc electrophoresis of human serum in a  $0.5 \times 4.0$ -cm polyacrylamide gel column. The proteins were visualized by staining them with **amido black**. [From B. J. Davis, *Annals of the New York Academy of Science* 121, 404 (1964), Fig. 8.]

used for the electrophoretic separation of nucleic acids with molecular masses of up to 50,000 kD.

### c. Gel Bands May Be Detected by Staining, Radioactive Counting, or Immunoblotting

Bands resulting from a gel electrophoretic separation can be located by a variety of techniques. Proteins are often visualized by staining. **Coomassie brilliant blue**,

**Coomassie brilliant blue**

which is the most widely used dye for this purpose, is applied by soaking the gel in an acidic, alcoholic solution containing the dye. This fixes the protein in the gel by denaturing it and complexes the dye to the protein. Excess dye is removed by extensively washing the gel with an acidic solution or by electrophoretic destaining. Protein bands containing as little as  $0.1 \mu\text{g}$  can thereby be detected. Gel bands containing less than this amount of protein may be visualized with **silver stain**, which is  $\sim 50$  times more sensitive but more difficult to apply. The recently developed **SYPRO dyes**, which strongly fluoresce under UV light when bound to protein, are equally sensitive as silver stain but easier to apply. **Fluorescamine**, a widely used protein stain, is a nonfluorescent molecule that reacts with primary amines, such as lysine residues, to yield an addition product that is highly UV-fluorescent.

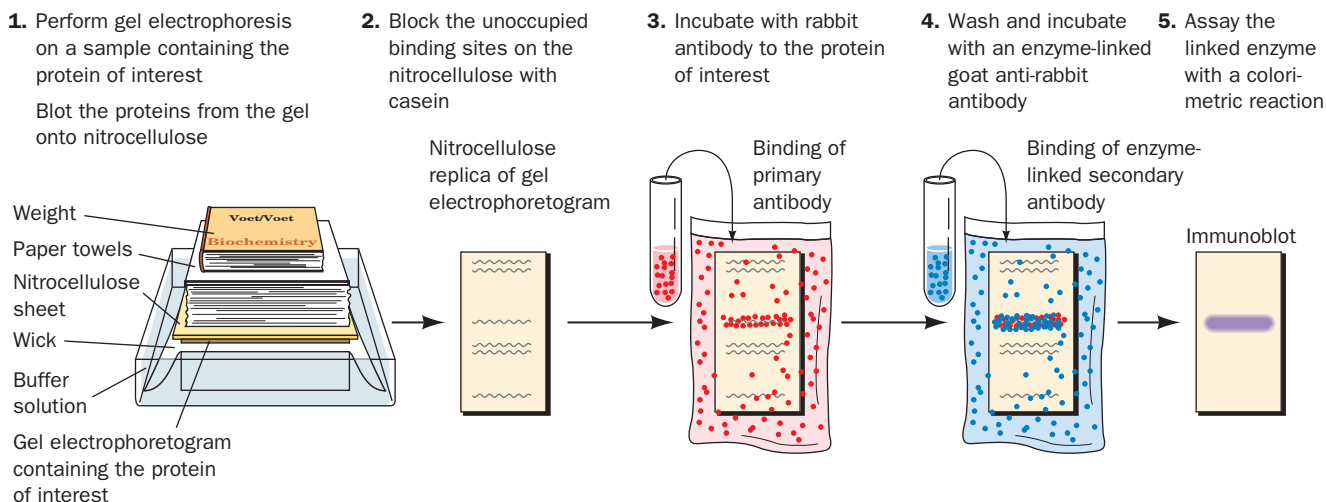

Proteins, as well as other substances, can be detected through the UV absorption of a gel along its length. If the sample is radioactive, the gel may be dried under vacuum to form a cellophane-like material or, alternatively, covered with plastic wrap, and then clamped over a sheet of X-ray film. After a time (from a few minutes to many weeks depending on the radiation intensity) the film is developed, and the resulting autoradiograph shows the positions of the radioactive components by a blackening of the film [alternatively, a phosphorimager (Section 5-5D) can be used to reveal the locations of the radioactive components within even a few seconds]. A gel may also be sectioned widthwise into many slices and the level of radioactivity in each slice determined using a **scintillation counter**. The latter method yields quantitatively more accurate results than autoradiography. Sample materials can also be eluted from gel slices for identification and/or further treatment.

If an antibody to the protein of interest is available, it is possible to specifically detect this protein on a gel in the presence of many other proteins by an **immunoblot** (also known as a **Western blot**). This procedure is a variation of Southern blotting (Section 5-5D) that uses a technique similar to ELISA (Section 6-1Da) to detect the protein(s) of interest (Fig. 6-23):

1. A completed gel electrophoretogram is blotted onto a sheet of nitrocellulose (much like in Fig. 5-48), which strongly and nonspecifically binds proteins [nylon or polyvinylidene fluoride (PVDF) membranes may also be used].

**Figure 6-23** Detection of proteins by immunoblotting.

**2.** The excess adsorption sites on the nitrocellulose are blocked with a nonspecific protein such as **casein** (milk protein; nonfat milk itself is often used) to prevent the nonspecific adsorption of the antibodies (which are also proteins) used in Steps 3 and 4.

**3.** The blot is treated with antibody to the protein of interest (the primary antibody). This is usually a rabbit antibody.

**4.** After washing away the unbound primary antibody, the blot is incubated with a goat antibody, directed against all rabbit antibodies, to which an easily assayed enzyme has been covalently linked (the secondary antibody).

**5.** After washing away the unbound secondary antibody, the enzyme in the bound secondary antibody is assayed with a color-producing reaction, causing colored bands to appear on the nitrocellulose where the protein of interest is bound.

Alternatively, the primary antibody used in Step 3 may be labeled with the radioactive isotope  $^{125}\text{I}$ , the unbound antibody washed away, and the position of the bound protein on the blot revealed by autoradiography.

### C. SDS-PAGE

Soaps and detergents are amphipathic molecules (Section 2-1Ba) that are strong protein denaturing agents for reasons explained in Section 8-4E. **Sodium dodecyl sulfate (SDS)**,

a detergent that is often used in biochemical preparations, binds quite tenaciously to proteins, causing them to assume a rodlike shape. Most proteins bind SDS in the same ratio, 1.4 g of SDS per gram of protein (about one SDS molecule for every two amino acid residues). The large negative

charge that the SDS imparts masks the protein's intrinsic charge so that SDS-treated proteins tend to have identical charge-to-mass ratios and similar shapes. Consequently, *the electrophoresis of proteins in an SDS-containing polyacrylamide gel separates them in order of their molecular masses because of gel filtration effects*. Figure 6-24 provides an example of the resolving power and the reproducibility of **SDS-PAGE**.

The molecular masses of "normal" proteins are routinely determined to an accuracy of 5 to 10% through SDS-PAGE. The relative mobilities of proteins on such gels vary linearly with the logarithm of their molecular masses (Fig. 6-25). In practice, a protein's molecular mass is determined by electrophoresing it together with several "marker" proteins of known molecular masses which bracket that of the protein of interest.

Many proteins consist of more than one polypeptide chain (Section 8-5A). SDS treatment disrupts the noncovalent interactions between these subunits. Therefore, SDS-PAGE yields the molecular masses of the protein's subunits rather than that of the intact protein unless the subunits are disulfide linked. However, mercaptoethanol is usually added to SDS-PAGE gels so as to reductively cleave these disulfide bonds (Section 7-1B).

### D. Isoelectric Focusing

A protein has charged groups of both polarities and therefore has an isoelectric point,  $pI$ , the pH at which it is immobile in an electric field (Section 4-1D). *If a mixture of proteins is electrophoresed through a solution having a stable pH gradient in which the pH smoothly increases from anode to cathode, each protein will migrate to the position in the pH gradient corresponding to its isoelectric point*. If a protein molecule diffuses away from this position, its net charge will change as it moves into a region of different pH, and the resulting electrophoretic forces will move it back to its isoelectric position. Each species of protein is

**Figure 6-24 SDS-PAGE.** The SDS-polyacrylamide disc electrophoretogram shows separation of proteins from the supernatant (*left*) and membrane fractions (*right*) of various strains of the bacterium *Salmonella typhimurium*. Samples of 200  $\mu\text{g}$  of protein each were run in parallel lanes on a 35-cm-long, 0.8-mm-thick slab gel containing 10% polyacrylamide. The lane marked MW contains molecular weight standards. [Courtesy of Giovanna F. Ames, University of California at Berkeley.]

thereby “focused” into a narrow band about its isoelectric point that may be as thin as 0.01 pH unit. Hence, this process is called **isoelectric focusing (IEF)**.

A pH gradient produced by mixing two different buffers together in continuously varying ratios is unstable in an electric field because the buffer ions migrate to the electrode of opposite polarity. Rather, the pH gradient in IEF is formed by a mixture of low molecular mass (600–900 D) oligomers bearing aliphatic amino and carboxylic acid groups (Fig. 6-26) that have a range of isoelectric points. Under the influence of an electric field in solution, these **ampholytes** (amphoteric electrolytes) will each migrate to their isoelectric points. Consequently, the most acidic ampholytes gather at the anode and the progressively more basic ones position themselves ever closer to the cathode. The pH gradient, which is maintained by the  $\sim 1000$  V electric field, arises from the buffering action of these ampholytes. The convection of the pH gradient is prevented by carrying out IEF in a lightly cross-linked polyacrylamide gel in the form of a rod or slab. IEF gels often con-

**Figure 6-25 Logarithmic relationship between the molecular mass of a protein and its relative electrophoretic mobility in SDS-PAGE.** This relationship is plotted for 37 polypeptides ranging from 11 to 70 kD. [After Weber, K. and Osborn, M., *J. Biol. Chem.* **244**, 4406 (1969).]

tain  $\sim 6M$  urea, a powerful protein denaturing agent that, unlike SDS, is uncharged and hence cannot directly affect the charge of a protein.

An alternative form of IEF utilizes gels containing **immobilized pH gradients**. These are made from acrylamide derivatives that are covalently linked to ampholytes. Through the use of a gradient maker (e.g., Fig. 6-7), a gel containing an immobilized pH gradient is polymerized from a continuously varying mixture of acrylamide derivatives with different  $pK$ 's so that the gel's pH varies smoothly from one end to the other.

The fact that IEF separates proteins into sharp bands makes it a useful analytical and preparative tool. In fact, many protein preparations once thought to be homogeneous have been resolved into several components by IEF. IEF can be combined with electrophoresis in an extremely powerful two-dimensional separation technique named

**Figure 6-26 General formula of the ampholytes used in isoelectric focusing.**

**Figure 6-27 Two-dimensional (2D) gel electrophoresis.** This autoradiogram shows the separation of *E. coli* proteins by 2D gel electrophoresis (isoelectric focusing horizontally and SDS-PAGE vertically). A 10- $\mu\text{g}$  sample of proteins from *E. coli* that had been labeled with  $^{14}\text{C}$ -amino acids was subjected to isoelectric focusing in a  $2.5 \times 130$ -mm tube of a urea-containing polyacrylamide gel. The gel was then extruded from its tube, placed in contact with one edge of an SDS-polyacrylamide slab gel, and subjected to electrophoresis. Over 1000 spots were counted on the original autoradiogram, which resulted from an 825-h exposure. [Courtesy of Patrick O'Farrell, University of California at San Francisco.]

**two-dimensional (2D) gel electrophoresis**; Fig. 6-27). Up to 5000 proteins can be observed on a single two-dimensional electrophoretogram. Hence two-dimensional gel electrophoresis is a valuable tool for **proteomics** (the study of the **proteome**, which, in analogy with the term “genome,” is defined as the aggregate of all the proteins expressed by a cell or organism, but with emphasis on their quantitation, localization, modifications, interactions, and activities, as well as their identification). Individual protein bands in a stained gel can be cut out from the gel (with a scalpel or by a robot guided by a digitized image of the gel acquired by an optical scanner or a digital camera), destained, and the protein eluted from the gel fragment for identification and/or characterization, often by mass spectrometry (Section 7-1J). Variant proteins can be found by comparing the positions and intensities of the bands in 2D gels of similar preparations. This can be done with the aid of a computer after acquiring digitized images of the stained gels. Numerous reference 2D gels are publicly available for this purpose in the Web-accessible databases listed at <http://www.expasy.org/swiss-2dpage?de>. These databases contain images of 2D gels of a variety of organisms and tissues and identify many of their component proteins.

### E. Capillary Electrophoresis

Although gel electrophoresis in its various forms is a common and highly effective method for separating charged

molecules, it typically requires an hour or more for a run and is difficult to quantitate and automate. These disadvantages are largely overcome through the use of **capillary electrophoresis (CE)**, a technique in which electrophoresis is carried out in very thin (10 to 100  $\mu\text{m}$  inner diameter) capillary tubes made of silica, glass, or plastic. Such narrow capillaries rapidly dissipate heat and hence permit the use of high electric fields (typically 100 to 300  $\text{V} \cdot \text{cm}^{-1}$ , about 10 times that of most other electrophoretic techniques), which reduces separation times to a few minutes. These rapid separations, in turn, minimize band broadening caused by diffusion, thereby yielding extremely sharp separations. Capillaries can be filled with buffer (as in moving boundary electrophoresis, but here the capillary's narrow bore all but eliminates convective mixing), SDS-polyacrylamide gel (separation according to molecular mass; Section 6-4C), or ampholytes (isoelectric focusing; Section 6-4D). These CE techniques have extremely high resolution and can be automated in much the same way as is HPLC, that is, with automatic sample loading and on-line sample detection. Since CE can only separate small amounts of material, it is largely limited to use as an analytical technique.

## 5 ULTRACENTRIFUGATION

If a container of sand and water is shaken and then allowed to stand quietly, the sand will rapidly sediment to the bottom of the container due to the influence of Earth's gravity (an acceleration  $g$  equal to  $9.81 \text{ m} \cdot \text{s}^{-2}$ ). Yet macromolecules in solution, which experience the same gravitational field, do not exhibit any perceptible sedimentation because their random thermal (Brownian) motion keeps them uniformly distributed throughout the solution. *Only when they are subjected to enormous accelerations will the sedimentation behavior of macromolecules begin to resemble that of sand grains.*

The ultracentrifuge was developed around 1923 by the Swedish biochemist The Svedberg. Using this instrument, Svedberg first demonstrated that proteins are macromolecules with homogeneous compositions and that many proteins are composed of subunits. Within a few decades, ultracentrifugation became an indispensable tool for the fractionation of proteins, nucleic acids, and subcellular particles. Modern ultracentrifuges can attain rotational speeds as high as 150,000 rpm (revolutions per minute) so as to generate centrifugal fields in excess of 1 million  $\times g$ . In this section we outline the theory and practice of ultracentrifugation.

### A. Sedimentation

The rate at which a particle sediments in the ultracentrifuge is related to its mass. The force,  $F_{\text{sedimentation}}$ , acting to sediment a particle of mass  $m$  that is located a distance  $r$  from a point about which it is revolving with angular velocity  $\omega$  (in radians  $\cdot \text{s}^{-1}$ ) is the centrifugal force ( $m\omega^2 r$ ) on the

particle less the buoyant force ( $V_p\rho\omega^2r$ ) exerted by the solution:

$$F_{\text{sedimentation}} = m\omega^2r - V_p\rho\omega^2r \quad [6.10]$$

Here  $V_p$  is the particle volume and  $\rho$  is the density of the solution. However, the motion of the particle through the solution, as we have seen in our study of electrophoresis, is opposed by the frictional force:

$$F_{\text{friction}} = vf \quad [6.7]$$

where  $v = dr/dt$  is the rate of migration of the sedimenting particle and  $f$  is its frictional coefficient. The particle's frictional coefficient can be determined from measurements of its rate of diffusion.

Under the influence of gravitational (centrifugal) force, the particle accelerates until the forces on it exactly balance:

$$m\omega^2r - V_p\rho\omega^2r = vf \quad [6.11]$$

The mass of 1 mol of particles,  $M$ , is

$$M = mN \quad [6.12]$$

where  $N$  is Avogadro's number ( $6.022 \times 10^{23}$ ). Thus, a particle's volume,  $V_p$ , may be expressed in terms of its molar mass:

$$V_p = \bar{V}m = \frac{\bar{V}M}{N} \quad [6.13]$$

where  $\bar{V}$ , the particle's **partial specific volume**, is the volume change when 1 g (dry weight) of particles is dissolved

in an infinite volume of the solute. For most proteins dissolved in pure water at 20°C,  $\bar{V}$  is near  $0.73 \text{ cm}^3 \cdot \text{g}^{-1}$  (Table 6-4). Indeed, for proteins of known amino acid composition,  $\bar{V}$  is closely approximated by the sum of the partial specific volumes of its component amino acid residues, thereby indicating that the atoms in proteins are closely packed (Section 8-3Bc).

#### a. A Particle May Be Characterized by Its Sedimentation Rate

Substituting Eqs. [6.12] and [6.13] into Eq. [6.11] yields

$$vf = \frac{M(1 - \bar{V}\rho)\omega^2r}{N} \quad [6.14]$$

Now define the **sedimentation coefficient**,  $s$ , as

$$s = \frac{v}{\omega^2r} = \frac{1}{\omega^2} \left( \frac{d \ln r}{dt} \right) = \frac{M(1 - \bar{V}\rho)}{Nf} \quad [6.15]$$

The sedimentation coefficient, a quantity that is analogous to the electrophoretic mobility (Eq. [6.9]) in that it is a velocity per unit force, is usually expressed in units of  $10^{-13} \text{ s}$ , which are known as **svedbergs (S)**. For the sake of uniformity, the sedimentation coefficient is customarily corrected to the value that would be obtained at 20°C in a solvent with the density and viscosity of pure water. This is symbolized  $s_{20,w}$ . Table 6-4 and Fig. 6-28 indicate the values of  $s_{20,w}$  in svedbergs for a variety of biological materials.

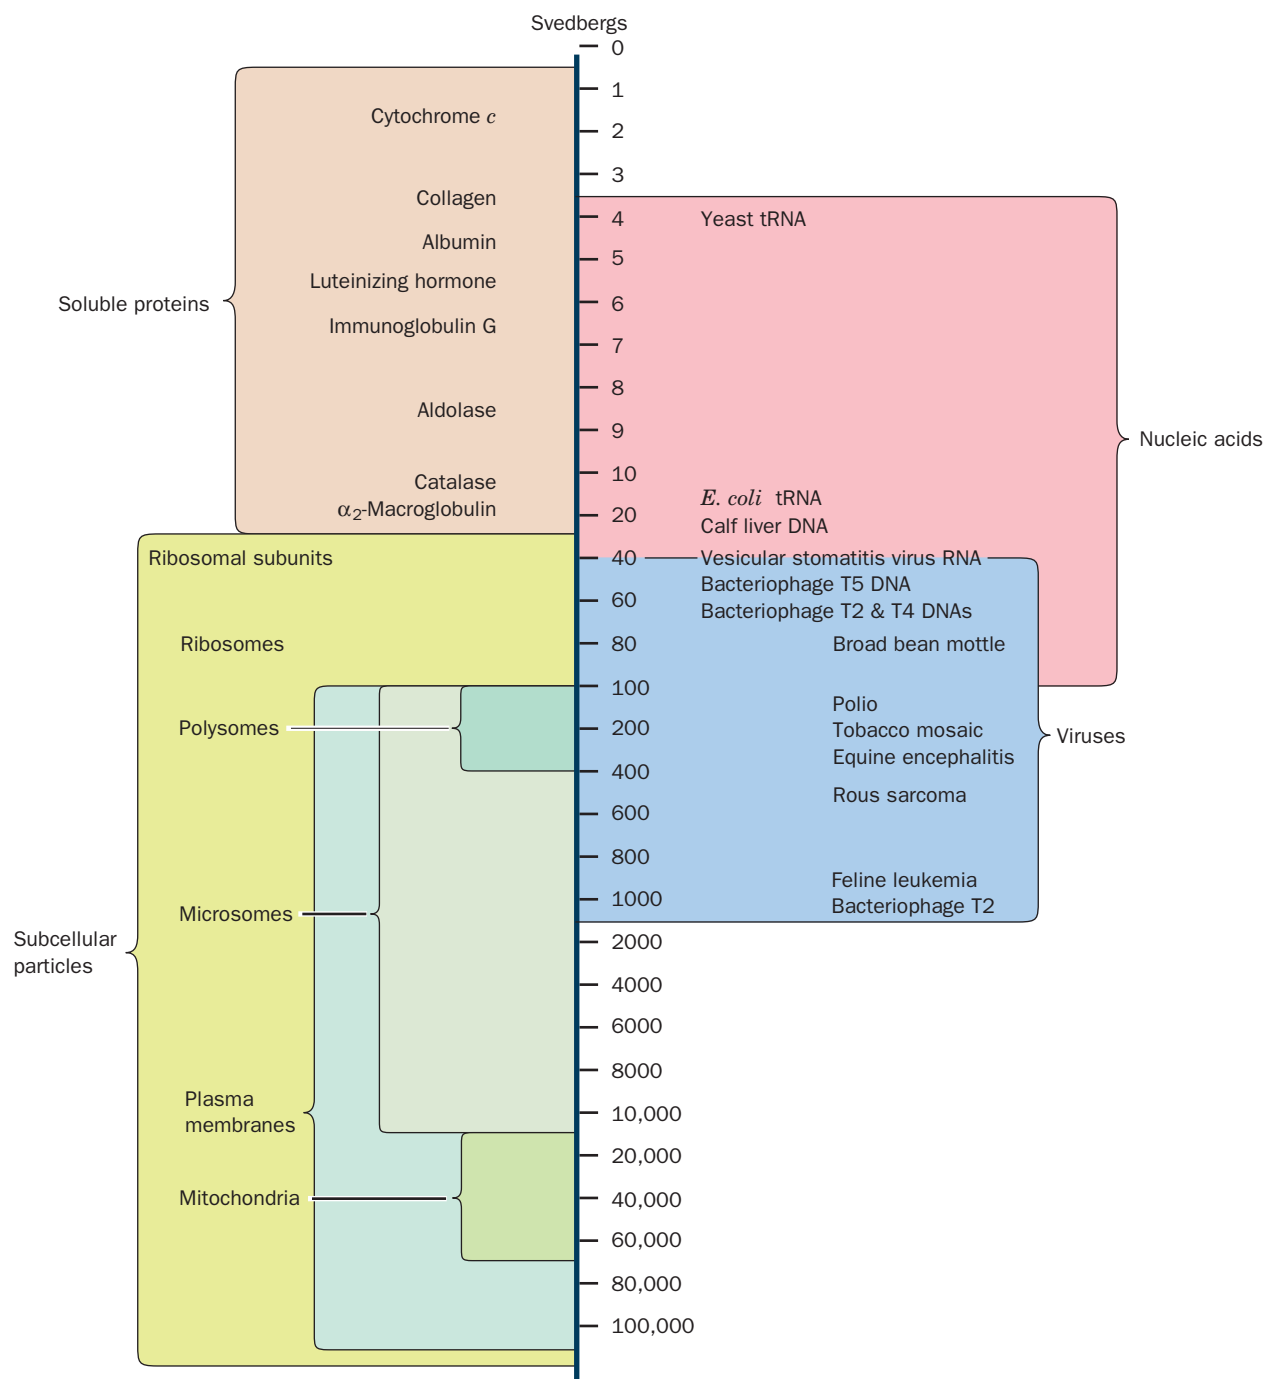

Equation [6.15] indicates that a particle's mass,  $m = M/N$ , can be determined from the measurement of its sedimentation coefficient,  $s$ , and the solution density,  $\rho$ , if its

**Table 6-4** Physical Constants of Some Proteins

Protein	Molecular Mass (kD)	Partial Specific Volume, $\bar{V}_{20,w}$ ( $\text{cm}^3 \cdot \text{g}^{-1}$ )	Sedimentation Coefficient, $s_{20,w}$ (S)	Frictional Ratio, $f/f_0$

**Figure 6-28** Sedimentation coefficients in svedbergs (S) for some biological materials. [After a diagram supplied by Beckman Coulter, Inc.]

frictional coefficient,  $f$ , and its partial specific volume,  $\bar{V}$ , are known. Indeed, before about 1970, most macromolecular mass determinations were made using the **analytical ultracentrifuge**, a device in which the sedimentation rates of molecules under centrifugation can be optically measured (the masses of macromolecules are too high to be accurately determined by such classic physical techniques as melting point depression or osmotic pressure measurements).

Although the advent of much simpler molecular mass determination methods, such as gel filtration chromatography (Section 6-3Ba) and SDS-PAGE (Section 6-4C), had caused analytical ultracentrifugation to largely fade from use, recently developed instrumentation has led to a resurgence in the use of analytical ultracentrifugal measurements. They are particularly useful in characterizing systems of associating macromolecules.

### b. The Frictional Ratio Is Indicative of Molecular Solvation and Shape

For an unsolvated spherical particle of radius  $r_p$  the frictional coefficient is determined according to the **Stokes equation**:

$$f = 6\pi\eta r_p \quad [6.16]$$

where  $\eta$  is the **viscosity** of the solution. Solvation increases the frictional coefficient of a particle by increasing its effective or **hydrodynamic volume**. Furthermore,  $f$  is minimal when the particle is a sphere. This is because a nonspherical particle has a larger surface area than a sphere of equal volume and therefore must, on the average, present a greater surface area toward the direction of movement than a sphere.

The frictional coefficient,  $f$ , of a particle of known mass and partial specific volume can be ultracentrifugally determined using Eq. [6.15]. The effective or **Stokes radius** of a particle in solution can be calculated by solving Eq. [6.16] for  $r_p$ , given the experimentally determined values of  $f$  and  $\eta$ . Conversely, the minimal frictional coefficient of a particle,  $f_0$ , can be calculated from the mass and the partial specific volume of the particle by assuming it to be spherical ( $V_p = \frac{4}{3}\pi r_p^3$ ) and unsolvated:

$$f_0 = 6\pi\eta \left( \frac{3M\bar{V}}{4\pi N} \right)^{1/3} \quad [6.17]$$

If the **frictional ratio**,  $f/f_0$ , of a particle is much greater than unity, it must be concluded that the particle is highly solvated and/or significantly elongated. The frictional ratios of a selection of proteins are presented in Table 6-4. The globular proteins, which are known from structural studies to be relatively compact and spheroidal (Section 8-3B), have frictional ratios ranging up to  $\sim 1.5$ . Fibrous molecules such as DNA and the blood clotting protein **fibrinogen** (Section 35-1Aa) have larger frictional ratios. On denaturation, the frictional coefficients of globular proteins increase by as much as twofold because denatured proteins assume flexible and fluctuating **random coil** conformations in which all parts of the molecule are in contact with solvent (Section 8-1D).

### B. Preparative Ultracentrifugation

**Preparative ultracentrifuges**, which as their name implies are designed for sample preparation, differ from analytical ultracentrifuges in that they lack sample observation facilities. Preparative rotors contain cylindrical sample tubes whose axes may be parallel, at an angle, or perpendicular to the rotor's axis of rotation, depending on the particular application (Fig. 6-29).

In the derivation of Eq. [6.15], it was assumed that sedimentation occurred through a homogeneous medium. Sedimentation may be carried out in a solution of an inert substance, however, such as sucrose or CsCl, in which the concentration, and therefore the density, of the solution increases from the top to the bottom of the centrifuge tube.

**Figure 6-29** A selection of preparative ultracentrifuge rotors.

The sample tubes of the swinging bucket rotors (*rear*) are hinged so that they swing from the vertical to the horizontal position as the rotor starts spinning, whereas the sample tubes of the other rotors have a fixed angle relative to the rotation axis. [Courtesy of Beckman Coulter, Inc.]

The use of such **density gradients** greatly enhances the resolving power of the ultracentrifuge. Two applications of density gradients are widely employed: (1) **zonal ultracentrifugation** and (2) **equilibrium density gradient ultracentrifugation**.

#### a. Zonal Ultracentrifugation Separates Particles According to Their Sedimentation Coefficients

In zonal ultracentrifugation, a macromolecular solution is carefully layered on top of a density gradient prepared by use of a device resembling that diagrammed in Fig. 6-7. The purpose of the density gradient is to allow smooth passage of the various macromolecular zones by damping out convective mixing of the solution. Sucrose, which forms a syrupy and biochemically benign solution, is commonly used to form a density gradient for zonal ultracentrifugation. The density gradient is normally rather shallow because the maximum density of the solution must be less than that of the least dense macromolecule of interest. Nevertheless, consideration of Eq. [6.15] indicates that the sedimentation rate of a macromolecule is a more sensitive function of molecular mass than density. Consequently, *zonal ultracentrifugation separates similarly shaped macromolecules largely on the basis of their molecular masses*.

During centrifugation, each species of macromolecule moves through the gradient at a rate largely determined by its sedimentation coefficient and therefore travels as a zone that can be separated from other such zones as is diagrammed in Fig. 6-30. After centrifugation, fractionation is commonly effected by puncturing the bottom of the celluloid centrifuge tube with a needle, allowing its contents to drip out, and collecting the individual zones for subsequent analysis.

**Figure 6-30 Zonal ultracentrifugation.** The sample is layered onto a sucrose gradient (*left*). During centrifugation (*middle*), each particle sediments at a rate that depends largely on its mass.

After the end of the run, the centrifugation tube is punctured and the separated particles (zones) are collected (*right*).

### b. Equilibrium Density Gradient Ultracentrifugation Separates Particles According to Their Densities

In **equilibrium density gradient ultracentrifugation** [alternatively, **isopycnic ultracentrifugation** (Greek: *isos*, equal + *pyknos*, dense)], the sample is dissolved in a relatively concentrated solution of a dense, fast-diffusing (and therefore low molecular mass) substance, such as  $\text{CsCl}$  or  $\text{Cs}_2\text{SO}_4$ , and is spun at high speed until the solution achieves equilibrium. *The high centrifugal field causes the low molecular mass solute to form a steep density gradient* (Fig. 6-31) *in which the sample components band at posi-*

**Figure 6-31 Equilibrium density distribution of a CsCl solution in an ultracentrifuge spinning at 39,460 rpm.** The initial density of the solution was  $1.7 \text{ g} \cdot \text{mL}^{-1}$ . [After Ifft, J.B., Voet, D.H., and Vinograd, J., *J. Phys. Chem.* **65**, 1138 (1961).]

*tions where their densities are equal to that of the solution; that is, where  $(1 - \bar{V}\rho)$  in Eq. [6.15] is zero* (Fig. 6-32). These bands are collected as separate fractions when the sample tube is drained as described above. The salt concentration in the fractions and hence the solution density is easily determined with an **Abbé refractometer**, an optical instrument that measures the refractive index of a solution. *The equilibrium density gradient technique is often the method of choice for separating mixtures whose components have a range of densities.* These substances include nucleic acids, viruses, and certain subcellular organelles such as ribosomes. However, isopycnic ultracentrifugation is rather ineffective for the fractionation of protein mixtures because most proteins have similar densities (high salt concentrations also salt out or possibly denature proteins). Density gradient ultracentrifugation in an analytical ultracentrifuge was used to show that DNA is semiconservatively replicated (Section 5-3B).

## 6 NUCLEIC ACID FRACTIONATION

In the preceding parts of this chapter we considered the most commonly used procedures for isolating and, to some extent, characterizing proteins. Most of these methods, often with some modification, are also regularly used to fractionate nucleic acids according to size, composition, and sequence. There are also many techniques that are applicable only to nucleic acids. In this section we outline some of the most useful of the procedures employed in the separation of nucleic acids.

### A. Solution Methods

Nucleic acids in cells are invariably associated with proteins. Once cells have been broken open (Section 6-1B),

**Figure 6-32 Isopycnic ultracentrifugation.** The centrifugation starts with a uniform mixture of a macromolecular sample dissolved in a solution of a dense, fast-diffusing solute such as

CsCl (*left*). At equilibrium in a centrifugal field, the solute forms a density gradient in which the macromolecules migrate to their positions of buoyant density (*right*).

their nucleic acids must be deproteinized. This can be accomplished by shaking (very gently if high molecular mass DNA is being isolated; Section 5-3D) the aqueous solution containing the protein–nucleic acid complex with a 25:24:1 mixture of phenol, chloroform, and isoamyl alcohol. The protein is thereby denatured and extracted into the water-immiscible organic phase, which is separated from the nucleic acid–containing aqueous phase by centrifugation (when a large amount of protein is present, it forms a white precipitate between the organic and aqueous phases). Alternatively (or in addition), protein can be dissociated from the nucleic acids by such denaturing agents as detergents, guanidinium chloride, or high salt concentrations, and/or it can be enzymatically degraded by proteases. In all cases, the nucleic acids, a mixture of RNA and DNA, can then be isolated by precipitation with ethanol. The RNA can be recovered from such a precipitate by treating it with **pancreatic DNase** to eliminate the DNA. Conversely, the DNA can be freed of RNA by treatment with **RNase**. Alternatively, RNA and DNA may be separated by ultracentrifugation (Section 6-6D).

In all these and subsequent manipulations, the nucleic acids must be protected from degradation by nucleases that occur both in the experimental materials and on human hands. Nucleases may be inhibited by the presence of chelating agents such as **ethylenediaminetetraacetic acid (EDTA)**,

**Ethylenediaminetetraacetic acid (EDTA)**

which sequester the divalent metal ions that nucleases require for activity. In cases where no nuclease activity can be tolerated, all glassware must be autoclaved to heat denature the nucleases and the experimenter should wear plastic gloves. Nevertheless, nucleic acids are generally easier to handle than proteins because their lack, in most cases, of a complex tertiary structure makes them relatively tolerant of extreme conditions.

## B. Chromatography

Many of the chromatographic techniques that are used to separate proteins (Section 6-3) are also applicable to nucleic acids. Oligonucleotides can be readily separated HPLC, particularly that using reverse-phase chromatography. Larger nucleic acids are often separated by procedures that include ion exchange chromatography and gel filtration chromatography.

### a. Hydroxyapatite Can Be Used to Isolate and Fractionate DNA

Hydroxyapatite (a form of calcium phosphate; Section 6-3Db) is particularly useful in the chromatographic purification and fractionation of DNA. Double-stranded DNA binds to hydroxyapatite more tightly than do most other molecules. Consequently, DNA can be rapidly isolated by passing a cell lysate through a hydroxyapatite column, washing the column with a phosphate buffer of concentration low enough to release only the RNA and proteins, and then eluting the DNA with a more concentrated phosphate solution. In addition, single-stranded DNA elutes from hydroxyapatite at a lower phosphate concentration than does double-stranded DNA.

### b. Messenger RNAs Can Be Isolated by Affinity Chromatography

Affinity chromatography (Section 6-3C) is useful in isolating specific nucleic acids. For example, most eukaryotic messenger RNAs (mRNAs) have a poly(A) sequence at their 3' ends (Section 5-4Ac). They can be isolated on an agarose or cellulose matrix to which poly(U) has been covalently attached. The poly(A) sequences specifically bind to the complementary poly(U) in high salt and at low temperatures and can later be released by altering these conditions. Moreover, if the (partial) sequence of an mRNA is known (e.g., as inferred from the corresponding protein's amino acid sequence), the complementary DNA strand may be synthesized (via methods discussed in Section 7-6Aa) and used to isolate that particular mRNA.

### C. Electrophoresis

Nucleic acids of a given type may be separated by polyacrylamide gel electrophoresis (Sections 6-4B and 6-4C) because their electrophoretic mobilities in such gels vary inversely with their molecular masses. However, DNAs of more than a few thousand base pairs are too large to penetrate even a weakly cross-linked polyacrylamide gel. This difficulty is partially overcome through the use of agarose gels. By using gels with an appropriately low agarose content, relatively large DNAs in various size ranges may be fractionated. In this manner, plasmids, for example, may be separated from the larger chromosomal DNA of bacteria.

#### a. Duplex DNA Is Detected by Selectively Staining It with Intercalation Agents

The various DNA bands in a gel must be detected if they are to be isolated. Double-stranded DNA is readily stained by planar aromatic cations such as **ethidium ion** and **acridine orange**.

**Ethidium**

**Acridine orange**

These dyes bind to duplex DNA by **intercalation** (slipping in between the stacked base pairs), where they exhibit a fluorescence under UV light that is far more intense than that of the free dye. As little as 50 ng of DNA may be detected in a gel by staining it with ethidium bromide (Fig. 6-33).

**Figure 6-33** Agarose gel electrophoretogram of double helical DNA. After electrophoresis, the gel was soaked in a solution of ethidium bromide, washed, and photographed under UV light. The fluorescence of the ethidium cation is strongly enhanced by binding to DNA, so each fluorescent band marks a different sized DNA fragment. [Klaus Guldbrandsen/Photo Researchers, Inc.]

Single-stranded DNA and RNA also stimulate the fluorescence of ethidium ion but to a lesser extent than does duplex DNA. Disadvantages of using these dyes are that they are mutagens and therefore must be handled and disposed of with caution and that exposure to UV light damages DNA (Section 30-5Aa). **SYBR Safe**, an equally sensitive nonmutagenic dye that fluoresces when it is bound to double-stranded DNA and excited by blue light, avoids these difficulties.

#### b. Very Large DNAs Are Separated by Pulsed-Field Gel Electrophoresis

The sizes of the DNAs that can be separated by conventional gel electrophoresis are limited to  $\sim 100,000$  bp even when gels containing as little as 0.1% agarose (which makes an extremely fragile gel) are used. However, the development of **pulsed-field gel electrophoresis (PFGE)** by Charles Cantor and Cassandra Smith extended this limit to DNAs with up to 10 million bp (6.6 million kD). The electrophoresis apparatus used in PFGE has two or more pairs of electrodes arrayed around the periphery of an agarose slab gel. The different electrode pairs are sequentially pulsed for times varying from 0.1 to 1000 s depending on the sizes of the DNAs being separated. Gel electrophoresis of DNA requires that these elongated molecules worm their way through the gel's labyrinthine channels more or less in the direction from the cathode to the anode. If the direction of the electric field abruptly changes, these DNAs must reorient their long axes along the new direction of the field before they can continue their passage through the gel. The time required to reorient very long gel-embedded

DNA molecules evidently increases with their size. Consequently, a judicious choice of electrode distribution and pulse lengths causes shorter DNAs to migrate through the gel faster than longer DNAs, thereby effecting their separation (Fig. 6-34).

#### D. Ultracentrifugation

Equilibrium density gradient ultracentrifugation (Section 6-5Bb) in CsCl constitutes one of the most commonly used DNA separation procedures. The buoyant density,  $\rho$ , of double-stranded Cs<sup>+</sup> DNA depends on its base composition:

$$\rho = 1.660 + 0.098X_{G+C} \quad [6.18]$$

where  $X_{G+C}$  is the mole fraction of G + C. Hence a CsCl density gradient fractionates DNA according to its base composition. For example, eukaryotic DNAs often contain minor fractions that band separately from the major species. Some of these **satellite bands** consist of mitochondrial and chloroplast DNAs. Another important class of satellite DNA is composed of **repetitive sequences** that are short segments of DNA tandemly repeated hundreds, thousands, and in some cases millions of times in a genome (Section 34-2B). Likewise, plasmids may be separated from bacterial chromosomal DNA by equilibrium density gradient ultracentrifugation.

Single-stranded DNA is  $\sim 0.015 \text{ g} \cdot \text{cm}^{-3}$  denser than the corresponding double-stranded DNA so that the two may be separated by equilibrium density gradient ultracentrifugation. RNA is too dense to band in CsCl but does so in Cs<sub>2</sub>SO<sub>4</sub> solutions. RNA–DNA hybrids will band in CsCl but at a higher density than the corresponding duplex DNA.

RNA may be fractionated by zonal ultracentrifugation through a sucrose gradient (Section 6-5Ba). RNAs are separated by this technique largely on the basis of their size. In fact, ribosomal RNA, which constitutes the major portion

**Figure 6-34** Pulsed-field gel electrophoresis (PFGE) of a set of yeast chromosomes. The yeast chromosomes, which were run as identical samples in the 13 inner lanes, have sizes 260, 290, 370, 460, 580/600, 700, 780, 820, and 850 kb. The two outer lanes, which provide molecular mass standards, contained twenty successively larger multimers of a  $\sim 43.5$ -kb bacteriophage  $\lambda$  DNA (top to bottom) to an observed limit of  $\sim 850$  kb. [Electrophoretogram by Margit Burmeister, University of Michigan, in Wilson, K. and Walker, J., *Principles and Techniques of Biochemistry and Molecular Biology* (6th ed.), p. 477, Cambridge University Press (2005).]

of cellular RNA, is classified according to its sedimentation rate; for example, the RNA of the *E. coli* small ribosomal subunit is known as **16S RNA** (Section 32-3A).

## CHAPTER SUMMARY

**1 Protein Isolation** Macromolecules in cells are solubilized by disrupting the cells by various chemical or mechanical means such as detergents or blenders. Partial purification by differential centrifugation is used after cell lysis to remove cell debris or to isolate a desired subcellular component. When out of the protective environment of the cell, proteins and other macromolecules must be treated so as to prevent their destruction by such influences as extremes of pH and temperature, enzymatic and chemical degradation, and rough mechanical handling. The state of purity of a substance being isolated must be monitored throughout the purification procedure by a specific assay.

**2 Solubilities of Proteins** Proteins are conveniently purified on a large scale by a fractional precipitation process called salting out, in which protein solubilities are varied by changing the salt concentration or pH.

**3 Chromatographic Separations** Ion exchange chromatography employs support materials such as cellulose or

cross-linked dextran gels. Separations are based on differential electrostatic interactions between charged groups on the ion exchange materials and those on the substances being separated. Molecules may be located through their UV absorbance, fluorescence, radioactivity, or enzymatic activity. In gel filtration chromatography, molecules are separated according to their size and shape through the use of cross-linked dextran, polyacrylamide, or agarose beads that have pores of molecular dimensions. A calibrated gel filtration column can be used to estimate the molecular masses of macromolecules. Affinity chromatography separates biomolecules according to their unique biochemical abilities to bind other molecules specifically. High-performance liquid chromatography (HPLC) utilizes any of the foregoing separation techniques but uses high-resolution chromatographic materials, high solvent pressures, and automatic solvent mixing and monitoring systems so as to obtain much greater degrees of separation than are achieved with the more conventional chromatographic procedures.

Adsorption chromatography, thin layer chromatography (TLC), reverse-phase chromatography (RPC), hydrophobic interaction chromatography (HIC), and metal chelate affinity chromatography also have valuable biochemical applications.

**4 Electrophoresis** In electrophoresis, charged molecules are separated according to their rates of migration in an electric field on a solid support such as paper, cellulose acetate, cross-linked polyacrylamide, or agarose. Gel electrophoresis employs a cross-linked polyacrylamide or agarose gel support, so that molecules are separated according to size by gel filtration as well as according to charge. The separated molecules may be visualized by means of stains, autoradiography, or immunoblotting. The anionic detergent sodium dodecyl sulfate (SDS) denatures proteins and uniformly coats them so as to give most proteins a similar charge density and shape. SDS-PAGE may be used to estimate macromolecular masses. In isoelectric focusing (IEF), macromolecules are immersed in a stable pH gradient and subjected to an electric field that causes them to migrate to their isoelectric positions. In capillary electrophoresis, the use of thin capillary tubes and high electric fields permits rapid and highly resolved separations of small amounts of material.

**5 Ultracentrifugation** In ultracentrifugation, molecules are separated by subjecting them to gravitational fields large enough to counteract diffusional forces. Molecules may be separated and their molecular masses estimated from their rates of sedimentation through a solvent or a preformed gradient of an inert low molecular mass material such as sucrose. Alternately, molecules may be separated according to their buoyant densities in a solution with a density gradient of a dense, fast-diffusing substance such as CsCl. The deviation of a molecule's frictional ratio from unity is indicative of its degrees of solvation and elongation.

**6 Nucleic Acid Fractionation** Nucleic acids can be fractionated by many of the techniques that are used to separate proteins. Hydroxyapatite chromatography separates single-stranded DNA from double-stranded DNA. Polyacrylamide or agarose gel electrophoresis separates DNA largely on the basis of size. Very large DNAs can be separated by pulsed-field gel electrophoresis (PFGE) on agarose gels. DNAs may be fractionated according to their base composition by CsCl density gradient ultracentrifugation. Different species of RNA can be separated by zonal ultracentrifugation through a sucrose gradient.

## PROBLEMS

- What are the ionic strengths of 1.0M solutions of NaCl,  $(\text{NH}_4)_2\text{SO}_4$ , and  $\text{K}_3\text{PO}_4$ ? In which of these solutions would a protein be expected to be most soluble; least soluble?
- An **isotonic saline solution** (one that has the same salt concentration as blood) is 0.9% NaCl. What is its ionic strength?
- In what order will the following amino acids be eluted from a column of P-cellulose ion exchange resin by a buffer at pH 6: arginine, aspartic acid, histidine, and leucine?
- In what order will the following proteins be eluted from a CM-cellulose ion exchange column by an increasing salt gradient at pH 7: fibrinogen, hemoglobin, lysozyme, pepsin, and ribonuclease A (see Table 6-1)?
- What is the order of elution of the following proteins from a Sephadex G-50 column: catalase,  $\alpha$ -chymotrypsin, concanavalin B, lipase, and myoglobin (see Table 6-4)?
- Estimate the molecular mass of an unknown protein that elutes from a Sephadex G-50 column between cytochrome *c* and ribonuclease A (see Table 6-4).
- A gel chromatography column of Bio-Gel P-30 with a bed volume of 100 mL is poured. The elution volume of the protein hexokinase (96 kD) on this column is 34 mL. That of an unknown protein is 50 mL. What are the void volume of the column, the volume occupied by the gel, and the relative elution volume of the unknown protein?
- What chromatographic method would be suitable for separating the following pairs of substances? (a) Ala-Phe-Lys, Ala-Ala-Lys; (b) lysozyme, ribonuclease A (see Table 6-1); and (c) hemoglobin, myoglobin (see Table 6-1).
- What is the order of the  $R_f$  values of the following amino acids in their paper chromatography with a water/butanol/acetic acid solvent system in which the pH of the aqueous phase is 4.5: alanine, aspartic acid, lysine, glutamic acid, phenylalanine, and valine?
- What fractionation procedure could be used to purify Protein 1 from a mixture of three proteins whose amino acid compositions are as follows?
  - 25% Ala, 20% Gly, 20% Ser, 10% Ile, 10% Val, 5% Asn, 5% Gln, 5% Pro
  - 30% Gln, 25% Glu, 20% Lys, 15% Ser, 10% Cys
  - 25% Asn, 20% Gly, 20% Asp, 20% Ser, 10% Lys, 5% Tyr
 All three proteins are similar in size and  $pI$ , and there is no antibody available for Protein 1.
- Purification tables are often used to keep track of the yield and purification of a protein. The specific activity is the ratio of the amount of the protein of interest, here myoglobin (Mb), obtained at given step (in  $\mu\text{mol}$  or enzyme units) divided by the amount (mg) of total protein. The yield is the ratio of the amount of the protein of interest obtained at a given purification step (in  $\mu\text{mol}$  or enzyme units) divided by the original amount present in the crude extract, often converted to percent yield by multiplying by 100. The fold purification is the ratio of the specific activity of the purified protein to that of the crude extract.
  - For the purification table below, calculate the specific activity, % yield, and fold purification for the empty cells.
  - Which step, DEAE or affinity chromatography, causes the greatest loss of Mb?
  - Which step causes the greater purification of Mb?
  - If you could use only one purification step, which technique would be best?

### Purification Table (for Problem 11)

Purification Step	mg Total Protein	$\mu\text{mol}$ Mb	Specific Activity ( $\mu\text{mol}$ protein/mg total protein)	% Yield	Fold Purification
1. Crude extract	1550	0.75	100	1	
2. DEAE-cellulose chromatography	550	0.35			
3. Affinity chromatography	5.0	0.28			

**12.** The neurotransmitter  $\gamma$ -aminobutyric acid is thought to bind to specific receptor proteins in nerve tissue. Design a procedure for the partial purification of such a receptor protein.

**13.** A mixture of amino acids consisting of arginine, cysteine, glutamic acid, histidine, leucine, and serine is applied to a strip of paper and subjected to electrophoresis using a buffer at pH 7.5. What are the directions of migration of these amino acids and what are their relative mobilities?

**\*14.** Sketch the appearance of a fingerprint of the following tripeptides: Asn-Arg-Lys, Asn-Leu-Phe, Asn-His-Phe, Asp-Leu-Phe, and Val-Leu-Phe. Assume the paper chromatographic step is carried out using a water/butanol/acetic acid solvent system (pH 4.5) and the electrophoretic step takes place in a buffer at pH 6.5.

**15.** What is the molecular mass of a protein that has a relative electrophoretic mobility of 0.5 in an SDS–polyacrylamide gel such as that of Fig. 6-25?

**16.** Explain why the molecular mass of fibrinogen is significantly overestimated when measured using a calibrated gel filtration column (Fig. 6-10) but can be determined with reasonable accuracy from its electrophoretic mobility on an SDS–polyacrylamide gel (see Table 6-4).

**17.** (a) What would be the relative arrangement of the following proteins after they had been subjected to isoelectric focusing: insulin, cytochrome *c*, histone, myoglobin, and ribonuclease A? (b) Sketch the appearance of a two-dimensional gel electrophoretogram of cytochrome *c*, myoglobin, and ribonuclease A (see Tables 6-1 and 6-4).

**18.** Calculate the centrifugal acceleration, in gravities ( $g$ 's), on a particle located 6.5 cm from the axis of rotation of an ultracentrifuge rotating at 60,000 rpm ( $1 g = 9.81 \text{ m} \cdot \text{s}^{-2}$ ).

**19.** In a dilute buffer solution at 20°C, rabbit muscle aldolase has a frictional coefficient of  $8.74 \times 10^{-8} \text{ g} \cdot \text{s}^{-1}$ , a sedimentation coefficient of 7.35 S, and a partial specific volume of  $0.742 \text{ cm}^3 \cdot \text{g}^{-1}$ . Calculate the molecular mass of aldolase assuming the density of the solution to be  $0.998 \text{ g} \cdot \text{cm}^{-3}$ .

**\*20.** The sedimentation coefficient of a protein was measured by observing its sedimentation at 20°C in an ultracentrifuge spinning at 35,000 rpm.

Time, $t$ (min)	Distance of Boundary from Center of Rotation, $r$ (cm)
4	5.944
6	5.966
8	5.987
10	6.009
12	6.032

The density of the solution is  $1.030 \text{ g} \cdot \text{cm}^{-3}$ , the partial specific volume of the protein is  $0.725 \text{ cm}^3 \cdot \text{g}^{-1}$ , and its frictional coefficient is  $3.72 \times 10^{-8} \text{ g} \cdot \text{s}^{-1}$ . Calculate the protein's sedimentation coefficient, in svedbergs, and its molecular mass.

Proteins are at the center of the action in biological processes. They function as enzymes, which catalyze the complex set of chemical reactions that are collectively referred to as life. Proteins serve as regulators of these reactions, both directly as components of enzymes and indirectly in the form of chemical messengers, known as hormones, as well as the receptors for those hormones. They act to transport and store biologically important substances such as metal ions, O<sub>2</sub>, glucose, lipids, and

many other molecules. In the form of muscle fibers and other contractile assemblies, proteins generate the coordinated mechanical motion of numerous biological processes, such as the separation of chromosomes during cell division and the movement of your eyes as you read this page. Proteins, such as **rhodopsin** in the retina of your eye, acquire sensory information that is processed through the actions of nerve cell proteins. The proteins of the immune system, such as the **immunoglobulins**, form an essential biological defense system in higher animals. Proteins are major active elements in, as well as products of, the expression of genetic information. However, proteins also have important passive roles, such as that of **collagen**, which provides bones, tendons, and ligaments with their characteristic tensile strength. Clearly, there is considerable validity to the old cliché that proteins are the “building blocks” of life.

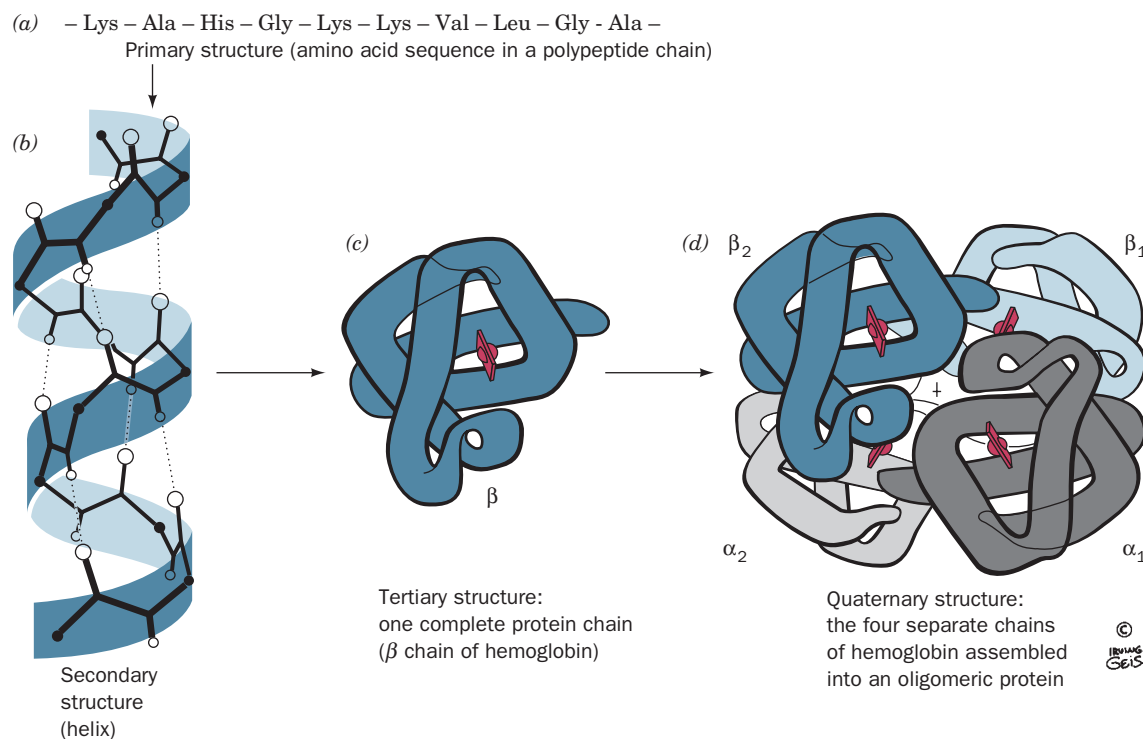

The function of DNA as the genetic archive and the association of RNA with protein synthesis have been known since the mid-twentieth century. However, it was not until the 1970s that it became clear that RNA can form structures whose complexities rival those of proteins, and it was not until the mid-1980s that it was shown that RNA has biologically important catalytic functions.

*Protein and nucleic acid function can best be understood in terms of their structures*, that is, the three-dimensional relationships between their component atoms. The structural descriptions of proteins and nucleic acids, as well as those of other polymeric materials, have been traditionally described in terms of four levels of organization (Fig. 7-1):

**1. Primary structure (1° structure)**, which for a protein is the amino acid sequence of its polypeptide chain(s) and for a nucleic acid is its base sequence.

**2. Secondary (2°) structure**, which is the local spatial arrangement of a polypeptide's or a nucleic acid's backbone atoms without regard to the conformations of their side chains or bases.

**3. Tertiary (3°) structure**, which refers to the three-dimensional structure of an entire polypeptide or polynucleotide chain. The distinction between secondary and tertiary structures is, of necessity, somewhat vague; in practice, the term “secondary structure” alludes to easily characterized structural entities such as helices.

**Figure 7-1 The structural hierarchy in proteins.** (a) Primary structure, (b) secondary structure, (c) tertiary structure, and (d) quaternary structure. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

4. Most proteins are composed of two or more polypeptide chains, loosely referred to as **subunits**, which associate through noncovalent interactions and, in some cases, disulfide bonds. A protein's **quaternary (4°) structure** refers to the spatial arrangement of its subunits. A nucleic acid's quaternary structure is similarly defined.

In this chapter, we discuss the 1° structures of proteins and nucleic acids: how they are elucidated and their biological and evolutionary significance. We also survey the field of bioinformatics as well as methods of chemically synthesizing polypeptide and oligonucleotide chains. The 2°, 3°, and 4° structures of proteins and nucleic acids, as we shall see, are a consequence of their 1° structures. For proteins, these topics are treated in Chapters 8 and 9, whereas for nucleic acids, they are discussed mainly in Chapters 29, 31, and 32.

## 1 PRIMARY STRUCTURE DETERMINATION OF PROTEINS

 **See Guided Exploration 4: Protein sequence determination** The first determination of the complete amino acid sequence of a protein, that of the bovine polypeptide hormone **insulin** by Frederick Sanger in 1953, was of enormous biochemical significance in that it definitively established that proteins have unique covalent structures. Since that time, the amino

acid sequences of tens of thousands of proteins have been elucidated. This extensive information has been of central importance in the formulation of modern concepts of biochemistry for several reasons:

1. The knowledge of a protein's amino acid sequence is essential for an understanding of its molecular mechanism of action as well as being prerequisite for the elucidation of its three-dimensional structure by both X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy (Section 8-3A).

2. Sequence comparisons among analogous proteins from the same individual, from members of the same species, and from members of related species have yielded important insights into how proteins function and have indicated the evolutionary relationships among the proteins and the organisms that produce them. These analyses, as we shall see in Section 7-3, complement and extend corresponding taxonomic studies based on anatomical comparisons.

3. Amino acid sequence analyses have important clinical applications because many inherited diseases are caused by mutations leading to an amino acid change in a protein. Recognition of this fact has led to the development of valuable diagnostic tests for many such diseases and, in many cases, to symptom-relieving therapy.

The elucidation of the 51-residue primary structure of insulin (Fig. 7-2) was the labor of many scientists over a

**Figure 7-2** Primary structure of bovine insulin. Note the intrachain and interchain disulfide bond linkages.

period of a decade that altogether utilized  $\sim 100$  g of protein. Procedures for primary structure determination have since been so refined and automated that proteins of similar size can be sequenced by an experienced technician in a few days using only a few micrograms of protein. The sequencing of the 1021-residue enzyme  **$\beta$ -galactosidase** in 1978 signaled that the sequence analysis of almost any protein could be reasonably attempted. Despite these technical advances, the basic procedure for primary structure determination using the techniques of protein chemistry is that developed by Sanger. The procedure consists of three conceptual parts, each of which requires several laboratory steps:

### 1. Prepare the protein for sequencing:

- Determine the number of chemically different polypeptide chains (subunits) in the protein.
- Cleave the protein's disulfide bonds.
- Separate and purify the unique subunits.

### 2. Sequence the polypeptide chains:

- Fragment the individual subunits at specific points to yield peptides small enough to be sequenced directly.
- Separate and purify the fragments.
- Determine the amino acid sequence of each peptide fragment.
- Repeat Step 2a with a fragmentation process of different specificity so that the subunit is cleaved at peptide bonds different from before. Separate these peptide fragments as in Step 2b and determine their amino acid sequences as in Step 2c.

### 3. Organize the completed structure:

- Span the cleavage points between one set of peptide fragments by the other. By comparison, the sequences of these sets of polypeptides can be arranged in the order that they occur in the subunit, thereby establishing its amino acid sequence.
- Elucidate the positions of the disulfide bonds, if any, between and within the subunits.

We discuss these various steps in the following sections.

## A. End Group Analysis: How Many Different Types of Subunits?

Each polypeptide chain (if it is not chemically blocked or circular) has an N-terminal residue and a C-terminal

residue. By identifying these **end groups**, we can establish the number of chemically distinct polypeptides in a protein. For example, insulin has equal amounts of the N-terminal residues Phe and Gly, which indicates that it has equal numbers of two nonidentical polypeptide chains.

### a. N-Terminus Identification

There are several effective methods by which a polypeptide's N-terminal residue may be identified. **1-Dimethylaminonaphthalene-5-sulfonyl chloride (dansyl chloride)** reacts with primary amines (including the  $\epsilon$ -amino group of Lys) to yield dansylated polypeptides (Fig. 7-3). Acid hydrolysis liberates the N-terminal residue as a **dansylamino acid**, which exhibits such intense yellow fluorescence that it can be chromatographically identified from as little as 100 picomoles of material [ $1 \text{ picomole (pmol)} = 10^{-12} \text{ mol}$ ].

In the most useful method of N-terminal residue identification, the **Edman degradation** (named after its inventor, Pehr Edman), **phenylisothiocyanate (PITC, Edman's reagent)** reacts with the N-terminal amino groups of proteins under mildly alkaline conditions to form their **phenylthiocarbamyl (PTC)** adduct (Fig. 7-4). This product is treated with an anhydrous strong acid such as trifluoroacetic acid, which cleaves the N-terminal residue as its **thiazolinone** derivative but does not hydrolyze other peptide bonds. *The Edman degradation therefore releases the N-terminal amino acid residue but leaves intact the rest of the polypeptide chain.* The thiazolinone-amino acid is selectively extracted into an organic solvent and is converted to the more stable **phenylthiohydantoin (PTH)** derivative by treatment with aqueous acid. This PTH-amino acid is most commonly identified by comparing its retention time on HPLC with those of known PTH-amino acids.

The most important difference between the Edman degradation and other methods of N-terminal residue identification is that *we can determine the amino acid sequence of a polypeptide chain from the N-terminus inward by subjecting the polypeptide to repeated cycles of the Edman degradation and, after every cycle, identifying the newly liberated PTH-amino acid.* This technique has been automated, resulting in great savings of time and materials (Section 7-1F).

### b. C-Terminus Identification

There is no reliable chemical procedure comparable to the Edman degradation for the sequential end group analysis from the C-terminus of a polypeptide. This can be done enzymatically, however, using **exopeptidases** (enzymes that

**Figure 7-3** The reaction of dansyl chloride in end group analysis.

cleave a terminal residue from a polypeptide). One class of exopeptidases, the **carboxypeptidases**, catalyzes the hydrolysis of the C-terminal residues of polypeptides:

Carboxypeptidases, like all enzymes, are highly specific (selective) for the chemical identities of the substances whose reactions they catalyze (Section 13-2). The side chain specificities of the various carboxypeptidases in common use are listed in Table 7-1. The second type of exopeptidase

listed in Table 7-1, the **aminopeptidases**, sequentially cleave amino acids from the N-terminus of a polypeptide and have been similarly used to determine N-terminal sequences.

Why can't carboxypeptidases be used to determine amino acid sequences? If a carboxypeptidase cleaved all C-terminal residues at the same rate, irrespective of their identities, then by following the course of appearance of the various free amino acids in the reaction mixture (Fig. 7-5a), the sequence of several amino acids at the C-terminus could be determined. If, however, the second amino acid residue, for example, were cleaved at a much faster rate than the first, both amino acids would appear to be released simultaneously (Fig. 7-5b). Carboxypeptidases, in fact, exhibit selectivity toward side chains, so their use, either singly or in mixtures, rarely reveals the order of more than the first few C-terminal residues of a polypeptide.

C-Terminal residues with a preceding Pro residue are not subject to cleavage by carboxypeptidases A and B (Table 7-1). Chemical methods are therefore usually employed to identify their C-terminal residue. In the most reliable such chemical method, **hydrazinolysis**, a polypeptide is treated with anhydrous **hydrazine** at  $90^\circ\text{C}$  for 20 to 100 h

**Figure 7-4 The Edman degradation.** Note that the reaction occurs in three separate stages that each require quite different conditions. Amino acid residues can therefore be sequentially removed from the N-terminus of a polypeptide in a controlled stepwise fashion.  See the Animated Figures

**Figure 7-5 Hypothetical rate of the carboxypeptidase-catalyzed release of amino acids from peptides having the indicated C-terminal sequences.** (a) All bonds cleaved at the same rate. (b) Ser removed slowly, Tyr cleaved rapidly, and Leu cleaved at an intermediate rate.

**Table 7-1** Specificities of Various Exopeptidases

Enzyme	Source	Specificity <sup>a</sup>
Carboxypeptidase A	Bovine pancreas	R <sub>n</sub> ≠ Arg, Lys, Pro; R <sub>n-1</sub> ≠ Pro
Carboxypeptidase B	Bovine pancreas	R <sub>n</sub> ≠ Arg, Lys, R <sub>n-1</sub> ≠ Pro
Carboxypeptidase C	Citrus leaves	All free C-terminal residues; pH optimum = 3.5
Carboxypeptidase Y	Yeast	All free C-terminal residues, but slowly with R <sub>n</sub> = Gly
Leucine aminopeptidase	Porcine kidney	R <sub>1</sub> ≠ Pro
Aminopeptidase M	Porcine kidney	All free N-terminal residues

<sup>a</sup>R<sub>1</sub> = the N-terminal residue; R<sub>n</sub> = the C-terminal residue.

in the presence of a mildly acidic ion exchange resin (which acts as a catalyst):

All the peptide bonds are thereby cleaved, yielding the aminoacyl hydrazides of all the amino acid residues except that of the C-terminal residue, which is released as the free amino acid and therefore can be identified chromatographically. Unfortunately, hydrazinolysis is subject to a great many side reactions that have largely limited its application to carboxypeptidase-resistant polypeptides.

### B. Cleavage of the Disulfide Bonds

The next step in the sequence analysis is to cleave the disulfide bonds between Cys residues. This is done for two reasons:

1. To permit the separation of polypeptide chains (if they are disulfide linked).

2. To prevent the native protein conformation, which is stabilized by disulfide bonds, from obstructing the action of the proteolytic (protein-cleaving) agents used in primary structure determinations (Section 7-1D).

Disulfide bond locations are established in the final step of the sequence analysis (Section 7-1H).

Disulfide bonds are most often cleaved reductively by treatment with sulfhydryl-containing compounds such as **2-mercaptoethanol**:

In order to expose all disulfide groups to the reducing agent, the reaction is usually carried out under conditions that denature the protein. The resulting free sulfhydryl groups are alkylated, usually by treatment with **iodoacetic acid**, to prevent the reformation of disulfide bonds through

oxidation by O<sub>2</sub>. S-Alkyl derivatives are stable in air and under the conditions used for the subsequent cleavage of peptide bonds.

### C. Separation, Purification, and Characterization of the Polypeptide Chains

A protein's nonidentical polypeptides must be separated and purified in preparation for their amino acid sequence determination. Subunit dissociation, as well as denaturation, occurs under acidic or basic conditions, at low salt concentrations, at elevated temperatures, or through the use of denaturing agents such as urea, guanidinium ion (Section 5-5G), or detergents such as sodium dodecyl sulfate (SDS; Section 6-4C). The dissociated subunits can then be separated by methods described in Chapter 6 that capitalize on small differences in polypeptide size and polarity. Ion exchange and gel filtration chromatography, usually by HPLC (Section 6-3Dg), are most often used.

It is, of course, desirable to know the number of residues in the polypeptide to be sequenced, which can be estimated from its molecular mass (~110 D/residue). Molecular mass can be measured with an accuracy of no better than 5 to

10% by the more traditional laboratory techniques of gel filtration chromatography and SDS-PAGE (Sections 6-3Ba and 6-4C). In recent years, however, mass spectrometry (Section 7-1I) has provided a faster and far more accurate means to determine the molecular masses of macromolecules. Mass spectrometry can determine the molecular masses of picomolar amounts of >100 kD polypeptides with accuracies of ~0.01%.

### D. Specific Peptide Cleavage Reactions

Polypeptides that are longer than 40 to 100 residues cannot be directly sequenced (Section 7-1F). Polypeptides of greater length must therefore be cleaved, either enzymatically or chemically, to fragments small enough to be sequenced (the polypeptides produced by *E. coli* and humans have broad distributions of lengths that average ~320 and ~470 residues, respectively). In either case, the cleavage process must be complete and highly specific so that the aggregate sequence of a subunit's peptide fragments, when correctly ordered, is that of the intact subunit.

#### a. Trypsin Specifically Cleaves Peptide Bonds after Positively Charged Residues

**Endopeptidases** (enzymes that catalyze the hydrolysis of internal peptide bonds), like exopeptidases, have side chain requirements for the residues flanking the **scissile** (to be cleaved) peptide bond. The side chain specificities of the endopeptidases most commonly used to fragment polypeptides are listed in Table 7-2. The digestive enzyme **trypsin** has the greatest specificity and is therefore the

**Table 7-2** Specificities of Various Endopeptidases

Enzyme	Source	Specificity	Comments
$  \begin{array}{c}  \text{R}_{n-1} \quad \text{O} \quad \quad \quad \text{R}_n \quad \text{O} \\    \quad \quad    \quad \quad \quad   \quad \quad    \\  -\text{NH}-\text{CH}-\text{C}-\text{NH}-\text{CH}-\text{C}- \\  \uparrow \\  \text{Scissile} \\  \text{peptide bond}  \end{array}  $			
Trypsin	Bovine pancreas	R <sub>n-1</sub> = positively charged residues: Arg, Lys; R <sub>n</sub> ≠ Pro	Highly specific
Chymotrypsin	Bovine pancreas	R <sub>n-1</sub> = bulky hydrophobic residues: Phe, Trp, Tyr; R <sub>n</sub> ≠ Pro	Cleaves more slowly for R <sub>n-1</sub> = Asn, His, Met, Leu
Elastase	Bovine pancreas	R <sub>n-1</sub> = small neutral residues: Ala, Gly, Ser, Val; R <sub>n</sub> ≠ Pro	
Thermolysin	<i>Bacillus thermoproteolyticus</i>	R <sub>n</sub> = Ile, Met, Phe, Trp, Tyr, Val; R <sub>n-1</sub> ≠ Pro	Occasionally cleaves at R <sub>n</sub> = Ala, Asp, His, Thr; heat stable
Pepsin	Bovine gastric mucosa	R <sub>n</sub> = Leu, Phe, Trp, Tyr; R <sub>n-1</sub> ≠ Pro	Also others; quite nonspecific; pH optimum 2
Endopeptidase Arg-C	Mouse submaxillary gland	R <sub>n-1</sub> = Arg	May cleave at R <sub>n-1</sub> = Lys
Endopeptidase Asp-N	<i>Pseudomonas fragi</i>	R <sub>n</sub> = Asp	May cleave at R <sub>n</sub> = Glu
Endopeptidase Glu-C	<i>Staphylococcus aureus</i>	R <sub>n-1</sub> = Glu	May cleave at R <sub>n-1</sub> = Gly
Endopeptidase Lys-C	<i>Lysobacter enzymogenes</i>	R <sub>n-1</sub> = Lys	May cleave at R <sub>n-1</sub> = Asn

most valuable member of the arsenal of peptidases used to fragment polypeptides. It cleaves peptide bonds on the C-side (toward the carboxyl terminus) of the positively charged residues Arg and Lys if the next residue is not Pro:

The other endopeptidases listed in Table 7-2 exhibit broader side chain specificities than trypsin and often yield a series of peptide fragments with overlapping sequences. However, through **limited proteolysis**, that is, by adjusting reaction conditions and limiting reaction times, these less specific endopeptidases can yield useful peptide fragments. This is because the complex native structure of a protein (subunit) buries many otherwise enzymatically susceptible peptide bonds beneath the surface of the protein molecule. With proper conditions and reaction times, only those peptide bonds in the native protein that are initially accessible to the peptidase will be hydrolyzed. Limited proteolysis is often employed to generate peptide fragments of useful size from subunits that have too many or too few Arg and Lys residues to do so with trypsin (although if too many are present, limited proteolysis with trypsin may also yield useful fragments).

#### b. Cyanogen Bromide Specifically Cleaves Peptide Bonds after Met Residues

Several chemical reagents promote peptide bond cleavage at specific residues. The most useful of these, **cyanogen bromide** (CNBr), causes specific and quantitative cleavage

on the C-side of Met residues to form a **peptidyl homoserine lactone**:

The reaction is performed in an acidic solvent (0.1M HCl or 70% formic acid) that denatures most proteins so that cleavage normally occurs at all Met residues.

A peptide fragment generated by a specific cleavage process may still be too large to sequence. In that case, after its purification, it can be subjected to a second round of fragmentation using a different cleavage process.

### E. Separation and Purification of the Peptide Fragments

Once again we must employ separation techniques, this time to isolate the peptide fragments of specific cleavage operations for subsequent sequence determinations. The nonpolar residues of peptide fragments are not excluded from the aqueous environment as they are in native proteins (Chapter 8). Consequently, many peptide fragments aggregate, precipitate, and/or strongly adsorb to chromatographic materials, which can result in unacceptable peptide losses. Until around 1980, the trial-and-error development of methods that could satisfactorily separate a mixture of peptide fragments constituted the major technical challenge of a protein sequence determination, as well as its most time-consuming step. Such methods involved the use of denaturants, such as urea and SDS, to solubilize the peptide fragments, and the selection of chromatographic materials and conditions that would reduce their adsorptive losses. The advent of reverse-phase chromatography by HPLC (Section 6-3Dh), however, has largely reduced the separation of peptide fragments to a routine procedure.

### F. Sequence Determination

Once the manageably sized peptide fragments that were formed through specific cleavage reactions have been isolated, their amino acid sequences can be determined. *This is done through repeated cycles of the Edman degradation* (Section 7-1Aa). An automated device for doing so was first developed by Edman and Geoffrey Begg. In modern

sequencers, the peptide sample is adsorbed onto a polyvinylidene fluoride (PVDF) membrane or dried onto glass fiber paper which is impregnated with **polybrene** (a polymeric quaternary ammonium salt). In either case, the peptide is immobilized but is readily accessible to Edman reagents. Accurately measured quantities of reagents, either in solution or as vapors in a stream of argon (which minimizes peptide loss), are then delivered to the reaction cell at programmed intervals. The thiazolinone-amino acids are automatically removed, converted to the corresponding PTH-amino acids (Fig. 7-4), and identified via HPLC. Such instruments are capable of processing up to one residue per hour.

*A peptide's 40 to 60 N-terminal residues can usually be identified (100 or more with the most advanced systems) before the cumulative effects of incomplete reactions, side reactions, and peptide loss make further amino acid identification unreliable.* As little as 0.1 pmol of a PTH-amino acid can be reliably identified by the UV detector-equipped reverse-phase HPLC systems used in advanced sequencers. Consequently, a peptide's N-terminal 5 to 25 residues can, respectively, be determined with as little as 1 to 10 pmol of the peptide—invisibly small amounts.

### G. Ordering the Peptide Fragments

With the peptide fragments individually sequenced, what remains is to elucidate the order in which they are connected in the original polypeptide. *We do so by comparing the amino acid sequences of one set of peptide fragments with those of a second set whose specific cleavage sites overlap those of the first set* (Fig. 7-6). The overlapping peptide segments must be of sufficient length to identify each cleavage site uniquely, but as there are 20 possibilities for each amino acid residue, an overlap of only a few residues is usually enough.

**Figure 7-6** The amino acid sequence of a polypeptide chain is determined by comparing the sequences of two sets of mutually overlapping peptide fragments. In this example, the two sets of peptide fragments are generated by cleaving the polypeptide after all its Arg and Lys residues with trypsin and, in a separate reaction, after all its Met residues by treatment with cyanogen bromide. The order of the first two tryptic peptides is established,

for example, by the observation that the Gly-Ala-Lys-Leu-Pro-Met cyanogen bromide peptide has its N- and C-terminal sequences in common with the C- and N-termini, respectively, of the two tryptic peptides. In this manner the order of the peptide fragments in their parent polypeptide chain is established.  See the **Animated Figures**

## H. Assignment of Disulfide Bond Positions

The final step in an amino acid sequence analysis is to determine the positions (if any) of the disulfide bonds. This is done by cleaving a sample of the native protein under conditions that leave its disulfide bonds intact. The resulting peptide fragments are then separated by reverse-phase HPLC. The disulfide-linked peptide fragments are easily identified because, for each such linkage, two of the original peptide fragments will be replaced by a larger one. The disulfide-linked fragments are then subjected to Edman degradation. Although such a fragment yields two PTH-amino acids in each step of this process (at least initially), their locations within the predetermined amino acid sequence of the protein are readily surmised, thereby establishing the positions of the disulfide bonds.

## I. Peptide Characterization and Sequencing by Mass Spectrometry

**Mass spectrometry (MS)** has emerged as an important technique for characterizing and sequencing polypeptides. *MS accurately measures the mass-to-charge ( $m/z$ ) ratio for ions in the gas phase* (where  $m$  is the ion's mass and  $z$  is its

charge). Yet, until about 1985, macromolecules such as proteins and nucleic acids could not be analyzed by MS. This was because the method by which mass spectrometers produced gas phase ions destroyed macromolecules: vaporization by heating followed by ionization via bombardment with electrons. However, the development of two techniques has eliminated this roadblock:

**1. Electrospray ionization (ESI; Fig. 7-7a)**, a technique pioneered by John Fenn in which a solution of a macromolecule such as a peptide is sprayed from a narrow capillary tube maintained at high voltage ( $\sim 4000$  V), forming fine, highly charged droplets from which the solvent rapidly evaporates. This yields a series of gas phase macromolecular ions that typically have ionic charges in the range  $+0.5$  to  $+2$  per kilodalton. For polypeptides, the ionic charges result from the protonation of basic side chains such as Lys and Arg [ $(M + nH)^{n+}$  ions].

**2. Matrix-assisted laser desorption/ionization (MALDI; Fig. 7-7b)**, in which the macromolecule is embedded in a crystalline matrix of a low molecular mass organic molecule (usually prepared by drying a droplet of solution containing the macromolecule and a large excess of the organic molecule) and irradiated with intense short

some other gas is used to promote the evaporation of the solvent from the droplets. [After Fitzgerald, M.C. and Siuzdak, G., *Chem. Biol.* **3**, 708 (1996).]

**Figure 7-8** The ESI-MS spectrum of the 16,951-D horse heart protein apomyoglobin. The measured  $m/z$  ratios and the inferred charges for most of the peaks are indicated. Note the bell-shaped distribution of the peaks, which is typical of ESI-MS spectra. The peaks all have shoulders because the polypeptide's component

elements contain small admixtures of heavier isotopes (e.g., naturally abundant carbon consists of 98.9%  $^{12}\text{C}$  and 1.1%  $^{13}\text{C}$  and naturally abundant sulfur consists of 0.8%  $^{33}\text{S}$ , 4.2%  $^{34}\text{S}$ , and 95.0%  $^{35}\text{S}$ ). [After Yates, J.R., *Methods Enzymol.* **271**, 353 (1996).]

(nanosecond) pulses of laser light at a wavelength absorbed by the matrix material but not the macromolecule. The energy absorbed by the matrix ejects the intact macromolecules from its surface into the gas phase, usually with a charge of +1 but, with larger molecules, occasionally with charges of +2, +3, etc. For polypeptides, **genetic acid** (2,5-dihydroxybenzoic acid) is one of the few substances found to have satisfactory properties as a matrix. Through the use of MALDI, polypeptides of >400 kD have been characterized.

In both of these techniques, the gas phase macromolecular ions are directed into the mass spectrometer, which measures their  $m/z$  values with an accuracy of >0.01%. Consequently, if an ion's  $z$  value can be determined, its molecular mass can be determined with far greater accuracy than by any other method. For example, Fig. 7-8 shows the ESI-based mass spectrum (**ESI-MS**) of the 16,951-D protein **myoglobin**. Note that successive peaks in this spectrum differ by a single ionic charge with the rightmost peak corresponding to an  $(M + 9\text{H})^{9+}$  ion. Consequently, for the mass spectrum of a macromolecule of molecular mass  $M$  containing two adjacent peaks with  $m/z$  values of  $p_1$  and  $p_2$  arising from ions with charges of  $z_1$  and  $z_1 - 1$ ,

$$p_1 = \frac{M + z_1}{z_1} \quad [7.1]$$

and

$$p_2 = \frac{M + z_1 - 1}{z_1 - 1} \quad [7.2]$$

These two linear equations can therefore be readily solved for their two unknowns,  $M$  and  $z_1$ .

Since most mass spectrometers are limited to detecting ions with  $m/z$  values less than several thousand, the use of ESI-MS has the advantage that the high ionic charges of the ions it produces has permitted the analysis of compounds with molecular masses >100 kD. Another advantage of ESI-MS is that it can be configured to operate in a continuous flow mode with the effluent of an HPLC or CE system. ESI-MS is used in this way, for example, to characterize the tryptic digest of a protein by determining the molecular masses of its component peptides (Section 7-1J).

#### a. Peptide Sequencing by Mass Spectrometry

Short polypeptides (<25 residues) can be directly sequenced though the use of a **tandem mass spectrometer (MS/MS; two mass spectrometers coupled in series; Fig. 7-9)**. The first mass spectrometer functions to select the peptide ion of interest from other peptide ions as well as any contaminants that may be present. The selected peptide ion ( $P_3$  in Fig. 7-9b) is then passed into a collision cell, where it

**Figure 7-9** The use of a tandem mass spectrometer (MS/MS) in amino acid sequencing. (a) An MS/MS consists of an ion source (here shown as an ESI system), a first mass spectrometer (MS-1), a collision cell, a second mass spectrometer (MS-2), and a detector. (b) The ion source generates gas phase peptide ions,  $P_1, P_2$ , etc., from a digest of the protein being analyzed. These peptides are separated by MS-1 according to their  $m/z$  values

and one of them, here  $P_3$ , is directed into the collision cell, where it collides with helium atoms. This treatment induces the breakdown of the polypeptide ion to yield the fragments  $F_1, F_2$ , etc., which are directed into MS-2, where their  $m/z$  values are determined. [Part a after Yates, J.R., *Methods Enzymol.* **271**, 358 (1996); Part b after Biemann, K. and Scoble, H.A., *Science* **237**, 992 (1987).]

collides with chemically inert atoms such as helium. The energy thereby imparted to a peptide ion causes it to fragment predominantly at only one of its several peptide bonds, yielding one or two charged fragments (Fig. 7-10). The molecular masses of the charged fragments are then determined by the second mass spectrometer.

By comparing the molecular masses of successively larger members of a family of fragments, the molecular masses and therefore the identities of the corresponding amino acid residues can be determined. The sequence of an entire polypeptide can thus be elucidated (although MS cannot distinguish the isomeric residues Ile and Leu because they have exactly the same mass and cannot always reliably distinguish Gln and Lys residues because their molecular masses differ by only 0.036 D). Computerization of this comparison process has reduced the time required to sequence a (short) polypeptide to only a few minutes as compared to the 30 to 50 min required per cycle of Edman degradation. The reliability of this process has been increased through the computerized matching of a measured mass spectrum with those of peptides of known sequence as maintained in databases.

The sequences of several polypeptides in a mixture can be determined, even in the presence of contaminants, by sequentially selecting the corresponding polypeptide ions in the first mass spectrometer of the tandem instrument. Hence, in separating and purifying the polypeptide fragments of a protein digest in preparation for their sequencing, less effort need be expended for MS/MS-based as compared to Edman techniques. MS/MS can also be used to sequence peptides with chemically blocked N-termini (a

common eukaryotic post-translational modification that prevents Edman degradation) and to characterize other post-translational modifications such as phosphorylations (Section 4-3A) and glycosylations (Section 11-3C). Finally, MS/MS can be used to locate disulfide bonds by chemically or enzymatically fragmenting both the disulfide-cleaved protein and the intact protein. From the disappearance of peaks from the mass spectrum of the latter relative to that of the former and the appearance of new peaks, the positions of the disulfide bonds in the protein can be deduced. Thus, MS/MS has become an indispensable tool for the characterization of polypeptides.

### J. Peptide Mapping

Once the primary structure of a protein has been elucidated, that of a nearly identical protein, such as one arising from a closely related species, a mutation, or a chemical modification, can be more easily determined. This was originally done through the combined paper chromatography and paper electrophoresis (Section 6-4A) of partial protein digests, a technique synonymously known as **fingerprinting** or **peptide mapping**. The peptide fragments incorporating the amino acid variations migrate to different positions on their fingerprint (peptide map) than do the corresponding peptides of the original protein (Fig. 7-11). The variant peptides could then be eluted and sequenced, thereby identifying the changes in the protein without the need to sequence it in its entirety.

In more recent times, peptide mapping has come to mean any method that fragments a protein in a repro-

**Figure 7-10** The tandem mass spectrum of the doubly charged ion of the 14-residue human [Glu<sup>1</sup>] fibrinopeptide B ( $m/z = 786$ ). (a) The peptide's sequence. The upper and lower rows of numbers are the molecular masses of the charged N-terminal and C-terminal fragments, respectively, that are formed by the cleavage indicated by their connecting diagonal line. (b) The mass spectrum of the fragmented peptide with the  $m/z$  values of the most abundant fragments indicated above the corresponding peaks. The energy of the collisions in the collision cell has been adjusted so that each peptide ion fragments an average of only once. Note that the predominant fragments under these conditions have  $z = 1$  and contain the intact peptide's C-terminus. [After Yates, J.R., *Methods Enzymol.* **271**, 354 (1996).]

ducible manner and then separates the resulting peptides to yield a pattern that can be used to distinguish differences between related proteins. Thus, peptide mapping can be carried out by two-dimensional gel electrophoresis or by such high resolution one-dimensional techniques as

HPLC, SDS-PAGE, IEF, or CE (Sections 6-3 and 6-4). With any of these methods, variant peptides can be isolated and sequenced to establish the sequence differences between the related proteins.

**Figure 7-11** Peptide mapping. A comparison of the fingerprints of trypsin-digested (a) hemoglobin A (HbA) and (b) hemoglobin S (HbS) shows two peptides that differ in these two forms of hemoglobin (boxes). These peptides constitute the eight N-terminal residues of the  $\beta$  subunit of hemoglobin. Their amino acid sequences are

## 2 NUCLEIC ACID SEQUENCING

The basic strategy of nucleic acid sequencing is identical to that of protein sequencing (Section 7-1). It involves

1. The specific degradation and fractionation of the polynucleotide of interest to fragments small enough to be fully sequenced.
2. The sequencing of the individual fragments.
3. The ordering of the fragments by repeating the preceding steps using a degradation procedure that yields a set of polynucleotide fragments that overlap the cleavage points in the first such set.

Before about 1975, however, nucleic acid sequencing techniques lagged far behind those of protein sequencing, largely because there were no available endonucleases that were specific for sequences greater than a nucleotide. Rather, RNAs were cleaved into relatively short fragments by partial digestion with enzymes such as **ribonuclease T1** (from *Aspergillus oryzae*), which cleaves RNA after guanine residues, or pancreatic **ribonuclease A**, which does so after pyrimidine residues. Moreover, there is no reliable polynucleotide reaction analogous to the Edman degradation for proteins (Section 7-1A). Consequently, the polynucleotide fragments were sequenced by their partial digestion with either of two exonucleases: **snake venom phosphodiesterase**, which removes residues from the 3' end of polynucleotides (Fig. 7-12), or **spleen phosphodiesterase**, which does so from the 5' end. The resulting oligonucleotide fragments were identified from their chromatographic and electrophoretic mobilities. Sequencing RNA in this manner is a lengthy and painstaking procedure.

The first biologically significant nucleic acid to be sequenced was that of yeast **alanine tRNA** (Section 32-2A). The sequencing of this 76-nucleotide molecule by Robert Holley, a labor of 7 years, was completed in 1965, some 12 years after Frederick Sanger had determined the amino acid sequence of insulin. This was followed, at an accelerating pace, by the sequencing of numerous species of tRNAs and the **5S ribosomal RNAs** (Section 32-3A) from several organisms. The art of RNA sequencing by these techniques reached its zenith in 1976 with the sequencing, by Walter Fiers, of the entire 3569-nucleotide genome of the **bacteriophage MS2**. In contrast, DNA sequencing was in a far more primitive state because of the lack of available DNA endonucleases with any sequence specificity.

After 1975, dramatic progress was made in nucleic acid sequencing technology. Three advances made this possible:

1. The discovery of restriction endonucleases to enable the cleavage of DNA at specific sequences (Section 5-5A).
2. The development of molecular cloning techniques to permit the acquisition of almost any identifiable DNA segment in the amounts required for sequencing (Section 5-5).
3. The development of DNA sequencing techniques.

These procedures are largely responsible for the enormous advances in our understanding of molecular biology that

**Figure 7-12** Sequence determination of an oligonucleotide by partial digestion with snake venom phosphodiesterase. This enzyme sequentially cleaves the nucleotides from the 3' end of a polynucleotide that has a free 3'-OH group. Partial digestion of an oligonucleotide with snake venom phosphodiesterase yields a mixture of fragments of all lengths, as indicated, that may be chromatographically separated. Comparison of the base compositions of pairs of fragments that differ in length by one nucleotide establishes the identity of the 3'-terminal nucleotide of the larger fragment. In this way the base sequence of the oligonucleotide may be elucidated.

have been made over the past three decades and which we discuss in succeeding chapters. DNA sequencing techniques are the subject of this section.

The pace of nucleic acid sequencing has become so rapid that directly determining a protein's amino acid sequence is far more time-consuming than determining the base sequence of its corresponding gene (although amino acid and base sequences provide complementary information; Section 7-2D). There has been such a flood of DNA sequence data—over 300 billion nucleotides in over 200 million sequences as of 2010, and doubling every ~18 months—that only computers can keep track of them. The first complete genome sequence to be determined, that of the gram-negative bacterium *Haemophilus influenzae*, was reported in 1995 by J. Craig Venter. By 2010, the genome sequences of over 1000 prokaryotes had been reported (with many more being determined) as well as sequences of over 120 eukaryotes (with many more in progress), including those of humans and many other vertebrates, insects, worms, plants, and fungi (Table 7-3).

### A. The Sanger Method

 See **Guided Exploration 5: DNA sequence determination by the chain-terminator method** After 1975, several methods were developed for the rapid sequencing of long stretches of DNA. Here we discuss the **Sanger method**, formulated by Frederick Sanger (the same individual who pioneered the amino acid sequencing of proteins), which is mainly responsible for the vast number of DNA sequences that have been elucidated.

The Sanger method (alternatively called the **chain-terminator method** and the **dideoxy method**) utilizes the *E. coli* enzyme DNA polymerase I (Section 5-4Cc) to synthesize complementary copies of the single-stranded DNA

**Table 7-3** Some Sequenced Genomes

Organism	Haploid Genome Size (kb)	Number of Chromosomes
<i>Carsonella ruddii</i> (insect endosymbiont; smallest known cellular genome)	160	1
<i>Mycoplasma genitalium</i> (human parasite)	580	1
<i>Rickettsia prowazekii</i> (bacterium; cause of typhus; putative mitochondrial relative)	1,112	1
<i>Haemophilus influenzae</i> (bacterium; human pathogen)	1,830	1
<i>Archaeoglobus fulgidus</i> (hyperthermophilic, sulfate-reducing archaeon)	2,178	1
<i>Synechocystis</i> sp. (cyanobacterium)	3,573	1
<i>Mycobacterium tuberculosis</i> (cause of tuberculosis)	4,412	1
<i>Escherichia coli</i> (bacterium, human symbiont)	4,639	1
<i>Saccharomyces cerevisiae</i> (baker's or budding yeast)	12,070	16
<i>Plasmodium falciparum</i> (protozoan; cause of malaria)	23,000	14
<i>Caenorhabditis elegans</i> (nematode worm)	97,000	6
<i>Drosophila melanogaster</i> (fruit fly)	180,000	4
<i>Arabidopsis thaliana</i> (flowering plant)	119,200	5
<i>Oryza sativa</i> (rice)	389,000	12
<i>Danio rerio</i> (zebra fish)	1,700,000	25
<i>Gallus gallus</i> (chicken)	1,200,000	40
<i>Ornithorhynchus anatinus</i> (platypus)	1,840,000	31
<i>Mus musculus</i> (mouse)	2,500,000	20
<i>Canis familiaris</i> (dog)	2,400,000	40
<i>Pan troglodytes</i> (chimpanzee)	3,100,000	24
<i>Homo sapiens</i> (human)	3,038,000	23

Source: <http://www.ncbi.nlm.nih.gov/sites/entrez?db=genome>.

being sequenced. As we have previously seen, under the direction of the strand being replicated (the template strand), DNA polymerase I assembles the four deoxynucleoside triphosphates (dNTPs), dATP, dCTP, dGTP, and dTTP, into a complementary polynucleotide chain that it elongates in the 5' to 3' direction (Fig. 5-31). To initiate DNA synthesis, DNA polymerase requires a primer in a stable base paired complex with the template DNA. If the DNA being sequenced is a restriction fragment, as it usually is, it begins and ends with a restriction site. The primer can therefore be a short DNA segment containing this restriction site annealed to the strand being replicated. The template DNAs are obtained in sufficient quantity to sequence by cloning them in M13-based vectors (Section 5-5Bb) or by PCR (Section 5-5F), both of which yield the required single-stranded DNAs.

DNA polymerase I's 5' → 3' exonuclease activity (Fig. 5-33) is catalyzed by a separate active site from those which mediate its polymerase and 3' → 5' exonuclease (Fig. 5-36) functions. This is demonstrated by the observation that on proteolytic cleavage of the enzyme into two fragments, the larger C-terminal fragment, which is known as the **Klenow fragment**, possesses the full polymerase and 3' → 5' exonuclease activities of the intact enzyme, whereas the smaller N-terminal fragment has its 5' → 3' exonuclease activity. Only the Klenow fragment is used in DNA sequencing to ensure that all replicated chains have the same 5' terminus.

#### a. The Synthesis of Labeled DNA by DNA Polymerase Is Terminated after Specific Bases

In the Sanger method (Fig. 7-13), the DNA to be sequenced is incubated with the Klenow fragment of DNA polymerase I, a suitable primer, and the four deoxynucleoside triphosphates (dNTPs). Either at least one dNTP (usually dATP) or the primer is  $\alpha$ - $^{32}$ P-labeled. In addition, a small amount of the 2',3'-dideoxynucleoside triphosphate (ddNTP)

**2',3'-Dideoxynucleoside triphosphate**

of one of the bases is added to the reaction mixture. When the dideoxy analog is incorporated in the growing polynucleotide in place of the corresponding normal nucleotide, chain growth is terminated because of the absence of a 3'-OH group. By using only a small amount of the ddNTP, a series of truncated chains is generated, each of which is terminated by the dideoxy analog at one of the positions occupied by the corresponding base. Each of the four ddNTPs is reacted in a separate vessel.

The four reaction mixtures are simultaneously electrophoresed in parallel lanes on a **sequencing gel**. This is a

**Figure 7-13** Flow diagram of the Sanger (chain-terminator or dideoxy) method of DNA sequencing. The symbol ddATP represents dideoxyadenosine triphosphate, etc. The sequence that is determined by reading the gel from bottom to top (from the smallest to the largest fragment) is complementary to the sequence of the template DNA.

long, thin (as little as 0.1 mm by up to 100 cm) polyacrylamide slab. It contains ~7M urea and is run at ~70°C so as to eliminate all hydrogen bonding associations. These conditions ensure that the DNA fragments separate only according to their size. The sequence of the DNA that is complementary to the template DNA can then be directly read off an autoradiogram of the sequencing gel, from bottom to top, as is indicated in Fig. 7-14. Indeed, computerized devices are available to aid in doing so. However, a single gel is incapable of resolving much more than 300 to 400 consecutive fragments. This limitation is circumvented by generating two sets of gels, one run for a longer time and perhaps at a higher voltage than the other, to obtain the sequence of up to 800-bp DNA fragments.

Improved gels can be obtained through the use of dNTPs whose α-phosphate groups are radioactively labeled with <sup>35</sup>S rather than <sup>32</sup>P.

This is because the β particles emitted by <sup>35</sup>S nuclei have

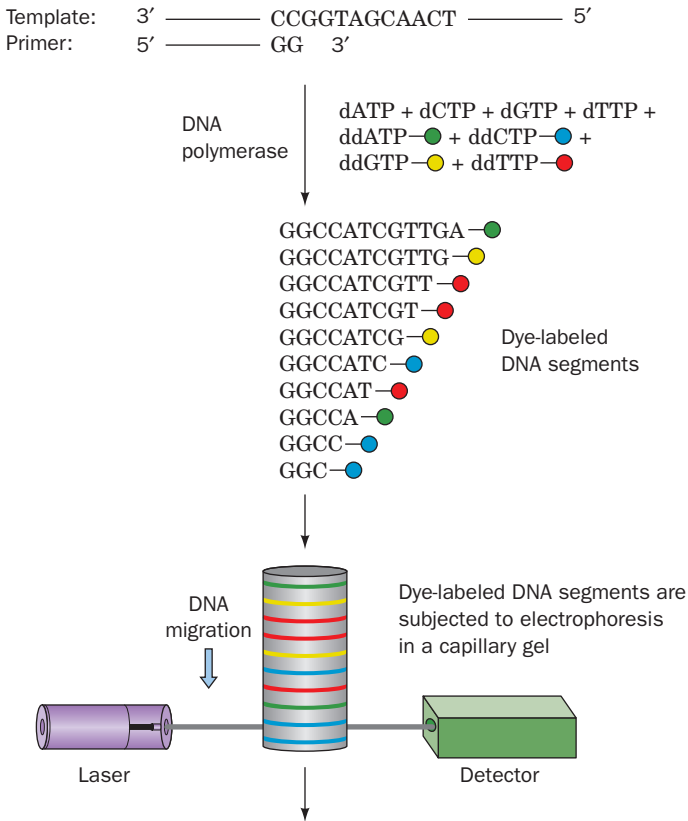

**Figure 7-14** Autoradiograph of a sequencing gel. DNA fragments were produced by the Sanger method of DNA sequencing. A second loading of the gel (right) was made 90 min after the initial loading (left). The deduced sequence of 140 nucleotides is written alongside. [From Hindley, J., DNA sequencing, in Work, T.S. and Burdon, R.H. (Eds.), *Laboratory Techniques in Biochemistry and Molecular Biology*, Vol. 10, p. 82, Elsevier (1983). Used by permission.]

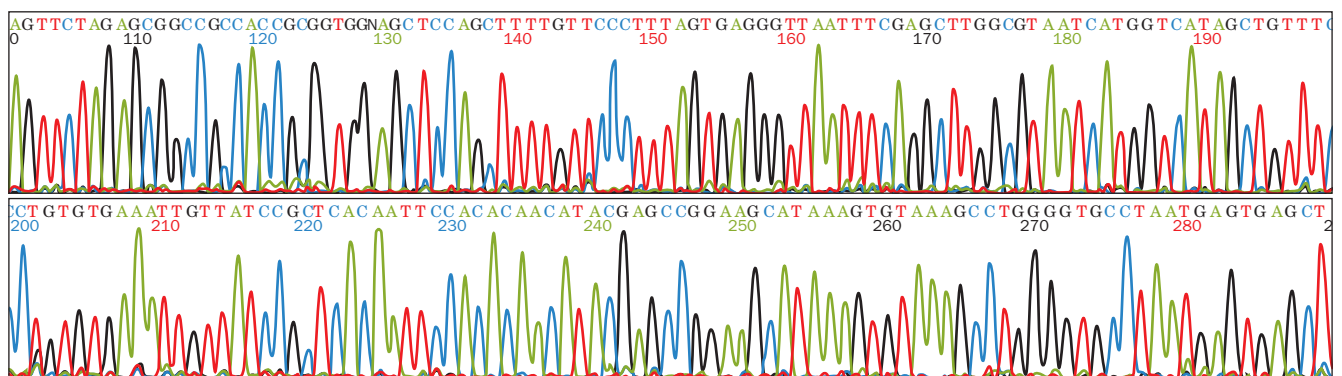

less energy and hence shorter path lengths than those of  $^{32}\text{P}$ , thereby yielding sharper gel bands. More readily interpretable gels may also be obtained by replacement of the Klenow fragment with DNA polymerases either from **bacteriophage T7 (T7 DNA polymerase)**, which is less sensitive

to the presence of ddNTPs than is Klenow fragment and hence yields gel bands of more even intensities) or from thermophilic bacteria such as *Thermus aquaticus* (*Taq* polymerase; Section 5-5F) that are stable above  $90^\circ\text{C}$  and hence can be used at the temperatures required to denature particularly stable segments of DNA.

(a)

(b)

**Figure 7-15 Automated DNA sequencing using the Sanger method.** (a) The primer that is base paired to the template strand being sequenced is extended in the presence of four differently fluorescently labeled dideoxynucleoside triphosphates (ddNTPs). The resulting mixture of dye-labeled DNA strands of all lengths is subject to gel electrophoresis in a capillary tube, thereby separating them according to size with smaller polynucleotides migrating faster than larger ones. As each polynucleotide passes the detector, its 3'-terminal nucleotide is identified according to the spectrum of its laser-stimulated

### b. RNA May Be Sequenced through Its Transcription to cDNA

RNA can be readily sequenced by only a slight modification of the above DNA sequencing procedures. The RNA to be sequenced is transcribed into a complementary strand of DNA (cDNA) through the action of reverse transcriptase (Section 5-5Fa). The resulting cDNA may then be sequenced normally.

### c. The Sanger Method Has Been Automated

In order to sequence large tracts of DNA such as entire chromosomes, the Sanger method has been greatly accelerated through automation. This required that the above-described radiolabeling techniques, which are not readily automated, be replaced by fluorescence labeling techniques (with the added benefit of eliminating the health hazards and storage problems of using radiolabeled nucleotides). In the most widely used such technique, each of the four ddNTPs used to terminate chain extension is covalently linked to a differently fluorescing dye, the chain-extension reactions are carried out in a single vessel containing all four of these labeled ddNTPs, and the resulting fragment mixture is subjected to sequencing gel electrophoresis in a single lane (Fig. 7-15a). As each fragment exits the gel, its terminal base is identified according to its characteristic fluorescence spectrum by a laser-activated fluorescence detection system (Fig. 7-15b).

fluorescence. (b) A portion of the output of an automated DNA sequencing system. Each of the four differently colored curves indicates the fluorescence intensity of a particular dye that is linked to a specific ddNTP in terminating the primer extension reaction (green, blue, black, and red for ddATP, ddCTP, ddGTP, and ddTTP, respectively; the letters above the bands identify the bases and the numbers indicate their positions in the DNA segment being sequenced). [Courtesy of Mark Adams, The Institute for Genomic Research, Gaithersburg, Maryland.]

The fluorescence detectors used in these devices, which have error rates of  $\sim 1\%$ , are computer-controlled and hence data acquisition is automated. In the most advanced such systems, the sequencing gel is contained in an array of up to 96 capillary tubes rather than in a slab-shaped apparatus, sample preparation and loading are performed by robotic systems, and electrophoresis and data analysis are fully automated. Such systems can simultaneously sequence 96 DNA samples averaging  $\sim 650$  bases each with a turn-around time of  $\sim 1$  h and hence can identify up to 1.6 million bases per day—all with only  $\sim 15$  min of human attention (vs the  $\sim 25,000$  bases per year that a skilled operator can identify using the above-described manual methods). Nevertheless, one such system would require  $\sim 10$  years of uninterrupted operation to sequence the 3 billion-bp human genome with only two sets of overlapping fragments. However, to ensure the complete coverage of a large tract of DNA (Section 5-5Ea) and to reduce its error rate to  $<0.01\%$ , at least 10 sets of overlapping segments must be sequenced (Section 7-2B). Hence, the major sequencing centers, where most genome sequencing is carried out, each have over 100 such sequencing systems in factory-like settings.

## B. Genome Sequencing

The major technical challenge in sequencing a genome is not the DNA sequencing itself but, rather, assembling the tens of thousands to tens of millions of sequenced segments (depending on the size of the genome) into contiguous blocks (called **contigs**) and assigning them to their proper positions in the genome. One way that contigs might be ordered is through chromosome walking (Section 5-5Ea). However, to do so for a eukaryotic genome would be prohibitively time-consuming and expensive (e.g., to “walk” the 125 million-bp length of an average length human chromosome using  $\sim 10$ -kb inserts from a plasmid library would require a minimum of  $1.25 \times 10^8 / 10,000 = 12,500$  labor-intensive “steps”).

### a. Map-Based Genome Sequencing

A more efficient technique of genome sequencing, the **map-based sequencing** strategy (Fig. 7-16a), was developed in the late 1980s. In this approach, low resolution physical maps of each chromosome are prepared by identifying shared landmarks on overlapping  $\sim 250$ -kb inserts that are cloned in yeast artificial chromosomes (YACs). These land-

**Figure 7-16** Genome sequencing strategies. (a) The map-based strategy uses three sets of progressively smaller cloned inserts and assembles the sequenced inserts through cosmid walking and the use of landmarks such as STSs and ESTs (see text). (b) The

WGS strategy uses only two levels of cloning and employs sophisticated computer algorithms as well as STCs to assemble the sequenced inserts into finished chromosomes. [After Venter, J.C., Smith, H.O., and Hood, L., *Science* **381**, 365 (1996).]

marks often take the form of 200- to 300-bp segments known as **sequence-tagged sites (STSs)**, whose exact sequence occurs nowhere else in the genome. Hence, two clones that contain the same STS must overlap. The STS-containing inserts are then randomly fragmented (usually by sonication; Section 5-3D) into ~40-kb segments that are subcloned into cosmid vectors so that a high resolution map can be constructed by identifying their landmark overlaps. The cosmid inserts are then randomly fragmented into overlapping 5- to 10-kb or 1-kb segments for insertion into plasmid or M13 vectors (shotgun cloning; Section 5-5E). These inserts (~800 M13 clones per cosmid) are then sequenced (~400 bp per clone) and the resulting so-called **reads** are assembled computationally into contigs to yield the sequence of their parent cosmid insert (with a redundancy of 400 bp per clone  $\times$  800 clones per cosmid/40,000 bp per cosmid = 8). Finally, the cosmid inserts are assembled, through **cosmid walking** (the computational analog of chromosome walking; Fig. 5-51), using their landmark overlaps (with landmarks ideally spaced at intervals of 100 kb or less), to yield the sequences of the YAC inserts which are then assembled, using their STSs, to yield the chromosome's sequence.

The genomes of most complex eukaryotes contain numerous tracts of **repetitive sequences**, that is, segments of DNA that are tandemly repeated hundreds, thousands, and in some cases millions of times (Section 34-2B). Lengthy tracts of repetitive sequences easily confound the foregoing assembly process, leading to gaps in the sequence. Moreover, such repetitive sequences greatly exacerbate the difficulty of finding properly spaced STSs. To partially circumvent the latter difficulty, STS-like sequences of cDNAs, known as **expressed sequence tags (ESTs)**, are used in place of STSs. Since the mRNAs from which cDNAs are reverse transcribed encode proteins, they are unlikely to contain repetitive sequences.

#### b. The Whole Genome Shotgun Assembly Strategy

Although the initial goal of the **human genome project** of identifying STSs and ESTs every ~100 kb in the human genome was achieved, advances in computational and cloning technology permitted a more straightforward sequencing procedure that eliminates the need for both the low resolution (YAC) and high resolution (cosmid) mapping steps. In this so-called **whole genome shotgun assembly (WGSA)** strategy, which was formulated by Venter, Hamilton Smith, and Leroy Hood, a genome is randomly fragmented, a large number of cloned fragments are sequenced, and the genome is assembled by identifying overlaps between pairs of fragments. Statistical considerations indicate that, using this strategy, the probability that a given base is not sequenced is ideally  $e^{-c}$ , where  $c$  is the redundancy of coverage [ $c = LN/G$ , where  $L$  is the average length of the reads in nucleotides (nt),  $N$  is the number of reads, and  $G$  is the length of the genome in nt], the aggregate length of the gaps between contigs is  $Ge^{-c}$ , and the average gap size is  $G/N$ . Moreover, without a long-range physical and/or genetic map of the genome being sequenced, the order of the contigs and their relative orientations would be unknown.

For bacterial genomes, the WGSA strategy is carried out straightforwardly by sequencing tens of thousands of fragments and assembling them (a task that required the development of computer algorithms capable of assembling contigs from very large numbers of reads). Then, in a task known as **finishing**, the gaps between contigs are filled in by several techniques including synthesizing PCR primers complementary to the ends of the contigs and using them to isolate the missing segments (chromosome walking; bacterial genomes have few if any repetitive sequences).

For eukaryotic genomes, their much greater sizes require that the WGSA strategy be carried out in stages as follows (Fig. 7-16b). A bacterial artificial chromosome (BAC) library of ~150-kb inserts is generated (for the human genome, an ~15-fold redundancy, which would still leave ~900 bases unsequenced, would require ~300,000 such clones; BACs are used because they are subject to fewer technical difficulties than are YACs). The insert in each of these BAC clones is identified by sequencing ~500 bp in from each end to yield segments known as **sequence-tagged connectors (STCs or BAC-ends)**; which for the above 300,000 clones would collectively comprise ~300,000 kb, that is, 10% of the entire human genome). One BAC insert is then fragmented and shotgun cloned into plasmid or M13 vectors (so as to yield ~3000 overlapping clones), and the fragments are sequenced and assembled into contigs. The sequence of this "seed" BAC is then compared with the database of STCs to identify the ~30 overlapping BAC clones. The two with minimal overlap at either end are then selected, sequenced, and the operation repeated until the entire chromosome is sequenced (BAC walking), which for the human genome required 27 million sequencing reads. This process is also confounded by repetitive sequences.

The WGSA strategy is readily automated through robotics and hence is faster and less expensive than the map-based strategy. Indeed, most known genome sequences have been determined using the WGSA strategy, many in a matter of a few months, and its advent reduced the time to sequence the human genome by several years. Nevertheless, it appears that for eukaryotic genomes, most of the residual errors in a WGSA-based genome sequence [mainly the failure to recognize long (>15 kb) segments that have nearly (>97%) identical sequences] can be eliminated by finishing it through the use of some of the techniques of the map-based strategy.

#### c. The Human Genome Has Been Sequenced

The "rough draft" of the human genome was reported in 2001 by two independent groups: the publicly funded International Human Genome Sequencing Consortium (IHGSC; a collaboration involving 20 sequencing centers in six countries), led by Francis Collins, Eric Lander, and John Sulston, which used the map-based strategy; and a privately funded group, mainly from Celera Genomics, led by Venter, which used the WGSA strategy. The IHGSC-determined genome sequence was a conglomerate from numerous anonymous individuals, whereas that from Celera Genomics

was derived from five individuals but mainly from Venter. These draft sequences lacked ~10% of the gene-rich chromosomal regions known as **euchromatin** (Section 34-1) and much of the largely if not entirely unexpressed chromosomal regions known as **constitutive heterochromatin** (Section 34-1; which consists of highly repetitive sequences that are mainly associated with the chromosomal centromeres; Section 34-3A). Moreover, both draft assemblies had sequencing error rates of ~1% and contained ~160,000 gaps so that the order and orientations of many contigs within local regions had not been established. But even this imperfect data greatly accelerated the pace of genetic research such that, for example, the genes for hundreds of inherited diseases were identified and cloned far more rapidly than had previously been possible.

In 2004, the IHGSC reported the finished sequence of the human genome. It covered ~99% of the euchromatic genome (2.851 billion nt of the entire 3.038-billion nt genome) with an error rate of <0.001% and had only 281 gaps, all of which were in regions of repetitive sequence. In 2007, Venter reported the finished sequence of his own **diploid genome** (that of all 46 chromosomes; previously reported genome sequences were those of **haploid genomes**, that is, of one member of each homologous chromosomal pair). These stunning achievements, the culmination of over a decade of intense effort by hundreds of scientists, is revolutionizing the way both biochemistry and medicine are viewed and practiced. A few of the major observations that have been made are as follows:

1. About 45% of the human genome consists of repeating sequences of various lengths.
2. Only ~28% of the genome is transcribed to RNA.
3. Only 1.2% of the genome (~4% of the transcribed RNA) encodes protein.
4. The human genome appears to contain only ~23,000 protein-encoding genes [also known as **open reading frames (ORFs)**] rather than the 50,000 to 140,000 ORFs that had previously been predicted based mainly on extrapolations (and the ~30,000 ORFs predicted from the rough draft). This compares with the ~6600 ORFs in yeast, ~14,000 in *Drosophila*, ~19,000 in *C. elegans*, and ~25,500 in *Arabidopsis*. Note that these numbers will almost certainly change as our presently imperfect ability to recognize ORFs improves.
5. Only a small fraction of human protein families is unique to vertebrates; most occur in other if not all life-forms.
6. Two randomly selected human genomes differ, on average, by only 1 nucleotide per 1000; that is, any two people are likely to be ~99.9% genetically identical.

The obviously greater complexity of humans (vertebrates) relative to “lower” (nonvertebrate) forms of life is unlikely to be due to the not much larger numbers of ORFs that vertebrates encode. Rather, it appears that vertebrate proteins themselves are more complex than those of nonver-

tebrates; that is, vertebrate proteins tend to have more domains (modules) than invertebrate proteins and these modules are more often selectively expressed through alternative gene splicing (Section 5-4Ac). Thus, many vertebrate genes encode several different although similar proteins. Moreover, mounting evidence indicates that vertebrate genomes encode large numbers of short RNA segments that participate in controlling gene expression (Section 31-4At).

The genomes of eukaryotes, including that of *Homo sapiens*, can be explored at <http://www.ncbi.nlm.nih.gov/projects/mapview/>.

### C. Next Generation DNA Sequencing Technologies

One of the goals of the human genome project is to sequence an individual’s genome at an affordable price (US\$1000 is the figure that is often quoted). This would permit the comparison of many thousands of human genome sequences and hence the correlation of specific sequences with susceptibility to particular diseases. This, in turn, would usher in an age of personalized medicine when the treatment of active disease and the prevention of anticipated disease would be tailored to an individual’s genetic makeup.

Like most aspects of science, genome sequencing is technology-driven. Thus the IHGSC-determined sequence cost ~US\$300 million and took over a decade to complete. In contrast, using “next generation” sequencing technology (see below), the diploid genome of James Watson (of Watson–Crick fame) was sequenced in 2 months at a cost of <US\$1 million—the third human genome to be sequenced. As even newer technologies are developed, the price and time to sequence a human genome is expected to drop even more precipitously.

All of the several available next generation sequencing technologies eliminate the time-consuming cloning steps used by the Sanger sequencing-based methods (Fig. 7-16). They do so by amplifying single isolated molecules of DNA and then sequencing them in a massively parallel way.

#### a. The 454 Sequencing System

The Watson genome was sequenced using a system developed by 454 Life Sciences that employs the following methodology (Fig. 7-17). The genomic DNA is randomly sheared to small (300–500 bp) fragments and ligated to adaptors, which in turn are specifically bound by ~30- $\mu$ m-in-diameter “DNA capture” beads under dilution conditions such that, at most, one DNA fragment is bound to each bead. The beads are suspended in a PCR mixture containing dNTPs, primers complementary to the adaptors, and *Taq* DNA polymerase. The suspension is emulsified with oil such that each aqueous droplet contains only one bead, that is, each bead is contained in its own microreactor, thus preventing the introduction of competing or contaminating sequences. The PCR (Section 5-5F) is carried out by thermocycling until ~10 million identical DNA fragments are bound to each DNA capture bead. The emulsion is broken by the addition of isopropanol, the DNA is denatured, and the resulting single-stranded DNA-

**Figure 7-17** Sample preparation for the 454 sequencing system. (a) Genomic DNA is isolated, fragmented, linked to adaptors, and denatured to yield single strands. (b) The single strands are bound to DNA capture beads under dilution conditions in which, at most, one single strand binds per bead, the beads are captured in a PCR-reaction-mixture-in-oil emulsion, and PCR amplification of the DNA occurs within each

bead-containing droplet. (c) The emulsion is broken by the addition of isopropanol, the now double-stranded DNA is denatured, and the resulting beads carrying single-stranded DNA clones are deposited in the wells of a fiber-optic slide. (d) Smaller beads linked to the enzymes ATP sulfurylase and luciferase are deposited into each well. [Courtesy of Jonathan Rothberg, 454 Life Sciences Corporation, Branford, Connecticut.]

bearing beads are deposited into 75-picoliter wells (1 picoliter =  $10^{-12}$  L) on a fiber-optic slide with one bead per well. The slide contains  $\sim 1.6$  million wells.

The DNA on each of the beads is sequenced using a series of coupled enzymatic reactions that are collectively known as **pyrosequencing** (Fig. 7-18):

**1.** A solution containing only one of the four dNTPs is flowed over the bead-containing slide. If that dNTP is complementary to the first unpaired base on a template strand, DNA polymerase catalyzes its addition to the primer strand and releases pyrophosphate ion (Fig. 5-31).

**2.** In a reaction catalyzed by the enzyme **ATP sulfurylase**, the pyrophosphate ion reacts with **adenosine-5'-phosphosulfate** to yield ATP.

**3.** In a reaction catalyzed by the firefly enzyme **luciferase**, the ATP reacts with **luciferin** and  $O_2$  to yield **oxyluciferin** and a flash of visible light (a phenomenon named **chemiluminescence**). The well from which the light flash emanated together with its intensity is recorded by an imaging system, thus identifying those wells in which the foregoing nucleotide was added to the primer strand. The intensity of the light is proportional to the number of nucleotides reacted so that when two or more consecutive nucleotides of the same type are added to the primer strand, their number is determined.

**4.** In preparation for the next reaction cycle, any unreacted dNTPs and ATP are hydrolyzed to mononucleotides (NMPs) and phosphate ion by a wash containing the enzyme **apyrase**.

**Figure 7-18** The reactions of pyrosequencing.

This series of reactions is automatically iterated by sequentially using all four dNTPs and then repeating the entire process. In this way, the sequence of ~400,000 DNA fragments (reads) can be simultaneously determined to a length of >400 nt, each with an accuracy of ~99%, in one 4-h run (and hence the 454 system is over 300-fold faster than state-of-the-art Sanger-based sequencing systems).

The 106 million reads of the Watson genome were assembled by mapping them to the IHGSC-determined human genome sequence (using programs similar to those described in Section 7-4Bg), thus bypassing the computationally difficult process of assembling the genome based on overlaps as well as eliminating the need for finishing. In fact, the relatively short read lengths of the 454 system (maximally ~400 nt vs ~800 nt for Sanger sequencing) makes it difficult to shotgun assemble a eukaryotic genome *de novo* (anew) so that Sanger sequencing is still useful. However, the ~4 million reads of the Watson genome with no or poor alignment to the IHGSC sequence were placed according to their overlaps [which identified 3.3 million single-base differences, which are known as **single nucleotide polymorphisms (SNPs)**; pronounced “snips”), relative to the IHGSC sequence and the gain or loss of numerous chromosomal segments ranging in length up to 1.5 million bp].

The read lengths of the 454 system are sufficient to assemble bacterial genomes *de novo*, although a 15-fold redundancy is necessary to do so accurately versus a 6- to 8-fold redundancy for Sanger sequencing. Nevertheless, with the use of a 454 system, the sequence of a typical bacterial genome can be determined in less than a week at a cost of several thousand U.S. dollars.

#### b. Other DNA Sequencing Technologies

Several other next generation DNA sequencing platforms, each using a different although massively parallel sequencing technology, are available. For example, the SOLiD system from Applied Biosystems can simultaneously sequence ~180 million DNA fragments with read lengths of up to 50 nt each for a total of up to ~9 billion nt in a single run, whereas the Genome Analyzer from Illumina (originally Solexa) can simultaneously sequence ~50 million DNA fragments with read lengths of up to 50 nt each for a total of up to 2.5 billion nt in a single run. The short read of both these systems makes them unsuitable for use in *de novo* genome sequencing. Nevertheless, by mid-2010, several hundred human genome sequences had been determined using the Illumina system and identifying the sequence changes in its reads relative to previously determined human genome sequences (a process called **resequencing**). Moreover, there are many applications for which systems generating short reads are well suited, such as selectively resequencing portions of the genomes of numerous individuals in order to discover disease-related SNPs, identifying the genetic changes in cancerous tumors, and screening for mutations among related populations of bacteria.

The so-called third generation sequencing technologies that are now on the horizon promise even faster and less

expensive DNA sequencing. These directly sequence single DNA molecules rather than first amplifying them by cloning or PCR as do all presently available sequencing technologies. For example, a system under development by Pacific Biosciences permanently attaches a single molecule of DNA polymerase to the bottom of a cylindrical well that is only ~50 nm in diameter. The DNA polymerase molecule synthesizes the complementary strand of the template strand that is being sequenced using dNTPs whose  $\gamma$ -phosphate groups are covalently linked to a fluorescent dye, with a differently fluorescing dye for each of the four bases. The volume of the wells is so small ( $2 \times 10^{-20}$  L) that freely diffusing dye-linked dNTP molecules in solution rarely enter a well and then for only a few microseconds before diffusing away. In contrast, a DNA polymerase that is incorporating a dNTP into a growing DNA chain holds it for tens of milliseconds before releasing the now dye-linked pyrophosphate ion into the solution and commencing another round of synthesis. During this time the laser-excited fluorescent dNTP emits light that is detected by a sophisticated optical system that only observes the light emanating from the bottom of the well, thus identifying the dNTP that is being incorporated. This system has been shown to produce reads of tens of thousands of nucleotides in each of thousands of wells. Even farther in the future are systems that pass single molecules of DNA through tiny holes (nanopores) and identify their bases by measuring the subtle electrical changes as each base passes through the nanopore.

#### D. Nucleic Acid Sequencing versus Amino Acid Sequencing

The amino acid sequences of proteins are specified by the base sequences of nucleic acids (Section 5-4Bb). Consequently, with a knowledge of the genetic code (Table 5-3) and the nature of transcriptional and translational initiation sequences (Sections 31-3 and 32-3C), a protein's primary structure can be inferred from that of a corresponding nucleic acid. Techniques for sequencing nucleic acids initially lagged far behind those for proteins, but by the late 1970s, DNA sequencing methods had advanced to the point that it became far easier to sequence a DNA segment than the protein it specified. Although the great majority of known protein primary structures have been inferred from DNA sequences, direct protein sequencing remains an important biochemical tool for several reasons:

1. Disulfide bonds can be located only by protein sequencing.
2. Many proteins are modified after their biosynthesis by the excision of certain residues and by the specific derivatization of others (Section 32-5). The identities of these modifications, which are often essential for the protein's biological function, can be determined only by directly sequencing the protein.
3. One of the most effective ways of identifying the gene that encodes a protein of interest is to determine the

amino acid sequence of at least a portion of the protein, infer the base sequence of the DNA segment that encodes this polypeptide segment, chemically synthesize this DNA, and use it to identify and isolate the gene(s) containing its base sequence through Southern blotting or PCR (Sections 5-5D and 5-5F). This process is known as **reverse genetics** because, in prokaryotes, genetics has been traditionally used to characterize proteins rather than vice versa. Of course, for organisms whose genomes have been sequenced, this process can be carried out *in silico* (by computer).

4. The “standard” genetic code is not universal: Those of mitochondria and certain protozoa are slightly different (Section 32-1Db). In addition, in certain species of protozoa, the RNA transcripts are “edited”; that is, their sequences are altered before they are translated (Sections 31-4Ar and 31-4As). These genetic code anomalies were discovered by comparing the amino acid sequences of proteins and the base sequences of their corresponding genes. If there are other genetic code anomalies, they will no doubt be discovered in a like manner.

### 3 CHEMICAL EVOLUTION

Individuals, as well as whole species, are characterized by their genomes. An organism’s genome specifies the amino acid sequences of all members of its **proteome** (all of the proteins encoded by its genome) together with their quantity and schedule of appearance in each cell. An organism’s proteomic composition is therefore the direct consequence of its genomic composition.

In this section, we concentrate on the evolutionary aspects of amino acid sequences, the study of the **chemical evolution** of proteins. Evolutionary changes, which stem from random mutational events, often alter a protein’s primary structure. A mutational change in a protein, if it is to be propagated, must somehow increase, or at least not decrease, the probability that its owner will survive to reproduce. Many mutations are deleterious and often lethal in their effects and therefore rapidly die out. On rare occasions, however, a mutation arises that, as we shall see below, improves the fitness of its host in its natural environment.

#### A. Sickle-Cell Anemia: The Influence of Natural Selection

**Hemoglobin**, the red blood pigment, is a protein whose major function is to transport oxygen throughout the body. A molecule of hemoglobin is an  $\alpha_2\beta_2$  tetramer; that is, it consists of two identical  $\alpha$  chains and two identical  $\beta$  chains (Fig. 7-1d). Hemoglobin is contained in the **erythrocytes** (red blood cells; Greek: *erythros*, red + *kytos*, a hollow vessel) of which it forms ~33% by weight in normal individuals, a concentration that is nearly the same as it has in the crystalline state. In every cycle of their voyage through the circulatory system, the erythrocytes, which are normally

(a)

(b)

**Figure 7-19 Scanning electron micrographs of human erythrocytes.** (a) Normal human erythrocytes revealing their biconcave disklike shape. [David M. Phillips/Visuals Unlimited.] (b) Sickled erythrocytes from an individual with sickle-cell anemia. [Bill Longcore/Photo Researchers, Inc.]

flexible biconcave disks (Fig. 7-19a), must squeeze through capillary blood vessels smaller in diameter than they are.

In individuals with the inherited disease **sickle-cell anemia**, many erythrocytes assume an irregular crescentlike shape under conditions of low oxygen concentration typical of the capillaries (Fig. 7-19b). This “sickling” increases the erythrocytes’ rigidity, which hinders their free passage through the capillaries. The sickled cells therefore impede the flow of blood in the capillaries such that, in a sickle-cell “crisis,” the blood flow in some areas may be completely blocked, thereby giving rise to extensive tissue damage and excruciating pain. Moreover, individuals with sickle-cell anemia suffer from severe **hemolytic anemia** (a condition characterized by red cell destruction) because the increased mechanical fragility of their erythrocytes halves the normal 120-day lifetime of these cells. The debilitating effects of this disease are such that, before the latter half of the twentieth century, individuals with sickle-cell anemia rarely survived to maturity (although modern treatments by no means constitute a cure).

#### a. Sickle-Cell Anemia Is a Molecular Disease

In 1945, Linus Pauling correctly hypothesized that *sickle-cell anemia*, which he termed a **molecular disease**, is a result of the presence of a mutant hemoglobin. Pauling and

his co-workers subsequently demonstrated, through electrophoretic studies, that normal human hemoglobin (**HbA**) has an anionic charge that is around two units more negative than that of sickle-cell hemoglobin (**HbS**; Fig. 7-20).

In 1956, Vernon Ingram developed the technique of fingerprinting peptides (Section 7-1J) in order to pinpoint the difference between HbA and HbS. Ingram’s fingerprints of tryptic digests of HbA and HbS revealed that their α subunits are identical but that their β subunits differ by a variation in one tryptic peptide (Fig. 7-11). Sequencing studies eventually indicated that this difference arises from the replacement of the Glu β6 of HbA (the Glu in the sixth position of each β chain) with Val in HbS (Glu β6 → Val), thus accounting for the charge difference observed by Pauling. This was the first time an inherited disease was shown to arise from a specific amino acid change in a protein. *This*

mutation causes deoxygenated HbS to aggregate into filaments of sufficient size and stiffness to deform erythrocytes—a remarkable example of the influence of primary structure on quaternary structure. The structure of these filaments is further discussed in Section 10-3B.

**b. The Sickle-Cell Trait Confers Resistance to Malaria**

Sickle-cell anemia is inherited according to the laws of Mendelian genetics (Section 1-4B). The hemoglobin of individuals who are homozygous for sickle-cell anemia is almost entirely HbS. In contrast, individuals heterozygous for sickle-cell anemia have hemoglobin that is ~40% HbS

(Fig. 7-20). Such persons, who are said to have the **sickle-cell trait**, lead a normal life even though their erythrocytes have a shorter lifetime than those of normal individuals.

The sickle-cell trait and disease occur mainly in persons of equatorial African descent. The regions of equatorial Africa where **malaria** is a major cause of death (contributing to childhood mortality rates as high as 50%), as Fig. 7-21 indicates, coincide closely with those areas where the sickle-cell gene is prevalent (possessed by as much as 40% of the population in some places). This observation led Anthony Allison to the discovery that *individuals heterozygous for HbS are resistant to malaria, that is, they are less likely to die of a malarial infection.*

**Figure 7-21** A map indicating the regions of the world where malaria caused by *P. falciparum* was prevalent before 1930, together with the distribution of the sickle-cell gene.

Malaria is one of the most lethal infectious diseases that presently afflict humanity: Of the 2.5 billion people living within malaria-endemic areas, 100 million are clinically ill with the disease at any given time and at least 1 million, mostly very young children, die from it each year. In Africa, malaria is caused by the mosquito-borne protozoan *Plasmodium falciparum*, which resides within an erythrocyte during much of its 48-h life cycle. Plasmodia increase the acidity of the erythrocytes they infect by  $\sim 0.4$  pH units and cause them to adhere to a specific protein lining capillary walls by protein knobs that develop on the erythrocyte surfaces (the spleen would otherwise remove the infected erythrocytes from the circulation, thereby killing the parasites). Death often results when so many erythrocytes are lodged in a vital organ (such as the brain in cerebral malaria) that its blood flow is significantly impeded.

How does the sickle-cell trait confer malarial resistance? Normally,  $\sim 2\%$  of the erythrocytes of individuals with the sickle-cell trait are observed to sickle under the low oxygen concentration conditions found in the capillaries. However, the lowered pH of infected erythrocytes increases their proportion of sickling in the capillaries to  $\sim 40\%$ . Thus, during the early stages of a malarial infection, parasite-enhanced sickling probably causes the preferential removal of infected erythrocytes from the circulation. In the later stages of infection, when the parasitized erythrocytes are attached to the capillary walls, the sickling induced by this low oxygen environment may mechanically and/or metabolically disrupt the parasite. Consequently, bearers of the sickle-cell trait in a malarial region have an adaptive advantage: The fractional population of heterozygotes (sickle-cell trait carriers) in such areas increases until their reproductive advantage becomes balanced by the inviability of the correspondingly increasing proportion of homozygotes (those with sickle-cell disease). Thus *sickle-cell anemia provides a classic Darwinian*

*example of a single mutation's adaptive consequences in the ongoing biological competition among organisms for the same resources.*

## B. Species Variations in Homologous Proteins: The Effects of Neutral Drift

The primary structures of a given protein from related species closely resemble one another. If one assumes, according to evolutionary theory, that related species have evolved from a common ancestor, then it follows that each of their proteins must have likewise evolved from the corresponding protein in that ancestor.

*A protein that is well adapted to its function, that is, one that is not subject to significant physiological improvement, nevertheless continues evolving.* The random nature of mutational processes will, in time, change such a protein in ways that do not significantly affect its function, a process called **neutral drift** (deleterious mutations are, of course, rapidly rejected through natural selection). *Comparisons of the primary structures of homologous proteins (evolutionarily related proteins) therefore indicate which of the proteins' residues are essential to its function, which are of lesser significance, and which have little specific function.* If, for example, we find the same side chain at a particular position in the amino acid sequence of a series of related proteins, we can reasonably conclude that the chemical and/or structural properties of that so-called **invariant residue** uniquely suit it to some essential function of the protein. Other amino acid positions may have less stringent side chain requirements so that only residues with similar characteristics (e.g., those with acidic properties: Asp and Glu) are required; such positions are said to be **conservatively substituted**. On the other hand, many different amino acid residues may be tolerated at a particular amino acid position, which indicates that the functional requirements of that position are rather nonspecific. Such a position is called **hypervariable**.

### a. Cytochrome c Is a Well-Adapted Protein

To illustrate these points, let us consider the primary structure of a nearly universal eukaryotic protein, **cytochrome c**. Cytochrome c has a single polypeptide chain that, in vertebrates, consists of 103 or 104 residues, but in other phyla has up to 8 additional residues at its N-terminus. It occurs in the mitochondrion as part of the **electron-transport chain**, a complex metabolic system that functions in the terminal oxidation of nutrients to produce adenosine triphosphate (ATP) (Section 22-2). The role of cytochrome c is to transfer electrons from a large enzyme complex known as **cytochrome c reductase** to one called **cytochrome c oxidase**.

It appears that the electron-transport chain took its present form between 1.5 and 2 billion years ago as organisms evolved the ability to respire (Section 1-5Cb). Since that time, the components of this multienzyme system have changed very little, as is evidenced by the observation that the cytochrome c from any eukaryotic organism, say a

pigeon, will react *in vitro* with the cytochrome oxidase from any other eukaryote, for instance, wheat. Indeed, hybrid cytochromes *c* consisting of covalently linked fragments from such distantly related species as horse and yeast (prepared via techniques of genetic engineering) exhibit biological activity.

### b. Protein Sequence Comparisons Yield Taxonomic Insights

Emanuel Margoliash, Emil Smith, and others elucidated the amino acid sequences of the cytochromes *c* from over 100 widely diverse eukaryotic species ranging in complexity from yeast to humans. The sequences from 38 of these organisms are arranged in Table 7-4 (page 186) so as to maximize the similarities between vertically aligned residues (methods of sequence alignment are discussed in Section 7-4B). The various residues in the table have been colored according to their physical properties in order to illuminate the conservative character of the amino acid substitutions. Inspection of Table 7-4 indicates that cytochrome *c* is an evolutionarily conservative protein. A total of 38 of its 105 residues (23 in all that have been sequenced) are invariant and most of the remaining residues are conservatively substituted (see the bottom row of Table 7-4). In contrast, there are 8 positions that each accommodate six or more different residues and, accordingly, are described as being hypervariable.

The clear biochemical role of certain residues makes it easy to surmise why they are invariant. For instance, His 18 and Met 80 form ligands to the redox-active Fe atom of cytochrome *c*; the substitution of any other residues in these positions inactivates the protein. However, the biochemical significance of most of the invariant and conservatively substituted residues of cytochrome *c* can only be profitably assessed in terms of the protein's three-dimensional structure and is therefore deferred until Section 9-6A. In what follows, we consider what insights can be gleaned solely from the comparisons of the amino acid sequences of related proteins. The conclusions we draw are surprisingly far reaching.

The easiest way to compare the evolutionary differences between two homologous proteins is simply to count the amino acid differences between them (more realistically, we should infer the minimum number of DNA base changes to convert one protein to the other but, because of the infrequency with which mutations are accepted, counting amino acid differences yields similar information). Table 7-5 is a tabulation of the amino acid sequence differences among 22 of the cytochromes *c* listed in Table 7-4. It has been boxed off to emphasize the relationships among groups of similar species. The order of these differences largely parallels that expected from classical taxonomy. Thus primate cytochromes *c* more nearly resemble those of other mammals than they do, for example, those of insects (8–12 differences for mammals vs 26–31 for insects). Similarly, the cytochromes *c* of fungi differ as much from those of mammals (45–51 differences) as they do from those of insects (41–47) or higher plants (47–54).

<sup>a</sup>Each table entry indicates the number of amino acid differences between the cytochromes *c* of the species noted to the left of and below that entry.

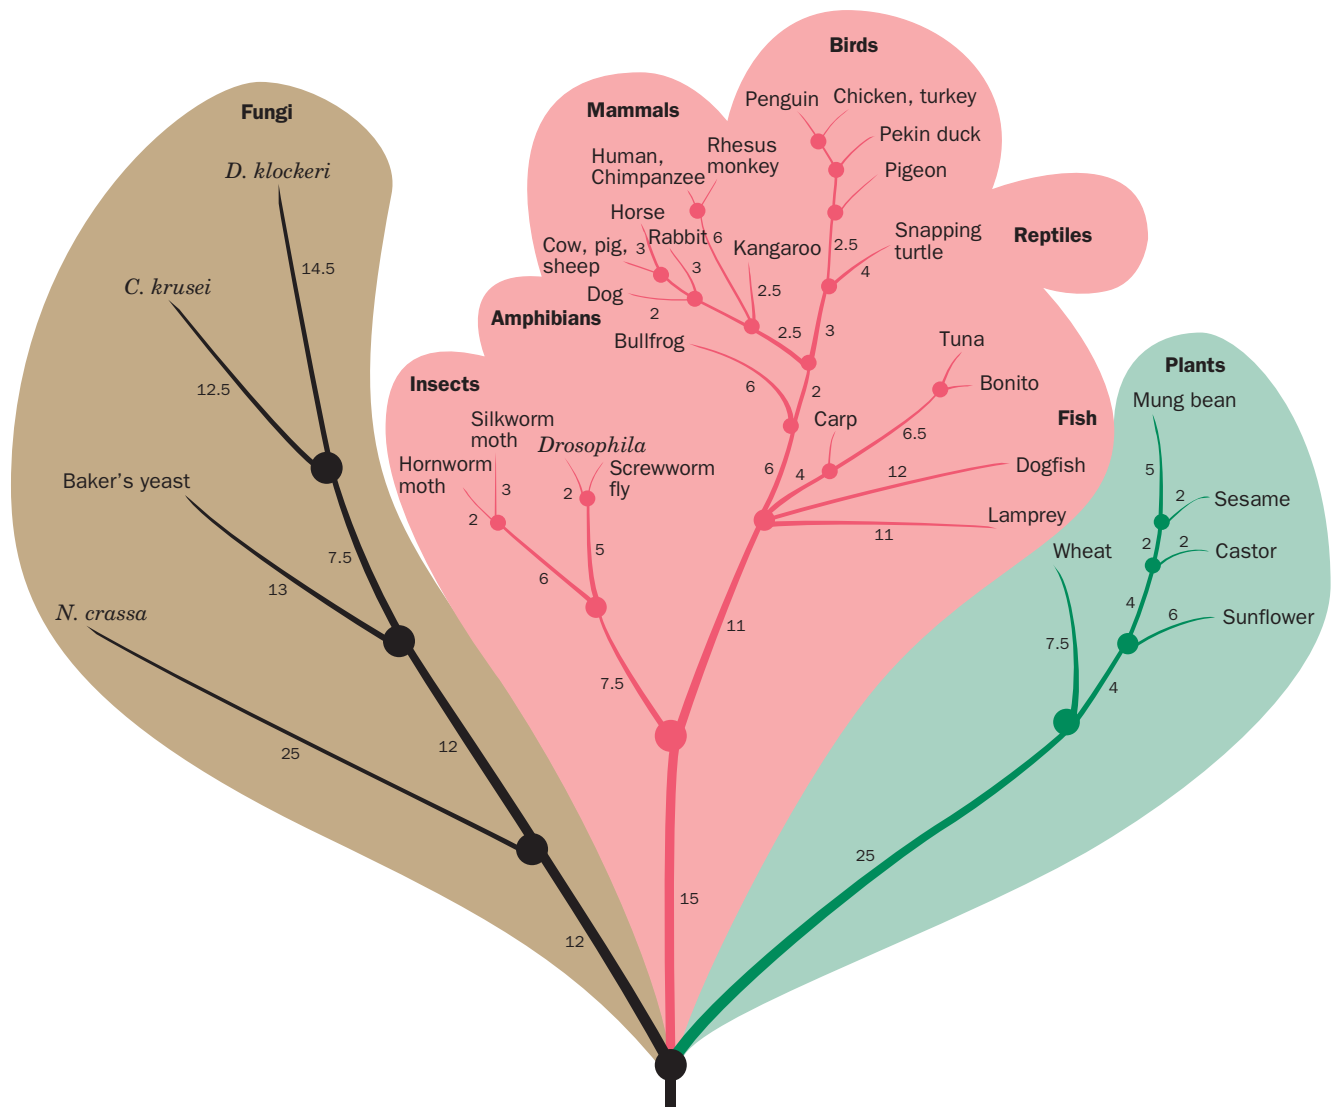

[Table copyrighted © by Irving Geis.]

Through the analysis of data such as those in Table 7-5, a phylogenetic tree (Section 1-1B) can be constructed that indicates the ancestral relationships among the organisms which produced the proteins (the methods used to construct phylogenetic trees are discussed in Section 7-4C). That for cytochrome *c* is sketched in Fig. 7-22. Similar trees have been derived for other proteins. Each branch point of a tree indicates the probable existence of a common ancestor for all the organisms above it. The relative evolutionary distances between neighboring branch points are expressed as the number of amino acid differences per 100 residues of the protein (percentage of accepted point mutations, or **PAM units**). This furnishes a quantitative measure of the degree of relatedness of the various species that macroscopic taxonomy cannot provide. Note that the evolutionary distances of modern cytochromes *c* from the lowest branch point on their tree are all approximately equal. Evidently, the cytochromes *c* of the so-called lower forms of life have evolved to the same extent as those of the higher forms.

### c. Proteins Evolve at Characteristic Rates

The evolutionary distances between various species can be plotted against the time when, according to radiodated fossil records, the species diverged. For cytochrome

**Figure 7-22** Phylogenetic tree of cytochrome *c*. The tree was generated by the computer-aided analysis of difference data such as that in Table 7-5 (Section 7-4C). Each branch point indicates the existence of an organism deduced to be ancestral to the species connected above it. The numbers beside each branch

indicate the inferred differences, in PAM units, between the cytochromes *c* of its flanking branch points or species. [After Dayhoff, M.O., Park, C.M., and McLaughlin, P.J., in Dayhoff, M.O. (Ed.), *Atlas of Protein Sequence and Structure*, p. 8, National Biomedical Research Foundation (1972).]

*c*, this plot is essentially linear, thereby indicating that cytochrome *c* has accumulated mutations at a constant rate over the geological time scale (Fig. 7-23). This is also true for the other three proteins whose rates of evolution are plotted in Fig. 7-23. Each has its characteristic rate of change, known as a **unit evolutionary period**, which is defined as the time required for the amino acid sequence of a protein to change by 1% after two species have diverged. For cytochrome *c*, the unit evolutionary period is 20.0 million years. Compare this with the much less variant **histone H4** (600 million years) and the more variant hemoglobin (5.8 million years) and **fibrinopeptides** (1.1 million years).

The foregoing information does not imply that the rates of mutation of the DNAs specifying these proteins differ,

but rather that *the rate that mutations are accepted into a protein depends on the extent that amino acid changes affect its function*. Cytochrome *c*, for example, is a rather small protein that, in carrying out its biological function, must interact with large protein complexes over much of its surface area. Any mutational change to cytochrome *c* will, most likely, affect these interactions unless, of course, the complexes simultaneously mutate to accommodate the change, a very unlikely occurrence. This accounts for the evolutionary stability of cytochrome *c*. Histone H4 is a protein that binds to DNA in eukaryotic chromosomes (Section 34-1A). Its central role in packaging the genetic archives evidently makes it extremely intolerant of any mutational changes. Indeed, histone H4 is so well adapted to its function that the histones H4 from peas and cows,

**Figure 7-23 Rates of evolution of four unrelated proteins.** The graph was constructed by plotting the average differences, in PAM units, of the amino acid sequences on two sides of a branch point of a phylogenetic tree (corrected to allow for more than one mutation at a given site) versus the time, according to the fossil record, since the corresponding species diverged from their

common ancestor. The error bars indicate the experimental scatter of the sequence data. Each protein's rate of evolution, which is inversely proportional to the slope of its line, is indicated beside the line as its unit evolutionary period. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

species that diverged  $\sim 1.2$  billion years ago, differ by only two conservative changes in their 102 amino acids. Hemoglobin, like cytochrome *c*, is an intricate molecular machine (Section 10-2). It functions as a free floating molecule, however, so that its surface groups are usually more tolerant of change than are those of cytochrome *c* (although not in the case of HbS; Section 10-3B). This accounts for hemoglobin's greater rate of evolution. The fibrinopeptides are polypeptides of  $\sim 20$  residues that are proteolytically cleaved from the vertebrate protein **fibrinogen** when it is

converted to **fibrin** in the blood clotting process (Section 35-1A). Once they have been excised, the fibrinopeptides are discarded, so there is relatively little selective pressure on them to maintain their amino acid sequence and thus their rate of variation is high. If it is assumed that the fibrinopeptides are evolving at random, then the foregoing unit evolutionary periods indicate that in hemoglobin only  $1.1/5.8 = 1/5$  of the random amino acid changes are acceptable, that is, innocuous, whereas this quantity is  $1/18$  for cytochrome *c* and  $1/550$  for histone H4.

**d. Mutational Rates Are Constant in Time**

Amino acid substitutions in a protein mostly result from single base changes in the gene specifying the protein (Section 5-4B). If such **point mutations** mainly occur as a consequence of errors in the DNA replication process, then the rate at which a given protein accumulates mutations would be constant with respect to numbers of cell generations. If, however, the mutational process results from the random chemical degradation of DNA, then the mutation rate would be constant with absolute time. To choose between these alternative hypotheses, let us compare the rate of cytochrome *c* divergence in insects with that in mammals.

Insects have shorter generation times than mammals. Therefore, if DNA replication were the major source of mutational error, then from the time the insect and mammalian lines diverged, insects would have evolved further from plants than have mammals. However, a simple phylogenetic tree (Fig. 7-24) indicates that the average number of amino acid differences between the cytochromes *c* of insects and plants (45.2) is essentially the same as that between mammals and plants (45.0). We must therefore conclude that cytochrome *c* accumulates mutations at a uniform rate with respect to time rather than number of cell generations. This, in turn, implies that *point mutations in DNA accumulate at a constant rate with time, that is, through random chemical change, rather than resulting mainly from errors in the replication process.*

**e. Sequence Comparisons Indicate when the Major Kingdoms of Life Diverged**

Estimates of when two species diverged, that is, when they last had a common ancestor, are based largely on the radiodated fossil record. However, the macrofossil record only extends back ~600 million years (after multicellular organisms arose) and phylogenetic comparisons of microfossils (fossils of single-celled organisms) based on their morphology are unreliable. Thus, previous estimates of when the major groupings of organisms (animals, plants, fungi, protozoa, eubacteria, and archaea; Figs. 1-4 and 1-11) diverged from one another (e.g., the right side of Fig. 7-23) are only approximations based mainly on considerations of shared characteristics.

The burgeoning databases of amino acid sequences (Section 7-4A) permitted Russell Doolittle to compare the sequences of a large variety of enzymes that each have homologous representatives in many of the above major groupings (531 sequences in 57 different enzymes). This analysis is consistent with the existence of a **molecular clock** that can provide reliable estimates of when these groupings diverged. This molecular clock, which is based on the supposition that homologous sequences diverge at a uniform rate, was calibrated using sequences from vertebrates for which there is a reasonably reliable fossil record. This analysis indicates that animals, plants, and fungi last had a common ancestor ~1 billion years ago, with plants having diverged from animals slightly before fungi; that the major protozoan lineages separated from those of other eukarya ~1.2 billion years ago; that eukarya last shared a

**Figure 7-24** Phylogenetic tree for cytochrome *c*. The tree shows the average number of amino acid differences between cytochromes *c* from mammals, insects, and plants. Mammals and insects have diverged equally far from plants since their common branch point. [Adapted from Dickerson, R.E. and Timkovich, R., in Boyer, P.D. (Ed.), *The Enzymes* (3rd ed.), Vol. 11, p. 447, Academic Press (1975).]

common ancestor with archaea ~1.8 billion years ago and with bacteria slightly more than 2 billion years ago; and that gram-positive and gram-negative bacteria diverged ~1.4 billion years ago.

**f. Protein Evolution May Not Be the Basis of Organismal Evolution**

Despite the close agreement between phylogenetic trees derived from sequence similarities and classic taxonomic analyses, it appears that protein sequence evolution is not the only or even the most important basis of organismal evolution. The genome sequences of humans and our closest relative, the chimpanzee, are nearly 99% identical with their corresponding proteins having, on average, only two amino acid differences and with ~29% of these proteins identical (including cytochrome *c*). This is the level of homology observed among sibling species of fruit flies and mammals. Yet the anatomical and behavioral differences between human and chimpanzee are so great that these species have been classified in separate families. *This suggests that the rapid divergence of human and chimpanzee stems from relatively few mutational changes in the segments of DNA that control gene expression, that is, how much of each protein will be made, where, and when.* Such mutations do not necessarily change protein sequences but can result in major organismal alterations.

**C. Evolution through Gene Duplication**

Most proteins have extensive sequence similarities with other proteins from the same organism. Such proteins arose through **gene duplication**, a result of an aberrant genetic recombination event in which a single chromosome acquired both copies of the primordial gene in question (the mechanism of genetic recombination is discussed in

Section 30-6A). *Gene duplication is a particularly efficient mode of evolution because one of the duplicated genes can evolve a new functionality through natural selection while its counterpart continues to direct the synthesis of the presumably essential ancestral protein.*

The **globin** family of proteins, which includes hemoglobin and **myoglobin**, provides an excellent example of evolution through gene duplication. Hemoglobin transports oxygen from the lungs (or gills or skin) to the tissues. Myoglobin, which occurs in muscles, facilitates rapid oxygen diffusion through these tissues and also functions as an oxygen storage protein. *The sequences of hemoglobin's  $\alpha$  and  $\beta$  subunits (recall that hemoglobin is an  $\alpha_2\beta_2$  tetramer) and myoglobin (a monomer) are quite similar.*

The globin family's phylogenetic tree indicates that its members, in humans, arose through the following chain of events (Fig. 7-25):

1. The primordial globin probably functioned simply as an oxygen-storage protein. Indeed, the globins in certain modern invertebrates still have this function. For example, treating a *Planorbis* snail with CO (the binding of which prevents globins from binding O<sub>2</sub>; Section 10-1A) does not affect its behavior in well-aerated water, but if the oxygen concentration is reduced, a poisoned *Planorbis* becomes even more sluggish than a normal one.

2. Duplication of a primordial globin gene, ~1.1 billion years ago, permitted the resulting two genes to evolve sep-

**Figure 7-25** Phylogenetic tree of the globin family. The circled branch points represent gene duplications and unmarked branch points are species divergences. [After Dickerson, R.E. and Geis, I., *Hemoglobin*, p. 82, Benjamin/Cummings (1983).]

arately so that, largely by a series of point mutations, a monomeric hemoglobin arose that had the lower oxygen-binding affinity required for it to transfer oxygen to the developing myoglobin. Such a monomeric hemoglobin can still be found in the blood of the **lamprey**, a primitive vertebrate that, according to the fossil record, has maintained its eel-like morphology for over 425 million years.

3. Hemoglobin's tetrameric character is a structural feature that greatly increases its ability to transport oxygen efficiently (Section 10-2C). This provided the adaptive advantage that gave rise to the evolution of the  $\beta$  chain from a duplicated  $\alpha$  chain.

4. In fetal mammals, oxygen is obtained from the maternal circulation. **Fetal hemoglobin**, an  $\alpha_2\gamma_2$  tetramer in which the  **$\gamma$  chain** is a gene-duplicated  $\beta$  chain variant, evolved to have an oxygen-binding affinity between that of normal adult hemoglobin and myoglobin.

5. Human embryos, in their first 8 weeks post conception, make a  $\zeta_2\varepsilon_2$  hemoglobin in which the  **$\zeta$**  and  **$\varepsilon$  chains** are, respectively, gene-duplicated  $\alpha$  and  $\beta$  variants.

6. In primates, the  $\beta$  chain has undergone a relatively recent duplication to form a  **$\delta$  chain**. The  $\alpha_2\delta_2$  hemoglobin, which occurs as a minor hemoglobin component in normal adults (~1%), has no known unique function. Perhaps it may eventually evolve one (although the human genome contains the relics of globin genes that are no longer expressed; Section 34-2Fa).

Homologous proteins in the same organism and the genes that encode them are said to be **paralogous** (Greek: *para*, alongside), whereas homologous proteins/genes in different organisms that arose through species divergence (e.g., the various cytochromes *c*) are said to be **orthologous** (Greek: *ortho*, straight). Hence, the  $\alpha$ - and  $\beta$ -globins and myoglobin are paralogs, whereas the  $\alpha$ -globins from different species are orthologs.

Our discussion of the globin family indicates that protein evolution through gene duplication leads to proteins of similar structural and functional properties. Another well-documented example of this phenomenon has resulted in the formation of a family of endopeptidases, which include trypsin, chymotrypsin, and elastase. These paralogous digestive enzymes, which are all secreted by the pancreas into the small intestine, are quite similar in their properties, differing mainly in their side chain specificities (Table 7-2). We examine how these functional variations are structurally rationalized in Section 15-3B. Individually, these three enzymes are limited in their abilities to degrade a protein, but in concert, they form a potent digestive system.

As we have stated previously and will explore in detail in Section 9-1, the *three-dimensional structure of a protein, and hence its function, is dictated by its amino acid sequence*. Most proteins that have been sequenced are more or less similar to several other known proteins. In fact, *many proteins are mosaics of sequence motifs that occur in a variety of other proteins*. It therefore seems likely that most of the myriads of proteins in any given

organism have arisen through gene duplications. This suggests that the appearance of a protein with a novel sequence and function is an extremely rare event in biology—one that may not have occurred since early in the history of life.

## 4 BIOINFORMATICS: AN INTRODUCTION

 **See Guided Exploration 6: Bioinformatics** The enormous profusion of sequence and structural data that have been generated over the last decades has led to the creation of a new field of inquiry, **bioinformatics**, which is loosely defined as being at the intersection of biotechnology and computer science. It is the computational tools that the practitioners of bioinformatics have produced that have permitted the “mining” of this treasure trove of biological data, thereby yielding surprisingly far-reaching biomolecular insights.

As we have seen in the previous section, the alignment of the sequences of homologous proteins yields valuable clues as to which of the proteins' residues are essential for function and is indicative of the evolutionary relationships among these proteins. Since proteins are encoded by nucleic acids, the alignment of homologous DNA or RNA sequences provides similar information. Moreover, DNA sequence alignment is an essential task for assembling chromosomal sequences (contigs) from large numbers of sequenced segments (Section 7-2B).

If the sequences of two proteins or nucleic acids are closely similar, one can usually line them up by eye. In fact, this is the way that the cytochrome *c* sequences in Table 7-4 were aligned. But how can one correctly align sequences that are so distantly related that their sequence similarities are no longer readily apparent? In this section we discuss the computational techniques through which this is done, preceded by a short introduction to publicly accessible sequence databases. In doing so, we shall concentrate on techniques of peptide alignment. We end with a short discussion of how phylogenetic trees are generated. Those aspects of bioinformatics concerned with the analysis of structures are postponed until Chapters 9 and 10.

### A. Sequence Databases

Since it became possible to elucidate protein and nucleic acid sequences, they have been determined at an ever-increasing rate. Although, at first, these sequences were printed in research journals, their enormous numbers and lengths (particularly for genome sequences) now make it impractical to do so. Moreover, it is far more useful to have sequences in computer-accessible form. Hence, researchers now directly deposit sequences, via the Web, into various publicly accessible databases, many of which share data on a daily basis. The Web addresses [uniform resource locators (URLs)] for the major protein and DNA sequence databases are listed in Table 7-6. The URLs for a variety of specialized sequence databases (e.g., those of specific organisms or organelles) can be found at the Life Science

Directory (<http://www.expasy.ch/links.html>). That website also contains links to numerous other biochemically useful databases as well as a great variety of computer tools for biomolecular analyses, bibliographic references, tutorials, and many other websites of biomedical interest. (Note that websites evolve far faster than organisms: Even well-established websites change addresses or even disappear with little warning and useful new websites appear on an almost daily basis.)

As an example of a sequence database, let us describe (in cursory detail) the annotated protein sequence database named Swiss-Prot. A sequence record in Swiss-Prot begins with the proteins' ID code of the form X\_Y where X is an up-to-four-character mnemonic indicating the protein's name (e.g., CYC for cytochrome *c* and HBA for hemoglobin  $\alpha$  chain) and Y is an up-to-five-character identification code indicating the protein's biological source that usually consists of the first three letters of the genus and the first two letters of the species [e.g., CANFA for *Canis familiaris* (dog)]. However, for the most commonly encountered organisms, Y is instead a self-explanatory code (e.g., BOVIN or ECOLI). This is followed by an accession number such as P04567, which is assigned by the database to ensure a stable way of identifying an entry from release to release, even if it becomes necessary to change its ID code. The entry continues with the date the entry was entered into Swiss-Prot and when it was last modified and annotated, a list of pertinent references (which are linked to MedLine), a description of the protein, and its links to other databases. A Feature Table describes regions or sites of interest in the protein such as disulfide bonds, post-translational modifications, elements of local secondary structure, binding sites, and conflicts between different

references. The entry ends with the length of the peptide in residues, its molecular weight, and finally its sequence using the one-letter code (Table 4-1). Other sequence databases are similarly constructed.

## B. Sequence Alignment

One can quantitate the sequence similarity of two polypeptides or two DNAs by determining their number of aligned residues that are identical. For example, human and dog cytochromes *c*, which differ in 11 of their 104 residues (Table 7-5) are  $[(104 - 11)/104] \times 100 = 89\%$  identical, whereas human and baker's yeast cytochromes *c* are  $[(104 - 45)/104] \times 100 = 57\%$  identical. Table 7-4 indicates that baker's yeast cytochrome *c* has 5 residues at its N-terminus that human cytochrome *c* lacks but lacks the human protein's C-terminal residue. When determining percent identity, the length of the shorter peptide/DNA is, by convention, used in the denominator. One can likewise calculate the percent similarity between two peptides, once it is decided which amino acid residues are to be considered similar (e.g., Asp and Glu).

### a. The Homology of Distantly Related Proteins May Be Difficult to Recognize

Let us examine how proteins evolve by considering a simple model. Assume that we have a 100-residue protein in which all point mutations have an equal probability of being accepted and occur at a constant rate. Thus at an evolutionary distance of one PAM unit (Section 7-3Bb), the original and evolved proteins are 99% identical. At an evolutionary distance of two PAM units, they are  $(0.99)^2 \times 100 = 98\%$  identical, whereas at 50 PAM units they are  $(0.99)^{50} \times 100 = 61\%$  identical. Note that the latter quantity is not 50%, as one might naively expect. This is because *mutation is a stochastic (probabilistic or random) process: At every stage of evolution, each residue has an equal chance of mutating.* Hence some residues may change twice or more before others change even once. Consequently, a plot of percent identity versus evolutionary distance (Fig. 7-26a) is an exponential curve that approaches but never equals zero. Even at quite large evolutionary distances, original and evolved proteins still have significant sequence identities.

Real proteins evolve in a more complex manner than our simple model predicts. This is in part because certain amino acid residues are more likely to form accepted mutations than others and in part because the distribution of amino acids in proteins is not uniform (e.g., 9.7% of the residues in proteins, on average, are Leu but only 1.1% are Trp; Table 4-1). Consequently real proteins evolve even more slowly than in our simple model (Fig. 7-26b).

At what point in the evolutionary process does homology become unrecognizable? If identical length polypeptides of random sequences were of uniform amino acid composition, that is, if they consisted of 5% of each of the 20 amino acids, then they would exhibit, on average, 5% identity. However, since mutations occur at random, there is considerable variation in such numbers. Thus, statistical

**Figure 7-26** Rate of sequence change in evolving proteins. (a) For a protein that is evolving at random and that initially consists of 5% of each of the 20 “standard” amino acid residues. (b) For a protein of average amino acid composition evolving as is observed in nature, that is, with certain residue changes more likely to be accepted than others and with occasional insertions and deletions. [Part b after Doolittle, R.F., *Methods Enzymol.* **183**, 103 (1990).]

considerations reveal that there is a 95% probability that such 100-residue peptides are between 0 and 10% identical. But, as we have seen for cytochrome *c*, homologous peptides may have different lengths because one may have more or fewer residues at its N- or C-termini. If we therefore permit our random 100-residue peptides to shift in their alignment by up to 5 residues, the average expected identity for the best alignment increases to 8%, with 95% of such comparisons falling between 4% and 12%. Consequently, one in 20 of such comparisons will be out of this range (>12% or <4%) and one in 40 will exhibit >12% sequence identity.

But this is not the whole story because mutational events may result in the insertion or deletion of one or more residues within a chain. Thus, one chain may have gaps relative to another. Yet, if we permit an unlimited number of gaps, we can always get a perfect match between any two chains. For example, two 15-residue peptides that have only one match (using the one-letter code; Table 4-1)

```
SQMC I L F K A Q M N Y G H
M F Y A C R L P M G A H Y W L
```

would have a perfect match over their aligned portions if we allowed unlimited gapping:

```
S Q M C I L F K A Q M N Y G H
-- M --- F ----- Y -- A C R L P M G A H Y W L
```

Thus we cannot allow unlimited gapping to maximize a match between two peptides, but neither can we forbid all gapping because insertions and deletions (collectively called **indels**) really do occur. Consequently, for each allowed gap, we must impose some sort of penalty in our alignment algorithm that strikes a balance between finding the best alignment between distantly related peptides and rejecting improper alignments. But if we do so (using methods discussed below), *unrelated proteins will exhibit sequence identities in the range 15% to 25%. Yet distantly related proteins may have similar levels of sequence identity.* This is the origin of the **twilight zone** in Fig. 7-26b. It requires the sophisticated alignment algorithms we discuss below to differentiate homologous proteins in the twilight zone from those that are unrelated.

#### b. Sequence Alignment Using Dot Matrices

How does one perform a sequence alignment between two polypeptides (a **pairwise alignment**)? The simplest way is to construct a **dot matrix** (alternatively, a **dot plot** or **diagonal plot**): Lay the sequence of one polypeptide horizontally and that of the other vertically and place a dot in the resulting matrix wherever the residues are identical. A dot plot of a peptide against itself results in a square matrix with a row of dots along the diagonal and a scattering of dots at points where there are chance identities. If the peptides are closely similar, there are only a few absences along the diagonal (e.g., Fig. 7-27a), whereas distantly related peptides have a large number of absences along the diagonal and a shift in its position wherever one peptide has a gap relative to the other (e.g., Fig. 7-27b).

Once an alignment has been established, it should be scored in some way to determine if it has any relationship to reality. A simple but effective way to calculate an **alignment score (AS)** is to add 10 for every identity but those of Cys, which count 20 (because Cys residues often have indispensable functions), and then subtract 25 for every gap. Furthermore, we can calculate the **normalized alignment score (NAS)** by dividing the AS by the number of residues in the shortest of the two polypeptides and multiplying by 100. Thus, for the alignment of the human hemoglobin  $\alpha$  chain (141 residues) and human myoglobin (153 residues; Fig. 7-28),  $AS = 37 \times 10 + 1 \times 20 - 1 \times 25 = 365$  and  $NAS = (365/141) \times 100 = 259$ . Statistical analysis (Fig. 7-29) indicates that this NAS is indicative of homology. Note that a perfect match would result in  $NAS = 1000$  in the absence of Cys residues or gaps. An acceptable NAS decreases with peptide length because a high proportion of matches is more likely to occur between short peptides than between long ones (e.g., 2 matches in 10 residues is more likely to occur at random than 20 matches in 100 residues, although both have  $NAS = 200$ ).

**Figure 7-27** Sequence alignment with dot matrices. Dot plots show alignments of (a) human cytochrome *c* (104 residues) vs tuna fish cytochrome *c* (103 residues) and (b) human cytochrome *c* vs *Rhodospirillum rubrum* cytochrome *c*<sub>2</sub> (a bacterial *c*-type cytochrome consisting of 112 residues). The N-termini of these peptides are at the top and left of the diagrams. The two proteins in Part *a* have 82 identities, whereas those in Part *b* have 40

identities. The diagonal in Part *b* is more clearly seen if the diagram is viewed edgewise from its lower right corner. Note that there are two horizontal displacements of this diagonal, one near its center and other toward the C-terminus. This is indicative of inserts in the *Rhodospirillum* protein relative to the human protein. [After Gibbs, A.J. and McIntyre, G.A., *Eur. J. Biochem.* **16**, 2 (1970).]

**c. Alignments Should Be Weighted According to the Likelihood of Residue Substitutions**

The foregoing techniques can easily (although tediously) be carried out by hand, particularly when there is an obvious alignment. But what if we have numerous polypeptides with which we want to align a new sequence (and, typically, one checks newly determined sequences against all other known sequences). Moreover, alignments in the twilight zone are difficult to discern. We must therefore turn to computerized statistical analyses so as to be

able to distinguish distant evolutionary relationships from chance similarities with maximum sensitivity.

A dot matrix can be cast in a more easily mathematized form by replacing each dot (match) with a 1 and each non-match with a 0. Then a self-dot matrix would become a square diagonal matrix (having all 1's along its diagonal) with a few off-diagonal 1's, and two closely related peptides would have several diagonal positions with 0's. But this is a particularly rigid system: It does not differentiate between conservative substitutions and those that are likely to be

hypervariable. Yet it is clear that certain substitutions are more readily accepted than others. What are these favored substitutions, how can we obtain a quantitative measure of them, and how can we use this information to increase the confidence with which we can align distantly related peptides?

One way we might assign a weight (a quantity that increases with the probability of occurrence) to a residue change is according to the genetic code (Table 5-3). Thus residue changes that require only a single base change [e.g., Leu (CUX)  $\rightarrow$  Pro (CCX)] are likely to occur more often and hence would be assigned a greater weight than a residue change that requires two base changes [e.g., Leu (CUX)  $\rightarrow$  Thr (ACX)], which likewise would be assigned a greater weight than a residue change that requires three base changes [e.g., His (CA $_C^U$ )  $\rightarrow$  Trp (UGG)]. Of course, no change (the most probable event) would be assigned the greatest weight of all. However, such a scheme only weights the probability of a mutation occurring, not that of a mutation being accepted, which depends on its Darwinian fitness. In fact, over half of the possible single-base residue changes are between physically dissimilar residues, which are therefore less likely to be accepted.

A more realistic weighting scheme would be to assign some sort of relative probability to two residues being exchanged according to their physical similarity. Thus it would seem that a Lys  $\rightarrow$  Arg mutation is more likely to be accepted than, say, a Lys  $\rightarrow$  Phe mutation. However, it is by no means obvious how to formulate such a weighting scheme based on theoretical considerations because it is unclear how to evaluate the various different sorts of prop-

erties that suit the different residues to the many functions they have in a large variety of proteins.

#### d. PAM Substitution Matrices Are Based on Observed Rates of Protein Evolution

An experimentally based method of determining the rates of acceptance of the various residue exchanges is to weight them according to the frequencies with which they are observed to occur. Margaret Dayhoff did so by comparing the sequences of a number of closely related proteins (>85% identical; similar enough so that we can be confident that their alignments are correct and that there are insignificant numbers of multiple residue changes at a single site) and determining the relative frequency of the  $20 \times 19/2 = 190$  different possible residue changes (we divide by two to account for the fact that changes in either direction, A  $\rightarrow$  B or B  $\rightarrow$  A, are equally likely). From these data one can prepare a symmetric square matrix, 20 elements on a side, whose elements,  $M_{ij}$ , indicate the probability that, in a related sequence, amino acid  $i$  will replace amino acid  $j$  after some specified evolutionary interval—usually one PAM unit. Using this **PAM-1** matrix, one can generate a mutation probability matrix for other evolutionary distances, say  $N$  PAM units, by multiplying the matrix by itself  $N$  times ( $[M]^N$ ), thereby generating a PAM- $N$  matrix. Then an element of the **relatedness odds matrix**,  $R$ , is

$$R_{ij} - M_{ij}/f_i = q_{ij}/f_j \quad [7.3]$$

where  $M_{ij}$  is now an element of the PAM- $N$  matrix,  $f_i$  is the probability that the amino acid  $i$  will occur in the second sequence by chance, and  $q_{ij}$  is the observed frequency with which residues of types  $i$  and  $j$  replace each other in a set of aligned polypeptides. Thus,  $R_{ij}$  is the probability that amino acid  $i$  will replace amino acid  $j$  (or vice versa) per occurrence of  $i$  per occurrence of  $j$ . When two polypeptides are compared with each other, residue by residue, the  $R_{ij}$ 's for each position are multiplied to obtain the **relatedness odds** for the entire polypeptide. For example, when the hexapeptide A-B-C-D-E-F evolves to the hexapeptide P-Q-R-S-T-U,

$$\text{Relatedness odds} = R_{AP} \times R_{BQ} \times R_{CR} \times R_{DS} \times R_{ET} \times R_{FU} \quad [7.4]$$

A more convenient way of making this calculation is to take the logarithm of each  $R_{ij}$ , thereby yielding the **log odds substitution matrix**. Then we add the resulting matrix elements rather than multiplying them to obtain the **log odds**. Thus for our hexapeptide pair:

$$\log \text{odds} = \log R_{AP} + \log R_{BQ} + \log R_{CR} + \log R_{DS} + \log R_{ET} + \log R_{FU} \quad [7.5]$$

*It is a peptide pair's log odds that we wish to maximize in obtaining their best alignment, that is, we will use log odds values as our alignment scores.*

Table 7-7 is the **PAM-250** log odds substitution matrix with all of its elements multiplied by 10 for readability (which only adds a scale factor). Each diagonal element in

the matrix indicates the mutability of the corresponding amino acid, whereas the off-diagonal elements indicate their exchange probabilities. A neutral (random) score is 0, whereas an amino acid pair with a score of -3 exchanges with only  $10^{-3/10} = 0.50$  of the frequency expected at random. This substitution matrix has been arranged such that the amino acid residues most likely to replace each other in related proteins (the pairs that have the highest  $\log R_{ij}$  values) are grouped together. Note that this grouping is more or less what is expected from their physical properties.

Identities (no replacement) tend to have the highest values in Table 7-7. Trp and Cys (diagonal values 17 and 12) are the residues least likely to be replaced, whereas Ser, Ala, and Asn (all 2) are the most readily mutated. The residue pair least likely to exchange is Cys and Trp (-8), whereas the pair most likely to exchange is Tyr and Phe (7), although these latter residues are among the least likely to exchange with other residues (mostly negative entries). Similarly, charged and polar residues are unlikely to exchange with nonpolar residues (entries nearly always negative).

The confidence that one can align sequences known to be distantly related has been investigated as a function of PAM values ( $N$ ). The PAM-250 log odds substitution matrix tends to yield the best alignments, that is, the highest alignment scores relative to those derived using substitution matrices based on larger or smaller PAM values. Note that Fig. 7-26b indicates that at 250 PAMs, 80% of the residues in the original polypeptide have been replaced.

#### e. Sequence Alignment Using the Needleman–Wunsch Algorithm

The use of a log odds substitution matrix to find an alignment is straightforward (although tedious). When comparing two sequences, rather than just making a matrix

with 1's at all matching positions, one enters the appropriate value in the log odds substitution matrix at every position. Such a matrix represents all possible pair combinations of the two sequences. In Fig. 7-30a, we use the PAM-250 log odds matrix with a 10-residue peptide horizontal and an 11-residue peptide vertical. Thus, the alignment of these two peptides must have at least one gap or overhang, assuming a significant alignment can be found at all.

An algorithm for finding the best alignment between two polypeptides (that with the highest log odds value) was formulated by Saul Needleman and Christian Wunsch. One starts at the lower right corner (C-termini) of the matrix, position ( $M$ ,  $N$ ) (where in Fig. 7-30a,  $M = 11$  and  $N = 10$ ), and adds its value (here 2) to the value at position ( $M - 1$ ,  $N - 1$ ) [here 12, so that the value at position ( $M - 1$ ,  $N - 1$ ), that is, (10, 9), becomes 14 in the transformed matrix]. Continuing this process in an iterative manner, add to the value of the element at position ( $i$ ,  $j$ ) the maximum value of the elements ( $p$ ,  $j + 1$ ), where  $p = i + 1, i + 2, \dots, M$ , and those of ( $i + 1$ ,  $q$ ), where  $q = j + 1, j + 2, \dots, N$ . Figure 7-30b shows this process at an intermediate stage with the original value of the (6, 5) position in a small box and the transformed values of the positions ( $p$ , 6), where  $p = 7, 8, \dots, 11$ , together with positions ( $7$ ,  $q$ ), where  $q = 6, 7, \dots, 10$ , in the L-shaped box. The maximum value of the matrix elements in this L-shaped box is 19 and hence this is the value to add to the value (0) at position (6, 5) to yield the value 19 in the transformed matrix. This process is iterated, from the lower right toward the upper left of the matrix, until all its elements have been so treated, yielding the fully transformed matrix shown in Fig. 7-30c. The **Needleman–Wunsch algorithm** thereby yields the log odds values for all possible alignments of the two sequences.

The best alignment (that with the highest log odds value) is found by tracing the ridgeline of the transformed matrix (Fig. 7-30c) from its maximum value at or near the upper left (N-terminus) to that at or near the lower right (C-terminus). This is because the alignment of a particular residue pair is independent of the alignment of any other residue pair, and hence the best score up to any point in an alignment is the best score through the previous step plus the incremental score of the new step. This additive scoring scheme is based on the assumption that mutations at different sites are independently accepted, which appears to be an adequate characterization of protein evolution even though specific interactions between residues are known to have critical structural and functional roles in proteins.

The line connecting the aligned residue pairs (those circled in Fig. 7-29c) must always extend down and to the right. This is because a move up or to the left, or even straight down or straight to the right, would imply that a residue in one peptide aligned with more than one residue in the other peptide. Any allowed deviation from a move of (+1, +1) implies the presence of a gap. The best alignment of the two polypeptides, that connected by the lines in Fig. 7-30c, is indicated in Fig. 7-30d. Note that this alignment is ambiguous; the alignment of S in the 10-mer with either T

does so even if it has no biological significance). However, since many proteins are modularly constructed from sequence motifs that occur in a variety of other proteins, a better approach would be to optimize the local alignment of two peptides, that is, maximize the alignment score only over their homologous regions. A variant of the Needleman–Wunsch algorithm, formulated by Temple Smith and Michael Waterman, was widely used to do so. This

**Smith–Waterman algorithm** exploits the property of the substitution matrix-based scoring system that the cumulative score for an alignment path decreases in regions in which the sequences are poorly matched. Where the cumulative score drops to zero, the Smith–Waterman algorithm terminates the extension of an alignment path. Two peptides may have several such local alignments.

#### f. Gap Penalties

If there are gaps in the alignment, one should now subtract the gap penalty from the overall alignment score to obtain the final alignment score. Since a single mutational event can insert or delete more than one residue, a long gap should be penalized only slightly more than a short gap. Consequently, gap penalties have the form  $a + bk$ , where  $a$  is the penalty for opening the gap,  $k$  is the length of the gap in residues, and  $b$  is the penalty for extending the gap by one residue. Current statistical theory provides little guidance for optimizing  $a$  and  $b$ , but empirical studies suggest that  $a = -8$  and  $b = -2$  are appropriate values for use with the PAM-250 matrix. Thus the final alignment score for both alignments in Fig. 7-29d (which have both a 1-residue gap and a 2-residue gap) is  $41 - (8 + 2 \times 1) - (8 + 2 \times 2) = 19$ .

#### g. Pairwise Alignments Using BLAST

The Needleman–Wunsch algorithm and later the Smith–Waterman algorithm (in their computerized forms) were widely used in the 1970s and 1980s to find relationships between proteins. However, the need to compare every newly determined sequence with the huge and rapidly growing number of sequences in publicly available databases requires that this process be greatly accelerated. Modern computers can do so using sequence alignment programs that employ sophisticated **heuristic algorithms** (algorithms that make educated “guesses”) but at the risk of obtaining suboptimal results (in the case of sequence alignments, the heuristic algorithms are based on knowledge of how sequences evolve). Consequently, in what follows, we shall describe how these programs are used rather than how they work.

The PAM-250 substitution matrix is based on an extrapolation: Its calculation assumes that the rate of mutation over one PAM unit of evolutionary distance is the same as that over 250 PAM units. This may not be the case. After all, homologous proteins that are separated by large evolutionary distances may diverge in their function and hence their rates of evolution may change (recall that different proteins have different rates of evolution; Fig. 7-23). To account for this possibility, and because of the huge amount of sequence data that had become available since the PAM matrices were calculated in the mid-1970s, a log odds substitution matrix based on  $\sim 2000$  blocks of aligned sequences that lacked gaps taken from  $\sim 500$  groups of related proteins was calculated. The substitution matrix that gives the most sensitive performance for ungapped alignments is called **BLOSUM62** [blosum (pronounced “blossom”) for *block substitution matrix*; the 62 indicates that all blocks of aligned polypeptides in which there is  $\geq 62\%$  identity are weighted as a single sequence in order to reduce con-

tributions from closely related sequences], whereas **BLOSUM45** appears to perform better for alignments with gaps. Sequence alignments based on the BLOSUM62 or BLOSUM45 matrices are more sensitive than are those based on the PAM-250 matrix.

**BLAST** (for *basic local alignment search tool*) is the most widely used, publicly available software package for making pairwise sequence alignments—both for polypeptides and for polynucleotides. This program uses a heuristic approach that approximates the Smith–Waterman algorithm so as to obtain the optimum mix of sensitivity (the ability to identify distantly related sequences) and selectivity (the avoidance of unrelated sequences with spuriously high alignment scores). It pairwise aligns up to a user-selected number of subject sequences (default 100) in the chosen database(s) that are the most similar to the query sequence. BLAST, which was originated by Stephen Altschul, is publicly available, free of charge, for interactive use over the Web (<http://www.ncbi.nlm.nih.gov/BLAST/Blast.cgi>) on a server at the National Center for Biotechnology Information (NCBI). Let us discuss the BLAST system in its comparison of proteins (protein blast or blastp).

Protein databases presently contain  $\sim 900,000$  nonredundant peptide sequences. BLAST therefore minimizes the time it spends on a sequence region whose similarity with the query sequence has little chance of exceeding some minimal alignment score. Pairwise alignments (e.g., Fig. 7-31a), which by default are found using BLOSUM62 (substitution matrices and gap penalties can be optionally selected under “Algorithm parameters”), are listed in order of decreasing statistical significance and are presented in a manner that indicates the positions of both the identical residues and similar residues in the query and subject sequences. The number of identical residues, positives (those residue pairs whose exchange has a positive value in the substitution matrix used), and gaps over the length of the alignment are indicated. BLAST assesses the statistical significance of an alignment in terms of its “E value” (E for Expect), which is the number of alignments with at least the same score that would have been expected to occur in the database by chance. For example, an alignment with an E value of 5 is statistically insignificant, whereas one with an E value of 0.01 is significant, and one with an E value of  $1 \times 10^{-20}$  offers extremely high confidence that the query and subject sequences are homologous. BLAST also reports a “bit score” for each alignment, which is a type of normalized alignment score.

#### h. Multiple Sequence Alignments with CLUSTAL

BLAST makes only pairwise alignments. To simultaneously align more than two sequences, that is, to obtain a **multiple sequence alignment** such as Table 7-4, a different program must be used. Perhaps the most widely used such program, **ClustalW2**, is publicly available for interactive use over the Web at <http://www.ebi.ac.uk/Tools/clustalw2/>. The input for the program is a file containing all the sequences (either peptides or DNA) to be aligned. As with BLAST, the user can select the substitution matrix and the gap penalty parameters that ClustalW2 uses. ClustalW2 begins by finding all possible pairwise alignments of the input sequences. This permits the

## (b) Clustal W2 Multiple Sequence Alignment

**Figure 7-31** Examples of peptide sequence alignments. (a) A BLAST pairwise alignment. The aligned proteins are **high potential iron-sulfur proteins (HiPIPs)**, small bacterial proteins whose sequences are archived in the SWISS-PROT database. The amino acid residues are indicated by their one-letter codes (Table 4-1) and gaps are indicated by dashes. The query sequence is HiPIP Isozyme 1 from *Halorhodospira halophila* (HIPI1\_HALHA, SWISS-PROT accession number P04168; **isozymes** are catalytically and structurally similar but genetically distinct enzymes from the same organism) and the subject sequence is HiPIP Isozyme 2 from *Ectothiorhodospira vacuolata* (HIPI2\_ECTVA, SWISS-PROT accession number P38524). The first two lines (green) identify the subject sequence and indicates its length in residues. This is followed by an assortment of

alignment statistics (black). The query and subject sequences are then shown vertically aligned (blue) with the line between them (black) indicating residues that are identical (by their one-letter codes) and similar [by a plus (+)]. The output of BLAST consists of a series of such pairwise alignments. (b) A ClustalW2 multiple sequence alignment of five HiPIP sequences: the two foregoing sequences, their corresponding Isozymes 1 and 2 (P38941 and P04169), and HiPIP from *Rhodocyclus gelatinosus* (P00265). Confidently aligned residues are shaded according to residue type. The bar graph below the alignment is indicative of the alignment quality based on the BLOSUM62 score of the observed substitutions. Note that the alignment of the residues numbered 9 through 29 of P04168 (the query sequence in Part a) with P38524 differs from that in Part a.

program to determine the relationships of the input sequences with one another based on their similarity scores and hence generate a crude phylogenetic tree called a dendrogram. Then, starting with the highest scoring pairwise alignment, it sequentially carries out realignments on the basis of the remaining sequences, which it adds in order of their decreasing relationships with the previously added sequences, while opening up gaps as necessary. The output of ClustalW2 is the aligned sequences (e.g., Fig. 7-31b).

Since multiple sequence alignment programs are easily confounded by such anomalies as sequences that are not homologous or that contain homologous segments in different orders, multiple sequence alignments should be carefully inspected to determine if they are sensible and, if necessary, corrected and trimmed by hand. Indeed, in Fig. 7-31a, the alignment of the first 21 residues of the query sequence (P04168) with the subject sequence (P38524) differs from that in Fig. 7-30b.

### i. The Use of Profiles Extends the Sensitivities of Sequence Alignments

Multiple sequence alignments can be used to improve the sensitivity of similarity searches, that is, to detect weak but significant sequence similarities. For example, in pair-

wise alignments, peptide A may appear to be similar to peptide B and peptide B to be similar to peptide C but peptides A and C may not appear to be similar. However, a multiple sequence alignment of peptides A, B, and C will reveal the similarities between peptides A and C. This idea has been extended through the construction of **profiles** (also called **position-specific score matrices**) that take into account the fact that some residues in a given protein are structurally and/or functionally more important than others and therefore are less subject to evolutionary change. Hence, at each residue position in a multiple sequence alignment, highly conserved residues are assigned a large positive score, weakly conserved positions are assigned a score near zero, and unconserved residues are assigned a large negative score. Many profile-generating algorithms are based on statistical models called **hidden Markov models (HMMs)**. The use of such conservation patterns has been successful in finding sequences that are so distantly related to a query sequence (so far into the twilight zone) that BLAST would not consider them to have significant sequence similarity.

The program **PSI-BLAST** (for *Position-Specific Iterated BLAST*), which is also available for use at <http://www.ncbi.nlm.nih.gov/blast/Blast.cgi>, uses the results of a BLAST search with a query sequence to generate

a profile and then employs the profile to search for new alignments. This is an iterative process in which the profile generated after each alignment search is used to make a new alignment search, etc., until no further significant alignments are found. For instance, for the query sequence used in Fig. 7-31a (HIP1\_HALHA; SWISS-PROT accession number P04168), BLAST finds only five sequences (called hits) that have E values less than 0.001 in the SWISS-PROT database (which includes a self-alignment). In contrast, PSI-BLAST finds 16 such hits after three iterations (and no additional hits in the fourth iteration, whereupon the search is said to have converged). Thus the use of profile analysis makes possible the detection of subtle but significant sequence relationships that, as we shall see in succeeding chapters, lead to considerable evolutionary and functional insights.

#### j. Structural Genes Should Be Aligned as Polypeptides

In many cases, only the base sequence of the DNA encoding a protein is known. Indeed, most of the known protein sequences have been inferred from DNA sequences. Although BLAST and ClustalW2 are both capable of aligning nucleic acid sequences (and are routinely used to do so), one should compare the inferred amino acid sequences of structural genes rather than just their base sequences. This is because amino acid sequence comparisons can routinely identify sequences that shared a common ancestor over 1 billion years ago (e.g., those of cytochrome *c* and histone H4; Fig. 7-23), whereas it is rare to detect homologies in noncoding DNA sequences that diverged >200 million years (Myr) ago and in coding sequences that diverged >600 Myr ago. The reasons for this are threefold:

1. DNA has only four different bases, whereas peptides consist of 20 different amino acid residues. Consequently, it is much easier to find spurious alignments with DNA, at least for short segments, than with peptides (a dot plot of two unrelated DNAs has, on average, 25% of its spaces filled vs 5% for unrelated polypeptides).

2. DNA evolves much more quickly than proteins. In the coding regions of structural genes, 24% of single base changes encode the same amino acid. There are few evolutionary constraints to maintain the sequence identity of these bases or of the gene's noncoding regions (e.g., those containing introns). Consequently, the evolutionary constraints on proteins are more stringent than those on DNA.

3. Direct DNA sequence alignments do not use amino acid substitution matrices such as PAM-250 and BLOSUM62 and, hence, are not constrained by the evolutionary information implicit in these matrices (although there are analogous  $4 \times 4$  matrices for base substitutions).

If the base sequence of a structural gene is known, its putative control regions, particularly its start and stop codons, can usually be identified. This, in turn, reveals which of two complementary DNA strands is the so-called **sense strand** (which has the same sequence as the mRNA transcribed from the DNA) and indicates its correct read-

ing frame. Even if it is unclear that a DNA segment that is flanked by what appear to be start and stop codons actually encodes a protein, one can compare the amino acid sequences from all six possible reading frames (three each from the DNA's two complementary strands). In fact, BLAST does so automatically when aligning peptide sequences based on DNA sequences.

### C. Construction of Phylogenetic Trees

Phylogenetic trees were first made by Linnaeus, the eighteenth century biologist who originated the system of taxonomy (biological classification) still in use today. These trees (e.g., Fig. 1-4) were originally based on morphological characteristics, whose measurements were largely subjective. It was not until the advent of sequence analysis, however, that the generation of phylogenetic trees was put on a firm quantitative basis (e.g., Fig. 7-22). In the following paragraphs we discuss the characteristics of phylogenetic trees and outline how they are generated.

Figure 7-32a is a phylogenetic tree diagramming the evolutionary relationships between four homologous genes, A, B, C, and D. The tree consists of four **leaves** or **external nodes**, each representing one of these genes, and two **branch points** or **internal nodes**, which represent ancestral genes, with the length of each **branch** indicating the degree of difference between the two nodes they connect. All branch points are binary, that is, one gene is considered to

**Figure 7-32** Phylogenetic trees. (a) An unrooted tree with four leaves (A, B, C, and D) and two branch points. (b) The five rooted trees that can be generated from the unrooted tree in Part a. The roots are drawn and numbered in red.

give rise to only two descendants at a time so that branches can only bifurcate (although branch points may turn out to be so close together that their order cannot be determined; e.g., the root of Fig. 7-22). Note that this is an **unrooted tree**, that is, it indicates the relationships between the four genes but provides no information as to the evolutionary events through which they arose. The five different evolutionary pathways that are possible for our unrooted tree are diagrammed in Fig. 7-32*b* as different **rooted trees**, where the node at which the root joins the tree represents the four genes' last common ancestor. With knowledge of only the A, B, C, and D genes, phylogenetic analysis cannot distinguish between these rooted trees. In order to find a tree's root, it is necessary to obtain the sequence of an **outgroup**, a homologous gene that is less closely related to the genes in the tree than they are to each other. This permits the root of the tree to be identified and hence the pathway through which the genes evolved to be elucidated.

The number of different bifurcating trees with the same  $n$  leaves increases extremely rapidly with  $n$  (e.g., for  $n = 10$ , it is over 2 million). Unfortunately, *there is no exact method for generating an optimal phylogenetic tree*. Indeed, there is no general agreement on what constitutes an optimal tree. Consequently, numerous methods have been formulated for constructing phylogenetic trees based on sequence alignments.

In one class of methods for constructing phylogenetic trees, the sequence data are converted into a **distance matrix**, which is a table showing the evolutionary distances between all pairs of genes in the data set (e.g., Table 7-5). Evolutionary distances are the number of sequence differences between two genes (ideally corrected for the possibility of multiple mutations at a given site). These quantities are used to calculate the lengths of the branches in a tree under the assumption that they are additive, that is, the distance between any pair of leaves is the sum of the lengths of the branches connecting them.

Perhaps the conceptually simplest (if it can be called that) way of generating a phylogenetic tree is the **neighbor-joining (N-J) method**, in which it is initially assumed that there is only one internal node, Y, and hence that all  $N$  leaves radiate from it in a starlike pattern (Fig. 7-33*a*). The branch lengths in the star are then calculated according to such relationships as  $d_{AB} = d_{AY} + d_{BY}$  (where  $d_{AB}$  is the total length of the branches connecting leaves A and B, etc.),  $d_{AC} = d_{AY} + d_{CY}$ , and  $d_{BC} = d_{BY} + d_{CY}$ , so that, for instance,  $d_{AY} = \frac{1}{2}(d_{AB} + d_{AC} - d_{BC})$ . A pair of leaves is then transferred from the star to a new internal node, X, that is connected to the center of the star by a new branch, XY (Fig. 7-33*b*), and the sum of all the branch lengths,  $S_{AB}$ , in this revised tree is calculated:

$$\begin{aligned} S_{AB} &= d_{AX} + d_{BX} + d_{XY} + \sum_{k \neq AB} d_{kY} \\ &= \frac{d_{AB}}{2} + \frac{[2Q - R_A - R_B]}{2(N-2)} \end{aligned} \quad [7.6]$$

where

$$Q = \sum_{i=1}^N \sum_{j=1}^{i-1} d_{ij} \quad [7.7]$$

**Figure 7-33** Manipulations employed in the neighbor-joining method for the construction of a phylogenetic tree. (a) The starting configuration. (b) The transfer of leaves A and B to a new branch point that is connected to the central star (red).

(that is, the sum of all the off-diagonal elements in the unique half of the distance matrix),

$$R_A = \sum_{i=1}^N d_{Ai} \quad [7.8]$$

(that is, the sum of the elements in the  $A$ th row of the distance matrix), and

$$R_B = \sum_{i=1}^N d_{Bi} \quad [7.9]$$

The two leaves are then returned to their initial positions, replaced by a second pair of leaves, and the total branch length again calculated. The process is repeated until all possible  $N(N-1)/2$  pairs of leaves have been so treated. The pair yielding the smallest value of  $S_{ij}$  (the shortest total branch length) in this process, which will be nearest neighbors in the final tree, are combined into a single unit of their average length, yielding a star with one less branch. If leaves A and B are chosen as neighbors, then the lengths of the branches connecting them are estimated to be

$$d_{AX} = \frac{d_{AB}}{2} + \frac{R_A - R_B}{2(N-2)} \quad [7.10]$$

$$d_{BX} = d_{AB} - d_{AX} \quad [7.11]$$

and

$$d_{XY} = \frac{(N-1)(R_i + R_j) - 2Q - (N^2 - 3N + 2)d_{AB}}{2(N-2)(N-3)} \quad [7.12]$$

**Figure 7-34** An unrooted phylogenetic tree of the five HiPIP sequences that are aligned in Fig. 7-31b. The tree was generated by Clustal using the neighbor-joining method. The numbers indicate the relative lengths of the associated branches.

Assuming that  $S_{AB}$  has the lowest value of all the  $S_{ij}$ , a new distance matrix is calculated whose elements,  $d'_{ij}$ , are the same as the  $d_{ij}$  with the exception that  $d'_{A-B,i} = d'_{i,A-B} = (d_{Ai} + d_{Bi})/2$ , where  $d'_{A-B,i}$  is the distance between the averaged leaves A and B and leaf  $i$ . The entire process is then iterated so as to find all pairs of nearest-neighbor sequences, thereby generating a phylogenetic tree. Figure 7-34 is an unrooted phylogenetic tree that Clustal generated from the multiple sequence alignment shown in Fig. 7-31b using the N-J method.

The N-J method is representative of **distance-based** tree-building procedures. There are two other types of tree-building criteria that are in widespread use:

**1. Maximum parsimony (MP)**, which is based on the principle of Occam's razor: The best explanation of the data is the simplest. Thus, MP-based methods assume (perhaps inaccurately) that evolution occurs via the fewest possible genetic changes and hence that the best phylogenetic tree requires the smallest number of sequence changes to account for a multiple sequence alignment.

**2. Maximum likelihood (ML)**, which finds the tree and branch lengths that have the highest probability of yielding the observed multiple sequence alignment. This, in turn, requires an evolutionary model that indicates the probability of occurrence for each type of residue change (e.g., the PAM substitution matrices).

Since the number of possible trees increases very rapidly with the number of leaves, the construction of a phylogenetic tree is a computer-intensive task for even relatively small sets of aligned sequences (e.g.,  $N = 20$ , although distance-based methods require far fewer computations than do MP- or ML-based methods). And, because of the ambiguities inherent in all known tree-building procedures, statistical tests have been developed to check the validity of any particular tree.

## 5 CHEMICAL SYNTHESIS OF POLYPEPTIDES

In this section we describe methods for the chemical synthesis of polypeptides from amino acids. The ability to manufacture polypeptides not available in nature has considerable biomedical potential:

1. To investigate the properties of polypeptides by systematically varying their side chains.
2. To obtain polypeptides with unique properties, particularly those with nonstandard side chains or with isotopic labels incorporated in specific residues (neither of which is easily accomplished using biological methods).
3. To manufacture pharmacologically active polypeptides that are biologically scarce or nonexistent.

One of the most promising applications of polypeptide synthesis is the production of synthetic vaccines. Vaccines, which have consisted of viruses that have been "killed" (inactivated) or attenuated ("live" but mutated so as not to cause disease in humans), stimulate the immune system to synthesize antibodies specifically directed against these viruses, thereby conferring immunity to them (the immune response is discussed in Section 35-2A). The use of such vaccines, however, is not without risk; attenuated viruses, for example, may mutate to a virulent form and "killed" virus vaccines have, on several occasions, caused disease because they contained "live" viruses. Moreover, it is difficult to culture many viruses and therefore to obtain sufficient material for vaccine production. Such problems would be eliminated by preparing vaccines from synthetic polypeptides that have the amino acid sequences of viral **epitopes** (antigenic determinants; molecular groupings that stimulate the immune system to manufacture antibodies against them). Indeed, several such synthetic vaccines are already in general use.

The first polypeptides to be chemically synthesized were composed of only one type of amino acid and are therefore known as **homopolypeptides**. Such compounds as **polyglycine**, **polyserine**, and **polylysine** are easily synthesized according to classic methods of polymer chemistry. They have served as valuable model compounds in studying the physicochemical properties of polypeptides, such as conformational behavior and interactions with the aqueous environment.

The first chemical synthesis of a biologically active polypeptide was that of the nonapeptide (9-amino acid residue) hormone **oxytocin** by Vincent du Vigneaud in 1953:

Improvements in polypeptide synthesis methodology since then have led to the synthesis of numerous biologically active polypeptides and several proteins.

### A. Synthetic Procedures

Polypeptides are chemically synthesized by covalently linking (coupling) amino acids, one at a time, to the terminus of a growing polypeptide chain. Imagine that a polypeptide is being synthesized from its C-terminus toward its N-terminus; that is, the growing chain ends with a free amino group. Then each amino acid being added to the chain must already have its own  $\alpha$ -amino group chemically protected (blocked) or it would react with other like molecules as well as with the N-terminal amino group of the chain. Once the new amino acid is coupled, its now N-terminal amino group must be deprotected (deblocked) so that the next peptide bond can be formed. *Every cycle of amino acid addition therefore requires a coupling step and a deblocking step.* Furthermore, reactive side chains must be blocked to prevent their participation in the coupling reactions, and then deblocked in the final step of the synthesis.

The reactions that were originally developed for synthesizing polypeptides such as oxytocin take place entirely in solution. The losses that are incurred on isolation and purifi-

cation of the reaction product in each of the many steps, however, contribute significantly to the low yields of final polypeptide. This difficulty was ingeniously circumvented in 1962 by Bruce Merrifield, through his development of **solid phase peptide synthesis (SPPS)**. In SPPS, a growing polypeptide chain is covalently anchored, usually by its C-terminus, to an insoluble solid support such as beads of polystyrene resin, and the appropriately blocked amino acids and reagents are added in the proper sequence (Fig. 7-35). This permits the quantitative recovery and purification of intermediate products by simply filtering and washing the beads.

When polypeptide chains are synthesized by amino acid addition to their N-terminus (the opposite direction to that in protein biosynthesis; Section 5-4Ba), the  $\alpha$ -amino group of each sequentially added amino acid must be chemically protected during the coupling reaction. The **tert-butyloxycarbonyl (Boc)** group is frequently used for this purpose,

**Figure 7-35** Flow diagram for polypeptide synthesis by the solid phase method. The symbol  $M_i$  represents the  $i$ th amino acid residue to be added to the polypeptide,  $S_i$  is its side chain protecting group, and  $Y$  represents the main chain protecting group. The specific reactions are discussed in the text. [After Erikson, B.W. and Merrifield, R.B., in Neurath, H. and Hill, R.L. (Eds.), *The Proteins* (3rd ed.), Vol. 2, p. 259, Academic Press (1979).]

as is the **9-fluorenylmethoxycarbonyl (Fmoc)** group:

**9-Fluorenylmethoxycarbonyl (Fmoc) group**

Both groups undergo analogous reactions, although, in what follows, we shall only discuss the Boc group.

### a. Anchoring the Chain to the Inert Support

The first step in SPPS is the coupling of the C-terminal amino acid to a solid support. The most commonly used support is a cross-linked polystyrene resin with pendant chloromethyl groups. Resin coupling occurs through the following reaction:

and the resulting  $\alpha$ -amino acid-derivatized resin is filtered and washed. The amino group is then deblocked by treatment with an anhydrous acid such as trifluoroacetic acid, which leaves intact the alkylbenzyl ester bond to the support resin:

### b. Coupling the Amino Acids

The reaction coupling two amino acids through a peptide bond is endergonic and therefore must be activated to obtain significant yields. **Carbodiimides** ( $R-N=C=N-R'$ ) such as **dicyclohexylcarbodiimide (DCCD)** are commonly used coupling agents:

The *O*-acylurea intermediate that results from the reaction of DCCD with the carboxyl group of a Boc-protected  $\alpha$ -amino acid readily reacts with the resin-bound  $\alpha$ -amino

acid to form the desired peptide bond in high yield. By subsequently alternating the deblocking and coupling reactions, a polypeptide with the desired amino acid sequence can be synthesized. *The repetitive nature of these operations allows the SPPS method to be easily automated.*

During the course of peptide synthesis, many of the side chains also require protection to prevent their reaction with the coupling agent. Although there are many different blocking groups, the benzyl group is the most widely used (Fig. 7-36).

### c. Releasing the Polypeptide from the Resin

The final step in SPPS is the cleavage of the polypeptide from the solid support. The benzyl ester link from the polypeptide's C-terminus to the support resin may be cleaved by treatment with liquid HF:

The Boc group linked to the polypeptide's N-terminus as well as the benzyl groups protecting its side chains are also removed by this treatment.

### B. Problems and Prospects

The steps just outlined seem simple enough, but they are not as straightforward as we have implied. A major difficulty with the entire procedure is its low cumulative yield. Let us examine the reasons for this. To synthesize a polypeptide chain with  $n$  peptide bonds requires at least  $2n$  reaction steps—one for coupling and one for deblocking each residue. If a protein-sized polypeptide is to be synthesized in reasonable yield, then each reaction step must be essentially quantitative; anything less greatly reduces the yield of final product. For example, in the synthesis of a 101-residue polypeptide chain, in which each reaction step occurs with an admirable 98% yield through 200 reaction steps, the overall yield is only  $0.98^{200} \times 100 = 2\%$ . Therefore, although oligopeptides can be routinely made, the synthesis of large polypeptides requires almost fanatical attention to chemical detail.

An ancillary problem is that the newly liberated synthetic polypeptide must be purified. This may be a difficult

**Boc,  $N^{\epsilon}$ -benzyloxycarbonyl-Lys**

**Boc, S-benzyl-Cys**

**Boc-Glu,  $\gamma$ -Benzyl ester**

**Boc, O-benzyl-Ser**

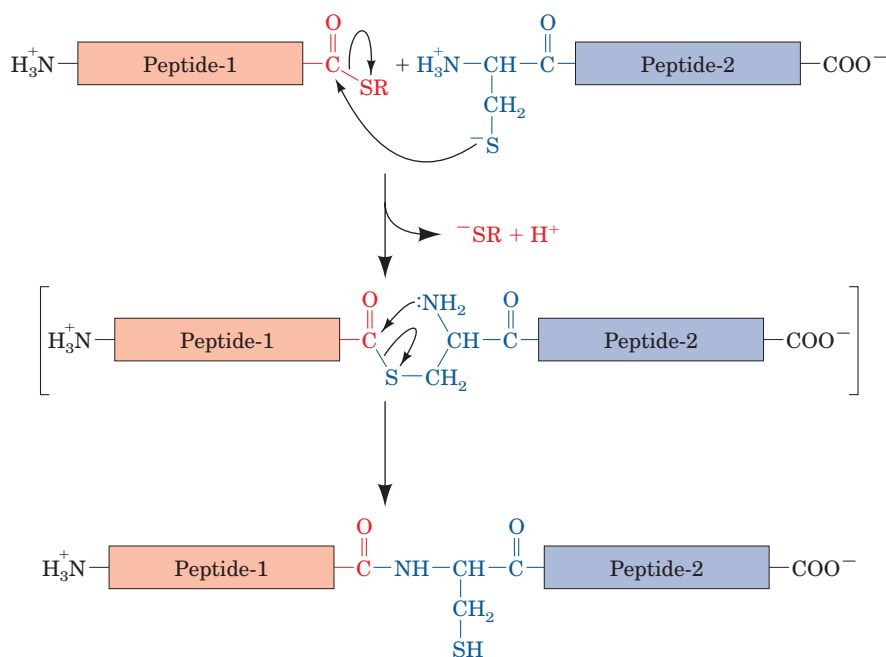

**Figure 7-36** A selection of amino acids with benzyl-protected side chains and a Boc-protected  $\alpha$ -amino group. These substances can be used directly in the coupling reactions forming peptide bonds.

task because a significant level of incomplete reactions and/or side reactions at every stage of SPPS will result in almost a continuum of closely related products for large polypeptides. The use of reverse-phase HPLC techniques (Section 6-3Dh), however, greatly facilitates this purification process, and the quality of both intermediate and final products can be readily assessed through mass spectrometric techniques (Section 7-1I).

Using automated SPPS, Merrifield synthesized the nonapeptide hormone **bradykinin** in 85% yield:

However, it was only in 1988, through steady progress in improving reaction yields (to >99.5% on average) and eliminating side reactions, that it became possible to synthesize  $\sim 100$ -residue polypeptides of reasonable quality. Thus, Stephen Kent synthesized the 99-residue **HIV-1 protease** [an enzyme that is essential for the maturation of

**Figure 7-37** The native chemical ligation reaction. Peptide-1 has a C-terminal thioester group (R is an alkyl group) and Peptide-2 has a N-terminal Cys residue. The reaction, which occurs in aqueous solution at pH 7, is initiated by the nucleophilic attack of Peptide-2's Cys thiol group on Peptide-1's thioester group to yield, in a thiol exchange reaction, a new thioester

group. This intermediate (as is indicated by the square brackets), undergoes a rapid intramolecular nucleophilic attack to yield a native peptide bond at the ligation site. [After Dawson, P.E., Muir, T.W., Clark-Lewis, I., and Kent, S.B.H., *Science* **266**, 777 (1994).]

**human immunodeficiency virus-1 (HIV-1, an AIDS virus;** Section 15-4C)] in such high yield and purity that, after being renatured (folded to its native conformation; Section 9-1A), it exhibited full biological activity. Indeed, this synthetic protein was crystallized and its X-ray structure was shown to be identical to that of biologically synthesized HIV-1 protease. Kent also synthesized HIV-1 protease from D-amino acids and experimentally verified, for the first time, that such a protein has the opposite chirality of its biologically produced counterpart. Moreover, this D-amino acid protease catalyzes the cleavage of its target polypeptide made from D-amino acids but not that made from L-amino acids as does naturally occurring HIV-1 protease.

Despite the foregoing, the accumulation of resin-bound side products limits the sizes of the polypeptides that can routinely be synthesized by SPPS to ~60 residues. Kent has partially circumvented this limitation through the development of the so-called **native chemical ligation** reaction, which links together two polypeptides in a peptide bond to routinely yield polypeptides as large as ~120 residues (Fig. 7-37). Moreover, several peptide segments can be consecutively linked by native chemical ligation, so that the chemical synthesis of polypeptides consisting of several hundred residues can be anticipated. In fact, using this technique, Kent synthesized the 203-residue “covalent dimer” of HIV-1 protease (Section 15-4C) from four synthetic peptides—the largest linear polypeptide yet synthesized—and showed that it was fully enzymatically active.

## 6 CHEMICAL SYNTHESIS OF OLIGONUCLEOTIDES

Molecular cloning techniques (Section 5-5) have permitted the genetic manipulation of organisms in order to investigate their cellular machinery, change their characteristics, and produce scarce or specifically altered proteins in large quantities. *The ability to chemically synthesize DNA oligonucleotides of specified base sequences is an indispensable part of this powerful technology.* Thus, as we have seen, specific oligonucleotides are required as probes in Southern blotting (Section 5-5D) and *in situ* hybridization (Section 5-5Ea), as primers in PCR (Section 5-5F), and to carry out site-directed mutagenesis (Section 5-5Gc).

### A. Synthetic Procedures

The basic strategy of oligonucleotide synthesis is analogous to that of polypeptide synthesis (Section 7-5A): *A suitably protected nucleotide is coupled to the growing end of the oligonucleotide chain, the protecting group is removed, and the process is repeated until the desired oligonucleotide has been synthesized.* The first practical technique for DNA synthesis, the **phosphodiester method**, which was developed by H. Gobind Khorana in the 1960s, is a laborious process in which all reactions are carried out in solution and the products must be isolated at each stage of the multistep synthesis. Khorana, nevertheless,

**Figure 7-38** Reaction cycle in the phosphoramidite method of oligonucleotide synthesis. Here B<sub>1</sub>, B<sub>2</sub>, and B<sub>3</sub> represent protected bases, and S represents an inert solid phase support such as controlled-pore glass.

used this method, in combination with enzymatic techniques, to synthesize a 126-nucleotide tRNA gene, a project that required several years of intense effort by numerous skilled chemists.

#### a. The Phosphoramidite Method

By the early 1980s, these difficult and time-consuming processes had been supplanted by much faster solid phase methodologies that permitted oligonucleotide synthesis to be automated. The presently most widely used chemistry, which was formulated by Robert Letsinger and further developed by Marvin Caruthers, is known as the **phosphoramidite method**. This series of nonaqueous reactions adds a single nucleotide to a growing oligonucleotide chain as follows (Fig. 7-38):

1. The **dimethoxytrityl (DMTr)** protecting group at the 5' end of the growing oligonucleotide chain (which is anchored via a linking group at its 3' end to a solid support, S) is removed by treatment with an acid such as **trichloroacetic acid** ( $\text{Cl}_3\text{CCOOH}$ ).

2. The newly liberated 5' end of the oligonucleotide is coupled to the 3'-phosphoramidite derivative of the next deoxynucleoside to be added to the chain. The coupling agent in this reaction is **tetrazole**, which protonates the incoming nucleotide's diisopropylamine moiety so that it becomes a good leaving group. Modified nucleosides (e.g., containing a fluorescent label) can be incorporated into the growing oligonucleotide at this stage. Likewise, a mixture of oligonucleotides containing different bases at this position can be synthesized by adding the corresponding mixture of nucleosides.

3. Any unreacted 5' end (the coupling reaction has a yield of over 99%) is capped by acetylation so as to block its extension in subsequent coupling reactions. This prevents the extension of erroneous oligonucleotides (failure sequences).

4. The phosphite triester group resulting from the coupling step is oxidized with to the more stable phosphotriester, thereby yielding a chain that has been lengthened by one nucleotide.

This reaction sequence, in commercially available automated synthesizers, can be repeated up to ~250 times with cycle times of 20 to 30 min. Once an oligonucleotide of desired sequence has been synthesized, it is treated with concentrated  $\text{NH}_4\text{OH}$  to release it from its support and remove its various blocking groups, including those protecting the exocyclic amines on the bases. The product can then be separated from the failure sequences and protecting groups by reverse-phase HPLC and/or gel electrophoresis.

The largest DNA molecule yet synthesized is the entire 582,970-bp genome of *Mycoplasma genitalium* (among the smallest bacterial genomes). Initially, overlapping 5- to 7-kb "cassettes" were constructed by sequentially ligating chemically synthesized double-stranded oligonucleotides of ~50 bp. The resulting 101 cassettes were then joined in

stages by utilizing their overlapping ends. Sequencing the final product confirmed that it had the correct sequence.

#### B. DNA Microarrays

The sequencing of the human genome (Section 7-2B) is really only the means to a highly complex end. The questions of real biochemical significance are these: What are the functions of its ~23,000 genes? In which cells, under what circumstances, and to what extent are each of them expressed? How do their gene products interact to yield a functional organism? And what are the medical consequences of variant genes? The traditional method of addressing such questions, the one-gene-at-a-time approach, is simply incapable of acquiring the vast amounts of data necessary to answer these questions. What is required are methods that can globally analyze biological processes, that is, techniques that can simultaneously monitor all the components of a biological system.

A technology that is capable of making such global assessments involves the use of **DNA microarrays** (also called **DNA chips**; Fig. 7-39). These are arrays of different

**Figure 7-39 DNA microarrays.** This ~6000-gene microarray contains most of the genes from baker's yeast, one per spot. The microarray had been hybridized to the cDNAs derived from mRNAs extracted from yeast. The cDNAs derived from cells that were grown in glucose were labeled with a red-fluorescing dye, whereas the cDNAs derived from cells grown in the absence of glucose were labeled with a green-fluorescing dye. Thus the red and green spots, respectively, reveal those genes that are transcriptionally activated by the presence or absence of glucose, whereas the yellow spots (*red plus green*) indicate genes whose expression is unaffected by the level of glucose. [Courtesy of Patrick Brown, Stanford University School of Medicine.]

**Figure 7-40** The photolithographic synthesis of a DNA microarray. In Step 1 of the process, oligonucleotides that are anchored to a glass or silicon surface, and each having a photosensitive protecting group (filled red square) at their 5' ends, are exposed to light through a mask that only permits the illumination of the oligonucleotides destined to be coupled, for example, to a T residue. The light deprotects these oligonucleotides so that only they react with the activated T nucleotide that is incubated with the chip in Step 2. The entire process is repeated

in Steps 3 and 4 with a different mask for G residues, and in subsequent reaction cycles for A and C residues, thereby extending all of the oligonucleotides by one residue. This quadruple cycle is then repeated for as many nucleotides as are to be added to form the final set of oligonucleotides. Each “feature” (position) on the microarray contains at least 1 million identical oligonucleotides. [After Pease, A.C., Solas, D., Sullivan, E.J., Cronin, M.T., Holmes, C.P., and Fodor, S.P.A., *Proc. Natl. Acad. Sci.* **91**, 5023 (1994).]

DNA molecules anchored to the surface of a glass, silicon, or nylon wafer in an  $\sim 1$ -cm-wide square grid. In one of several methodologies that are presently used to manufacture DNA microarrays, large numbers (up to  $\sim 1$  million) of different oligonucleotides are simultaneously synthesized via a combination of photolithography (the process used to fabricate electronic chips) and solid phase DNA synthesis. In this process (Fig. 7-40), which was developed by Stephen Fodor, the nucleotides from which the oligonucleotides are synthesized each have a photochemically removable protective group at their 5' end that has the same function as the DMTr group in conventional solid phase DNA synthesis (Fig. 7-38). At a given stage in the synthetic procedure, oligonucleotides that, for example, require a T at their next position are deprotected by shining light on them through a mask that blocks the light from hitting those grid posi-

tions that require a different base at this next position (in an alternative methodology called maskless array synthesis, an array of individually programmable micromirrors directs light to the desired locations). The chip is then incubated with a solution of activated thymidine nucleotide, which couples only to the deprotected oligonucleotides. After washing away the unreacted thymidine nucleotide, the process is repeated with different masks (light patterns for maskless array synthesis) for each of the remaining three bases. By repeating these four steps  $N$  times, an array of all  $4^N$  possible  $N$ -residue sequences can be synthesized simultaneously in  $4N$  coupling cycles, where  $N \leq 30$  (up to 100 for maskless array synthesis). A DNA microarray is shown in Fig. 7-41.

In one application of DNA microarrays,  $L$ -residue oligonucleotides (the probes) are arranged in an array of  $L$

**Figure 7-41** A DNA microarray assembly. This so-called GeneChip protects its enclosed DNA microarray and provides a convenient hybridization chamber. To interrogate it requires a specialized fluorescence measurement device. [Courtesy of Affymetrix, Inc., Santa Clara, California.]

columns by 4 rows for a total of  $4L$  sequences. The probe in the array's  $M$ th column has the "standard" sequence with the exception of the probe's  $M$ th position, where it has a different base, A, C, G, or T, in each row. Thus, one of the four probe DNAs in every column will have the standard sequence, whereas the other three will differ from the standard DNA by only one base change. The probe array is then hybridized with the complementary DNA or RNA, whose variation relative to the standard DNA is to be determined, and the unhybridized DNA or RNA is washed away. This "target" DNA or RNA is fluorescently labeled so that, when interrogated by a laser, the positions on the probe array to which it binds are revealed by fluorescent spots. Since hybridization conditions can be adjusted so that a single base mismatch will significantly reduce the level of binding, a target DNA or RNA that varies from the complement of the standard DNA by a single base change at its  $M$ th position, say C to A, would be readily detected by an increased fluorescence at the row corresponding to A in the  $M$ th column relative to that at other positions [a target DNA or RNA that was exactly complementary to the standard DNA would exhibit high fluorescence in each of its columns at the base position (row) corresponding to the standard sequence]. The intensity of the fluorescence at every position in the array, and hence the sequence variation from the standard DNA, is rapidly determined with a computerized fluorescence scanning device. In this manner, single nucleotide polymorphisms (SNPs) can be automatically detected. It is becoming increasingly apparent that genetic variations, and in particular SNPs, are largely responsible for an individual's susceptibility to many diseases as well as to adverse reactions to drugs (side effects; Section 15-4B).

In an alternative DNA microarray methodology, different DNAs are robotically spotted (deposited) to precise locations on a coated glass surface. These DNAs most often consist of PCR-amplified inserts from cDNA clones or expressed sequence tags (ESTs), which are usually robotically synthesized. The DNAs are spotted in nanoliter-sized droplets that rapidly evaporate leaving the DNA attached to the glass substrate. Up to 30,000 DNAs representing all of the genes in an organism can be spotted onto a single glass "chip." Such DNA microarrays, many of which are commercially available, are used to monitor the level of expression of the genes in a tissue of interest by the degree of hybridization of its fluorescently labeled mRNA or cDNA population. They can therefore be used to determine the pattern of gene expression (the **expression profile**) in different tissues of the same organism (e.g., Fig. 7-42) and how specific diseases and drugs (or drug candidates) affect gene expression. Thus, DNA microarrays are the major tool for the study of a cell's **transcriptome** (which, in analogy with the word "genome," is the entire collection of RNAs that the cell transcribes). Moreover, DNA microarrays are used to specifically identify infectious agents by detecting unique segments of their DNA. Consequently, DNA microarrays hold enormous promise for understanding the interplay of genes during cell growth and changes in the environment, for the characterization and diagnosis of both infectious and noninfectious diseases (e.g., cancers), for identifying genetic risk factors and designing specific treatments, and as tools in drug development.

### C. SELEX

Although nucleic acids such as DNA and mRNA are widely thought of as being passive molecular "tapes" whose structures have only incidental significance, it is now abundantly clear that certain nucleic acids, for example, tRNAs and ribosomal RNAs (Sections 32-2B and 32-3A), have functions that require that these molecules maintain well-defined three-dimensional structures. This has led to the development of a process called **SELEX** (for Systematic Evolution of Ligands by *EX*ponential enrichment) for generating single-stranded oligonucleotides that specifically bind target molecules with high affinity and specificity.

SELEX, a technique pioneered by Larry Gold, starts with a library of polynucleotides that have fixed known sequences at their 5' and 3' ends and a central region of randomized sequences. Such sequences are synthesized via solid phase methods by adding a mixture of all four nucleoside triphosphates rather than a single nucleoside triphosphate at the positions to be randomized. For a variable region that is 30 nucleotides long, this will yield a mixture of  $4^{30} \approx 10^{18}$  different oligonucleotides. The next step in the SELEX process is to select those sequences in the mixture that selectively bind to a target molecule, X. Those oligonucleotides that bind to X with higher than average affinity can be separated from the other oligonucleotides in the mixture by a variety of techniques including affinity

**Figure 7-42** Variation in the expression of genes that encode proteins known as cyclins (Section 34-4D) in human tissues. The levels of hybridization of the various cyclin mRNAs produced in

each tissue were measured through the use of DNA microarrays. [After Gerhold, D., Rushmore, T., and Caskey, C.T., *Trends Biochem. Sci.* **24**, 172 (1999).]

chromatography (Section 6-3C) with X linked to a suitable matrix and the precipitation of X–oligonucleotide complexes by anti-X antibodies. The oligonucleotides are then separated from X and amplified by cloning or PCR. This selection and amplification process is then repeated for several cycles (usually 10–15), thereby yielding oligonucleotides that tenaciously bind X. Several such enrichment cycles are necessary because those few oligonucleotides in a library with the highest affinity for X must compete for binding X with the far more abundant weak binders.

The results of SELEX are remarkable. Its oligonucleotide products, which are known as **aptamers**, bind to

their target molecule, X, with dissociation constants that are typically around  $10^{-9}$  M if X is a protein and between  $10^{-3}$  M and  $10^{-6}$  M if X is a small molecule (for the reaction  $A + B \rightleftharpoons A \cdot B$ , the dissociation constant,  $K_D = [A][B]/[A \cdot B]$ ). Moreover, aptamers bind to their target molecules with great specificity. Thus, aptamers selected for their affinity toward a particular member of a protein family do not bind other members of that family. Aptamers bind a wide variety of target molecules including simple ions, small molecules, proteins, organelles, and even whole cells. These various properties give aptamers great promise both as diagnostic tools and as therapeutic agents.

## CHAPTER SUMMARY

**1 Primary Structure Determination of Proteins** The initial step in the amino acid sequence determination of a protein is to ascertain its content of chemically different polypeptides by end group analysis. The protein's disulfide bonds are then chemically cleaved, the different polypeptides are separated and purified, and their amino acid compositions are determined. Next, the purified polypeptides are specifically

cleaved, by enzymatic or chemical means, to smaller peptides that are separated, purified, and then sequenced by (automated) Edman degradation. Repetition of this process, using a cleavage method of different specificity, generates overlapping peptides whose amino acid sequences, when compared to those of the first group of peptide fragments, indicate their order in the parent polypeptide. The primary structure determi-

nation is completed by establishing the positions of the disulfide bonds, which requires the degradation of the protein with its disulfide bonds intact. Mass spectrometry using electrospray ionization (ESI) or matrix-assisted laser desorption/ionization (MALDI) to vaporize and ionize peptides can be used to determine their molecular masses. By using these techniques in a tandem mass spectrometer equipped with a collision cell, the sequences of short peptides can be rapidly determined. Once the primary structure of a protein is known, its minor variants, which may arise from mutations or chemical modifications, can be readily identified by peptide mapping.

**2 Nucleic Acid Sequencing** Nucleic acids may be sequenced by the same basic strategy used to sequence proteins. In the Sanger method, the DNA fragment to be sequenced is replicated by a DNA polymerase in the presence of all four deoxynucleoside triphosphates, one of which is  $\alpha$ - $^{32}\text{P}$ -labeled, and a small amount of the dideoxy analog of one of the deoxynucleoside triphosphates. This results in a series of  $^{32}\text{P}$ -labeled chains that are terminated after the various positions occupied by the corresponding base. The electrophoresis of the four differently terminated DNA samples in parallel lanes of a sequencing gel resolves fragments that differ in size by one nucleotide. An autoradiograph of the sequencing gel containing the four sets of fragments reveals the base sequence of the complementary DNA. RNA may be sequenced by determining the sequence of its corresponding cDNA. Automated methods, which use fluorescently labeled DNA fragments, have greatly accelerated DNA sequence determinations. They have been used to sequence very large tracts of DNA such as the chromosomes of the human genome.

In the conventional strategy for genome sequencing, the genome is mapped by sequencing large numbers of landmark sequences such as sequence-tagged sites (STSs) and expressed sequence tags (ESTs). Landmark-containing YAC clones are then fragmented, the fragments subcloned and sequenced, and the sequences are computationally assembled into contigs, which are further assembled into chromosomes based on the landmark sequences. Advances in cloning and computational techniques permitted genome sequencing via a shotgun strategy. For bacterial genomes this is carried out straightforwardly. For eukaryotic genomes, large segments are cloned in bacterial artificial chromosomes (BACs), whose ends are sequenced to yield sequence-tagged connectors (STCs). The BAC inserts are fragmented, shotgun cloned, and the clones sequenced and assembled into contigs. The STCs are used to further assemble the sequenced BAC inserts into chromosomes via BAC walking. Next generation DNA sequencing technologies, such as those employing pyrosequencing, have enormously accelerated the rate that DNA is being sequenced relative to Sanger-based techniques. Even faster single molecule sequencing techniques are under development.

**3 Chemical Evolution** Sickle-cell anemia is a molecular disease of individuals who are homozygous for a gene specifying an altered  $\beta$  chain of hemoglobin. Fingerprinting and sequencing studies have identified this alteration as arising from a point mutation that changed Glu  $\beta 6$  to Val. In the heterozygous state, the sickle-cell trait confers resistance to malaria without causing deleterious effects. This accounts for its high incidence in populations living in malarial regions. The cytochromes *c* from many eukaryotic species contain many

amino acid residues that are invariant or conservatively substituted. Hence, this protein is well adapted to its function. The amino acid differences between the various cytochromes *c* have permitted the generation of their phylogenetic tree, which closely parallels that determined by classical taxonomy. The number of sequence differences between homologous proteins from related species plotted against the time when, according to the fossil record, these species diverged from a common ancestor reveals that point mutations are accepted into proteins at a constant rate. Proteins whose functions are relatively intolerant to sequence changes evolve more slowly than those that are more tolerant to such changes. Phylogenetic analysis of the globin family—myoglobin and the  $\alpha$  and  $\beta$  chains of hemoglobin—reveals that these proteins arose through gene duplication. In this process, the original function of the protein is maintained, while the duplicated copy evolves a new function. Many, if not most, proteins have evolved through gene duplication.

**4 Bioinformatics: An Introduction** The sequences of nucleic acids and proteins are archived in large and rapidly growing databases that are publicly available over the World Wide Web. The alignment of homologous sequences provides insights into their function and evolution. The alignment of distantly related sequences requires statistically and computationally sophisticated algorithms such as BLAST and ClustalW2. The construction of an optimal phylogenetic tree based on aligned sequences is a computationally intensive process for which there is no known exact solution.

**5 Chemical Synthesis of Polypeptides** The strategy of polypeptide chemical synthesis involves coupling amino acids, one at a time, to the N-terminus of a growing polypeptide chain. The  $\alpha$ -amino group of each amino acid must be chemically protected during the coupling reaction and then unblocked before the next coupling step. Reactive side chains must also be chemically protected but then unblocked at the conclusion of the synthesis. The difficulties in recovering the intermediate product of each of the many steps of such a synthesis has been eliminated by the development of solid phase synthesis techniques. These methods have led to the synthesis of numerous biologically active polypeptides and are capable of synthesizing small proteins in useful amounts. The use of the native chemical ligation technique significantly increases the sizes of the polypeptides that can be chemically synthesized.

**6 Chemical Synthesis of Oligonucleotides** Oligonucleotides are indispensable to recombinant DNA technology. They are used to identify normal and mutated genes and to alter specific genes through site-directed mutagenesis. Oligonucleotides of defined sequence are efficiently synthesized by the phosphoramidite method, a cyclic, nonaqueous, solid phase process that has been automated. DNA chips, which can be manufactured through photolithographically based DNA synthesis or by the robotic deposition of DNA on a glass substrate, are finding increasing numbers of applications. These include the detection of single nucleotide polymorphisms, monitoring patterns of gene expression, and identifying infectious agents. SELEX is a technique for selecting and amplifying those members of a large polynucleotide library that specifically bind to a target molecule. The resulting aptamers, which have remarkably high affinity and specificity for their target molecules, may be useful diagnostic and therapeutic agents.

## BIOINFORMATICS EXERCISES

Bioinformatics Exercises are available at [www.wiley.com/college/voet](http://www.wiley.com/college/voet)

### Chapter 7

#### Databases for the Storage and “Mining” of Genome Sequences and to Compare and Identify Related Protein Sequences

- 1. Finding Databases.** Locate databases for genome sequences and explore the meaning of terms related to them.
- 2. The Institute for Genomic Research.** Explore a prokaryotic genome and find listings for eukaryotic genomes.
- 3. Analyzing a DNA Sequence.** Given a DNA sequence, identify its open reading frame and translate it into a protein sequence.
- 4. Sequence Homology.** Perform a BLAST search for homologs of a protein sequence.

5. **Plasmids and Cloning.** Predict the sizes of the fragments produced by the action of various restriction enzymes on plasmids.
6. **Obtaining Protein Sequences from BLAST.** Using a known protein sequence, find and retrieve the sequences of related proteins from other organisms.
7. **Multiple Sequence Alignment.** Examine the various sequences for similarities, and view their relatedness as a tree diagram.
8. **Phylogenetic Trees.** Create a tree based on cytochrome *c*.
9. **Proteomics.** Gain a broader understanding of proteomics.
10. **Microarrays.** Learn how microarrays are made and used.

## PROBLEMS

**Note:** Amino acid compositions of polypeptides with unknown sequences are written in parentheses with commas separating amino acid abbreviations such as in (Gly, Tyr, Val). Known amino acid sequences are written with residue names in order and separated by hyphens; for example, Tyr-Val-Gly.

1. State the cleavage pattern of the following polypeptides by the indicated agents.

- a. Ser-Ala-Phe-Lys-Pro by chymotrypsin
- b. Thr-Cys-Gly-Met-Asn by NCB<sub>r</sub>
- c. Leu-Arg-Gly-Asp by carboxypeptidase A
- d. Gly-Phe-Trp-Asp-Phe-Arg by endopeptidase Asp-N
- e. Val-Trp-Lys-Pro-Arg-Glu by trypsin

2. A protein is subjected to end group analysis by dansyl chloride. The liberated dansylamino acids are found to be present with a molar ratio of two parts Ser to one part Ala. What conclusions can be drawn about the nature of the protein?

3. A protein is subjected to degradation by carboxypeptidase B. Within a short time, Arg and Lys are liberated, following which no further change is observed. What does this information indicate concerning the primary structure of the protein?

4. Before the advent of the Edman degradation, the primary structures of proteins were elucidated through the use of partial acid hydrolysis. The resulting oligopeptides were separated and their amino acid compositions were determined. Consider a polypeptide with amino acid composition (Ala<sub>2</sub>, Asp, Cys, Leu, Lys, Phe, Pro, Ser<sub>2</sub>, Trp<sub>2</sub>). Treatment with carboxypeptidase A released only Leu. Oligopeptides with the following compositions were obtained by partial acid hydrolysis:

(Ala, Lys)	(Ala, Ser <sub>2</sub> )	(Cys, Leu)
(Ala, Lys, Trp)	(Ala, Trp)	(Cys, Leu, Pro)
(Ala, Pro)	(Asp, Lys, Phe)	(Phe, Ser, Trp)
(Ala, Pro, Ser)	(Asp, Phe)	(Ser, Trp)
(Ser <sub>2</sub> , Trp)		

Determine the amino acid sequence of the polypeptide.

\*5. A polypeptide is subjected to the following degradative techniques resulting in polypeptide fragments with the indicated amino acid sequences. What is the amino acid sequence of the entire polypeptide?

**I. Cyanogen bromide treatment:**

1. Asp-Ile-Lys-Gln-Met
2. Lys
3. Lys-Phe-Ala-Met
4. Tyr-Arg-Gly-Met

**II. Trypsin hydrolysis:**

5. Gln-Met-Lys
6. Gly-Met-Asp-Ile-Lys
7. Phe-Ala-Met-Lys
8. Tyr-Arg

6. Treatment of a polypeptide by 2-mercaptoethanol yields two polypeptides that have the following amino acid sequences:

1. Ala-Phe-Cys-Met-Tyr-Cys-Leu-Trp-Cys-Asn
2. Val-Cys-Trp-Val-Ile-Phe-Gly-Cys-Lys

Chymotrypsin-catalyzed hydrolysis of the intact polypeptide yields polypeptide fragments with the following amino acid compositions:

3. (Ala, Phe)
4. (Asn, Cys<sub>2</sub>, Met, Tyr)
5. (Cys, Gly, Lys)
6. (Cys<sub>2</sub>, Leu, Trp<sub>2</sub>, Val)
7. (Ile, Phe, Val)

Indicate the positions of the disulfide bonds in the original polypeptide.

7. A polypeptide was subjected to the following treatments with the indicated results. What is its primary structure?

**I. Acid hydrolysis:**

1. (Ala, Arg, Cys, Glx, Gly, Lys, Leu, Met, Phe, Thr)

**II. Aminopeptidase M:**

2. No fragments

**III. Carboxypeptidase A + carboxypeptidase B:**

3. No fragments

**IV. Trypsin followed by Edman degradation of the separated products:**

4. Cys-Gly-Leu-Phe-Arg
5. Thr-Ala-Met-Glu-Lys

\*8. While on an expedition to the Amazon jungle, you isolate a polypeptide you suspect of being the growth hormone of a newly discovered species of giant spider. Unfortunately, your portable sequencer was so roughly treated by the airport baggage handlers that it refuses to provide the sequence of more than four consecutive amino acid residues. Nevertheless, you persevere and obtain the following data:

**I. Hydrazinolysis:**

1. (Val)

**II. Dansyl chloride treatment followed by acid hydrolysis:**

2. (Dansyl-Pro)

**III. Trypsin followed by Edman degradation of the separated fragments:**

3. Gly-Lys
4. Phe-Ile-Val
5. Pro-Gly-Ala-Arg
6. Ser-Arg

Provide as much information as you can concerning the amino acid sequence of the polypeptide.

9. In taking the electrospray ionization mass spectrum of an unknown protein, you find that four successive peaks have  $m/z$  values of 953.9, 894.4, 841.8, and 795.1. What is the molecular mass of the protein and what are the ionic charges of the ions responsible for the four peaks?

10. Figure 7-43 pictures an autoradiograph of the sequencing gel of a DNA that was treated according to the Sanger method of DNA sequencing. What is the sequence of the template strand corresponding to bases 50 to 100? If there are any positions on the gel where a band seems to be absent, leave a question mark in the sequence for the indeterminate base.

11. Using Table 7-5, compare the relatedness of fungi to higher plants and to animals. Fungi are sometimes said to be non-green plants. In light of your analysis, is this a reasonable classification?

12. Below is a list of the first 10 residues of the B helix in myoglobin from different organisms.

Position	1	2	3	4	5	6	7	8	9	10
Human	D	I	P	G	H	G	Q	E	V	L
Chicken	D	I	A	G	H	G	H	E	V	L
Alligator	K	L	P	E	H	G	H	E	V	I
Turtle	D	L	S	A	H	G	Q	E	V	I
Tuna	D	Y	T	T	M	G	G	L	V	L
Carp	D	F	E	G	T	G	G	E	V	L

Based on this information, which positions (a) appear unable to tolerate substitutions, (b) can tolerate conservative substitution, and (c) are highly variable?

Figure 7-43 [Courtesy of Barton Slatko, New England Biolabs Inc., Beverly, Massachusetts.]

13. The inherited hemoglobin disease  $\beta$ -thalassemia is common to people from around the Mediterranean Sea and areas of Asia where malaria is prevalent (Fig. 7-21). The disease is characterized by a reduction in the amount of synthesis of the  $\beta$  chain of hemoglobin. Heterozygotes for the  $\beta$ -thalassemia gene, who are said to have **thalassemia minor**, are only mildly affected with adverse symptoms. Homozygotes for this gene, however, suffer from **Cooley's anemia** or **thalassemia major**; they are so severely afflicted that they do not survive their childhood. About 1% of the children born in the malarial regions around the Mediterranean Sea have Cooley's anemia. Why do you suppose the  $\beta$ -thalassemia gene is so prevalent in this area? Justify your answer.

14. Leguminous plants synthesize a monomeric oxygen-binding globin known as **leghemoglobin**. (Section 26-6). From your knowledge of biology, sketch the evolutionary tree of the globins (Fig. 7-25) with leghemoglobin included in its most likely position.

15. Since point mutations mostly arise through random chemical change, it would seem that the rate at which mutations appear in a gene expressing a protein should vary with the size of the gene (number of amino acid residues the gene expresses). Yet, even though the rates at which proteins evolve vary quite widely, these rates seem to be independent of protein size. Explain.

16. Sketch the self-dot matrices of the following: (a) A 100-residue peptide with nearly identical segments spanning its residues 20 to 40 and 60 to 80. (b) A 100-nucleotide DNA that is palindromic.

\*17. (a) Using the PAM-250 log odds substitution matrix and the Needleman–Wunsch algorithm, find the best alignment of the two peptides PQRSTV and PDLRSCSV. (b) What is its alignment score using a gap penalty of  $-8$  for opening a gap and  $-2$  for every "residue" in the gap? (c) What is its normalized alignment score (NAS) using the scoring system of 10 for each identity, 20 for each identity involving Cys, and  $-25$  for every gap? (d) Is this NAS indicative of a homology? Explain.

18. You have been given an unknown protein to identify. You digest it with trypsin and, by using Edman degradation, find that one of the resulting peptide fragments has the sequence GIHWGEDTLMEYLENPK. Using BLAST, find the most probable identity (or identities) of the unknown protein. [To carry out a search on the BLAST server, go to <http://www.ncbi.nlm.nih.gov/BLAST/Blast.cgi> and, under "Basic BLAST," click on "protein blast" (which is BLAST for comparing an amino acid query sequence against a protein sequence database). In the window that comes up, enter the above sequence (without spaces or punctuation) into the "Enter Query Sequence" box, from the "Database" pulldown menu select "Non-redundant protein sequences (nr)," under "Program Selection" select the "blastp (protein-protein BLAST)" button, and click on the "BLAST" button at the bottom of the window.]

\*19. A desiccated dodo bird in a reasonable state of preservation has been found in a cave on Mauritius Island. You have been given a tissue sample in order to perform biochemical analyses and have managed to sequence its cytochrome *c*. The amino acid difference matrix for a number of birds including the dodo is shown here.

Chicken, turkey	0				
Penguin	2	0			
Pigeon	4	4	0		
Pekin duck	3	3	3	0	
Dodo	4	4	2	3	0

(a) Determine the phylogenetic tree for these species using the neighbor-joining method. (b) To which of the other birds does the dodo appear most closely related? (c) What additional information do you require to find the root of this tree? Without making further computations, indicate the most likely possibilities.

**20.** In a tragic accident, the desiccated dodo discussed in Problem 19 has been eaten by a deranged cat. The sequence of the dodo cytochrome *c* that you had determined before the accident led you to suspect that this cytochrome *c* has some unique biochemical properties. To test this hypothesis, you are forced to synthesize dodo cytochrome *c* by chemical means. As with other known avian cytochromes *c*, that of the dodo consists of 104 amino acid residues. In planning a solid phase synthesis, you expect a 99.7% yield for each coupling step and a 99.3% yield for each deblocking step. The cleavage of the completed polypeptide from the resin and the side chain deblocking step should yield an

80% recovery of product. (a) What percentage of the original resin-bound C-terminal amino acid can you expect to form unmodified dodo cytochrome *c* if you synthesize the entire polypeptide in a single run? (b) You have found that dodo cytochrome *c* has a Cys residue at its position 50. What would be your overall yield if you used the native chemical ligation reaction (assume it has a 75% yield) to synthesize dodo cytochrome *c*? Compare this yield with that from Part a and discuss the implications of this comparison for synthesizing long polypeptides.

**21.** You have manufactured a DNA chip consisting of 4 rows and 10 columns in which the *M*th column contains DNAs of the sequence 5'-GACCTGACGT-3' but with a different base in the *M*th position for each of the 4 rows (from top to bottom, G, A, T, and C). Draw the appearance of the chip after it is hybridized to fluorescently labeled RNA of sequence (a) 5'-ACGUCAGGUC-3' and (b) 5'-ACGUCUGGUC-3'.

# Three-Dimensional Structures of Proteins

## CHAPTER 8

### 1 Secondary Structure

- A. The Peptide Group
- B. Helical Structures
- C. Beta Structures
- D. Nonrepetitive Structures

### 2 Fibrous Proteins

- A.  $\alpha$  Keratin—A Helix of Helices
- B. Collagen—A Triple Helical Cable

### 3 Globular Proteins

- B. Hydrogen Bonding Forces
- C. Hydrophobic Forces
- D. Disulfide Bonds
- E. Protein Denaturation
- F. Explaining the Stability of Thermostable Proteins

### 5 Quaternary Structure

- A. Subunit Interactions
- B. Symmetry in Proteins
- C. Determination of Subunit Composition

### Appendix: Viewing Stereo Pictures

The properties of a protein are largely determined by its three-dimensional structure. One might naively suppose that since proteins are all composed of the same 20 types of amino acid residues, they would be more or less alike in their properties. Indeed, **denatured** (unfolded) proteins have rather similar characteristics, a kind of homogeneous “average” of their randomly dangling side chains. However, the three-dimensional structure of a **native** (physiologically folded) protein is specified by its primary structure, so that it has a unique set of characteristics.

In this chapter, we shall discuss the structural features of proteins, the forces that hold them together, and their hierarchical organization to form complex structures. This will form the basis for understanding the structure–function relationships necessary to comprehend the biochemical roles

of proteins. Detailed consideration of the dynamic behavior of proteins and how they fold to their native structures is deferred until Chapter 9.

### 1 SECONDARY STRUCTURE

A polymer's **secondary structure** (**2° structure**) is defined as the local conformation of its backbone. For proteins, this has come to mean the specification of regular polypeptide backbone folding patterns: helices, pleated sheets, and turns. However, before we begin our discussion of these basic structural motifs, let us consider the geometrical properties of the peptide group because its understanding is prerequisite to that of any structure containing it.

#### A. The Peptide Group

In the 1930s and 1940s, Linus Pauling and Robert Corey determined the X-ray structures of several amino acids and dipeptides in an effort to elucidate the structural constraints on the conformations of a polypeptide chain. These studies indicated that *the peptide group has a rigid, planar structure* (Fig. 8-1), which, Pauling pointed out, is a

**Figure 8-1** The **trans-peptide group**. The standard dimensions (in angstroms, Å, and degrees, °) of this planar group were derived by averaging the corresponding quantities in the X-ray crystal structures of amino acids and peptides. [After Marsh, R.E. and Donohue, J., *Adv. Protein Chem.* **22**, 249 (1967).]

 See Kinemage Exercise 3-1

consequence of resonance interactions that give the peptide bond an  $\sim 40\%$  double-bond character:

This explanation is supported by the observations that a peptide's C—N bond is  $0.13 \text{ \AA}$  shorter than its N—C $_{\alpha}$  single bond and that its C=O bond is  $0.02 \text{ \AA}$  longer than that of aldehydes and ketones. The peptide bond's resonance energy has its maximum value,  $\sim 85 \text{ kJ} \cdot \text{mol}^{-1}$ , when the peptide group is planar because its  $\pi$ -bonding overlap is maximized in this conformation. This overlap, and thus the resonance energy, falls to zero as the peptide bond is twisted to  $90^\circ$  out of planarity, thereby accounting for the planar peptide group's rigidity. (The positive charge on the above resonance structure should be taken as a formal charge; quantum mechanical calculations indicate that the peptide N atom, in fact, has a partial negative charge arising from the polarization of the C—N  $\sigma$  bond.)

*Peptide groups, with few exceptions, assume the trans conformation: that in which successive C $_{\alpha}$  atoms are on opposite sides of the peptide bond joining them* (Fig. 8-1). This is partly a result of steric interference, which causes the cis conformation (Fig. 8-2) to be  $\sim 8 \text{ kJ} \cdot \text{mol}^{-1}$  less stable than the trans conformation (this energy difference is somewhat less in peptide bonds followed by a Pro residue and, in fact,  $\sim 10\%$  of the Pro residues in proteins follow a cis peptide bond, whereas cis peptides are otherwise extremely rare).

### a. Polypeptide Backbone Conformations May Be Described by Their Torsion Angles

The above considerations are important because they indicate that *the backbone of a protein is a linked sequence of rigid planar peptide groups* (Fig. 8-3). We can therefore specify a polypeptide's backbone conformation by the **torsion angles** (rotation angles or **dihedral angles**) about the C $_{\alpha}$ —N bond ( $\phi$ ) and the C $_{\alpha}$ —C bond ( $\psi$ )

**Figure 8-2** The cis-peptide group. See Kinemage Exercise 3-1

of each of its amino acid residues. These angles,  $\phi$  and  $\psi$ , are both defined as  $180^\circ$  when the polypeptide chain is in its planar, fully extended (all-trans) conformation and increase for a clockwise rotation when viewed from C $_{\alpha}$  (Fig. 8-4).

There are several steric constraints on the torsion angles,  $\phi$  and  $\psi$ , of a polypeptide backbone that limit its conformational range. The electronic structure of a single ( $\sigma$ ) bond, such as a C—C bond, is cylindrically symmetrical about its bond axis, so that we might expect such a bond to exhibit free rotation. If this were the case, then in ethane, for example, all torsion angles about the C—C bond would be equally likely. Yet certain conformations in ethane are favored due to quantum mechanical effects arising from the interactions of its molecular orbitals. The **staggered conformation** (Fig. 8-5a; torsion angle =  $180^\circ$ ) is ethane's most stable arrangement, whereas the **eclipsed conformation** (Fig. 8-5b; torsion angle =  $0^\circ$ ) is least stable. The energy difference between the staggered and eclipsed conformations in ethane is  $\sim 12 \text{ kJ} \cdot \text{mol}^{-1}$ , a quantity that represents an **energy barrier** to free rotation about the C—C single bond. Substituents other than hydrogen exhibit greater steric interference; that is, they increase the size of this energy barrier due to their greater bulk.

**Figure 8-3** A polypeptide chain in its fully extended conformation showing the planarity of each of its peptide groups. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

**Figure 8-4 The torsional degrees of freedom in a peptide unit.** The only reasonably free movements are rotations about the  $C_{\alpha}$ -N bond ( $\phi$ ) and the  $C_{\alpha}$ -C bond ( $\psi$ ). The torsion angles are both  $180^\circ$  in the conformation shown and increase, as is indicated, in a clockwise manner when viewed from  $C_{\alpha}$ . [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]  See Kinemage Exercise 3-1

**Figure 8-6 Steric interference between adjacent residues.** The collision between a carbonyl oxygen and the following amide hydrogen prevents the conformation  $\phi = -60^\circ$ ,  $\psi = 30^\circ$ . [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]  See Kinemage Exercise 3-1.

(a) Staggered

(b) Eclipsed

**Figure 8-5 Conformations of ethane.** Newman projections indicating the (a) staggered conformation and (b) eclipsed conformation of ethane.

Indeed, with large substituents, some conformations may be sterically forbidden.

### b. Allowed Conformations of Polypeptides Are Indicated by the Ramachandran Diagram

The sterically allowed values of  $\phi$  and  $\psi$  can be determined by calculating the distances between the atoms of a tripeptide at all values of  $\phi$  and  $\psi$  for the central peptide unit. Sterically forbidden conformations, such as that shown in Fig. 8-6, are those in which any nonbonding interatomic distance is less than its corresponding van der Waals distance. Such information is summarized in a **conformation map** or **Ramachandran diagram** (Fig. 8-7), which was invented by G.N. Ramachandran.

Figure 8-7 indicates that 77% of the Ramachandran diagram (most combinations of  $\phi$  and  $\psi$ ) is conformationally inaccessible to a polypeptide chain. The particular regions of the Ramachandran diagram that represent allowed conformations depend on the van der Waals radii chosen to calculate it. But with any realistic set of values, such as that in Table 8-1, *only three small regions of the conformational map are physically accessible to a polypeptide chain*. Nevertheless, as we shall see, all of the common types of regular secondary structures found in proteins fall within allowed regions of the Ramachandran diagram. Indeed, the

**Figure 8-7 The Ramachandran diagram.** It shows the sterically allowed  $\phi$  and  $\psi$  angles for poly-L-alanine and was calculated using the van der Waals distances in Table 8-1. Regions of “normally allowed”  $\phi$  and  $\psi$  angles are shaded in blue, whereas green-shaded regions correspond to conformations having “outer limit” van der Waals distances. The conformation angles,  $\phi$  and  $\psi$ , of several secondary structures are indicated below:

Secondary Structure	$\phi$ (deg)	$\psi$ (deg)
Right-handed $\alpha$ helix ( $\alpha$ )	-57	-47
Parallel $\beta$ pleated sheet ( $\uparrow\uparrow$ )	-119	113
Antiparallel $\beta$ pleated sheet ( $\uparrow\downarrow$ )	-139	135
Right-handed $3_{10}$ helix (3)	-49	-26
Right-handed $\pi$ helix ( $\pi$ )	-57	-70
2.2 <sub>7</sub> ribbon (2)	-78	59
Left-handed polyglycine II and polyproline II helices (II)	-79	150
Collagen (C)	-51	153
Left-handed $\alpha$ helix ( $\alpha_L$ )	57	47

[After Flory, P.J., *Statistical Mechanics of Chain Molecules*, p. 253, Interscience (1969); and IUPAC-IUB Commission on Biochemical Nomenclature, *Biochemistry* **9**, 3475 (1970).]

observed conformational angles of most non-Gly residues in proteins whose X-ray structures have been determined lie in these allowed regions (Fig. 8-8).

Most points that fall in forbidden regions of Fig. 8-8 lie between its two fully allowed areas near  $\psi = 0$ . However, these “forbidden” conformations, which arise from the collision of successive amide groups, are allowed if twists of only a few degrees about the peptide bond are permitted. This is not unreasonable since the peptide bond offers little resistance to small deformations from planarity.

**Figure 8-8 Distribution of conformation angles in proteins.** The conformation angle distribution of all residues but Gly in 207 high-resolution ( $\leq 1.2$  Å) X-ray structures comprising 25,327 residues is superimposed on the Ramachandran diagram (resolution is discussed in Section 8-3Aa). [Courtesy of Scott Hollingsworth and Andrew Karplus, Oregon State University, Corvallis, Oregon.]

**Table 8-1 van der Waals Distances for Interatomic Contacts**

Contact Type	Normally Allowed (Å)	Outer Limit (Å)
H ... H	2.0	1.9
H ... O	2.4	2.2
H ... N	2.4	2.2
H ... C	2.4	2.2
O ... O	2.7	2.6
O ... N	2.7	2.6
O ... C	2.8	2.7
N ... N	2.7	2.6

Gly, the only residue without a  $C_{\beta}$  atom, is much less sterically hindered than the other amino acid residues. This is clearly apparent in comparing the Ramachandran diagram for Gly in a polypeptide chain (Fig. 8-9) with that of other residues (Fig. 8-7). In fact, Gly often occupies positions where a polypeptide backbone makes a sharp turn

**Figure 8-9** The Ramachandran diagram of Gly residues in a polypeptide chain. “Normally allowed” regions are shaded in blue, whereas green-shaded regions correspond to “outer limit” van der Waals distances. Gly residues have far greater conformational freedom than do other (bulkier) amino acid residues, as the comparison of this figure with Fig. 8-7 indicates. [After Ramachandran, G.N. and Sasisekharan, V., *Adv. Protein Chem.* **23**, 332 (1968).]

which, with any other residue, would be subject to steric interference.

Figure 8-7 was calculated for three consecutive Ala residues. Similar plots for larger residues that are unbranched at  $C_{\beta}$ , such as Phe, are nearly identical. In Ramachandran diagrams of residues that are branched at  $C_{\beta}$ , such as Thr, the allowed regions are somewhat smaller than for Ala. The cyclic side chain of Pro limits its  $\phi$  to the range  $-60^{\circ} \pm 25^{\circ}$ , making it, not surprisingly, the most conformationally restricted amino acid residue. The conformations of residues in chains longer than tripeptides are even more restricted than the Ramachandran diagram indicates because a polypeptide chain with all its  $\phi$  and  $\psi$  angles allowed nevertheless cannot assume a conformation in which it passes through itself. We shall see, however, that despite the great restrictions that peptide bond planarity and side chain bulk place on the conformations of a polypeptide chain, different unique primary structures have correspondingly unique three-dimensional structures.

## B. Helical Structures

 See Guided Exploration 7: Stable helices in proteins: The  $\alpha$  helix Helices are the most striking elements of protein  $2^{\circ}$  structure. If a polypeptide chain is twisted by the same amount about each of its  $C_{\alpha}$  atoms, it assumes a helical conformation. As an alternative to specifying its  $\phi$  and  $\psi$  angles, a helix may be characterized by the number,  $n$ , of peptide units per helical turn and by its **pitch**,  $p$ , the distance the helix rises along its axis per turn. Several examples of helices are diagrammed in Fig. 8-10. Note that a helix has chirality; that

**Figure 8-10** Examples of helices. These provide definitions of the helical pitch,  $p$ , the number of repeating units per turn,  $n$ , and the helical rise per repeating unit,  $d = p/n$ . Right- and left-handed helices are defined, respectively, as having positive and negative

values of  $n$ . For  $n = 2$ , the helix degenerates to a nonchiral ribbon. For  $p = 0$ , the helix degenerates to a closed ring. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

is, it may be either right handed or left handed (a right-handed helix turns in the direction that the fingers of a right hand curl when its thumb points along the helix axis in the direction that the helix rises). In proteins, moreover,  $n$  need not be an integer and, in fact, rarely is.

A polypeptide helix must, of course, have conformation angles that fall within the allowed regions of the Ramachandran diagram. As we have seen, this greatly limits the possibilities. Furthermore, if a particular conformation is to have more than a transient existence, it must be more than just allowed, it must be stabilized. The “glue” that holds polypeptide helices and other 2° structures together is, in part, hydrogen bonds.

### a. The $\alpha$ Helix

Only one helical polypeptide conformation has simultaneously allowed conformation angles and a favorable hydrogen bonding pattern: the  $\alpha$  helix (Fig. 8-11), a particularly rigid arrangement of the polypeptide chain. Its discovery through model building, by Pauling in 1951, ranks as one of the landmarks of structural biochemistry.

For a polypeptide made from L- $\alpha$ -amino acid residues, the  $\alpha$  helix is right handed with torsion angles  $\phi = -57^\circ$  and  $\psi = -47^\circ$ ,  $n = 3.6$  residues per turn, and a pitch of 5.4 Å. (An  $\alpha$  helix of D- $\alpha$ -amino acid residues is the mirror image of that made from L-amino acid residues: It is left handed with conformation angles  $\phi = +57^\circ$ ,  $\psi = +47^\circ$ , and  $n = -3.6$  but with the same value of  $p$ .)

Figure 8-11 indicates that the hydrogen bonds of an  $\alpha$  helix are arranged such that the peptide N—H bond of the  $n$ th residue points along the helix toward the peptide C=O group of the  $(n - 4)$ th residue. This results in a strong hydrogen bond that has the nearly optimum N  $\cdots$  O distance of 2.8 Å. In addition, the core of the  $\alpha$  helix is tightly packed; that is, its atoms are in van der Waals contact across the helix, thereby maximizing their association energies (Section 8-4Ab). The R groups, whose positions, as we saw, are not fully dealt with by the Ramachandran diagram, all project backward (downward in Fig. 8-11) and outward from the helix so as to avoid steric interference with the polypeptide backbone and with each other. Such an arrangement can also be seen in Fig. 8-12. Indeed, a major reason why the left-handed  $\alpha$  helix has never been observed (its helical parameters are but mildly forbidden; Fig. 8-7) is that its side chains contact its polypeptide backbone too closely. Note, however, that 1 to 2% of the individual non-Gly residues in proteins assume this conformation (Fig. 8-8).

The  $\alpha$  helix is a common secondary structural element of both fibrous and globular proteins. In globular proteins,  $\alpha$  helices have an average span of  $\sim 12$  residues, which corresponds to over three helical turns and a length of 18 Å. However,  $\alpha$  helices with over 140 residues are known.

### b. Other Polypeptide Helices

Figure 8-13 indicates how hydrogen bonded polypeptide helices may be constructed. The first two, the **2.2<sub>7</sub> ribbon** and the **3<sub>10</sub> helix**, are described by the notation,  $n_m$ ,

**Figure 8-11 The right-handed  $\alpha$  helix.** Hydrogen bonds between the N—H groups and the C=O groups that are four residues back along the polypeptide chain are indicated by dashed lines. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

See Kinemage Exercise 3-2 and the Animated Figures

where  $n$ , as before, is the number of residues per helical turn and  $m$  is the number of atoms, including H, in the ring that is closed by the hydrogen bond. With this notation, an  $\alpha$  helix is a 3.6<sub>13</sub> helix.

**Figure 8-12** Stereo, space-filling representation of an  $\alpha$  helical segment of sperm whale myoglobin (its E helix) as determined by X-ray crystal structure analysis. Backbone atoms are colored according to type (C green, N blue, O red, and H white) and the side chain atoms are gold. Instructions for viewing stereo

diagrams are given in the appendix to this chapter. [Based on an X-ray structure by Ilme Schlichting, Max Planck Institut für Molekulare Physiologie, Dortmund, Germany. PDBid 1A6M (for the definition of “PDBid,” see Section 8-3Ca).]  See **Kinemage Exercise 3-2**

**Figure 8-13** The hydrogen bonding pattern of several polypeptide helices. In the cases shown, the polypeptide chain is helically wound such that the N—H group on residue  $n$  forms a hydrogen bond with the C=O groups on residues  $n - 2$ ,  $n - 3$ ,  $n$

$- 4$ , or  $n - 5$ . [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

**Figure 8-14** Comparison of the two polypeptide helices that occasionally occur in proteins with the commonly occurring  $\alpha$  helix. (a) The  $3_{10}$  helix, which has 3.0 peptide units per turn and a pitch of 6.0 Å, making it thinner and more elongated than the  $\alpha$  helix. (b) The  $\alpha$  helix, which has 3.6 peptide units per turn and a

pitch of 5.4 Å (also see Fig. 8-11). (c) The  $\pi$  helix, which has 4.4 peptide units per turn and a pitch of 5.2 Å, making it wider and shorter than the  $\alpha$  helix. The peptide planes are indicated.

[Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

The right-handed  $3_{10}$  helix (Fig. 8-14a), which has a pitch of 6.0 Å, is thinner and rises more steeply than does the  $\alpha$  helix (Fig. 8-14b). Its torsion angles place it in a mildly forbidden zone of the Ramachandran diagram that is rather near the position of the  $\alpha$  helix (Fig. 8-7), and its R groups experience some steric interference. This explains why the  $3_{10}$  helix is only occasionally observed in proteins, and then mostly in short segments that are frequently distorted from the ideal  $3_{10}$  conformation (the longest known  $3_{10}$  helix in a protein has 15 residues). The  $3_{10}$  helix most often occurs as a single-turn transition between one end of an  $\alpha$  helix and the adjoining portion of a polypeptide chain.

The  $\pi$  helix ( $4.4_6$  helix), which also has a mildly forbidden conformation (Fig. 8-7), has only rarely been observed and then only as segments of longer helices. This is probably because its comparatively wide and flat conformation (Fig. 8-14c) results in an axial hole that is too small to admit water molecules but too wide to allow van der Waals associations across the helix axis; this greatly reduces its stability relative to more closely packed conformations. The 2.2,

ribbon, which, as Fig. 8-7 indicates, has strongly forbidden conformation angles, has never been observed.

Certain synthetic homopolypeptides assume conformations that are models for helices in particular proteins. **Polyproline** is unable to assume any common secondary structure due to the conformational constraints imposed by its cyclic pyrrolidine side chains. Furthermore, the lack of a hydrogen substituent on its backbone nitrogen precludes any polyproline conformation from being knit together by hydrogen bonding. Nevertheless, under the proper conditions, polyproline precipitates from solution as a left-handed helix of all-trans peptides that has 3.0 residues per helical turn and a pitch of 9.4 Å (Fig. 8-15). This rather extended conformation, which is known as the **polyproline II helix**, permits the Pro side chains to avoid each other. Curiously, **polyglycine**, the least conformationally constrained polypeptide, precipitates from solution as a helix whose parameters are essentially identical to those of polyproline, the most conformationally constrained polypeptide (although the polyglycine helix may be either

right or left handed because Gly is nonchiral). The structures of the polyglycine and polyproline helices are of biological significance because they form the basic structural motif of collagen, a structural protein that contains a remarkably high proportion of both Gly and Pro (Section 8-2B). In addition, the polyproline II helical conformation is commonly assumed by polypeptide segments of up to 12 residues, even though it lacks intrahelical hydrogen bonds.

### C. Beta Structures

 See **Guided Exploration 8: Hydrogen bonding in  $\beta$  sheets** and **Guided Exploration 9: Secondary structures in proteins** In 1951, the year that they proposed the  $\alpha$  helix, Pauling and Corey also

**Figure 8-15** The polyproline II helix. Polyglycine forms a nearly identical helix (polyglycine II). [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

postulated the existence of a different polypeptide secondary structure, the  **$\beta$  pleated sheet**. As with the  $\alpha$  helix, the  $\beta$  pleated sheet's conformation has repeating  $\phi$  and  $\psi$  angles that fall in the allowed region of the Ramachandran diagram (Fig. 8-7) and utilizes the full hydrogen bonding capacity of the polypeptide backbone. In  $\beta$  pleated sheets, however, hydrogen bonding occurs between neighboring polypeptide chains rather than within one as in  $\alpha$  helices.

$\beta$  Pleated sheets come in two varieties:

1. The antiparallel  $\beta$  pleated sheet, in which neighboring hydrogen bonded polypeptide chains run in opposite directions (Fig. 8-16a).

2. The parallel  $\beta$  pleated sheet, in which the hydrogen bonded chains extend in the same direction (Fig. 8-16b).

The conformations in which these  $\beta$  structures are optimally hydrogen bonded vary somewhat from that of a fully extended polypeptide ( $\phi = \psi = \pm 180^\circ$ ), as indicated in

**Figure 8-16**  $\beta$  Pleated sheets. Hydrogen bonds are indicated by dashed lines and side chains are omitted for clarity. (a) The antiparallel  $\beta$  pleated sheet. (b) The parallel  $\beta$  pleated sheet. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]  See **Kinemage Exercise 3-3** and the **Animated Figures**

**Figure 8-17** A two-stranded  $\beta$  antiparallel pleated sheet drawn to emphasize its pleated appearance. Dashed lines indicate hydrogen bonds. Note that the R groups (purple balls) on each polypeptide chain alternately extend to opposite sides of the sheet and that they are in register on adjacent chains. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

See Kinemage Exercise 3-3

Fig. 8-7. They therefore have a rippled or pleated edge-on appearance (Fig. 8-17), which accounts for the appellation “pleated sheet.” In this conformation, successive side chains of a polypeptide chain extend to opposite sides of the pleated sheet with a two-residue repeat distance of 7.0 Å.

$\beta$  Sheets are common structural motifs in proteins. In globular proteins, they consist of from 2 to as many as 22 polypeptide strands, the average being 6 strands, which have an aggregate width of  $\sim 25$  Å. The polypeptide chains in a  $\beta$  sheet are known to be up to 15 residues long, with the average being 6 residues that have a length of  $\sim 21$  Å. A 7-stranded antiparallel  $\beta$  sheet, for example, occurs in the jack bean protein **concanavalin A** (Fig. 8-18).

Parallel  $\beta$  sheets of less than five strands are rare. This observation suggests that parallel  $\beta$  sheets are less stable than antiparallel  $\beta$  sheets, possibly because the hydrogen bonds of parallel sheets are distorted in comparison to those of the antiparallel sheets (Fig. 8-16). Mixed parallel–antiparallel  $\beta$  sheets are common but, nevertheless, only  $\sim 20\%$  of the strands in  $\beta$  sheets have parallel bonding on one side and antiparallel bonding on the other (vs an expected 50% for the random mixing of strand directions).

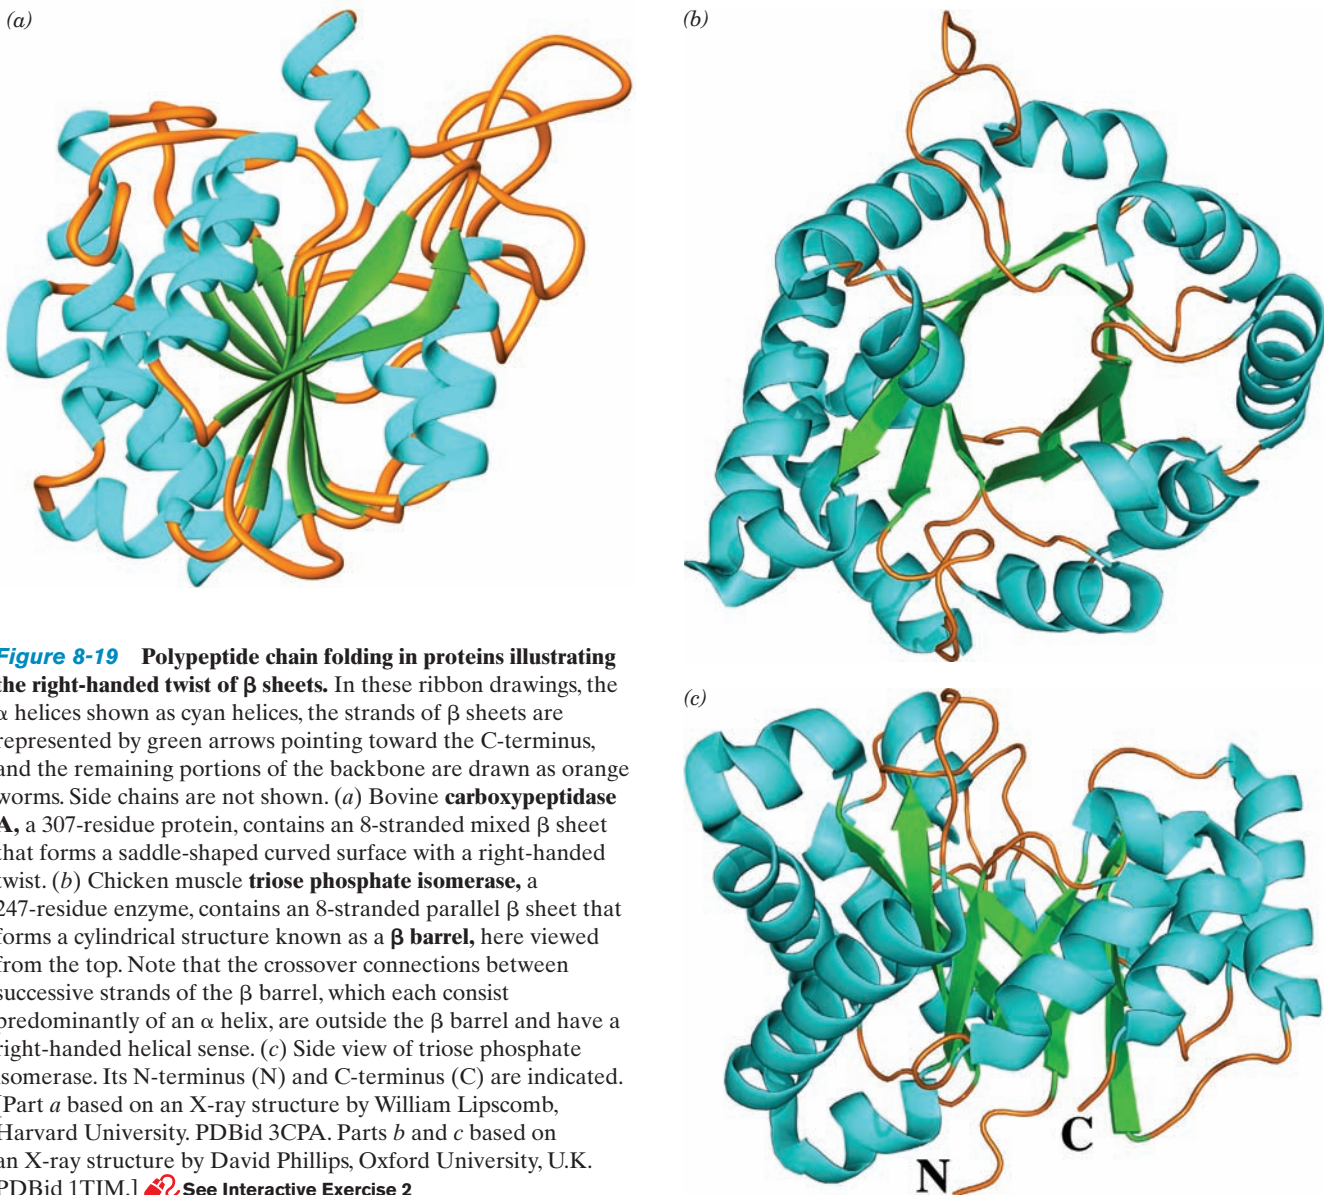

The  $\beta$  pleated sheets in globular proteins invariably exhibit a pronounced right-handed twist when viewed along their polypeptide strands (e.g., Fig. 8-19). Such twisted  $\beta$  sheets are important architectural features of globular proteins since  $\beta$  sheets often form their central cores (Fig. 8-19). Conformational energy calculations indicate that a  $\beta$  sheet’s right-handed twist is a consequence of nonbonded interactions between the chiral L-amino acid residues in the sheet’s extended polypeptide chains. These interactions tend to give the polypeptide chains a slight right-handed helical twist (Fig. 8-19) which distorts and hence weakens the  $\beta$  sheet’s interchain hydrogen bonds. A particular  $\beta$  sheet’s geometry is thus the result of a compromise between optimizing the conformational energies of its polypeptide chains and preserving its hydrogen bonds.

The **topology** (connectivity) of the polypeptide strands in a  $\beta$  sheet can be quite complex; the connecting links of these assemblies often consist of long runs of polypeptide chain which frequently contain helices (e.g., Fig. 8-19). The link connecting two consecutive antiparallel strands is topologically equivalent to a simple hairpin turn (Fig. 8-20a). However, tandem parallel strands must be linked by a crossover connection that is out of the plane of the  $\beta$  sheet. Such crossover connections almost always have a right-handed helical sense (Fig. 8-20b), which is thought to better fit the  $\beta$  sheets’ inherent right-handed twist (Fig. 8-21).

#### D. Nonrepetitive Structures

*Globular proteins consist of, on average,  $\sim 31\%$   $\alpha$  helix and  $\sim 28\%$   $\beta$  sheet.* The protein’s remaining polypeptide segments are said to have a **coil or loop conformation**. That is not to say that these nonrepetitive secondary structures are any less ordered than are helices or  $\beta$  sheets; they are simply irregular and hence more difficult to describe. You should therefore not confuse the term coil conformation with the

**Figure 8-18** Stereo, space-filling representation of the 7-stranded antiparallel  $\beta$  pleated sheet in jack bean concanavalin A as determined by X-ray crystal structure analysis. The  $\beta$  strands are approximately horizontal with their backbone atoms colored according to type (C green, N blue, O red, and H white) and their side chains represented by magenta spheres. Instructions for viewing stereo drawings are given in the appendix to this chapter. [Based on an X-ray structure by Gerald Edelman, The Rockefeller University. PDBid 2CNA.]  See Kinemage Exercise 3-3.

**Figure 8-20** Connections between adjacent polypeptide strands in  $\beta$  pleated sheets. (a) The hairpin connection between antiparallel strands is topologically in the plane of the sheet. (b) A right-handed crossover connection between successive strands of a parallel  $\beta$  sheet. Nearly all such crossover connections in

proteins have this chirality (see, e.g., Fig. 8-19b). (c) A left-handed crossover connection between parallel  $\beta$  sheet strands. Connections with this chirality are rare. [After Richardson, J.S., *Adv. Protein Chem.* **34**, 290, 295 (1981).]

term **random coil**, which refers to the totally disordered and rapidly fluctuating set of conformations assumed by denatured proteins and other polymers in solution.

Globular proteins consist largely of approximately straight runs of secondary structure joined by stretches of polypeptide that abruptly change direction. Such **reverse turns** or  **$\beta$  bends** (so named because they often connect successive strands of antiparallel  $\beta$  sheets) almost always occur at protein surfaces; indeed, they partially define these surfaces. Most reverse turns involve four successive amino acid residues more or less arranged in one of two ways, Type I and Type II, that differ by a  $180^\circ$  flip of the peptide unit linking residues 2 and 3 (Fig. 8-22). Both types of  $\beta$  bends contain a hydrogen bond, although deviations from these ideal conformations often disrupt this hydrogen bond. Type I  $\beta$  bends may be considered to be distorted sections of  $3_{10}$  helix. In Type II  $\beta$  bends, the oxygen atom of residue 2 crowds the  $C_\beta$  atom of residue 3, which is therefore usually Gly. Residue 2 of either type of  $\beta$  bend is often Pro since it can readily assume the required conformation.

Many proteins have regions that are truly disordered. Extended, charged surface groups such as Lys side chains or the N- or C-termini of polypeptide chains are good examples: They often wave around in solution because there are few forces to hold them in place (Section 8-4). Often entire peptide chain segments are disordered. Such segments may have functional roles, such as the binding of a specific molecule, so they may be disordered in one state of

the protein (molecule absent) and ordered in another (molecule bound). This is one mechanism whereby a protein can interact flexibly with another molecule in the performance of its biological function.

## 2 FIBROUS PROTEINS

*Fibrous proteins* are highly elongated molecules whose secondary structures are their dominant structural motifs. Many fibrous proteins, such as those of skin, tendon, and bone, function as structural materials that have a protective, connective, or supportive role in living organisms. Others, such as muscle and ciliary proteins, have motive functions. In this section, we shall discuss structure–function relationships in two common and well-characterized fibrous proteins: keratin and collagen (muscle and ciliary proteins are considered in Section 35-3). The structural simplicity of these proteins relative to those of globular proteins (Section 8-3) makes them particularly amenable to understanding how their structures suit them to their biological roles.

Fibrous molecules rarely crystallize and hence are usually not subject to structural determination by single-crystal X-ray structure analysis (Section 8-3A). Rather than crystallizing, they associate as fibers in which their long molecular axes are more or less parallel to the fiber axis but in which they lack specific orientation in other directions. The X-ray diffraction pattern of such a fiber, Fig. 8-23, for

**Figure 8-21** Origin of a right-handed crossover connection. A possible folding scheme illustrates how right-handed polypeptide chain twisting favors the formation of right-handed crossover connections between successive strands of a parallel  $\beta$  sheet.

(a) Type I  $\beta$  bend(b) Type II  $\beta$  bend

**Figure 8-22** Reverse turns in polypeptide chains. (a) A Type I  $\beta$  bend, which has the following torsion angles:

$$\phi_2 = -60^\circ / \psi_2 = -30^\circ$$

$$\phi_3 = -90^\circ / \psi_3 = 0^\circ$$

(b) A Type II  $\beta$  bend, which has the following torsion angles:

$$\phi_2 = -60^\circ / \psi_2 = 120^\circ$$

$$\phi_3 = -90^\circ / \psi_3 = 0^\circ$$

Variations from these ideal conformation angles by as much as  $30^\circ$  are common. Hydrogen bonds are represented by dashed lines. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]  See Kinemage Exercise 3-4

**Figure 8-23** X-ray diffraction photograph of a fiber of *Bombyx mori* silk. The photograph was obtained by shining a collimated beam of monochromatic X-rays through the silk fiber and recording the diffracted X-rays on a sheet of photographic film placed behind the fiber. The photograph has only a few spots and thus contains little structural information. [From March, R.E., Corey, R.B., and Pauling, L., *Biochim. Biophys. Acta* **16**, 5 (1955).]

example, contains little information, far less than would be obtained if the fibrous protein could be made to crystallize. Consequently, the structures of fibrous proteins are not known in great detail. Nevertheless, the original X-ray studies of proteins were carried out in the early 1930s by William Astbury on such easily available protein fibers as wool and tendon. Since the first X-ray crystal structure of a protein was not determined until the late 1950s, these fiber studies constituted the first tentative steps in the elucidation of the structural principles governing proteins and formed much of the experimental basis for Pauling's formulation of the  $\alpha$  helix and  $\beta$  pleated sheet.

### A. $\alpha$ Keratin—A Helix of Helices

**Keratin** is a mechanically durable and chemically unreactive protein that occurs in all higher vertebrates. It is the principal component of their horny outer epidermal layer, comprising up to 85% of the cellular protein, and its related appendages such as hair, horns, nails, and feathers. Keratins have been classified as either  $\alpha$  keratins, which occur in mammals, or  $\beta$  keratins, which occur in birds and reptiles. Mammals have over 50 keratin genes, which are expressed in a tissue-specific manner and whose products are classified as belonging to families of relatively acidic (Type I) and

relatively basic (Type II) polypeptides. Keratin filaments, which form the intermediate filaments of skin cells (Section 1-2Ae), must contain at least one member of each type.

Electron microscopic studies indicate that hair, which is composed mainly of  $\alpha$  keratin, consists of a hierarchy of structures (Figs. 8-24 and 8-25). A typical hair is  $\sim 20\ \mu\text{m}$  in diameter and is constructed from dead cells, each of which contains packed **macrofibrils** ( $\sim 2000\ \text{\AA}$  in diameter) that are oriented parallel to the hair fiber (Fig. 8-24). The macrofibrils are constructed from **microfibrils** ( $\sim 80\ \text{\AA}$  wide) that are cemented together by an amorphous protein matrix of high sulfur content.

Moving to the molecular level, the X-ray diffraction pattern of  $\alpha$  keratin resembles that expected for an  $\alpha$  helix (hence the name  $\alpha$  keratin). Yet  $\alpha$  keratin exhibits a  $5.1\text{-\AA}$  spacing rather than the  $5.4\text{-\AA}$  distance corresponding to the pitch of the  $\alpha$  helix. This observation, together with a variety of physical and chemical evidence, suggests that  *$\alpha$  keratin polypeptides form closely associated pairs of  $\alpha$  helices in which each pair is composed of a Type I and a Type II keratin chain twisted in parallel into a left-handed coil* (Fig. 8-25a). The normal  $5.4\text{-\AA}$  repeat distance of each  $\alpha$  helix in the pair is thereby tilted with respect to the axis of this assembly, yielding the observed  $5.1\text{-\AA}$  spacing. This assembly is said to have a **coiled coil** structure because each  $\alpha$  helix axis itself follows a helical path.

*The conformation of  $\alpha$  keratin's coiled coil is a consequence of its primary structure:* The central  $\sim 310$ -residue segment of each polypeptide chain has a heptad (7-residue) pseudorepeat, *a-b-c-d-e-f-g*, with nonpolar residues predominating at positions *a* and *d*. Since an  $\alpha$  helix has 3.6 residues per turn,  $\alpha$  keratin's *a* and *d* residues line up on one side of the  $\alpha$  helix to form a hydrophobic strip that promotes its lengthwise associ-

ation with a similar strip on another such  $\alpha$  helix (Fig. 8-26; hydrophobic residues, as we shall see in Section 8-4C, have a strong tendency to associate). Indeed, the slight discrepancy between the 3.6 residues per turn of a normal  $\alpha$  helix and the  $\sim 3.5$ -residue repeat of  $\alpha$  keratin's hydrophobic strip is responsible for the coiled coil's coil. The resulting  $18^\circ$  inclination of the  $\alpha$  helices relative to one another permits the helical ridges formed by the side chains on one helix to fit into the grooves between these ridges on the other helix, thereby greatly increasing their favorable interactions. Coiled coils, as we shall see, are common components of globular proteins as well as of other fibrous proteins.

The higher order substructure of  $\alpha$  keratin is poorly understood. The N- and C-terminal portions of each polypeptide probably have a flexible conformation and facilitate the assembly of the coiled coils into  $\sim 30\text{-\AA}$ -wide protofilaments. These are thought to consist of two staggered antiparallel rows of head-to-tail aligned coiled coils (Fig. 8-25b). Two such protofilaments are thought to comprise an  $\sim 50\text{-\AA}$ -wide protofibril, four of which, in turn, coil around each other to form a microfibril (Fig. 8-25c).

$\alpha$  Keratin is rich in Cys residues, which form disulfide bonds that cross-link adjacent polypeptide chains. This accounts for  $\alpha$  keratin's insolubility and resistance to stretching, two of its most important biological properties. The  $\alpha$  keratins are classified as "hard" or "soft" according to whether they have a high or low sulfur content. Hard keratins, such as those of hair, horn, and nail, are less pliable

**Figure 8-24** The macroscopic organization of hair. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

**Figure 8-25** The structure of  $\alpha$  keratin. (a) The central  $\sim 310$  residues of one polypeptide chain each of Types I and II  $\alpha$  keratins associate in a dimeric coiled coil. The conformations of the polypeptides' globular N- and C-terminal domains are unknown. (b) Protofilaments are formed from two staggered antiparallel rows of associated head-to-tail coiled coils. (c) The protofilaments dimerize to form a protofibril, four of which form a microfibril. The structures of these latter assemblies are poorly characterized but are thought to form helical arrays.

**Figure 8-26** The two-stranded coiled coil. (a) View down the coil axis showing the interactions between the nonpolar edges of the  $\alpha$  helices. The  $\alpha$  helices have the pseudorepeating heptameric sequence *a-b-c-d-e-f-g* in which residues *a* and *d* are predominantly nonpolar. [After McLachlan, A.D. and Stewart, M., *J. Mol. Biol.* **98**, 295 (1975).] (b) Side view of the polypeptide backbones drawn in stick form (left) and of the entire polypeptides drawn in space-filling form (right). The atoms are colored according to type with C green in one chain and cyan in the other, N blue, O red, and S yellow. The 81-residue chains are parallel with their N-terminal ends above. Note that in the space-filling model the side chains contact each other. This coiled coil is a portion of the muscle protein tropomyosin (Section 35-3Ac). [Based on an X-ray structure by Carolyn Cohen, Brandeis University. PDBid 1IC2.]  See Kinemage Exercises 4-1 and 4-2

than soft keratins, such as those of skin and callus, because the disulfide bonds resist any forces tending to deform them. The disulfide bonds can be reductively cleaved with mercaptans (Section 7-1B). Hair so treated can be curled and set in a “permanent wave” by application of an oxidizing agent which reestablishes the disulfide bonds in the new “curled” conformation. Although the insolubility of  $\alpha$  keratin prevents most animals from digesting it, the clothes moth larva,

which has a high concentration of mercaptans in its digestive tract, can do so to the chagrin of owners of woolen clothing.

The springiness of hair and wool fibers is a consequence of the coiled coil’s tendency to untwist when stretched and to recover its original conformation when the external force is relaxed. After some of its disulfide bonds have been cleaved, however, an  $\alpha$  keratin fiber can be stretched to over twice its original length by the application of moist heat. In this process, as X-ray analysis indicates, the  $\alpha$  helical structure extends with concomitant rearrangement of its hydrogen bonds to form a  $\beta$  pleated sheet.  $\beta$  Keratin, such as that of feathers, exhibits a similar X-ray pattern in its native state (hence the name  $\beta$  sheet).

#### a. Keratin Defects Result in a Loss of Skin Integrity

The inherited skin diseases **epidermolysis bullosa simplex (EBS)** and **epidermolytic hyperkeratosis (EHK)** are characterized by skin blistering arising from the rupture of epidermal basal cells (Fig. 1-14d) and suprabasal cells, respectively, as caused by mechanical stresses that normally would be harmless. Symptomatic variations in these conditions range from severely incapacitating, particularly in early childhood, to barely noticeable. In families afflicted with EBS, sequence abnormalities may be present in either keratin 14 or keratin 5, the dominant Types I and II keratins in basal skin cells. EHK is similarly caused by defects in keratins 1 or 10, the dominant Types I and II keratins in suprabasal cells (which arise through the differentiation of basal cells, a process in which the synthesis of keratins 14 and 5 is switched off and that of keratins 1 and 10 is turned on). These defects evidently interfere with normal filament formation, thereby demonstrating the function of the keratin cytoskeleton in maintaining the mechanical integrity of the skin.

#### B. Collagen—A Triple Helical Cable

**Collagen** (Greek: *kolla*, glue) occurs in all multicellular animals and is the most abundant protein of vertebrates, comprising  $\sim 30\%$  of their protein mass. It is an extracellular protein that is organized into insoluble fibers of great tensile strength. This suits collagen to its role as the major stress-bearing component of **connective tissues** such as bone, teeth, cartilage, tendon, ligament, and the fibrous matrices of skin and blood vessels. Collagen occurs in virtually every tissue.

Vertebrates have 46 genetically distinct polypeptide chains comprising 28 distinct collagen types that occur in different tissues of the same individual. The most prominent of these are listed in Table 8-2. A single molecule of

**Table 8-2** The Most Abundant Types of Collagen

Type	Chain Composition	Distribution
I	$[\alpha 1(\text{I})]_2\alpha 2(\text{I})$	Skin, bone, tendon, blood vessels, cornea
II	$[\alpha 1(\text{II})]_3$	Cartilage, intervertebral disk
III	$[\alpha 1(\text{III})]_3$	Blood vessels, fetal skin

Source: Eyre, D.R., *Science* **207**, 1316 (1980).

Type I collagen is composed of three polypeptide chains with an aggregate molecular mass of ~285 kD. It has a rod-like shape with a length of ~3000 Å and a width of ~14 Å.

Collagen has a distinctive amino acid composition: Nearly one-third of its residues are Gly; another 15 to 30% of them are Pro and **4-hydroxyprolyl (Hyp)** residues:

#### 5-Hydroxylysyl residue (Hyl)

**3-Hydroxyprolyl** and **5-hydroxylysyl (Hyl)** residues also occur in collagen but in smaller amounts. Radioactive labeling experiments have established that these nonstandard hydroxylated amino acids are not incorporated into collagen during polypeptide synthesis: If  $^{14}\text{C}$ -labeled 4-hydroxyproline is administered to a rat, the collagen synthesized is not radioactive, whereas radioactive collagen is produced if the rat is fed  $^{14}\text{C}$ -labeled proline. The hydroxylated residues appear after the collagen polypeptides are synthesized, when certain Pro residues are converted to Hyp in a reaction catalyzed by the enzyme **prolyl hydroxylase**.

Hyp confers stability on collagen, possibly through intramolecular hydrogen bonds that involve bridging water molecules. If, for example, collagen is synthesized under conditions that inactivate prolyl hydroxylase, it loses its native conformation (denatures) at 24°C, whereas normal collagen denatures at 39°C (heat-denatured collagen is known as **gelatin**). Prolyl hydroxylase requires **ascorbic acid (vitamin C)**

**Ascorbic acid (vitamin C)**

to maintain its enzymatic activity. In the vitamin C deficiency disease **scurvy**, the collagen synthesized cannot form

fibers properly. This results in the skin lesions, blood vessel fragility, and poor wound healing that are symptomatic of this ultimately fatal vitamin deficiency disease.

#### a. Collagen Has a Triple Helical Structure

The amino acid sequence of bovine collagen  $\alpha 1(I)$ , which is similar to that of other collagens, consists of monotonously repeating triplets of sequence Gly-X-Y over a continuous 1011-residue stretch of its 1042-residue polypeptide chain (Fig. 8-27). Here X is often Pro (~28%) and Y is often Hyp (~38%). The restriction of Hyp to the Y position stems from the specificity of prolyl hydroxylase. Hyl is similarly restricted to the Y position.

The high Gly, Pro, and Hyp content of collagen suggests that its polypeptide backbone conformation resembles those of the polyglycine II and polyproline II helices (Fig. 8-15). X-ray fiber diffraction and model building studies by Alexander Rich and Francis Crick and by Ramachandran led them to independently propose, in 1955, that collagen's three polypeptide chains, which individually resemble polyproline II helices, are parallel and wind around each other with a gentle, right-handed, ropelike twist to form a triple helical structure (Fig. 8-28). It was not until 1994, however, that Helen Berman and Barbara Brodsky confirmed this model through their X-ray crystal structure determination of the collagenlike polypeptide (Pro-Hyp-Gly)<sub>10</sub> in which the fifth Gly is replaced by Ala (Fig. 8-29a). In this structure, every third residue of each polypeptide chain passes through the center of the triple helix, which is so crowded that only a Gly side chain can fit there (Fig. 8-29b). This crowding explains the absolute requirement for a Gly at every third position of a collagen polypeptide chain (Fig. 8-27). It also requires that the three polypeptide chains be staggered so that the Gly, X, and Y residues from the three chains occur at similar levels (Fig. 8-30). The staggered peptide groups are oriented such that the N—H of each Gly makes a strong hydrogen bond with the carbonyl oxygen of

**Figure 8-27** The amino acid sequence at the C-terminal end of the triple helical region of the bovine  $\alpha 1(I)$  collagen chain. Note the repeating triplets Gly-X-Y, where X is often Pro and Y is often Hyp. Here Gly is shaded in purple, Pro in tan, and Hyp and Hyp\* (3-hydroxyPro) in brown. [From Bornstein, P. and Traub, W., in Neurath, H. and Hill, R.L. (Eds.), *The Proteins* (3rd ed.), Vol. 4, p. 483, Academic Press (1979).]

**Figure 8-28 The triple helix of collagen.** This diagram indicates how the left-handed polypeptide helices are twisted together to form a right-handed superhelical structure. Ropes and cables are similarly constructed from hierarchies of fiber bundles that are alternately twisted in opposite directions. An individual collagen polypeptide helix has 3.3 residues per turn and a pitch of 10.0 Å (in contrast to polyproline II's 3.0 residues per turn and pitch of 9.4 Å; Fig. 8-15). The collagen triple helix has 10 Gly-X-Y units per turn and a pitch of 86.1 Å. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

**Figure 8-30** A schematic diagram showing the interchain hydrogen bonding (dashed lines) in the Gly-containing regions of the triple helix. This is a cylindrical projection with Chain 1 repeated on the right for clarity. Note that the three chains are each vertically staggered by one residue so that a Gly, a Pro, and a Hyp from the three different chains occur on the same level. [After Bella, J., Eaton, M., Brodsky, B., and Berman, H.M., *Science* 266, 78 (1994).] See Kinemage Exercises 4-3 and 4-4

**Figure 8-29 Structure of a collagen model peptide.** In this X-ray structure of (Pro-Hyp-Gly)<sub>10</sub>, the fifth Gly of each peptide has been replaced by Ala. (a) A stick model of the central portion of the triple helix oriented with its N-termini at the bottom. The C atoms of the three chains are colored orange, magenta, and gray. The N and O atoms on all chains are blue and red. Note how the replacement of Gly with the bulkier Ala (C atoms green) distorts the triple helix. (b) This view from the N-terminus down the helix axis shows the interchain hydrogen bonding associations. Three consecutive residues from each chain are shown in stick form (C atoms green). Hydrogen bonds are represented by dashed lines from Gly N atoms to Pro O atoms in adjacent chains. Dots represent the van der Waals surfaces of the backbone atoms of the central residue in each chain. Note the close packing of the atoms along the triple helix axis. The substitution of a centrally located Gly C<sub>α</sub> atom (CH<sub>2</sub> group) by any other residue would distort the triple helix. [Based on an X-ray structure by Helen Berman, Rutgers University, and Barbara Brodsky, UMDNJ—Robert Wood Johnson Medical School. PDBid 1CAG.] See Kinemage Exercises 4-3 and 4-4

an X (Pro) residue on a neighboring chain. The bulky and relatively inflexible Pro and Hyp residues confer rigidity on the entire assembly.

*Collagen's well-packed, rigid, triple helical structure is responsible for its characteristic tensile strength.* As with the twisted fibers of a rope, the extended and twisted polypeptide chains of collagen convert a longitudinal tensional force to a more easily supported lateral compressional force on the almost incompressible triple helix. This occurs because the oppositely twisted directions of collagen's polypeptide chains and triple helix (Fig. 8-28) prevent the twists from being pulled out under tension (note that successive levels of fiber bundles in ropes and cables are likewise oppositely twisted). The successive helical hierarchies in other fibrous proteins exhibit similar alternations of twist directions, for example, keratin (Section 8-2A) and muscle (Section 35-3Aa).

### b. Collagen Is Organized into Fibrils

Types I, II, III, V, and XI collagens form distinctive banded fibrils (Fig. 8-31) that are mostly, if not entirely, composed of several different types of collagens. These fibrils have a periodicity of  $\sim 670$  Å and a diameter of 100 to 2000 Å depending on the types of collagen they contain and their tissue of origin (the other collagen types form different sorts of aggregates such as networks; we will not discuss them further). X-ray fiber diffraction studies reveal that the molecules in fibrils of Type I collagen are packed in a hexagonal array. Computerized model building studies further indicate that these collagen molecules are precisely staggered parallel to the fibril axis (Fig. 8-32). The darker

**Figure 8-31** Electron micrograph of collagen fibrils from skin. [Courtesy of Jerome Gross, Massachusetts General Hospital.]

portions of the banded structures correspond to the 400-Å “holes” on the surface of the fibril between head-to-tail aligned collagen molecules. Structural and energetic considerations suggest that the conformations of individual collagen molecules, much like those of individual  $\alpha$  helices and  $\beta$  sheets, are but marginally stable (Section 8-4). The driving force for the assembly of collagen molecules into a fibril is apparently provided by the added hydrophobic interactions within the fibrils in a manner analogous to the packing of secondary structural elements to form a globular protein (Section 8-3B).

Collagen contains covalently attached carbohydrates in amounts that range from  $\sim 0.4$  to 12% by weight, depending on the collagen's tissue of origin. The carbohydrates, which consist mostly of glucose, galactose, and their disaccharides, are covalently attached to collagen at its Hyl residues by specific enzymes:

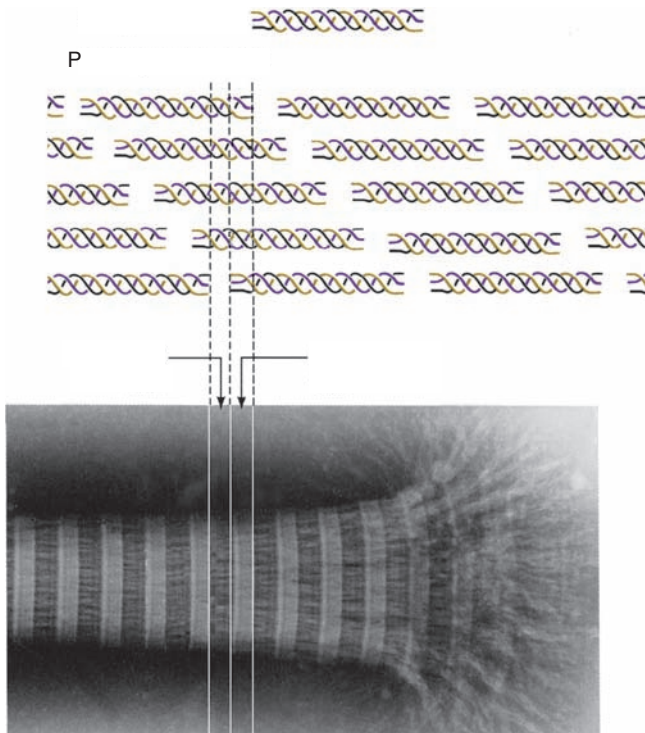

Although the function of carbohydrates in collagen is unknown, the observation that they are located in the “hole” regions of the collagen fibrils suggests that they are involved in directing fibril assembly.

### c. Collagen Fibrils Are Covalently Cross-Linked

Collagen's insolubility in solvents that disrupt hydrogen bonding and ionic interactions is explained by the observation that it is both intramolecularly and intermolecularly covalently cross-linked. The cross-links cannot be disulfide bonds, as in keratin, because collagen is almost devoid of Cys residues. Rather, they are derived from Lys and His side chains in reactions such as those in Fig. 8-33. **Lysyl oxidase**, a Cu-containing enzyme that converts Lys residues to those of the aldehyde **allysine**, is the only enzyme implicated in this cross-linking process. Up to four side chains can be covalently bonded to each other. The cross-links do not form at random but, instead, tend to occur near the N- and C-termini of the collagen molecules.

The importance of cross-linking to the normal functioning of collagen is demonstrated by the disease **lathyrism**,

**Figure 8-32** Banded appearance of collagen fibrils. The banded appearance in the electron microscope arises from the schematically represented staggered arrangement of collagen molecules (*top*) that results in a periodically indented surface. *D*, the distance between cross striations, is  $\sim 670$  Å, so the length of a 3000-Å-long collagen molecule is  $4.4D$ . [Courtesy of Karl A. Piez, Collagen Corporation.]

which occurs in humans and other animals as a result of the regular ingestion of seeds from the sweet pea *Lathyrus odoratus*. The symptoms of this condition are serious abnormalities of the bones, joints, and large blood vessels, which are caused by an increased fragility of the collagen fibers. The causative agent of lathyrism,  **$\beta$ -aminopropionitrile**,

inactivates lysyl oxidase by covalently binding to its active site. This results in markedly reduced cross-linking in the collagen of lathyratic animals.

**Figure 8-33** A biosynthetic pathway for cross-linking Lys, Hyl, and His side chains in collagen. The first step in the reaction is the lysyl oxidase-catalyzed oxidative deamination of Lys to form the aldehyde allysine. Two such aldehydes then undergo an aldol condensation to form **allysine aldol**. This product can react with His to form **aldol-histidine**, which in turn, can react with Hyl to form a Schiff base (an imine bond), thereby cross-linking four side chains.

**Table 8-3** The Arrangement of Collagen Fibrils in Various Tissues

Tissue	Arrangement
Tendon	Parallel bundles
Skin	Sheets of fibrils layered at many angles
Cartilage	No distinct arrangement
Cornea	Planar sheets stacked crossways so as to minimize light scattering

The degree of cross-linking of the collagen from a particular tissue increases with the age of the animal. This is why meat from older animals is tougher than that from younger animals. In fact, individual molecules of collagen (called **tropocollagen**) can only be extracted from the tissues of very young animals. Collagen cross-linking is not the central cause of aging, however, as is demonstrated by the observation that lathyrogenic agents do not slow the aging process.

The collagen fibrils in various tissues are organized in ways that largely reflect the functions of the tissues (Table 8-3). Thus tendons (the “cables” connecting muscles to bones), skin (a tear-resistant outer fabric), and cartilage (which has a load-bearing function) must support stress in predominantly one, two, and three dimensions, respectively, and their component collagen fibrils are arrayed accordingly. How collagen fibrils are laid down in these arrangements is unknown. However, some of the factors guiding collagen molecule assembly are discussed in Sections 32-5Aa and 32-5Ba.

#### d. Collagen Defects Are Responsible for a Variety of Human Diseases

Numerous heritable disorders of collagen are known. Mutations of Type I collagen, which constitutes the major structural protein in most human tissues, usually result in **osteogenesis imperfecta (brittle bone disease)**. The severity of this disease varies with the nature and position of the mutation: Even a single amino acid change can have lethal consequences. Mutations may affect the structure of the collagen molecule or how it forms fibrils. For example, the substitution of Ala for the central Gly in each polypeptide chain of the structure shown in Fig. 8-29a, which reduces the denaturation temperature of this model compound from 62°C to 29°C, locally distorts the collagen triple helix. The need to accommodate the three additional methyl groups in the tightly packed interior of the triple helix pries apart the polypeptide chains in the region of the substitutions so as to rupture the hydrogen bonds that would otherwise link the main chain N—H group of each Ala (normally Gly) to the carbonyl oxygen of the adjacent Pro in a neighboring chain (Fig. 8-34). Rather, these hydrogen bonding groups are bridged by water molecules that insinuate themselves into the distorted part of the structure. Similar distortions almost certainly occur in the Gly → X mutated collagens responsible for such diseases as osteoge-

**Figure 8-34** Distorted structure in abnormal collagen. This schematic diagram shows hydrogen bonding interactions in the Ala-containing portions of the X-ray structure of (Pro-Hyp-Gly)<sub>10</sub> in which the fifth Gly is replaced by Ala. This cylindrical projection is in the style of Fig. 8-30. Note how the Ala side chains (large green balls) distort the triple helix so as to disrupt the normally occurring Gly NH ⋯ Pro O hydrogen bonds and replace them with water-bridged hydrogen bonds. [After Bella, J., Eaton, M., Brodsky, B., and Berman, H.M., *Science* **266**, 78 (1994).]

nesis imperfecta. Such mutations tend to be dominant because they affect either the folding of the triple helix or fibril formation even when normal chains are also members of the triple helix. All known amino acid changes within Type I collagen’s triple helical region result in abnormalities, indicating that the structural integrity of this region is essential for proper collagen function.

Many collagen disorders are characterized by deficiencies in the amount of a particular collagen type synthesized or by abnormal activities of collagen-processing enzymes such as lysyl hydroxylase or lysyl oxidase. One group of at least 10 different collagen deficiency diseases, the **Ehlers–Danlos syndromes**, are all characterized by hyperextensibility of the joints (really the ligaments holding them together) and skin. This is because these tissues also contain large amounts of **elastin**, a protein with rubberlike elastic properties. Consequently, the loss of the rigidity normally conferred by collagen coupled with the presence of elastin results in the hyperextensibility of the affected tissues. Several degenerative diseases exhibit collagen abnormalities in certain tissues, including cartilage in **osteoarthritis** and the fibrous **atherosclerotic plaques** in human arteries.

### 3 GLOBULAR PROTEINS

**Globular proteins** comprise a highly diverse group of substances that, in their native states, exist as compact spheroidal molecules. Enzymes are globular proteins, as are transport and receptor proteins. In this section we consider the tertiary structures of globular proteins. However, since most of our detailed structural knowledge of proteins, and thus to a large extent their function, has resulted from X-ray crystal structure determinations of globular proteins and, more recently, from their nuclear magnetic resonance (NMR) structure determinations, we begin this section with a discussion of the capabilities and limitations of these powerful techniques.

#### A. Interpretation of Protein X-Ray and NMR Structures

*X-ray crystallography is a technique that directly images molecules.* X-rays must be used to do so because, according to optical principles, the uncertainty in locating an object is approximately equal to the wavelength of the radiation used to observe it (covalent bond distances and the wavelengths of the X-rays used in structural studies are both  $\sim 1.5 \text{ \AA}$ ; individual molecules cannot be seen in a light microscope because visible light has a minimum

**Figure 8-35** X-ray diffraction photograph of a single crystal of sperm whale myoglobin. The intensity of each diffraction maximum (the darkness of each spot) is a function of the myoglobin crystal's electron density. The photograph contains only a small fraction of the total diffraction information available from a myoglobin crystal. [Courtesy of John Kendrew, Cambridge University, U.K.]

wavelength of  $4000 \text{ \AA}$ ). There is, however, no such thing as an X-ray microscope because there are no X-ray lenses. Rather, a crystal of the molecule to be imaged is exposed to a collimated beam of X-rays and the consequent diffraction pattern is recorded by a radiation detector or, now infrequently, on photographic film (Fig. 8-35). The X-rays used in structural studies are produced by laboratory X-ray generators or, increasingly often, by **synchrotrons**, a type of particle accelerator that produces X-rays of far greater intensity. The intensities of the diffraction maxima (darkness of the spots on a film) are then used to construct mathematically the three-dimensional image of the crystal structure through methods that are beyond the scope of this text. In what follows, we discuss some of the special problems associated with interpreting the X-ray crystal structures of proteins.

X-rays interact almost exclusively with the electrons in matter, not the far more massive nuclei. An X-ray structure is therefore an image of the **electron density** of the object under study. Such **electron density maps** may be presented as a series of parallel sections through the object. On each section, the electron density is represented by contours (Fig. 8-36a) in the same way that altitude is represented by the contours on a topographic map. A stack of such sections, drawn on transparencies, yields a three-dimensional electron density map (Fig. 8-36b). Modern structural analysis, however, is carried out with the aid of computers that graphically display electron density maps that are contoured in three dimensions (Fig. 8-36c).

#### a. Most Protein Crystal Structures Exhibit Less than Atomic Resolution

The molecules in protein crystals, as in other crystalline substances, are arranged in regularly repeating three-dimensional lattices. Protein crystals, however, differ from those of most small organic and inorganic molecules in being highly hydrated; they are typically 40 to 60% water by volume. The aqueous solvent of crystallization is necessary for the structural integrity of the protein crystals, as J.D. Bernal and Dorothy Crowfoot Hodgkin first noted in 1934 when they carried out the original X-ray studies of protein crystals. This is because water is required for the structural integrity of native proteins themselves (Section 8-4).

The large solvent content of protein crystals gives them a soft, jellylike consistency, so that their molecules often lack the rigid order characteristic of crystals of small molecules such as NaCl or glycine. The molecules in a protein crystal are typically disordered by more than an angstrom, so that the corresponding electron density map lacks information concerning structural details of smaller size. The crystal is therefore said to have a resolution limit of that size. Protein crystals typically have resolution limits in the range  $1.5$  to  $3.0 \text{ \AA}$ , although some are better ordered (have higher resolution, that is, a lesser resolution limit) and many are less ordered (have lower resolution).

Since an electron density map of a protein must be interpreted in terms of its atomic positions, the accuracy and

**Figure 8-36** Electron density maps of proteins. (a) A section through the 2.0-Å-resolution electron density map of sperm whale myoglobin, which contains the heme group (red). The large peak at the center of the map represents the electron-dense Fe atom. [After Kendrew, J.C., Dickerson, R.E., Strandberg, B.E., Hart, R.G., Davies, D.R., Phillips, D.C., and Shore, V.C., *Nature* **185**, 434 (1960).] (b) A portion of the 2.4-Å-resolution electron density map of myoglobin constructed from a stack of contoured transparencies. Dots have been placed at the positions deduced for the nonhydrogen atoms. The heme group is seen edge-on together with its two associated His residues and a water molecule, W. An  $\alpha$  helix, the so-called E helix (Fig. 8-12), extends across the bottom of the map. Another  $\alpha$  helix, the C helix, extends into the plane of the paper on the upper right. Note the hole along its axis. [Courtesy of John Kendrew, Cambridge University, U.K.] (c) A thin section through the 1.5-Å-resolution electron density map of *E. coli* 6-hydroxymethyl-7,8-dihydropterin pyrophosphokinase (which catalyzes the first reaction in the biosynthesis of folic acid; Section 26-4D) contoured in three dimensions. Only a single contour level (cyan) is shown, together with an atomic model of the corresponding polypeptide segments colored according to atom type (C yellow, O red, and N blue), with a water molecule represented by a red sphere. [Courtesy of Xinhua Ji, NCI-Frederick Cancer Research and Development Center, Frederick, Maryland.]

even the feasibility of a crystal structure analysis depends on the crystal's resolution limit. Indeed, the ability to obtain crystals of sufficiently high resolution is a major limiting factor in determining the X-ray crystal structure of a protein or other macromolecule. Figure 8-37 indicates how the quality (degree of focus) of an electron density map varies with its resolution limit. At 6-Å resolution, the presence of a molecule the size of diketopiperazine is difficult to discern. At 2.0-Å resolution, its individual atoms cannot yet be distinguished, although its molecular shape has be-

come reasonably evident. At 1.5-Å resolution, which roughly corresponds to a bond distance, individual atoms become partially resolved. At 1.1-Å resolution, atoms are clearly visible.

Most protein crystal structures are too poorly resolved for their electron density maps to reveal clearly the positions of individual atoms (e.g., Fig. 8-36). Nevertheless, the distinctive shape of the polypeptide backbone usually permits it to be traced, which, in turn, allows the positions and orientations of its side chains to be deduced (e.g., Fig. 8-37c).

**Figure 8-37** Sections through the electron density map of diketopiperazine calculated at the indicated resolution levels. Hydrogen atoms are not apparent in this map because of their low electron density. [After Hodgkin, D.C., *Nature* **188**, 445 (1960).]

Yet side chains of comparable size and shape, such as those of Leu, Ile, and Thr, cannot always be differentiated with a reasonable degree of confidence (hydrogen atoms, having but one electron, are only visible in the few macromolecular X-ray structures with resolution limits less than  $\sim 1.2$  Å), so that a protein structure cannot be elucidated from its electron density map alone. Rather, the primary structure of the protein must be known, thereby permitting the sequence of amino acid residues to be fitted to its electron density map. Mathematical refinement can then reduce the uncertainty in the crystal structure's atomic positions to as little as 0.1 Å (in contrast, positional errors in the most accurately determined small molecule X-ray structures are as little as 0.001 Å).

### b. Most Crystalline Proteins Maintain Their Native Conformations

What is the relationship between the structure of a protein in a crystal and that in solution, where globular proteins normally function? Several lines of evidence indicate that *crystalline proteins assume very nearly the same structures that they have in solution*:

1. A protein molecule in a crystal is essentially in solution because it is bathed by the solvent of crystallization over all of its surface except for the few, generally small patches that contact neighboring protein molecules. In fact, the 40 to 60% water content of typical protein crystals is similar to that of many cells (e.g., see Fig. 1-13).

2. A protein may crystallize in one of several forms or "habits," depending on crystallization conditions, that differ in how the protein molecules are arranged in space relative to each other. In the numerous cases in which different crystal forms of the same protein have been independently analyzed, the molecules have virtually identical conformations. Similarly, in the several cases in which both the X-ray crystal structure and the solution NMR structure of the same protein have been determined, the

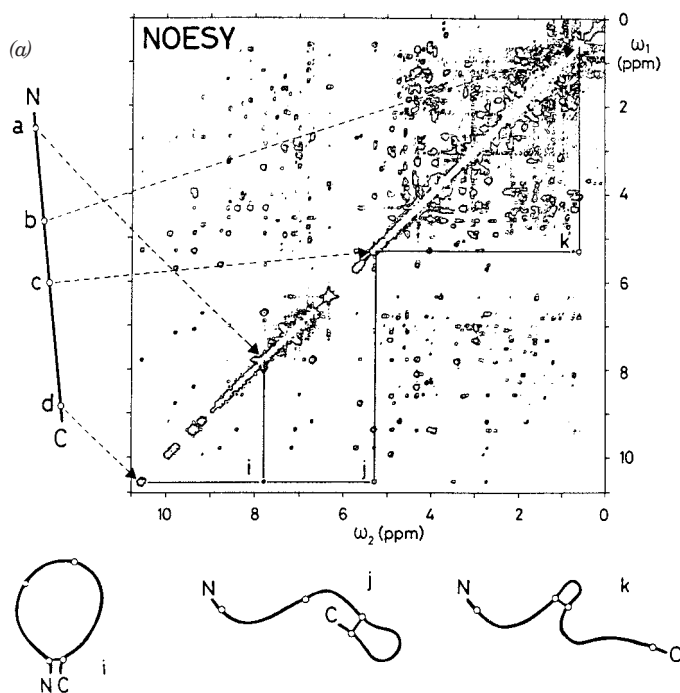

two structures are, for the most part, identical to within experimental error (see below). Evidently, crystal packing forces do not greatly perturb the structures of protein molecules.

3. The most compelling evidence that crystalline proteins have biologically relevant structures, however, is the observation that many enzymes are catalytically active in the crystalline state. The catalytic activity of an enzyme is very sensitive to the relative orientations of the groups involved in binding and catalysis (Chapter 15). Active crystalline enzymes must therefore have conformations that closely resemble their solution conformations.

### c. Protein Structure Determination by NMR

The determination of the three-dimensional structures of small globular proteins in aqueous solution has become possible, since the mid 1980s, through the development of **two-dimensional (2D) NMR spectroscopy** (and, more recently, of 3D and 4D techniques), in large part by Kurt Wüthrich. Such NMR measurements, whose description is beyond the scope of this text, yield the interatomic distances between specific protons that are  $< 5$  Å apart in a protein of known sequence. The interproton distances may be either through space, as determined by nuclear Overhauser effect spectroscopy (NOESY, Fig. 8-38a), or through bonds, as determined by correlated spectroscopy (COSY). These distances, together with known geometric constraints such as covalent bond distances and angles, group planarity, chirality, and van der Waals radii, are used to compute the protein's three-dimensional structure. However, since interproton distance measurements are imprecise, they are insufficient to imply a unique structure. Rather, they are consistent with an ensemble of closely related structures. Consequently, an NMR structure of a protein (or any other macromolecule with a well-defined structure) is often presented as a representative sample of structures that are consistent with the constraints (e.g., Figure 8-38b). The "tightness" of a bundle of such structures is

indicative both of the accuracy with which the structure is known, which in the most favorable cases is roughly comparable to that of an X-ray crystal structure with a resolution of 2 to 2.5 Å, and of the conformational fluctuations that the protein undergoes (Section 9-4). Although present NMR methods are limited to determining the structures of macromolecules with molecular masses no greater than ~100 kD, advances in NMR technology suggest that this limit may increase to ~1000 kD or more.

In most of the several cases in which both the NMR and X-ray crystal structures of a particular protein have been determined, the two structures are in good agreement. There are, however, a few instances in which there are real differences between the corresponding X-ray and NMR structures. These, for the most part, involve surface residues that, in the crystal, participate in inter-

**Figure 8-38** The 2D proton NMR structures of proteins. (a) A NOESY spectrum of a protein presented as a contour plot with two frequency axes,  $\omega_1$  and  $\omega_2$ . The conventional 1D-NMR spectrum of the protein, which occurs along the diagonal of the plot ( $\omega_1 = \omega_2$ ), is too crowded with peaks to be directly interpretable (even a small protein has hundreds of protons). The off-diagonal peaks, the so-called cross peaks, each arise from the interaction of two protons that are  $<5$  Å apart in space and whose 1D-NMR peaks are located where the horizontal and vertical lines through the cross peak intersect the diagonal [a nuclear Overhauser effect (NOE)]. For example, the line to the left of the spectrum represents the extended polypeptide chain with its N- and C-terminal ends identified by the letters N and C and with the positions of four protons, a to d, represented by small circles. The dashed arrows indicate the diagonal NMR peaks to which these protons give rise. Cross peaks, such as i, j, and k, which are each located at the intersections of the horizontal and vertical lines through two diagonal peaks, are indicative of an NOE between the corresponding two protons, indicating that they are  $<5$  Å apart. These distance relationships are schematically indicated by the three looped structures drawn below the spectrum. Note that the assignment of a distance relationship between two protons in a polypeptide requires that the NMR peaks to which they give rise and their positions in the polypeptide be known, which requires that the polypeptide's amino acid sequence has been previously determined. [After Wüthrich, K., *Science* **243**, 45 (1989).] (b) The NMR structure of a 64-residue polypeptide comprising the **Src protein SH3 domain** (Section 19-3C). The drawing represents 20 superimposed structures that are consistent with the 2D- and 3D-NMR spectra of the protein (each calculated from a different, randomly generated starting structure). The polypeptide backbone, as represented by its connected  $C_\alpha$  atoms, is white and its Phe, Tyr, and Trp side chains are yellow, red, and blue, respectively. It can be seen that the polypeptide backbone folds into two three-stranded antiparallel  $\beta$  sheets that form a sandwich. [Courtesy of Stuart Schreiber, Harvard University.]

molecular contacts and are thereby perturbed from their solution conformations. NMR methods, besides providing mutual cross-checks with X-ray techniques, can determine the structures of proteins and other macromolecules that fail to crystallize. Moreover, since NMR can probe motions over time scales spanning 10 orders of magnitude, it can be used to study protein folding and dynamics (Chapter 9).

#### d. Protein Molecular Structures Are Most Effectively Illustrated in Simplified Form

The several hundred nonhydrogen atoms of even a small protein makes understanding a protein's detailed structure a considerable effort. This complexity makes building a skeletal or ball-and-stick model of a protein such a time-consuming task that such models are rarely available. Moreover, a drawing of a protein showing all its nonhydrogen atoms (e.g., Fig. 8-39a) is too complicated to be of much use. In order to be intelligible, drawings of proteins must be selectively simplified. One way of doing so is to represent the polypeptide backbone only by its  $C_\alpha$  atoms (its  **$C_\alpha$  backbone**) and to display only a few key side chains (e.g., Fig. 8-39b). A further level of abstraction

may be obtained by representing the protein in a cartoon form that emphasizes its secondary structure (e.g., Figs. 8-39c and 8-19). Computer-generated drawings of space-filling models, such as Figs. 8-12 and 8-18, may also be em-

(a)

**Figure 8-39 Representations of the X-ray structure of sperm whale myoglobin.** (a) The protein and its bound heme are drawn in stick form, with protein C atoms green, heme C atoms red, N atoms blue, and O atoms red. The Fe and its bound water molecule are shown as orange and gray spheres and hydrogen bonds are gray. In this one-of-a-kind painting of the first known protein structure, the artist has employed “creative distortions” to emphasize the protein’s structural features, particularly its  $\alpha$  helices. (b) A diagram in which the protein is represented by its computer-generated  $C_{\alpha}$  backbone, with its  $C_{\alpha}$  atoms, shown as balls, consecutively numbered from the N-terminus. The 153-residue polypeptide chain is folded into eight  $\alpha$  helices (highlighted here by hand-drawn envelopes), designated A through H, that are connected by short polypeptide links. The protein’s bound heme group (purple, with its Fe atom represented by a red sphere), in complex with a water molecule (orange sphere), is shown together with its two closely associated His side chains (blue). One of the heme group’s propionic acid side chains has been displaced for clarity. Hydrogen atoms are not visible in the X-ray structure. (c) A computer-generated cartoon drawing in an orientation similar to that of Part b, emphasizing the protein’s secondary structure. Here helices are green and the intervening coil regions are yellow. The heme group with its bound  $O_2$  molecule and its two associated His side chains are shown in ball-and-stick form with C magenta, N blue, O red, and Fe orange. [Parts a and b are based on an X-ray structure by John Kendrew, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 1MBN. [Illustration, Irving Geis. Kinemage Exercise 6-1

ployed to illustrate certain features of protein structures. However, the most instructive way to examine a macromolecular structure is through the use of interactive computer graphics programs. The use of such programs is discussed in Section 8-3Cc.

## B. Tertiary Structure

The **tertiary structure (3° structure)** of a protein is its three-dimensional arrangement; that is, the folding of its 2° structural elements, together with the spatial dispositions of its side chains. The first protein X-ray structure, that of sperm

(b)

(c)

whale **myoglobin**, was elucidated in the late 1950s by John Kendrew and co-workers. Its polypeptide chain follows such a tortuous, wormlike path (Fig. 8-39) that these investigators were moved to indicate their disappointment at its lack of regularity. In the intervening years,  $\sim 70,000$  protein structures have been reported. Each of them is a unique, highly complicated entity. Nevertheless, their tertiary structures have several outstanding features in common, as we shall see below.

#### a. Globular Proteins May Contain Both $\alpha$ Helices and $\beta$ Sheets

The major types of secondary structural elements,  $\alpha$  helices and  $\beta$  pleated sheets, commonly occur in globular proteins but in varying proportions and combinations. Some proteins, such as myoglobin, consist only of  $\alpha$  helices spanned by short connecting links that have coil conformations (Fig. 8-39). Others, such as concanavalin A, have a large proportion of  $\beta$  sheets but are devoid of  $\alpha$  helices (Fig. 8-40). Most proteins, however, have significant amounts of both types of secondary structure (on average,  $\sim 31\%$   $\alpha$  helix and  $\sim 28\%$   $\beta$  sheet, with nearly all of their inner cores so arranged). Human **carbonic anhydrase** (Fig. 8-41) as well as carboxypeptidase A and triose phosphate isomerase (Fig. 8-19) are examples of such proteins.

**Figure 8-40** X-ray structure of the jack bean protein **concanavalin A**. This protein largely consists of antiparallel  $\beta$  pleated sheets, here represented by flat arrows pointing toward the polypeptide chain's C-terminus. The polypeptide chain is colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The spheres represent protein-bound  $Mn^{2+}$  (*magenta*) and  $Ca^{2+}$  (*cyan*) ions. The front sheet is shown in a space-filling representation in Fig. 8-18 but viewed from the opposite side as seen here. [Based on an X-ray structure by George Reeke, Jr., Joseph Becker, and Gerald Edelman, The Rockefeller University. PDBid 2CNA.]

#### b. Side Chain Location Varies with Polarity

The primary structures of globular proteins generally lack the repeating or pseudorepeating sequences that are responsible for the regular conformations of fibrous proteins. The amino acid side chains in globular proteins are, nevertheless, spatially distributed according to their polarities:

1. *The nonpolar residues Val, Leu, Ile, Met, and Phe largely occur in the interior of a protein, out of contact with the aqueous solvent.* The hydrophobic interactions that promote this distribution, which are largely responsible for the three-dimensional structures of native proteins, are further discussed in Section 8-4C.

2. *The charged polar residues Arg, His, Lys, Asp, and Glu are largely located on the surface of a protein in contact with the aqueous solvent.* This is because the immersion of an ion in the virtually anhydrous interior of a protein results in the uncompensated loss of much of its hydration energy. In the instances that these groups occur in the interior of a protein, they often have a specific chemical function such as promoting catalysis or participating in metal ion binding (e.g., the metal ion–liganding His residues in Figs. 8-39 and 8-41).

3. The uncharged polar groups Ser, Thr, Asn, Gln, Tyr, and Trp are usually on the protein surface but frequently

**Figure 8-41** X-ray structure of human **carbonic anhydrase**. The polypeptide backbone is drawn in ribbon form colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). The purple sphere in the center represents a  $Zn^{2+}$  ion that is coordinated by three His side chains in stick form colored with C yellow and N blue. Note that the C-terminus is tucked through the plane of a surrounding loop of polypeptide chain, so that carbonic anhydrase is one of the rare native proteins in which a polypeptide chain forms a knot. (a)

**Figure 8-42** X-ray structure of horse heart cytochrome *c*. The protein (*blue*) is illuminated by the Fe atom of its heme group (*orange*). In Part *a*, the hydrophobic side chains are red, and in Part *b*, the hydrophilic side chains are green. [Based on an X-ray

(b)

structure by Richard Dickerson, UCLA; [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]  See [Kinemage Exercise 5](#) and [Interactive Exercise 4](#)

occur in the interior of the molecule. In the latter case, these residues are almost always hydrogen bonded to other groups in the protein. In fact, *nearly all buried hydrogen bond donors form hydrogen bonds with buried acceptor groups*; in a sense, the formation of a hydrogen bond “neutralizes” the polarity of a hydrogen bonding group.

Such a side chain distribution is clearly apparent in Fig. 8-42, which displays the X-ray structure of cytochrome *c*. This arrangement is also seen in Fig. 8-43, which shows the surface and interior exposures of the amino acid side chains of myoglobin’s H helix, and in Fig. 8-44, which shows one of the antiparallel  $\beta$  pleated sheets of concanavalin A.

### c. Globular Protein Cores Are Efficiently Arranged with Their Side Chains in Relaxed Conformations

Globular proteins are quite compact; there is very little space inside them, so that water is largely excluded from their interiors. The micellelike arrangement of their side chains (polar groups outside, nonpolar groups inside) has led to their description as “oil drops with polar coats.” This generalization, although picturesque, lacks precision. The

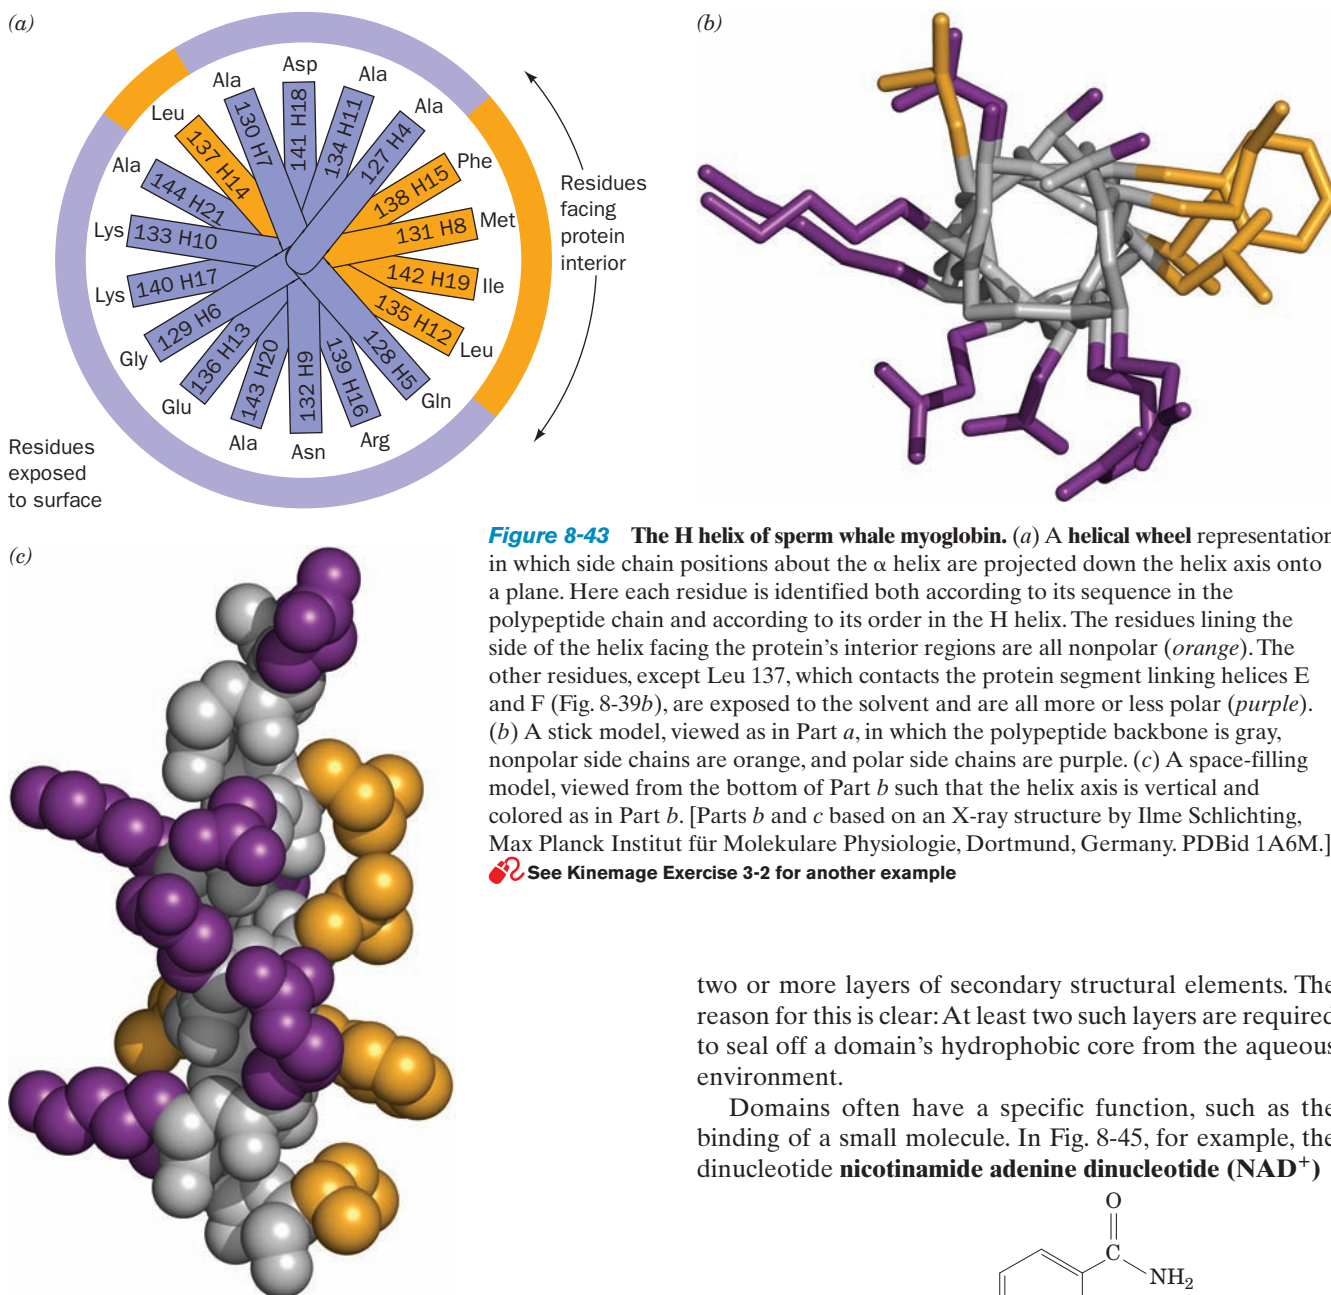

**packing density** (ratio of the volume enclosed by the van der Waals envelopes of the atoms in a region to the total volume of the region) of the internal regions of globular proteins averages  $\sim 0.75$ , which is in the same range as that of molecular crystals of small organic molecules. In comparison, equal-sized close-packed spheres have a packing density of 0.74, whereas organic liquids (oil drops) have packing densities that are mostly between 0.60 and 0.70. *The interior of a protein is therefore more like a molecular crystal than an oil drop; that is, it is efficiently packed.*

The bonds of protein side chains, including those occupying protein cores, almost invariably have low-energy staggered torsion angles (Fig. 8-5a). Evidently, interior side chains adopt relaxed conformations despite their profusion of intramolecular interactions (Section 8-4).

### d. Large Polypeptides Form Domains

Polypeptide chains that consist of more than  $\sim 200$  residues usually fold into two or more globular clusters known as **domains**, which often give these proteins a bi- or multilobal appearance. Most domains consist of 100 to 200 amino acid residues and have an average diameter of  $\sim 25$  Å.

**Figure 8-43** The H helix of sperm whale myoglobin. (a) A helical wheel representation in which side chain positions about the  $\alpha$  helix are projected down the helix axis onto a plane. Here each residue is identified both according to its sequence in the polypeptide chain and according to its order in the H helix. The residues lining the side of the helix facing the protein's interior regions are all nonpolar (orange). The other residues, except Leu 137, which contacts the protein segment linking helices E and F (Fig. 8-39b), are exposed to the solvent and are all more or less polar (purple). (b) A stick model, viewed as in Part a, in which the polypeptide backbone is gray, nonpolar side chains are orange, and polar side chains are purple. (c) A space-filling model, viewed from the bottom of Part b such that the helix axis is vertical and colored as in Part b. [Parts b and c based on an X-ray structure by Ilme Schlichting, Max Planck Institut für Molekulare Physiologie, Dortmund, Germany. PDBid 1A6M.]  
 See Kinemage Exercise 3-2 for another example

Each subunit of the enzyme **glyceraldehyde-3-phosphate dehydrogenase**, for example, has two distinct domains (Fig. 8-45). A polypeptide chain wanders back and forth within a domain, but neighboring domains are usually connected by one, or less commonly two, polypeptide segments. *Domains are therefore structurally independent units that each have the characteristics of a small globular protein.* Indeed, limited proteolysis of a multidomain protein often liberates its domains without greatly altering their structures or enzymatic activities. Nevertheless, the domain structure of a protein is not always obvious since its domains may make such extensive contacts with each other that the protein appears to be a single globular entity.

An inspection of the various protein structures diagrammed in this chapter reveals that domains consist of

two or more layers of secondary structural elements. The reason for this is clear: At least two such layers are required to seal off a domain's hydrophobic core from the aqueous environment.

Domains often have a specific function, such as the binding of a small molecule. In Fig. 8-45, for example, the dinucleotide **nicotinamide adenine dinucleotide (NAD<sup>+</sup>)**

**Nicotinamide adenine dinucleotide (NAD<sup>+</sup>)**

binds to the first domain of the enzyme glyceraldehyde-3-phosphate dehydrogenase. Small molecule binding sites in multidomain proteins often occur in the clefts between domains; that is, the small molecules are bound by groups from two domains. This arrangement arises, in part, from

**Figure 8-44** A space-filling model of an antiparallel  $\beta$  sheet from concanavalin A. The  $\beta$  sheet is shown in side view with the interior of the protein (the surface of a second antiparallel  $\beta$  sheet; Fig. 8-40) to the right and the exterior to the left. The main chain is gray, nonpolar side chains are orange, and polar side chains are purple.  See Kinemage Exercise 3-3

the need for a flexible interaction between the protein and the small molecule that the relatively pliant covalent connection between the domains can provide.

#### e. Supersecondary Structures Are the Building Blocks of Proteins

Certain groupings of secondary structural elements, named **supersecondary structures** or **motifs**, occur in many unrelated globular proteins:

1. The most common form of supersecondary structure is the  **$\beta\alpha\beta$  motif** (Fig. 8-46a), in which the usually right-handed crossover connection between two consecutive parallel strands of a  $\beta$  sheet consists of an  $\alpha$  helix.
2. Another common supersecondary structure, the  **$\beta$  hairpin motif** (Fig. 8-46b), consists of an antiparallel  $\beta$  sheet formed by sequential segments of polypeptide chain that are connected by relatively tight reverse turns.
3. In an  **$\alpha\alpha$  motif** (Fig. 8-46c), two successive antiparallel  $\alpha$  helices pack against each other with their axes inclined so

**Figure 8-46** Schematic diagrams of supersecondary structures. (a) A  $\beta\alpha\beta$  motif, (b) a  $\beta$  hairpin motif, (c) an  $\alpha\alpha$  motif, and (d) a Greek key motif, showing how it is constructed from a folded-over  $\beta$  hairpin.

**Figure 8-45** One subunit of the enzyme glyceraldehyde-3-phosphate dehydrogenase from *Bacillus stearothermophilus*. The polypeptide folds into two distinct domains. The N-terminal domain (light blue, residues 1–146) binds  $\text{NAD}^+$  (drawn in stick form with C green, N blue, O red, and P magenta) near the C-terminal ends of its parallel  $\beta$  strands, and the C-terminal domain (orange, residues 148–333) binds glyceraldehyde-3-phosphate (not shown). [After Biesecker, G., Harris, J.I., Thierry, J.C., Walker, J.E., and Wonacott, A., *Nature* **266**, 331 (1977).]  See Interactive Exercise 5

as to permit their contacting side chains to interdigitate efficiently. Such energetically favorable associations stabilize the coiled coil conformation of  $\alpha$  keratin (Section 8-2A).

4. In the **Greek key motif** (Fig. 8-46*d*; named after an ornamental design commonly used in ancient Greece; see inset), a  $\beta$  hairpin is folded over to form a four-stranded antiparallel  $\beta$  sheet. Of the 10 possible ways of connecting the strands of a four-stranded antiparallel  $\beta$  sheet, the two that form Greek key motifs are, by far, the most common in proteins of known structure.

Groups of motifs combine in overlapping and nonoverlapping ways to form the tertiary structure of a domain, which is called a **fold**.

The number of possible different folds would, of course, seem to be unlimited. However, comparisons of the now large number of known protein structures have revealed that *few protein folds are unique; that is, most proteins of known structure have folds that also occur in unrelated proteins*. Indeed, theoretical considerations suggest there are less than 8000 naturally occurring folds. Of

**Figure 8-47** X-ray structures of 4-helix bundle proteins. (a) *E. coli* cytochrome  $b_{562}$  and (b) human growth hormone. The proteins are represented by their peptide backbones drawn in ribbon form colored in rainbow order from N-terminus (red) to C-terminus (blue). Cytochrome  $b_{562}$ 's bound heme group is shown in ball-and-stick form with C magenta, N blue, O red, and Fe orange. The inset below each ribbon diagram is a topological diagram indicating the connectivity of the  $\alpha$  helices in each 4-helix bundle. Cytochrome  $b_{562}$  (106 residues) has up-down-up-

down topology, whereas human growth hormone (191 residues) has up-up-down-down topology. Note that the N- and C-terminal helices of human growth hormone are longer than its other two helices, so that, at one end, these longer helices associate as an  $\alpha\alpha$  motif. [Based on X-ray structures by (a) F. Scott Matthews, Washington University School of Medicine, and (b) Alexander Wlodawer, National Cancer Institute, Frederick, Maryland. PDBids (a) 256B and (b) 1HGU.]

these, ~1200 have already been observed, with around half of the proteins of known structure belonging to only 20 fold groups.

Although there are numerous ways in which domain structures might be categorized (see, e.g., Section 8-3C), perhaps the simplest way to do so is to classify them as  **$\alpha$  domains** (containing secondary structural elements that are exclusively  $\alpha$  helices),  **$\beta$  domains** (containing only  $\beta$  sheets), and  **$\alpha/\beta$  domains** (containing both  $\alpha$  helices and  $\beta$  sheets). The  **$\alpha/\beta$  domain** category may be further divided into two main groups:  **$\alpha/\beta$  barrels** and **open  $\beta$  sheets**. In the following paragraphs we describe some of the most common folds in each of these domain categories.

#### f. $\alpha$ Domains

We are already familiar with a fold that contains only  $\alpha$  helices: the **globin fold**, which contains 8 helices in two layers and occurs in myoglobin (Fig. 8-39) and in both the  $\alpha$  and  $\beta$  chains of hemoglobin (Section 10-2B). In another common all- $\alpha$  fold, two  $\alpha\alpha$  motifs combine to form a **4-helix bundle** such as occurs in **cytochrome  $b_{562}$**  (Fig. 8-47a, opposite). The helices in this fold are inclined such that their contacting side chains intermesh and are therefore out of contact with the surrounding aqueous solution. They are consequently largely hydrophobic. The 4-helix bundle is a relatively common fold that occurs in a variety of proteins. However, not all of them have the up-down-up-down topology (connectivity) of cytochrome  $b_{562}$ . For example, human **growth hormone** is a 4-helix bundle with up-up-down-down topology (Fig. 8-47b). The successive parallel

helices in this fold are, of necessity, joined by longer loops than those joining successive antiparallel helices.

Different types of  $\alpha$  domains occur in **transmembrane proteins**. We study these proteins in Section 12-3A.

#### g. $\beta$ Domains

$\beta$  Domains contain from 4 to >10 predominantly antiparallel  $\beta$  strands that are arranged into two sheets that pack against each other to form a  **$\beta$  sandwich**. For example, the **immunoglobulin fold** (Fig. 8-48), which forms the basic domain structure of most immune system proteins (Section 35-2Be), consists of a 4-stranded antiparallel  $\beta$  sheet in face-to-face contact with a 3-stranded antiparallel  $\beta$  sheet. Note that the strands in the two sheets are not parallel to one another, a characteristic of stacked  $\beta$  sheets. The side chains between the two stacked  $\beta$  sheets are out of contact with the aqueous medium and thereby form the domain's hydrophobic core. Since successive residues in a  $\beta$  strand alternately extend to opposite sides of the  $\beta$  sheet (Fig. 8-17), these residues are alternately hydrophobic and hydrophilic.

The inherent curvature of  $\beta$  sheets (Section 8-1C) often causes sheets of more than 6 strands to roll up into  **$\beta$  barrels**. Indeed,  $\beta$  sandwiches may be considered to be flattened  $\beta$  barrels. Several different  $\beta$  barrel topologies have been observed, most commonly:

1. The **up-and-down  $\beta$  barrel**, which consists of 8 successive antiparallel  $\beta$  strands that are arranged like the staves of a barrel. An example of an up-and-down  $\beta$  barrel

**Figure 8-48** The immunoglobulin fold. The X-ray structure of the N-terminal domain of the human immunoglobulin fragment **Fab New** shows its immunoglobulin fold. The peptide backbone of this 103-residue domain is drawn in ribbon form colored in rainbow order from N-terminus (red) to C-terminus (blue) with its  $\beta$  strands represented by flat arrows pointing toward the

C-terminus. The inset is the topological diagram of the immunoglobulin fold showing the connectivity of its stacked 4-stranded and 3-stranded antiparallel  $\beta$  sheets. [Based on an X-ray structure by Roberto Poljak, Johns Hopkins School of Medicine. PDBid 7FAB.]

**Figure 8-49 Retinol binding protein.** Its X-ray structure shows its up-and-down  $\beta$  barrel (residues 1–142 of this 182-residue protein). Its peptide backbone is drawn in ribbon form colored in rainbow order from N-terminus (*red*) to C-terminus (*blue*). Note that each  $\beta$  strand is linked via a short loop to its clockwise-adjacent

strand as seen from the top. The protein's bound retinol molecule is represented by a gray ball-and-stick model. The inset is the protein's topological diagram. [Based on an X-ray structure by T. Alwyn Jones, Uppsala University, Uppsala, Sweden. PDBid 1RBP.]

occurs in **retinol binding protein** (Fig 8-49), which functions to transport the nonpolar visual pigment precursor **retinol** (**vitamin A**) in the bloodstream:

**Retinol**

2. A fold consisting of two Greek key motifs, which thereby constitutes an alternative way of connecting the strands of an 8-stranded antiparallel  $\beta$  barrel. Figure 8-50 indicates how two Greek key motifs in the C-terminal domain of the eye lens protein  **$\gamma$ -B crystallin** are arranged to form a  $\beta$  barrel.

3. The **jelly roll** or **Swiss roll barrel** (which is named for its topological resemblance to these rolled up pastries), in which a 4-segment  $\beta$  hairpin is rolled up into an 8-stranded antiparallel  $\beta$  barrel of yet different topology, as is diagrammed in Fig. 8-51*a*. The X-ray structure of the enzyme **peptide- $N^4$ -(*N*-acetyl- $\beta$ -D-glucosaminyl)asparagine amidase F** contains a domain consisting of a jelly roll barrel (Fig. 8-51*b*).

#### h. $\alpha/\beta$ Barrels

In  $\alpha/\beta$  domains, a central parallel or mixed  $\beta$  sheet is flanked by  $\alpha$  helices. The  $\alpha/\beta$  barrel, which is diagrammed in Fig. 8-19*b*, is a remarkably regular structure that consists of 8 tandem  $\beta\alpha$  units (essentially 8 overlapping  $\beta\alpha\beta$  motifs) wound in a right-handed helical sense to form an inner 8-stranded parallel  $\beta$  barrel concentric with an outer barrel of 8  $\alpha$  helices. Each  $\beta$  strand is approximately antiparallel to the succeeding  $\alpha$  helix and all are inclined at around the same angle to the barrel axis. Figure 8-52 shows the X-ray structure of chicken **triose phosphate isomerase (TIM)**, determined by David Phillips, which consists of an  $\alpha/\beta$  barrel. This is the first known structure of an  $\alpha/\beta$  barrel, which is therefore also called a **TIM barrel**.

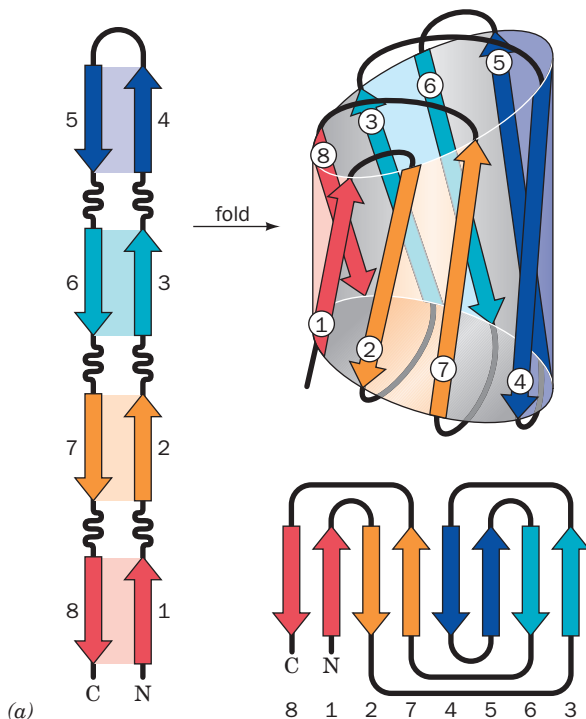

The side chains that point inward from the  $\alpha$  helices interdigitate with the side chains that point outward from the  $\beta$  strands. A large fraction (~40%) of these side chains are those of the branched aliphatic residues Ile, Leu, and Val. The side chains that point inward from the  $\beta$  strands tend to be bulky and hence fill the core of the  $\beta$  barrel (contrary to the impression that Figs. 8-19*b* and 8-52 might provide,  $\alpha/\beta$  barrels, with one known exception, do not have hollow cores). Those side chains that fill the ends of the barrel are in contact with solvent and hence tend to be polar, whereas those in its center are out of contact with solvent and are therefore nonpolar. Thus,  $\alpha/\beta$  barrels have four layers of polypeptide backbone interleaved by regions of hydrophobic

**Figure 8-50** X-ray structure of the C-terminal domain of bovine  $\gamma$ -B crystallin. (a) A topological diagram showing how its two Greek key motifs are arranged in a  $\beta$  barrel. One Greek key motif (red) is formed by  $\beta$  strands 1 to 4 and the other (blue) is formed by  $\beta$  strands 5 to 8. [After Branden, C. and Tooze, J., *Introduction to Protein Structure* (2nd ed.), p. 75, Garland (1999).] (b) The 83-residue peptide backbone displayed in ribbon form.

Here the members of an antiparallel pair of  $\beta$  strands in a Greek key motif are colored alike with the N-terminal Greek key colored red (strands 1 & 4) and orange (2 & 3) and the C-terminal Greek key colored blue (5 & 8) and cyan (6 & 7). The N-terminal domain of this two-domain protein is nearly superimposable on its C-terminal domain. [Based on an X-ray structure by Tom Blundell, Birkbeck College, London, U.K. PDBid 4GCR.]

**Figure 8-51** X-ray structure of the enzyme peptide- $N^4$ -(*N*-acetyl- $\beta$ -D-glucosaminy)asparagine amidase F from *Flavobacterium meningosepticum*. (a) A diagram indicating how an 8-stranded  $\beta$  barrel is formed by rolling up a 4-segment  $\beta$  hairpin. A topological diagram of the jelly roll barrel is also shown. [After Branden, C. and Tooze, J., *Introduction to Protein Structure* (2nd ed.), pp. 77–78, Garland (1999).] (b) A ribbon diagram of the domain formed by residues 1 to 140 of this 314-residue enzyme. Here the two  $\beta$  strands in each segment of the  $\beta$  hairpin are

colored alike, with strands 1 & 8 (the N- and C-terminal strands) red, strands 2 & 7 orange, strands 3 & 6 cyan, and strands 4 & 5 blue. [Based on an X-ray structure by Patrick Van Roey, New York State Department of Health, Albany, New York. PDBid 1PNG.]

**Figure 8-52** X-ray structure of the 247-residue enzyme **triose phosphate isomerase (TIM)** from chicken muscle. The protein is viewed approximately along the axis of its  $\alpha/\beta$  barrel. The peptide backbone is shown as a ribbon diagram with its successive  $\beta\alpha$  units colored, from N- to C-terminus, in rainbow order, red to blue. The inset is its topological diagram (with  $\alpha$  helices represented by rectangles). Two other views of this protein are drawn in Figures 8-19*b* and 8-19*c* [Based on an X-ray structure by David Phillips, Oxford University, U.K. PDBid 1TIM.]

side chains. In contrast, both  $\alpha$  domains and  $\beta$  domains consist of two layers of polypeptide backbone sandwiching a hydrophobic core.

Around 10% of known enzyme structures contain an  $\alpha/\beta$  barrel, making it the most common fold assumed by enzymes. Moreover, nearly all known  $\alpha/\beta$  barrel proteins are enzymes. Intriguingly, the active sites of  $\alpha/\beta$  barrel enzymes are almost all located in funnel-shaped pockets formed by the loops that link the C-termini of the  $\beta$  strands to the succeeding  $\alpha$  helices and hence surround the mouth of the  $\beta$  barrel, an arrangement that has no obvious structural rationale. Thus, despite the observation that few  $\alpha/\beta$  barrel proteins exhibit significant sequence homology, it has been postulated that all of them descended from a common ancestor and are therefore (distantly) related by **divergent evolution**. On the other hand, it has been argued that the  $\alpha/\beta$  barrel is structurally so well suited for its enzymatic roles that it independently arose several times and hence that  $\alpha/\beta$  enzymes are related by **convergent evolution** (i.e., nature has discovered the same fold on several

occasions). Convincing evidence supporting either view has not been forthcoming, so that the nature of the evolutionary relationships among the  $\alpha/\beta$  barrel enzymes remains an open question.

### i. Open $\beta$ Sheets

We have previously encountered examples of an open  $\beta$  sheet in the structures of carboxypeptidase A (Fig. 8-19*a*) and the N-terminal domain of glyceraldehyde-3-phosphate dehydrogenase (Fig. 8-45). Their topological diagrams are drawn in Fig. 8-53. The X-ray structures and topological diagrams of two other such proteins, those of the enzymes **lactate dehydrogenase** (N-terminal domain) and **adenylate kinase**, are shown in Fig. 8-54. Such folds consist of a central parallel or mixed  $\beta$  sheet flanked on both sides by  $\alpha$  helices that form the right-handed crossover connections between successive parallel  $\beta$  strands (Fig. 8-20*b*). The strands of such a  $\beta$  sheet do not follow their order in the peptide sequence. Rather, the  $\beta$  sheet has a long crossover that reverses the direction of the succeeding section of sheet and turns it upside down, thereby putting its helical crossovers on the opposite side of the sheet from those of the preceding section (Fig. 8-55). Such assemblies are therefore also known as **doubly wound sheets** (in contrast to singly wound  $\alpha/\beta$  barrels, whose helices are all on the same side of their  $\beta$  sheets). Doubly wound sheets consist of three layers of polypeptide backbone interspersed by regions of hydrophobic side chains (in contrast to four such layers for  $\alpha/\beta$  barrels and two for  $\alpha$  domains and  $\beta$  domains). Note that both types of domains containing parallel  $\beta$  sheets are hydrophobic on both sides of the sheet, whereas antiparallel sheets are hydrophobic on only one side. This additional stabilization of parallel  $\beta$  sheets probably compensates for the reduced strength of their nonlinear hydrogen bonds relative to the linear hydrogen bonds of antiparallel  $\beta$  sheets (Fig. 8-16).

**Figure 8-53** Topological diagrams of (a) carboxypeptidase A and (b) the N-terminal domain of glyceraldehyde-3-phosphate dehydrogenase. The X-ray structures of these proteins are diagrammed in Figs. 8-19*a* and 8-45. The thin black vertical arrows mark the proteins' topological switch points.

**Figure 8-54** X-ray structures of open  $\beta$  sheet-containing enzymes. (a) Dogfish lactate dehydrogenase, N-terminal domain (residues 20–163 of this 330-residue protein), and (b) porcine adenylate kinase (195 residues). The peptide backbones are shown as ribbon diagrams with successive  $\beta\alpha$  units colored, from N- to C-terminus, in rainbow order, red to blue. In Part b, structural elements that are not components of the open  $\beta$  sheet are gray. The insets are topological diagrams of these proteins, with the thin black vertical arrows marking their topological

switch points. [Based on X-ray structures by (a) Michael Rossmann, Purdue University, and (b) Georg Schulz, Institut für Organische Chemie und Biochemie, Freiburg, Germany. PDBids (a) 6LDH and (b) 3ADK.]

There are few geometric constraints on the number of strands in open  $\beta$  sheets; they have been observed to contain from 4 to 10  $\beta$  strands, with 6  $\beta$  strands being the most common. Since the position where the chain reverses its winding direction, the so-called **topological switch point**, can occur between any consecutive  $\alpha$  helix and  $\beta$  strand, doubly wound sheets can have many different folds. Moreover, some  $\beta$  strands may run in an antiparallel direction to yield mixed sheets (e.g., carboxypeptidase A; Figs. 8-19a and 8-53a), and in several instances, there is more than one topological switch point (e.g., adenylate kinase; Fig. 8-54b).

The open  $\beta$  sheet is the most common domain structure that occurs in globular proteins. Moreover, nearly all such

**Figure 8-55** Doubly wound sheets. (a) A schematic diagram of a doubly wound sheet indicating how the long crossover (green) between its N- and C-terminal segments (red and blue) reverses the direction of the sheet's C-terminal segment and places its  $\alpha$  helical crossover connections on the opposite side of the sheet. (b) The corresponding topological diagram, with the thin black vertical arrow marking the topological switch point. [After Branden, C. and Tooze, J., *Introduction to Protein Structure* (2nd ed.), p. 49, Garland (1999).]

proteins are enzymes, many of which bind mono- or dinucleotides. In fact, the fold exemplified by lactate dehydrogenase (**LDH**; Fig. 8-54a) is known as the **dinucleotide-binding fold** or **Rossmann fold** (after Michael Rossmann, who first pointed out its significance). This is because mononucleotide units are commonly bound by  $\beta\alpha\beta\alpha\beta$  units, of which LDH (which binds the dinucleotide  $\text{NAD}^+$ ) has two. In some proteins, the second  $\alpha$  helix in a  $\beta\alpha\beta\alpha\beta$  unit is replaced by a length of nonhelical polypeptide. This occurs, for example, between the  $\beta_5$  and  $\beta_6$  strands of glyceraldehyde-3-phosphate dehydrogenase (Figs. 8-45 and 8-53b), which also binds  $\text{NAD}^+$ .

At the topological switch point of an open  $\beta$  sheet, the loops emerging from the C-terminal ends of the flanking  $\beta$  strands go to opposite sides of the sheet and thereby form a crevice between them. In nearly all of the  $>100$  known structures of open  $\beta$  sheet-containing enzymes, as Carl-Ivar Brändén first pointed out, this crevice forms at least part of the enzyme's active site. Thus the active sites of both  $\alpha/\beta$  barrels and the open  $\beta$  sheet enzymes are formed by loops emanating from the C-terminal ends of the  $\beta$  strands. In contrast, the active sites of enzymes that have other types of domain structures exhibit no apparent regularities in the positions of their active sites.

### C. Structural Bioinformatics

In Section 7-4, we discussed the rapidly developing field of inquiry known as bioinformatics as it applies to the sequences of proteins and nucleic acids, that is, how sequence alignments are determined and how phylogenetic trees are generated. An equally important aspect of bioinformatics,

which we discuss below, is how macromolecular structures are displayed and compared.

#### a. The Protein Data Bank

The atomic coordinates of most known macromolecular structures are archived in the **Protein Data Bank (PDB)**. Indeed, most scientific journals that publish macromolecular structures require that authors deposit their structure's coordinates in the PDB. The PDB contains the atomic coordinates of  $\sim 70,000$  macromolecular structures (proteins, nucleic acids, and carbohydrates as determined by X-ray and other diffraction-based techniques, NMR, and electron microscopy) and is growing exponentially at a rate that is presently  $\sim 7500$  structures per year. The PDB's Website (URL), from which these coordinates are publicly available, is listed in Table 8-4.

Each independently determined structure in the PDB is assigned a unique four-character identifier (its **PDBid**) in which the first character must be a digit (1–9) and no distinction is made between uppercase and lowercase letters (e.g., 1 MBO is the PDBid of the myoglobin structure illustrated in Fig. 8-39c, although PDBids do not necessarily have a relationship to the corresponding macromolecule's name). A coordinate file begins with information that identifies/describes the macromolecule, the date the coordinate file was deposited, its source (the organism from which it was obtained), the author(s) who determined the structure, and key journal references. The file continues with a synopsis of how the structure was determined together with indicators of its accuracy and information that could be helpful in its interpretation, such as a description of its symmetry and which residues, if any, were not observed. The sequences of the

**VAST (vector alignment search tool):** <http://www.ncbi.nlm.nih.gov/Structure/VAST/>

structure's various chains are then listed together with the descriptions and formulas of its so-called HET (for heterogen) groups, which are molecular entities that are not among the "standard" amino acid or nucleotide residues (e.g., organic molecules such as the heme group, nonstandard residues such as Hyp, metal ions, and bound water molecules). The positions of the structure's secondary structural elements and its disulfide bonds are then provided.

The bulk of a PDB file consists of a series of ATOM (for "standard" residues) and HETATM (for heterogens) records (lines), each of which provides the coordinates for one atom in the structure. An ATOM or HETATM record identifies its corresponding atom according to its serial number (usually just its sequence in the list), atom name (e.g., C and O for an amino acid residue's carbonyl C and O atoms, CA and CB for C<sub>α</sub> and C<sub>β</sub> atoms, N1 for atom N1 of a nucleic acid base, C4\* for atom C4' of a ribose or deoxyribose residue), residue name [e.g., PHE, G (for a guanosine residue), HEM (for a heme group), MG (for an Mg<sup>2+</sup> ion), and HOH (for a water molecule)], chain identifier (e.g., A, B, C, etc., for structures consisting of more than one chain, whether or not the chains are chemically identical), and the residue sequence number in the chain. The record then continues with the atom's Cartesian (orthogonal) coordinates (X, Y, Z), in angstroms relative to an arbitrary origin, the atom's occupancy (which is the fraction of sites that actually contain the atom in question, a quantity that is usually 1.00 but, for groups that have multiple conformations or for molecules/ions that are only partially bound to a protein, may be a positive number less than 1.00), and its isotropic temperature factor (a quantity that is indicative of the atom's thermal motion, with larger numbers denoting a greater degree of motion). The ATOM records are listed in the order of the residues in a chain. For NMR-based structures, the PDB file contains a full set of ATOM and HETATM records for each member of the ensemble of structures that were calculated in solving the structure (Section 8-3A; the most representative member of such a coordinate set can be obtained from <http://www.ebi.ac.uk/msd-srv/olderado>). PDB files usually end with CONECT (connectivity) records, which denote the nonstandard connectivities between ATOMs such as disulfide bonds and hydrogen bonds as well as connectivities between HETATMs.

A particular PDB file may be located according to its PDBid or, if this is unknown, by searching with a variety of criteria including a protein's name, its source, the author(s), keywords, and/or the experimental technique used to determine the structure. Selecting a particular macromolecule in the PDB initially displays a Structure Summary page with options for interactively viewing the structure, for viewing or downloading the coordinate file, and for classifying or analyzing the structure in terms of its geometric properties and sequence (see below).

### b. The Nucleic Acid Database

The **Nucleic Acid Database (NDB)** archives the atomic coordinates of structures that contain nucleic acids. Its coordinate files have substantially the same format as do

those of the PDB, where this information is also kept. However, the NDB's organization and search algorithms are specialized for dealing with nucleic acids. This is useful, in part, because many nucleic acids of known structure are identified only by their sequences rather than by names, as are proteins (e.g., myoglobin), and consequently could easily be overlooked in a search of the PDB.

### c. Viewing Macromolecular Structures in Three Dimensions

The most informative way to examine a macromolecular structure is through the use of molecular graphics programs that permit the user to interactively rotate a macromolecule and thereby perceive its three-dimensional structure. This impression may be further enhanced by simultaneously viewing the macromolecule in stereo. Most molecular graphics programs use PDB files as input. The programs described here can be downloaded from the Internet addresses listed in Table 8-4, some of which also provide instructions for the program's use.

**Jmol**, which functions as both a Web browser-based applet or as a standalone program, allows the user to display user-selected macromolecules in a variety of colors and formats (e.g., ball and stick, backbone, wireframe, space-filling, and cartoon). The Interactive Exercises on the Website that accompanies this textbook (<http://wiley.com/college/voet/>) all use Jmol (this site also contains a Jmol tutorial). **FirstGlance** uses Jmol to display macromolecules via a user-friendly interface. **KiNG**, which also has Web browser-based and standalone versions, displays the so-called **Kinemages** on this textbook's accompanying Website. KiNG provides a generally more author-directed user environment than does Jmol. Macromolecules can be displayed directly from their corresponding PDB page using Jmol, KiNG, and several other viewers. The **Swiss-Pdb Viewer** (also called **DeepView**), in addition to displaying molecular structures, provides tools for basic model building, homology modeling, energy minimization, and multiple sequence alignment. One advantage of the Swiss-PDB Viewer is that it allows users to easily superimpose two or more models. **Proteopedia** is a 3D interactive encyclopedia of proteins and other macromolecules that resembles Wikipedia in that it is user edited. It uses mainly Jmol as a viewer.

### d. Structural Classification and Comparison

Most proteins are structurally related to other proteins. Indeed, as we shall see in Section 9-6, *evolution tends to conserve the structures of proteins rather than their sequences*. The computational tools described below facilitate the classification and comparison of protein structures. They can be accessed directly via their websites (Table 8-4) and, in some cases, accessed directly from the PDB. Studies using these programs yield functional insights, reveal distant evolutionary relationships that are not apparent from sequence comparisons (Section 7-4B), generate libraries of unique folds for structure prediction, and provide indications as to why certain types of structures are preferred over others.

**1. CATH** (for Class, Architecture, Topology, and Homologous superfamily), as its name suggests, categorizes proteins in a four-level structural hierarchy. (1) “Class,” the highest level, places the selected protein in one of four categories of gross secondary structure: Mainly  $\alpha$ , Mainly  $\beta$ ,  $\alpha/\beta$  (having both  $\alpha$  helices and  $\beta$  sheets), and Few Secondary Structures. (2) “Architecture” is the description of the gross arrangement of secondary structure independent of topology. (3) “Topology” is indicative of both the overall shape and connectivity of the protein’s secondary structures. (4) “Homologous superfamily” is those proteins of known structure that are homologous to (share a common ancestor with) the selected protein. For 1 MBO (sperm whale myoglobin), the CATH classification is Class (C): Mainly alpha; Architecture (A): Orthogonal bundle; Topology (T): Globin-like; and Homologous superfamily (H): Globin. CATH permits the user to navigate up and down the various hierarchies and thereby structurally compare them.

**2. CE** (for Combinatorial Extension of the optimal path) finds all proteins in the PDB that can be structurally aligned with the query structure to within user-specified geometric criteria. The amino acid sequences of these proteins are also aligned on the basis of this structural alignment rather than sequence alignment (Section 7-4B). The structurally aligned proteins can be simultaneously displayed by a Java applet called Compare3D that displays both the aligned  $C_{\alpha}$  backbones and the structurally aligned sequences. CE can likewise align and display two user-selected structures. The atomic coordinates of the aligned structures can also be downloaded in PDB format for use with other programs such as display by Jmol and KiNG.

**3. Pfam** (for Protein families) is a database of nearly 11,000 multiple sequence alignments of protein domains (called **Pfam families**). Using Pfam, one can analyze a protein for Pfam matches (74% of proteins have at least one match in Pfam), view Pfam family annotations and alignments, determine the domain organization of a protein based on its sequence or its structure, find groups of related Pfam families (called **clans**), examine the phylogenetic tree of a Pfam family, and view the occurrence of a protein’s domains across different species.

**4. SCOP** (Structural Classification Of Proteins) classifies protein structures based mainly on manually generated topological considerations according to a 6-level hierarchy: Class [All- $\alpha$ , All- $\beta$ ,  $\alpha/\beta$  (having  $\alpha$  helices and  $\beta$  strands that are largely interspersed),  $\alpha + \beta$  (having  $\alpha$  helices and  $\beta$  strands that are largely segregated), and Multi-domain (having domains of different classes)], Fold (groups that have similar arrangements of secondary structural elements), Superfamily (indicative of distant evolutionary relationships based on structural criteria and functional features), Family (indicative of near evolutionary relationships based on sequence as well as on structure), Protein, and Species. For 1 MBO these are Class: All- $\alpha$ ; Fold: Globin-like; Superfamily: Globin-like; Family: Globins; Protein: Myoglobin; and Species: Sperm whale (*Physeter catodon*). SCOP permits the user to navigate through its treelike hierarchical organization and lists the known

members of any particular branch. Thus, with 1MBO, SCOP displays a list of the 174 structures in the PDB that contain sperm whale myoglobin (a protein that has received far more structural study than most).

**5. VAST** (Vector Alignment Search Tool), a component of the National Center for Biotechnology Information (NCBI) Entrez system, reports a precomputed list of proteins of known structure that structurally resemble the query protein. The VAST system uses the **Molecular Modeling Database (MMDB)**, an NCBI-generated database that is derived from PDB coordinates but in which molecules are represented by connectivity graphs rather than sets of atomic coordinates. VAST displays the superposition of the query protein in its structural alignment with a user-selected list of the related proteins using **Cn3D** [a molecular graphics program that displays MMDB files and that is publicly available for a variety of computer platforms (Table 8-4)]. VAST also reports the structure-based sequence alignment of these proteins.

In addition, several “Structure Analysis” tools can be invoked from a PDB Structure Summary page. The “Sequence Details” page provides the sequence of each chain in the structure and, for polypeptides, indicates the secondary structure of each of its residues.

#### e. The Structural Genomics Project

As we shall see in Section 9-3B, proteins with similar sequences are likely to have similar three-dimensional structures. Yet, of the  $\sim 7$  million polypeptides of known sequence, only  $<40,000$  have known structures comprising  $\sim 1200$  of the estimated 8000 different protein folds. Consequently,  $\sim 40\%$  of the open reading frames (ORFs; DNA sequences that appear to encode proteins) in known genomes specify proteins whose structures and functions are unknown. The need to better characterize such proteins has led to the **structural genomics** project, a loosely organized international consortium of structure determination centers dedicated to elucidating the structures of representative proteins from every protein family and hence making the structures of most proteins readily obtainable from their gene sequences.

Traditionally, the determination of protein structures by X-ray and NMR techniques has been carried out through hypothesis-driven research, that is, the proteins are being studied to solve specific biochemical problems, and hence these proteins tend to be functionally well characterized. In contrast, structural genomics endeavors to determine the structures of large numbers of uncharacterized proteins (except for their sequences) and has a long-range goal of determining the structures of all members of selected **proteomes** (the collections of all proteins encoded by the corresponding genomes). To effectively do so required that the rate of protein structure determination be greatly accelerated. Hence the first phase of the structural genomics project concentrated on developing high-throughput (i.e., robotic) methods of expressing, purifying, crystallizing, and structurally elucidating the proteins to be studied. This has been followed, since 2005, by a production phase in which large numbers of protein structures have been determined.

Indeed, ~14% of the structures in the PDB are products of the structural genomics project (a percentage that is increasing) with many of these proteins having novel folds. Unfortunately, the knowledge of a protein's structure does not necessarily reveal its function. Hence even though the cost of determining a protein's X-ray structure by the structural genomics project appears to be significantly less than that by hypothesis-driven research (although the latter are adopting high-throughput methods), it is still a matter of debate as to whether the structural genomics project is a cost-effective way of obtaining biochemically useful information relative to hypothesis-driven research.

#### 4 PROTEIN STABILITY

Incredible as it may seem, thermodynamic measurements indicate that *native proteins are only marginally stable entities under physiological conditions*. The free energy required to denature them is ~0.4 kJ · mol<sup>-1</sup> of amino acid residues, so that 100-residue proteins are typically stable by only around 40 kJ · mol<sup>-1</sup>. In contrast, the energy required to break a typical hydrogen bond is ~20 kJ · mol<sup>-1</sup>. The various noncovalent influences to which proteins are subject—electrostatic interactions (both attractive and repulsive), hydrogen bonding (both intramolecular and to water), and hydrophobic forces—each have energetic magnitudes that may total thousands of kilojoules per mole over an entire protein molecule. Consequently, *a protein structure arises from a delicate balance among powerful countervailing forces*. In this section we discuss the nature of these forces and end by considering protein denaturation, that is, how these forces can be disrupted.

##### A. Electrostatic Forces

Molecules are collections of electrically charged particles and hence, to a reasonable degree of approximation, their interactions are determined by the laws of classical electrostatics (more exact calculations require the application of quantum mechanics). The energy of association,  $U$ , of two electric charges,  $q_1$  and  $q_2$ , that are separated by the distance  $r$  is found by integrating the expression for Coulomb's law, Eq. [2.1], to determine the work necessary to separate these charges by an infinite distance:

$$U = \frac{kq_1q_2}{Dr} \quad [8.1]$$

Here  $k = 9.0 \times 10^9 \text{ J} \cdot \text{m} \cdot \text{C}^{-2}$  and  $D$  is the dielectric constant of the medium in which the charges are immersed (recall that  $D = 1$  for a vacuum and, for the most part, increases with the polarity of the medium; Table 2-1). The dielectric constant of a molecule-sized region is difficult to estimate. For the interior of a protein, it is usually taken to be in the range 3 to 5 in analogy with the measured dielectric constants of substances that have similar polarities, such as benzene and diethyl ether.

Coulomb's law is only valid for point or spherically symmetric charges that are immersed in a medium of constant

$D$ . However, proteins are by no means spherical and their internal  $D$  values vary with position. Moreover, a protein in solution associates with mobile ions such as Na<sup>+</sup> and Cl<sup>-</sup>, which modulate the protein's electrostatic potential. Consequently, calculating the electrostatic potential of a protein requires mathematically sophisticated and computationally intensive algorithms that are beyond the scope of this text. These methods are widely used to calculate the surface electrostatic potentials of proteins using a program called **GRASP** (for *Graphical Representation and Analysis of Surface Properties*) written by Anthony Nicholls, Kim Sharp, and Barry Honig. Figure 8-56 shows a GRASP diagram of human growth hormone in which the protein's surface is colored according to its electrostatic potential. Such diagrams are useful for assessing how a protein might associate with charged molecules such as other proteins, nucleic acids, and substrates. Similar computations are used to predict the  $pK$ 's of protein surface groups, which can have significant application in the elucidation of an enzyme's mechanism of action (Section 15-1).

##### a. Ionic Interactions Are Strong but Do Not Greatly Stabilize Proteins

The association of two ionic protein groups of opposite charge is known as an **ion pair** or **salt bridge**. According to Eq. [8.1], the energy of a typical ion pair, say the carboxyl

**Figure 8-56** A GRASP diagram of human growth hormone.

The diagram shows the protein's surface colored according to its electrostatic potential, with its most negative areas dark red, its most positive areas dark blue, and its neutral areas white. The protein's orientation is the same as that in Fig. 8-47b. [Based on an X-ray structure by Alexander Wlodawer, National Cancer Institute, Frederick, Maryland. PDBid 1HGU.]

**Figure 8-57** Examples of ion pairs in myoglobin. In each case, oppositely charged side chain groups from residues far apart in sequence closely approach each other through the formation of ion pairs.

group of Glu and the ammonium group of Lys, whose charge centers are separated by  $4.0 \text{ \AA}$  in a medium of dielectric constant 4, is  $-86 \text{ kJ} \cdot \text{mol}^{-1}$  (one electronic charge =  $16.0 \times 10^{-19} \text{ C}$ ). However, free ions in aqueous solution are highly solvated, and the formation of a salt bridge has the entropic penalty of localizing the salt bridge's charged side chains. Consequently, the free energy of solvation of two separated ions is about equal to the free energy of formation of their unsolvated ion pair. *Ion pairs therefore contribute little stability toward a protein's native structure.* This accounts for the observations that although  $\sim 75\%$  of charged residues occur in ion pairs (e.g., Fig. 8-57), very few ion pairs are buried (unsolvated), and ion pairs that are exposed to the aqueous solvent tend to be but poorly conserved among homologous proteins.

#### b. Dipole–Dipole Interactions Are Weak but Significantly Stabilize Protein Structures

The noncovalent associations between electrically neutral molecules, collectively known as **van der Waals forces**, arise from electrostatic interactions among permanent and/or induced dipoles. These forces are responsible for numerous interactions of varying strengths between nonbonded neighboring atoms. (The hydrogen bond, a special class of dipolar interaction, is considered separately in Section 8-4B.)

Interactions among permanent dipoles are important structural determinants in proteins because many of their groups, such as the carbonyl and amide groups of the peptide backbone, have permanent dipole moments. These interactions are generally much weaker than the charge–charge interactions of ion pairs. Two carbonyl groups, for example, each with dipoles of  $4.2 \times 10^{-30} \text{ C} \cdot \text{m}$  (1.3 debye units) that are oriented in an optimal head-to-tail arrangement (Fig. 8-58a) and separated by  $5 \text{ \AA}$  in a medium of dielectric constant 4, have a calculated attrac-

tive energy of only  $-9.3 \text{ kJ} \cdot \text{mol}^{-1}$ . Furthermore, these energies vary with  $r^{-3}$ , so they rapidly attenuate with distance. In  $\alpha$  helices, however, the negative ends of the dipolar amide and carbonyl groups of the polypeptide backbone all point in the same direction (Fig. 8-11), so that their interactions and bond dipoles are additive (these groups, of course, also form hydrogen bonds, but here we are concerned with their residual electric fields). The  $\alpha$  helix therefore has a significant dipole moment that is positive toward the N-terminus and negative toward the C-terminus. Consequently, *in the low dielectric constant core of a protein, dipole–dipole interactions significantly influence protein folding.*

A permanent dipole also induces a dipole moment on a neighboring group so as to form an attractive interaction (Fig. 8-58b). Such dipole–induced dipole interactions are generally much weaker than are dipole–dipole interactions.

Although nonpolar molecules are nearly electrically neutral, at any instant they have a small dipole moment resulting from the rapid fluctuating motions of their electrons. This transient dipole moment polarizes the electrons in a neighboring group, thereby giving rise to a dipole moment (Fig. 8-58c) such that, near their van der Waals contact distances, the groups are attracted to one another (a quantum mechanical effect that cannot be explained in terms of only classical physics). These so-called **London dispersion forces** are extremely weak. The  $8.2\text{-kJ} \cdot \text{mol}^{-1}$  heat of vaporization of  $\text{CH}_4$ , for example, indicates that the attractive interaction of a nonbonded  $\text{H} \cdots \text{H}$  contact between neighboring  $\text{CH}_4$  molecules is roughly  $-0.3 \text{ kJ} \cdot \text{mol}^{-1}$  (in the liquid, a  $\text{CH}_4$  molecule touches its 12 nearest neighbors with  $\sim 2 \text{ H} \cdots \text{H}$  contacts each).

London forces are only significant for contacting groups because their association energy is proportional to  $r^{-6}$ . Nevertheless, *the great numbers of interatomic contacts in the closely packed interiors of proteins make London forces*

**Figure 8-58 Dipole-dipole interactions.** The strength of each dipole is represented by the thickness of the accompanying arrow. (a) Interactions between permanent dipoles. These interactions, here represented by carbonyl groups lined up head to tail, may be attractive, as shown, or repulsive, depending on the relative orientations of the dipoles. (b) Dipole-induced dipole interactions. A permanent dipole (here shown as a carbonyl group) induces a dipole in a nearby group (here represented by a methyl group) by electrostatically distorting its electron distribution (*shading*). This always results in an attractive interaction. (c) London dispersion forces. The instantaneous charge imbalance (*shading*) resulting from the motions of the electrons in a molecule (*left*) induces a dipole in a nearby group (*right*); that is, the motions of the electrons in neighboring groups are correlated. This always results in an attractive interaction.

a major influence in determining their conformations. London forces also provide much of the binding energy in the sterically complementary interactions between proteins and the molecules that they specifically bind.

## B. Hydrogen Bonding Forces

Hydrogen bonds ( $D-H \cdots A$ ), as we discussed in Section 2-1Aa, are predominantly electrostatic interactions (but with  $\sim 10\%$  covalent character) between a weakly acidic donor group ( $D-H$ ) and an acceptor ( $A$ ) that bears a lone pair of electrons. In biological systems,  $D$  and  $A$  can both be the highly electronegative  $N$  and  $O$  atoms and occasion-

ally  $S$  atoms. In addition, a relatively acidic  $C-H$  group (e.g., a  $C_\alpha-H$  group) can act as a weak hydrogen bond donor, and the polarizable  $\pi$  electron system of an aromatic ring (e.g., that of Trp) can act as a weak acceptor.

Hydrogen bonds have association energies that are normally in the range  $-12$  to  $-40 \text{ kJ} \cdot \text{mol}^{-1}$  (but only around  $-8$  to  $-16 \text{ kJ} \cdot \text{mol}^{-1}$  for  $C-H \cdots A$  and  $D-H \cdots \pi$  hydrogen bonds and  $-2$  to  $-4 \text{ kJ} \cdot \text{mol}^{-1}$  for  $C-H \cdots \pi$  hydrogen bonds), values which are between those for covalent bonds and van der Waals forces. Hydrogen bonds (**H bonds**) are much more directional than are van der Waals forces but less so than are covalent bonds. The  $D \cdots A$  distance is normally in the range  $2.7$  to  $3.1 \text{ \AA}$ , although since  $H$  atoms are unseen in all but the very highest resolution macromolecular X-ray structures, a possible  $D-H \cdots A$  interaction (where  $D$  and  $A$  are either  $N$  or  $O$ ) is assumed to be a H bond if its  $D \cdots A$  distance is significantly less than the  $3.7 \text{ \AA}$  sum of a  $D-H$  bond length ( $\sim 1.0 \text{ \AA}$ ) and the van der Waals contact distance between  $H$  and  $A$  ( $\sim 2.7 \text{ \AA}$ ). Keep in mind, however, that there is no rigid cutoff distance beyond which H bonds cease to exist because the energy of an H bond, which is mainly electrostatic in character, varies inversely with the distance between the negative and positive centers (Eq. [8.1]).

H bonds tend to be linear, with the  $D-H$  bond pointing along the acceptor's lone pair orbital (or, in  $D-H \cdots \pi$  hydrogen bonds, roughly perpendicular to the aromatic ring and pointing at its center with the distance from the  $D$  atom to the center of the aromatic ring normally in the range  $3.2$ – $3.8 \text{ \AA}$ ). Large deviations from this ideal geometry are not unusual, however. For example, in the H bonds of both  $\alpha$  helices (Fig. 8-11) and antiparallel  $\beta$  pleated sheets (Fig. 8-16a), the  $N-H$  bonds point approximately along the  $C=O$  bonds rather than along an  $O$  lone pair orbital, and in parallel  $\beta$  pleated sheets (Fig. 8-16b), the H bonds depart significantly from linearity. Indeed, many of the H bonds in proteins are members of networks in which each donor is H bonded to two acceptors (**a bifurcated hydrogen bond**) and each acceptor is H bonded to two donors. For example, although the H bonds in ideal  $\alpha$  helices form between the  $N-H$  group at residue  $n$  and the  $C=O$  group at residue  $n-4$  ( $n \rightarrow n-4$  H bonds; Fig. 8-11), many of the  $N-H$  groups in real  $\alpha$  helices associate via bifurcated H bonds with two adjacent  $C=O$  groups to form both  $n \rightarrow n-4$  and  $n \rightarrow n-3$  H bonds.

### a. Hydrogen Bonds Only Weakly Stabilize Proteins

A protein's internal H bonding groups are arranged such that most possible H bonds are formed (Section 8-3B). Clearly, H bonding has a major influence on the structures of proteins. However, an unfolded protein makes most of its H bonds with the water molecules of the aqueous solvent (water, it will be recalled, is a strong H bonding donor and acceptor). The free energy of stabilization that internal H bonds confer on a native protein is therefore equal to the difference in the free energy of H bonding between the native protein and the unfolded protein. Consequently, it might be expected that H bonds do not stabilize (and perhaps even slightly destabilize) the structure of a native

protein relative to its unfolded state. However, since H bonding interactions are largely electrostatic in nature, they are likely to be stronger in the low polarity interior of a protein than they are in the high polarity aqueous medium. Moreover, there may be an entropic effect that destabilizes the H bonds between water and an unfolded polypeptide relative to intraprotein H bonds: The water molecules that are H bonded to a polypeptide are likely to be more positionally and orientationally constrained (ordered) than those that are H bonded to only other water molecules, thus favoring the formation of intraprotein H bonds. These effects may very well account for the observation that the mutagenic removal of an H bond from a protein generally reduces the protein's stability by  $-2$  to  $8 \text{ kJ} \cdot \text{mol}^{-1}$ .

Despite their low stability, *a protein's hydrogen bonds provide a structural basis for its native folding pattern*: If a protein folded in a way that prevented some of its internal H bonds from forming, their free energy would be lost and such conformations would be less stable than those that are fully H bonded. In fact, the formation of  $\alpha$  helices and  $\beta$  sheets efficiently satisfies the polypeptide backbone's H bonding requirements. This argument also applies to the van der Waals forces discussed in the previous section.

### b. Most Hydrogen Bonds in Proteins Are Local

How can as complex a molecule as a protein fold so as to make nearly all of its potential H bonds? The answer to this question was revealed by a survey of the H bonds in high resolution protein X-ray structures by Ken Dill and George Rose: *Most of the H bonds in a protein are local, that is, they involve donors and acceptors that are close together in sequence and hence can readily find their H bonding mates.*

1. On average, 68% of the H bonds in proteins are between backbone atoms. Of these,  $\sim 1/3$  form  $n \rightarrow n - 4$  H bonds (as in ideal  $\alpha$  helices),  $\sim 1/3$  form  $n \rightarrow n - 3$  H bonds (as in reverse turns and ideal  $3_{10}$  helices), and  $\sim 1/3$  are between paired strands in  $\beta$  sheets. In fact, only  $\sim 5\%$  of the H bonds between backbone atoms are not wholly within a helix, sheet, or turn.

2. Hydrogen bonds between side chains and backbones are clustered at **helix-capping** positions. In an  $\alpha$  helix, the first four N—H groups and the last four C=O groups cannot form H bonds within the helix (which accounts for half the potential H bonds involving backbone atoms in an  $\alpha$  helix of 12 residues, the average length of  $\alpha$  helices). These potential H bonds are often made with nearby side chains. In particular,  $\sim 1/2$  of the N-terminal N—H groups of  $\alpha$  helices form H bonds with polar side chains that are 1 to 3 residues distant, and  $\sim 1/3$  of their C-terminal C=O groups form H bonds with polar side chains that are 2 to 5 residues distant.

3. Over half the H bonds between side chains are between charged residues (i.e., they form salt bridges) and are therefore located on protein surfaces between and within surface loops (e.g., Fig. 8-57). However,  $\sim 85\%$  of the remaining side chain–side chain H bonds are between side chains that are 1 to 5 residues apart. Hence with the exception of those in salt bridges, side chain–side chain H bonds also tend to be local.

### C. Hydrophobic Forces

*The hydrophobic effect is the name given to those influences that cause nonpolar substances to minimize their contacts with water and amphipathic molecules, such as soaps and detergents, to form micelles in aqueous solutions (Section 2-1Ba).* Since native proteins form a sort of intramolecular micelle in which their nonpolar side chains are largely out of contact with the aqueous solvent, *hydrophobic interactions must be an important determinant of protein structures.*

The hydrophobic effect derives from the special properties of water as a solvent, only one of which is its high dielectric constant. In fact, other polar solvents, such as dimethyl sulfoxide (DMSO) and *N,N*-dimethylformamide (DMF), tend to denature proteins. The thermodynamic data of Table 8-5 provide considerable insight as to the origin of the hydrophobic effect because the transfer of a hydrocarbon from water to a nonpolar solvent resembles the transfer of a nonpolar side chain from the exterior of a protein in aqueous solution to its interior. The isothermal Gibbs free energy changes ( $\Delta G = \Delta H - T\Delta S$ ) for the transfer of a hydrocarbon from an aqueous solution to a nonpolar solvent is negative in all cases, which indicates, as we know to be the case, that such transfers are spontaneous processes (oil and water don't mix). What is perhaps unexpected is that these transfer processes are endothermic (positive  $\Delta H$ ) for aliphatic compounds and athermic ( $\Delta H = 0$ ) for aromatic compounds; that is, *it is enthalpically more or equally favorable for nonpolar molecules to dissolve in water than in nonpolar media.* In contrast, the entropy component of the unitary free energy change,  $-T\Delta S_u$  (see footnote a to Table 8-5), is large and negative in all cases. Evidently, *the transfer of a hydrocarbon from an aqueous medium to a nonpolar medium is entropically driven. The same is true of the transfer of a nonpolar protein group from an aqueous environment to the protein's nonpolar interior.*

What is the physical mechanism whereby nonpolar entities are excluded from aqueous solutions? Recall that entropy is a measure of the order of a system; it decreases with increasing order (Section 3-2). Thus the decrease in entropy when a nonpolar molecule or side chain is solvated by water (the reverse of the foregoing process) must be due to an ordering process. This is an experimental observation, not a theoretical conclusion. The magnitudes of the entropy changes are too large to be attributed only to changes in the conformations of the hydrocarbons; rather, as Henry Frank and Marjorie Evans pointed out in 1945, *these entropy changes mainly arise from some sort of ordering of the water structure.*

Liquid water has a highly ordered and extensively H bonded structure (Section 2-1A). The insinuation of a nonpolar group into this structure disrupts it: A nonpolar group can neither accept nor donate H bonds, so the water molecules at the surface of the cavity occupied by the nonpolar group cannot H bond to other molecules in their usual fashion. In order to recover the lost H bonding energy, these surface waters must orient themselves so as to form an H bonded network enclosing the cavity (Fig. 8-59). This orientation constitutes an ordering of the water structure, since the number of ways that water molecules can form H bonds

**Table 8-5** Thermodynamic Changes for Transferring Hydrocarbons from Water to Nonpolar Solvents at 25°C<sup>a</sup>

Process	$\Delta H$ (kJ · mol <sup>-1</sup> )	$-T\Delta S_u$ (kJ · mol <sup>-1</sup> )	$\Delta G_u$ (kJ · mol <sup>-1</sup> )

<sup>a</sup> $\Delta G_u$ , the **unitary Gibbs free energy change**, is the Gibbs free energy change,  $\Delta G$ , corrected for its concentration dependence so that it reflects only the inherent properties of the substance in question and its interaction with solvent. This relationship, according to Equation [3.13], is

$$\Delta G_u = \Delta G - nRT \ln \frac{[A_f]}{[A_i]}$$

where  $[A_i]$  and  $[A_f]$  are the initial and final concentrations of the substance under consideration, respectively, and  $n$  is the number of moles of that substance. Since the second term in this equation is a purely entropic term (concentrating a substance increases its order),  $\Delta S_u$ , the **unitary entropy change**, is expressed

$$\Delta S_u = \Delta S + nR \ln \frac{[A_f]}{[A_i]}$$

<sup>b</sup>Data measured at 18°C.

about the surface of a nonpolar group is less than the number of ways that they can H bond in bulk water.

Unfortunately, the complexity of liquid water's basic structure (Section 2-1Ac) has not yet allowed a detailed structural description of this ordering process. One model

**Figure 8-59** The orientational preference of water molecules next to a nonpolar solute. In order to maximize their H bonding energy, these water molecules tend to straddle the inert solute such that, for relatively small solutes, two or three of their tetrahedral directions are tangential to its surface. This permits them to form H bonds (black) with neighboring water molecules lining the nonpolar surface. However, for larger (flatter) nonpolar solutes, the adjacent water molecules are each geometrically limited to participating in no more than three H bonds. In either case, the ordering of water molecules extends several layers of water molecules beyond the first hydration shell of the nonpolar solute. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

that has been proposed is that water forms quasi-crystalline H bonded cages about the nonpolar groups similar to those of **clathrates** (Fig. 8-60). The magnitudes of the entropy changes that result when nonpolar substances are dissolved in water, however, indicate that the resulting water structures can only be slightly more ordered than bulk water. They also must be quite different from that of ordinary ice,

**Figure 8-60** Structure of the clathrate  $(n\text{-C}_4\text{H}_9)_3\text{S}^+\text{F}^- \cdot 23\text{H}_2\text{O}$ . Clathrates are crystalline complexes of nonpolar compounds with water (usually formed at low temperatures and high pressures) in which the nonpolar molecules are enclosed, as shown, by a polyhedral cage of tetrahedrally H bonded water molecules (here represented by only their oxygen atoms). The H bonding interactions of one such water molecule (arrow) are shown in detail. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

**Figure 8-61** Hydropathic index plot for bovine chymotrypsinogen. The sum of the hydropathies of nine consecutive residues (see Table 8-6) are plotted versus the residue sequence number. A large positive hydropathic index is indicative of a hydrophobic region of the polypeptide chain, whereas a

large negative value is indicative of a hydrophilic region. The bars above the midpoint line denote the protein's interior regions, as determined by X-ray crystallography, and the bars below the midpoint line indicate the protein's exterior regions. [After Kyte, J. and Doolittle, R.F., *J. Mol. Biol.* **157**, 111 (1982).]

because, for instance, the solvation of nonpolar groups by water causes a large decrease in water volume (e.g., the transfer of  $\text{CH}_4$  from hexane to water shrinks the water solution by  $22.7 \text{ mL} \cdot \text{mol}^{-1}$  of  $\text{CH}_4$ ), whereas the freezing of water results in a  $1.6\text{-mL} \cdot \text{mol}^{-1}$  expansion.

The unfavorable free energy of hydration of a nonpolar substance caused by its ordering of the surrounding water molecules has the net result that *the nonpolar substance is excluded from the aqueous phase*. This is because the surface area of a cavity containing an aggregate of nonpolar molecules is less than the sum of the surface areas of the cavities that each of these molecules would individually occupy. The aggregation of the nonpolar groups thereby minimizes the surface area of the cavity and therefore the entropy loss of the entire system. In a sense, the nonpolar groups are squeezed out of the aqueous phase by the hydrophobic interactions. Thermodynamic measurements indicate that the free energy change of removing a  $-\text{CH}_2-$  group from an aqueous solution is about  $-3 \text{ kJ} \cdot \text{mol}^{-1}$ . Although this is a relatively small amount of free energy, *in molecular assemblies involving large numbers of nonpolar contacts, hydrophobic interactions are a potent force*.

Walter Kauzmann pointed out in 1958 that *hydrophobic forces are a major influence in causing proteins to fold into their native conformations*. Figure 8-61 indicates that the amino acid side chain **hydropathies** (indexes of combined hydrophobic and hydrophilic tendencies; Table 8-6) are, in fact, good predictors of which portions of a polypeptide chain are inside a protein, out of contact with the aqueous solvent, and which portions are outside, in contact with the aqueous solvent. In proteins, the effects of hydrophobic forces are often termed **hydrophobic bonding**, presumably to indicate the specific nature of protein folding under the influence of the hydrophobic effect. You should keep in mind, however, that hydrophobic bonding does not generate the directionally specific interactions usually associated with the term “bond.”

#### D. Disulfide Bonds

Since disulfide bonds form as a protein folds to its native conformation (Section 9-1A), they function to stabilize its three-dimensional structure. The relatively reducing chemical character of the cytoplasm, however, greatly diminishes the stability of intracellular disulfide bonds. In fact, almost all proteins with disulfide bonds are secreted to more oxidized extracellular destinations, where their disulfide bonds

**Table 8-6** Hydropathy Scale for Amino Acid Side Chains

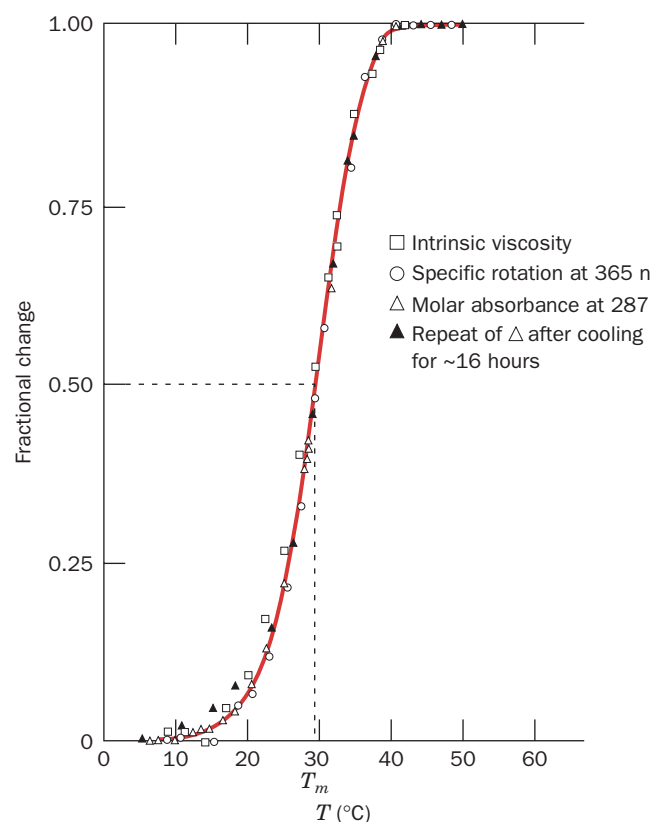

Side Chain	Hydropathy

are effective in stabilizing protein structures [secreted proteins fold to their native conformations—and hence form their disulfide bonds—in the endoplasmic reticulum (Section 12-4Ba), which, unlike other cellular compartments, has an oxidizing environment]. Apparently, the relative “hostility” of extracellular environments toward proteins (e.g., uncontrolled temperatures and pH’s) requires the additional structural stability conferred by disulfide bonds.

### E. Protein Denaturation

The low conformational stabilities of native proteins make them easily susceptible to denaturation by altering the balance of the weak nonbonding forces that maintain the native conformation. When a protein in solution is heated, its conformationally sensitive properties, such as optical rotation (Section 4-2A), viscosity, and UV absorption, change abruptly over a narrow temperature range (e.g., Fig. 8-62). *Such a nearly discontinuous change indicates that the native protein structure unfolds in a cooperative manner: Any partial unfolding of the structure destabilizes the remaining structure, which must simultaneously collapse to the random coil.* The temperature at the midpoint of this process is known as the protein’s **melting temperature**,  $T_m$ , in analogy

**Figure 8-62 Protein denaturation.** The heat-induced denaturation of bovine pancreatic ribonuclease A (RNase A) in an HCl–KCl solvent at pH 2.1 and 0.019 ionic strength was monitored by several conformationally sensitive techniques. The curve is drawn only through the points  $\Delta$ . The melting temperature,  $T_m$ , is defined as the temperature at the midpoint of the transition. Compare the shape of this melting curve with that of duplex DNA (Fig. 5-16). [After Ginsburg, A. and Carroll, W.R., *Biochemistry* **4**, 2169 (1965).]

with the melting of a solid. Most proteins have  $T_m$  values well below 100°C. Recall that nucleic acids likewise have characteristic  $T_m$ ’s (Section 5-3Ca).

In addition to high temperatures, proteins are denatured by a variety of other conditions and substances:

1. pH variations alter the ionization states of amino acid side chains (Table 4-1), which changes protein charge distributions and H bonding requirements.

2. Detergents, some of which significantly perturb protein structures at concentrations as low as  $10^{-6}$  M, hydrophobically associate with the nonpolar residues of a protein, thereby interfering with the hydrophobic interactions responsible for the protein’s native structure.

3. High concentrations of water-soluble organic substances, such as aliphatic alcohols, interfere with the hydrophobic forces stabilizing protein structures through their own hydrophobic interactions with water. Organic substances with several hydroxyl groups, such as ethylene glycol or sucrose,

however, are relatively poor denaturants because their H bonding ability renders them less disruptive of water structure.

The influence of salts is more variable. Figure 8-63 shows the effects of a number of salts on the  $T_m$  of bovine

**Figure 8-63 Melting temperature of RNase A as a function of the concentrations of various salts.** All solutions also contained 0.15M KCl and 0.013M sodium cacodylate buffer, pH 7. [After von Hippel, P.J. and Wong, K. Y., *J. Biol. Chem.* **10**, 3913 (1965).]

pancreatic **ribonuclease A (RNase A)**. Some salts, such as  $(\text{NH}_4)_2\text{SO}_4$  and  $\text{KH}_2\text{PO}_4$ , stabilize the native protein structure (raise its  $T_m$ ); others, such as  $\text{KCl}$  and  $\text{NaCl}$ , have little effect; and yet others, such as  $\text{KSCN}$  and  $\text{LiBr}$ , destabilize it. The order of effectiveness of the various ions in stabilizing a protein, which is largely independent of the identity of the protein, parallels their capacity to salt out proteins (Section 6-2A). This order is known as the **Hofmeister series**:

The ions in the Hofmeister series that tend to denature proteins,  $\text{I}^-$ ,  $\text{ClO}_4^-$ ,  $\text{SCN}^-$ ,  $\text{Li}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ , and  $\text{Ba}^{2+}$ , are said to be **chaotropic**. This list should also include the guanidinium ion ( $\text{Gu}^+$ ) and the nonionic urea, which, in concentrations in the range 5 to 10 M, are the most commonly used protein denaturants. The effect of the various ions on proteins is largely cumulative:  $\text{GuSCN}$  is a much more potent denaturant than the often used  $\text{GuCl}$ , whereas  $\text{Gu}_2\text{SO}_4$  stabilizes protein structures.

Chaotropic agents increase the solubility of nonpolar substances in water. Consequently, their effectiveness as denaturing agents stems from their ability to disrupt hydrophobic interactions, although the manner in which they do so is not well understood. Conversely, those substances listed that stabilize proteins strengthen hydrophobic forces, thus increasing the tendency of water to expel proteins. This accounts for the correlation between the abilities of an ion to stabilize proteins and to salt them out.

### F. Explaining the Stability of Thermostable Proteins

Certain species of bacteria known as **hyperthermophiles** grow at temperatures near  $100^\circ\text{C}$  (they live in such places as hot springs and submarine hydrothermal vents, with the most extreme, an Fe(III)-reducing archaeon, growing at  $121^\circ\text{C}$  and remaining viable as high as  $130^\circ\text{C}$ ). These organisms have many of the same metabolic pathways as do **mesophiles** (organisms that grow at “normal” temperatures). Yet, most mesophilic proteins denature at the temperatures at which hyperthermophiles thrive. What is the structural basis for the thermostability of hyperthermophilic proteins?

The difference in the thermal stabilities of the corresponding (hyper)thermophilic and mesophilic proteins does not exceed  $\sim 100 \text{ kJ} \cdot \text{mol}^{-1}$ , the equivalent of a few noncovalent interactions. This is probably why comparisons of the X-ray structures of hyperthermophilic enzymes with their mesophilic counterparts have failed to reveal any striking differences between them. These proteins exhibit some variations in secondary structure but no more so than is often the case for homologous proteins from distantly related mesophiles. However, several of these thermostable enzymes have a superabundance of salt bridges on their surfaces, many of which are arranged in extensive

networks. Indeed, one such network from *Pyrococcus furiosus* **glutamate dehydrogenase** consists of 18 side chains.

The idea that salt bridges can stabilize a protein structure appears to contradict the conclusion of Section 8-4Aa that ion pairs are, at best, marginally stable. The key to this apparent paradox is that the salt bridges in thermostable proteins form networks. Thus, the gain in charge-charge free energy on associating a third charged group with an ion pair is comparable to that between the members of this ion pair, whereas the free energy lost on desolvating and immobilizing the third side chain is only about half that lost in bringing together the first two side chains. The same, of course, is true for the addition of a fourth, fifth, etc., side chain to a salt bridge network.

Not all thermostable proteins have such a high incidence of salt bridges. Structural comparisons suggest that these proteins are stabilized by a combination of small effects, the most important of which are an increased size in the protein's hydrophobic core, an increased size in the interface between its domains and/or subunits, and a more tightly packed core as evidenced by a reduced surface-to-volume ratio.

The fact that the proteins of hyperthermophiles and mesophiles are homologous and carry out much the same functions indicates that mesophilic proteins are by no means maximally stable. This, in turn, strongly suggests *that the marginal stability of most proteins under physiological conditions (averaging  $\sim 0.4 \text{ kJ/mol}$  of amino acid residues) is an essential property that has arisen through evolutionary design*. Perhaps this marginal stability helps confer the structural flexibility that many proteins require to carry out their physiological functions (Section 9-4). Other possibilities are that it may facilitate the elimination of otherwise stable non-native conformations (Section 9-2C), it may promote the unfolding of proteins so as to permit their insertion into or transport through membranes (Section 12-4E), and/or it may expedite their programmed degradation (Section 32-6).

## 5 QUATERNARY STRUCTURE

Proteins, because of their multiple polar and nonpolar groups, stick to almost anything; anything, that is, but other proteins. This is because the forces of evolution have arranged the surface groups of proteins so as to prevent their association under physiological conditions. If this were not the case, their resulting nonspecific aggregation would render proteins functionally useless (recall, e.g., the consequences of sickle-cell anemia; Section 7-3A). In his pioneering ultracentrifugational studies on proteins, however, The Svedberg discovered that some proteins are composed of more than one polypeptide chain. Subsequent studies established that this is, in fact, true of most proteins, including nearly all those with molecular masses  $> 100 \text{ kD}$ . Furthermore, these polypeptide **subunits** associate in a geometrically specific manner. The spatial arrangement of these subunits is known as a protein's **quaternary structure (4° structure)**.

There are several reasons why multisubunit proteins are so common. In large assemblies of proteins, such as collagen fibrils, the advantages of subunit construction over the synthesis of one huge polypeptide chain are analogous to those of using prefabricated components in constructing a building: Defects can be repaired by simply replacing the flawed subunit rather than the entire protein, the site of subunit manufacture can be different from the site of assembly into the final product, and the only genetic information necessary to specify the entire edifice is that specifying its few different self-assembling subunits. In the case of enzymes, increasing a protein's size tends to better fix the three-dimensional positions of the groups forming the enzyme's active site. Increasing the size of an enzyme through the association of identical subunits is more efficient, in this regard, than increasing the length of its polypeptide chain since each subunit has an active site. Additionally, in some multimeric enzymes, the active site occurs at the interface between subunits where it is comprised of groups from two or more subunits. More importantly, however, the subunit construction of many enzymes provides the structural basis for the regulation of their activities. Mechanisms for this indispensable function are discussed in Sections 10-4 and 13-4.

In this section we discuss how the subunits of multisubunit proteins associate, what sorts of symmetries they have, and how their stoichiometries may be determined.

### A. Subunit Interactions

A multisubunit protein may consist of identical or non-identical polypeptide chains. Recall that hemoglobin, for example, has the subunit composition  $\alpha_2\beta_2$ . We shall refer to proteins with identical subunits as **oligomers** and to these identical subunits as **protomers**. A protomer may therefore consist of one polypeptide chain or several unlike polypeptide chains. In this sense, hemoglobin is a **dimer** (oligomer of two protomers) of  $\alpha\beta$  protomers (Fig. 8-64).

The association of two subunits typically buries 1000 to 2000  $\text{\AA}^2$  of surface area (minimally  $\sim 600 \text{\AA}^2$ ) that would

otherwise be exposed to solvent. The resulting contact regions superficially resemble the interiors of single subunit proteins: They contain closely packed nonpolar side chains, hydrogen bonds, and in some cases, interchain disulfide bonds. However, protein-protein interfaces differ from subunit interiors in several respects:

1. They tend to have hydrophobicities between those of protein interiors and exteriors. In particular, the subunit interfaces of proteins that dissociate *in vivo* have lesser hydrophobicities than do permanent interfaces.
2. An average of  $\sim 77\%$  of intersubunit hydrogen bonds are between side chains. In contrast, an average of  $\sim 68\%$  of the hydrogen bonds within subunits are between backbone atoms. This is mainly because secondary structural elements are not continued across subunit boundaries (with the occasional exception of  $\beta$  sheets; see below).
3. Around 56% of protein-protein interfaces contain salt bridges. These contribute to the specificity as well as to the stability of subunit associations.

In addition, there are negligibly few hydrogen bonds and salt bridges at the edges of the contact regions. Not surprisingly, the residues at protein-protein interfaces are evolutionarily well conserved compared to other surface residues.

### B. Symmetry in Proteins

In the vast majority of oligomeric proteins, the protomers are *symmetrically arranged*; that is, the protomers occupy geometrically equivalent positions in the oligomer. This implies that each protomer has exhausted its capacity to bind to other protomers; otherwise, higher oligomers would form. As a result of this limited binding capacity, protomers pack about a single point to form a closed shell, a phenomenon known as **point symmetry**. Proteins cannot have inversion or mirror symmetry, however, because such symmetry operations convert chiral L-residues to D-residues. Thus, *proteins can only have rotational symmetry*.

**Figure 8-64** The quaternary structure of hemoglobin. The  $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$ , and  $\beta_2$  subunits in this stereo, space-filling drawing are colored yellow, green, blue, and cyan, respectively. Heme groups are red. The protein is viewed along its molecular 2-fold rotation axis, which relates the  $\alpha_1\beta_1$  protomer to the  $\alpha_2\beta_2$  protomer.

Instructions for viewing stereo drawings are given in the appendix to this chapter. [Based on an X-ray structure by Max Perutz, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 2DHB.]

Various types of rotational symmetry occur in proteins, as X-ray crystal structure determinations have shown:

### 1. Cyclic symmetry

In the simplest type of rotational symmetry, **cyclic symmetry**, subunits are related (brought to coincidence) by a single axis of rotation (Fig. 8-65a). Objects with 2-, 3-, . . . , or  $n$ -fold rotational axes are said to have  $C_2$ ,  $C_3$ , . . . , or  $C_n$  symmetry, respectively. An oligomer with  $C_n$  symmetry consists of  $n$  protomers that are related by  $(360/n)^\circ$  rotations.  $C_2$  symmetry is the most common symmetry in proteins; higher cyclic symmetries are relatively rare.

A common mode of association between protomers related by a twofold rotation axis is the continuation of a  $\beta$  sheet across subunit boundaries. In such cases, the 2-fold axis is perpendicular to the  $\beta$  sheet so that two symmetry equivalent  $\beta$  strands hydrogen bond in an antiparallel fashion. In this manner, the sandwich of two 4-stranded  $\beta$  sheets in a protomer of **transthyretin** (also known as **prealbumin**) is extended across a 2-fold axis to form a sandwich of two 8-stranded  $\beta$  sheets (Fig. 8-66). Hemoglobin's two  $\alpha\beta$  protomers are also related by  $C_2$  symmetry (Fig. 8-64).

### 2. Dihedral symmetry

**Dihedral symmetry** ( $D_n$ ), a more complicated type of rotational symmetry, is generated when an  $n$ -fold rotation axis and a 2-fold rotation axis intersect at right angles (Fig. 8-65b). An oligomer with ( $D_n$ ) symmetry consists of

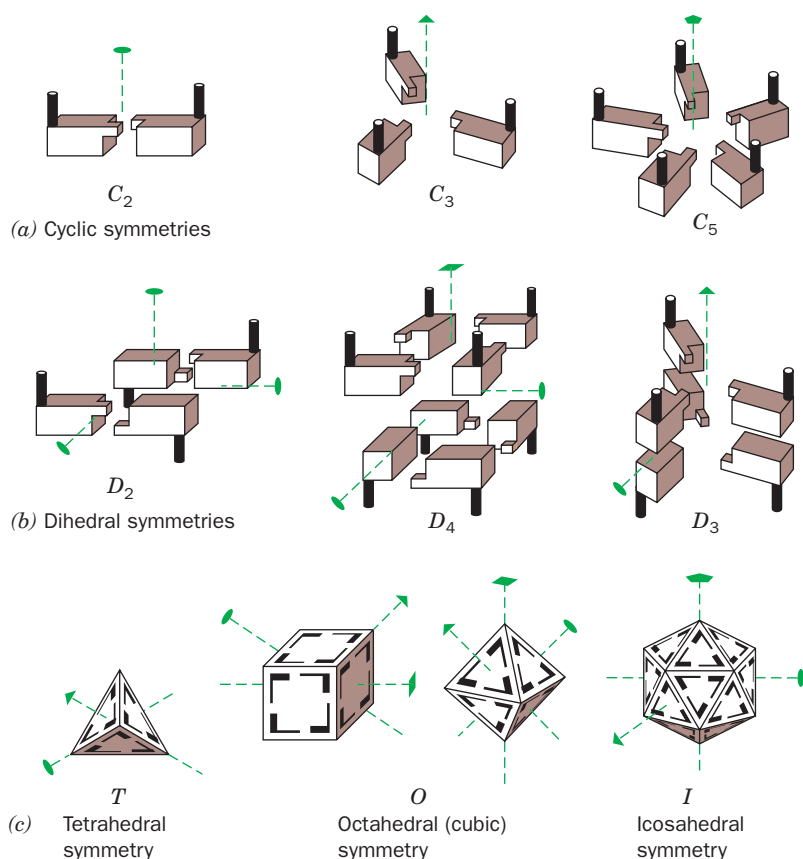

$2n$  protomers.  $D_2$  symmetry is, by far, the most common type of dihedral symmetry in proteins.

Hemoglobin's  $\alpha$  and  $\beta$  subunits have such similar structures that, in the hemoglobin  $\alpha_2\beta_2$  tetramer, they are related by pseudo-2-fold rotational axes that are perpendicular to the tetramer's exact 2-fold axis (lie in the plane of Fig. 8-64; Section 10-2B). Hence the tetramer is said to be **pseudosymmetric** and have pseudo- $D_2$  symmetry. The X-ray structure of **glutamine synthetase** reveals that this enzyme consists of 12 identical subunits that are related by  $D_6$  symmetry (Fig. 8-67).

Under the proper conditions, many oligomers with  $D_n$  symmetry dissociate into two oligomers, each with  $C_n$  symmetry (and which are related by the 2-fold rotation axes in the  $D_n$  oligomer). These, in turn, dissociate to their component protomers under more stringent denaturing conditions.

### 3. Other rotational symmetries

The only other types of rotationally symmetric objects are those that have the rotational symmetries of a tetrahedron ( $T$ ), a cube or octahedron ( $O$ ), or a dodecahedron or icosahedron ( $I$ ), and hence have 12, 24, and 60 equivalent positions, respectively (Fig. 8-65c). Certain multienzyme complexes are based on octahedral symmetry (Section 21-2A), whereas others have icosahedral symmetry (Section 21-2Aa). The protein coats of the so-called spherical viruses also have icosahedral symmetry (Section 33-2A).

**Figure 8-65** Some possible symmetries of proteins with identical protomers. The lenticular shape, the triangle, the square, and the pentagon at the ends of the dashed lines indicate, respectively, the unique 2-fold, 3-fold, 4-fold, and 5-fold rotational axes of the objects shown. (a) Assemblies with the cyclic symmetries  $C_2$ ,  $C_3$ , and  $C_5$ . (b) Assemblies with the dihedral symmetries  $D_2$ ,  $D_4$ , and  $D_3$ . In these objects, a 2-fold axis is perpendicular to the vertical 2-, 4-, and 3-fold axes. (c) Assemblies with  $T$ ,  $O$ , and  $I$  symmetry. Note that the tetrahedron has some but not all of the symmetry elements of the cube, and that the cube and the octahedron have the same symmetry. [Illustration, Irving Geis. **Figure 8-66** A dimer of transthyretin as viewed down its 2-fold axis (black lenticular symbol). Each protomer, which is colored in rainbow order from its N-terminus (blue) to its C-terminus (red), consists of a  $\beta$  barrel (really a  $\beta$  sandwich) containing two Greek keys (Fig. 8-50a). Note how both of its  $\beta$  sheets are continued in an antiparallel fashion in the symmetry-related protomer to form a sandwich of two 8-stranded  $\beta$  sheets. Two of these dimers associate back to back in the native protein to form a tetramer with  $D_2$  symmetry. [Based on an X-ray structure by Colin Blake, Oxford University, U.K. PDBid 2PAB.]

### a. Helical Symmetry

Some protein oligomers have **helical symmetry** (Fig. 8-68). The chemically identical subunits in a helix are not strictly equivalent because, for instance, those at the ends of the helix have a different environment than those in the middle. Nevertheless, the surroundings of all subunits in a long helix, except those near its ends, are sufficiently similar that the subunits are said to be **quasi-equivalent**. The subunits of many structural proteins, for example, those of **actin** (Section 35-3Ad) and **tubulin** (Section 35-3Gc), assemble into fibers with helical symmetry.

**Figure 8-67** X-ray structure of glutamine synthetase from *Salmonella typhimurium*. The enzyme consists of 12 identical subunits, here drawn in worm form, arranged with  $D_6$  symmetry. (a) View down the 6-fold axis of symmetry showing only the six subunits of the upper ring in alternating blue and green. The subunits of the lower ring are roughly directly below those of the upper ring. The protein, including its side chains (not shown), has a diameter of 143 Å. The six active sites shown are marked by pairs of bound  $Mn^{2+}$  ions (magenta spheres). Also drawn in one active site are ADP (cyan) and the inhibitor phosphinothricin (red). (b) Side view along one of the protein's 2-fold axes showing only its eight nearest subunits. The molecule extends 103 Å along the 6-fold axis, which is vertical in this view. [Based on an X-ray structure by David Eisenberg, UCLA. PDBid 1FPY.]

**Figure 8-68** A helical structure composed of a single kind of subunit.

### b. Obtaining the Atomic Coordinates of a Biologically Functional Quaternary Structure

Crystals consist of three-dimensional lattices of identical **unit cells** (the smallest portion of a crystal lattice that is repeated by translation) that usually have internal symmetry. The crystal's **asymmetric unit** is the unique portion of the unit cell from which the entire unit cell can be generated through the operation of its symmetry elements. In a crystal of a symmetrical protein, if one or more of protein's symmetry axes are coincident with unit cell's symmetry axes, the asymmetric unit would contain a subset of the protein's protomers (often only one), which would be related to the other such subsets by **crystallographic symmetry**. Alternatively, the asymmetric units in crystals of many oligomeric proteins contain one or more entire proteins, in which case their protomers are said to be related by **non-crystallographic symmetry**.

A Protein Data Bank (PDB) coordinate file for an X-ray crystal structure contains the atomic coordinates of the protomers occupying an asymmetric unit. The entire crystal structure can then be generated through the application of its crystallographic symmetry. Thus, a symmetric protein's PDB coordinate file might contain the coordinates of only one of its several symmetry-related protomers. Moreover, in some cases, the intermolecular contacts in a crystal may sufficiently resemble the contacts between the protomers in an oligomer so that its quaternary structure may be ambiguous.

To alleviate these difficulties, computerized procedures have been devised to generate the coordinates of the most

probable biologically functional molecule based on several criteria, including maximizing the solvent-accessible surface area that is buried on forming the oligomer. The coordinates of the most probable quaternary structures of macromolecules whose structures have been determined by X-ray crystallography are publicly available at [http://www.ebi.ac.uk/msd-srv/prot\\_int/pistart.html](http://www.ebi.ac.uk/msd-srv/prot_int/pistart.html). The biological unit may also be viewed directly from the corresponding PDB Structure Summary page, although note that the two algorithms do not always agree.

### C. Determination of Subunit Composition

In the absence of an X-ray or NMR structure, the number of different types of subunits in an oligomeric protein may be determined by end group analysis (Section 7-1A). In principle, the subunit composition of a protein may be determined by comparing its molecular mass with those of its component subunits. In practice, however, experimental difficulties, such as the partial dissociation of a supposedly intact protein and uncertainties in molecular mass determinations, often provide erroneous results.

#### a. Cross-Linking Agents Stabilize Oligomers

A method for 4° structure analysis, which is especially useful for oligomeric proteins that decompose easily, employs **cross-linking agents** such as **dimethylsuberimidate** or **glutaraldehyde** (Fig. 8-69). If carried out at sufficiently low protein concentrations to eliminate intermolecular reactions, cross-linking reactions will covalently join only the

**Figure 8-69** Cross-linking agents. Dimethylsuberimidate and glutaraldehyde are bifunctional reagents that react to covalently cross-link two Lys residues.

subunits in a molecule that are no farther apart than the length of the cross-link (assuming, of course, that the proper amino acid residues are present). The molecular mass of a cross-linked protein therefore places a lower

limit on its number of subunits. Such studies can also provide some indication of the distance between subunits, particularly if a series of cross-linking agents with different lengths is employed.

## APPENDIX Viewing Stereo Pictures

Although we live in a three-dimensional world, the images that we see have been projected onto the two-dimensional plane of our retinas. Depth perception therefore involves binocular vision: The slightly different views perceived by each eye are synthesized by the brain into a single three-dimensional impression.

Two-dimensional pictures of complex three-dimensional objects are difficult to interpret because most of the information concerning the third dimension is suppressed. This information can be recovered by presenting each eye with the image only it would see if the three-dimensional object were actually being viewed. A **stereo pair** therefore consists of two images, one for each eye. Corresponding points of stereo pairs are generally separated by ~6 cm, the average distance between human eyes. Stereo drawings are usually computer generated because of the required precision of the geometric relationship between the members of a stereo pair.

In viewing a stereo picture, one must overcome the visual habits of a lifetime because each eye must see its corresponding view independently. Viewers are commercially available to aid in this endeavor. However, with some training and practice, equivalent results can be obtained without their use.

To train yourself to view stereo pictures, you should become aware that each eye sees a separate image. Hold your finger up about a foot (30 cm) before your eyes while fixing your gaze on some object beyond it. You may realize that you are seeing two images of your finger. If, after some concentration, you are still aware of only one image, try blinking your eyes alternately to ascertain which of your eyes is seeing the image you perceive. Perhaps alternately covering and uncovering this dominant eye while staring past your finger will help you become aware of the independent workings of your eyes.

The principle involved in seeing a stereo picture is to visually fuse the left member of the stereo pair seen by the left eye with the right member seen by the right eye. To do this, sit comfortably at a desk, center your eyes about a foot over a stereo drawing such as Fig. 8-70 and stare through it at a point about a foot (30 cm) below the drawing. Try to visually fuse the central members of the four out-of-focus images you see. When you have succeeded, your visual system will “lock onto” it and this fused central image will appear three-dimensional. Ignore the outer images. You may have to slightly turn the book, which should be held perfectly flat, or your head in order to bring the two images to the same level. It may help to place the book near the edge of a desk, center your finger about a foot below the drawing, and fixate on your finger while concentrating on the stereo pair. Another trick is to hold your flattened hand or an index card between your eyes so that the left eye sees only the left half of the stereo pair and the right eye sees only the right half and then fuse the two images you see.

The final step in viewing a stereo picture is to focus on the image while maintaining fusion. This may not be easy because our ingrained tendency is to focus on the point at which our gaze converges. It may help to move your head closer to or farther from the picture. Most people (including the authors) require a fair amount of practice to become proficient at seeing stereo without a viewer. However, the three-dimensional information provided by stereo pictures, not to mention their aesthetic appeal, makes it worth the effort. In any case, the few stereo figures used in this textbook have been selected for their visual clarity without the use of stereo; stereo will simply enhance their impression of depth.

**Figure 8-70** Stereo drawing of a tetrahedron inscribed in a cube. When properly viewed, the apex of the tetrahedron should appear to be pointing toward the viewer.

## CHAPTER SUMMARY

**1 Secondary Structure** The peptide group is constrained by resonance effects to a planar, trans conformation. Steric interactions further limit the conformations of the polypeptide backbone by restricting the torsion angles,  $\phi$  and  $\psi$ , of each peptide group to three small regions of the Ramachandran diagram. The  $\alpha$  helix, whose conformation angles fall within the allowed regions of the Ramachandran diagram, is held together by hydrogen bonds. The  $3_{10}$  helix, which is more tightly coiled than the  $\alpha$  helix, lies in a mildly forbidden region of the Ramachandran diagram. Its infrequent occurrences are most often as single-turn terminations of  $\alpha$  helices. In the parallel and antiparallel  $\beta$  pleated sheets, two or more almost fully extended polypeptide chains associate such that neighboring chains are hydrogen bonded. These  $\beta$  sheets have a right-handed curl when viewed along their polypeptide chains. The polypeptide chain often reverses its direction through a  $\beta$  bend. Other arrangements of the polypeptide chain, which are collectively known as coil conformations, are more difficult to describe but are no less ordered than are  $\alpha$  or  $\beta$  structures.

**2 Fibrous Proteins** The mechanical properties of fibrous proteins can often be correlated with their structures. Keratin, the principal component of hair, horn, and nails, forms protofibrils that consist of two pairs of  $\alpha$  helices in which the members of each pair are twisted together into a left-handed coil. The pliability of keratin decreases as the content of disulfide cross-links between the protofibrils increases. Collagen is the major protein component of connective tissue. Its every third residue is Gly, and many of the others are Pro and Hyp. This permits collagen to form a ropelike triple helical structure that has great tensile strength. Collagen molecules aggregate in a staggered array to form fibrils that are covalently cross-linked by groups derived from their His and Lys side chains. Mutations in collagen or the inactivation of the enzymes that process it usually cause a loss in the structural integrity of the affected tissues.

**3 Globular Proteins** The accuracies of protein X-ray structure determinations are limited by crystalline disorder to resolutions that are mostly in the range 1.5 to 3.0 Å. This requires that a protein's structure be determined by fitting its primary structure to its electron density map. Several lines of evidence indicate that protein crystal structures are nearly identical to their solution structures. The structures of small proteins may also be determined in solution by 2D- or multidimensional-NMR techniques which, for the most part, yield results similar to those of X-ray crystal structures.

A globular protein's  $3^\circ$  structure is the arrangement of its various elements of  $2^\circ$  structure together with the spatial dispositions of its side chains. Its amino acid residues tend to segregate according to residue polarity. Nonpolar residues preferentially occupy the interior of a protein out of contact with the aqueous solvent, whereas charged polar residues are located on its surface. Uncharged polar residues may occur at either location but, if they are internal, they form hydrogen bonds with other protein groups. The interior of a protein molecule resembles a crystal of an organic molecule in its packing

efficiency. Larger proteins often fold into two or more domains that may have functionally and structurally independent properties. Certain groupings of secondary structural elements, known as motifs or supersecondary structures, repeatedly occur as components of globular proteins. They combine in numerous ways to form a fold, that is, the tertiary structure of a domain. Among the common folds in globular proteins are the globin fold, 4-helix bundles, various  $\beta$  barrels (up-and-down, Greek key, and jelly roll), the  $\alpha/\beta$  barrel, and the various open  $\beta$  sheets. The atomic coordinates of the  $\sim 70,000$  proteins and nucleic acids whose structures have been determined are archived in the Protein Data Bank (PDB). These macromolecules may be visually examined through the use of a variety of molecular graphics programs and may be analyzed by programs that compare and classify their structures in various ways.

**4 Protein Stability** Proteins have marginally stable native structures that form as a result of a fine balance among the various noncovalent forces to which they are subject: ionic and dipolar interactions, hydrogen bonding, and hydrophobic forces. Ionic interactions are relatively weak in aqueous solutions due to the solvating effects of water. The various interactions among permanent and induced dipoles, which are collectively referred to as van der Waals forces, are even weaker and are effective only at short range. Nevertheless, because of their large numbers, they cumulatively have an important influence on protein structures. Hydrogen bonding forces are far more directional than are other noncovalent forces. They add little stability to a protein structure, however, because the H bonds that native proteins form internally are only marginally stronger than those that unfolded proteins form with water. Yet, because most H bonds are local, a protein can only fold stably in ways such that almost all of its possible internal H bonds are formed. Hence H bonding is important in specifying the native structure of a protein. Hydrophobic forces arise from the unfavorable ordering of water structure that results from the hydration of nonpolar groups. By folding such that its nonpolar groups are out of contact with the aqueous solvent, a protein minimizes these unfavorable interactions. The fact that most protein denaturants interfere with the hydrophobic effect demonstrates the importance of hydrophobic forces in stabilizing native protein structures. Disulfide bonds often stabilize the native structures of extracellular proteins. The proteins from (hyper)thermophilic organisms have higher  $T_m$ 's than their mesophilic counterparts. Several hyperthermophilic proteins are stabilized by extensive surface networks of salt bridges.

**5 Quaternary Structure** Many proteins consist of noncovalently linked aggregates of subunits in which the subunits may or may not be identical. Most oligomeric proteins are rotationally symmetric. The protomers in many fibrous proteins are related by helical symmetry. The quaternary structures of proteins are best elucidated using X-ray or NMR techniques. In their absence, cross-linking studies can indicate the subunit composition of an oligomeric protein.

## BIOINFORMATICS EXERCISES

Bioinformatics Exercises are available at [www.wiley.com/college/voet](http://www.wiley.com/college/voet)

### Chapter 8

#### Visualization of Three-Dimensional Protein Structures Using Jmol and Pymol

- 1. Obtaining Structural Information.** Compare different secondary structure predictions for a given protein sequence, then inspect its X-ray crystallographic structure.
- 2. Exploring the Protein Data Bank.** Learn how to locate and download specific protein structure files, sequences, and images. Explore additional educational resources and links to additional structural biology resources. Examine a protein structure file and use Jmol and Pymol to visualize the protein and highlight selected features.
- 3. Protein Families.** Identify homologous proteins in other structural databases.

## PROBLEMS

**1.** What is the length of an  $\alpha$  helical section of a polypeptide chain of 20 residues? What is its length when it is fully extended (all trans)?

**\*2.** From an examination of Fig. 8-7, it is apparent that the polypeptide conformation angle  $\phi$  is more constrained than is  $\psi$ . By referring to Fig. 8-4, or better yet, by examining a molecular model, indicate the sources of the steric interference that limit the allowed values of  $\phi$  when  $\psi = 180^\circ$ .

**3.** For a polypeptide chain made of  $\gamma$ -amino acids, state the nomenclature of the helix analogous to the  $3_{10}$  helix of  $\alpha$ -amino acids. Assume the helix has a pitch of 9.9 Å and a rise per residue of 3.2 Å.

**\*4.** Table 8-7 (page 276) gives the torsion angles,  $\phi$  and  $\psi$ , of hen egg white lysozyme for residues 24–73 of this 129-residue protein. (a) What is the secondary structure of residues 26–35? (b) What is the secondary structure of residues 42–53? (c) What is the probable identity of residue 54? (d) What is the secondary structure of residues 56–68? (e) What is the secondary structure of residues 69–71? (f) What additional information besides the torsion angles,  $\phi$  and  $\psi$ , of each of its residues is required to define the three-dimensional structure of a protein?

**5.** Hair splits most easily along its fiber axis, whereas fingernails tend to split across the finger rather than along it. What are the directions of the keratin fibrils in hair and in fingernails? Explain your reasoning.

**6.** What is the growth rate, in turns per second, of the  $\alpha$  helices in a hair that is growing  $15 \text{ cm} \cdot \text{year}^{-1}$ ?

**7.** Can polyproline form a collagenlike triple helix? Explain.

**8.** As Mother Nature's chief engineer, you have been asked to design a five-turn  $\alpha$  helix that is destined to have half its circumference immersed in the interior of a protein. Indicate the helical wheel projection of your prototype  $\alpha$  helix and its amino acid sequence (see Fig. 8-43a).

**9.**  $\beta$ -Aminopropionitrile is effective in reducing excessive scar tissue formation after an injury (although its use is contraindicated by side effects). What is the mechanism of action of this lathyrogen?

**\*10.** Using your network browser, visit the Protein Data Bank (PDB) at <http://www.rcsb.org/> (for this exercise, you should use some other browser besides Safari because it is not fully compatible with CE). To explore the structure of  $\gamma$ -B crystallin, click the

“Enter a PDB id or keyword” button, enter “4GCR” in the field to its right, and click the “Site Search” button. On the left of the “Structure Summary” window that comes up, click on “PDB File” under “Display Files” and inspect the file that appears. (a) How many residues does this protein have and how many water molecules have been found to be associated with it in this crystal structure? (b) Draw skeletal diagrams of an Arg, a Glu, and a Tyr residue and label their atoms using the nomenclature employed in the PDB file. (c) What are the atomic coordinates of the S atom of Cys 32? What is the identity of atom 1556, which is labeled “OXT”? (d) Return to the Structure Summary page and, under “Display Options” on the right, examine the structure of the protein using the viewer of your choice. Can you see that the protein is composed of two well-separated and apparently similar domains? (e) To structurally classify this protein, return to the Structure Summary page and state the different ways that SCOP and CATH (near the bottom of the page) classify this protein. (f) To structurally compare the protein's two domains, point your browser to CE (<http://cl.sdsc.edu/>) and, in the subsequent window, click on “Two Chains.” In the window that comes up, for both Chain 1 and Chain 2, click on the “PDB:” button, enter “4GCR” in the box to its right, and check the “Use Fragment From:” box. Then for Chain 1 enter the range 1 to 83 and for Chain 2 enter the range 84 to 174. Then click on the “Calculate Alignment” button (at the top). The window that appears shows the aligned sequences of the two peptides based on their structure. What is the percent identity of the two peptides (upper right)? Describe the gaps, if any, in the alignment. Now click on the “Press to Start Compare3D” button. The window that comes up shows the superimposed  $C_\alpha$  backbones of the two peptide segments in blue and magenta. Rotate this model by clicking on it and dragging your mouse. Describe what you see. What is the “RMSD (Å)” (root mean square deviation in Å) of the superimposed backbone segments? What is the significance of the short white segment of chain? What are the two gray segments? Click on specific residues in the sequences below to highlight their positions in the aligned structures.

**\*11.** Using a molecular graphics viewer, inspect the structures of the following proteins as indicated by their PDBIDs. Draw the corresponding topological diagrams and name the fold, if it is a standard one, for each domain in the protein. (a) 1 RCP, (b) 1 RCB, (c) 1 TNF, (d) 2 CMD, (e) 1 RHD, and (f) 2 TAA. [Note: Although all of these proteins consist of only one type of subunit, some of the PDB files contain the coordinates for more

**Table 8-7** Torsion Angles ( $\phi$ ,  $\psi$ ) for Residues 24 to 73 of Hen Egg White Lysozyme

Source: Imoto, T., Johnson, L.N., North, A.C.T., Phillips, D.C., and Rupley, J.A., in Boyer, P.D. (Ed.), *The Enzymes* (3rd ed.), Vol. 7, pp. 693-695, Academic Press (1972).

than one chain. Your task will be simplified if you display only one of these chains (their structures are essentially identical). If you use the stand-alone version of Jmol as your viewer (a Jmol tutorial is on the “Student Companion Site” at <http://www.wiley.com/college/voet/>), this is easily done by typing, for example, “restrict \*a” into the Console window to restrict the display to the A chain. For proteins consisting of more than one domain, inspect each domain individually using the same technique (for example, after typing “restrict \*a”, typing “restrict 1-20” will display only residues 1–20 of the A chain). A polypeptide chain is most easily followed if it is displayed in Backbone, Cartoons, Ribbons, Strands, or Trace form and assigned Group colors by opening the Console and entering the command “color group all” (which colors the chain, from N- to C-terminus, in rainbow order, blue to red).]

**12.** It is often stated that proteins are quite large compared to the molecules they bind. However, what constitutes a large molecule depends on your point of view. Calculate the ratio of the volume of a hemoglobin molecule (65 kD) to that of the four O<sub>2</sub> molecules it binds. Also calculate the ratio of the volume of a typical office (4 × 4 × 3 m) to that of a typical office worker (70 kg) that occupies it. Assume that the molecular volumes of hemoglobin and O<sub>2</sub> are in equal proportion to their molecular masses and that the office worker has a density of 1.0 g · cm<sup>-3</sup>. Compare these ratios. Is this the answer you expected?

**13.** Why are London dispersion forces always attractive?

**14.** Membrane-bound proteins are generally closely associated with the nonpolar groups of lipid molecules (Section 12-3A). Explain how detergents affect the structural integrity of membrane-bound proteins in comparison to their effects on normal globular proteins.

**15.** The coat protein of **tomato bushy stunt virus** consists of 180 chemically identical subunits, each of which is composed of ~386 amino acid residues. The probability that a wrong amino acid residue will be biosynthetically incorporated in a polypeptide chain is 1 part in 3000 per residue. Calculate the average number of coat protein subunits that would have to be synthesized in order to produce a perfect viral coat. What would this number be if the viral coat were a single polypeptide chain with the same number of residues that it actually has?

**16.** State the rotational symmetries of each of the following objects: (a) a starfish, (b) a square pyramid, (c) a rectangular box, and (d) a trigonal bipyramid.

**\*17.** Through the use of your favorite molecular graphics viewer, state the rotational symmetries of the proteins with the following PDBids: (a) 1 TIM, (b) 1 TNF, (c) 6 PFK, and (d) 1 AIY. [Note: When using Jmol, individual polypeptide chains are most easily differentiated by displaying the protein in Backbone, Cartoons, Ribbons, Strands, or Trace form and assigning them Chain

colors (e.g., Color > Structure > Cartoon > By Scheme > Chain), which makes each polypeptide chain a different color.)]

**18.** Myoglobin and the subunits of hemoglobin are polypeptides of similar size and structure. Compare the expected ratio of nonpolar to polar amino acid residues in myoglobin and in hemoglobin.

**19.** Sickle-cell hemoglobin (HbS) differs from normal human adult hemoglobin (HbA) by a single mutational change, Glu β6 → Val, which causes the HbS molecules to aggregate under proper conditions (Section 7-3A). Under certain conditions, the HbS filaments that form at body temperature disaggregate when the temperature is lowered to 0°C. Explain.

**20.** Indicate experimental evidence that is inconsistent with the hypothesis that urea and guanidinium ion act to denature proteins by competing for their internal hydrogen bonds.

**21.** Proteins in solution are often denatured if the solution is shaken violently enough to cause foaming. Indicate the mechanism of this process. (*Hint:* The nonpolar groups of detergents extend into the air at air–water interfaces.)

**22.** An oligomeric protein in a dilute buffer at pH 7 dissociates to its component subunits when exposed to the following agents. Which of these observations would not support the contention that the quaternary structure of the protein is stabilized exclusively by hydrophobic interactions? Explain. (a) 6M guanidinium chloride, (b) 20% ethanol, (c) 2M NaCl, (d) temperatures below 0°C, (e) 2-mercaptoethanol, (f) pH 3, and (g) 0.01M SDS.

**\*23.** The SDS–polyacrylamide gel electrophoresis of a protein yields two bands corresponding to molecular masses of 10 and 17 kD. After cross-linking this protein with dimethylsuberimidate under sufficient dilution to eliminate intermolecular cross-linking, SDS–polyacrylamide gel electrophoresis of the product yields 12 bands with molecular masses 10, 17, 20, 27, 30, 37, 40, 47, 54, 57, 64, and 74 kD. Assuming that dimethylsuberimidate can cross-link only contacting subunits, diagram the quaternary structure of the protein.

**\*24.** Mammals possess two genetically distinct but closely related forms of lactate dehydrogenase (LDH), the M type (which predominates in skeletal muscle) and the H type (which predominates in heart tissue). Before the X-ray structure of LDH was known, the oligomeric state of LDH was determined by dissociating M type and H type LDH to their component subunits and then reconstituting the mixture. This treatment yielded five electrophoretically distinct **isozymes** (catalytically and structurally similar but genetically distinct enzymes from the same organism), M<sub>4</sub>, M<sub>3</sub>H, M<sub>2</sub>H<sub>2</sub>, MH<sub>3</sub>, and H<sub>4</sub>, thereby demonstrating that LDH is a tetramer. What are the relative amounts of each isozyme formed when equimolar amounts of M<sub>4</sub> and H<sub>4</sub> are so hybridized?

# Protein Folding, Dynamics, and Structural Evolution

## CHAPTER 9

### 1 Protein Folding: Theory and Experiment

- A. Protein Renaturation
- B. Determinants of Protein Folding
- C. Folding Pathways

### 2 Folding Accessory Proteins

- A. Protein Disulfide Isomerase
- B. Peptidyl Prolyl Cis-Trans Isomerase
- C. Molecular Chaperones: The GroEL/ES System

### 3 Protein Structure Prediction and Design

- A. Secondary Structure Prediction
- B. Tertiary Structure Prediction
- C. Protein Design

### 4 Protein Dynamics

### 5 Conformational Diseases: Amyloids and Prions

- A. Amyloid Diseases
- B. Alzheimer's Disease
- C. Prion Diseases

### 6 Structural Evolution

- A. Structures of Cytochromes c
- B. Gene Duplication

In the preceding chapters, we saw how proteins are constructed from their component parts. This puts us in a similar position to a mechanic who has learned to take apart and put together an automobile engine without any inkling of how the engine works. What we need in order to understand the workings of a protein is knowledge of the types of internal motions it can and must undergo in order to carry out its biological function as well as how it achieves its native structure. Put in terms of our deprived auto mechanic, we wish to understand the operations of the “gears” and “levers” with which proteins carry out their function. This is a problem of enormous complexity whose solution we are only beginning to understand. We shall see in later chapters, for example, that even though the catalytic mechanisms of many enzymes of known structure have been studied in great detail, it cannot be said that we fully understand any of these mechanisms. This is because our comprehension of the ways in which a protein's component groups interact is far from complete. As far as proteins are concerned, we have not greatly surpassed our hypothetical mechanic's level of understanding.

In this third of four chapters on protein structure, we consider the temporal behavior of proteins. Specifically, we first take up the problem of how random coil polypeptides fold to their native structures and how this process is facilitated by other proteins. This is followed by a consideration of the progress that has been made in predicting protein structures based on their sequences and in understanding their dynamic properties, that is, the nature and functional significance of their internal motions. Next we consider the diseases caused by proteins taking up alternate conformations. We end by extending the discussions we began in Section 7-3 on protein evolution but do so in terms of the three-dimensional structures of proteins.

### 1 PROTEIN FOLDING: THEORY AND EXPERIMENT

Solving the so-called **protein folding problem**, that is, determining how and why proteins fold to their native states, is considered to be one of the grand challenges of biochemistry. Early notions of protein folding postulated the existence of “templates” that somehow caused proteins to assume their native conformations. Such an explanation begs the question of how proteins fold because, even if it were true, one would still have to explain how the template achieved its conformation. In fact, *proteins spontaneously fold into their native conformations under physiological conditions*. This implies that *a protein's primary structure dictates its three-dimensional structure*. In general, under the proper conditions, biological structures are **self-assembling** so that they have no need of external templates to guide their formation.

#### A. Protein Renaturation

Although evidence had been accumulating since the 1930s that proteins could be reversibly denatured, it was not until 1957 that the elegant experiments of Christian Anfinsen on bovine pancreatic **RNase A** put **protein renaturation** on a quantitative basis. RNase A, a 124-residue single-chain protein, is completely unfolded and its four disulfide bonds reductively cleaved in an 8M urea solution containing 2-mercaptoethanol (Fig. 9-2). Yet dialyzing away the urea and exposing the resulting solution to O<sub>2</sub> at pH 8

**Figure 9-1** [Drawing by T.A. Bramley, in Robson, B., *Trends Biochem. Sci.* 1, 50 (1976). Copyright © Elsevier Biomedical Press, 1976. Used by permission.]

**Figure 9-2** Reductive denaturation and oxidative renaturation of RNase A. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

yields a protein that is virtually 100% enzymatically active and physically indistinguishable from native RNase A. The protein must therefore have spontaneously renatured. Any reservations that this occurs only because RNase A is really not totally denatured by 8M urea have been satisfied by the chemical synthesis of enzymatically active RNase A (Section 7-5).

The renaturation of RNase A demands that its four disulfide bonds reform. The probability of one of the eight Cys residues from RNase A randomly reforming a disulfide bond with its proper (native) mate among the other seven Cys residues is  $\frac{1}{7}$ ; that of one of the remaining six Cys residues then randomly reforming its proper disulfide bond is  $\frac{1}{5}$ ; etc. The overall probability of RNase A reforming its four native disulfide links at random is

$$\frac{1}{7} \times \frac{1}{5} \times \frac{1}{3} \times \frac{1}{1} = \frac{1}{105}$$

Clearly, the disulfide bonds from RNase A do not randomly reform under renaturing conditions.

If the RNase A is reoxidized in 8M urea so that its disulfide bonds reform while the polypeptide chain is a random coil, then after removal of the urea, the RNase A is, as expected, only ~1% enzymatically active. This “scrambled” RNase A can be made fully active by exposing it to a trace of 2-mercaptoethanol, which, over about a 10-h period,

**Figure 9-3** Plausible mechanism for the thiol- or enzyme-catalyzed disulfide interchange reaction in a protein. The purple ribbon represents the polypeptide backbone of the protein. The attacking thiol group must be in its ionized thiolate form.

catalyzes disulfide bond interchange reactions until the native structure is achieved (Fig. 9-3). The native state of RNase A under physiological conditions is therefore, most probably, its thermodynamically most stable conformation (if the protein has a conformation that is more stable than the native state, conversion to it must involve such a large activation barrier so as to make it kinetically inaccessible; rate processes are discussed in Section 14-1C).

The time for renaturation of “scrambled” RNase A is reduced to ~2 min through the use of an enzyme, **protein disulfide isomerase (PDI)**, that catalyzes disulfide interchange reactions. (In fact, the supposition that *in vivo* folding to the native state requires no more than a few minutes prompted the search that led to this enzyme’s discovery.) PDI itself contains two active site Cys residues, which must be in the —SH form for the isomerase to be active. The enzyme evidently catalyzes the random cleavage and reformation of a protein’s disulfide bonds (Fig. 9-3), thereby interchanging them as the protein progressively attains thermodynamically more favorable conformations. PDI is further discussed in Section 9-2A.

#### a. Post-Translationally Modified Proteins May Not Readily Renature

Many “scrambled” proteins are renatured through the action of PDI and are unaffected by it in their native state (their PDI-cleaved disulfide bonds rapidly reform because these native proteins are in their most stable local conformations). In post-translationally modified proteins, however, the disulfide bonds may serve to hold the protein in its otherwise unstable native state. For instance, the 51-residue polypeptide hormone **insulin**, which consists of two polypeptide chains joined by two disulfide bonds (Fig. 7-2), is inactivated by PDI. This observation led to the discovery that insulin is derived from a single-chain, 84-residue precursor named **proinsulin** (Fig. 9-4). Only after its disulfide bonds have formed is proinsulin converted to the two-chained active hormone by the specific proteolytic excision of an internal 33-residue segment known as its C chain. Nevertheless, two

sets of observations suggest that the C chain does not direct the folding of the A and B chains but, rather, simply holds them together while they form their native disulfide bonds: (1) Under proper renaturing conditions, native

**Figure 9-4** Primary structure of porcine proinsulin. Its C chain (brown) is proteolytically excised from between its A and B chains to form the mature hormone. [After Chance, R.E., Ellis, R.M., and Brommer, W.W., *Science* **161**, 165 (1968).]

insulin is obtained from scrambled insulin in 25 to 30% yield, which increases to 75% when the A and B chains are chemically cross-linked; and (2) sequence comparisons of proinsulins from a variety of species indicate that mutations are accepted into the C chain at a rate which is eight times that for the A and B chains.

## B. Determinants of Protein Folding

In Section 8-4, we discussed the various interactions that stabilize native protein structures. In this section we extend the discussion by considering how these interactions are organized in native proteins. Keep in mind that only a small fraction of the myriads of possible polypeptide sequences are likely to have unique stable conformations. Evolution has, of course, selected such sequences for use in biological systems.

### a. Helices and Sheets May Predominate in Proteins Simply because They Fill Space Efficiently

Why do proteins contain such a high proportion (~60%, on average) of  $\alpha$  helices and  $\beta$  pleated sheets? Hydrophobic interactions, although the dominant influence responsible for the compact nonpolar cores of proteins, lack the specificity to restrict polypeptides to particular conformations. Similarly, the observation that polypeptide segments in the coil conformation are no less hydrogen bonded than helices and sheets suggests that the conformations available to polypeptides are not greatly limited by their hydrogen bonding requirements. Rather, as Ken Dill has shown, it appears that helices and sheets form largely as a consequence of steric constraints in compact polymers. Exhaustive simulations of the conformations which simple flexible chains (such as a string of pearls) can assume indicate that the proportion of helices and sheets increases dramatically with a chain's level of compaction (number of intrachain contacts); that is, helices and sheets are particularly compact entities. Thus, most ways to compact a chain involve the formation of helices and sheets. In native proteins, such elements of secondary structure are fine tuned to form  $\alpha$  helices and  $\beta$  sheets by short-range forces such as hydrogen bonding, ion pairing, and van der Waals interactions. It is probably these less dominant but more specific forces that "select" the unique native structure of a protein from among its relatively small number of hydrophobically generated compact conformations (recall that most hydrogen bonds in proteins link residues that are close together in sequence; Section 8-4Bb).

### b. Protein Folding Is Directed Mainly by Internal Residues

Numerous protein modification studies have been aimed at determining the role of various classes of amino acid residues in protein folding. In one particularly revealing study, the free primary amino groups of RNase A (Lys residues and the N-terminus) were derivatized with 8-residue chains of poly-DL-alanine. Intriguingly, these large, water-soluble poly-Ala chains could be simultaneously coupled to RNase's 11 free amino groups without significantly altering the protein's native conformation or its ability to

refold. Since these free amino groups are all located on the exterior of RNase A, this observation suggests that *it is largely a protein's internal residues that direct its folding to the native conformation*. Similar conclusions have been reached from studies of protein structure and evolution (Section 9-6): Mutations that change surface residues are accepted more frequently and are less likely to affect protein conformations than are changes of internal residues. It is therefore not surprising that the perturbation of protein folding by limited concentrations of denaturing agents indicates that *protein folding is driven by hydrophobic forces*.

### c. Protein Structures Are Hierarchically Organized

Large protein subunits consist of domains, that is, of contiguous, compact, and physically separable segments of the polypeptide chain. Furthermore, as George Rose showed, domains consist of subdomains, which in turn consist of sub-subdomains, etc. Conceptually, this means that if a polypeptide segment of any length in a native protein is viewed as a tangle of string, a single plane can be found that divides the string into only two segments rather than many smaller segments (such as would happen if a ball of yarn were cut in this way). This is readily demonstrated by coloring the first  $n/2$  residues of an  $n$ -residue domain red and the second  $n/2$  residues blue. If this process is iterated, as is shown in Fig. 9-5 for high potential iron-sulfur protein (HiPIP), it is clear that at every stage of the process, the red

**Figure 9-5 Hierarchical organization of globular proteins.** Here the X-ray structure of high potential iron-sulfur protein (HiPIP) is represented by its  $C_{\alpha}$  atoms shown as spheres. In the top drawing, the first  $n/2$  residues of this  $n$ -residue protein (where  $n = 71$ ) are colored red and the remaining  $n/2$  residues are colored blue. In the second row, the process is iterated such that, on the right, for example, the first and last halves of the second half of the protein are red and blue, with the remainder of the chain gray. In the third row, the process is again iterated. Note that at each stage of this hierarchy, the red and blue regions do not intermingle. [Courtesy of George Rose, Johns Hopkins University, and Robert Baldwin, Stanford University School of Medicine.]

and blue regions do not interpenetrate. Evidently, *protein structures are organized hierarchically*, that is, polypeptide chains form locally compact structures that associate with similar adjacent (in sequence) structures to form larger compact structures, etc. This structural organization is, of course, consistent with the observation that hydrogen bonding interactions in proteins are mostly local (Section 8-4Bb). It also has important implications for how polypeptides fold to form native proteins (Section 9-1C).

#### d. Protein Structures Are Highly Adaptable

Globular proteins have packing densities comparable to those of organic crystals (Section 8-3Bc) because the side chains in a protein's interior fit together with exquisite complementarity. To ascertain whether this phenomenon is an important determinant of protein structure, Eaton Lattman and Rose analyzed 67 globular proteins of known structure for the existence of preferred interactions between side chains. They found none, thereby indicating that, at least in globular proteins, *the native fold determines the packing but packing does not determine the native fold*. This view is corroborated by the widespread occurrence of protein families whose members assume the same fold even though they may be so distantly related as to have no recognizable sequence similarity (e.g., the  $\alpha/\beta$  barrel proteins; Section 8-3Bh).

The foregoing study indicates that *there are a large number of ways in which a protein's internal residues can pack together efficiently*. This was perhaps most clearly shown by Brian Matthews in an extensive series of studies on **T4 lysozyme** (a product of bacteriophage T4) in which the X-ray structures of over 300 mutant varieties of this 164-residue monomeric enzyme were compared. Replacements of one or a few residues in T4 lysozyme's hydrophobic core were accommodated mainly by local shifts in the protein backbone rather than by any global structural changes. In many cases, T4 lysozyme could accommodate the insertion of up to four residues without a major structural change or even a loss of enzymatic activity. Moreover, assays of the enzymatic activities of 2015 single-residue substitutions in T4 lysozyme indicated that only 173 of these mutants had significantly decreased enzymatic activity. Clearly protein structures are highly resilient.

#### e. Secondary Structure Can Be Context-Dependent

The structure of a native protein is determined by its amino acid sequence, but to what extent is the conformation of a given polypeptide segment influenced by the surrounding protein? The NMR structure of **protein GB1** (the B1 domain of streptococcal **protein G**, which helps the bacterium evade the host's immunological defenses by binding to the antibody protein **immunoglobulin G**) reveals that this 56-residue domain, which lacks disulfide bonds, consists of a long  $\alpha$  helix lying across a 4-stranded mixed  $\beta$  sheet (Fig. 9-6). In mutagenesis experiments by Peter Kim, the 11-residue "chameleon" sequence AWTVEKAFKTF was made to replace either residues 23 to 33 of GB1's  $\alpha$  helix (AATAEKVFVQY in GB1; a 7-residue change) to yield Chm- $\alpha$ , or residues 42 to 52 of its C-terminal  $\beta$  hairpin

**Figure 9-6** NMR structure of protein GB1. Residues 23 to 33 are green and residues 42 to 53 are cyan. The 11-residue chameleon sequence AWTVEKAFKTF can occupy either of these positions without significantly altering the native protein's backbone conformation. [NMR structure by Angela Gronenborn and Marius Clore, National Institutes of Health, Bethesda, Maryland. PDBid 1GB1.]

(EWTYDDATKTF in GB1; a 5-residue change) to yield Chm- $\beta$ . Both Chm- $\alpha$  and Chm- $\beta$  display reversible thermal unfolding typical of compact single-domain globular proteins, and their 2D NMR spectra indicate that each assumes a structure similar to that of native GB1. Yet NMR measurements also demonstrate that the isolated chameleon peptide (Ac-AWTVEKAFKTF-NH<sub>2</sub>, where Ac is acetyl) is unfolded in solution, which indicates that this sequence has no strong preference for either an  $\alpha$  helix or a  $\beta$  sheet conformation. This suggests that the information specifying  $\alpha$  helix or  $\beta$  sheet secondary structures can be nonlocal; that is, context-dependent effects may be important in protein folding (but see Section 9-1Ci).

#### f. Changing the Fold of a Protein

Proteins that share as little as ~20% sequence identity may be structurally similar. To what degree must a protein's sequence be changed in order to convert its fold to that of another protein? This question was answered, at least for the protein GB1, by the finding that changing 50% of its 56 residues converted its fold to that of **Rop protein** (Rop for *repressor of primer*; a transcriptional regulator). Rop is a homodimer whose 63-residue subunits each form an  $\alpha\alpha$  motif (Fig. 8-46c) that dimerizes with its 2-fold axis perpendicular to the helix axes to form a 4-helix bundle

**Figure 9-7** X-ray structure of Rop protein, a homodimer of  $\alpha$  motifs that associate to form a 4-helix bundle. On a change of 50% of its residues, protein GB1, whose structure is shown in Fig. 9-6, assumes the structure of Rop protein. One of the subunits of the structure shown here is colored according to the sequence of the GB1-derived polypeptide with purple residues identical in both native proteins, magenta residues unchanged from native GB1, cyan residues identical to those in native Rop, and green residues different from those in either native protein. The N-terminus of this subunit is at the lower right. [Based on an X-ray structure by Demetrius Tsernoglou, Università di Roma, Rome, Italy. PDBid 1ROP.]

(Fig. 9-7). Fifty percent of the residues of GB1 were changed based largely on a secondary structure prediction algorithm (Section 9-3Ad), energy minimization, and visual modeling to yield a new polypeptide named Janus (after the two-faced Roman god of new beginnings) that is 41% identical to Rop. In this manner, GB1 residues with high helix-forming propensities were retained, whereas in regions required to be  $\alpha$  helical, a number of residues with high  $\beta$  sheet-forming propensities were replaced (helix- and sheet-forming propensities are discussed in Section 9-3Aa); hydrophobic residues were incorporated at the appropriate *a* and *d* positions of a heptad repeat (Fig. 8-26) to form the core of Rop's 4-helix bundle; and residue changes were made to mimic Rop's distribution of surface charges. Fluorescence

and NMR measurements reveal that Janus assumes a stable Rop-like conformation. These studies indicate that not all residues have equally important roles in specifying a particular fold. Indeed, the Janus sequence is more closely related to that of GB1 (50% identity) than to that of Rop (41% identity), even though Janus structurally resembles Rop but not GB1.

### 9. Many Proteins Are Natively Unfolded

In recent years it has become evident that many entire native proteins and long protein segments (>30 residues) are fully unfolded. Such intrinsically disordered proteins lack specific tertiary structures and are therefore composed of ensembles of conformations. They are characterized by low sequence complexity, a low proportion of the bulky hydrophobic amino acids that form the cores of globular proteins (Val, Leu, Ile, Met, Phe, Trp, and Tyr), and a high proportion of certain polar and charged amino acids (Gln, Ser, Pro, Glu, Lys, Gly, and Ala). Structure prediction techniques based on amino acid sequences (Section 9-3) indicate that an organism's proportion of natively disordered proteins increases with its complexity with ~2% of archeal proteins, ~4% of eubacterial proteins, and ~33% of eukaryotic proteins predicted to contain long disordered regions.

Most natively disordered proteins specifically bind to some other molecule such as a protein, a nucleic acid, or a membrane component, and in doing so fold into stable secondary or tertiary structures. For example, the phosphorylated kinase-inducible domain (pKID) of the transcription factor **cyclic AMP response element-binding protein (CREB)** is disordered when free in solution, but folds to an ordered conformation when it binds to the KID-binding domain of **CREB-binding protein (CBP)**, Fig. 9-8). Apparently, the increased flexibility of natively disordered proteins enables them to perform a relatively unhindered conformational

**Figure 9-8** The binding of the pKID domain of rat CREB to the KID-binding domain of mouse CBP. The pKID, whose backbone is drawn in worm form (pink), is unstructured when free in solution (left) but forms two perpendicular helices when bound to the KID-binding domain (right). The image on the right shows the NMR structure of the pKID-KID-binding domain complex with the side chains of pKID phosphoSer 133 and Leu 141 drawn in ball-and-stick form with C green, O red, and P yellow and with the KID-binding domain (gray) represented by its solvent-accessible surface. [Courtesy of Peter Wright, Scripps Research Institute, La Jolla, California. PDBid 1KDX.]

search when binding to their target molecules. It has also been suggested that a structured globular protein would have to be two to three times larger than a disordered protein to provide the same size intermolecular interface and hence the use of disordered proteins provides genetic economy and reduces intracellular crowding. Disordered regions may also aid in the transport of proteins across membranes (Section 12-4Ea) and facilitate selective protein degradation (Section 32-6B).

The functions of natively disordered proteins are quite varied. Their most common function appears to be binding to specific DNA sequences to facilitate such processes as replication, transcription, repair, and transposition (Chapter 30). However, they have also been implicated in a variety of other functions including intracellular signal transduction (Chapter 19), forming phosphorylation sites in proteins whose activities are regulated by phosphorylation (Section 18-3C), and in aiding other proteins and RNAs to fold to their native conformations (Section 9-2C).

### C. Folding Pathways

How does a protein fold to its native conformation? We, of course, cannot hope to answer this question in detail until we better understand why native protein structures are stable. Moreover, as one might guess, the folding process itself is one of enormous complexity. Nevertheless, as we shall see below, the broad outlines of how proteins fold to their native conformations are beginning to come into focus.

The simplest folding mechanism one might envision is that a protein randomly explores all of the conformations available to it until it eventually “stumbles” onto its native conformation. A back-of-the-envelope calculation first made by Cyrus Levinthal, however, convincingly demonstrates that this cannot possibly be the case: Assume that the  $2n$  backbone torsional angles,  $\phi$  and  $\psi$ , of an  $n$ -residue protein each have three stable conformations. This yields  $3^{2n} \approx 10^n$  possible conformations for the protein, which is a gross underestimate, if only because the side chains are ignored. If a protein can explore new conformations at the rate at which single bonds can reorient, it can find  $\sim 10^{13}$  conformations per second, which is, no doubt, an overestimate. We can then calculate the time  $t$ , in seconds, required for a protein to explore all the conformations available to it:

$$t = \frac{10^n}{10^{13} \text{ s}^{-1}} \quad [9.1]$$

For a small protein of  $n = 100$  residues,  $t = 10^{87}$  s, which is immensely more than the apparent age of the universe ( $\sim 13.7$  billion years =  $4.3 \times 10^{17}$  s).

It would obviously take even the smallest protein an absurdly long time fold to its native conformation by randomly exploring all its possible conformations, an inference known as the **Levinthal paradox**. Yet several proteins fold to their native conformations in microseconds. Therefore, as Levinthal suggested, *proteins must fold by some sort of ordered pathway or set of pathways in which the approach to the native state is accompanied by sharply increasing conformational stability (decreasing free energy).*

### a. Rapid Measurements Are Required to Monitor Protein Folding

Folding studies on several small single-domain proteins, including RNase A, cytochrome *c*, and **apomyoglobin** (myoglobin that lacks its heme group), indicate that these proteins fold to a significant degree within one millisecond or less of being brought to native conditions. Hence, if the earliest phases of the folding process are to be observed, denatured proteins must be brought to native conditions in significantly less time. This is most often done using a rapid mixing device such as a **stopped-flow** apparatus (Fig. 9-9) in which a protein solution at a pH that denatures the protein or containing guanidinium chloride or urea at a concentration that does so is rapidly changed in pH or diluted to initiate folding. Most such instruments have “dead times” (the interval between the times when mixing is initiated and meaningful measurements can first be made) of  $\sim 0.5$  ms. However, recently developed ultrarapid mixing devices have dead times of at little as 40  $\mu$ s.

An alternative technique involves the refolding of **cold denatured proteins**. [For proteins whose folding has both  $\Delta H$  and  $\Delta S$  positive, a decrease in temperature is destabilizing (Table 3-2). Since  $\Delta G = \Delta H - T\Delta S$ , these proteins are unstable, that is denature, when  $T < \Delta H/\Delta S$ . For many of these proteins, solution conditions can be found for which this temperature is  $>0^\circ\text{C}$ .] The refolding of the cold-denatured protein is initiated by a so-called **temperature-jump** in which the solution is heated with an infrared laser pulse by 10 to  $30^\circ\text{C}$  in  $<100$  ns.

With either of the above methods, the folding protein must be monitored by a technique that can report rapid structural changes in a protein. The three such techniques that have been most extensively used are (1) **circular dichroism (CD)** spectroscopy, (2) **pulsed HD exchange** followed by 2D-NMR spectroscopy or mass spectrometry, and (3) **fluorescence resonance energy transfer (FRET)**. We discuss these methods below.

### b. The Circular Dichroism Spectrum of a Protein Is Indicative of Its Conformation

Polypeptides absorb strongly in the ultraviolet (UV) region of the spectrum ( $\lambda = 100$  to  $400$  nm) largely because their aromatic side chains (those of Phe, Trp, and Tyr) have particularly large molar extinction coefficients (Section 5-3Ca)

**Figure 9-9** A stopped-flow device. The reaction is initiated by simultaneously and rapidly discharging the contents of both syringes through the mixer. On hitting the stop switch, the stopping syringe triggers the computer to commence optically monitoring the reaction (via its UV/visible, fluorescence, or CD spectrum).

**Figure 9-10** UV absorbance spectra of the three aromatic amino acids, phenylalanine, tryptophan, and tyrosine. Note that the molar absorptance,  $\epsilon$ , is displayed on a log scale. [After Wetlauffer, D.B., *Adv. Prot. Chem.* **7**, 310 (1962).]

in this spectral region (ranging into the tens of thousands; Fig. 9-10). However, polypeptides do not absorb visible light ( $\lambda = 400$  to  $800$  nm), so that they are colorless.

For chiral molecules such as proteins,  $\epsilon$  has different values for left and right circularly polarized light,  $\epsilon_L$  and  $\epsilon_R$ . The variation with  $\lambda$  of the difference in these quantities,  $\Delta\epsilon = \epsilon_L - \epsilon_R$ , constitutes the **circular dichroism (CD)** spectrum of the solute of interest (for nonchiral molecules  $\epsilon_L = \epsilon_R$  and hence they have no CD spectrum). In proteins,  $\alpha$  helices,  $\beta$  sheets, and random coils exhibit characteristic CD spectra (Fig. 9-11). Hence the CD spectrum of a polypeptide provides a rough estimate of its secondary structure.

### c. Pulsed H/D Exchange Provides Structural Details on How Proteins Fold

**Pulsed H/D exchange**, a method devised by Walter Englander and Robert Baldwin, is the only known technique that can follow the time course of individual residues in a folding protein. Weakly acidic protons ( $^1\text{H}$ ), such as those of amine and hydroxyl groups ( $\text{X}-\text{H}$ ), exchange with those of water, a process known as **hydrogen exchange** that can be demonstrated with the use of deuterated water [ $\text{D}_2\text{O}$ ; deuterium ( $\text{D}$  or  $^2\text{H}$ ) is a stable isotope of  $^1\text{H}$ ]:

Since  $^1\text{H}$  has an NMR spectrum in a different frequency range from that of  $\text{D}$ , the exchange of  $^1\text{H}$  for  $\text{D}$  can be readily followed by NMR spectroscopy. Under physiological conditions, small organic molecules, such as amino acids and dipeptides, completely exchange their weakly acidic protons for  $\text{D}$  in times ranging from milliseconds to seconds.

**Figure 9-11** Circular dichroism (CD) spectra of polypeptides. Polypeptides in the  $\alpha$  helix,  $\beta$  sheet, and random coil (rc) conformations were determined from the CD spectra of proteins of known X-ray structures. By comparing these spectra with the absorption spectra in Fig. 9-10, it can be seen that  $\Delta\epsilon = \epsilon_L - \epsilon_R$  is a small difference of two large numbers. [After Saxena, V.P. and Wetlauffer, D.B., *Proc. Natl. Acad. Sci.* **66**, 971 (1971).]

Proteins bear numerous exchangeable protons, particularly those of its backbone amide groups. However, protons that are engaged in hydrogen bonding do not exchange with solvent and, moreover, groups in the interior of a native protein are not in contact with solvent.

Through the use of 2D-NMR (Section 8-3Ac), pulsed H/D exchange can be used to follow the time course of protein folding. The protein of interest, usually with its native disulfide bonds intact, is denatured by guanidinium chloride or urea in  $\text{D}_2\text{O}$  solution such that all of the protein's peptide nitrogen atoms become deuterated ( $\text{N}-\text{D}$ ). Folding is then initiated in a stopped-flow apparatus by diluting the denaturant solution with  $^1\text{H}_2\text{O}$  while the pH is simultaneously lowered so as to arrest hydrogen exchange (near neutrality, hydrogen exchange reactions are catalyzed by  $\text{OH}^-$  and, therefore, their rates are highly pH dependent). After a preset folding time,  $t_f$ , the pH is rapidly increased (using a third independently triggered syringe; the so-called labeling pulse) to initiate hydrogen exchange. Peptide nitrogen atoms whose  $\text{D}$  atoms have not formed hydrogen bonds by time  $t_f$  exchange with  $^1\text{H}$ , whereas those that are hydrogen bonded at  $t_f$ , and hence unavailable for hydrogen exchange, remain deuterated. After a short time (10 to 40 ms), the labeling pulse is terminated by rapidly lowering the pH (with a fourth syringe). Folding is then allowed to go to completion and the H/D ratio at each exchangeable site is determined by 2D-NMR (the peaks in the 2D proton NMR spectrum must have been previously assigned). By repeating the analysis for several values of  $t_f$ , the

time course of hydrogen bond formation at each residue can be determined.

Pulsed H/D exchange–NMR studies do not directly indicate the structures of the folding intermediates. However, if the native structure of the protein under investigation is known (as it almost always is for proteins whose folding is being investigated) and if it is assumed that the protein folds without forming secondary structures not present in the native protein, then the 2D-NMR spectra reveal the time course of the formation of the elements of the native structure together with how fast they are excluded from the bulk solvent.

The time course of protein folding may also be followed by combining pulsed H/D exchange with mass spectrometry. In this method, a partially deuterated protein is fragmented by pepsin (a protease that functions under the acidic conditions necessary to prevent further hydrogen exchange; Table 7-2), the resulting fragments separated by HPLC, and their degree of deuteration determined by mass spectrometry. This method does not yield the residue-level structural information that NMR provides. However, unlike NMR, it can determine if a sample contains subpopulations of protein fragments with different degrees of deuteration and hence that have followed different folding pathways.

#### d. Fluorescence Resonance Energy Transfer Monitors Distances

**Fluorescence** is the phenomenon whereby an electronically excited molecule or group decays to its ground state by emitting a photon. The initial excited state rapidly decays, via nonradiative processes (e.g., heating; Section 24-2Aa), to an excited state of lower energy before the photon is emitted. Hence the molecule or group's emission spectrum has a longer wavelength than its absorption spectrum (Fig. 9-12).

**Figure 9-12** Schematic diagram of the absorption and emission spectra of a donor and an acceptor in fluorescence resonance energy transfer (FRET). Note that the absorption spectrum occurs at shorter wavelengths than the corresponding emission spectrum and that the donor's emission spectrum must overlap the acceptor's absorption spectrum (cyan) for FRET to occur.

When two fluorescent molecules or groups, a donor (D) and an acceptor (A), are within 100 Å of each other and D is electronically excited (say, by a laser with a wavelength within its absorption spectrum), some of the excitation energy will be transferred from D to A,

where the asterisk indicates an electronically excited state. A will then fluoresce with its characteristic emission spectrum (Fig. 9-12), whose intensity can be measured. This phenomenon is known as **fluorescence resonance energy transfer (FRET)**. Its efficiency  $E$ , the fraction of the energy transferred to the acceptor per donor excitation event, is given by

$$E = \frac{1}{1 + (r/R_0)^6} \quad [9.2]$$

where  $r$  is the distance between D and A, and  $R_0$ , their **Förster distance** (named after Theodor Förster, who formulated the theory for the mechanism of long-range nonradiative energy transfer), is the value of  $r$  at which the FRET efficiency is 50%.  $R_0$  varies with the degree of overlap between the donor's emission spectrum and the acceptor's absorption spectrum (Fig. 9-12) as well as with the relative orientation of the donor and acceptor. Hence, the intensity of the acceptor's fluorescence is indicative of the distance between D and A as well as their relative orientation.

In proteins, D and A can be the side chains of Trp or Tyr residues. The number and placement of these residues in the protein of interest can be manipulated by site-directed mutagenesis (Section 5-5Gc). Alternatively, fluorescent groups may be covalently linked to reactive side chains such as Cys, which can also be placed via site-directed mutagenesis. FRET measurements can then be used to track how the distances between specific residues vary with time in a folding protein.

#### e. The Earliest Protein Folding Events Are Initiated by a Hydrophobic Collapse

Stopped-flow–CD measurements indicate that *for many, if not all, small single-domain proteins, much of the secondary structure that is present in native proteins forms within a few milliseconds of when folding is initiated.* This is called the **burst phase** because subsequent folding events occur over much longer time intervals. Pulsed H/D exchange measurements of these small proteins show that some protection against hydrogen exchange in some secondary structural elements develops by ~5 ms after folding initiation.

Since globular proteins contain a compact hydrophobic core, it seems likely that the driving force in protein folding is a so-called **hydrophobic collapse**, in which the protein's hydrophobic groups coalesce so as to expel most of their surrounding water molecules. The polypeptide's radius of gyration is thereby dramatically reduced (from ~30 to ~15 Å for a 100-residue polypeptide), a phenomenon that is

generally characteristic of polymers on being transferred from a good to a poor solvent.

This hydrophobic collapse mechanism is consistent with the observation that the hydrophobic dye **8-anilino-1-naphthalenesulfonate (ANS)**

**8-Anilino-1-naphthalene sulfonate (ANS)**

binds to folding proteins. ANS undergoes a significant enhancement of its fluorescence when it occupies a nonpolar environment, an enhancement that is observed within the burst phase when ANS is present in a solution of a folding protein. Since ANS is expected to preferentially bind to hydrophobic groups, this indicates that the hydrophobic core of a protein rapidly forms once folding has been initiated.

The initial collapsed state of a folding protein is known as a **molten globule**. Such a species has a radius of gyration that is only 5 to 15% greater than that of the native protein and has significant amounts of the native secondary structure and overall fold. However, a molten globule's side chains are extensively disordered, its structure fluctuates far more than that of the native protein, and it has only marginal thermodynamic stability. Nevertheless, to continue folding toward its native state, the polypeptide chain need not undergo large rearrangements in the crowded core of the partially folded protein.

#### **f. Nativelike Tertiary Structure Appears During Intermediate Folding Events**

After the burst phase, small proteins exhibit increased ANS binding, further changes in their CD spectrum, and enhanced protection against H/D exchange. These intermediate folding events typically occur over a time interval of 5 to 1000 ms. This is the stage at which the protein's secondary structure becomes stabilized and its tertiary structure begins to form. These nativelike elements are thought to take the form of subdomains that are not yet properly docked to each other. Side chains are probably still mobile, so that, at this stage of folding, the protein can be described as an ensemble of closely related and rapidly interconverting structures.

#### **g. Final Folding Events Often Require Several Seconds**

In the final stage of folding, a protein achieves its native structure. To do so, the polypeptide must undergo a series of complex motions that permit the attainment of the relatively

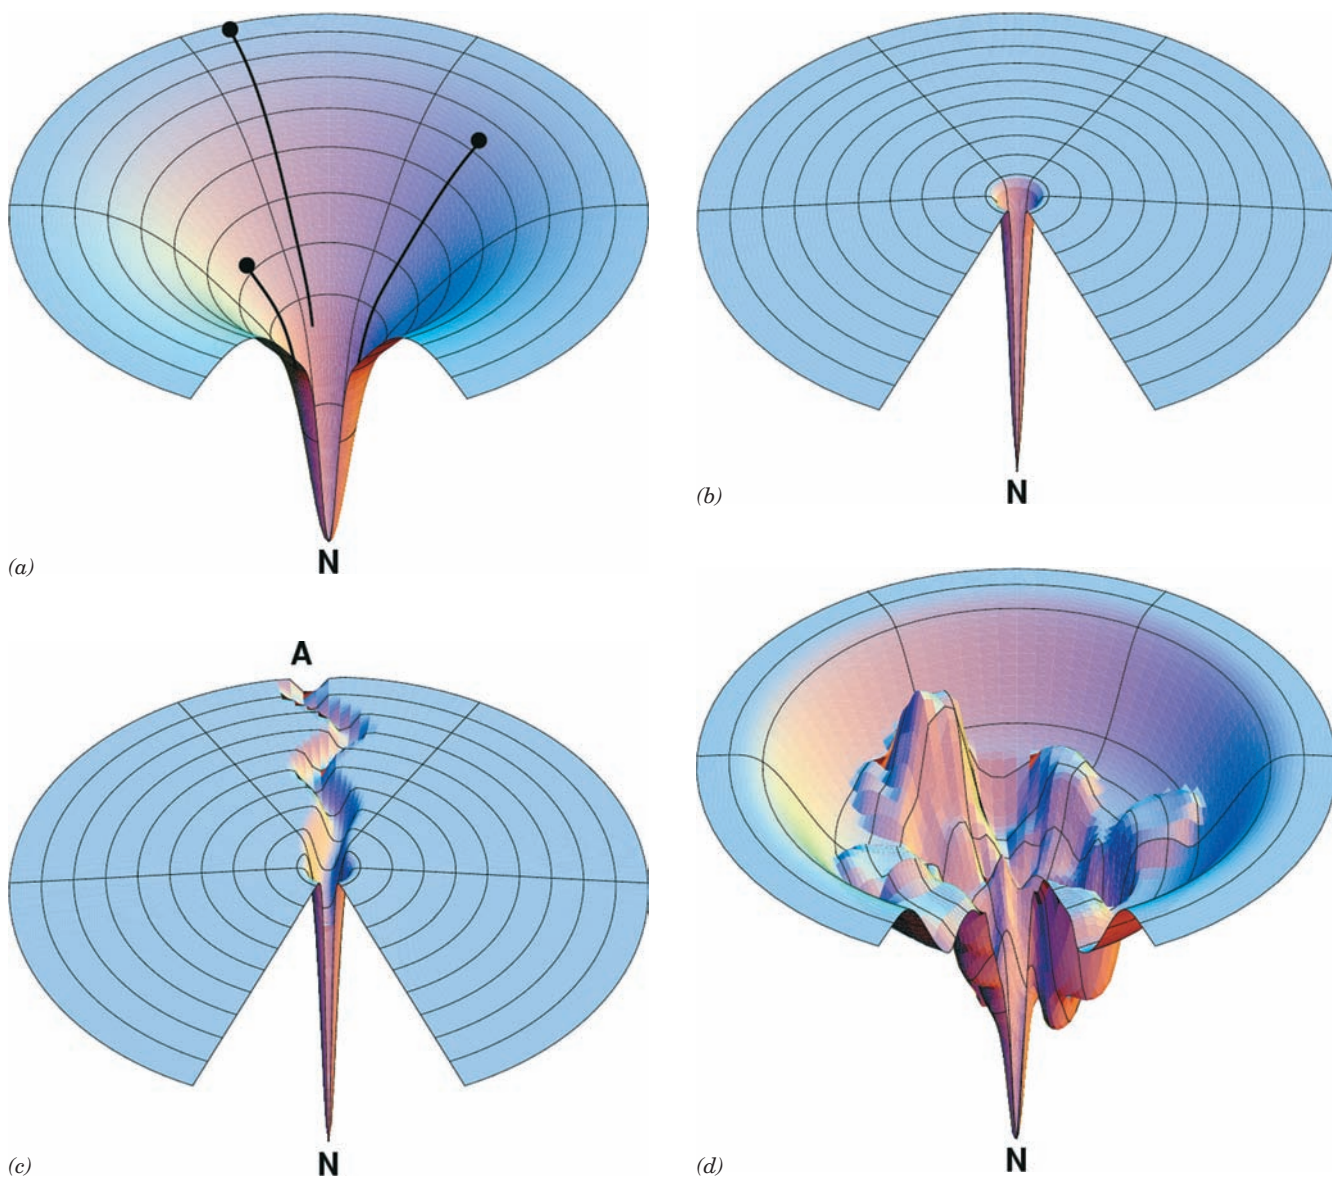

rigid native core packing and hydrogen bonding, while expelling the remaining water molecules from its hydrophobic core. For small single-domain proteins, this takes place over a time interval of several seconds or less.

#### **h. Landscape Theory of Protein Folding**

The classic view of protein folding was that proteins fold through a series of well-defined intermediates. The folding of a random coil polypeptide was thought to begin with the random formation of short stretches of 2° structure, such as  $\alpha$  helices and  $\beta$  turns, that acted as **nuclei** (scaffolding) for the stabilization of additional ordered regions of the protein. Nuclei with the proper nativelike structure then grew by the diffusion, random collision, and adhesion of two or more such nuclei. The stabilities of these ordered regions were thought to increase with size, so, after having randomly reached a certain threshold size, they spontaneously grew in a cooperative fashion until they formed a nativelike domain. Finally, through a series of relatively small conformational adjustments, the domain rearranged to the more compact 3° structure of the native conformation.

The advent of experimental methods that could observe early events in protein folding led to a somewhat different view of how proteins fold. In this so-called **landscape theory**, which was formulated in large part by Peter Wolynes, Baldwin, and Dill, folding is envisioned to occur on an **energy surface** or landscape that represents the conformational energy states available to a polypeptide under the prevailing conditions. The horizontal coordinates of a point on this surface represent a particular conformation of the polypeptide, that is, the values of  $\phi$  and  $\psi$  for each of its amino acid residues and the torsion angles for each of its side chains (but here projected onto two dimensions from its multidimensional space). The vertical coordinate of a point on the energy surface represents the polypeptide's internal free energy in this conformation. The above-described measurements indicate that the energy surface of a folding polypeptide is funnel-shaped, with the native state represented by the bottom of the funnel, the global (overall) free energy minimum (Fig. 9-13a). The width of the funnel at any particular height (free energy) above the native state is indicative of the number of conformational states with that free energy, that is, the entropy of the polypeptide.

*Polypeptides fold via a series of conformational adjustments that reduce their free energy and entropy until the native state is reached.* Since a collection of unfolded polypeptides all have different conformations (have different positions on the folding funnel), they cannot follow precisely the same pathway in folding to the native state. If the polypeptide actually folded to its native state via a random conformational search, as Levinthal conjectured, its energy surface would resemble a flat disk with a single small hole, much like the surface of a golf course (Fig. 9-13b). Thus, it would take an enormously long time for a polypeptide (a golf ball) to achieve the native state (to fall in the hole) via a random conformational search (by rolling about aimlessly on the surface of the golf course).

**Figure 9-13** Folding funnels. (a) An idealized funnel landscape. As the chain forms increasing numbers of intrachain contacts, its internal free energy (its height above the native state, N) decreases together with its conformational freedom (the width of the funnel). Polypeptides with differing conformations (black dots) follow different pathways (black lines) in achieving the native fold. (b) The Levinthal “golf course” landscape in which the chain must search for the native fold (the hole)

randomly, that is, on a level energy surface. (c) The classic folding landscape in which the chain must search at random on a level energy surface until it encounters the canyon that leads it to the native state. (d) A rugged energy surface containing local minima in which a folding polypeptide can become transiently trapped. The folding funnels of real proteins are thought to have such topographies. [Courtesy of Ken Dill, University of California at San Francisco.]

The energy surface of a protein that follows the classic view of protein folding would have a deep radial groove in its disklike surface that slopes toward the hole representing the native state (Fig. 9-13c). The extent of the conformational search to randomly find this groove would be much reduced relative to the Levinthal model, so that such a polypeptide would readily fold to its native state. However, the conformational search for the pathway (groove) leading to the native state would still take time, so that the polypeptide would require perhaps several seconds to start down the folding pathway.

The observation that many polypeptides acquire significant natively like structure within fractions of a millisecond after folding commences indicates that their energy surfaces are, in fact, funnel-shaped; that is, they tend to slope toward the native conformation at all points. Thus, the various pathways followed by initially unfolded polypeptides in folding to their native state are analogous to the various trajectories that could be taken by skiers initially distributed around the top of a bowl-shaped valley to reach the valley’s lowest point. Apparently, *there is no single pathway or closely related set of*

pathways that a polypeptide must follow in folding to its native conformation.

The foregoing does not imply that the surface of the folding funnel is necessarily smooth, as is drawn in Fig. 9-13a. Indeed, landscape theory suggests that this energy surface has a relatively rugged topography, that is, has many local energy minima and maxima (Fig. 9-13d). Consequently, in following any particular folding pathway, a polypeptide is likely to become trapped in a local minimum until it randomly acquires sufficient thermal energy to surmount this kinetic barrier and continue the folding process. Thus, in landscape theory, the local energy maxima (transition states; Section 14-1C) that govern the rate of folding are not specific structures as the classic theory of protein folding suggests but, rather, are ensembles of structures.

### i. Protein Folding Is Hierarchical

The observation that protein structures are hierarchically organized (Section 9-1B) suggests that they also fold in a hierarchic manner. By this it is meant that folding begins with the formation of marginally stable nativelylike microstructures known as **foldons** (e.g., Fig. 9-14) that are local in sequence and that these foldons diffuse and collide with nearby (in sequence) foldons to yield intermediates of increasing complexity and stability that sequentially grow to form the native protein. In contrast, in nonhierarchical folding, a protein's tertiary structure would not only stabilize its local structures but also determine them. Landscape theory is consistent with hierarchical folding, whereas the classic theory of protein folding is more in accord with nonhierarchical folding. Moreover, since a polypeptide *in vivo* begins folding as it is being synthesized, that is, as it is extruded from the ribosome, it would seem that it would most readily achieve its native state if it folded in a hierarchical manner.

Several lines of evidence indicate that proteins, in fact, fold in a hierarchical manner.

1. H/D exchange studies have established the existence of foldons in numerous proteins. Indeed, it appears that foldons rather than individual amino acid residues carry out the unit steps in protein folding pathways.

2. Many peptide fragments excised from proteins either form or exhibit a tendency to form foldons in the absence of long-range ( $3^\circ$ ) interactions. Moreover, when proteins such as cytochrome *c* and apomyoglobin are brought to a pH sufficiently low to destabilize their native structures, their foldons persist.

3. The boundaries of helices in native proteins are fixed by their flanking sequences (Section 9-3) rather than by  $3^\circ$  interactions.

4. The folding rates of proteins increase, on average, with the degree to which their native contacts are local. Thus fast folders tend to have a high proportion of helices and tight turns, whereas slow folders tend to have a high proportion of  $\beta$  sheets.

In Section 9-1B we saw that in protein GB1 (Fig. 9-6), the 11-residue “chameleon” sequence assumed either an  $\alpha$  helix or a  $\beta$  hairpin, depending on its position in the protein.

**Figure 9-14** Ribbon diagram of cytochrome *c*. Its several foldon units are shown in different colors. Its heme group and several of its functionally important side chains are drawn in ball-and-stick form with C black, N blue, O red, S yellow, and Fe a large red sphere. [Courtesy of Walter Englander, University of Pennsylvania.]

Thus, its conformation appears to be determined by its context rather than by local interactions. However, computer simulations suggest that the conformation of the chameleon sequence is actually determined by local interactions beyond its boundaries.

The folds of native proteins, as we have seen, are highly resistant to sequence changes. Evidently, *the sequence information specifying a particular fold is both distributed throughout the polypeptide chain and highly overdetermined*. It is these characteristics that appear to be responsible for hierarchical folding.

### j. Primary Structures Determine Protein Folding Pathways as Well as Structures

The above discussions suggest that *protein primary structures evolved to specify efficient folding pathways as well as stable native conformations*. Evidence corroborating this hypothesis has been obtained by Jonathan King in his study of the renaturation of the **tail spike protein** of bacteriophage P22. The tail spike protein is a trimer of identical 76-kD polypeptides, whose  $T_m = 88^\circ\text{C}$ . However, certain mutant varieties of the protein fail to renature at  $39^\circ\text{C}$ . Nevertheless, at  $30^\circ\text{C}$ , these mutant proteins fold to structures whose properties, including their  $T_m$ 's, are indistinguishable from that of the wild-type tail spike protein. The amino acid changes causing these temperature-sensitive folding mutations apparently act to destabilize intermediate states in the folding process but do not affect the native protein's stability. This observation suggests that *a protein's amino acid sequence dictates its native structure by specifying how it folds to its native conformation*.

This hypothesis is supported by the observation that, in native proteins, a greater number of polar residues than would be randomly expected occupy helix-capping positions (Section 8-4Bb) even though they do not make helix-capping hydrogen bonds. This suggests that they do so as the helix forms so as to facilitate the protein's proper folding.

## 2 FOLDING ACCESSORY PROTEINS

Most unfolded proteins renature *in vitro* over periods ranging from minutes to days and, quite often, with low efficiency,

that is, with a large fraction of the polypeptide chains assuming quasi-stable non-native conformations and/or forming nonspecific aggregates. *In vivo*, however, polypeptides efficiently fold to their native conformations as they are being synthesized, a process that normally requires a few minutes or less. This is because all cells contain three types of accessory proteins that function to assist polypeptides in folding to their native conformations and in assembling to their 4° structures: **protein disulfide isomerases**, **peptidyl prolyl cis-trans isomerases**, and **molecular chaperones**. We discuss these essential proteins in this section.

**Figure 9-15** Reactions catalyzed by protein disulfide isomerase (PDI). (a) Reduced PDI catalyzes the rearrangement of the non-native disulfide bonds in a substrate protein (purple ribbon) via disulfide interchange to yield the native disulfide bonds (horizontal reactions). If a disulfide bond between PDI and the substrate protein is resistant to disulfide interchange, it is reduced by PDI's second SH group to yield reduced substrate protein and oxidized PDI (vertical reaction and dashed curved arrow). (b) The oxidized PDI-dependent synthesis of disulfide bonds in proteins. The reaction occurs with the intermediate formation of a mixed disulfide between PDI and the protein. The reduced PDI reaction product reacts with cellular oxidizing agents to regenerate oxidized PDI. See the Animated Figures

### A. Protein Disulfide Isomerase

**Protein disulfide isomerase (PDI)**, which we encountered in Section 9-1A, is an ~510-residue eukaryotic enzyme that inhabits the lumen of the endoplasmic reticulum, where disulfide-containing proteins fold and are post-translationally processed (Section 12-4B). In its reduced form, PDI catalyzes disulfide interchange reactions, thereby facilitating the shuffling of the disulfide bonds in proteins (Fig. 9-15a, *horizontal reactions*) until they achieve their native pairings, which are resistant to further rearrangement. Moreover, PDI must facilitate the correct folding of those proteins that denature in the absence of their native disulfide bonds. Intriguingly, PDI is also the  $\beta$  subunit of the  $\alpha_2\beta_2$  heterotetramer prolyl hydroxylase, the enzyme that hydroxylates the Pro residues of collagen (Section 8-2B). The significance of this latter finding is unknown.

Sequence comparisons indicate that PDI contains four ~100-residue domains that are arranged, from N- to C-terminus, as a–b–b'–a', in which domains a and a' are homologs that are 30% identical in sequence. They are also homologous to the ubiquitous disulfide-containing redox protein **thioredoxin** (Section 28-3Ae), and hence belong to the thioredoxin superfamily. Prokaryotes have enzymes with functions similar to those of PDI that also assume the thioredoxin fold.

PDI's a and a' domains each contain the active site sequence motif Cys-Gly-His-Cys, in which the first Cys residue, in its —SH form, participates in the disulfide interchange reaction diagrammed in Fig. 9-15a (the catalytic motif of the thioredoxin superfamily is Cys-X-X-Cys, where X is any amino acid residue). If the second Cys residue is mutated, PDI's isomerization activity drops to

<1% of the wild type and it accumulates in disulfide-linkage to substrate proteins. This suggests that this second Cys residue functions, in its —SH form, to release PDI from the otherwise stable disulfide bonds that its first Cys residue occasionally forms with substrate proteins, thereby yielding reduced substrate proteins and PDI with a disulfide bond linking its two active site Cys residues (Fig. 9-15a, *vertical reaction*).

The X-ray structure of yeast PDI, determined by William Lennarz and Hermann Schindelin, reveals that it adopts a twisted U-shape in which the N-terminal active site Cys S atoms of the a and a' domains face each other across the top of the U at a distance of 28 Å (Fig. 9-16). As expected, a and a' have folds that are similar to each other (Fig. 9-17, *top*) and to those of other members of the thioredoxin superfamily. Surprisingly, although b and b' exhibit no significant sequence similarity with a and a' or with each other, they also adopt the thioredoxin fold (Fig. 9-17, *bottom*). Nevertheless, both b and b' lack Cys residues and hence cannot participate directly in the catalytic reaction. The b and b' domains share an extensive interface (burying ~700 Å<sup>2</sup>) and hence appear to be rigidly linked together, whereas the a–b and a'–b' interfaces are negligibly small (burying ~200 Å<sup>2</sup>). This suggests that the a and a' domains are flexibly linked to a rigid base formed by the b and b' domains, thereby enabling PDI to accommodate a diverse set of substrates of up to ~100 residues within the U.

The inner face of the U has a continuous hydrophobic surface that also surrounds the a and a' active sites. This surface appears to be essential for the binding of PDI to its substrate proteins, which tend to be partially or fully unfolded

**Figure 9-16** X-ray structure of yeast protein disulfide isomerase (PDI). The protein is represented by its transparent molecular surface with its polypeptide chain in ribbon form with its a, b, b', and a' domains colored magenta, cyan, yellow, and red, respectively. The 16-residue loop, x, linking the b' and a' domains is blue and the C-terminal extension, c, is green. The side chains of the N-terminal active site Cys residues of the a and a' domains are drawn in space-filling form with C green and S yellow. [Based on an X-ray structure by William Lennarz and Hermann Schindelin, State University of New York, Stony Brook, New York. PDBid 2B5E.]

**Figure 9-17** Structural comparison of the a, b, b', and a' domains of yeast PDI. The domains are shown in similar orientations and drawn in ribbon form colored in rainbow order from their N-terminus (blue) to their C-terminus (red). The side chains of the N-terminal active site Cys residues of the a and a' domains are drawn in space-filling form with C green and S yellow. [Based on an X-ray structure by William Lennarz and Hermann Schindelin, State University of New York, Stony Brook, New York. PDBid 2B5E.]

and hence have exposed hydrophobic groups. Moreover, as we shall see in Section 9-2C, PDI's hydrophobic surface facilitates the proper folding of its unfolded substrate proteins. Efficient catalysis of disulfide bond rearrangement requires that reduced PDI be intact, thus suggesting that PDI's two active sites act in concert. The isomerase reaction is driven by the release of conformational strain in the unfolded substrate protein as it folds to its native conformation.

Disulfide bonds in native proteins are usually buried and frequently occur in hydrophobic environments. Indeed, it is probably the burial of the correctly paired Cys residues in a native protein that terminates the action of PDI. However, the N-terminal S atoms in the both the a and a' active sites of PDI are exposed on the protein surface. Although their disulfide bonds almost always stabilize proteins (Section 8-4D) and are usually unreactive, oxidized a and a' are less stable than their reduced forms and therefore have highly reactive, that is, strongly oxidizing, disulfide bonds. This permits oxidized PDI to directly introduce disulfide bonds into newly synthesized and hence reduced polypeptides via a disulfide interchange mechanism (Fig. 9-15b). For this latter process to continue, reduced PDI must be reoxidized (its disulfide bond reformed) by cellular oxidizing agents.

### B. Peptidyl Prolyl Cis-Trans Isomerase

Although polypeptides are probably biosynthesized with almost all of their X-Pro peptide bonds (where X is any amino acid residue) in the trans conformation, ~10% of these bonds assume the cis conformation in globular proteins because, as we have seen in Section 8-1A, the energy difference between their cis and trans conformations is relatively small. **Peptidyl prolyl cis-trans isomerases (PPIs;** alternatively known as **rotamases**) catalyze the otherwise slow interconversion of X-Pro peptide bonds between their cis and trans conformations, thereby accelerating the folding of Pro-containing polypeptides. Two structurally unrelated families of PPIs, collectively named the **immunophilins**, have been characterized: the **cyclophilins** (so named because they are inhibited by the immunosuppressive drug **cyclosporin A**,

a fungally produced 11-residue cyclic peptide) and the fam-

ily for which the 12-kD **FK506 binding protein (FKBP12)** is prototypic (**FK506**

is a fungally produced macrocyclic lactone that is also an immunosuppressive drug; medicinal chemists tend to identify the often huge numbers of related drug candidates they deal with by serial numbers rather than by trivial names).

The X-ray structure of human cyclophilin in complex with succinyl-Ala-Ala-Pro-Phe-*p*-nitroanilide reveals that this model substrate binds to the enzyme with its Ala-Pro peptide bond in the cis conformation and that it could not do so if it had the trans conformation. This suggests that the enzyme predominantly catalyzes the trans to cis isomerization of peptidyl-prolyl amide bonds. In addition, the Arg 55 → Ala mutation in cyclophilin reduces its enzymatic activity 100-fold. This, together with the observation that Arg 55 is positioned so that it could hydrogen bond to the N atom of the Ala-Pro peptide bond (although it does not do so in the crystal structure) suggests that the formation of a hydrogen bond from Arg 55 to this N atom facilitates the cis-trans isomerization by deconjugating and hence weakening the peptidyl-prolyl amide bond.

#### a. Cyclosporin A and FK506 Are Clinically Important Immunosuppressive Agents

Cyclosporin A and FK506 are highly effective agents for the treatment of autoimmune disorders and for preventing organ-transplant rejection. Indeed, until the advent of cyclosporin A in the early 1980s, the long-term survival of a transplanted organ (and its recipient) was a rare occurrence. The more recently discovered FK506 is an even more potent immunosuppressant. The immunosuppressive properties of both cyclosporin A and FK506 stem from the abilities of their respective complexes with cyclophilin and FKBP12 to prevent the expression of genes involved in the activation of **T lymphocytes** (the immune system cells responsible for **cellular immunity**; the immune response is discussed in Section 35-2) by interfering with these cells'

intracellular signaling pathways. Enigmatically, there is no obvious relationship between the immunophilins' immunosuppressive properties and rotamase activities: Both cyclosporin A and FK506 are effective immunosuppressants at concentrations far below those of the cyclophilin and FKBP12 in cells; and mutational changes that destroy cyclophilin's rotamase activity do not eliminate its ability to bind cyclosporin A or the ability of the resulting complex to interfere with T lymphocyte signaling. This conundrum is explained in Section 19-3Ff.

### C. Molecular Chaperones: The GroEL/ES System

Newly synthesized and hence unfolded proteins contain numerous solvent-exposed hydrophobic groups. Moreover, proteins *in vivo* fold in the presence of extremely high concentrations of other macromolecules (~300 g/L, which occupy ~25% of the available volume). Consequently, unfolded proteins *in vivo*, particularly larger proteins (those >15 kD), have a great tendency to form both intramolecular and intermolecular aggregates. **Molecular chaperones**, which are also known as **heat shock proteins** (so named because their rates of synthesis increase at elevated temperatures), are proteins that function to prevent or reverse such improper associations, particularly in multidomain and multisubunit proteins. They do so by binding to an unfolded or aggregated polypeptide's solvent-exposed hydrophobic surfaces and subsequently releasing them, often repeatedly, in a manner that facilitates their proper folding and/or 4° assembly. Most molecular chaperones are **ATPases** (enzymes that catalyze ATP hydrolysis), which bind to unfolded polypeptides and apply the free energy of ATP hydrolysis to effect their release in a favorable manner. Thus it appears, as John Ellis has pointed out, that molecular chaperones function analogously to their human counterparts: *They inhibit inappropriate interactions between potentially complementary surfaces and disrupt unsuitable liaisons so as to facilitate more favorable associations.*

The molecular chaperones comprise several unrelated classes of proteins that have somewhat different functions including:

1. The **heat shock proteins 70 (Hsp70)**, which are ~70-kD monomeric proteins that are highly conserved in both prokaryotes and eukaryotes (in which different species occur in the cytosol, the endoplasmic reticulum, mitochondria, and chloroplasts; the *E. coli* Hsp70 is called **DnaK** because it was discovered through the isolation of mutants that do not support the growth of bacteriophage  $\lambda$  and hence was initially thought to participate in DNA replication). They function in an ATP-driven process to reverse the denaturation and aggregation of proteins (processes that are accelerated at elevated temperatures), to facilitate the proper folding of newly synthesized polypeptides as they emerge from the ribosome, to unfold proteins in preparation for their transport through membranes (Section 12-4Ea), and to subsequently help them refold. Hsp70 works in association with the **cochaperone** protein **Hsp40**

(**DnaJ** in *E. coli*) to bind and release small hydrophobic regions of misfolded proteins.

2. **Trigger factor**, which is a ribosome-associated prokaryotic protein. It prevents the intra- and intermolecular aggregation of newly synthesized polypeptides as they emerge from the ribosome by shielding their hydrophobic segments. Unlike most other chaperones, trigger factor does not bind ATP. Trigger factor and the Hsp70/40 system appear to have redundant functions: *E. coli* can tolerate the loss of either one but the loss of both is lethal above 30°C and is accompanied by the massive aggregation of newly synthesized proteins. Trigger factor and Hsp70/40 are the first chaperones that newly synthesized polypeptides encounter. Subsequently, many of the resulting partially folded proteins are handed off to other chaperones, such as those listed below, to complete the folding process. Eukaryotes lack a homolog of trigger factor but contain other small chaperones that may have similar functions.

3. The **chaperonins**, which are heat shock proteins that form large, multisubunit, cage-like assemblies that are universal components of prokaryotes and eukaryotes. They bind improperly folded globular proteins via their exposed hydrophobic surfaces and then, in an ATP-driven process, induce the protein to fold while enveloping it in an internal cavity, thereby protecting the folding protein from nonspecific aggregation with other unfolded proteins (see below). There are two classes of chaperonins: the **Group I chaperonins**, which occur in eubacteria, mitochondria, and chloroplasts, and the **Group II chaperonins**, which occur in archaea and eukaryotes.

4. The **Hsp90** proteins, which are homodimeric, ATP-dependent, eukaryotic proteins of ~730-residue subunits that mainly facilitate the late stage folding of proteins involved in signaling, including **steroid hormone receptors** (Section 34-3Bn) and **receptor tyrosine kinases** (Section 19-3A). Like other chaperones, they do so by binding to exposed hydrophobic surfaces of their substrate proteins so as to prevent nonspecific aggregation. Unlike other chaperones, however, Hsp90 proteins have a regulatory role in that they induce conformational changes in natively substrate proteins that result in their activation or stabilization. They do so through their interactions with a large variety of cochaperones. Hsp90 proteins are among the most abundant proteins in eukaryotes, constituting 1 to 2% of their soluble proteins under normal conditions and 4 to 6% under stressful conditions that destabilize proteins such as high temperatures.

5. The **nucleoplasmins**, which are decameric, acidic, nuclear proteins whose presence is required for the proper *in vivo* assembly of **nucleosomes** (particles in which eukaryotic DNA is packaged) from their component DNA and histones (Section 34-1B).

In the following paragraphs we concentrate on the structure and function of the chaperonins, as these are the best characterized molecular chaperones. This discussion also constitutes our introduction to the dynamic functions of proteins, that is, to proteins as molecular machines.

### a. The GroEL/ES System Forms a Large Cavity in Which Substrate Protein Folds

Group I chaperonins consist of two families of proteins that work in concert: (1) the **Hsp60** proteins (**GroEL** in *E. coli* and **Cpn60** in chloroplasts), which, as electron microscopic images first revealed, consist of 14 identical ~60-kD subunits arranged in two apposed rings of 7 subunits each (Fig. 9-18); and (2) the **Hsp10** proteins (**GroES** in *E. coli* and **Cpn10** in chloroplasts), which form single heptameric rings of identical ~10-kD proteins. These proteins, which are essential to the survival of *E. coli* under all conditions tested, facilitate the folding of improperly folded proteins to their native conformations (their discovery in *E. coli* as being necessary for the growth of certain bacteriophages is why they have the designation “Gro”).

The X-ray structure of GroEL (Fig. 9-19), determined by Arthur Horwich and Paul Sigler, shows, as expected, that GroEL's 14 identical 547-residue subunits associate to form a porous thick-walled hollow cylinder that consists of two 7-fold symmetric rings of subunits stacked back to back with 2-fold symmetry to yield a complex with  $D_7$  symmetry (Section 8-5B). Each GroEL subunit consists of three domains: a large equatorial domain (residues 1–135 and 410–547) that forms the waist of the protein and holds

**Figure 9-18** Electron micrograph–derived 3D image of the **Hsp60** chaperonin from the photosynthetic bacterium *Rhodobacter sphaeroides*. Hsp60 consists of 14 identical ~60-kD subunits arranged to form two apposed rings of 7 subunits, each surrounding a central cavity. The image of Hsp60, which is viewed with its 7-fold axis tipped toward the viewer, indicates that each subunit consists of two major domains, one in contact with the opposing heptameric ring, and the other at the end of the cylindrical protein molecule. The spherical density occupying the protein's central cavity is thought to represent a bound polypeptide. The cavity provides a protected microenvironment in which a polypeptide can fold. [Courtesy of Helen Saibil and Steve Wood, Birkbeck College, London, U.K.]

its subunits together through both intra- and inter-ring interactions, a loosely structured apical domain (residues 191–376) that forms the open ends of the GroEL cylinder, and a small intermediate domain (residues 136–190 and 377–409) that connects the equatorial and apical domains. The X-ray structure suggests that GroEL encloses an ~45-Å-diameter central channel that runs the length of the complex. We shall see below that this channel, in part, forms the chambers in which partially folded proteins fold to their native states. However, both electron microscopy–based images and neutron scattering studies indicate that the channel is obstructed in its equatorial region, so that proteins cannot pass between two GroEL rings. The obstruction is apparently caused by each subunit's N-terminal 5 residues and C-terminal 22 residues, which are not seen in the X-ray structure and hence are almost certainly disordered.

The X-ray structure of GroEL with **ATP $\gamma$ S** bound to each subunit (ATP $\gamma$ S is a poorly hydrolyzable analog of ATP in which S replaces one of the O atoms substituent to P $\gamma$ )

**ATP $\gamma$ S**

indicates that ATP binds to a pocket in the equatorial domain that opens onto the central channel. The residues forming this pocket are highly conserved among chaperonins. The only significant differences between the structures of the GroEL–ATP $\gamma$ S complex and that of GroEL alone are modest movements of the residues in the vicinity of the ATP pocket.

The X-ray structure of GroES (Fig. 9-20), determined by Lila Gierasch and Johann Deisenhofer, shows that this protein's 7 identical 97-residue subunits form a domelike structure with  $C_7$  symmetry. Each GroES subunit consists of an irregular antiparallel  $\beta$  barrel from which two  $\beta$  hairpins project. One of these  $\beta$  hairpins (residues 47–55) extends from the top of the  $\beta$  barrel toward the protein's 7-fold axis, where it interacts with the other such  $\beta$  hairpins to form the roof of the dome. The second  $\beta$  hairpin (residues 16–33) extends from the opposite side of the  $\beta$  barrel outward from the bottom outer rim of the dome. This so-called mobile loop is seen in only one of GroES's 7 subunits; it is apparently disordered in the other subunits in agreement with the results of NMR studies of uncomplexed GroES in solution. The inner surface of the GroES dome is lined with hydrophilic residues.

Both electron microscopic and neutron scattering studies reveal that partially unfolded proteins bind in the mouth of the GroEL barrel in a manner reminiscent of a cork in a champagne bottle (Fig. 9-18). Mutations that impair polypeptide binding to GroEL all map to a poorly

(a)

**Figure 9-19 X-ray structure of GroEL.** (a) Side view perpendicular to the 7-fold axis in which the seven identical subunits of the lower ring are gold and those of the upper ring are silver, with the exception of the two subunits nearest the viewer, whose equatorial, intermediate, and apical domains are colored blue, green, and red on the right subunit and cyan, yellow, and magenta on the left subunit. The two rings of the complex

(b)

are held together through side chain interactions that are not seen in this drawing. (b) Top view along the 7-fold axis in which only the upper ring is shown for the sake of clarity. Note the large central channel that appears to run the length of the protein. [Based on an X-ray structure by Axel Brünger, Arthur Horwich, and Paul Sigler, Yale University. PDBid 1OEL.]

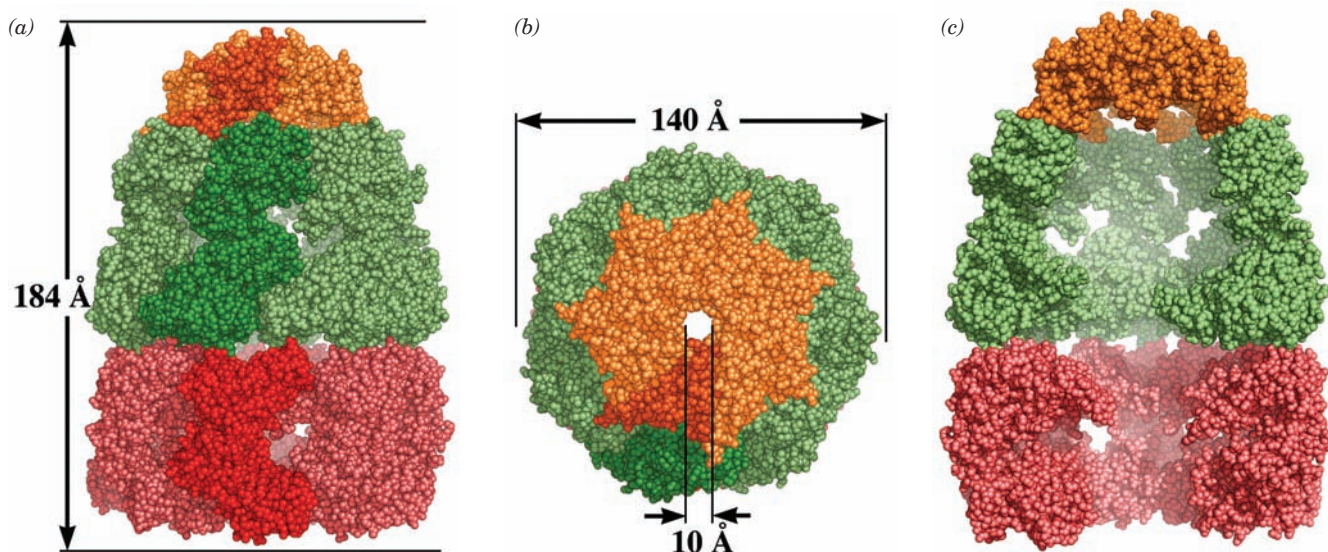

**Figure 9-20 X-ray structure of GroES as viewed along its 7-fold axis.** The mobile loop of only one of the protein's 7 identical subunits (*left*) is visible in the structure. The polypeptide segments that flank the mobile loop are yellow. [Courtesy of Johann Deisenhofer, University of Texas Southwest Medical Center, Dallas.]

resolved (and presumably flexible) segment at the top of the apical domain that, in the structure of GroEL alone, faces the central channel. In fact, changing any of nine highly conserved hydrophobic residues in this region to a hydrophilic residue abolishes polypeptide binding. It therefore seems likely that these residues provide the binding site(s) for non-native polypeptides. Interestingly, mutations of these same residues also abolish the binding of GroES.

The X-ray structure of the GroEL-(ADP)<sub>7</sub>-GroES complex (Fig. 9-21), also determined by Horwich and Sigler, provides considerable insight into how this chaperonin carries out its function. In this complex, a GroES heptamer and the 7 ADPs are bound to the same GroEL ring (the so-called *cis* ring; the opposing GroEL ring is known as the *trans* ring) such that the GroES cap closes over the GroEL *cis* ring barrel like a lid on a pot, thereby forming a bullet-shaped complex with *C*<sub>7</sub> symmetry. The *trans* ring subunits have conformations that closely resemble those in the structure of GroEL alone. In contrast, the apical and intermediate domains of the *cis* ring have undergone large *en bloc* movements relative to their positions in GroEL alone (Fig. 9-22). This widens and elongates the *cis* cavity in a way that more than doubles its volume (from 85,000 to 175,000 Å<sup>3</sup>; Fig. 9-21c), thereby permitting it to enclose a partially folded substrate protein of up to ~70 kD. *These en bloc movements are concerted, that is, they occur simultaneously*

**Figure 9-21** X-ray structure of the GroEL-(ADP)<sub>7</sub>-GroES complex. (a) A space-filling drawing as viewed perpendicularly to the complex's 7-fold axis with the GroES ring orange, the cis ring of GroEL green, and the trans ring of GroEL red with one subunit in each ring shaded more brightly. The dimensions of the complex are indicated. Note the different conformations of the two GroEL rings. The ADPs, whose binding sites are in the base of each cis ring GroEL subunit, are not seen because they are

surrounded by protein. (b) As in Part a but viewed along the 7-fold axis. (c) As in Part a but with the two GroEL subunits closest to the viewer in both the cis and the trans rings removed to expose the interior of the complex. The level of fog increases with the distance from the viewer. Note the much larger size of the cavity formed by the cis ring and GroES in comparison to that of the trans ring. [Based on an X-ray structure by Paul Sigler, Yale University. PDBid 1AON.]

**Figure 9-22** Domain movements in GroEL. (a) Ribbon diagram of a single subunit of GroEL in the X-ray structure of GroEL alone. Its equatorial, intermediate, and apical subunits are colored blue, green, and red. The inset shows a space-filling drawing of GroEL with the colored subunit oriented identically. Circles and arrows indicate the pivot points for domain movements. (b) A GroEL subunit in the X-ray structure of GroEL-(ADP)<sub>7</sub>-GroES displayed as in Part a. The ADP, which is bound in a pocket at the top of the equatorial domain, is shown in space-filling form in pink. (c) Schematic diagram indicating the conformational changes in GroEL when it binds GroES. Its equatorial (E), intermediate (I), and apical (A) domains are colored as in Part a and GroES is yellow. The arrows indicate the extent of the domain movements in the cis ring of GroEL. [Parts a and b courtesy of Arthur Horwich, Yale University; Part c after Richardson, A., Landry, S.J., and Georgopoulos, C., *Trends Biochem. Sci.* **23**, 138 (1998).]

**Figure 9-23** Apical domain of GroEL in complex with a tight-binding 12-residue polypeptide (SWMTPWGFLHP). To generate this drawing, the  $C_{\alpha}$  atoms of the apical domain in the X-ray structure of the complex were superimposed on those of the apical domains in the X-ray structure of GroEL alone (Fig. 9-19). Each apical subunit is represented by a ribbon diagram in which the two helices involved in binding the polypeptide (helices H and I in Fig. 9-22a) are red and the remainder of the subunit is green. The polypeptides are shown in space-filling form in red. [Courtesy of Lingling Chen, Yale University. PDBid 1DKD.]

in all seven subunits of a GroEL ring, most probably because if one GroEL subunit did not undergo these conformational shifts, it would mechanically block its adjacent subunits from doing so.

In forming the GroEL-(ADP)<sub>7</sub>-GroES complex, the ADP becomes completely enclosed by protein through the collapse of the intermediate domain onto the equatorial domain (Fig. 9-22b). This movement activates GroEL's ATPase function by shifting the side chain of its catalytically essential Asp 398, which extends from the L helix of the equatorial domain, into its catalytically active position near the ADP's  $\beta$  phosphate group. Electron microscopy studies at 10-Å resolution by Horwich and Helen Saibil reveal that similar movements occur when ATP binds to GroEL.

The hydrophobic groups lining the inner surface of the trans ring's apical domain, which extend from its H and I helices and an underlying loop (Fig. 9-22), presumably bind to the improperly exposed hydrophobic groups of substrate proteins. Indeed, an X-ray structure of the apical domain of GroEL in complex with a 12-residue peptide that binds strongly to GroEL reveals that this peptide binds to these exposed hydrophobic groups (Fig. 9-23). However, in the cis ring of the GroEL-(ADP)<sub>7</sub>-GroES complex, these hydrophobic groups participate either in binding GroES via its flexible loops or in stabilizing the newly formed interface between the rotated and elevated apical domains. Consequently, *these hydrophobic groups are no longer exposed on the inner surface of the cis cavity (Fig. 9-24), thereby depriving a substrate protein of its binding sites.*

**Figure 9-24** Movements of the polypeptide-binding helices of GroEL. (a) A space-filling drawing of GroEL in the structure of GroEL alone and (b) in the structure of GroEL-(ADP)<sub>7</sub>-GroES. The GroEL cis and trans rings are pale cyan and pale yellow and the cis ring's H and I helices (Figs. 9-22a,b), which form most of the hydrophobic binding sites for improperly folded proteins, are drawn in cartoon form and colored green and red, respectively. On

the addition of GroES and ATP to GroEL, neighboring binding sites separate by 8 Å and non-neighboring sites separate by up to 20 Å. A substrate protein initially bound to two of these sites will likely be forcibly stretched and hence partially unfolded before being released as the binding sites become occluded. [After drawings by George Lorimer, University of Maryland; and Walter Englander, University of Pennsylvania. PDBids 1OEL and 1AON.]

### b. GroEL/ES Undergoes Coordinated Conformational Changes That Are Paced by ATP Binding and Hydrolysis

The binding of ATP and GroES to the cis ring of GroEL strongly inhibits their binding to the trans ring. The X-ray structure of the GroEL-(ADP)<sub>7</sub>-GroES complex suggests that this occurs through concerted small conformational shifts in the GroEL equatorial domains that apparently prevent the trans ring from assuming the conformation of the cis ring. However, once the cis ring has hydrolyzed its bound ATP (which it is committed to do once its nucleotide binding sites close off and its ATPase active sites form), the trans ring can bind ATP and the resulting conformational shifts release GroES from the cis ring. This explains why a mutant form of GroEL that has only a single ring (and hence is known as SR1) can bind substrate protein and GroES but does not release them after it hydrolyzes its bound ATP. *The proper functioning of GroEL requires two rings, even though their central cavities are unconnected.*

A mutant form of GroEL, D398A (in which Asp 398 has been changed to Ala), binds but cannot hydrolyze ATP. In the presence of ATP, D398A GroEL binds GroES together with substrate protein. However, it does not release GroES or the protein when the trans ring is exposed to ATP, as is the case when the cis ring can hydrolyze ATP. Evidently, *ATP's  $\gamma$ -phosphate group provides strong contacts that stabilize the GroEL-GroES interaction. When the ATP in the cis ring is hydrolyzed, the resulting phosphate group is released and these interactions are lost.*

### c. ATP Hydrolysis in the Cis Ring Must Occur before Substrate Protein and GroES Can Bind to the Trans Ring

The foregoing indicates that *events in the cis and trans rings of the GroEL-GroES complex are coordinated through concerted conformational changes in one ring that influence the conformation of the opposing ring.* What is the sequence of events in the trans ring relative to those in the cis ring, that is, at what stage of the folding cycle in the cis ring do substrate protein and GroES bind to the trans ring? Horwich answered this question using fluorescence labeling techniques. D398A GroEL that had been mixed with ADP and GroES so as to form a stable complex [D398A GroEL-(ADP)<sub>7</sub>-GroES] was then mixed with a substrate protein to which a fluorescent group had been covalently linked. When this mixture was subjected to gel filtration chromatography (Section 6-3B), the label migrated with the GroEL, thereby indicating that the substrate protein had bound to the complex's trans ring. However, when the initial complex was instead made with ATP (recall that D398A GroEL cannot hydrolyze ATP), the substrate protein did not associate with the GroEL. In similar experiments, fluorescently labeled GroES associated with preformed D398A GroEL-(ADP)<sub>7</sub>-GroES in the presence of ATP but not with preformed D398A GroEL-(ATP)<sub>7</sub>-GroES. Evidently, *the cis ring of the GroEL-GroES complex must hydrolyze its bound ATP before the trans ring can bind either substrate protein or GroES + ATP.*

### d. The GroEL/ES System Functions as a Two-Stroke Engine

Taken together, all of the preceding observations indicate how the GroEL/ES system functions (Fig. 9-25):

1. A GroEL ring that is binding 7 ATP and an improperly folded substrate protein via the hydrophobic patches on its apical domains (Fig. 9-25, *upper left*) binds GroES. This induces a conformational change in the now cis GroEL ring, thereby releasing the substrate protein into the resulting enlarged and closed cavity, where the substrate protein commences folding. The cavity, which is now lined only with hydrophilic groups, provides the substrate protein with an isolated microenvironment that prevents it from nonspecifically aggregating with other unfolded proteins (a so-called **Anfinsen cage**).

2. Within ~10 s (the time the substrate protein has to fold), the cis ring catalyzes the hydrolysis of its 7 bound ATPs to ADP + P<sub>i</sub> (where P<sub>i</sub> is the symbol for inorganic phosphate) and the P<sub>i</sub> is released. The absence of ATP's  $\gamma$ -phosphate group weakens the interactions that bind GroES to GroEL.

3. A second molecule of substrate protein binds to the trans ring followed by 7 ATP.

4. The binding of substrate protein and ATP to the trans ring induces the cis ring to release its bound GroES, 7 ADP, and the now possibly natively folded substrate protein. This leaves only ATP and substrate protein bound to the previous trans ring of GroEL, which becomes the cis ring on binding GroES when the complex again cycles through Step 1.

Substrate protein that has not achieved its native state or is not committed to do so is readily recaptured by GroEL. Substrate protein that has achieved its native fold lacks exposed hydrophobic groups and hence cannot bind to GroEL. It is the irreversible hydrolysis of ATP that drives the folding cycle in only the direction indicated in Fig. 9-25.

### e. GroEL Unfolds Its Substrate Proteins before Facilitating Their Refolding

How does the foregoing cycle promote the proper folding of an improperly folded protein? Two models, not mutually exclusive, have received the most consideration:

1. The Anfinsen cage model, in which the GroEL/ES complex provides the substrate protein with a protected microenvironment in which it can fold to its native conformation without interference by nonspecific aggregation with other misfolded proteins. Moreover, the confinement of the substrate protein to the relatively small volume of the cis ring cavity eliminates nonproductive folding pathways involving extended conformations, and the hydrophilic character of the cavity walls promotes productive folding pathways by favoring the burial of hydrophobic residues. In terms of landscape theory (Section 9-1Ch), this would smooth the walls of the folding funnel (Fig. 9-13d) and thus facilitate the folding of the substrate protein toward its global free energy minimum, that is, its native state.

**Figure 9-25** Reaction cycle of the GroEL/ES chaperonin system in protein folding. See the text for an explanation.

**2. The iterative annealing** model, in which the ATP-driven unfolding of a misfolded and conformationally trapped substrate protein followed by its release permits it to resume folding to its native state. This would occur through the binding of a misfolded protein to the hydrophobic patches on two or more of the GroEL cis rings's seven apical domains, followed by the stretching and ultimate release of the protein as GroEL changes conformation on binding ATP and GroES [recall that these patches are further apart in the GroEL-(ADP)<sub>7</sub>-GroES complex than they are in GroEL alone; Fig. 9-24]. In terms of landscape theory, this stretching would expel the substrate protein (raise its free energy) from a local energy minimum in which it had become trapped and thereby permit it to continue, but not necessarily complete, its conformational journey down the folding funnel toward its native state.

Fluorescence resonance energy transfer (FRET; Section 9-1Cd) measurements by Hays Rye indicate that the forced unfolding of substrate protein by GroEL enhances its rate of folding. **Ribulose-1,5-bisphosphate carboxylase oxygenase (RuBisCO;** Sections 24-3Ac and 24-3C) from *Rhodospirillum rubrum*,

which requires GroEL/ES to fold to its native state, was covalently labeled on its N- and C-terminal domains by acceptor and donor fluorescent probes, respectively (which does not affect RuBisCO's stability or its GroEL-mediated folding rate). FRET measurements indicated that on binding to the trans ring of a GroEL-(ADP)<sub>7</sub>-GroES complex, the fluorescently labeled RuBisCO's end-to-end distance increases slightly. However, on the subsequent addition of ATP, this distance greatly increases within 0.2 s and then decreases to less than its original value over a ~5 s period. This indicates that the initial binding of ATP to GroEL significantly unfolds its bound substrate protein, which then folds to a more compact state within the now cis cavity of GroEL/ES. Further measurements indicate that the fraction of unfolded RuBisCO that folds to its native state increases with the extent of its unfolding previous to being released into the cis cavity.

As diagrammed in Fig. 9-25, the GroEL/ES system releases its substrate protein after each reaction cycle, whether or not the protein is properly folded. In contrast, SR1, the single-ring mutant form of GroEL, in its complex with GroES, cannot release its bound substrate protein.

Nevertheless, the trapped substrate protein refolds nearly quantitatively to its native state over a period of several minutes, about the same rate as it does so in the cycling system. Evidently, the efficiency with which a substrate protein folds to its native state varies with the length of time that it spends in the cis cavity (Anfinsen cage). Then why hasn't a GroEL/ES system evolved that allows an unfolded protein to complete its folding before it is released? The answer may be that the release of the substrate protein from the cis cavity with each turn of the GroEL/ES cycle is a protective mechanism that prevents irretrievably damaged proteins from permanently clogging GroEL. In a cycling system, a substrate protein spends only a fraction of the time in a cis cavity. Thus, since forced unfolding increases folding efficiency, it is a major contributor to the GroEL/ES system's multilayered protein folding mechanism. Moreover, forced unfolding explains how the GroEL/ES system is able to facilitate the folding of several proteins that are too large to completely fit inside the GroEL cavity.

A variety of experiments indicate that substrate proteins bound to the open ring of GroEL alone are largely unstructured. For example, NMR measurements indicate that the 21-kD enzyme **dihydrofolate reductase (DHFR; Section 28-3Bd)** bound to GroEL or SR1 has no stable structure, and hydrogen exchange measurements (Section 9-1Cc) on several substrate proteins bound to GroEL indicate that they exhibit little or no secondary structure. Moreover, FRET measurements on the 41-kD **maltose binding protein** bound to the trans ring of the GroEL–GroES complex reveal that it undergoes a rapid conformational expansion on ATP addition (as does RuBisCO), and NMR measurements indicate that DHFR inside the SR1–GroES cavity follows the same folding trajectory as does DHFR free in solution. Thus GroEL/ES-mediated folding appears to be an all-or-none process rather than an iterative one in which the substrate protein progressively acquires more native-like structure with each round of folding. This suggests that each time a substrate protein binds to the trans ring of GroEL–GroES, it is raised to the top of its folding funnel in an ATP-driven process from which it commences folding via a different trajectory.

Typically, only ~5% of substrate proteins fold to their native state in each reaction cycle. Thus, to fold half the substrate protein present would require  $\log(1 - 0.5)/\log(1 - 0.05) \approx 14$  reaction cycles and hence  $7 \times 14 = 98$  ATPs. This may seem like a profligate use of ATP, but it is only a fraction of the 1200 ATPs expended in ribosomally synthesizing a 300-residue protein from its component amino acids (4 ATPs per residue; Sections 32-2C and 32-3D), not to mention the far greater number of ATPs required to synthesize these amino acids (Section 26-5).

#### **f. GroEL/ES Is Required for the Folding of ~85 *E. coli* Proteins *in vivo***

The GroEL/ES system only interacts *in vivo* with a subset of *E. coli* proteins. Ulrich Hartl identified these proteins by modifying GroES to have a C-terminal His<sub>6</sub> segment (a His-Tag) and isolating the resulting GroEL–GroES–

substrate protein complexes from *E. coli* lysates by metal chelation affinity chromatography (Section 6-3Dg). These complexes were separated by SDS–PAGE (Section 6-4C) and the substrate proteins identified by mass spectrometry (Section 7-1I).

Approximately 250 of *E. coli*'s ~2400 cytosolic proteins were found to be associated with GroEL/ES. Of these, ~165 proteins either show little tendency to aggregate during folding or can utilize other chaperone proteins such as trigger factor or DnaK/J to fold to their native states. However, the remaining ~85 proteins have an absolute dependence on the GroEL/ES system for folding, that is, they invariably aggregate in the absence of GroEL/ES. Thirteen of these proteins are indispensable for *E. coli* viability, thereby explaining why GroEL/ES is also essential for *E. coli* viability. About 75% to 80% of the GroEL/ES binding sites are occupied by the ~85 GroEL/ES-dependent proteins, even though they have only low to intermediate abundance in the *E. coli* cytosol.

What are the characteristics of proteins that are obligate substrates of GroEL/ES? Analysis, using the SCOP database (Section 8-3Cd), of those proteins of known structure or with homologs of known structure revealed that many of them contain  $\alpha/\beta$  domains (Section 8-3Bh). In particular, ~35% by mass of all GroEL/ES substrate proteins contain  $\alpha/\beta$  barrels (also called TIM barrels; Section 8-3Bh), even though they comprise only ~6% of the cytosol's total protein mass. These proteins, whose molecular masses range from 23 to 54 kD, are stabilized by numerous long range (in sequence) interactions and hence would be expected to have particularly rugged folding funnels with many local free energy minima that could trap the unaided protein.

What are the substrate protein sequence motifs that bind to GroEL? During the GroEL/ES cycle, the GroES mobile loops (sequence GGIVLTGSA) displace these motifs (Section 9-2Ca), thus suggesting that they have similar sequences. Moreover, to be stretched by GroEL, a substrate protein must have at least two such motifs separated by at least 10 residues. By searching GroEL's ~250 substrate proteins for motifs with these characteristics, George Lorimer and Devarajan Thirumalai found that they have the consensus sequence P\_HHH\_P\_H, where P, H, and \_ respectively represent polar, hydrophobic, and any residues and where the core sequence is P\_HHH. This is corroborated by the observation that in natively folded substrate proteins of known structure, nearly all of these sequence motifs are buried (<50% of their surface area is solvent-accessible), although since they occur in helices, sheets, and loops, they apparently have little other structural preferences.

The obligate GroEL/ES substrate proteins belong to fold classes that tend to have a greater number of superfamilies than do other *E. coli* proteins. This suggests that GroEL/ES may have facilitated the evolutionary diversification of certain protein folds, perhaps by “buffering” mutations that would otherwise cause severe aggregation. Indeed, the GroEL/ES system likely played an essential role in the evolution of the  $\alpha/\beta$  barrel into the most versatile structural platform for enzymatic functions (Section 8-3Bh).

### g. Group II Chaperonins Have Built-In Lids

Group II chaperonins structurally and functionally resemble Group I chaperonins but consist of back-to-back rings of 8 or 9 subunits and have no corresponding cochaperones such as GroES. Archaeal Group II chaperonins, which are called **thermosomes**, consist of 1 to 3 different types of subunits. Eukaryotic Group II chaperonins, which are named **TRiC** (for *TCP-1 ring complex*; TCP for *T-complex polypeptide*) or alternatively **CCT** (for chaperonin-containing TCP-1), have dual octameric rings, each consisting of eight genetically distinct but homologous subunits arranged in a specific order. Like GroEL/ES, each of the TRiC subunits couple the hydrolysis of ATP to the folding of substrate proteins. Around 10% of eukaryotic cytosolic proteins transiently interact with TRiC, many of which have an absolute requirement for TRiC-aided folding. These include a variety of essential structural and regulatory proteins including the muscle proteins **actin** and **myosin** (Section 35-3A), the major microtubule components **tubulins  $\alpha$**  and  **$\beta$**  (Section 35-3G), and proteins that participate in signal transduction (Chapter 19) and cell cycle

regulation (Section 34-4D). The only characteristic that these proteins appear to have in common is that they form homo- or hetero-oligomeric complexes.

**Cryo-electron microscopic (cryo-EM)** studies of bovine testes TRiC by Wah Chiu and Judith Frydman (Fig. 9-26) revealed that, unlike GroEL, its overall shape is closer to spherical than cylindrical. [In cryo-EM, the sample is cooled to near liquid N<sub>2</sub> temperatures ( $-196^{\circ}\text{C}$ ) so rapidly (in a few milliseconds) that the water in the sample does not have time to crystallize but, rather, assumes a vitreous (glasslike) state. Consequently, the sample remains hydrated and hence retains its native shape to a greater extent than in conventional electron microscopy (in which the sample is vacuum dried).] Like GroEL, TRiC's subunits each consist of equatorial, intermediate, and apical domains. However, the tip of each TRiC apical domain has a helical extension that GroEL lacks. TRiC has two conformational states: an open state (Fig. 9-26a) in which each helical extension is oriented more or less tangentially to the inner portion of the ring, and a closed state (Fig. 9-26b) in which each helical extension has swung to a more radial

**Figure 9-26** Structure of bovine testes TRiC. (a) Its open state and (b) its closed state. Surface diagrams of the cryo-EM-based structures at  $\sim 16$  Å resolution (transparent gray) are shown as viewed along the protein's 8-fold axis (left) and as viewed from the side with the 8-fold axis tipped toward the viewer (right). The X-ray structure of a homologous archaeal chaperonin was modeled into the upper ring of the cryo-EM-based image with each subunit represented by a differently colored ribbon diagram. [Courtesy of Judith Frydman, Stanford University.]

orientation so as to form an iris-like lid that closes off the TRiC cavity in a manner similar to the way that GroES closes off the GroEL cavity. A lidless mutant of TRiC still hydrolyzes ATP and binds unfolded actin with wild-type affinity but is unable to induce its folding. This suggests that the TRiC lid has a GroES-like function in coupling ATP hydrolysis to the productive folding of substrate protein. Interestingly, the putative substrate binding sites in TRiC are not all hydrophobic as some of its subunits are lined with polar residues. Perhaps each different substrate protein interacts with a specific combination of binding sites on the apical domains in the open state of TRiC.

#### h. The Concept of Self-Assembly Must Take Accessory Proteins into Account

Many proteins can fold/assemble to their native conformations in the absence of accessory proteins, albeit often with low efficiency. Moreover, accessory proteins are not components of the native proteins whose folding/assembly they facilitate. Hence, accessory proteins must mediate the proper folding/assembly of a polypeptide to a conformation/complex governed solely by the polypeptide's amino acid sequence. Nevertheless, the concept that proteins are self-assembling entities must be modified to incorporate the effects of accessory proteins.

### 3 PROTEIN STRUCTURE PREDICTION AND DESIGN

Since the primary structure of a protein specifies its three-dimensional structure, it should be possible, at least in principle, to predict the native structure of a protein from a knowledge of only its amino acid sequence. This might be done using theoretical methods based on physicochemical principles, or by empirical methods in which predictive schemes are distilled from the analyses of known protein structures. Theoretical methods, which usually attempt to determine the minimum energy conformation of a protein, are mathematically quite sophisticated and require extensive computations. The enormous difficulty in making such calculations sufficiently accurate and yet computationally tractable has, so far, limited their success. Nevertheless, an understanding of how and why proteins fold to their native structures must ultimately be based on such theoretical methods. In this section we outline various methods that have been used to predict the secondary and tertiary structures of proteins and end with a discussion of a related technique, that of designing proteins that will have a particular structure.

#### A. Secondary Structure Prediction

The most reliable way to determine the secondary structure taken up by a polypeptide is to map its amino acid sequence onto that of a homolog of known structure. If, however, no such structure is available, the above-mentioned predictive methods must be employed. Here we discuss the use of empirical methods for secondary structure prediction. The theoretical methods discussed in the following

section to predict a polypeptide's tertiary structure will, of necessity, also predict its secondary structure.

#### a. The Chou–Fasman Method

Empirical methods have had reasonable success in secondary structure prediction. Clearly, certain amino acid sequences limit the conformations available to a polypeptide chain in an easily understood manner. For example, a Pro residue cannot fit into the interior portions of a regular  $\alpha$  helix or  $\beta$  sheet because its pyrrolidine ring would fill the space normally occupied by part of an abutting segment of chain and because it lacks the backbone N—H group with which to contribute a hydrogen bond. Likewise, steric interactions between several consecutive amino acid residues with side chains branched at  $C_\beta$  (e.g., Ile and Thr) will destabilize an  $\alpha$  helix. Furthermore, there are more subtle effects that may not be apparent without a detailed analysis of known protein structures. Here we shall discuss simple empirical methods for predicting the positions of  $\alpha$  helices,  $\beta$  sheets, and reverse turns in proteins of known sequence.

The empirical structure prediction scheme developed by Peter Chou and Gerald Fasman can be readily applied by hand and is reasonably reliable. Its use requires two definitions. The frequency,  $f_\alpha$ , with which a given residue occurs in an  $\alpha$  helix in a set of protein structures is defined as

$$f_\alpha = \frac{n_\alpha}{n} \quad [9.3]$$

**Table 9-1 Propensities and Classifications of Amino Acid Residues for  $\alpha$  Helical and  $\beta$  Sheet Conformations**

where  $n_\alpha$  is the number of amino acid residues of the given type that occur in  $\alpha$  helices and  $n$  is the total number of residues of this type in the set. The propensity of a particular amino acid residue to occur in an  $\alpha$  helix is defined as

$$P_\alpha = \frac{f_\alpha}{\langle f_\alpha \rangle} \quad [9.4]$$

where  $\langle f_\alpha \rangle$  is the average value of  $f_\alpha$  for all 20 residues. Accordingly, a value of  $P_\alpha > 1$  indicates that a residue occurs with greater than average frequency in an  $\alpha$  helix. The propensity,  $P_\beta$ , of a residue to occur in a  $\beta$  sheet is similarly defined.

Table 9-1 contains a list of  $\alpha$  and  $\beta$  propensities based on the analysis of 29 X-ray structures. In accordance with its value of a given propensity, a residue is classified as a strong former ( $H$ ), former ( $h$ ), weak former ( $I$ ), indifferent former ( $i$ ), breaker ( $b$ ), or strong breaker ( $B$ ) of that secondary structure. Using these data, Chou and Fasman formulated the following empirical rules (the **Chou-Fasman method**) to predict the secondary structures of proteins:

1. A cluster of four helix-forming residues ( $H_\alpha$  or  $h_\alpha$ , with  $I_\alpha$  counting as one-half  $h_\alpha$ ) out of six contiguous residues will nucleate a helix. The helix segment propagates in both directions until the average value of  $P_\alpha$  for a tetrapeptide segment falls below 1.00. A Pro residue, however, can occur only at the N-terminus of an  $\alpha$  helix.

2. A cluster of three  $\beta$  sheet formers ( $H_\beta$  or  $h_\beta$ ) out of five contiguous residues nucleates a sheet. The sheet is propagated in both directions until the average value of  $P_\beta$  for a tetrapeptide segment falls below 1.00.

3. For regions containing both  $\alpha$ - and  $\beta$ -forming sequences, the overlapping region is predicted to be helical if its average value of  $P_\alpha$  is greater than its average value of  $P_\beta$ ; otherwise a sheet conformation is assumed.

These easily applied empirical rules predict the  $\alpha$  helix and  $\beta$  sheet strand positions in a protein with an average reliability of  $\sim 50\%$  and, in the most favorable cases,  $\sim 80\%$  (Fig. 9-27; note, however, that because proteins consist, on average, of  $\sim 31\%$   $\alpha$  helix and  $\sim 28\%$   $\beta$  sheet, random predictions of these secondary structures would average  $\sim 30\%$  correct).

**Figure 9-27 Secondary structure prediction.** The prediction of  $\alpha$  helices and  $\beta$  sheets was made by the Chou-Fasman method and the prediction of reverse turns by the method of Rose for the N-terminal 24 residues of adenylate kinase. The helix and sheet propensities and classifications are taken from Table 9-1. The solid lines indicate all hexapeptide sequences that can nucleate an  $\alpha$  helix (top) and all pentapeptide sequences that can nucleate a  $\beta$  sheet (bottom), as is explained in the text. The average helix and sheet propensities for each tetrapeptide segment in the helix

and sheet regions are given above the corresponding dashed lines. Twelve of the 15 residues are observed to have their predicted secondary structures (middle), so that the prediction accuracy, in this case, is 80%. Reverse turns are predicted to occur in sequences in which the hydrophathy (Table 8-6) is a minimum and which do not occur in regions predicted to be helical. The region that matches this criterion is observed to have a reverse turn. [After Schultz, G.E. and Schirmer, R.H., *Principles of Protein Structure*, p. 121, Springer-Verlag (1979).]

### b. Reverse Turns Are Characterized by a Minimum in Hydrophobicity Along a Polypeptide Chain

The positions of reverse turns can also be predicted by the Chou–Fasman method. However, since a reverse turn usually consists of four consecutive residues, each with a different conformation (Section 8-1D), their prediction algorithm is necessarily more cumbersome than those for sheets and helices.

Rose has proposed a simpler empirical method for predicting the positions of reverse turns. Reverse turns nearly always occur on the surface of a protein and, in part, define that surface. Since the core of a protein consists of hydrophobic groups and its surface is relatively hydrophilic, reverse turns occur at positions along a polypeptide chain where the hydrophathy (Table 8-6) is a minimum. Using these criteria for partitioning a polypeptide chain, we can deduce the positions of most reverse turns by inspection (Fig. 9-27). Since this method often predicts reverse turns to occur in helical regions (helices are all turns), it should be applied only to regions that are not predicted to be helical.

### c. Physical Basis of $\alpha$ Helix Propensity

Why do amino acid residues have such different propensities for forming  $\alpha$  helices? This question has been answered, in part, by Matthews through the structural and thermodynamic analysis of T4 lysozyme (Section 9-1Bd) in which Ser 44, a solvent-exposed residue in the middle of a 12-residue (3.3-turn)  $\alpha$  helix, was mutagenically replaced, in turn, by all 19 other amino acids. The X-ray structures of 13 of these variant proteins revealed that, with the exception of Pro, the substitutions caused no significant distortion to the  $\alpha$  helix backbone and, hence, that differences in  $\alpha$  helix propensities are unlikely to arise from strain. However, for 17 of the amino acids (all but Pro, Gly, and Ala), the stability of the  $\alpha$  helix increases with the amount of side chain hydrophobic surface that is buried (brought out of contact with the solvent) when residue 44 is transferred from a fully extended state to an  $\alpha$  helix. The low  $\alpha$  helix propensity of Pro is due to the strain generated by its presence in an  $\alpha$  helix, and that of Gly arises from the entropic cost associated with restricting this most conformationally flexible of residues to an  $\alpha$  helical conformation (compare Figs. 8-7 and 8-9) and its lack of hydrophobic stabilization. The high  $\alpha$  helix propensity of Ala, however, is caused by its lack of a  $\gamma$  substituent (possessed by all residues but Gly and Ala) and hence the absence of the entropic cost associated with conformationally restricting such a group within an  $\alpha$  helix together with its small amount of hydrophobic stabilization.

### d. Computer-Based Secondary Structure Prediction Algorithms

A number of sophisticated computer-based secondary structure prediction algorithms have been developed. Most of them, like the Chou–Fasman method, employ sets of parameters whose values are determined by the analysis of (learning from) a set of nonhomologous proteins with known structures, in some cases coupled with energy mini-

mization techniques. These algorithms are typically ~60% accurate in predicting which of three conformational states, helix, sheet, or coil, a given residue in a protein adopts. However, a significant increase in accuracy has been gained (to over 80%) by employing evolutionary information through the use of multiple sequence alignments. This is because knowledge of the distribution of residue identities at and around each position in a series of homologous and presumably structurally similar proteins provides a better indication of the protein's structural tendencies than does a single sequence.

Several secondary structure prediction algorithms are freely available over the Web. Among them is **Jpred3** (<http://www.compbio.dundee.ac.uk/www-jpred/>), which classifies residue conformations as being either helical (H), extended/ $\beta$  sheet (E), or coil (–) with 81.5% reliability. It requires as input either the sequence of a single polypeptide or a multiple sequence alignment. However, if Jpred3 is supplied with only a single sequence, it will first use PSI-BLAST (Section 7-4Bi) to construct a multiple sequence alignment.

Although we have seen that secondary structure is mainly dictated by local sequences, we have also seen that tertiary structure can influence secondary structure (Section 9-1Be). The inability of sophisticated secondary structure prediction schemes to surpass ~80% reliability is therefore partially explained by their failure to take tertiary interactions into account.

## B. Tertiary Structure Prediction

The sequence databases (Section 7-4A) contain the sequences of ~7 million polypeptides, and the rapid rate at which entire genomes are being sequenced (Section 7-2C) promises that many more such sequences will soon be known. Yet, only a small fraction of the ~70,000 protein structures in the PDB (Section 8-3B) are unique because many of them are of the same protein binding different small molecules, mutant forms of the same protein, or closely related proteins. Moreover, around 40% of the **open reading frames (ORFs; nucleic acid sequences that appear to encode proteins)** in known genome sequences specify proteins whose function is unknown. Consequently, formulating a method to reliably predict the native structure of a polypeptide from only its sequence is a major goal of biochemistry. In the following paragraphs we discuss the progress that has been made in achieving this goal.

There are currently several major approaches to tertiary structure prediction. The simplest and most reliable approach, **comparative or homology modeling**, aligns the sequence of interest with the sequences of one or more homologous proteins of known structure, compensating for amino acid substitutions as well as insertions and deletions (indels) through modeling and energy minimization calculations. For proteins with as little as 30% sequence identity, this method can yield a root-mean-square deviation (rmsd) between the predicted and observed positions of corresponding  $C_{\alpha}$  atoms of the “unknown” protein (once its structure has been determined) of as little as ~2.0 Å. However, the accuracy of this method decreases precipitously

(the rmsd's rapidly increase) as the degree of sequence identity drops below 30%. Conversely, for polypeptides that are >60% identical, a homology model may have rmsd's of  $\sim 1$  Å (the accuracy of the atomic positions in an  $\sim 2.5$ -Å-resolution X-ray structure).

There are numerous instances of proteins that are structurally similar even though their sequences have diverged to such an extent that they have no apparent similarity. **Fold recognition** or **threading** is a computational technique that attempts to determine the unknown fold of a protein by ascertaining whether its sequence is compatible with any of the members of a library of known protein structures. It does so by placing the “unknown” protein's residues along the backbone of a known protein structure, determining the stability of the side chains of the unknown protein in that arrangement, and then sliding (threading) the sequence of the unknown protein along that of the known protein by one residue and repeating the calculation, etc., while allowing for the possibility of indels. If the “correct” fold can be found (and there is no guarantee that the fold of the unknown protein will resemble that of any member of the library), the resulting model can be improved via homology modeling. This method has yielded encouraging results, although it cannot yet be considered to be reliable. Of course, as sequence alignment algorithms (Section 7-4B) improve in their ability to recognize distant homologs, sequences that previously would have been candidates for fold recognition can instead be directly treated by comparative modeling.

Since the native structure of a protein depends only on its amino acid sequence, it should be possible, in principle, to predict the structure of a protein based only on its physicochemical properties (e.g., solvent interactions, atomic volume, charge, hydrogen bonding properties, van der Waals interactions, and bond torsion angle potentials for all of its atoms). A major problem faced by such *de novo* (Latin: from the beginning; synonymously *ab initio*) **methods** is that polypeptide chains have astronomical numbers of non-native low-energy conformations, so that it requires extensive and highly detailed calculations to determine a polypeptide's lowest energy conformation.

To assess the effectiveness of the numerous *de novo* algorithms that have been formulated, as well as other structure prediction schemes, a **Critical Assessment of Structure Prediction (CASP)** has been held every 2 years starting in 1994. CASP participants are provided with the sequences of proteins whose structures will soon be determined by X-ray crystallography or NMR spectroscopy and submit their predicted structures of these proteins for comparison with the subsequently experimentally determined structures. Over the years, *de novo* methods have steadily improved from being little better than random guesses to predicting the folding topologies of <200-residue proteins with a success rate of  $\sim 20\%$  and occasionally with near-atomic accuracy. **Rosetta**, the most consistently successful *de novo* algorithm in the past few CASPs, which was formulated by David Baker, is enormously computer-intensive. To satisfy its computational needs, Baker has organized a distributed computer network known as Rosetta@home that uses the

**Figure 9-28** Examples of successful modeling predictions by **Rosetta**. Each panel shows the superposition of a predicted model (*gray*) with the corresponding experimentally determined X-ray structure colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*) with core side chains drawn as sticks. (a) A protein of unknown function from *Thermus thermophilus* HB8 (PDBid 1WHZ). The backbones are aligned with an accuracy of  $1.6$  Å over 70 residues. otherwise idle time of nearly 100,000 volunteered computers so that an average of  $\sim 500,000$  CPU-hours can be devoted to predicting the structure of each domain. Examples of successful protein structure predictions by Rosetta are shown in Fig. 9-28.

### C. Protein Design

Although we have not yet fully solved the protein folding problem, considerable progress has been made in solving the inverse problem: generating polypeptide sequences to assume specific three-dimensional structures, that is, **protein design**. This is probably because a polypeptide can be “overengineered” to take up a desired conformation. Consequently, protein design has provided insights into protein folding and stability, and it promises to yield useful proteins that are “made to order.” Protein design begins with a target structure such as a 4-helix bundle and attempts to find an amino acid sequence that will form this structure. The designed polypeptide is then synthesized and its structure elucidated.

Successful design requires not only that the desired fold be stable but that other folds be significantly less stable (by  $\sim 15$ – $40$   $\text{kJ} \cdot \text{mol}^{-1}$ ). Otherwise a sequence that has been found to be the most stable in the desired conformation may actually be more stable in other conformations. Before such **negative design** concepts were implemented, efforts to design proteins typically yielded an ensemble of molten globulelike states rather than the desired folds.

Most successful protein design projects have redesigned naturally occurring proteins so as to enhance their stability or provide them with new functionalities. Because of the

strict steric constraints in the cores of globular proteins, this has largely yielded proteins whose internal side chain packings resemble those of the original proteins. Consequently, designing a protein with a novel fold should be a more rigorous test of protein design methods. Indeed, it is unlikely that a polypeptide of arbitrary sequence will have a stable native structure.

Baker designed a topologically novel, 93-residue,  $\alpha/\beta$  protein he named **Top7** as follows. A rough two-dimensional model of the target protein was created and structural constraints that defined its topology (e.g., hydrogen bonds and reverse turns) were identified. Rosetta was then used to generate 172 three-dimensional, backbone-only models with the required topology by assembling 3- and 9-residue fragments with the required secondary structures from the Protein Data Bank (PDB). Side chains were initially placed by considering all sets of energetically allowed torsion angles (which are known as **rotamers**) for each type of side chain but Cys at the 71 core positions and for only polar residues at the remaining 22 surface positions and using Rosetta to identify the lowest energy structures. These models were then structurally optimized through 15 cycles of using Rosetta to calculate the lowest energy backbone conformation for a fixed amino acid sequence followed by sequence redesign as previously described, ultimately yielding Top7. Although the structural differences between Top7 and its initial model were small (their backbones have an rmsd of 1.1 Å), they had dramatic changes in sequence (with only 31% of the residues in Top7 being identical to those in its initial model).

A gene for Top7 with a C-terminal His tag was synthesized (Section 7-6A) and expressed and the protein was purified by metal chelation affinity chromatography (Section 6-3Dg) followed by anion exchange chromatography (Section 6-3A). Top7 is highly soluble in aqueous solution and is monomeric as indicated by gel filtration chromatography (Section 6-3B). It is remarkably stable: Its circular dichroism (CD; Section 9-1Ca) spectrum at 98°C closely resembles that at 25°C. The X-ray structure of Top7 is all but identical, within experimental error, to the structure of the designed model: Their rmsd over all backbone atoms is 1.17 Å and many of their core side chains are effectively superimposable (Fig. 9-29). Evidently, protein folds that have not been observed in nature are not only physically possible but can be highly stable.

Baker also used the principles of protein design to generate enzymes that catalyze nonbiological reactions. He did so by grafting designed constellations of side chains onto the surfaces of naturally occurring proteins so as to form the desired active sites. As we shall see in Chapter 15, the catalytic activities of enzymes are extraordinarily sensitive to the positions of their catalytic groups.

#### 4 PROTEIN DYNAMICS

The fact that X-ray studies yield time-averaged “snapshots” of proteins may leave the false impression that proteins have fixed and rigid structures. In fact, as is becoming increasing

**Figure 9-29** Superposition of the designed model of Top7 (blue) with its X-ray structure (red). Core side chains are drawn as sticks. [Courtesy of Gautam Dantas, Washington University School of Medicine. PDBid 1QYS.]

clear, *proteins are flexible and rapidly fluctuating molecules whose structural mobilities have considerable functional significance*. For example, X-ray studies indicate that the heme groups of myoglobin and hemoglobin are so surrounded by protein that there is no clear path for O<sub>2</sub> to approach or escape from its binding pocket. Yet we know that myoglobin and hemoglobin readily bind and release O<sub>2</sub>. These proteins must therefore undergo conformational fluctuations, **breathing motions**, that permit O<sub>2</sub> reasonably free access to their heme groups (Fig. 9-30). The three-dimensional structures of myoglobin and hemoglobin undoubtedly evolved the flexibility to facilitate the diffusion of O<sub>2</sub> to its binding pocket.

**Figure 9-30** Conformational fluctuations in myoglobin. An artist's conception of the “breathing” motions in myoglobin that permit the escape of its bound O<sub>2</sub> molecule (double red spheres). The dotted lines trace a trajectory an O<sub>2</sub> molecule might take in worming its way through the rapidly fluctuating protein before finally escaping. O<sub>2</sub> binding presumably resembles the reverse of this process. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

The intramolecular motions of proteins have been classified into three broad categories according to their coherence:

**1. Atomic fluctuations**, such as the vibrations of individual bonds, which have time periods ranging from  $10^{-15}$  to  $10^{-11}$  s and spatial displacements between 0.01 and 1 Å.

**2. Collective motions**, in which groups of covalently linked atoms, which vary in size from amino acid side chains to entire domains, move as units with time periods ranging from  $10^{-12}$  to  $10^{-3}$  s and spatial displacements between 0.01 and  $>5$  Å. Such motions may occur frequently or infrequently compared with their characteristic time period.

**3. Triggered conformational changes**, in which groups of atoms varying in size from individual side chains to complete subunits move in response to specific stimuli such as the binding of a small molecule, for example, the binding of ATP to GroEL (Section 9-2Ca). Triggered conformational changes occur over time spans ranging from  $10^{-9}$  to  $10^3$  s and result in atomic displacements between 0.5 and  $>10$  Å.

In this section, we discuss how these various motions are characterized and their structural and functional significance. We shall mainly be concerned with atomic fluctuations and collective motions; triggered conformational changes are considered in later chapters in connection with specific proteins.

### a. Proteins Have Mobile Structures

X-ray crystallographic analysis is a powerful technique for the analysis of motion in proteins; it reveals not only the average positions of the atoms in a crystal, but also their mean-square displacements from those positions. X-ray analysis indicates, for example, that myoglobin has a rigid core surrounding its heme group and that the regions toward the periphery of the molecule have a more mobile character. Similarly, the apical domain of GroEL and the mobile loop of GroES are both highly flexible in the individual proteins, but when they interact in the GroEL–GroES–(ADP)<sub>7</sub> complex, they become significantly more rigid (Fig. 9-31; Section 9-2Ca). Indeed, as we have seen (Section 9-1Bg), portions of the binding sites of many proteins rigidify on binding their target molecules.

**Molecular dynamics simulations**, a theoretical technique pioneered by Martin Karplus, has revealed the nature of the atomic motions in proteins. In this technique, the atoms of a protein of known structure and its surrounding solvent are initially assigned random motions with velocities that are collectively characteristic of a chosen temperature. Then, after a time step of  $\sim 1$  femtosecond ( $1 \text{ fs} = 10^{-15} \text{ s}$ ) the aggregate effects of the various interatomic

**Figure 9-31 The mobility of the GroEL subunit.** (a) In the X-ray structure of GroEL alone and (b) in the X-ray structure of GroEL–GroES–(ADP)<sub>7</sub>. The polypeptide backbone is colored in rainbow order according to its degree of thermal motion, with blue being the least mobile (cool) and red being the most mobile (hot). The subunits are oriented as in Fig. 9-22a,b. Note that the

outer end of the apical domain, which functions to bind both substrate protein and the mobile loop of GroES (Section 9-2Ca), is more mobile in GroEL alone (*red and red-orange*) than it is in GroEL–GroES–(ADP)<sub>7</sub> (*orange and yellow*). [Based on X-ray structures by Axel Brünger, Arthur Horwich, and Paul Sigler, Yale University. PDBids (a) 1OEL and (b) 1AON.]

forces in the system (those due to departures from ideal covalent bond lengths, angles, and torsion angles as well as noncovalent interactions) on the velocities of each of its atoms are calculated according to Newton's equations of motion. Since all the atoms in the system will have moved after this time step (by a distance that is only a small fraction of a bond length), the interatomic forces (their potential field) on each atom will likewise have changed (although by only a small amount). Then, using this altered potential field together with the new positions and velocities of the atoms, the calculation is repeated for an additional time step. This computationally intensive process has been iterated for up to  $\sim 1 \mu\text{s}$  for  $\sim 100$ -residue proteins (a time that is increasing with the available computational power), thereby yielding a record of the positions and velocities of all the atoms in the system over this time period.

Molecular dynamics simulations (e.g., Fig. 9-32) have revealed that *a protein's native structure really consists of a large collection of conformational substates that have essentially equal stabilities*. These substates, which each have slightly different atomic arrangements, randomly interconvert at rates that increase with temperature. Consequently, the interior of a protein typically has a fluidlike character for structural displacements of up to  $\sim 2 \text{ \AA}$ , that is, over excursions that are somewhat larger than a bond length.

Gregory Petsko and Dagmar Ringe have demonstrated the functional significance of the internal motions in proteins. Both experimental and theoretical evidence indicates that below  $\sim 220 \text{ K}$  ( $-53^\circ\text{C}$ ), collective motions in proteins are arrested, leaving atomic fluctuations as the dominant intramolecular motions. For example, X-ray studies have shown that, at  $228 \text{ K}$ , the enzyme RNase A, in its crystalline form, readily binds an unreactive substrate analog (protein crystals generally contain large solvent-filled channels through which small molecules rapidly diffuse; at low temperatures, the water is

prevented from freezing by the addition of an antifreeze such as methanol). Yet, when the same experiment is performed at  $212 \text{ K}$ , the substrate analog does not bind to the enzyme, even after 6 days of exposure. Likewise, at  $228 \text{ K}$ , substrate-free solvent washes bound substrate analog out of the crystal within minutes but, if the temperature is first lowered to  $212 \text{ K}$ , the substrate analog remains bound to the crystalline enzyme for at least 2 days. Evidently, RNase A assumes a glasslike state below  $220 \text{ K}$  that is too rigid to bind or release substrate. In terms of landscape theory, this is interpreted as the protein being trapped in a single energy well.

### b. Protein Core Mobility Is Revealed by Aromatic Ring Flipping

The rate at which an internal Phe or Tyr ring in a protein undergoes  $180^\circ$  "flips" about its  $C_\beta-C_\gamma$  bonds is indicative of the surrounding protein's rigidity. This is because, in the close packed interior of a protein, these bulky asymmetric groups can move only when the surrounding groups move aside transiently (although note that these rings have the shape of flattened ellipsoids rather than thin disks).

NMR spectroscopy can determine the mobilities of protein groups over a wide range of time scales. Consequently, the rate at which a particular aromatic ring in a protein flips is best inferred from an analysis of its NMR spectrum (infrequent motions such as ring flipping are not detected by X-ray crystallography since this technique only reveals the average structure of a protein). NMR measurements indicate that the ring flipping rate varies from over  $10^6 \text{ s}^{-1}$  to one of immobility ( $< 1 \text{ s}^{-1}$ ) depending on both the protein and the location of the aromatic ring within the protein. For example, **bovine pancreatic trypsin inhibitor (BPTI)** is a 58-residue monomeric protein that has eight Phe and Tyr residues. At  $4^\circ\text{C}$ , four of these Phe and Tyr rings flip at rates  $> 5 \times 10^4 \text{ s}^{-1}$ , whereas the remaining four rings flip at rates

(a)

(b)

**Figure 9-32** The internal motions of myoglobin as determined by a molecular dynamics simulation. Several "snapshots" of the molecule calculated at intervals of  $5 \times 10^{-12} \text{ s}$  are superimposed. (a) The  $C_\alpha$  backbone and the heme group. The backbone is shown in blue, the heme in yellow, and the His residue liganding the Fe in orange. (b) An  $\alpha$  helix. The backbone is shown in blue, the side chains in green, and the helix hydrogen bonds as dashed orange lines. Note that the helices tend to move in a coherent fashion so as to retain their shape. [Courtesy of Martin Karplus, Harvard University.]

ranging between 30 and  $<1 \text{ s}^{-1}$ . These ring-flipping rates sharply increase with temperature, as expected.

### c. Infrequent Motions Can Be Detected through Hydrogen Exchange

Conformational changes occurring over time spans of more than several seconds can be chemically characterized through hydrogen exchange studies (Sections 9-1Cc). These show that the exchangeable protons of native proteins exchange at rates that vary from milliseconds to many years (Fig. 9-33). Protein interiors, as we have seen (Section 8-3B), are largely excluded from contact with their surrounding aqueous solvent, and, moreover, protons cannot exchange with solvent while they are engaged in hydrogen bonding. The observation that the internal protons of proteins do, in fact, exchange with solvent must therefore be a consequence of transient local unfolding or “breathing” that physically and chemically exposes these exchangeable protons to the solvent. Hence, *the rate at which a particular proton undergoes hydrogen exchange is a reflection of the conformational mobility of its surroundings*. This hypothesis

**Figure 9-33** The hydrogen–tritium “exchange-out” curve for hemoglobin that has been pre-equilibrated with tritiated water. The vertical axis expresses the ratio of exchangeable protons to heme Fe atoms. Exchange-out was initiated by replacing the protein’s tritiated water solvent with untritiated water through rapid gel filtration (Section 6-3B). As the exchange-out proceeded, additional gel filtration separations were performed and the amount of tritium remaining bound to the protein was measured. At the arrow,  $\text{O}_2$  was added to exchanging deoxyhemoglobin (hemoglobin lacking bound  $\text{O}_2$ ). The changing slopes of these curves indicate that the hydrogen exchange rates of the  $\sim 80$  exchangeable protons of each hemoglobin subunit vary by factors of many decades and that  $\text{O}_2$  binding increases the exchange rates for  $\sim 10$  of these protons (the structural changes that  $\text{O}_2$  binding induces in hemoglobin are discussed in Section 10-2). [After Englander, S.W. and Mauel, C., *J. Biol. Chem.* **247**, 2389 (1972).]

is corroborated by the observation that the hydrogen exchange rates of proteins decrease as their denaturation temperatures increase and that these exchange rates are sensitive to the proteins’ conformational states (Fig. 9-33).

## 5 CONFORMATIONAL DISEASES: AMYLOID AND PRIONS

Most proteins in the body maintain their native conformations or, if they become partially denatured, are either renatured through the auspices of molecular chaperones (Section 9-2C) or are proteolytically degraded (Section 32-6). However,  $\sim 35$  different, often fatal, human diseases are associated with the extracellular deposition of normally soluble proteins in certain tissues in the form of insoluble aggregates known as **amyloid** (starchlike; a misnomer because it was originally thought that this material resembled starch). These include **Alzheimer’s disease** and **Parkinson’s disease**, neurodegenerative diseases that mainly strike the elderly; the **transmissible spongiform encephalopathies (TSEs)**, a family of infectious neurodegenerative diseases that are propagated in a most unusual way; and the **amyloidoses**, a series of diseases caused by the deposition of an often mutant protein in organs such as the heart, liver, or kidney. The deposition of amyloid interferes with normal cellular function, resulting in cell death and eventual organ failure.

Although the various types of amyloidogenic proteins are unrelated and their native structures have widely different folds, their amyloid forms have remarkably similar core structures: Each consists of an array of  $\sim 10$ -nm-diameter **amyloid fibrils** (Fig. 9-34) in which, as infrared, NMR, and X-ray diffraction methods indicate, certain segments

**Figure 9-34** An electron micrograph of amyloid fibrils of the protein PrP 27–30 (Section 9-5Ce). They are visually indistinguishable from amyloid fibrils formed by other proteins. The black dots are colloidal gold beads that are coupled to anti-PrP antibodies that are adhering to the PrP 27–30. [Courtesy of Stanley Prusiner, University of California at San Francisco Medical Center.]

of the proteins form extended  $\beta$  sheets whose planes extend parallel to the fibril axis so that their  $\beta$  strands are perpendicular to the fibril axis (see below). Thus, *these proteins each have two radically different stable conformations, their native forms and their amyloid forms.*

We begin this section with a discussion of the amyloidoses as exemplified by **islet amyloid polypeptide (IAPP)**; also called **amylin**) and certain mutants forms of lysozyme. We then consider Alzheimer's disease and finally the TSEs and their bizarre mode of propagation.

### A. Amyloid Diseases

Many amyloidogenic proteins are mutant forms of normally occurring proteins. These include lysozyme (an enzyme that hydrolyzes bacterial cell walls; Section 15-2) in the disease **lysozyme amyloidosis**, **transthyretin** [Fig. 8-66; a blood plasma protein that functions as a carrier for the water-insoluble thyroid hormone **thyroxin** (Section 19-1D) as well as retinol through its association with retinol binding protein (Section 8-3Bg)] in **familial amyloidotic polyneuropathy**, and **fibrinogen** (the precursor of **fibrin**, which forms blood clots; Section 35-1A) in **fibrinogen amyloidosis**. Most such diseases do not present (become symptomatic) until the third to seventh decades of life and typically progress over 5 to 15 years ending in death.

#### a. IAPP Forms a Cross- $\beta$ Spine Structure

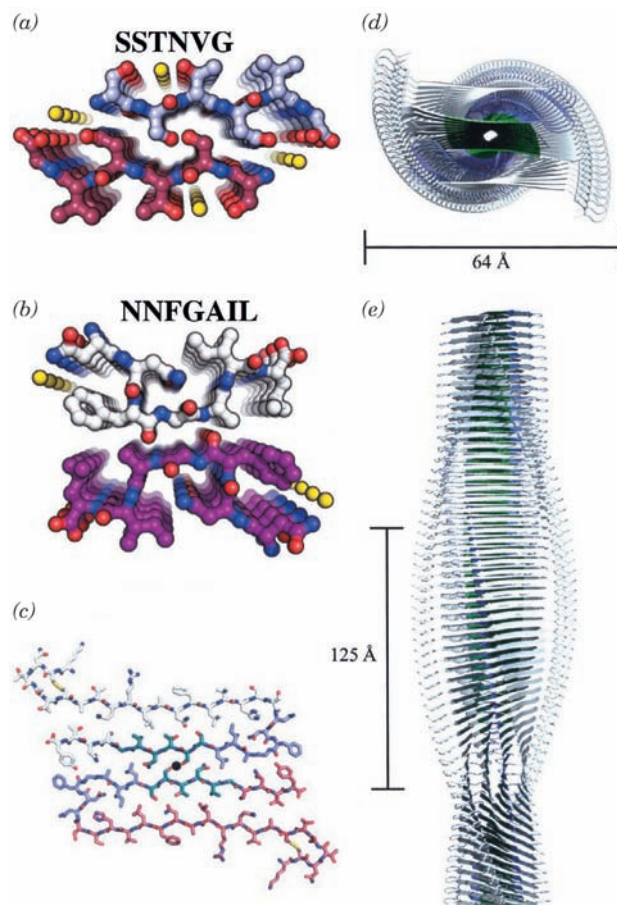

IAPP is a 37-residue peptide that is associated with **type 2 diabetes mellitus** (also called **non-insulin dependent and maturity-onset diabetes mellitus**; Section 27-4B), an often fatal disease that afflicts  $\sim 100$  million mainly older people worldwide. IAPP is expressed and secreted by the pancreatic  $\beta$  islet cells, which also synthesize the polypeptide hormone insulin (Fig. 7-2; whose lack is responsible for **type I** or **juvenile-onset diabetes mellitus**). Although the role of IAPP in the development of type 2 diabetes is unclear, the pancreases of 95% of individuals with type 2 diabetes contain amyloid deposits of IAPP with the extent of this deposition increasing with the severity of the disease. Interestingly, mouse IAPP, which differs from human IAPP in 6 of its 37 residues, does not form amyloid and mice do not develop type 2 diabetes, although transgenic mice that express human IAPP sometimes do so.

Attempts to crystallize IAPP, either in its native conformation or its amyloid form, have been unsuccessful. However, through the use of structure prediction techniques (Section 9-3B), Baker and David Eisenberg identified two of its segments that have high fibril-forming potential: **NNFGAIL** and **SSTNVG**, which comprise IAPP's residues 21 to 27 and 28 to 33 (5 of the 6 residue differences between human and mouse IAPP occur in the segment 23–29). Both of these peptides form amyloidlike fibrils as well as very thin needle-shaped crystals.

The X-ray structure of **SSTNVG**, determined by Eisenberg, reveals that this hexapeptide forms an extended parallel  $\beta$  sheet with two such sheets facing each other such that their protruding side chains interdigitate so tightly that they completely exclude water (Fig. 9-35a). The X-ray

structure of **NNFGAIL** is similar but contains a pronounced bend in its backbone, such that the interface between the two  $\beta$  sheets is formed between main chains (Fig. 9-35b). Such structures, which are known as **cross- $\beta$  spines**, are assumed by a variety of other amyloid-forming peptides, although many of them contain antiparallel rather than parallel  $\beta$  sheets.

Figures 9-35c–e exhibit a model of the IAPP amyloid fibril based on the forgoing X-ray structures. Its is a 4-sheet,

**Figure 9-35** The IAPP amyloid fibril. (a) The X-ray structure of **SSTNVG** drawn in ball-and-stick form as viewed along the planes of the  $\beta$  sheets that they form. Atoms are colored according to type with C on one chain white and the other magenta, N blue, O red, and water molecules represented by yellow spheres. (b) The X-ray structure of **NNFGAIL** viewed and colored as in Part a. (c) Model of the fibril as viewed along its axis (black dot). Atoms are colored according to type with the C atoms of the **SSTNVG** segment green, those of the **NNFGAIL** segment light blue, those of the N-terminal 20 residues and the C-terminal 4 residues light red or white, N blue, O red, and S atoms, which form disulfide bonds, yellow. (d) Schematic view along the fibril axis in which the **SSTNVG** segments are green, the **NNFGAIL** segments are light blue, and the modeled residues are white. (e) View perpendicular to the fibril axis represented as in Part d. The helix has a gentle left-handed twist of 3.4 Å per layer so that it makes a quarter turn every 125 Å. [Courtesy of David Eisenberg, UCLA. PDBids 3DG1 for **SSTNVG** and 3DGJ for **NNFGAIL**.]

left-handed helix which has a pitch (rise per turn) of 500 Å. The SSTNVG segment's cross-β spine is centered on the fibril axis. It is extended by NNFGAIL segments that also form hairpin turns. IAPP's final 4 residues were modeled to complete the inner β strands and its initial 20 residues were modeled to form the outer strands. The calculated X-ray diffraction pattern of this assembly closely resembles the observed diffraction pattern of IAPP fibrils.

Other amyloid-forming proteins have segments that form similar cross-β spines. However, the structures of the loops connecting the β strands must vary with the identity of the protein.

### b. Amyloidogenic Lysozyme Variants Have Conformationally Flexible Native Structures

There are two known amyloidogenic variants of the 130-residue human lysozyme, I56T and D67H. These form amyloid fibrils that are deposited in the viscera (internal organs), usually resulting in death by the fifth decade. The amyloid fibrils consist exclusively of the variant lysozymes, thereby explaining why these mutations are dominant. Structural studies on these variant proteins have shed light on how they form amyloid fibrils.

The X-ray structures of both mutant lysozymes resemble that of the wild-type enzyme. However, the replacement of Asp 67 by His interrupts a network of hydrogen bonds that stabilizes the domain containing the structure's only β sheet (its so-called β domain), resulting in the movements of the β sheet and an adjoining loop away from each other by displacements of up to 11 Å (Fig. 9-36). Although the replacement of Ile 56 by Thr causes only subtle changes in the protein structure, it insinuates a hydrophilic residue in a critical hydrophobic interface that links the protein's two domains.

The melting temperatures ( $T_m$ 's) of both variants are at least 10°C less than those of the wild-type enzyme, and both variants eventually lose all enzymatic activity when incubated at physiological temperature and pH (37°C and 7.4), conditions under which wild-type lysozyme remains fully active. The variants also aggregate on heating *in vitro*, and a variety of physical measurements indicate that, in doing so, they form amyloidlike fibrils. In hydrogen exchange experiments (Section 9-1Cc), wild-type lysozyme strongly protects 55 protons from exchange with D<sub>2</sub>O under conditions (37°C and pH 5) in which these protons are essentially unprotected in the amyloidogenic variants, thereby confirming that the native protein's tertiary structure is greatly loosened in the two mutant forms. This suggests that the partially folded, aggregation-prone forms are in dynamic equilibrium with the native conformation, even under conditions in which the native state is thermodynamically stable [keep in mind that the ratio of unfolded (U) to native (N) protein molecules in the reaction  $N \rightleftharpoons U$  is governed by Eq. [3.17]:  $[U]/[N] = e^{-\Delta G^\circ/RT}$ , where  $\Delta G^\circ$  is the standard free energy of unfolding, so that as  $\Delta G^\circ$  decreases, the proportion of U increases]. It has therefore been proposed that lysozyme fibrillogenesis is initiated by the association of the β domains of two partially unfolded

**Figure 9-36** Superpositions of wild-type human lysozyme and its D67H mutant. Wild-type lysozyme is gray and its D67H mutant is color-ramped in rainbow order from blue at its N-terminus to red and back to blue at its C-terminus. The white arrows indicate the conformational shifts of residues 45 to 54 and 67 to 75 in the D67H mutant relative to those in the wild-type protein. The four disulfide bonds present in both the wild-type and mutant protein are shown in yellow. The positions of residues 56 and 67 are indicated. [Courtesy of Margaret Sunde, University of Oxford, UK and Colin Blake, University of Oxford, UK.]

lysozyme variants to form a more extensive β sheet. This would provide a template or nucleus for the recruitment of additional polypeptide chains to form the growing fibril in a process that may involve the conformational conversion of α helices to β strands. Such an autocatalytic refolding process may be a general mechanism for amyloid fibrillogenesis. However, the several decades that many hereditary amyloid diseases require to become symptomatic suggest that the spontaneous generation of an amyloid nucleus is a rare event, that is, has a high free energy of activation (activation barriers and their relationship to reaction rates are discussed in Section 14-1C).

### B. Alzheimer's Disease

**Alzheimer's disease (AD)**, a neurodegenerative condition that afflicts ~20 million mainly elderly people worldwide (~10% of those over the age of 65 and ~50% of those over 85), causes devastating mental deterioration and eventual death. It is characterized by brain tissue containing abundant amyloid plaques (deposits) surrounded by dead and dying neurons. In addition, many neuronal cell bodies contain abnormal ~20-nm-diameter fibers known as **neurofibrillary tangles**. The amyloid plaques consist mainly of amyloid fibrils of a 40- to 42-residue peptide named **amyloid-β**

**peptide (A $\beta$ )** [the neurofibrillary tangles, which we shall not further discuss, consist of a hyperphosphorylated form of a protein named **tau** that is normally associated with microtubules (Section 1-2Ae)].

The sequence of the gene encoding A $\beta$ , which was identified via reverse genetics (Section 7-2D) based on the sequence of A $\beta$ , reveals that A $\beta$  is a segment of a 770-residue transmembrane protein named **A $\beta$  precursor protein ( $\beta$ PP)**; transmembrane proteins are discussed in Section 12-3A).  $\beta$ PP has a receptorlike sequence (Section 19-2B) although its normal function is unknown. A $\beta$  is excised from  $\beta$ PP in a multistep process through the actions of two membrane-anchored proteolytic enzymes dubbed  $\beta$ - and  $\gamma$ -**secretases**.

It had been hotly debated whether A $\beta$  causes AD or is merely a product of its neurodegenerative processes. This argument was largely put to rest by the observation that microinjecting 200 pg of fibrillar but not soluble A $\beta$  (the approximate quantity in a single A $\beta$  plaque) into the cerebral cortexes of aged but not young rhesus monkeys causes marked neuronal loss and other microscopic changes characteristic of AD as far as 1.5 mm from the injection site. Evidently, *the neurotoxic agents in AD are the A $\beta$ -containing amyloid fibrils before their deposition in amyloid plaques*.

The age-dependence of AD suggests that  **$\beta$ -amyloid** deposition is an ongoing process, at least in the later decades of life. Indeed, there are several rare variants of the  $\beta$ PP gene with mutations in their A $\beta$  regions that result in the onset of AD as early as the fourth decade of life. These mutations have been shown to affect the proteolytic processing of  $\beta$ PP in a way that increases the rate of A $\beta$  production. A similar phenomenon is seen in **Down's syndrome**, a condition characterized by mental retardation and a distinctive physical appearance caused by the trisomy (3 copies per cell) of chromosome 21 rather than the normal two copies. Individuals with Down's syndrome invariably develop AD by their fortieth year. This is because the gene encoding  $\beta$ PP is located on chromosome 21, and hence individuals with Down's syndrome produce  $\beta$ PP and presumably A $\beta$  at an accelerated rate.

A second gene that has been implicated in the premature onset of AD encodes the cholesterol transport protein **apolipoprotein E (apoE)**; (Section 12-5Bd). The *apoE* gene has several normally occurring variants (alleles) in the population, one of which, ***apoE4***, is a major risk factor for both the development of AD and its earlier onset. Moreover, AD victims with *apoE4* have significantly higher densities of  $\beta$ -amyloid plaques in their brain tissue than AD victims with other apoE variants. These observations motivated experiments showing that ApoE4 induces enhanced aggregation of synthetic A $\beta$  *in vitro*. This suggests that ApoE4 facilitates A $\beta$  aggregation *in vivo* (although another possibility is that ApoE4 inhibits the clearance of A $\beta$  from the extracellular spaces).

There is, at present, no known treatment that arrests the progress of AD. However, the foregoing suggests several strategies for therapeutic intervention, including decreasing the rate of production of A $\beta$  through the administration of substances that inhibit the action of  $\beta$ - or  $\gamma$ -secretase and through the administration of agents that

would interfere with the formation of  $\beta$ -amyloid fibrils from soluble A $\beta$ .

### C. Prion Diseases

Certain infectious diseases that affect the mammalian central nervous system were originally classified as being caused by "slow viruses" because they take months, years, or even decades to develop. Among them are **scrapie**, a neurological disorder of sheep and goats, so named for the tendency of infected sheep to scrape off their wool [they rub against fences in an effort to stay upright due to ataxia (loss of muscle coordination)]; **bovine spongiform encephalopathy (BSE or mad cow disease)**, which similarly afflicts cattle; and **kuru**, a degenerative brain disease that occurred among the Fore people of Papua New Guinea (kuru means trembling) and that was transmitted by ritual cannibalism. There is also a sporadic (apparently spontaneously arising) human disease with similar symptoms, **Creutzfeldt-Jakob disease (CJD)**, a rare, progressive, cerebellar disorder, which resembles and may be identical to kuru. These diseases, all of which are ultimately fatal, have similar symptoms, which suggests that they are closely related. Since, in all of these diseases, neurons develop large vacuoles that gives brain tissue a spongelike microscopic appearance, they are collectively known as **transmissible spongiform encephalopathies (TSEs)**. None of the TSEs exhibit any sign of an inflammatory process or fever, which indicates that the immune system, which is not impaired by the disease, is not activated by it.

The classic technique for isolating the agent causing an infectious disease involves the fractionation of diseased tissue as monitored by assays for the disease. The long incubation time for scrapie, the most extensively studied "slow virus" disease, enormously hampered initial efforts to characterize its disease agent. Indeed, in the early work on scrapie in the 1930s, an entire herd of sheep and several years of observation were necessary to evaluate the results of a single fractionation. Assays for scrapie were greatly accelerated, however, by the discovery that Syrian hamsters, after intracerebral inoculation of the scrapie agent, develop the disease in a time, minimally 60 days, that decreases as the dose given is increased. Using a hamster assay, Stanley Prusiner purified the scrapie agent to a high degree and was instrumental in characterizing it.

#### a. Scrapie Is Caused by Prion Protein

*The scrapie agent apparently is a single species of protein.* This astonishing conclusion was established by the observations that the scrapie agent is inactivated by substances that modify proteins, such as proteases, detergents, phenol, urea, and reagents that react with specific amino acid side chains, whereas it is unaffected by agents that alter nucleic acids, such as nucleases, UV irradiation, and substances that specifically react with nucleic acids. For example, scrapie agent is inactivated by treatment with **diethylpyrocarbonate**, which carboxyethylates the His residues of proteins (Fig. 9-37a), but is unaltered by the cytosine-specific reagent **hydroxylamine** (Fig. 9-37b). In

**Figure 9-37** Evidence that the scrapie agent is a protein.

(a) Scrapie agent is inactivated by treatment with diethylpyrocarbonate, which specifically reacts with His side chains. (b) Scrapie agent is unaffected by treatment by hydroxylamine, which reacts with cytosine residues. (c) However, hydroxylamine rescues diethylpyrocarbonate-inactivated scrapie reagent, presumably by the reaction shown.

fact, the infectivity of diethylpyrocarbonate-inactivated scrapie agent is restored by treatment with hydroxylamine, presumably by the reaction shown in Fig. 9-37c.

The novel properties of scrapie agent, which distinguish it from viruses and plasmids, have resulted in its being termed a **prion** (for *proteinaceous infectious particle* that lacks nucleic acid). The scrapie protein, which is named **PrP** (for *Prion Protein*), consists of 280 mostly hydrophobic residues. This hydrophobicity, as we shall see below, causes partially proteolyzed PrP to aggregate as clusters of rodlike particles. There is a close resemblance between these clusters and the amyloid fibrils that are seen on electron microscopic examination of prion-infected brain tissue (Fig. 9-34). In fact, brain tissue from CJD victims contains

protease-resistant protein that cross-reacts with antibodies raised against scrapie PrP.

### b. PrP Is a Widely Expressed Product of a Normal Cellular Gene That Has No Known Function

The bizarre composition of prions immediately raises the question: How are they synthesized? Three possibilities have been suggested:

1. Despite all evidence to the contrary, prions contain a nucleic acid genome that is somehow shielded from detection; that is, prions are conventional viruses. The enormous and still growing body of information concerning the nature of prions, however, makes this notion increasingly untenable.

2. Prions might somehow specify their own amino acid sequence by “reverse translation” to yield a nucleic acid that is normally translated by the cellular system. Such a process, of course, would directly contravene the “central dogma” of molecular biology (Section 5-4), which states that genetic information flows unidirectionally from nucleic acids to proteins. Alternatively, prions might directly catalyze their own synthesis. Such protein-directed protein synthesis is likewise unknown (although many small bacterial polypeptides are enzymatically rather than ribosomally synthesized).

3. Susceptible cells carry a gene that codes for the corresponding PrP. Infection of such cells by prions activates this gene and/or alters its protein product in some autocatalytic way.

The latter hypothesis seems to be the most plausible mechanism of prion replication. Indeed, the use of oligonucleotide probes complementary to the PrP gene (which is named *Prn-p* for *prion protein*), as inferred from the amino acid sequence of PrP’s N-terminus (Section 7-2D), established that the brains of both scrapie-infected and normal mice contain *Prn-p*. The most surprising discovery, however, is that *Prn-p* is transcribed at similar levels in both normal and scrapie-infected brain tissue. Moreover, the use of the above probes has revealed that *Prn-p* genes occur in all vertebrates so far tested, including humans, as well as in invertebrates such as *Drosophila*. This evolutionary conservation suggests that PrP, a membrane-anchored protein (via glycosylphosphatidylinositol groups; Section 12-3Bc) that occurs mainly on neuron surfaces, has an important function. Thus it came as a further surprise that knockout mice (Section 5-5H) in which both *Prn-p* genes have been disrupted appear to be normal and that mating two such *Prn-p*<sup>0/0</sup> mice gives rise to normal *Prn-p*<sup>0/0</sup> progeny (although there is some evidence that *Prn-p*<sup>0/0</sup> mice develop neurological abnormalities late in life). Nevertheless, evidence is accumulating that PrP is normally a cell-surface signal receptor, although the identity of its corresponding signal and its consequences are as yet unknown.

### c. Scrapie Disease Requires the Expression of the Corresponding PrP<sup>C</sup> Protein

*Prn-p*<sup>0/0</sup> mice remain completely free of scrapie symptoms after inoculation with a dose of mouse scrapie PrP

(PrP<sup>Sc</sup>; Sc for scrapie) that causes wild-type (*Prn-p*<sup>+/+</sup>) mice to die of scrapie within 6 months after inoculation. Evidently, PrP<sup>Sc</sup> induces the conversion of normal PrP (PrP<sup>C</sup>; C for cellular) to PrP<sup>Sc</sup>. This unorthodox notion, the so-called **prion hypothesis**, is supported by the observation that when wild-type mice are inoculated with PrP<sup>Sc</sup> that has been continuously passaged (incubated) in hamsters, the incubation time for developing disease symptoms is, at first, 500 days but then, in all further passages in mice, diminishes to 140 days. Conversely, when PrP<sup>Sc</sup> that has been passaged in mice is inoculated into hamsters, the incubation time is first 400 days but subsequently shortens to 75 days. This suggests that the conversion of host PrP<sup>C</sup> (whose sequence in mice differs from that in hamsters) to PrP<sup>Sc</sup> by a foreign PrP<sup>Sc</sup> is a rare event; once it has occurred, however, the newly formed host PrP<sup>Sc</sup> catalyzes the conversion much more efficiently. Indeed, after inoculation with hamster PrP<sup>Sc</sup>, transgenic mice expressing hamster PrP have incubation times that are reduced to between 48 and 250 days, depending on the transgenic line.

The foregoing experiments provide indirect support for the prion hypothesis. However, direct support has recently been provided by the demonstration that PrP<sup>Sc</sup> induces the conversion of PrP<sup>C</sup> to PrP<sup>Sc</sup> in a cell-free system.

#### d. Mutant *Prn-p* Genes Give Rise to Prion Diseases

Three dominantly inherited neurodegenerative disorders in humans have been traced to mutations in the *Prn-p* gene. These are **familial CJD**, **Gerstmann–Sträussler–Scheinker syndrome (GSS)**, and **fatal familial insomnia (FFI)**. All of them are extremely rare. In fact, FFI has been found in only five families. The mutant PrP<sup>Sc</sup>s causing these diseases are nevertheless infectious.

#### e. PrP<sup>Sc</sup> Is a Stable Conformational Variant of PrP<sup>C</sup>

The NMR structure of residues 23 to 230 of the 280-residue human PrP<sup>C</sup>, determined by Kurt Wüthrich, consists of a flexibly disordered (and hence unobserved) 98-residue N-terminal “tail” and a 110-residue C-terminal globular domain containing three  $\alpha$  helices and a short 2-stranded antiparallel  $\beta$  sheet (Fig. 9-38a). As expected, this structure closely resembles those of the homologous mouse and hamster PrP<sup>C</sup>s.

How does PrP<sup>Sc</sup> differ from PrP<sup>C</sup>? The direct sequencing of PrP<sup>Sc</sup> indicates that its amino acid sequence is identical to that deduced from the *Prn-p* gene sequence, thereby eliminating any post-transcriptional sequence variation as a possible cause for the pathogenic properties of PrP<sup>Sc</sup>. Furthermore, mass spectrometric studies on PrP<sup>Sc</sup> designed to reveal previously uncharacterized post-translational modifications indicated that, in fact, PrP<sup>Sc</sup> and PrP<sup>C</sup> are chemically identical. Thus, although the possibility that only a small fraction of PrP<sup>Sc</sup> is chemically modified has not been eliminated, it seems more likely that PrP<sup>Sc</sup> and PrP<sup>C</sup> differ in their secondary and/or tertiary structures. Unfortunately, the insolubility of PrP<sup>Sc</sup> (see below) has precluded its structural determination. However, CD measurements show that, in fact, the conformations of PrP<sup>Sc</sup> and PrP<sup>C</sup> are quite different: PrP<sup>C</sup> has a high (~40%)  $\alpha$  helix content but little (~3%)  $\beta$  sheet content (in good agreement with the NMR structure of its globular domain), whereas PrP<sup>Sc</sup> has a lesser (~30%)  $\alpha$  helix content but a high (~45%)  $\beta$  sheet content. In a plausible model of PrP<sup>Sc</sup> (Fig. 9-38b), its N-terminal region has refolded to form a so-called  **$\beta$  helix** in which the polypeptide strand forms a left-handed helix containing three parallel  $\beta$  sheets. Only the two C-terminal helices of PrP<sup>C</sup>, which are

**Figure 9-38 Prion protein conformations.** (a) The NMR structure of human prion protein (PrP<sup>C</sup>). The protein is drawn in ribbon form colored according to its secondary structure with helices red,  $\beta$  sheets green, and other segments orange. Its disulfide bond is shown in stick form in yellow. Its N-terminal “tail” (residues 23–121) is flexibly disordered (the protein’s

N-terminal 23 residues had been post-translationally excised). (b) A plausible model for the structure of PrP<sup>Sc</sup> represented as in Part a. [Courtesy of Fred Cohen, University of California at San Francisco. Part a based on an NMR structure by Kurt Wüthrich, Eidgenössische Technische Hochschule, Zurich, Switzerland. PDBid 1QLX.]

joined by a disulfide bond, maintain their original conformation. The high  $\beta$  sheet content of PrP<sup>Sc</sup> would, presumably, facilitate the aggregation of PrP<sup>Sc</sup> as amyloid fibrils. *Evidently, the PrP<sup>C</sup>  $\rightarrow$  PrP<sup>Sc</sup> conformational change is autocatalytic; that is, PrP<sup>Sc</sup> induces PrP<sup>C</sup> to convert to PrP<sup>Sc</sup>.* In fact, PrP<sup>Sc</sup> in a cell-free system has been shown to catalyze the conversion of PrP<sup>C</sup> from an uninfected source to PrP<sup>Sc</sup>.

In cells, PrP<sup>Sc</sup> is deposited in cytosolic vesicles rather than being anchored to the cell-surface membrane as is PrP<sup>C</sup>. Both PrP<sup>C</sup> and PrP<sup>Sc</sup> are subject to eventual proteolytic degradation in the cell (Section 32-6). However, although PrP<sup>C</sup> is completely degraded, PrP<sup>Sc</sup> only loses its N-terminal 67 residues to form a 27- to 30-kD protease-resistant core, known as **PrP 27–30**, which still exhibits a high  $\beta$  sheet content. *PrP 27–30 then aggregates to form the amyloid plaques that appear to be directly responsible for the neuronal degeneration characteristic of prion diseases.*

According to the prion hypothesis, sporadically occurring prion diseases such as CJD (which strikes one person per million per year) arise from the spontaneous although infrequent conversion of sufficient quantities of PrP<sup>C</sup> to PrP<sup>Sc</sup> to support the autocatalytic conformational isomerization reaction. This model is corroborated by the observation that transgenic mice that overexpress wild-type *Prn-p* invariably develop scrapie late in life. The prion hypothesis similarly explains inherited prion diseases such as FFI as arising from a lower free energy barrier and hence higher rate for the conversion of the mutant PrP<sup>C</sup> to PrP<sup>Sc</sup> relative to that of normal PrP<sup>C</sup>.

#### f. Prions Have Different Strains

Prions from different sources, when passaged in mice or hamsters, reproducibly exhibit characteristic incubation times, neurological symptoms, and neuropathologies. *Evidently, there are different strains of prions, each of whose corresponding PrP<sup>Sc</sup>s must have a different stable conformation and induce PrP<sup>C</sup> to take up this conformation.* The existence of different prion strains (as many as 30 for scrapie in sheep and at least 4 for CJD in humans) was cited as evidence against the prion hypothesis. However, there is now ample physical evidence that the PrP<sup>Sc</sup>s in different prion strains have different structures.

BSE or mad cow disease was first reported in the U.K. in late 1985. It soon became an epidemic that, in total, infected  $\sim 2$  million cattle in the U.K. BSE is surmised to have arisen as a consequence of feeding cattle meat-and-bone meal made from scrapie-infected sheep (and eventually from BSE-infected cattle). BSE, which has an  $\sim 5$ -year incubation period, was unknown before 1985, most likely because the process for manufacturing meat-and-bone meal was changed in the late 1970s from a way that fully inactivates scrapie prions to one that fails to do so. In 1988, the U.K. banned the feeding of ruminants with ruminant-derived protein (other than milk), so that, following its peak in 1993, the BSE epidemic rapidly abated (a process accelerated by the slaughter of large numbers of cattle at risk of having BSE). However, since humans consumed meat from BSE-infected cattle for over a decade, the question remained, had BSE been transmitted to humans? It

should be noted that scrapie-infected sheep have long been consumed worldwide and yet the incidence of CJD in mainly meat-eating countries such as the U.K. (in which sheep are particularly abundant) is no greater than that in largely vegetarian countries such as India. Nevertheless, in 1994, several cases of CJD in teenagers and young adults were reported in the U.K., although heretofore CJD before the age of 40 was extremely rare (its average age of onset is  $\sim 64$ ). Individuals with this **new variant CJD (vCJD or nvCJD)**, of which there have been  $\sim 200$  cases yet reported, almost entirely in the U.K., have neurological symptoms and neuropathology that are atypical for sporadic CJD. Moreover, when transmitted to mice expressing bovine PrP<sup>C</sup>, vCJD has an incubation time, neurological symptoms, and neuropathology indistinguishable from that caused by BSE. It therefore seems highly likely that vCJD is caused by a prion strain that humans acquired by eating meat products from BSE-infected cattle.

#### g. Prions Occur in Yeast

Although prions were originally defined to be scrapielike infectious pathogens, it is now evident that this definition must be broadened to include all proteins with stable conformational variants that catalyze their own formation from “wild-type” protein. For example, *Saccharomyces cerevisiae* (baker’s yeast) can harbor a genetic element designated [URE3] that, in sexual reproduction with cells that lack [URE3], is inherited by all progeny rather than according to the rules of Mendelian genetics (Section 1-4B). Yet [URE3] is a chromosomal gene rather than a plasmid-based or mitochondrial gene (which would account for its non-Mendelian inheritance).

[URE3] is identical to the chromosomal gene *URE2*, which specifies a protein, **Ure2**, that in the presence of yeast’s preferred nitrogen sources (ammonia or glutamine) represses the expression of the proteins required to metabolize yeast’s less preferred nitrogen sources (e.g., proline). Yeast that have the [URE3] phenotype (trait) lack this regulation of nitrogen metabolism (nitrogen metabolism is discussed in Chapter 26). However, [URE3] yeast can be “cured” of this condition by treatment with 5 mM guanidinium chloride; that is, they and their progeny then exhibit normal regulation of nitrogen metabolism. Nevertheless, about one yeast cell per million spontaneously reverts to the [URE3] phenotype. This is because Ure2 has a “wild-type” conformational state, which regulates nitrogen metabolism, and a [URE3] form, which catalyzes its own formation from “wild-type” Ure2 to yield amyloid fibers that do not influence nitrogen metabolism. Thus, *Ure2 is a type of prion.*

The yeast genetic element [PSI] encodes a protein, **Sup35**, with similar prionlike properties that participates in transcriptional termination (Section 32-3E). Indeed, the introduction of Sup35 in its [PSI] conformation into the cytoplasm of yeast containing “wild-type” Sup35 induced the formation of the [PSI] phenotype, an experiment that constituted the first direct evidence supporting the prion hypothesis. Moreover, Sup35 can adopt several different fiber conformations *in vitro*, which when introduced into [psi<sup>-</sup>]

cells, produce clearly distinguishable strain variants. Several other fungal proteins that can form prions have also been characterized.

## 6 STRUCTURAL EVOLUTION

Proteins, as we discussed in Section 7-3, evolve through point mutations and gene duplications. Over eons, through processes of natural selection and/or neutral drift, homologous proteins thereby diverge in character and develop new functions. How these primary structure changes affect function, of course, depends on the protein's three-dimensional structure. In this section, we explore the effects of evolutionary change on protein structures.

### A. Structures of Cytochromes *c*

 **See Guided Exploration 10: Protein evolution** The *c*-type cytochromes are small globular proteins that contain a covalently bound heme group (**iron-protoporphyrin IX**; Fig. 9-39). The X-ray structures of the cytochromes *c* from horse (Fig. 8-42), tuna, bonito, rice, and yeast are closely similar and thus permit the structural significance of cytochrome *c*'s amino acid sequences (Section 7-3B) to be assessed. The internal residues of cytochrome *c*, particularly those lining its heme pocket, tend to be invariant or conservatively substituted, whereas surface positions have greater variability. This observation is, in part, an indication of the more exacting packing requirements of a protein's internal regions compared to those of its surface (Section 8-3Bc).

Certain invariant or highly conserved residues (Table 7-4) have specific structural and/or functional roles in cytochrome *c*:

1. The invariant Cys 14, Cys 17, His 18, and Met 80 residues form covalent bonds with the heme group (Fig. 9-39).
2. The nine invariant or highly conserved Gly residues occupy close-fitting positions in which larger side chains would significantly alter the protein's three-dimensional structure.
3. The highly conserved Lys residues 8, 13, 25, 27, 72, 73, 79, 86, and 87 are distributed in a ring around the exposed edge of the otherwise buried heme group. There is considerable evidence that this unusual constellation of positive charges specifically associates with complementary sets of negative charges on the physiological reaction partners of cytochrome *c*, cytochrome *c* reductase, and cytochrome *c* oxidase.

#### a. Prokaryotic *c*-Type Cytochromes Are Structurally Related to Cytochrome *c*

Although cytochrome *c* occurs only in eukaryotes, similar proteins known as ***c*-type cytochromes** are common in prokaryotes, where they function to transfer electrons at analogous positions in a variety of respiratory and photosynthetic electron-transport chains. Unlike the eukaryotic proteins, however, the prokaryotic *c*-type cytochromes

**Figure 9-39** Molecular formula of iron-protoporphyrin IX (heme). In *c*-type cytochromes, the heme is covalently bound to the protein (red) by two thioether bonds linking what were the heme vinyl groups to two Cys residues that occur in the sequence Cys-X-Y-Cys-His (residues 14–18 in Table 7-4). Here X and Y symbolize any amino acid residues. A fifth and sixth ligand to the Fe atom, both normal to the heme plane, are formed by a side chain nitrogen of His 18 and the sulfur of Met 80. The iron atom, which is thereby octahedrally liganded, can stably assume either the Fe(II) or the Fe(III) oxidation state. Heme also occurs in myoglobin and hemoglobin but without the thioether bonds or the Met ligand.

exhibit considerable sequence variability among species. For example, the numerous bacterial *c*-type cytochromes whose primary structures are known have from 82 to 134 amino acid residues, whereas eukaryotic cytochromes *c* have a narrower range, from 103 to 112 residues. The primary structures of several representative *c*-type cytochromes have few obvious similarities (Fig. 9-40). Yet their X-ray structures closely resemble each other, particularly in their backbone conformations and side chain packing in the regions surrounding the heme group (Fig. 9-41). Furthermore, most of them have aromatic rings in analogous positions and orientations relative to their heme groups as well as similar distributions of positively charged Lys residues about the perimeters of their heme crevices. The major structural differences among these *c*-type cytochromes stem from various loops of polypeptide chain that are located on their surfaces.

Before the advent of sophisticated sequence alignment algorithms such as BLAST (Section 7-4Bg), the correct alignments of analogous *c*-type cytochrome residues (thin lines in Fig. 9-40) could not have been made on the basis of only their primary structures: These proteins have diverged so far that their three-dimensional structures were essential guides for this task. Three-dimensional structures are evidently more indicative of the similarities among these distantly related proteins than are primary structures. *It is the essential structural and functional elements of proteins, rather than their amino acid residues, that are conserved during evolutionary change.*

**Figure 9-40 Primary structures of some representative  $c$ -type cytochromes.** (a) Cytochrome  $c_{550}$  (the subscript indicates the protein's peak absorption wavelength in visible light, in nm) from *Paracoccus denitrificans*, a respiring bacterium that can use nitrate as an oxidant. (b) Cytochrome  $c_2$  (the subscript has only historical significance) from *Rhodospirillum rubrum*, a purple photosynthetic bacterium. (c) Cytochrome  $c$  from tuna

mitochondria. (d) Cytochrome  $c_{555}$  from *Chlorobium limicola*, a green photosynthetic bacterium that utilizes  $H_2S$  as a hydrogen source. Thin lines connect structurally significant or otherwise invariant residues (*uppercase*). Helical regions are indicated to facilitate structural comparisons with Fig. 9-41. [After Salemme, F.R., *Annu. Rev. Biochem.* **46**, 307 (1977).]

## B. Gene Duplication

*Gene duplication may promote the evolution of new functions through structural evolution* (Section 7-3C). In over half of the multidomain proteins of known structure, two or more of the domains are structurally quite similar. Consider, for example, the four domains of yeast protein disulfide isomerase (PDI; Fig. 9-17). It seems highly unlikely that these complex but topologically similar domains could have independently evolved their present structures—a process

known as **convergent evolution**. Almost certainly, they arose through duplications of the gene specifying an ancestral domain accompanied by the fusion of the resulting four genes to yield a single gene specifying a polypeptide that folds into four similar domains. The differences between the four domains are therefore due to their **divergent evolution**.

Structurally similar domains often occur in proteins whose other domains bear no resemblance to one another.

**Figure 9-41 Three-dimensional structures of the  $c$ -type cytochromes whose primary structures are displayed in Fig. 9-40.** The polypeptide backbones (*blue*) are shown in analogous orientations such that their heme groups (*red*) are viewed edge on. The Cys, Met, and His side chains that covalently link the heme to

the protein are also shown. (a) Cytochrome  $c_{550}$  from *P. denitrificans*. (b) Cytochrome  $c_2$  from *Rs. rubrum*. (c) Tuna cytochrome  $c$ . (d) Cytochrome  $c_{555}$  from *C. limicola*. The redox enzymes known as **dehydrogenases**, for example, each consist of two domains: a domain that binds redox-active dinucleotides such as  $\text{NAD}^+$  and which is structurally similar in all the dehydrogenases, and a dissimilar substrate-binding domain that determines the specificity and mode of action of each enzyme. Indeed, in some dehydrogenases, such as glyceraldehyde-3-phosphate dehydrogenase (Fig. 8-45), the dinucleotide-binding domain occurs at the N-terminal end of the polypeptide chain, whereas in others it occurs at the C-terminal end. Each of these dehydrogenases must have arisen by the fusion of the

gene specifying an ancestral dinucleotide-binding domain with a gene encoding a proto-substrate-binding domain. This must have happened very early in evolutionary history, perhaps in the precellular stage (Section 1-5Ca), because there are no significant sequence similarities among these dinucleotide-binding domains. Evidently, *a domain is as much a unit of evolution as it is a unit of structure. By genetically combining these structural modules in various ways, nature can develop new functions far more rapidly than it can do so by the evolution of completely new structures through point mutations.*

## CHAPTER SUMMARY

**1 Protein Folding: Theory and Experiment** Under renaturing conditions, many proteins fold to their native structures in a matter of seconds. Helices and sheets, which together constitute ~60% of the average protein, are so common because they efficiently fill space. Proteins are hierarchically organized, that is, they consist of domains, which consist of subdomains, etc. They are highly tolerant of sequence changes, to which they adapt by local rather than global structural alterations. Some proteins are natively unfolded, although they assume stable structures when binding to their target molecules.

The rapidity with which proteins renature indicates that they fold in an ordered manner rather than via a random search of all their possible conformations. Thus the study of protein folding requires rapid mixing and observational techniques such as stopped-flow devices, circular dichroism (CD), pulsed H/D exchange followed by NMR, and fluorescence resonance energy transfer (FRET). The folding of small single-domain proteins is initiated by a hydrophobic collapse to yield a molten globule, which appears within ~5 ms. This is followed by the stabilization of secondary structure and then the formation of tertiary structure to yield the native protein in a matter of several seconds. Folding is thought to follow landscape theory, which postulates that a polypeptide folds via a folding funnel and hence can take any of a great variety of pathways to reach its native state. This is consistent with the finding that proteins fold in a hierarchical manner. The sequence of a protein appears to specify its folding pathway as well as its native structure.

**2 Folding Accessory Proteins** Even though it is clear that a protein's primary structure dictates its three-dimensional structure, many proteins require the assistance of accessory proteins such as protein disulfide isomerase (PDI), peptidyl prolyl cis–trans isomerases, and molecular chaperones to fold/assemble to their native structures. PDI consists of four thioredoxinlike domains, two of which contain exposed Cys residues that form disulfide bonds, either internally or with another protein in a disulfide interchange reaction. Two families of peptidyl prolyl cis–trans isomerases have been characterized, the cyclophilins, which bind cyclosporin A, and FK506 binding protein, which binds FK506.

The chaperonins, such as GroEL and GroES, stimulate the proper folding of certain misfolded proteins through a cyclic sequence of concerted conformational changes that is driven by the binding and hydrolysis of ATP. GroES is a cap-shaped heptamer

and GroEL is a 14-mer arranged in two apposed heptameric rings that form two unconnected end-to-end hollow barrels. Together, GroEL and GroES form a bullet-shaped complex that contains a closed cavity (an Anfinsen cage) in which misfolded proteins can fold without interference by aggregation with other misfolded proteins. In doing so, GroEL/ES partially unfolds a misfolded and conformationally trapped protein of up to ~70 kD and releases it so as to enable it to travel down its folding funnel via a new route. Such proteins undergo an average of 14 cycles of binding and release before achieving their native folds. Many of the ~85 *E. coli* proteins that stringently require the GroEL/ES system for proper folding contain  $\alpha/\beta$  domains, whose structural complexity is largely responsible for their misfolding. Eukaryotic Group II chaperonins have built in lids that appear to function analogously to GroES.

**3 Protein Structure Prediction and Design** The prediction of protein secondary structures from only amino acid sequences has been reasonably successful using empirical techniques such as the Chou–Fasman method. However, sophisticated computational techniques yield more reliable predictions. Comparative (homology) modeling can provide accurate tertiary structures for polypeptides with >30% identity to a protein of known structure. Fold recognition (threading) techniques have only been marginally successful for determining the structures of proteins that have no apparent homology with proteins of known structure. (Modern) *de novo* structure determination methods yield correct folding topologies with a success rate of ~20% and occasionally reasonably accurate atomic models. The reverse process, computationally based protein design, has been more successful, in part, because one can “overengineer” a protein to take up a desired conformation.

**4 Protein Dynamics** Proteins are flexible and fluctuating molecules whose group motions have characteristic periods ranging from  $10^{-15}$  to over  $10^3$  s. X-ray analysis, which reveals the average atomic mobilities in a protein, indicates that proteins tend to be more mobile at their peripheries than in their interiors. Molecular dynamics simulations indicate that native protein structures each consist of a large number of closely related and rapidly interconverting conformational substates of nearly equal stabilities. Without this flexibility, enzymes would be nonfunctional. The rates of aromatic ring flipping, as revealed by NMR measurements, indicate that internal group mobilities within proteins vary both with the protein and with

the position within the protein. The exchange of a protein's internal protons with solvent requires its transient local unfolding. Hydrogen exchange studies therefore demonstrate that proteins have a great variety of infrequently occurring internal motions.

**5 Conformational Diseases: Amyloids and Prions** A number of often fatal human diseases are associated with the deposition of amyloid in the brain and other organs. Although the various amyloidogenic proteins are unrelated in both sequence and native structure, all form similar amyloid fibrils that consist mainly of  $\beta$  sheets whose planes extend along the fibril axis. The two known human lysozyme variants that have amyloidogenic properties are conformationally much looser than wild-type lysozyme. In Alzheimer's disease, a neurodegenerative disease of mainly the elderly, the proteolysis of A $\beta$ -precursor protein ( $\beta$ PP) in brain tissue yields the 40- to 42-residue amyloid- $\beta$  protein (A $\beta$ ), which forms the amyloid fibrils that kill neurons.

Humans and other mammals are subject to infectious neurodegenerative diseases such as scrapie, which are caused by prions. Prions appear to consist of only a single species of protein named PrP. PrP exists in two forms: the normal cellular form, PrP<sup>C</sup>, a conserved membrane-anchored cell-surface protein on neurons; and PrP<sup>Sc</sup>, which although chemically identical to PrP<sup>C</sup>, has a different conformation. PrP<sup>Sc</sup> autocatalytically converts PrP<sup>C</sup> to PrP<sup>Sc</sup> thereby accounting for the infectious properties of

PrP<sup>Sc</sup> and the observation that *Prn-p*<sup>0/0</sup> mice are resistant to scrapie. PrP<sup>Sc</sup> is proteolytically degraded in the cell to form a protease-resistant core, PrP 27–30, that aggregates to form the neurotoxic amyloid fibrils thought to be responsible for the symptoms of prion diseases. A given species of PrP may take up several different self-propagating fibrous conformations to yield different prion strains. Fungi, such as yeast, also have proteins with prionlike properties.

**6 Structural Evolution** The X-ray structures of eukaryotic cytochromes *c* demonstrate that internal residues and those having specific structural and functional roles tend to be conserved during evolution. Prokaryotic *c*-type cytochromes from a variety of organisms structurally resemble each other and those of eukaryotes even though they have little sequence similarity. This indicates that the three-dimensional structures of proteins rather than their amino acid sequences are conserved during evolutionary change. The structural similarities between the domains in many multidomain proteins indicate that these proteins arose through the duplication of the genes specifying the ancestral domains followed by their fusion. For example, the structural resemblance between the dinucleotide-binding domains of dehydrogenases suggests that these proteins arose by duplication of a primordial dinucleotide-binding domain followed by its fusion with a gene specifying a proto-substrate-binding domain. In this manner, proteins with new functions can evolve much faster than by a series of point mutations.

## PROBLEMS

**1.** How long will it take the polypeptide backbone of a 6-residue folding nucleus to explore all its possible conformations? Repeat the calculation for 10-, 15-, and 20-residue folding nuclei. Why, in the classic view of protein folding, are folding nuclei thought to be no larger than 15 residues?

**\*2.** Consider a protein with 10 Cys residues. On air oxidation, what fraction of the denatured and reduced protein will randomly reform the native set of disulfide bonds if: (a) The native protein has five disulfide bonds? (b) The native protein has three disulfide bonds?

**3.** Why are  $\beta$  sheets more commonly found in the hydrophobic interiors of proteins than on their surfaces?

**4.** Under physiological conditions, polylysine assumes a random coil conformation. Under what conditions might it form an  $\alpha$  helix?

**5.** Explain how landscape theory is consistent with the observation that many small proteins appear to fold to their native conformations without detectable intermediates, that is, via two-state mechanisms.

**6.** Explain why Pro residues can occupy the N-terminal turn of an  $\alpha$  helix.

**7.** Explain why  $\beta$  sheets are less likely to form than  $\alpha$  helices during the earliest stages of protein folding.

**8.** Molten globules are thought to be predominantly stabilized by hydrophobic forces. Why aren't hydrogen bonding forces implicated in doing so?

**\*9.** The GroEL/ES cycle diagrammed in Fig. 9-25 only circulates in the clockwise direction. Explain the basis for this irreversibility in terms of the sequence of structural and binding changes in the GroEL/ES system.

**\*10.** Predict the secondary structure of the C peptide of proinsulin (Fig. 9-4) using the methods of Chou–Fasman and Rose.

**11.** As Mother Nature's chief engineer, now certified as a master helix builder, you are asked to repeat Problem 8-8 with the stipulation that the  $\alpha$  helix really be helical. Use Table 9-1.

**\*12.** Predict the secondary structure of the N-terminal domain of yeast protein disulfide isomerase using Jpred3 (<http://www.compbio.dundee.ac.uk/www-jpred/>). How does this prediction compare with the observed structure of this domain (PDBid 2B5E; the domain in Fig. 9-17)? [To enter the sequence of this domain into Jpred3, first point your browser at the PDB (<http://www.rcsb.org/pdb>), enter the PDBid 2B5E, click on the "Sequence Details" tab at the top of the resulting page, and determine the sequence range of the N-terminal domain. Then click on the UniProt reference (P17967), scroll down to the sequence, copy the relevant portion to the Jpred3 input box, edit out everything but the sequence, and click on the "Make Prediction" button. On the page that comes up indicating that sequence matches were found in the PDB, click on the "continue" button. When the Results page appears (you may have to wait some time for it), click on "View Simple" to see the Jpred3 prediction. The observed secondary structure of the N-terminal domain is diagrammed on the foregoing "Sequence Details" page.]

**13.** Indicate the probable effects of the following mutational changes on the structure of a protein. Explain your reasoning. (a) Changing a Leu to a Phe, (b) changing a Lys to a Glu, (c) changing a Val to a Thr, (d) changing a Gly to an Ala, and (e) changing a Met to a Pro.

**14.** Explain why Trp rings are usually completely immobile in proteins that have rapidly flipping Phe and Tyr rings.

**15.** Explain why *Prn-p*<sup>0/0</sup> mice are resistant to scrapie. What might be the susceptibility of heterozygous *Prn-p*<sup>+/0</sup> mice to scrapie?

**\*16.** Discuss the merits of the hypothesis that the dinucleotide-binding domains of the dehydrogenases arose by convergent evolution.

# Hemoglobin: Protein Function in Microcosm

## CHAPTER 10

### 1 Hemoglobin and Myoglobin Function

- A. Heme
- B. Oxygen Binding
- C. Carbon Dioxide Transport and the Bohr Effect
- D. Effect of BPG on O<sub>2</sub> Binding

### 2 Structure and Mechanism

- A. Structure of Myoglobin
- B. Structure of Hemoglobin
- C. Mechanism of Oxygen-Binding Cooperativity
- D. Testing the Perutz Mechanism
- E. Origin of the Bohr Effect
- F. Structural Basis of BPG Binding
- G. Role of the Distal Histidine Residue

### 3 Abnormal Hemoglobins

- A. Molecular Pathology of Hemoglobin
- B. Molecular Basis of Sickle-Cell Anemia

### 4 Allosteric Regulation

- A. The Adair Equation
- B. The Symmetry Model
- C. The Sequential Model
- D. Hemoglobin Cooperativity

### Appendix: Derivation of Symmetry Model Equations

- A. Homotropic Interactions—Equation [10.22]
- B. Heterotropic Interactions—Equation [10.23]

The existence of hemoglobin (Greek: *haimato*, blood), the red blood pigment, is evident to every child who scrapes a knee. Its brilliant red color, widespread occurrence, and ease of isolation have made it an object of inquiry since ancient times. Indeed, the early history of protein chemistry is essentially that of hemoglobin. The observation of crystalline hemoglobin was first reported by Friedrich Hünefeld in 1840, and by 1909 Edward Reichert and Amos Brown had published a photographic atlas of hemoglobin crystals from several hundred species. In contrast, it was not until 1926 that crystals of an enzyme, those of jack bean **urease**, were first reported. Hemoglobin was one of the first proteins to have its molecular mass accurately determined, the first protein to be characterized by ultracentrifugation, the first to be associated with a specific physiological function (that of oxygen transport), and, in sickle-cell anemia, the first in which a point mutation was demonstrated to cause a single amino acid change (Section 7-3Aa). Theories formulated to account for the cooperative binding of oxygen to hemoglobin (Section 10-4) have

also been successful in explaining the control of enzyme activity. The first protein X-ray structures to be elucidated were those of hemoglobin and myoglobin (Greek: *mys*, muscle). This central role in the development of protein chemistry together with its enzymelike O<sub>2</sub>-binding properties have caused hemoglobin to be dubbed an “honorary enzyme.”

Hemoglobin is not just a simple oxygen tank. Rather, it is a sophisticated oxygen delivery system that provides the proper amount of oxygen to the tissues under a wide variety of circumstances. In this chapter, we discuss hemoglobin’s properties, structure, and mechanism of action, both to understand the workings of this physiologically essential molecule and to illustrate the principles of protein structure that we have developed in the preceding chapters. We also consider the properties of abnormal hemoglobins and their relationship to human disease. Finally, we discuss theories of cooperative interactions among proteins, both to better understand the properties of hemoglobin and to set the stage for our later consideration of how enzyme action is regulated.

### 1 HEMOGLOBIN AND MYOGLOBIN FUNCTION

Hemoglobin (**Hb**), as we have seen in Chapters 7 and 8, is a 65-kD heterotetramer,  $\alpha_2\beta_2$  (alternatively, a dimer of  $\alpha\beta$  protomers). The  $\alpha$  and  $\beta$  subunits are structurally and evolutionarily related to each other and to myoglobin (**Mb**), the 18-kD monomeric oxygen-binding protein of skeletal and heart muscle (Section 7-3C).

Hemoglobin transports oxygen from the lungs, gills, or skin of an animal to its capillaries for use in respiration. Very small organisms do not require such a protein because their respiratory needs are satisfied by the simple passive diffusion of O<sub>2</sub> through their bodies. However, since the transport rate of a diffusing substance varies inversely with the square of the distance it must diffuse, the O<sub>2</sub> diffusion rate through tissue thicker than ~1 mm is too slow to support life. The evolution of organisms as large and complex as annelids (e.g., earthworms) therefore required the development of circulatory systems that actively transport O<sub>2</sub> and nutrients to the tissues. The blood of such organisms must contain an oxygen transporter such as Hb because the solubility of O<sub>2</sub> in **blood plasma** (the fluid component of

blood) is too low ( $\sim 10^{-4} M$  under physiological conditions) to carry sufficient amounts of  $O_2$  for metabolic needs. In contrast, whole blood, which normally contains  $\sim 150 \text{ g of Hb} \cdot \text{L}^{-1}$ , can carry  $O_2$  at concentrations as high as  $0.01 M$ , about the same as in air.

Although Mb was originally assumed to store oxygen, it is now clear that this function is significant only in aquatic mammals such as seals and whales, which have Mb concentrations in their muscles 10- to 30-fold greater than those in terrestrial mammals. It would seem more likely that Mb's major physiological role in terrestrial mammals is to facilitate oxygen transport in rapidly respiring muscle. The rate at which  $O_2$  can diffuse from the capillaries to the tissues, and thus the level of respiration, is limited by oxygen's low solubility in aqueous solution. Mb increases the effective solubility of  $O_2$  in muscle, the most rapidly respiring tissue under conditions of high exertion. Hence, in rapidly respiring muscle, Mb functions as a kind of molecular bucket brigade to facilitate  $O_2$  diffusion. It therefore came as a surprise when knockout mice for the gene encoding Mb exhibited no obvious abnormalities (except for the pale color of their muscles) and exhibited normal exercise capacity and response to low oxygen levels. However, further investigations revealed that these knockout mice had compensatory adaptations including increases in their **hematocrit** (the fraction of blood volume occupied by red blood cells; normally  $\sim 45\%$ ) and the capillary density in their muscles. Moreover, many of the mutant embryos died *in utero* due to cardiovascular defects. Additional physiological functions for Mb have recently been recognized: the detoxification of the highly reactive biological signaling molecule **nitric oxide (NO)** through its conversion to **nitrate ion** ( $\text{NO}_3^-$ ) under normal conditions and its synthesis from **nitrite ion** ( $\text{NO}_2^-$ ) under **hypoxic** (having an inadequate supply of  $O_2$ ) conditions (see below).

In this section, we begin our discussions of hemoglobin by considering its chemical and physical properties and how they relate to its physiological function. Hemoglobin structure and the mechanisms by which it carries out these physiological functions are discussed in Section 10-2.

### A. Heme

Myoglobin and each of the four subunits of hemoglobin noncovalently bind a single **heme group** (Fig. 10-1; spelled "haem" in British English). This is the same group that occurs in the cytochromes (Section 9-6A) and in certain redox enzymes such as **catalase**. Heme is responsible for the characteristic red color of blood and is the site at which each **globin** monomer binds one molecule of  $O_2$  (globins are the heme-free proteins of Hb and Mb). The heterocyclic ring system of heme is a **porphyrin** derivative; it consists of four **pyrrole** rings (labeled A–D in Fig. 10-1) linked by methene bridges. The porphyrin in heme, with its particular arrangement of four methyl, two propionate, and two vinyl substituents, is known as **protoporphyrin IX**. Heme, then, is protoporphyrin IX with a centrally bound iron atom. In Hb and Mb, the iron atom normally remains in the

**Figure 10-1** The heme group. Fe(II)–heme (ferroprotoporphyrin IX) is shown liganded to His and  $O_2$  as it is in oxygenated myoglobin and oxygenated hemoglobin. Note that the heme is a conjugated system so that, although two of its Fe–N bonds are coordinate covalent bonds (bonds in which the bonding electron pair is formally contributed by only one of the atoms forming the bond), all of the Fe–N bonds are equivalent. The pyrrole ring lettering scheme is shown.

*Fe(II)* (ferrous) oxidation state whether or not the heme is oxygenated (binds  $O_2$ ).

The Fe atom in deoxygenated Hb and Mb is 5-coordinated by a square pyramid of N atoms: four from the porphyrin and one from a His side chain of the protein. On oxygenation, the  $O_2$  binds to the Fe(II) on the opposite side of the porphyrin ring from the His ligand, so that the Fe(II) is octahedrally coordinated; that is, the ligands occupy the six corners of an octahedron centered on the Fe atom (Fig. 10-1). Oxygenation changes the electronic state of the Fe(II)–heme, as is indicated by the color change of blood from the dark purplish hue characteristic of venous blood to the brilliant scarlet color of arterial blood and blood from a cut finger (Fig. 10-2).

Certain small molecules, such as CO, NO,  $\text{CN}^-$ , and  $\text{H}_2\text{S}$ , coordinate to the sixth liganding position of the Fe(II) in Hb and Mb with much greater affinity than does  $O_2$ . This, together with their similar binding to the hemes of cytochromes, accounts for the highly toxic properties of these substances.

The Fe(II) of Hb and Mb can be oxidized to Fe(III) to form **methemoglobin (metHb)** and **metmyoglobin (metMb)**. MetHb and metMb do not bind  $O_2$ ; their Fe(III) is already octahedrally coordinated with an  $\text{H}_2\text{O}$  molecule in the sixth liganding position. The brown color of dried blood and old meat is that of metHb and metMb. Erythrocytes contain the enzyme **methemoglobin reductase**, which converts the

**Figure 10-2** The visible absorption spectra of oxygenated and deoxygenated hemoglobins.

small amount of metHb that spontaneously forms back to the Fe(II) form.

#### a. Myoglobin Both Detoxifies and Synthesizes Nitric Oxide

NO, which is synthesized in many tissues, functions as a locally active signaling molecule, most notably to induce vasodilation (Section 19-1L). Once NO has delivered its message, it is important that it be rapidly eliminated to prevent its interference with subsequent NO signals (or lack of them). Moreover, NO is a highly reactive and hence toxic substance. In muscle, under normal O<sub>2</sub> concentrations, NO is detoxified through its reaction with oxygenated myoglobin (**oxyMb**) to yield nitrate ion and metmyoglobin:

Since the metMb is subsequently reduced to Mb through the action of an intracellular **metmyoglobin reductase**, myoglobin functions as an enzyme in this process. Oxygenated hemoglobin (**oxyHb**) likewise detoxifies the NO that is present in blood.

Paradoxically, the tissue damage caused by **ischemia** (inadequate blood flow, such as in a heart attack or stroke) is often exacerbated when blood flow to the deprived tissues is reestablished. This so-called **reperfusion injury** is caused, in part, by the highly destructive **reactive oxygen species (ROS)**, such as the **superoxide ion** (O<sub>2</sub><sup>-</sup>) and the **hydroxyl radical** (·OH), initially produced by hypoxic mitochondria when the blood supply is restored. Nitrite ion is normally present in blood and tissues at low (micromolar) concentrations. Under hypoxic conditions, deoxyMb catalyzes the formation of NO from nitrite ion:

NO suppresses the ROS-producing mitochondrial electron-transport chain (Chapter 22) and thereby protects against reperfusion injury. Indeed, the administration of nitrite ion

to the hearts of normal mice immediately before their blood supply was cut off for 30 minutes provided a significant protective effect against tissue damage, but afforded no such protection to the hearts of Mb-knockout mice.

#### b. Other Globins and Oxygen-Transport Proteins

Hb and Mb belong to the globin superfamily, whose members occur widely in all three kingdoms of life, where most participate in a variety of enzymatic and O<sub>2</sub>-sensing functions. Evidently, Hb's O<sub>2</sub>-transport function is a relatively recent evolutionary adaptation.

Invertebrate hemoglobins vary in quaternary structure from dimers to as many as 180 subunits. The larger of these, which are known as **erythrocruorins** (Latin: *cruor*, blood), are extracellular proteins rather than being packaged within cells; their large sizes (up to 3.5 million kD) permit them to be retained within their circulatory systems. The related **chlorocruorins** (Greek, *chloros*, pale green), which occur in the blood of certain annelids, contain a porphyrin that differs from protoporphyrin IX by the replacement of its A-ring vinyl group with a formyl group. Consequently, chlorocruorins are green when deoxygenated and light red when oxygenated.

Antarctic icefish, the only adult vertebrates that lack hemoglobin—their blood is colorless—are viable because of their reduced need for O<sub>2</sub> at low temperatures combined with the relatively high aqueous solubility of O<sub>2</sub> at the -1.9°C temperature of their environment (recall that the solubilities of gases increase with decreasing temperature).

Many invertebrates lack Hb but instead produce one of two alternative types of O<sub>2</sub>-transport proteins:

- 1. Hemocyanins**, which occur in many species of mollusks and arthropods, form a family of large, multimeric, extracellular proteins that differ in their primary through quaternary structures. However, they have highly similar O<sub>2</sub>-binding sites that each contain two Cu ions. Hemocyanins are blue in complex with O<sub>2</sub> and colorless otherwise.

- 2. Hemerythrins**, which are intracellular proteins, occur in only a few species of marine worms. Their O<sub>2</sub>-binding sites contain two non-heme Fe ions. Hemerythrins are violet-pink in complex with O<sub>2</sub> and colorless otherwise.

Vertebrates also express two recently discovered globins: **neuroglobin**, which is present mainly in brain, retina, and endocrine tissues, and **cytoglobin**, which occurs in most tissues. Neuroglobin protects neurons (nerve cells) from damage under conditions of hypoxia, most likely by preventing reperfusion injury in much the same way as does myoglobin in muscle. Cytoglobin may have similar functions.

#### B. Oxygen Binding

The binding of O<sub>2</sub> to myoglobin is described by a simple equilibrium reaction

with dissociation constant

$$K = \frac{[\text{Mb}][\text{O}_2]}{[\text{MbO}_2]} \quad [10.1]$$

(biochemists usually express equilibria in terms of dissociation constants, the reciprocals of the more chemically traditional association constants). The  $\text{O}_2$  dissociation of Mb may be characterized by its **fractional saturation**,  $Y_{\text{O}_2}$ , defined as the fraction of  $\text{O}_2$  binding sites occupied by  $\text{O}_2$ .

$$Y_{\text{O}_2} = \frac{[\text{MbO}_2]}{[\text{Mb}] + [\text{MbO}_2]} = \frac{[\text{O}_2]}{K + [\text{O}_2]} \quad [10.2]$$

Since  $\text{O}_2$  is a gas, its concentration is conveniently expressed by its partial pressure,  $p\text{O}_2$  (also called the **oxygen tension**). Equation [10.2] may therefore be expressed:

$$Y_{\text{O}_2} = \frac{p\text{O}_2}{K + p\text{O}_2} \quad [10.3]$$

Now define  $p_{50}$  as the value of  $p\text{O}_2$  when  $Y_{\text{O}_2} = 0.50$ , that is, when half of myoglobin's  $\text{O}_2$ -binding sites are occupied. Substituting this value into Eq. [10.3] and solving for  $K$  yields  $K = p_{50}$ . Hence our expression for the fractional saturation of Mb finally becomes

$$Y_{\text{O}_2} = \frac{p\text{O}_2}{p_{50} + p\text{O}_2} \quad [10.4]$$

#### a. Hemoglobin Cooperatively Binds $\text{O}_2$

Myoglobin's  $\text{O}_2$ -dissociation curve (Fig. 10-3) closely follows the hyperbolic curve described by Eq. [10.4]; its  $p_{50}$  is 2.8 torr (1 torr = 1 mm Hg at  $0^\circ\text{C} = 0.133$  kPa; 760 torr = 1 atm). Mb therefore gives up little of its bound  $\text{O}_2$

**Figure 10-3** Oxygen-dissociation curves of Mb and of Hb in whole blood. The normal sea level values of human arterial and venous  $p\text{O}_2$  values are indicated. The dashed line is a hyperbolic  $\text{O}_2$ -dissociation curve with the same  $p_{50}$  as Hb (26 torr). See the Animated Figures

over the normal physiological range of  $p\text{O}_2$  in blood (100 torr in arterial blood and 30 torr in venous blood); for example,  $Y_{\text{O}_2} = 0.97$  at  $p\text{O}_2 = 100$  torr and 0.91 at 30 torr. In contrast, hemoglobin's  $\text{O}_2$ -dissociation curve (Fig. 10-3), which has a **sigmoidal** shape (S shape) that Eq. [10.4] does not describe, indicates that the amount of  $\text{O}_2$  bound by Hb changes significantly over the normal physiological range of  $p\text{O}_2$  in blood. For example,  $Y_{\text{O}_2} = 0.95$  at 100 torr and 0.55 at 30 torr in whole blood for a difference in  $Y_{\text{O}_2}$  of 0.40. Mb therefore binds  $\text{O}_2$  under conditions in which Hb releases it. Thus, the two proteins form a sophisticated  $\text{O}_2$  transport system that delivers  $\text{O}_2$  from lung to muscle (where  $p\text{O}_2$  may be  $<20$  torr). Hemoglobin's sigmoidal  $\text{O}_2$ -dissociation curve is of great physiological importance; *it permits the blood to deliver much more  $\text{O}_2$  to the tissues than it could if Hb had a hyperbolic  $\text{O}_2$ -dissociation curve with the same  $p_{50}$  (26 torr; dashed curve in Fig. 10-3).* Such a hyperbolic curve has  $Y_{\text{O}_2} = 0.79$  at 100 torr and 0.54 at 30 torr for a difference in  $Y_{\text{O}_2}$  of only 0.25.

A sigmoidal dissociation curve is diagnostic of a **cooperative interaction** between a protein's small molecule binding sites; that is, the binding of one small molecule affects the binding of others. In this case, the binding of  $\text{O}_2$  increases the affinity of Hb for binding additional  $\text{O}_2$ . The structural mechanism of hemoglobin cooperativity is discussed in Section 10-2C.

#### b. The Hill Equation Phenomenologically Describes Hemoglobin's $\text{O}_2$ -Binding Curve

The earliest attempt to analyze hemoglobin's sigmoidal  $\text{O}_2$ -dissociation curve was formulated by Archibald Hill in 1910. We shall follow his analysis in general form because it is useful for characterizing the cooperative behavior of oligomeric enzymes as well as that of hemoglobin.

Consider a protein E consisting of  $n$  subunits that can each bind a molecule S, which, in analogy with the substituents of metal ion complexes, is known as a **ligand**. Assume that the ligand binds with infinite cooperativity,

that is, the protein either has all or none of its ligand-binding sites occupied, so that there are no observable intermediates  $\text{ES}_1, \text{ES}_2$ , etc. The dissociation constant for this reaction is

$$K = \frac{[\text{E}][\text{S}]^n}{[\text{ES}_n]} \quad [10.5]$$

and, as before, its fractional saturation is expressed:

$$Y_{\text{S}} = \frac{n[\text{ES}_n]}{n([\text{E}] + [\text{ES}_n])} \quad [10.6]$$

Combining Eqs. [10.5] and [10.6] yields

$$Y_{\text{S}} = \frac{[\text{E}][\text{S}]^n/K}{[\text{E}](1 + [\text{S}]^n/K)}$$

which on algebraic rearrangement and cancellation of terms becomes the **Hill equation**:

$$Y_{\text{S}} = \frac{[\text{S}]^n}{K + [\text{S}]^n} \quad [10.7]$$

which, in a manner analogous to Eq. [10.4], describes the degree of saturation of a multisubunit protein as a function of ligand concentration.

Infinite ligand-binding cooperativity ( $n$  equal to the number of protein subunits), as assumed in deriving the Hill equation, is a physical impossibility. Nevertheless,  $n$  may be taken to be a noninteger parameter related to the degree of cooperativity among interacting ligand-binding sites rather than the number of subunits per protein. The Hill equation then becomes a useful empirical curve-fitting relationship rather than an indicator of a particular model of ligand binding. *The quantity  $n$ , the Hill constant, increases with the degree of cooperativity of a reaction and thereby provides a convenient, although simplistic, characterization of a ligand-binding reaction.* If  $n = 1$ , Eq. [10.7] describes a hyperbola, as do Eqs. [10.3] and [10.4] for Mb, and the ligand-binding reaction is said to be **noncooperative**. A reaction with  $n > 1$  is described as **positively cooperative**: Ligand binding increases the affinity of E for further ligand binding (cooperativity is infinite in the limit that  $n$  is equal to the number of ligand-binding sites in E). Conversely, if  $n < 1$ , the reaction is termed **negatively cooperative**: Ligand binding reduces the affinity of E for subsequent ligand binding.

### c. Hill Equation Parameters May Be Graphically Evaluated

The Hill constant,  $n$ , and the dissociation constant,  $K$ , that best describe a saturation curve can be graphically determined by rearranging Eq. [10.7] as follows:

$$\frac{Y_S}{1 - Y_S} = \frac{[S]^n}{K + [S]^n} = \frac{[S]^n}{K}$$

and then taking the log of both sides to yield a linear equation:

$$\log\left(\frac{Y_S}{1 - Y_S}\right) = n \log[S] - \log K \quad [10.8]$$

The linear plot of  $\log[Y_S/(1 - Y_S)]$  versus  $\log[S]$ , the **Hill plot**, has a slope of  $n$  and an intercept on the  $\log[S]$  axis of  $(\log K)/n$  (recall that the linear equation  $y = mx + b$  describes a line with a slope of  $m$  and an  $x$  intercept of  $-b/m$ ).

For Hb, if we substitute  $pO_2$  for  $[S]$  as was done for Mb, the Hill equation becomes:

$$Y_{O_2} = \frac{(pO_2)^n}{K + (pO_2)^n} \quad [10.9]$$

As in Eq. [10.4], let us define  $p_{50}$  as the value of  $pO_2$  at  $Y_{O_2} = 0.50$ . Then, substituting this value into Eq. [10.9],

$$0.50 = \frac{(p_{50})^n}{K + (p_{50})^n}$$

so that

$$K = (p_{50})^n \quad [10.10]$$

Substituting this result back into Eq. [10.9] yields

$$Y_{O_2} = \frac{(pO_2)^n}{(p_{50})^n + (pO_2)^n} \quad [10.11]$$

(Note: Equation [10.4] is a special case of Eq. [10.11] with  $n = 1$ ). Equation [10.8] for the Hill plot of Hb therefore takes the form

$$\log\left(\frac{Y_{O_2}}{1 - Y_{O_2}}\right) = n \log pO_2 - n \log p_{50} \quad [10.12]$$

so that this plot has a slope of  $n$  and an intercept on the  $\log pO_2$  axis of  $\log p_{50}$ .

Figure 10-4 shows the Hill plots for Mb and Hb. For Mb it is linear with a slope of 1, as expected. Although Hb does

**Figure 10-4** Hill plots for Mb and purified ("stripped") Hb. Note that this is a log-log plot. Hence the horizontal axis,  $\log[Y_{O_2}/(1 - Y_{O_2})] = 0$ , occurs where  $Y_{O_2}/(1 - Y_{O_2}) = 1$  (and  $pO_2 = p_{50}$ ).

not bind  $O_2$  in a single step as is assumed in deriving the Hill equation, its Hill plot is essentially linear for values of  $Y_{O_2}$  between 0.1 and 0.9. Its maximum slope, which occurs near  $pO_2 = p_{50}$  [ $(Y_{O_2} = 0.5; Y_{O_2}/(1 - Y_{O_2}) = 1)$ ], is normally taken to be the Hill constant. For normal human Hb, the Hill constant is between 2.8 and 3.0; that is, hemoglobin oxygen binding is highly, but not infinitely, cooperative. Many abnormal hemoglobins exhibit smaller Hill constants (Section 10-3A), indicating that they have a less than normal degree of cooperativity. At  $Y_{O_2}$  values near 0, when few Hb molecules have bound even one  $O_2$  molecule, the Hill plot of Hb assumes a slope of 1 (Fig. 10-4, lower asymptote) because the Hb subunits independently compete for  $O_2$  as do molecules of Mb. At  $Y_{O_2}$  values near 1, when at least three of each of hemoglobin's four  $O_2$ -binding sites are occupied, the Hill plot also assumes a slope of 1 (Fig. 10-4, upper asymptote) because the few remaining unoccupied sites are on different molecules and therefore bind  $O_2$  independently.

Extrapolating the lower asymptote in Fig. 10-4 to the horizontal axis indicates, according to Eq. [10.11], that  $p_{50} = 30$  torr for binding the first  $O_2$  to Hb. Likewise, extrapolating the upper asymptote yields  $p_{50} = 0.3$  torr for binding hemoglobin's fourth  $O_2$ . Thus the fourth  $O_2$  to bind to Hb does so with 100-fold greater affinity than the first. This difference, as we shall see in Section 10-2C, is entirely due to the influence of the globin on the  $O_2$  affinity of heme. It corresponds to a free energy difference of  $11.4 \text{ kJ} \cdot \text{mol}^{-1}$  between binding the first and binding the last  $O_2$  to Hb (Section 3-4A).

More sophisticated mathematical models than the Hill equation have been developed for analyzing the cooperative binding of ligands to proteins. We examine some of them in Section 10-4.

**Figure 10-5** A picket-fence Fe(II)-porphyrin complex with bound  $O_2$ . [After Collman, J.P., Brauman, J.I., Rose, E., and Suslick, K.S., *Proc. Natl. Acad. Sci.* **75**, 1053 (1978).]

#### d. Globin Prevents Oxyheme from Autooxidizing

Globin not only modulates the  $O_2$ -binding affinity of heme, but makes reversible  $O_2$  binding possible. Fe(II)-heme by itself is incapable of binding  $O_2$  reversibly. Rather, in the presence of  $O_2$  it autooxidizes irreversibly to the Fe(III) form through the intermediate formation of a complex consisting of an  $O_2$  bridging the Fe atoms of two hemes. This reaction can be inhibited by derivatizing the heme with bulky groups that sterically prevent the close face-to-face approach of two hemes. Such **picket-fence** Fe(II)-porphyrin complexes (Fig. 10-5), which James Collman first synthesized, bind  $O_2$  reversibly. The back side of this porphyrin is unhindered and is complexed with a substituted imidazole in a manner similar to that in Mb and Hb. In fact, the  $O_2$  affinity of the picket-fence complex is similar to that of Mb. Thus, the globins of Mb and Hb function to prevent the autooxidation of oxyheme by surrounding it, rather like a hamburger bun surrounds a hamburger, so that only its propionate side chains are exposed to the aqueous solvent (Section 10-2B).

#### C. Carbon Dioxide Transport and the Bohr Effect

In addition to being an  $O_2$  carrier, Hb plays an important role in the transport of  $CO_2$  by the blood. When Hb (but not Mb) binds  $O_2$  at physiological pH's, it undergoes a conformational change (Section 10-2Ba) that makes it a slightly stronger acid. It therefore releases protons on binding  $O_2$ :

where  $n = 0, 1, 2,$  or  $3$  and  $x \approx 0.6$  under physiological conditions. Conversely, increasing the pH, that is, removing protons, stimulates Hb to bind  $O_2$  (Fig. 10-6). This phenomenon, whose molecular basis is discussed in Section 10-2E, is known as the **Bohr effect** after Christian Bohr (the father

**Figure 10-6** Effect of pH on the  $O_2$ -dissociation curve of Hb: the Bohr effect. The vertical dashed line indicates the  $pO_2$  in actively respiring muscle tissue. [After Benesch, R.E. and Benesch, R., *Adv. Prot. Chem.* **28**, 212 (1974).]  See the **Animated Figures**

of the pioneering atomic physicist Niels Bohr), who first reported it in 1904.

#### a. The Bohr Effect Facilitates O<sub>2</sub> Transport

The ~0.8 molecules of CO<sub>2</sub> formed per molecule of O<sub>2</sub> consumed by respiration diffuse from the tissues to the capillaries largely as dissolved CO<sub>2</sub> as a result of the slowness of the reaction forming bicarbonate:

This reaction, however, is catalyzed in the erythrocyte by carbonic anhydrase (Fig. 8-41). Accordingly, most of the CO<sub>2</sub> in the blood is carried in the form of bicarbonate (in the absence of carbonic anhydrase, the hydration of CO<sub>2</sub> would equilibrate 100-fold more slowly, so bubbles of the only slightly soluble CO<sub>2</sub> would form in the blood and tissues).

*In the capillaries, where pO<sub>2</sub> is low, the H<sup>+</sup> generated by bicarbonate formation is taken up by Hb, which is thereby induced to unload its bound O<sub>2</sub>. This H<sup>+</sup> uptake, moreover, facilitates CO<sub>2</sub> transport by stimulating bicarbonate formation. Conversely, in the lungs, where pO<sub>2</sub> is high, O<sub>2</sub> binding by Hb releases the Bohr protons, which drive off the CO<sub>2</sub>. These reactions are closely matched, so they cause very little change in blood pH.*

The Bohr effect provides a mechanism whereby additional O<sub>2</sub> can be supplied to highly active muscles. Such muscles generate acid (Section 17-3A) so fast that they lower the pH of the blood passing through them from 7.4 to 7.2. At pH 7.2, Hb releases ~10% more O<sub>2</sub> at the <20 torr pO<sub>2</sub> in these muscles than it does at pH 7.4 (Fig. 10-6).

#### b. CO<sub>2</sub> and Cl<sup>-</sup> Modulate Hemoglobin's O<sub>2</sub> Affinity

CO<sub>2</sub> modulates O<sub>2</sub> binding directly and by combining reversibly with the N-terminal amino groups of blood proteins to form carbamates:

The conformation of deoxygenated Hb (**deoxyHb**), as we shall see in Section 10-2Ba, is significantly different from that of oxygenated Hb (**oxyHb**). Consequently, deoxyHb binds more CO<sub>2</sub> as carbamate than does oxyHb. CO<sub>2</sub> like H<sup>+</sup>, is therefore a modulator of hemoglobin's O<sub>2</sub> affinity: A high CO<sub>2</sub> concentration, as occurs in the capillaries, stimulates Hb to release its bound O<sub>2</sub>. Note the complexity of this Hb-O<sub>2</sub>-CO<sub>2</sub>-H<sup>+</sup> equilibrium: The protons released by carbamate formation are, in part, taken up through the Bohr effect, thereby increasing the amount of O<sub>2</sub> that Hb would otherwise release. Although the difference in CO<sub>2</sub> binding between the oxy and deoxy states of hemoglobin accounts for only ~5% of the total blood CO<sub>2</sub>, it is nevertheless responsible for around half of the CO<sub>2</sub> transported by blood. This is because only ~10% of the total blood CO<sub>2</sub> turns over in each circulatory cycle.

Cl<sup>-</sup> is also bound more tightly to deoxyHb than to oxyHb (Section 10-2E). Accordingly, hemoglobin's O<sub>2</sub> affinity also varies with [Cl<sup>-</sup>]. HCO<sub>3</sub><sup>-</sup> freely permeates the

erythrocyte membrane (Section 12-3D), so that once formed, it equilibrates with the surrounding plasma. The need for charge neutrality on both sides of the membrane, however, requires that Cl<sup>-</sup>, which also freely permeates the membrane, replace the HCO<sub>3</sub><sup>-</sup> that leaves the erythrocyte (the erythrocyte membrane is impermeable to cations). Consequently, [Cl<sup>-</sup>] in the erythrocyte is greater in the venous blood than it is in the arterial blood. Cl<sup>-</sup> is therefore also a modulator of hemoglobin's O<sub>2</sub> affinity.

#### D. Effect of BPG on O<sub>2</sub> Binding

Purified (stripped) hemoglobin has a much greater O<sub>2</sub> affinity than does hemoglobin in whole blood (Fig. 10-7). This observation led Joseph Barcroft, in 1921, to speculate that blood contains some other substance that complexes with Hb so as to reduce its O<sub>2</sub> affinity. In 1967, Reinhold and Ruth Benesch demonstrated that this substance is **D-2,3-bisphosphoglycerate (BPG)**

**D-2,3-Bisphosphoglycerate (BPG)**

[previously known as **2,3-diphosphoglycerate (DPG)**]. BPG binds tightly to deoxyHb in a 1:1 mole ratio ( $K = 1.5 \times 10^{-5} M$ ) but only weakly to oxyHb. The presence of BPG therefore decreases hemoglobin's oxygen affinity by keeping it in the deoxy conformation; for example, the  $p_{50}$  of stripped hemoglobin is increased from 12 to 22 torr by 4.7 mM BPG, its normal concentration in erythrocytes

**Figure 10-7** Comparison of the O<sub>2</sub>-dissociation curves of "stripped" Hb and whole blood in 0.01M NaCl at pH 7.0. [After Benesch, R.E. and Benesch, R., *Adv. Prot. Chem.* **28**, 217 (1974).]

(similar to that of Hb). Organic polyphosphates, such as **inositol hexaphosphate (IHP)**

**Inositol hexaphosphate (IHP)**

and ATP, also have this effect on Hb. In fact, in birds, IHP functionally replaces BPG and ATP does so in fish and in most amphibians. The  $\sim 2$  mM ATP normally present in

**Figure 10-8** The effects of BPG and  $\text{CO}_2$ , both separately and combined, on hemoglobin's  $\text{O}_2$ -dissociation curve compared with that of whole blood (red curve). In the Hb solutions, which were 0.1M KCl and pH 7.22,  $p\text{CO}_2 = 40$  torr and the BPG concentration was 1.2 times that of Hb. The blood had  $p\text{CO}_2 = 40$  torr and a plasma pH of 7.40, which corresponds to a pH of 7.22 inside the erythrocyte. [After Kilmartin, J.V. and Rossi-Bernardi, L., *Physiol. Rev.* **53**, 884 (1973).] See the Animated Figures

mammalian erythrocytes is prevented from binding to Hb by its complexation with  $\text{Mg}^{2+}$ .

BPG has an indispensable physiological function: In arterial blood, where  $p\text{O}_2$  is  $\sim 100$  torr, Hb is  $\sim 95\%$  saturated with  $\text{O}_2$ , but in venous blood, where  $p\text{O}_2$  is  $\sim 30$  torr, it is only  $\sim 55\%$  saturated (Fig. 10-3). Consequently, in passing through the capillaries, Hb unloads  $\sim 40\%$  of its  $\text{O}_2$ . *In the absence of BPG, little of this  $\text{O}_2$  is released since hemoglobin's  $\text{O}_2$  affinity is increased, thus shifting the  $\text{O}_2$ -dissociation curve significantly toward lower  $p\text{O}_2$  (Fig. 10-8, left).*

$\text{CO}_2$  and BPG independently modulate hemoglobin's  $\text{O}_2$  affinity. Figure 10-8 indicates that stripped Hb can be made to have the same oxygen-dissociation curve as the Hb in whole blood by adding  $\text{CO}_2$  and BPG in the concentrations found in erythrocytes (the pH and  $[\text{Cl}^-]$  are also the same). Hence, *the presence of these four substances in whole blood—BPG,  $\text{CO}_2$ ,  $\text{H}^+$ , and  $\text{Cl}^-$ —accounts for the  $\text{O}_2$ -binding properties of Hb.*

#### a. Increased BPG Levels Are Partially Responsible for High-Altitude Adaptation

High-altitude adaptation is a complex physiological process that involves an increase in the amount of hemoglobin per erythrocyte and in the number of erythrocytes. It normally requires several weeks to complete. Yet, as is clear to anyone who has quickly climbed to high altitude, even a 1-day stay there results in a noticeable degree of adaptation. This effect results from a rapid increase in the erythrocyte BPG concentration (Fig. 10-9; BPG, which cannot pass through the erythrocyte membrane, is synthesized in the erythrocyte; Section 17-2Hb). The consequent decrease in  $\text{O}_2$ -binding affinity, as indicated by its elevated

**Figure 10-9** The effect of high-altitude exposure on the  $p_{50}$  and the BPG concentration of blood in sea level-adapted individuals. The region on the right marked "Sea level" indicates the effects of exposure to sea level on high altitude-adapted individuals. [After Lenfant, C., Torrance, J.D., English, E., Finch, C.A., Reynafarje, C., Ramos, J., and Faura, J., *J. Clin. Invest.* **47**, 2653 (1968).]

$p_{50}$ , increases the amount of  $O_2$  that hemoglobin unloads in the capillaries (Fig. 10-10). Similar increases in BPG concentration occur in individuals suffering from disorders that limit the oxygenation of the blood (hypoxia), such as various anemias and cardiopulmonary insufficiency.

### b. Fetal Hemoglobin Has a Low BPG Affinity

The effects of BPG also help supply the fetus with oxygen. A fetus obtains its  $O_2$  from the maternal circulation via the placenta. This process is facilitated because fetal hemoglobin (HbF) has a higher  $O_2$  affinity than does maternal hemoglobin (HbA; recall that HbF has the subunit composition  $\alpha_2\gamma_2$ , in which the  $\gamma$  subunit is a variant of HbA's  $\beta$  subunit; Section 7-3C). BPG occurs in about the same concentrations in adult and fetal erythrocytes but binds more tightly to deoxyHbA than to deoxyHbF; this accounts for HbF's greater  $O_2$  affinity. In the next section we shall develop the structural rationale for the effect of BPG and for the other aspects of  $O_2$  binding.

**Figure 10-10** The  $O_2$ -dissociation curves of blood adapted to sea level (black curve) and to high altitude (red curve). Between the sea level arterial and venous  $pO_2$  values of 100 and 30 torr, respectively, Hb normally unloads 38% of the  $O_2$  it can maximally carry. However, when the arterial  $pO_2$  drops to 55 torr, as it does at an altitude of 4500 m, this difference is reduced to 30% in nonadapted blood. High-altitude adaptation increases the BPG concentration in erythrocytes, which shifts the  $O_2$ -dissociation curve of Hb to the right. The amount of  $O_2$  that Hb delivers to the tissues is thereby restored to 37% of its maximum load.

## 2 STRUCTURE AND MECHANISM

The determination of the first protein X-ray structures, those of sperm whale myoglobin by John Kendrew in 1959 and of human deoxyhemoglobin and horse methemoglobin by Max Perutz shortly thereafter, ushered in a revolution in biochemical thinking that has reshaped our understanding of the chemistry of life. Before the advent of protein crystallography, macromolecular structures, if they were considered at all, were thought of as having a rather hazy existence of uncertain biological significance. However, as the elucidation of macromolecular structures has continued at an ever quickening pace, it has become clear that *life is based on the interactions of complex, structurally well-defined macromolecules*.

The story of hemoglobin's structural determination is a tale of enormous optimism and tenacity. Perutz began this study in 1937 at Cambridge University as a graduate student of J. D. Bernal (who, with Dorothy Crowfoot Hodgkin, had taken the first X-ray diffraction photographs of hydrated protein crystals in 1934). In 1937, the X-ray crystal structure determination of even the smallest molecule required many months of hand computation, and the largest structure yet determined was that of the dye phthalocyanin, which has 40 nonhydrogen atoms. Since hemoglobin has  $\sim 4500$  nonhydrogen atoms, it must have seemed to Perutz's colleagues that he was pursuing an impossible goal. Nevertheless, the laboratory director, Lawrence Bragg (who in 1912, with his father William Bragg, had determined the first X-ray structure, that of NaCl), realized the tremendous biological significance of determining a protein structure and supported the project.

It was not until 1953 that Perutz finally hit on the method that would permit him to solve the X-ray structure of hemoglobin, that of isomorphous replacement. Kendrew, a colleague of Perutz, used this technique to solve the X-ray structure of sperm whale myoglobin, first at low resolution in 1957, and then at high resolution in 1959. Hemoglobin's greater complexity delayed its low-resolution structural determination until 1959, and it was not until 1968, over 30 years after he had begun the project, that Perutz and his associates obtained the high-resolution X-ray structure of horse methemoglobin. Those of human and horse deoxyhemoglobins followed shortly thereafter. Since then, the X-ray structures of hemoglobins from numerous different species, from mutational variants, and with different bound ligands have been elucidated. This, together with many often ingenious physicochemical investigations, has made hemoglobin the most intensively studied, and perhaps the best understood, of proteins.

In this section, we examine the molecular structures of myoglobin and hemoglobin and consider the structural basis of hemoglobin's oxygen-binding cooperativity, the Bohr effect, and BPG binding.

### A. Structure of Myoglobin

Myoglobin consists of eight helices (labeled A–H) that are linked by short polypeptide segments to form an ellipsoidal

**Table 10-1** The Amino Acid Sequences of the  $\alpha$  and  $\beta$  Chains of Human Hemoglobin and of Human Myoglobin<sup>a,b</sup>

molecule of approximate dimensions  $44 \times 44 \times 25$  Å (Fig. 10-11; see also Fig. 8-39). The helices range in length from 7 to 26 residues and incorporate 121 of myoglobin's 153 residues (Table 10-1). They are largely  $\alpha$  helical but with some distortions from this geometry such as a tightening of the final turns of helices A, C, E, and G to form segments of  $3_{10}$  helix.

In a helix numbering convention peculiar to globins, residues are designated according to their position in a helix or interhelical segment. For example, residue B5 is the fifth residue from the N-terminus of the B helix and residue FG3 is the third residue from the N-terminus in the nonhelical segment connecting helices F and G. The

nonhelical N- and C-terminal segments are designated NA and HC, respectively. The usual convention of sequentially numbering all amino acid residues from the N-terminal residue of the polypeptide is also used, and often both conventions are used together. For example, Glu EF7(83) of human Mb is the 83rd residue from its N-terminus and the 7th residue in the nonhelical segment connecting its E and F helices.

The heme is tightly wedged in a hydrophobic pocket formed mainly by helices E and F but which includes contacts with helices B, C, G, and H as well as the CD and FG segments. The fifth ligand of the heme Fe(II) is His F8, the **proximal** (near) **histidine**. In oxyMb, the Fe(II) is positioned  $0.22$  Å out of the heme plane on the side of the proximal His and is coordinated by  $O_2$  with the bent geometry shown in Fig. 10-12. His E7, the **distal** (distant) **histidine**, hydrogen bonds to the  $O_2$ . In deoxyMb, the sixth liganding position of the Fe(II) is unoccupied because the distal His is too far away from the Fe(II) to coordinate with it. Furthermore, the Fe(II) has moved to a point  $0.55$  Å out of the heme plane. Other structural changes in Mb on changing oxygenation states consist of small motions of various chain segments and slight readjustments of side chain conformations. *By and large, however, the structures of oxy- and deoxyMb are nearly superimposable.*

**Figure 10-11** Structure of sperm whale myoglobin. Its 153  $C_\alpha$  positions are numbered from the N-terminus and its eight helices are sequentially labeled A through H. The last half of the EF corner is now regarded as a turn of helix and is therefore designated the F' helix. The heme group is shown in red. Also see Fig. 8-39. [Illustration, Irving Geis. ## B. Structure of Hemoglobin

The hemoglobin tetramer is a spheroidal molecule of dimensions  $64 \times 55 \times 50$  Å. Its two  $\alpha\beta$  protomers are symmetrically related by a twofold rotation (Fig. 10-13; see also Fig. 8-64). *The tertiary structures of the  $\alpha$  and  $\beta$  subunits are remarkably similar, both to each other and to that of Mb (Figs. 10-11 and 10-13), even though only 18% of the corresponding residues are identical among these three polypeptides (Table 10-1) and there is no D helix in hemoglobin's  $\alpha$  subunit. Indeed, the  $\alpha$  and  $\beta$  subunits in the tetramer are related by pseudo- (inexact) 2-fold rotations so that the subunits occupy the vertices of a tetrahedron (pseudo- $D_2$  symmetry; Section 8-5B).*

*The polypeptide chains of Hb are arranged such that there are extensive interactions between unlike subunits. The  $\alpha_1$ - $\beta_1$  interface (and its  $\alpha_2$ - $\beta_2$  symmetry equivalent) involves 35 residues, whereas the  $\alpha_1$ - $\beta_2$  (and  $\alpha_2$ - $\beta_1$ ) interface involves 19 residues. These associations are predominantly*

**Figure 10-12** The heme complex in oxyMb. In the upper drawing, atoms are represented as spheres of van der Waals radii. The lower drawing shows the corresponding skeletal model with a dashed line representing the hydrogen bond between the distal His and the bound O<sub>2</sub>. [After Phillips, S.E.V., *J. Mol. Biol.* **142**, 544 (1980). PDBid 1MBO.]  See Kinemage Exercise 6-1

hydrophobic in character, although numerous hydrogen bonds and several ion pairs are also involved (Section 10-2C). In contrast, contacts between like subunits,  $\alpha_1$ – $\alpha_2$  and  $\beta_1$ – $\beta_2$ , are few and largely polar in character. This is because like subunits face each other across an  $\sim 20$ -Å-diameter solvent-filled channel that parallels the 50-Å length of the exact 2-fold axis (Figs. 8-64 and 10-13).

#### a. Oxy- and Deoxyhemoglobins Have Different Quaternary Structures

Oxygenation causes such extensive quaternary structural changes to Hb that oxy- and deoxyHb have different crystalline forms; indeed, crystals of deoxyHb shatter on exposure to O<sub>2</sub>. The crystal structures of hemoglobin's oxy and deoxy forms therefore had to be determined independently. *The quaternary structural change preserves hemoglobin's exact 2-fold symmetry and takes place entirely across its  $\alpha_1$ – $\beta_2$  (and  $\alpha_2$ – $\beta_1$ ) interface.* The  $\alpha_1$ – $\beta_1$  (and  $\alpha_2$ – $\beta_2$ ) contact is unchanged, presumably as a result of its more extensive close associations. This contact provides a convenient frame of reference from which the oxy and deoxy conformations may be compared. Viewed in this way, oxygenation rotates the  $\alpha_1\beta_1$  dimer  $\sim 15^\circ$  with respect to the  $\alpha_2\beta_2$  dimer (Fig. 10-14), so that some atoms at the  $\alpha_1$ – $\beta_2$  interface shift by as much as 6 Å relative to each other (compare Figs. 10-13a and 10-13b).

The quaternary conformation of deoxyHb is named the **T state** (T for “tense”). That of oxyHb, which is essentially independent of the ligand used to induce it (e.g., O<sub>2</sub>, met, CO, CN<sup>−</sup>, and NO hemoglobins all have the same quaternary structure), is called the **R state** (R for “relaxed”). Similarly, the tertiary conformational states for the deoxy and liganded subunits are designated as the **t** and **r states**, respectively. The structural differences between the quaternary and tertiary conformations are described in the following subsection in terms of hemoglobin's O<sub>2</sub>-binding mechanism.

(a)

**Figure 10-13** The X-ray structures of (a) deoxyHb and (b) oxyHb as viewed down their exact 2-fold axes. The  $C_{\alpha}$  atoms, numbered from each N-terminus, and the heme groups are shown. The Hb tetramer contains a solvent-filled central channel paralleling its 2-fold axis, whose flanking  $\beta$  chains draw closer together on oxygenation (compare the lengths of the double-headed arrows). In the deoxy state, His FG4(97) $\beta$  (small single-headed arrow) fits between Thr C6(41) $\alpha$  and Pro CD2(44) $\alpha$  (lower right and upper left). The relative movements of the two

$\alpha\beta$  protomers on oxygenation (large gray arrows in Part b) shift His FG4(97) $\beta$  to a new position between Thr C3(38) $\alpha$  and Thr C6(41) $\alpha$ . See Fig. 8-64 for a similarly viewed space-filling model of deoxyHb. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. ### C. Mechanism of Oxygen-Binding Cooperativity

The positive cooperativity of  $O_2$  binding to Hb arises from the effect of the ligand-binding state of one heme on the ligand-binding affinity of another. Yet the distances of 25 to 37 Å between the hemes in an Hb molecule are too large for these heme–heme interactions to be electronic in character. Rather, they are mechanically transmitted by the protein. The elucidation of how this occurs has motivated much of the structural research on Hb for the past four decades.

X-ray crystal structure analysis has provided “snapshots” of the R and T states of Hb in various states of ligation but

does not indicate how the protein changes states. It is difficult to determine the sequence of events that result in such transformations because to do so requires an understanding of the inner workings of proteins that is presently lacking. It is as if you were asked to explain the mechanism of a complicated mechanical clock from its out-of-focus photographs when you had only a hazy notion of how gears, levers, and springs might function. Nevertheless, largely on the basis of the X-ray structures of Hb, Perutz formulated the following mechanism of Hb oxygenation, the **Perutz mechanism**.

(b)  
**Figure 10-13** (continued)

**Figure 10-14** The major structural differences between the quaternary conformations of (a) deoxyHb and (b) oxyHb. On oxygenation, the  $\alpha_1\beta_1$  (shaded) and  $\alpha_2\beta_2$  (outline) dimers move, as indicated on the right, as rigid units such that there is an  $\sim 15^\circ$  off-center rotation of one protomer relative to the other that preserves the molecule's exact 2-fold symmetry. Note how the

position of His FG4 $\beta$  (pentagons) changes with respect to Thr C3 $\alpha$ , Thr C6 $\alpha$ , and Pro CD2 $\alpha$  (yellow dots) at the  $\alpha_1$ - $\beta_1$  and  $\alpha_2$ - $\beta_1$  interfaces. The view is from the right side relative to that in Fig. 10-13. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

**Figure 10-15** The heme group and its environment in the unliganded  $\alpha$  chain of human Hb.

Only selected side chains are shown and the heme D propionate group is omitted for clarity. The F helix runs along the left side of the drawing. The close contact between the proximal His and the heme group that inhibits oxygenation of t-state hemes is indicated by a dashed red line.

### a. The Movement of Fe(II) Into the Heme Plane Triggers the T $\rightarrow$ R Conformational Shift

In the t state, the Fe(II) is situated  $\sim 0.6$  Å out of the heme plane on the side of the proximal His because of a pyramidal doming of the porphyrin skeleton and because the Fe—N<sub>porphyrin</sub> bonds are too long to allow the Fe to lie in the porphyrin plane (Figs. 10-15 and 10-16). The change in the heme's electronic state on binding O<sub>2</sub>, however, causes the doming to subside and the Fe—N<sub>porphyrin</sub> bonds to contract by  $\sim 0.1$  Å. Consequently, on changing from the t to the r state, the Fe(II) moves to the center of the heme plane (Fig. 10-16) where O<sub>2</sub> can coordinate it without steric interference from the porphyrin. The Fe's movement drags the proximal His along with it, which tilts the attached F helix and translates it  $\sim 1$  Å across the heme plane (Fig. 10-16). This lateral translation occurs because, in the t state, the imidazole ring of the proximal His is oriented such that its direct movement of  $\sim 0.6$  Å toward the heme plane would cause it to collide with the heme (Figs. 10-15 and 10-16); however, the F helix shift reorients the imidazole ring, thereby permitting the Fe(II) to move into the heme plane. In addition, in the t state of the  $\beta$  but not the  $\alpha$  subunits, Val E11 partially occludes the O<sub>2</sub>-binding pocket so that it must be moved aside before O<sub>2</sub> binding can occur.

### b. The $\alpha_1$ - $\beta_2$ and $\alpha_2$ - $\beta_1$ Contacts Have Two Stable Positions

As we saw above, the difference between hemoglobin's R and T conformations occurs mainly in the  $\alpha_1$ - $\beta_2$  (and the

**Figure 10-16** Triggering mechanism for the T  $\rightarrow$  R transition in Hb.

In the T form (blue), the Fe is  $\sim 0.6$  Å above the mean plane of the domed porphyrin ring. On assuming the R form (red), the Fe moves into the plane of the now undomed porphyrin, where it can readily bind O<sub>2</sub>, and, in doing so, pulls the proximal His F8 and its attached F helix with it. The Fe—O<sub>2</sub> bond is thereby strengthened because of the relaxation of the steric interference between the O<sub>2</sub> and the heme. See Kinemage Exercise 6-4 and the Animated Figures

**Figure 10-17** The  $\alpha_1\text{C}$ – $\beta_2\text{FG}$  interface of Hb in (a) the T state and (b) the R state. The upper drawings show the C helix in ribbon form (purple) and its contacting portion of the FG region in ball-and-stick form colored according to atom type (C green, N blue, and O red). The dots outline the contacting van der Waals surfaces and are also colored according to atom type. The lower drawings are the corresponding schematic diagrams of the  $\alpha_1\text{C}$ – $\beta_2\text{FG}$  contact. On a T  $\rightarrow$  R transformation, this contact snaps from one position to the other with no stable intermediate

(note how, in both conformations, the knobs formed by the side chains of His 97 $\beta$  and Asp 99 $\beta$  fit between the grooves on the C helix formed by the side chains of Thr 38 $\alpha$ , Thr 41 $\alpha$ , and Pro 44 $\alpha$ ). The subunits are joined by different hydrogen bonds in the two quaternary states. Figures 10-13 and 10-14 provide additional structural views of these interactions. [Based on X-ray structures by Giulio Fermi, Max Perutz, and Boaz Shaanan, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBids (a) 2HHB and (b) 1HHO.] See Kinemage Exercise 6-5

symmetrically related  $\alpha_2$ – $\beta_1$ ) interface, which consists of the C helix and FG segment of  $\alpha_1$ , respectively, contacting the FG segment and C helix of  $\beta_2$ . The quaternary change results in a 6-Å relative shift at the  $\alpha_1\text{C}$ – $\beta_2\text{FG}$  interface (Fig. 10-14). In the T state, His FG4(97) $\beta$  is in contact with

Thr C6(41) $\alpha$  (Figs. 10-13a and 10-17a), whereas in the R state it is in contact with Thr C3(38) $\alpha$ , one turn back along the C helix (Figs. 10-13b and 10-17b). In both conformations, the “knobs” on one subunit mesh nicely with the “grooves” on the other (Fig. 10-17). An intermediate position,

however, would be severely strained because it would bring His FG4(97) $\beta$  and Thr C6(41) $\alpha$  too close together (knobs on knobs). Hence *these contacts, which are joined by different but equivalent sets of hydrogen bonds in the two states (Fig. 10-17), act as a binary switch that permits only two stable positions of the subunits relative to each other.* In contrast, the quaternary change causes only a 1-Å shift at the  $\alpha_1$ FG- $\beta_2$ C contact, so its side chains maintain the same associations throughout the change. *These side chains therefore act as flexible joints or hinges about which the  $\alpha_1$  and  $\beta_2$  subunits pivot during the quaternary change.*

### c. The T State Is Stabilized by a Network of Salt Bridges That Must Break to Form the R State

The R state is stabilized by ligand binding. But in the absence of ligand, why is the T state more stable than the R state? In the electron density maps of R-state Hb, the C-terminal residues of each subunit (Arg 141 $\alpha$  and His 146 $\beta$ ) appear as a blur, which suggests that these residues are free to wave about in solution. Maps of the T form, however, show these residues firmly anchored in place via several intersubunit and intrasubunit salt bridges, which evidently help stabilize the T state (Fig. 10-18). *The structural changes accompanying the T  $\rightarrow$  R transition tear away these salt bridges in a process driven by the Fe—O<sub>2</sub> bonds' energy of formation.*

### d. Hemoglobin's O<sub>2</sub>-Binding Cooperativity Derives from the T $\rightarrow$ R Conformational Shift

The hemoglobin molecule resembles a finely tooled mechanism that has very little slop. The binding of O<sub>2</sub> requires a series of tightly coordinated movements:

1. The Fe(II) of any subunit cannot move into its heme plane without the reorientation of its proximal His

so as to prevent this residue from bumping into the porphyrin ring.

2. The proximal His is so tightly packed by its surrounding groups that it cannot reorient unless this movement is accompanied by the previously described translation of the F helix across the heme plane.

3. The F helix translation is only possible in concert with the quaternary shift that steps the  $\alpha_1$ C- $\beta_2$ FG contact one turn along the  $\alpha_1$ C helix.

4. The inflexibility of the  $\alpha_1$ - $\beta_1$  and  $\alpha_2$ - $\beta_2$  interfaces requires that this shift simultaneously occur at both the  $\alpha_1$ - $\beta_2$  and the  $\alpha_2$ - $\beta_1$  interfaces.

Consequently, *no one subunit or dimer can greatly change its conformation independently of the others. Indeed, the two stable positions of the  $\alpha_1$ C- $\beta_2$ FG contact limit the Hb molecule to only two quaternary forms, R and T.*

We are now in a position to structurally rationalize hemoglobin's O<sub>2</sub>-binding cooperativity. Any deoxyHb subunit binding O<sub>2</sub> is constrained to remain in the t state by the T conformation of the tetramer. However, *the t state has reduced O<sub>2</sub> affinity, most probably because its Fe—O<sub>2</sub> bond is stretched beyond its normal length by the steric repulsions between the heme and the O<sub>2</sub> and in the  $\beta$  subunits, by the need to move Val E11 out of the O<sub>2</sub>-binding site.* As more O<sub>2</sub> is bound to the Hb tetramer, this strain, which derives from the Fe—O<sub>2</sub> bond energy, accumulates in the liganded subunits until it is of sufficient strength to snap the molecule into the R conformation. *All the subunits are thereby converted to the r state whether or not they are liganded. Unliganded subunits in the r state have an increased O<sub>2</sub> affinity because they are already in the O<sub>2</sub>-binding conformation.* This accounts for the high O<sub>2</sub> affinity of nearly saturated Hb.

**Figure 10-18** Networks of salt bridges and hydrogen bonds in deoxyHb. These bonds, which involve the last two residues of (a) the  $\alpha$  chains and (b) the  $\beta$  chains, are all ruptured in the T  $\rightarrow$  R transition. The two groups that participate in the Bohr effect by

becoming partially deprotonated in the R state are indicated by white plus signs. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

### e. Hemoglobin's Sigmoidal O<sub>2</sub>-Binding Curve Is a Composite of Its Hyperbolic R- and T-State Curves

The relative stabilities of the T and R states, as indicated by their free energies, vary with fractional saturation (Fig. 10-19a). In the absence of ligand, the T state is more stable than the R state, and vice versa when all ligand-binding sites are occupied. The formation of Fe—O<sub>2</sub> bonds causes the free energy of both the T and the R states to decrease (become more stable) with oxygenation, although the rate of this decrease is smaller for the T state as a result of the strain that liganding imposes on t-state subunits. The  $R \rightleftharpoons T$  transformation is, of course, an equilibrium process, so that Hb molecules, at intermediate levels of fractional saturation (1, 2, or 3 bound O<sub>2</sub> molecules), continually interconvert between the R and the T states.

The O<sub>2</sub>-binding curve of Hb can be understood as a composite of those of its R and T states (Fig. 10-19b). For pure states, such as R or T, these curves are hyperbolic because ligand binding at one protomer is unaffected by the state of other protomers in the absence of a quaternary structural change. At low  $pO_2$ 's, Hb follows the low-affinity T-state curve and at high  $pO_2$ 's, it follows the high-affinity R-state curve. At intermediate  $pO_2$ 's, Hb exhibits an O<sub>2</sub> affinity that changes from T-like to R-like as  $pO_2$  increases. The switchover results in the sigmoidal shape of hemoglobin's O<sub>2</sub>-binding curve.

### D. Testing the Perutz Mechanism

The Perutz mechanism is a description of the dynamic behavior of Hb that is largely based on the static structures of its R and T end states. Accordingly, without the direct demonstration that Hb actually follows the postulated

pathway in changing conformational states, the Perutz mechanism must be taken as being at least partially conjectural. Unfortunately, the physical methods that can follow dynamic changes in proteins are, as yet, incapable of providing detailed descriptions of these changes. Nevertheless, certain aspects of the Perutz mechanism are supported by static measurements, as is described below and in Section 10-3.

#### a. C-Terminal Salt Bridges Are Required to Maintain the T State

The proposed function of the C-terminal salt bridges in stabilizing the T state has been corroborated by chemically modifying human Hb. Removal of the C-terminal Arg 141 $\alpha$  (by treating isolated  $\alpha$  chains with carboxypeptidase B followed by reconstitution) drastically reduces the cooperativity of O<sub>2</sub> binding (Hill constant of 1.7, reduced from its normal value of 2.8). Cooperativity is abolished by the further removal of the other C-terminal residue, His 146 $\beta$  (Hill constant of  $\sim 1.0$ ). Apparently, in the absence of its C-terminal salt bridges, the T form of Hb is unstable. Indeed, human deoxy-Hb, with its C-terminal residues removed, crystallizes in a form very similar to that of normal human oxyHb.

#### b. Fe—O<sub>2</sub> Bond Tension Has Been Spectroscopically Demonstrated

If movement of the Fe into the heme plane on oxygenation is mechanically coupled via the proximal His to the T  $\rightarrow$  R transformation, then conversely, forcing oxyHb into the T form must exert a tension on the Fe, through the proximal His, that tends to pull the Fe out of the heme plane. Perutz demonstrated the existence of this tension as follows.

**Figure 10-19** Free energy and saturation curves for O<sub>2</sub> binding to hemoglobin. (a) The variation of the free energies of hemoglobin's T and R states with their fractional saturation,  $Y_{O_2}$ . In the absence of O<sub>2</sub> the T state is more stable, and when saturated with O<sub>2</sub> the R state is more stable. The free energy of both states is reduced with increasing oxygenation as a consequence of O<sub>2</sub> liganding. The Fe(II)—O<sub>2</sub> bonding is more

exergonic in the R state than it is in the T state, however, so that the relative stabilities of these two states reverse order at intermediate levels of oxygenation. (b) The sigmoid O<sub>2</sub>-binding curve of Hb (purple) is a composite of its hyperbolic R-state (red) and T-state (blue) binding curves: It is more T-like at lower  $pO_2$  values and more R-like at higher  $pO_2$  values.

IHP's six phosphate groups cause it to bind to deoxyHb with much greater affinity than does BPG (the structural basis of BPG binding to Hb is discussed in Section 10-2F); the presence of IHP therefore tends to force Hb into the T state. Conversely, nitric oxide (NO) binds to Hb far more strongly than does O<sub>2</sub> and thereby tends to force Hb into the R state. Spectroscopic analysis indicates the consequences of simultaneously binding both NO and IHP to Hb:

1. The NO, as expected, pulls the Fe into the plane of the heme.
2. The IHP forces the Hb molecule into the T state, which through the “gears and levers” coupling the 4° and 3° conformational changes, pulls the proximal His in the opposite direction, away from the Fe.

The bond between the proximal His and the Fe lacks the strength to withstand these two opposing “irresistible” forces; it simply breaks. The spectroscopic observation of this phenomenon therefore confirms the existence of the heme–protein tension predicted by the Perutz mechanism.

### c. Detaching the Proximal His from the F Helix Eliminates Most Cooperativity

In a further experimental investigation of the origin of cooperativity in hemoglobin, Chien Ho mutagenically changed the proximal His residue to Gly on only the  $\alpha$  subunits, on only the  $\beta$  subunits, and on both the  $\alpha$  and  $\beta$  subunits. The missing imidazole ring of the proximal His was then replaced by imidazole (which a variety of evidence indicates ligands the heme Fe as does the proximal His). This, in effect, detaches the proximal His from the protein, thereby cutting the covalent bond that, according to the Perutz model, links the ligand-induced movement of the Fe into the heme plane to the accompanying movement of helix F. In all three cases, this proximal detachment, in agreement with the Perutz model, significantly increases hemoglobin's ligand-binding affinity, reduces its cooperativity, and prevents its T  $\rightarrow$  R quaternary switch. However, these mutant hemoglobins exhibit a small amount of residual cooperativity, suggesting that the heme groups also communicate via pathways that do not require covalent coupling between the F helix and the proximal His. These pathways may involve movements of protein groups in contact with the heme (see Figs. 10-12 and 10-15) in response to the subsidence of heme doming on ligand binding. They may also involve movements of the distal His residues of the  $\alpha$  and  $\beta$  subunits, and/or the movement of Val E11 of the  $\beta$  subunits, all of whose side chains must move aside when ligand binds to Hb.

### E. Origin of the Bohr Effect

The Bohr effect, hemoglobin's release of H<sup>+</sup> on binding O<sub>2</sub>, is also observed when Hb binds other ligands. *It arises from pK changes of several groups caused by changes in their local environments that accompany hemoglobin's T  $\rightarrow$  R transition.* The groups involved include the N-terminal amino groups of the  $\alpha$  subunits and the C-terminal His of the  $\beta$  subunits. These have been identified through chemi-

**Figure 10-20** Reaction of cyanate with the unprotonated (nucleophilic) forms of primary amino groups. At physiological pH's, N-terminal amino groups, which have pK's near 8.0, readily react with cyanate. Lys  $\epsilon$ -amino groups (pK  $\approx$  10.8), however, are fully protonated under these conditions and are therefore unreactive.

cal and structural studies, and their quantitative contributions to the Bohr effect have been estimated.

Reaction of the  $\alpha$  subunits of Hb with **cyanate** results in the specific **carbamoylation** of the N-terminal amino groups (Fig. 10-20). When such carbamoylated  $\alpha$  subunits are mixed with normal  $\beta$  subunits, the resulting reconstituted Hb lacks 20 to 30% of the normal Bohr effect. The reason for this is seen on comparing the X-ray structure of deoxyHb with that of carbamoylated deoxyHb. In deoxyHb, a Cl<sup>-</sup> ion binds between the N-terminal amino group of Val 1 $\alpha_2$  and the guanidino group of Arg 141 $\alpha_1$  (the C-terminal residue; Fig. 10-18a). This Cl<sup>-</sup> is absent in carbamoylated deoxyHb. It is also absent in normal R-state Hb because its C-terminal residues are not held in place by salt bridges (which partially accounts for the preferential binding of Cl<sup>-</sup> to deoxyHb; Section 10-1C). N-Terminal amino groups of polypeptides normally have pK's near 8.0. On deoxyHb  $\alpha$  subunits, however, the N-terminal amino group is electrostatically influenced by its closely associated Cl<sup>-</sup> to increase its positive charge by binding protons more tightly, that is, to increase its pK. Since at the pH of blood (7.4) N-terminal amino groups are normally only partially charged, this pK shift causes them to bind significantly more protons in the T state than in the R state.

The Hb  $\beta$  chain also contributes to the Bohr effect. Removal of its C-terminal residue, His 146 $\beta$ , reduces the Bohr effect by 40%. In normal deoxyHb, the imidazole ring of His 146 $\beta$  associates with the carboxylate of Asp 94 $\beta$  on the same subunit (Fig. 10-18b) to form a salt bridge that is absent in the R state. Proton NMR measurements indicate that formation of this salt bridge increases the pK of the imidazole group from 7.1 to 8.0. This effect more than accounts for His 146 $\beta$ 's share of the Bohr effect.

We have not yet accounted for about 30 to 40% of the Bohr effect. It is largely due to small contributions from the numerous surface-exposed His residues whose environments are altered on hemoglobin's T  $\rightarrow$  R transition [since His is the only residue with an intrinsic pK (6.04) in the physiological range, small changes in its pK will significantly alter the number of protons it binds]. Indeed, NMR measurements by Ho indicate that the T  $\rightarrow$  R transition induces small shifts in the pK's of these various His residues, although, interestingly, some of these shifts are in the direction that diminishes the magnitude of the Bohr effect.

### F. Structural Basis of BPG Binding

BPG decreases the oxygen-binding affinity of Hb by preferentially binding to its deoxy state (Section 10-1D). The binding of the physiologically quadruply charged BPG to deoxyHb is weakened by high salt concentrations, which suggests that this association is ionic in character. This explanation is corroborated by the X-ray structure of a BPG–deoxyHb complex, which indicates that BPG binds in the central cavity of deoxyHb on its 2-fold axis (Fig. 10-21). The anionic groups of BPG are within hydrogen bonding and salt bridging distances of the cationic Lys EF6(82), His H21(143), His NA2(2), and N-terminal amino groups of both  $\beta$  subunits (Fig. 10-21). The T  $\rightarrow$  R transformation brings the two  $\beta$  H helices together, which narrows the central cavity (compare Figs. 10-13a and 10-13b) and expels the BPG. It also widens the distance between the  $\beta$  N-terminal amino groups from 16 to 20 Å, which prevents their simultaneous hydrogen bonding with BPG's phosphate groups. BPG therefore stabilizes the T conformation of Hb by cross-linking its  $\beta$  subunits. This shifts the T  $\rightleftharpoons$  R equilibrium toward the T state, which lowers hemoglobin's O<sub>2</sub> affinity.

The structure of the BPG–deoxyHb complex also indicates why fetal hemoglobin (HbF) has a reduced affinity for BPG relative to HbA (Section 10-1D). The cationic His H21(143) $\beta$  of HbA is changed to an uncharged Ser residue in HbF's  $\beta$ -like  $\gamma$  subunit, thereby eliminating a pair of ionic interactions stabilizing the BPG–deoxyHb complex (Fig. 10-21).

The excess positive charge lining Hb's central cavity is also partially responsible for the allosteric effect of Cl<sup>−</sup> ions in stabilizing the T state relative to the R state (the remainder being due to the participation of Cl<sup>−</sup> in the T-state salt bridge networks; Fig. 10-18a). The central cavity is larger in the T state than in the R state (Fig. 10-13), so that more Cl<sup>−</sup> ions occupy this channel in the T state than in the R state. The additional Cl<sup>−</sup> ions, through electrostatic shielding, reduce the mutual repulsions of the positive charges, thereby stabilizing the T state.

### G. Role of the Distal Histidine Residue

O<sub>2</sub> binding paradoxically protects the heme iron from autooxidation: The rate of Mb oxidation decreases as the partial pressure of O<sub>2</sub> increases. This is because heme iron oxidation is catalyzed by protons that are reduced by the heme iron and that in turn reduce O<sub>2</sub> in the solvent to **superoxide ion** (O<sub>2</sub><sup>•−</sup>). Bound O<sub>2</sub> evidently shields the Fe from the attacking protons.

The mutagenic replacement of the distal His residue in Mb by any other residue reduces Mb's oxygen affinity and increases its rate of autooxidation. Asp, a proton source, at this position increases the rate of Mb autooxidation by 350-fold, the largest increase of all residue replacements, whereas Phe, Met, and Arg provide only 50-fold accelerations, the smallest observed increases. The imidazole ring of the distal His, which has a pK of 5.5 and is therefore neutral at neutral pH and whose unprotonated N<sub>ε</sub> atom faces the heme pocket (Fig. 10-12), acts as a proton trap, thereby

**Figure 10-21** Binding of BPG to deoxyHb. The view is down the molecule's exact twofold axis (the same view as in Fig. 10-13a). BPG (red), with its five anionic groups, binds in the central cavity of deoxyHb, where it is surrounded by a ring of eight cationic side chains (blue) extending from the two  $\beta$  subunits. In the R state, the central cavity is too narrow to admit BPG (Fig. 10-13b). The arrangement of salt bridges and hydrogen bonds between the  $\alpha_1$  and  $\beta_2$  subunits that partially stabilizes the T state (Fig. 10-18b) is indicated at the lower right. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]  See Kinemage

#### Exercise 6-3

protecting the Fe from protons. Thus, to quote Perutz, "Evolution is a brilliant chemist."

## 3 ABNORMAL HEMOGLOBINS

Mutant hemoglobins provided the original opportunity to study structure–function relationships in proteins because Hb is a readily isolated protein of known structure that has a large number of well-characterized naturally occurring variants. The examination of individuals with physiological disabilities, together with the routine electrophoretic screening of human blood samples, has led to the discovery of over 1000 variant hemoglobins, >90% of which result from single amino acid substitutions in a globin polypeptide

chain (a compendium of variant human hemoglobins is located at <http://globin.cse.psu.edu/>). In this section, we consider the nature of these **hemoglobinopathies**. Hemoglobin diseases characterized by defective globin synthesis, the **thalassemias**, are the subject of Section 34-2G. It should be noted that ~300,000 individuals with serious hemoglobin disorders are born every year and that ~5% of the world's population are carriers of an inherited variant hemoglobin.

### A. Molecular Pathology of Hemoglobin

The physiological effect of an amino acid substitution on Hb can, in most cases, be understood in terms of its molecular location:

#### 1. Changes in surface residues

*Changes of surface residues are usually innocuous because most of these residues have no specific functional role [although sickle-cell Hb (HbS) is a glaring exception to this generalization; Section 10-3Ba].* For example, **HbE** [Glu B8(26) $\beta$   $\rightarrow$  Lys], the most common human Hb mutant after HbS (possessed by up to 10% of the population in parts of Southeast Asia), has no clinical manifestations in either heterozygotes or homozygotes. About half of the known Hb mutations are of this type and have been discovered only accidentally or through surveys of large populations.

#### 2. Changes in internally located residues

*Changing an internal residue often destabilizes the Hb molecule.* The degradation products of these hemoglobins, particularly those of heme, form granular precipitates (known as **Heinz bodies**) that hydrophobically adhere to the erythrocyte cell membrane. The membrane's permeability is thereby increased, causing premature cell lysis. Carriers of unstable hemoglobins therefore suffer from **hemolytic anemia** of varying degrees of severity.

The structure of Hb is so delicately balanced that small structural changes may render it nonfunctional. This can occur through the weakening of the heme-globin association or as a consequence of other conformational changes. For instance, the heme group is easily dislodged from its closely fitting hydrophobic binding pocket. This occurs in **Hb Hamersmith** (Hb variants are often named after the locality of their discovery), in which Phe CD1(42) $\beta$ , an invariant residue that wedges the heme into its pocket (see Fig. 10-12), is replaced by Ser. The resulting gap permits water to enter the heme pocket, which causes the hydrophobic heme to drop out easily (Phe CD1 and the proximal His F8 are the only invariant residues among all known hemoglobins). Similarly, in **Hb Bristol**, the substitution of Asp for Val E11(67) $\beta$ , which partially occludes the O<sub>2</sub> pocket, places a polar group in contact with the heme. This weakens the binding of the heme to the protein, probably by facilitating the access of water to the subunit's otherwise hydrophobic interior.

Hb may also be destabilized by the disruption of elements of its 2°, 3°, and/or 4° structures. The instability of **Hb Bibba** results from the substitution of a helix-breaking Pro for Leu H19(136) $\alpha$ . Likewise, the instability of **Hb Savannah** is caused by the substitution of Val for the highly con-

served Gly B6(24) $\beta$ , which is located on the B helix where it crosses the E helix with insufficient clearance for side chains larger than an H atom (Fig. 10-13). The  $\alpha_1$ - $\beta_1$  contact, which does not significantly dissociate under physiological conditions, may do so on structural alteration. This occurs in **Hb Philly**, in which Tyr C1(35) $\beta$ , which participates in the hydrogen bonded network that helps knit together the  $\alpha_1$ - $\beta_1$  interface, is replaced by Phe.

### 3. Changes stabilizing methemoglobin

*Changes at the O<sub>2</sub>-binding site that stabilize the heme in the Fe(III) oxidation state eliminate the binding of O<sub>2</sub> to the defective subunits.* Such methemoglobins are designated **HbM** and individuals carrying them are said to have **methemoglobinemia**. These individuals usually have bluish skin, a condition known as **cyanosis**, which results from the presence of deoxyHb in their arterial blood.

All known methemoglobins arise from substitutions that provide the Fe atom with an anionic oxygen atom ligand. In **Hb Boston**, the substitution of Tyr for His E7(58) $\alpha$  (the distal His, which protects the heme from oxidation; Section 10-2G) results in the formation of a 5-coordinate Fe(III) complex, with the phenolate ion of the mutant Tyr E7 displacing the imidazole ring of His F8(87) as the apical ligand (Fig. 10-22a). In **Hb Milwaukee**, the  $\gamma$ -carboxyl group of the Glu that replaces Val E11(67) $\beta$  forms an ion pair with a 5-coordinate Fe(III) complex (Fig. 10-22b). Both the phenolate and glutamate ions in these methemoglobins so stabilize the Fe(III) oxidation state that methemoglobin reductase is ineffective in converting them to the Fe(II) form.

Individuals with HbM are alarmingly cyanotic and have blood that is chocolate brown, even when their normal subunits are oxygenated. In northern Japan, this condition is named "black mouth" and has been known for centuries; it is caused by the presence of **HbM Iwate** [His F8(87) $\alpha$   $\rightarrow$  Tyr]. Methemoglobins have Hill constants of ~1.2. This indicates a reduced cooperativity in comparison with HbA even though HbM, which can bind only two oxygen molecules, can have a maximum Hill constant of 2 (the unmutated  $\alpha$  or  $\beta$  chains remain functional). Surprisingly, heterozygotes with HbM, which have an average of one nonfunctional  $\alpha$  or  $\beta$  subunit per Hb molecule, have no apparent physical disabilities. Evidently, the amount of O<sub>2</sub> released in their capillaries is within normal limits. Homozygotes of HbM, however, are unknown; this condition is, no doubt, lethal.

### 4. Changes at the $\alpha_1$ - $\beta_2$ contact

*Changes at the  $\alpha_1$ - $\beta_2$  contact often interfere with hemoglobin's quaternary structural changes.* Most such hemoglobins have an increased O<sub>2</sub> affinity so that they release less than normal amounts of O<sub>2</sub> in the tissues. Individuals with such defects compensate for it by increasing their hematocrit (concentration of erythrocytes in their blood). This condition, which is named **polycythemia**, often gives them a ruddy complexion. Some amino acid substitutions at the  $\alpha_1$ - $\beta_2$  interface instead result in a reduced O<sub>2</sub> affinity. Individuals carrying such hemoglobins are cyanotic.

Amino acid substitutions at the  $\alpha_1$ - $\beta_2$  contact may change the relative stabilities of hemoglobin's R and T forms,

**Figure 10-22** Mutations stabilizing the Fe(III) oxidation state of heme. (a) Alterations in the heme pocket of the  $\alpha$  subunit on changing from deoxyHbA to Hb Boston [His E7(58) $\alpha$   $\rightarrow$  Tyr]. The phenolate ion of the mutant Tyr becomes the fifth ligand of the Fe atom, thereby displacing the proximal His [F8(87)a]. [After Pulsinelli, P.D., Perutz, M.F., and Nagel, R.L., *Proc. Natl.*

*Acad. Sci.* **70**, 3870 (1973).] (b) The structure of the heme pocket of the  $\beta$  subunit in Hb Milwaukee [Val E11(67) $\beta$   $\rightarrow$  Glu]. Here the mutant Glu residue's carboxyl group forms an ion pair with the heme iron atom so as to stabilize its Fe(III) state. [From Perutz, M.F., Pulsinelli, P.D., and Ranney, H.M., *Nature New Biol.* **237**, 259 (1972).]

thereby altering its  $O_2$  affinity. For example, the replacement of Asp G1(99) $\beta$  by His in **Hb Yakima** eliminates the hydrogen bond at the  $\alpha_1$ - $\beta_2$  contact that stabilizes the T form of Hb (Fig. 10-17a). The interloping imidazole ring also acts as a wedge that pushes the subunits apart and displaces them toward the R state. This change shifts the T  $\rightarrow$  R equilibrium almost entirely to the R state, which results in Hb Yakima having an increased  $O_2$  affinity ( $p_{50} = 12$  torr under physiological conditions vs 26 torr for HbA) and a total lack of cooperativity (Hill constant = 1.0). In contrast, the replacement of Asn G4(102) $\beta$  by Thr in **Hb Kansas** eliminates the hydrogen bond in the  $\alpha_1$ - $\beta_2$  contact that stabilizes the R state (Fig. 10-17b), so that this Hb variant remains in the T state on binding  $O_2$ . Hb Kansas therefore has a low  $O_2$  affinity ( $p_{50} = 70$  torr) and a low cooperativity (Hill constant = 1.3).

### B. Molecular Basis of Sickle-Cell Anemia

Most harmful Hb variants occur in only a few individuals, in many of whom the mutation apparently originated. However,  $\sim 10\%$  of American blacks and as many as 25% of African blacks are heterozygotes for **sickle-cell hemoglobin (HbS)**. HbS arises, as we have seen (Section 7-3Aa), from the substitution of a hydrophobic Val residue for the hydrophilic surface residue Glu A3(6) $\beta$  (Fig. 10-13). The prevalence of HbS results from the protection it affords heterozygotes against malaria. However, homozygotes for HbS, of which there are  $\sim 50,000$  in the United States, are severely afflicted by hemolytic anemia together with painful, debilitating, and sometimes fatal blood flow blockages

caused by the irregularly shaped and inflexible erythrocytes characteristic of the disease (Fig. 7-19b).

#### a. HbS Fibers Are Stabilized by Intermolecular Contacts Involving Val $\beta 6$ and Other Residues

The sickling of HbS-containing erythrocytes results from the aggregation (polymerization) of deoxyHbS into rigid fibers that extend throughout the length of the cell (Fig. 10-23).

**Figure 10-23** Electron micrograph of deoxyHbS fibers spilling out of a ruptured erythrocyte. [Courtesy of Robert Josephs, University of Chicago.]

**Figure 10-24** The 220-Å-diameter fibers of deoxyHbS. (a) An electron micrograph of a negatively stained fiber. The accompanying cutaway interpretive drawing indicates the relationship between the inner and outer strands; each sphere represents an individual HbS molecule. The fiber has a layer repeat distance of 64 Å and a moderate twist such that it repeats every 350 Å along the fiber axis. [Courtesy of Stuart Edelstein, University of Geneva.] (b) A model, viewed in cross section, of the HbS fiber based on the crystal structure of HbS and three-dimensional reconstructions of electron micrographs of HbS

Electron microscopy indicates that these fibers are ~220-Å-diameter elliptical rods consisting of 14 hexagonally packed and helically twisting strands of deoxyHbS molecules that associate in parallel pairs (Figs. 10-24 and 10-25a).

The structural relationship among the HbS molecules in the pairs of parallel HbS strands has been established by the X-ray structure analysis of deoxyHbS crystals. When this crystal structure was first determined, it was unclear whether the intermolecular contacts in the crystal resembled those in the fiber. However, the subsequent observation that HbS fibers slowly convert to these crystals with little change in their overall X-ray diffraction pattern indicates that the fibers structurally resemble the crystals. The crystal structure of deoxyHbS consists of double filaments of HbS molecules whose several different intermolecular contacts are diagrammed in Fig. 10-25b. Only one of the two Val 6 $\beta$ 's per Hb molecule contacts a neighboring molecule. In this contact, the mutant Val side chain occupies a hydrophobic surface pocket on the  $\beta$  subunit of an adja-

cent molecule whose Val 6 $\beta$  does not make an intermolecular contact (Fig. 10-25c). This pocket is absent in oxyHb. Other contacts involve residues that also occur in HbA, including Asp 73 $\beta$  and Glu 23 $\alpha$  (Fig. 10-25b). The observation that deoxyHbA does not aggregate into fibers, however, even at very high concentrations, indicates that *the contact involving Val 6 $\beta$  is essential for fiber formation*. This conclusion is corroborated by the observation that a genetically engineered human Hb in which Glu 6 $\beta$  is replaced by Ile (which differs from Val by an additional CH<sub>2</sub> group and is therefore even more hydrophobic) has half the solubility of HbS in 1.8M phosphate.

The importance of the other intermolecular contacts to the structural integrity of HbS fibers has been demonstrated by studying the effects of other mutant hemoglobins on HbS gelation (polymerization). For example, the doubly mutated **Hb Harlem** (Glu 6 $\beta$  → Val + Asp 73 $\beta$  → Asn) requires a higher concentration to gel than does HbS (Glu 6 $\beta$  → Val); similarly, mixtures of HbS and **Hb Korle-Bu** (Asp 73 $\beta$  → Asn) gel less readily than equivalent

cent molecule whose Val 6 $\beta$  does not make an intermolecular contact (Fig. 10-25c). This pocket is absent in oxyHb. Other contacts involve residues that also occur in HbA, including Asp 73 $\beta$  and Glu 23 $\alpha$  (Fig. 10-25b). The observation that deoxyHbA does not aggregate into fibers, however, even at very high concentrations, indicates that *the contact involving Val 6 $\beta$  is essential for fiber formation*. This conclusion is corroborated by the observation that a genetically engineered human Hb in which Glu 6 $\beta$  is replaced by Ile (which differs from Val by an additional CH<sub>2</sub> group and is therefore even more hydrophobic) has half the solubility of HbS in 1.8M phosphate.

**Figure 10-25** Structure of the deoxyHbS fiber. (a) The arrangement of the deoxyHbS molecules in the fiber. The yellow dots represent the side chains of Glu 6 $\beta_2$ . [Illustration, Irving Geis/Geis Archives Trust. Copyright Howard Hughes Medical Institute. Reproduced with permission.] (b) A schematic diagram indicating the intermolecular contacts in the crystal structure of deoxyHbS. The white-lettered residues are implicated in forming these contacts. Note that the only intermolecular association in which the mutant residue Val 6 $\beta_2$  participates involves subunit  $\beta_2$ ;

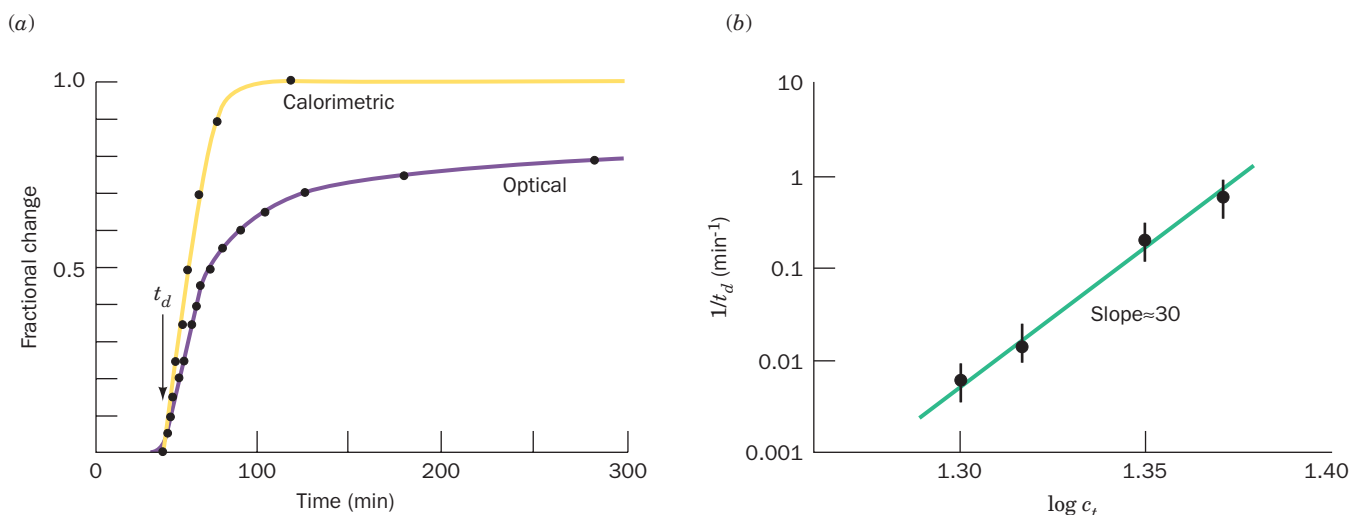

Val 6 of subunit  $\beta_1$  is free. [After Wishner, B.C., Ward, K.B., Lattman, E.E., and Love, W.E., *J. Mol. Biol.* **98**, 192 (1975).] (c) The mutant Val 6 $\beta_2$  fits neatly into a hydrophobic pocket formed mainly by Phe 85 and Leu 88 of an adjacent  $\beta_1$  subunit. This pocket, which is located between helices E and F at the periphery of the heme pocket, is absent in oxyHb and is too hydrophobic to contain the normally occurring Glu 6 $\beta$  side chain. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

mixtures of HbS and HbA. These observations suggest that Asp 73 $\beta$  occupies an important intermolecular contact site in HbS fibers (Fig. 10-25b). Likewise, the observation that hybrid tetramers consisting of  $\alpha$  subunits from **Hb Memphis** (Glu 23 $\alpha$   $\rightarrow$  Gln) and  $\beta$  subunits from HbS gel less readily than does HbS indicates that Glu 23 $\alpha$  also participates in the polymerization of HbS fibers (Fig. 10-25b). The other white-lettered residues in Fig. 10-25b have been similarly implicated in sickling interactions.

#### b. The Initiation of HbS Gelation Is a Complex Process

The gelation of HbS, both in solution and within the red cell, follows an unusual time course. A solution of HbS can be brought to conditions under which it will gel by lowering the  $pO_2$ , raising the HbS concentration, and/or raising the temperature. *On achieving gelation conditions, there is a reproducible delay that varies according to conditions from milliseconds to days: During this time, no HbS fibers can be*

**Figure 10-26** Time course of deoxyHbS gelation. (a) The extent of gelation as monitored calorimetrically (yellow) and optically (purple). Gelation of the  $0.233 \text{ g} \cdot \text{mL}^{-1}$  deoxyHbS solution was initiated by rapidly increasing the temperature from  $0^\circ\text{C}$ , where HbS is soluble, to  $20^\circ\text{C}$ ;  $t_d$  is the delay time. (b) A

detected. Only after the delay do fibers first appear, and gelation is then completed in about half the delay time (Fig. 10-26a).

William Eaton and James Hofrichter discovered that the delay time,  $t_d$ , has a concentration dependence described by

$$\frac{1}{t_d} = k \left( \frac{c_t}{c_s} \right)^n \quad [10.13]$$

where  $c_t$  is the total deoxyHbS concentration prior to gelation,  $c_s$  is the solubility of deoxyHbS measured after gelation is complete, and  $k$  and  $n$  are constants. Graphical analysis of the data indicates that  $k \approx 10^{-7} \text{ s}^{-1}$  and that  $n$  is between 30 and 50 (Fig. 10-26b). This is a remarkable result: *No other known solution process even approaches a 30th power concentration dependence.*

A two-stage process accounts for Eq. [10.13]:

**1.** At first, HbS molecules sequentially aggregate to form a **nucleus** consisting of  $m$  HbS molecules (Fig. 10-27a):

Prenuclear aggregates are unstable and easily decompose, but once a nucleus has formed it assumes a stable structure that rapidly elongates to form an HbS fiber.

**2.** Once a fiber has formed, it can nucleate the growth of other fibers (Fig. 10-27b). These newly formed fibers, in turn, nucleate the growth of yet other fibers, etc., so that this latter process is autocatalytic.

The initial **homogeneous nucleation** process (taking place in solution) accounts for the very high concentration dependence in Eq. [10.13], whereas the secondary **heterogeneous nucleation** process (taking place on a surface—that of a fiber in this case) is responsible for the rapid onset of gelation (Fig. 10-26a).

log–log plot showing the concentration dependence of  $1/t_d$  for the gelation of deoxyHbS at  $30^\circ\text{C}$ . The slope of this line is  $\sim 30$ . [After Hofrichter, J., Ross, P.D., and Eaton, W.A., *Proc. Natl. Acad. Sci.* **71**, 4865, 4867 (1974).]

The foregoing kinetic hypothesis suggests why sickle-cell anemia is characterized by episodic “crises” caused by blood flow blockages. HbS fibers dissolve essentially instantaneously on oxygenation, so that none are present in arterial blood. Erythrocytes take from 0.5 to 2 s to pass through the capillaries, where deoxygenation renders HbS insoluble. If the delay time,  $t_d$ , for sickling is greater than this transit time, no blood flow blockage occurs (although sickling that occurs in the veins damages the erythrocyte membrane). However, Eq. [10.13] indicates that small increases in HbS concentration,  $c_t$ , and/or small decreases in HbS solubility,  $c_s$ , caused by conditions known to trigger sickle-cell crises, such as dehydration,  $\text{O}_2$  deprivation, and fever, result in significant decreases of  $t_d$ . Once a blockage occurs, the resulting lack of  $\text{O}_2$  and slowdown of blood flow in the area compound the situation.

The kinetic hypothesis of sickling has profound clinical implications for the treatment of sickle-cell anemia. Heterozygotes of HbS, whose blood usually contains  $\sim 60\%$  HbA and  $40\%$  HbS, rarely show any symptoms of sickling. The  $t_d$  for the gelation of their Hb is  $\sim 10^6$ -fold greater than that of homozygotes. Accordingly, a treatment of sickle-cell anemia that increases  $t_d$  by this amount, which corresponds to decreasing the ratio  $c_t/c_s$  by a factor of  $\sim 1.6$ , would relieve the symptoms of this disease. This has suggested three different therapeutic strategies (besides gene therapy; Section 5-5Hb) to increase  $t_d$ , and thus inhibit HbS gelation:

**1.** The disruption of intermolecular interactions, thus increasing  $c_s$ . Of particular interest are compounds that have been designed with the aid of the X-ray structure of HbS to bind stereospecifically to its intermolecular contact regions. However, a large amount of any such compound would be necessary to bind to the  $\sim 400 \text{ g}$  of hemoglobin in the human body. Consequently, no antisickling drug yet tested has had a sufficiently high ratio of efficacy to toxicity to merit clinical use.

(a) Homogeneous nucleation

(b) Heterogeneous nucleation

Growth of  
thermodynamically  
unstable aggregates

**Figure 10-27 Double nucleation mechanism for deoxyHbS gelation.** (a) The initial aggregation of HbS molecules (*spheres*) occurs very slowly because this process is thermodynamically unfavorable and hence the intermediates tend to decompose rather than grow. However, once an aggregate reaches a certain

size, the **critical nucleus**, its further growth becomes thermodynamically favorable, leading to rapid fiber formation. (b) Each fiber, in turn, can nucleate the growth of other fibers, leading to the explosive appearance of polymer. [After Ferrone, F.A., Hofrichter, J., and Eaton, W.A., *J. Mol. Biol.* **183**, 614 (1985).]

**2.** The use of agents that increase hemoglobin's  $O_2$  affinity, thus decreasing  $c_i$ . For example, the administration of cyanate carbamoylates the N-terminal amino groups of Hb (Fig. 10-20). This treatment eliminates some of the salt bridges that stabilize the T state (Section 10-2E) and thereby increases the  $O_2$  affinity of Hb. Although cyanate is an effective *in vitro* antisickling agent, its clinical use has been discontinued because of toxic side effects, cataract formation and peripheral nervous system damage, that probably result from the carbamoylation of proteins other than Hb.

**3.** Lowering the HbS concentration ( $c_i$ ) in erythrocytes. Agents that alter erythrocyte membrane permeability so as to permit the influx of water have promise in this regard.

The first, and as yet the only, effective treatment for sickle-cell anemia is a variation of the latter strategy through the administration of **hydroxyurea**.

Adults with sickle-cell anemia have two types of red blood cells: S cells, which contain only HbS; and F cells, which

contain ~20% HbF and the remainder HbS. In most adults, the fraction of F cells is ~30%. However, in those treated with hydroxyurea, this fraction increases to ~50%. Although the mechanism by which hydroxyurea stimulates the production of F cells is unknown, the mechanism by which increased levels of F cells prevent sickling seems clear. F cells contain three species of hemoglobin: HbS ( $\alpha_2\beta_2^S$ ), HbF ( $\alpha_2\gamma_2$ ), and their hybrid ( $\alpha_2\beta^S\gamma$ ), where  $\beta^S$  subunits are the sickle-cell variants of the normal  $\beta$  subunits. Since neither HbF nor the  $\alpha_2\beta^S\gamma$  hybrid Hb can form sickle-cell fibers, they act to dilute the HbS in a cell. This, in turn, increases the time it takes the F cells to sickle by a factor of ~1000, so that F cells do not significantly sickle in the period (10–20 s) it takes them pass from the tissues to the lungs, where they are oxygenated. Thus, the greater the proportion of F cells in the blood, the smaller the proportion of S cells that can sickle.

#### 4 ALLOSTERIC REGULATION

One of the outstanding characteristics of life is the high degree of control exercised in almost all of its processes. Through a great variety of regulatory mechanisms, the

exploration of which constitutes a significant portion of this textbook, an organism is able to respond to changes in its environment, maintain intra- and intercellular communications, and execute an orderly program of growth and development. Regulation is exerted at every organizational level in living systems, from the control of rates of reactions on the molecular level, through the control of expression of genetic information on the cellular level, to the control of behavior on the organismal level. It is therefore not surprising that many, if not most, diseases are caused by aberrations in biological control processes.

Our exploration of the structure and function of hemoglobin continues with a theoretical discussion of the regulation of ligand binding to proteins through **allosteric interactions** (Greek: *allos*, other + *stereos*, solid or space). These cooperative interactions occur when the binding of one ligand at a specific site is influenced by the binding of another ligand, known as an **effector** or **modulator**, at a different (allosteric) site on the protein. If the ligands are identical, this is known as a **homotropic effect**, whereas if they are different, it is described as a **heterotropic effect**. These effects are termed **positive** or **negative** depending on whether the effector increases or decreases the protein's ligand-binding affinity.

Hemoglobin, as we have seen, exhibits both homotropic and heterotropic effects. The binding of O<sub>2</sub> to Hb results in a positive homotropic effect since it increases hemoglobin's O<sub>2</sub> affinity. In contrast, BPG, CO<sub>2</sub>, H<sup>+</sup>, and Cl<sup>-</sup> are negative heterotropic effectors of O<sub>2</sub> binding to Hb because they decrease its affinity for O<sub>2</sub> (negative) and are chemically different from O<sub>2</sub> (heterotropic). The O<sub>2</sub> affinity of Hb, as we have seen, depends on its quaternary structure. *In general, allosteric effects result from interactions among subunits of oligomeric proteins.*

Even though hemoglobin catalyzes no chemical reaction, it binds ligands in the same manner as do enzymes. Since an enzyme cannot catalyze a reaction until after it has bound its **substrate(s)** [the molecule(s) undergoing reaction], the enzyme's catalytic rate varies with its substrate-binding affinity. Consequently, the cooperative binding of O<sub>2</sub> to Hb is taken as a model for the allosteric regulation of enzyme activity. Indeed, in this section, we shall consider several models of allosteric regulation that, for the most part, were formulated to explain the O<sub>2</sub>-binding properties of Hb. Following this, we shall compare these models with the realities of Hb behavior.

### A. The Adair Equation

The derivation of the Hill equation (Section 10-1B) is predicated on the assumption of all-or-none O<sub>2</sub> binding. The observation of partially oxygenated Hb molecules, however, led Gilbert Adair, in 1924, to propose that the binding of ligands to proteins occurs sequentially with dissociation constants that are not necessarily equal. The expression for the saturation function under this model is straightforwardly derived.

For a protein such as Hb with four ligand-binding sites, the reaction sequence is

where the  $K_i$  are the **macroscopic** or **apparent dissociation constants** for binding the  $i$ th ligand to the protein,

$$K_i = \frac{[ES_{i-1}][S]}{[ES_i]} \quad [10.14]$$

and the  $k_i$  are the **microscopic** or **intrinsic dissociation constants**, that is, the individual dissociation constants for the ligand-binding sites. The intrinsic dissociation constants are equal to the apparent dissociation constants multiplied by **statistical factors**,  $4, \frac{3}{2}, \frac{2}{3},$  and  $\frac{1}{4}$ , that account for the number of ligand-binding sites on the protein molecule. The statistical factor 4 derives from the fact that a tetrameric protein E bears four sites that can bind ligand to form ES (that is, the concentration of ligand-binding sites is  $4[E]$ ) but only one site from which ES can dissociate ligand to form E (that is, the concentration of bound ligand is  $1[E]$ ); the statistical factor  $\frac{3}{2}$  is a result of there being three remaining sites on ES that can bind ligand to form ES<sub>2</sub> and two sites from which ES<sub>2</sub> can dissociate ligand to form ES; etc. In general, for a protein with  $n$  equivalent binding sites:

$$k_i = \frac{(n-i+1)[ES_{i-1}][S]}{i[ES_i]} = \left(\frac{n-i+1}{i}\right)K_i \quad [10.15]$$

since  $(n-i+1)[ES_{i-1}]$  is the concentration of free ligand-binding sites in ES<sub>*i-1*</sub> and  $i[ES_i]$  is the concentration of bound ligand on ES<sub>*i*</sub>. Therefore, solving sequentially for the concentration of each protein-ligand species in a tetrameric protein, we obtain:

$$\begin{aligned} [ES] &= [E][S]/K_1 = 4[E][S]/k_1 \\ [ES_2] &= [ES][S]/K_2 = \frac{3}{2}[ES][S]/k_2 = 6[E][S]^2/k_1k_2 \\ [ES_3] &= [ES_2][S]/K_3 = \frac{2}{3}[ES_2][S]/k_3 = 4[E][S]^3/k_1k_2k_3 \\ [ES_4] &= [ES_3][S]/K_4 = \frac{1}{4}[ES_3][S]/k_4 = [E][S]^4/k_1k_2k_3k_4 \end{aligned}$$

The fractional saturation of ligand binding, the fraction of occupied ligand-binding sites divided by the total concentration of ligand-binding sites, is expressed

$$Y_S = \frac{[ES] + 2[ES_2] + 3[ES_3] + 4[ES_4]}{4([E] + [ES] + [ES_2] + [ES_3] + [ES_4])} \quad [10.16]$$

so that, substituting in the above relationships and canceling terms, we obtain

$$Y_S = \frac{\frac{[S]}{k_1} + \frac{3[S]^2}{k_1k_2} + \frac{3[S]^3}{k_1k_2k_3} + \frac{[S]^4}{k_1k_2k_3k_4}}{1 + \frac{4[S]}{k_1} + \frac{6[S]^2}{k_1k_2} + \frac{4[S]^3}{k_1k_2k_3} + \frac{[S]^4}{k_1k_2k_3k_4}} \quad [10.17]$$

This is the **Adair equation** for four ligand-binding sites. Equations describing ligand binding to proteins with different numbers of binding sites are similarly derived.

If the microscopic dissociation constants of the Adair equation are not equal, the fractional saturation curve will

**Table 10-2 Adair Constants for Hemoglobin A at pH 7.40**

Solution	$k_1$ (torr)	$k_2$ (torr)	$k_3$ (torr)	$k_4$ (torr)
Stripped	8.8	6.1	0.85	0.25
0.1M NaCl	41.	13.	12.	0.14
2 mM BPG	74.	112.	23.	0.24
0.1M NaCl + 2 mM BPG	97.	43.	119.	0.09

Source: Tyuma, I., Imai, K., and Shimizu, K., *Biochemistry* **12**, 1493, 1495 (1973).

describe cooperative ligand binding. Decreasing and increasing values of these constants lead to positive and negative cooperativity, respectively. Of course, the values of the microscopic dissociation constants may also alternate so that, for example,  $k_1 < k_2 > k_3 < k_4$ .

In our discussion of the  $O_2$ -dissociation curve of Hb (Section 10-1B), we have seen how its values of  $k_1$  and  $k_4$  may be obtained by extrapolating the lower and upper asymptotes of the Hill plot to the  $\log pO_2$  axis. The remaining microscopic dissociation constants can be evaluated by fitting Eq. [10.17] to the Hill plot. The values of these **Adair constants** for Hb are given in Table 10-2. Note that  $k_4$  is relatively insensitive to the presence of BPG. Hb therefore binds and releases its last  $O_2$  almost independently of the BPG concentration.

Although the Adair equation is the most general relationship describing ligand binding to a protein and is widely used to do so, it provides no physical insight as to why the various microscopic dissociation constants differ from each other. Yet, if the protein consists, as so many do, of identical subunits that are symmetrically related, it is desirable to understand how ligand binding at one site influences the ligand-binding affinity at a seemingly identical site. This need led to the development of models for ligand binding that rationalize how the binding sites of oligomeric proteins can exhibit different affinities. Two of these models are described in the following sections.

### B. The Symmetry Model

Perhaps the most elegant model for describing cooperative ligand binding to a protein is the **symmetry model** of allosterism, which was formulated in 1965 by Jacques Monod, Jeffries Wyman, and Jean-Pierre Changeux. This model, alternatively termed the **MWC model**, is defined by the following rules:

1. An allosteric protein is an oligomer of protomers that are symmetrically related (for hemoglobin, we shall assume, for the sake of algebraic simplicity, that all four subunits are functionally identical).

2. Each protomer can exist in (at least) two conformational states, designated T and R; these states are in equilibrium whether or not ligand is bound to the oligomer.

3. The ligand can bind to a protomer in either conformation. *Only the conformational change alters the affinity of a protomer for the ligand.*

4. *The molecular symmetry of the protein is conserved during conformational change.* Protomers must therefore change conformation in a concerted manner, which implies that the conformation of each protomer is constrained by its association with the other protomers; in other words, there are no oligomers that simultaneously contain R- and T-state protomers.

For a ligand S and an allosteric protein consisting of  $n$  protomers, these rules imply the following equilibria for conformational conversion and ligand-binding reactions (for the sake of brevity,  $T_i \equiv TS_i$  and  $R_i \equiv RS_i$ ).

This is illustrated in Fig. 10-28 for a tetramer.

**Figure 10-28** The species and reactions permitted under the **symmetry model of allosterism**. Squares and circles represent T- and R-state protomers, respectively.

The equilibrium constant  $L$  for the conformational interconversion of the oligomeric protein in the absence of ligand is expressed

$$L = \frac{[T_0]}{[R_0]} \quad [10.19]$$

The microscopic dissociation constant for the R state,  $k_R$ , which according to Rule 3 is independent of the number of ligands bound to R, is expressed according to Eq. [10.15]:

$$k_R = \left( \frac{n-i+1}{i} \right) \frac{[R_{i-1}][S]}{[R_i]} \quad (i = 1, 2, 3, \dots, n) \quad [10.20]$$

The microscopic dissociation constant for ligand binding to the T state,  $k_T$ , is similarly expressed. The fractional saturation,  $Y_s$ , for ligand binding is

$$Y_s = \frac{([R_1] + 2[R_2] + \dots + n[R_n]) + ([T_1] + 2[T_2] + \dots + n[T_n])}{n\{([R_0] + [R_1] + \dots + [R_n]) + ([T_0] + [T_1] + \dots + [T_n])\}} \quad [10.21]$$

We shall make two definitions:

$$\alpha = [S]/k_R \quad c = k_R/k_T$$

$\alpha$  may be considered a normalized ligand concentration.  $c$  is the ratio of the ligand-binding dissociation constants;  $c$  increases with the ligand-binding affinity of the T state relative to that of the R state. Then, combining the foregoing relationships as is shown in Section A of the Appendix to this chapter, we obtain the equation describing the symmetry model of allosterism for homotropic interactions:

$$Y_s = \frac{\alpha(1+\alpha)^{n-1} + Lc\alpha(1+c\alpha)^{n-1}}{(1+\alpha)^n + L(1+c\alpha)^n} \quad [10.22]$$

Note that this equation depends on three parameters,  $\alpha$ ,  $c$ , and  $L$ , which are, respectively, the normalized ligand concentration, the relative affinities of the T and R states for

ligand, and the relative stabilities of the T and R states. In contrast, the Hill equation (Section 10-1B) has but two parameters,  $K$  and  $n$ , whereas the number of parameters in the Adair equation is equal to the number of ligand-binding sites on the protein.

### a. Homotropic Interactions

Let us examine the nature of the symmetry model by plotting Eq. [10.22] for a tetramer ( $n = 4$ ) as a function of  $\alpha$  for different values of the parameters  $L$  and  $c$  (Fig. 10-29). Three major points are evident from an inspection of these plots:

1. The degree of upward curvature exhibited by the initial sections of these sigmoid curves is indicative of their level of cooperativity.

2. When only the R state binds ligand ( $c = 0$ ), the ligand-binding cooperativity increases as the oligomer's conformational preference for the non-ligand-binding T state increases ( $L$  increases; Fig. 10-29a). For high  $L$  values, if a single ligand is to bind, it must "force" the protein into its less preferred R state. The requirement that all protomers change their conformational states in a concerted manner causes the remaining three ligand-binding sites to become available. The binding of the first ligand therefore promotes the binding of subsequent ligands, which is the essence of a positive homotropic effect. Note that cooperativity and ligand-binding affinity are different quantities; in fact, for  $c = 0$ , curves indicative of high ligand-binding affinity (those with low  $L$ ) exhibit low cooperativity and vice versa.

3. When the T state is highly preferred ( $L$  is large), ligand-binding cooperativity increases with the R state's ligand-binding affinity relative to that of the T state (decreasing  $c$ ; Fig. 10-29b). At low ligand concentrations (low  $\alpha$ ) the amount of ligand bound ( $Y_s$ ) increases with the ligand-binding affinity of the T state (increasing  $c$ ) since the protein is largely in the T state. As  $\alpha$  increases, however, the amount of ligand bound to the intrinsically less stable R state eventually surpasses that of the T state, thereby resulting in a cooperative effect. This is because the free

**Figure 10-29** Symmetry model saturation function curves for tetramers according to Eq. [10.22]. Here  $L = [T_0]/[R_0]$ ,  $c = k_R/k_T$ , and  $\alpha = [S]/k_R$ . (a) Their variation with  $L$  when  $c = 0$ . (b) Their variation with  $c$  when  $L = 1000$ . [After Monod, J., Wyman, J., and Changeux, J.P., *J. Mol. Biol.* **12**, 92 (1965).]

energy of ligand binding stabilizes the R state with respect to the T state.

### b. Heterotropic Interactions

The symmetry model of allosterism is also capable of accounting for heterotropic effects. This comes about by assuming that each protomer has specific and independent binding sites for the three types of ligands: a substrate, S, that for simplicity let us assume binds only to the R state ( $c = 0$ ); an **activator**, A, that also binds only to the R state; and an **inhibitor**, I, that binds only to the T state (Fig. 10-30). Then, through the derivation in Section B of the Appendix to this chapter, we obtain a more general equation for the symmetry model that describes heterotropic interactions as well as homotropic interactions:

$$Y_S = \frac{\alpha(1 + \alpha)^{n-1}}{(1 + \alpha)^n + \frac{L(1 + \beta)^n}{(1 + \gamma)^n}} \quad [10.23]$$

where  $\alpha = [S]/k_R$  as before and, analogously,  $\beta = [I]/k_I$  and  $\gamma = [A]/k_A$ .

Note that this equation differs from Eq. [10.22] for  $c = 0$  only in that the second term in the denominator is modulated by terms related to the amounts of activator and inhibitor bound to the oligomer.

Figure 10-31 indicates the consequences of effector binding to a tetramer that follows this model:

1. Activator binding ( $\gamma > 0$ ) increases the concentration of the substrate-binding R state (the second term in the denominator of Eq. [10.23] decreases) because it is the only state capable of binding activator. *The presence of activator therefore increases the protein's substrate-binding affinity* (a positive heterotropic effect), although it decreases the protein's degree of substrate-binding cooperativity (compare Curves 1 and 2 in Fig. 10-31). (Note: There is nothing in the derivation of Eq. [10.23] that differentiates the roles of substrate and activator; consequently, the substrate and the activator each bind to the protein with a positive homotropic effect as well as being positive heterotropic effectors of each other.)

2. *The presence of inhibitor ( $\beta > 0$ ), which only binds to the T state, reduces the binding affinity for substrate* (a negative heterotropic effect) by increasing the concentration of the T state (the second term in the denominator of Eq. [10.23] increases). Therefore, since substrate must “work harder” to convert the oligomer to the substrate-binding R state, inhibitor increases the cooperativity of substrate binding (compare Curves 2 and 3 of Fig. 10-31), as well as that for activator binding.

The model derived here is a rather simple one. In a more realistic but algebraically much more complicated symmetry model, all types of ligands would bind to both conformational states of the oligomer. Nevertheless, this model demonstrates that *both homotropic and heterotropic effects can be explained solely by the requirement that the molecular symmetry of the oligomer be conserved rather than by the existence of any direct interactions between ligands*. In Section 10-4D, we compare the theoretical predictions of

**Figure 10-30** Heterotropic interactions in the symmetry model of allosterism. Heterotropic effects arise when substrates and activators bind exclusively (or at least preferentially) to the R state (right), and inhibitors bind exclusively (or at least preferentially) to the T state (left). The binding of substrate and/or activator to the oligomer therefore facilitates the further binding of substrate and activator. Conversely, the binding of inhibitor prevents (or at least inhibits) the oligomer from binding substrate or activator.

the symmetry model with our experimentally based model of hemoglobin oxygen binding.

### C. The Sequential Model

The symmetry model provides a reasonable rationalization for the ligand-binding properties of many proteins. There are, however, several valid objections to it. Foremost of these is that it is difficult to believe that oligomeric symmetry is invariably preserved in all proteins so that there are never any hybrid conformations such as  $R_{n-2}T_2$ . Furthermore,

**Figure 10-31** The effects of allosteric activator ( $\gamma = [A]/k_A$ ) and inhibitor ( $\beta = [I]/k_I$ ) on the shape of the fractional saturation curve for substrate ( $\alpha = [S]/k_R$ ) according to Eq. [10.23] for tetramers. [After Monod, J., Wyman, J., and Changeux, J.-P., *J. Mol. Biol.* **12**, 94 (1965).]

there are well-established instances of negative homotropic effects (e.g., in the GroEL–GroES complex, the binding of ATP to the cis ring of GroEL prevents ATP from binding to the trans ring; Section 9-2Cd), although the symmetry model, which permits only positive homotropic effects, is unable to account for them.

The symmetry model implicitly assumes Emil Fischer's "lock-and-key" model of ligand binding in which ligand-binding sites of proteins are rigid and complementary in shape to their ligand (Fig. 10-32, left). A more sophisticated extension of the lock-and-key model, known as the **induced-fit hypothesis**, postulates that *a flexible interaction between ligand and protein induces a conformational change in the protein, which results in its increased ligand-binding affinity* (Fig. 10-32, right). The observation, through X-ray crystal structure analysis, that such conformational changes occur in numerous proteins has established the validity of the induced-fit hypothesis.

Daniel Koshland, George Némethy, and David Filmer adapted the induced-fit hypothesis to explain allosteric effects. In the resulting **sequential model** (alternatively, the **induced-fit** or **KNF model**), *ligand binding induces a conformational change in a subunit; cooperative interactions arise through the influence that these conformational changes have on neighboring subunits* (Fig. 10-33). If, for example, they increase the neighbor's ligand-binding affinity, then ligand binding is positively cooperative. *The strengths of these interactions depend on the degree of mechanical coupling*

**Figure 10-32** Models of ligand binding. In the lock-and-key mechanism of ligand binding (left), proteins are postulated to have preformed ligand-binding sites that are complementary in shape to their ligand. Under the induced-fit mechanism, a protein does not have this complementary binding site in the absence of ligand (right). Rather, the ligand induces a conformational change at the binding site that results in the complementary interaction.

between subunits. In the limit of very strong coupling, conformational changes become concerted, so that the oligomer maintains its symmetry (the symmetry model). With looser coupling, however, conformational changes occur sequentially as more and more ligand is bound (Fig. 10-34). Thus, *the essence of the sequential model is that a protein's ligand-binding affinity varies with its number of bound ligands, whereas in the symmetry model this affinity depends only on the protein's quaternary state*.

The degree of coupling between oligomer subunits depends on how these subunits are arranged, that is, on the protein's symmetry. Consequently, in the sequential model, the fractional saturation has a different algebraic form for each oligomeric symmetry. The form of the Adair equation (Eq. [10.17] for a tetramer) similarly depends on the number of subunits in the protein. In fact, the sequential model of allosterism may be considered an extension of the Adair model that provides a physical rationalization for the values of its microscopic dissociation constants,  $k_i$ .

#### D. Hemoglobin Cooperativity

Hemoglobin's fractional saturation curve is closely approximated by both the symmetry model and the sequential model (Fig. 10-35). Clearly such curves cannot by themselves be used to differentiate between these two models, if, in fact, either is correct. It is of interest, however, to compare these models with the mechanistic model of Hb we developed in Section 10-2C.

Hb, of course, is not composed of identical subunits, as the symmetry model demands. At least to a first approximation, however, the functional differences of Hb's closely related  $\alpha$  and  $\beta$  subunits may be ignored (although their structural differences are essential to the molecular mechanism of Hb cooperativity). *To this approximation, Hb largely follows the symmetry model, although it also exhibits some features of the sequential model*. The quaternary T  $\rightarrow$  R conformation change is concerted as the symmetry model requires. Yet ligand binding to the T state does cause small tertiary structural changes as the sequential model predicts. This phenomenon is evident in the X-ray structure of crystals of human Hb whose  $\alpha$  subunits are fully oxygenated and whose  $\beta$  subunits are unliganded. This particular crystal form constrains

**Figure 10-33** The sequential model of allosterism. Substrate binding to the low-affinity T state induces conformational changes in unliganded subunits that give them ligand-binding affinities between those of the low-affinity T state and the high-affinity R state.

**Figure 10-34** Sequential binding of ligand in the sequential model of allosterism. Ligand binding progressively induces conformational changes in the subunits, with the greatest changes occurring in those subunits that have bound ligand. The coupling

between subunits is not necessarily of sufficient strength to maintain the symmetry of the oligomer as it is in the symmetry model.

the partially liganded Hb to remain in the T state. Nevertheless, its  $\alpha$  subunit Fe's are 0.15 Å closer to the still domed porphyrins than they are in deoxyHb (25% of the total distance moved in the T  $\rightarrow$  R transition). *Such tertiary structural changes are undoubtedly responsible for the buildup of strain that eventually triggers the T  $\rightarrow$  R transition.*

A more telling but more difficult question to answer is does ligand-binding cooperativity in Hb arise solely from the T  $\rightarrow$  R transition, in agreement with the symmetry model, or do the T and R states themselves exhibit at least some degree of cooperativity, in accord with the sequential model? Put another way, does the ligand-binding affinity of Hb subunits depend only on Hb's quaternary state (symmetry model) or does this affinity vary with the number of ligands bound to Hb (sequential model)? Although this matter has been under experimental scrutiny and a subject of spirited debate for over four decades, it is still not fully resolved. For example, the determination, by Andrea Mozzarelli and Eaton, of the Hill plot of the above-described single crystals of T-state Hb via sophisticated optical spectroscopic techniques is indicative of noncooperative ligand binding, in accord with the symmetry model. Likewise, time-resolved spectroscopic measurements covering the picosecond to

microsecond time scales after ligand binding was initiated indicate that the conformational changes that Hb initially undergoes on binding ligand are consistent with the symmetry model. However, detailed thermodynamic analysis, by Gary Ackers, of the interactions associated with the formation of each of Hb's 10 different ligation microstates (Fig. 10-36) indicates that the Hb tetramer undergoes a T  $\rightarrow$  R transition

**Figure 10-35** The sequential and the symmetry models of allosterism can provide equally good fits to the measured  $O_2$ -dissociation curve of Hb. [After Koshland, D.E., Jr., Némethy, G., and Filmer, D., *Biochemistry* **5**, 382 (1966).]

**Figure 10-36** Free energy penalties for binding  $O_2$  to various ligation states of Hb tetramers relative to  $O_2$ -binding to noncooperative Hb  $\alpha\beta$  dimers. Only the ten unique ligation states are diagrammed (an additional six states are related to those shown by Hb's 2-fold symmetry). Penalties (in  $\text{kJ} \cdot \text{mol}^{-1}$ ) for individual binding steps are shown beside the arrows. Cumulative free energy penalties are shown to the left of each Hb tetramer state. Ligation states that predominantly assume the T state are blue and those that predominantly assume the R state are red. The preferred pathways, those in which the free energy penalty of ligand binding progressively decreases with each successively bound ligand (those with all solid arrows), pass through the T state in which  $O_2$  is bound to both sites on one  $\alpha\beta$  dimer before its conversion to the R state. Note that the T  $\rightarrow$  R transition predominantly occurs via pathways in which at least one subunit in each  $\alpha\beta$  protomer is liganded. [Based on data from Ackers, G.K., *Adv. Prot. Chem.* **51**, 193 (1998).]

only when at least one liganding site on each of its  $\alpha\beta$  protomers is occupied. This heretofore unrecognized symmetry is inconsistent with the symmetry model. Moreover, as Takashi Yonetani has shown, heterotropic effectors such as BPG can decrease Hb's oxygen affinity without changing its quaternary

state. Evidently, cooperativity arises both from concerted quaternary switching (as called for by the symmetry model) and from sequential modulation of ligand binding within each quaternary state through ligand-induced alterations in tertiary structure (in accord with the sequential model).

## APPENDIX Derivations of Symmetry Model Equations

### A. Homotropic Interactions—Equation [10.22]

The fractional saturation  $Y_S$  for ligand binding is expressed:

$$Y_S = \frac{([R_1] + 2[R_2] + \cdots + n[R_n]) + ([T_1] + 2[T_2] + \cdots + n[T_n])}{n\{([R_0] + [R_1] + \cdots + [R_n]) + ([T_0] + [T_1] + \cdots + [T_n])\}} \quad [10.21]$$

Defining  $\alpha = [S]/k_R$  and  $c = k_R/k_T$ , and using Eq. [10.20] to substitute  $[R_{n-1}]$  for  $[R_n]$ ,  $[R_{n-2}]$  for  $[R_{n-1}]$  etc., the terms enclosed by the first set of parentheses in the numerator of Eq. [10.21] are reduced to

$$\begin{aligned} [R_0] & \left\{ n\alpha + \frac{2n(n-1)\alpha^2}{2} + \cdots + \frac{n n! \alpha^n}{n!} \right\} \\ & = [R_0] \alpha n \left\{ 1 + \frac{2(n-1)\alpha}{2} + \cdots + \frac{n(n-1)! \alpha^{n-1}}{n(n-1)!} \right\} \\ & = [R_0] \alpha n (1 + \alpha)^{n-1} \end{aligned}$$

and similarly, the terms in the first set of parentheses of the denominator of Eq. [10.21] become

$$[R_0] \left\{ 1 + n\alpha + \cdots + \frac{n! \alpha^n}{n!} \right\} = [R_0] (1 + \alpha)^n$$

Likewise, the terms in the second set of parentheses of the numerator and the denominator of Eq. [10.21] assume the respective forms

$$[T_0] ([S]/k_T) n (1 + [S]/k_T)^{n-1} = L [R_0] c \alpha n (1 + c\alpha)^{n-1}$$

and

$$[T_0] (1 + [S]/k_T)^n = L [R_0] (1 + c\alpha)^n$$

Accordingly,

$$Y_S = \frac{[R_0] \alpha n (1 + \alpha)^{n-1} + L [R_0] c \alpha n (1 + c\alpha)^{n-1}}{n\{[R_0] (1 + \alpha)^n + L [R_0] (1 + c\alpha)^n\}}$$

which, on cancellation of terms, yields the equation describing the symmetry model for homotropic interactions:

$$Y_S = \frac{\alpha(1 + \alpha)^{n-1} + Lc\alpha(1 + c\alpha)^{n-1}}{(1 + \alpha)^n + L(1 + c\alpha)^n} \quad [10.22]$$

### B. Heterotropic Interactions—Equation [10.23]

For an oligomer that binds activator A and substrate S to only its R state, and inhibitor I to only its T state, the fractional saturation for substrate,  $Y_S$ , the fraction of substrate-binding sites occupied by substrate, is expressed:

$$Y_S = \frac{\sum_{i=1}^n \sum_{j=0}^n i [R_{i,j}]}{n \left( \sum_{i=0}^n \sum_{j=0}^n [R_{i,j}] + \sum_{k=0}^n [T_k] \right)}$$

Here the subscripts  $i$ ,  $j$ , and  $k$  indicate the respective numbers of S, A, and I molecules that are bound to one oligomer; that is,  $R_{i,j} \equiv RS_i A_j$  and  $T_k \equiv TI_k$ . Then defining  $\alpha = [S]/k_R$  and following the foregoing derivation of Eq. [10.22]:

$$Y_S = \frac{\left( \sum_{j=0}^n [R_{0,j}] \right) \alpha n (1 + \alpha)^{n-1}}{n \left\{ \left( \sum_{j=0}^n [R_{0,j}] \right) (1 + \alpha)^n + \sum_{k=0}^n [T_k] \right\}} = \frac{\alpha(1 + \alpha)^{n-1}}{(1 + \alpha)^n + L'}$$

where

$$L' = \sum_{k=0}^n [T_k] / \sum_{j=0}^n [R_{0,j}]$$

In analogy with the definition of  $\alpha$ , we define  $\beta = [I]/k_I$  and  $\gamma = [A]/k_A$ , and again follow the derivation of Eq. [10.22] to obtain

$$\sum_{k=0}^n [T_k] = [T_0] (1 + \beta)^n$$

and

$$\sum_{j=0}^n [R_{0,j}] = [R_{0,0}] (1 + \gamma)^n$$

so that

$$L' = \frac{L(1 + \beta)^n}{(1 + \gamma)^n}$$

The symmetry model equation extended to include heterotropic effects is therefore expressed

$$Y_S = \frac{\alpha(1 + \alpha)^{n-1}}{(1 + \alpha)^n + \frac{L(1 + \beta)^n}{(1 + \gamma)^n}} \quad [10.23]$$

## CHAPTER SUMMARY

**1 Hemoglobin Function** The heme group in myoglobin and in each subunit of hemoglobin reversibly binds  $O_2$ . In deoxyHb, the Fe(II) is five-coordinated to the four pyrrole nitrogen atoms of the protoporphyrin IX and to the protein's proximal His. On oxygenation,  $O_2$  becomes the sixth ligand of Fe(II). Mb has a hyperbolic fractional saturation curve (Hill constant,  $n = 1$ ). However, that of Hb is sigmoidal ( $n \approx 2.8$ ) as a consequence of its cooperative  $O_2$  binding: Hb binds its fourth  $O_2$  with 100-fold greater affinity than its first  $O_2$ . The variation of  $O_2$  affinity with pH, the Bohr effect, causes Hb to release  $O_2$  in the tissues in response to the binding of protons liberated by the hydration of  $CO_2$  to  $HCO_3^-$ . Hb facilitates the transport of  $CO_2$ , both directly, by binding  $CO_2$  as N-terminal carbamate, and indirectly, by increasing the concentration of  $HCO_3^-$  through the Bohr effect. The presence of BPG in erythrocytes, which only binds to deoxyHb, further modulates the  $O_2$  affinity of Hb. Short-term high-altitude adaptation results from an increase of BPG concentration in the erythrocytes, which increases the amount of  $O_2$  delivered to the tissues by decreasing hemoglobin's  $O_2$  affinity.

**2 Structure and Mechanism** The  $\alpha$  and  $\beta$  subunits of Hb consist mostly of seven or eight consecutive helices arranged to form a hydrophobic pocket that almost completely envelops the heme. Oxygen binding moves the Fe(II) from a position  $\sim 0.6 \text{ \AA}$  out of the heme plane on the side of the proximal His to the center of the heme, thereby relieving the steric interference that would otherwise occur between the bound  $O_2$  and the porphyrin. The Fe(II) pulls the attached proximal His after it in a motion that can only occur if its imidazole ring reorients so as to avoid collision with the heme. In the T  $\rightarrow$  R conformational transition, the symmetry equivalent  $\alpha_1C-\beta_2FG$  and  $\alpha_2C-\beta_1FG$  contacts simultaneously shift between two stable positions. Intermediate positions are sterically prevented, so that these contacts act as a two-position conformational switch.

The Perutz mechanism of  $O_2$  binding proposes that the low  $O_2$  affinity of the T state arises from strain that prevents the Fe(II) from moving into the heme plane to form a strong Fe— $O_2$  bond. This strain is relieved by the concerted  $4^\circ$  shift of the Hb molecule to the high  $O_2$  affinity R state. The quaternary shift is opposed by a network of salt bridges in the T state that involve the C-terminal carboxyl groups and that are ruptured in the R state. The stability of the R state relative to the T state increases with the degree of oxygenation as a result of the strain of binding  $O_2$  in the T state. The existence of this strain has been demonstrated through the breakage of the Fe(II)–proximal His bond on hemoglobin's simultaneous binding of IHP, a tight-binding BPG analog that forces Hb into the T state, and NO, a strong ligand that forces Hb into the R state. Conversely, mutagenically detaching the proximal His from the protein eliminates most of hemoglobin's cooperativity.

The Bohr effect results from increases in the  $pK$ 's of the  $\alpha$  N-terminal amino group and His 146 $\beta$  on forming the T-state salt bridges. Surface-exposed His residues also participate in the Bohr effect. BPG binding occurs in the central cavity of T-state Hb through several salt bridges. The distal His residue protects deoxyHb from autooxidation by taking up the protons that would otherwise catalyze the oxidation of the heme Fe.

**3 Abnormal Hemoglobins** Over 1000 mutant varieties of Hb are known. About half of them are innocuous because they result in surface residue changes. However, alterations of internal residues often disrupt the structure of Hb, which causes hemolytic anemia. Changes at the  $O_2$ -binding site that stabilize the Fe(III) state eliminate  $O_2$  binding to these subunits, which results in cyanosis. Mutations affecting subunit interfaces may stabilize either the R state or the T state, which, respectively, increase and decrease hemoglobin's  $O_2$  affinity. Sickle-cell anemia is caused by the homozygous Hb mutant Glu 6 $\beta$   $\rightarrow$  Val, which promotes the gelation of the resulting deoxyHbS to form rigid 14-strand fibers that deform erythrocytes. Under gelation conditions, fiber growth occurs via a two-stage nucleation mechanism, resulting in a delay time that varies with the 30th to 50th power of the initial HbS concentration. Agents that increase this delay time to longer than the transit times of erythrocytes through the capillaries should therefore prevent sickle-cell crises and thus relieve the symptoms of sickle-cell anemia.

**4 Allosteric Regulation** The Adair equation rationalizes the  $O_2$ -binding cooperativity of Hb by assigning a separate dissociation constant to each  $O_2$  bound. Positive cooperativity results if these constants decrease sequentially. However, the Adair equation offers no physical insight as to why this occurs. The symmetry model proposes that symmetrical oligomers can exist in one of two conformational states, R and T, that differ in ligand-binding affinity. Ligand binding to the high-affinity state forces the oligomer to assume this conformation, which facilitates the binding of additional ligand. This homotropic model is extended to heterotropic effects by postulating that activator and substrate can bind only to the R state and inhibitor can bind only to the T state. The binding of activator forces the oligomer into the R state, which facilitates the binding of substrate and additional activator. The binding of inhibitor, however, forces the oligomer into the T state, which prevents substrate and activator binding. The sequential model postulates that an induced fit between ligand and substrate confers conformational strain on the protein that alters its affinity for binding other ligands without requiring the oligomer to maintain its symmetry. The Perutz mechanism for  $O_2$  binding to Hb is structurally largely consistent with the symmetry model but exhibits some elements of the sequential model. However, Hb's ligand-binding cooperativity is in full accord with the symmetry model.

## PROBLEMS

1. The urge to breathe in humans results from a high blood  $\text{CO}_2$  content; there are no direct physiological sensors of blood  $p\text{O}_2$ . Skindivers often **hyperventilate** (breathe rapidly and deeply for several minutes) just before making a protracted dive in the belief that they will thereby increase the  $\text{O}_2$  content of their blood. This belief results from the fact that hyperventilation represses the breathing urge by expelling significant quantities of  $\text{CO}_2$  from the blood. In light of what you know about the properties of hemoglobin, is hyperventilation a useful procedure? Is it safe? Explain.

2. Explain why the Hill constant,  $n$ , can never be larger than the number of ligand-binding sites on the protein.

\*3. In the Bohr effect, protonation of the N-terminal amino groups of hemoglobin's  $\alpha$  chains is responsible for  $\sim 30\%$  of the 0.6 mol of  $\text{H}^+$  that combine with Hb on the release of 1 mol of  $\text{O}_2$  at pH 7.4. Assuming that this group has  $pK = 7.0$  in oxyHb, what is its  $pK$  in deoxyHb?

4. As one of the favorites to win the La Paz, Bolivia, marathon, you have trained there for the several weeks it requires to become adapted to its 3700-m altitude. A manufacturer of running equipment who sponsors an opponent has invited you for the weekend to a prerace party at a beach house near Lima, Peru, with the assurance that you will be flown back to La Paz at least a day before the race. Is this a token of his respect for you or an underhanded attempt to handicap you in the race? Explain (see Fig. 10-9).

5. In active muscles, the  $p\text{O}_2$  may be 10 torr at the cell surface and 1 torr at the mitochondria (the organelles where oxidative metabolism occurs). How might myoglobin ( $p_{50} = 2.8$  torr) facilitate the diffusion of  $\text{O}_2$  through these cells? Active muscles consume  $\text{O}_2$  much faster than do other tissues. Could myoglobin also be an effective  $\text{O}_2$ -transport protein in other tissues? Explain.

6. Erythrocytes that have been stored for over a week in standard acid-citrate-dextrose medium become depleted in BPG. Discuss the merits of using fresh versus week-old blood in blood transfusions.

7. The following fractional saturation data have been measured for a certain blood sample:

$p\text{O}_2$	$Y_{\text{O}_2}$	$p\text{O}_2$	$Y_{\text{O}_2}$
20	0.14	60	0.59
30	0.26	70	0.66
40	0.39	80	0.72
50	0.50	90	0.76

What are the Hill constant and the  $p_{50}$  of this blood sample? Are they normal?

8. An anemic individual, whose blood has only half the normal Hb content, may appear to be in good health. Yet a normal individual is incapacitated by exposure to sufficient carbon monoxide to occupy half of his/her heme sites ( $p\text{CO}$  of 1 torr for  $\sim 1$  h; CO binds to Hb with 200-fold greater affinity than does  $\text{O}_2$ ). Explain.

\*9. The X-ray structure of Hb Rainier (Tyr 145 $\beta$   $\rightarrow$  Cys) indicates that the mutant Cys residue forms a disulfide bond with Cys 93 $\beta$  of the same subunit. This holds the  $\beta$  subunit's C-terminal residue in a quite different orientation than it assumes in HbA. How would the following quantities for Hb Rainier compare with those of HbA? Explain. (a) The oxygen affinity, (b) the Bohr effect, (c) the Hill constant, and (d) the BPG affinity.

10. The crocodile, which can remain under water without breathing for up to 1 h, drowns its air-breathing prey and then dines at its leisure. An adaptation that aids the crocodile in doing so is that it can utilize virtually 100% of the  $\text{O}_2$  in its blood, whereas humans, for example, can extract only  $\sim 65\%$  of the  $\text{O}_2$  in their blood. Crocodile Hb does not bind BPG. However, crocodile deoxyHb preferentially binds  $\text{HCO}_3^-$ . How does this help the crocodile obtain its dinner?

11. The gelation time of an equimolar mixture of HbA and HbS is less than that of a solution of only HbS in the same concentration

that it has in the mixture. What does this observation imply about the participation of HbA in the gelation of HbS?

**12.** The severely anemic condition of homozygotes for HbS results in an elevated BPG content in their erythrocytes. Discuss whether or not this is a beneficial effect.

**13.** As organizer of an expedition that plans to climb several very high mountains, it is your responsibility to choose its members. Each of the applicants for one of the positions on the team is a heterozygote for one of the following variant hemoglobins: (1) HbS, (2) **Hb Hyde Park** [His F8(92) $\beta$   $\rightarrow$  Tyr], (3) **Hb Riverdale–Bronx** [Gly B6(24) $\beta$   $\rightarrow$  Arg], (4) **Hb Memphis** [Glu B4(23) $\alpha$   $\rightarrow$  Gln], and (5) **Hb Cowtown** [His HC3(146) $\beta$   $\rightarrow$  Leu]. Assuming that all of these candidates are equal in ability at low altitudes, which one would you choose for the position? Explain your reasoning.

**14.** Show that the Adair equation for a tetramer reduces to the Hill equation for  $k_1 \approx k_2 \approx k_3 \gg k_4$  and to a hyperbolic relationship for  $k_1 = k_2 = k_3 = k_4$ .

**15.** Derive the equilibrium constant for the reaction  $R_2 \rightleftharpoons T_2$  for a symmetry model  $n$ -mer in terms of the parameters  $L$ ,  $c$ , and  $\alpha$ .

**\*16.** Derive the equation for the fraction of protein molecules in the R state,  $\bar{R}$ , for the homotropic symmetry model in terms of the parameters  $n$ ,  $L$ ,  $c$ , and  $\alpha$ . Plot this function versus  $\alpha$  for  $n = 4$ ,  $L = 1000$ , and  $c = 0$  and discuss its physical significance.

**17.** In the symmetry model of allosterism, why must an inhibitor (which causes a negative heterotropic effect with the substrate) undergo a positive homotropic effect?

**18.** At low concentrations, the hemoglobin tetramer reversibly dissociates into two  $\alpha_1\beta_1$  dimers. What is the Hill constant for  $O_2$  binding to these dimers? Explain.

**19.** Describe the nature of the allosteric changes (homotropic or heterotropic, positive or negative) that take place in the GroEL/ES system during the various stages of its catalytic cycle (Fig. 9-25).

# Sugars and Polysaccharides

## CHAPTER 11

### 1 Monosaccharides

- A. Classification
- B. Configurations and Conformations
- C. Sugar Derivatives

### 2 Polysaccharides

- A. Carbohydrate Analysis
- B. Disaccharides
- C. Structural Polysaccharides: Cellulose and Chitin
- D. Storage Polysaccharides: Starch and Glycogen
- E. Glycosaminoglycans

### 3 Glycoproteins

- A. Proteoglycans
- B. Bacterial Cell Walls
- C. Glycoprotein Structure and Function
- D. Glycomics

**Carbohydrates** or **saccharides** (Greek: *sakcharon*, sugar) are essential components of all living organisms and are, in fact, the most abundant class of biological molecules. The name carbohydrate, which literally means “carbon hydrate,” stems from their chemical composition, which is roughly  $(C \cdot H_2O)_n$ , where  $n \geq 3$ . The basic units of carbohydrates are known as **monosaccharides**. Many of these compounds are synthesized from simpler substances in a process named **gluconeogenesis** (Section 23-1). Others (and ultimately nearly all biological molecules) are the products of **photosynthesis** (Section 24-3), the light-powered combination of  $CO_2$  and  $H_2O$  through which plants and certain bacteria form “carbon hydrates.” The metabolic breakdown of monosaccharides (Chapters 17 and 21) provides much of the energy used to power biological processes. Monosaccharides are also principal components of nucleic acids (Section 5-1A), as well as important elements of complex lipids (Section 12-1D).

**Oligosaccharides** consist of a few covalently linked monosaccharide units. They are often associated with proteins (**glycoproteins**) and lipids (**glycolipids**) in which they have both structural and regulatory functions (glycoproteins and glycolipids are collectively called **glycoconjugates**). **Polysaccharides** consist of many covalently linked monosaccharide units and have molecular masses ranging well into the millions of daltons. They have indispensable structural functions in all types of organisms but are most conspicuous in plants because **cellulose**, their principal structural material, comprises up to 80% of their dry

weight. Polysaccharides such as **starch** in plants and **glycogen** in animals serve as important nutritional reservoirs.

The elucidation of the structures and functions of carbohydrates has lagged well behind those of proteins and nucleic acids. This can be attributed to several factors. Carbohydrate compounds are often heterogeneous, both in size and in composition, which greatly complicates their physical and chemical characterization. They are not subject to the types of genetic analysis that have been invaluable in the study of proteins and nucleic acids because saccharide sequences are not genetically specified but are built up through the sequential actions of specific enzymes (Section 23-3B). Furthermore, it has been difficult to establish assays for the biological activities of polysaccharides because of their largely passive roles. Nevertheless, it is abundantly clear that carbohydrates are essential elements in many, if not most, biological processes.

In this chapter, we explore the structures, chemistry, and, to a limited extent, the functions of carbohydrates, alone and in association with proteins. Glycolipid structures are considered in Section 12-1D. The biosynthesis of complex carbohydrates is discussed in Section 23-3.

## 1 MONOSACCHARIDES

Monosaccharides or **simple sugars** are aldehyde or ketone derivatives of straight-chain polyhydroxy alcohols containing at least three carbon atoms. Such substances, for example, **D-glucose** and **D-ribulose**, cannot be hydrolyzed to form simpler saccharides.

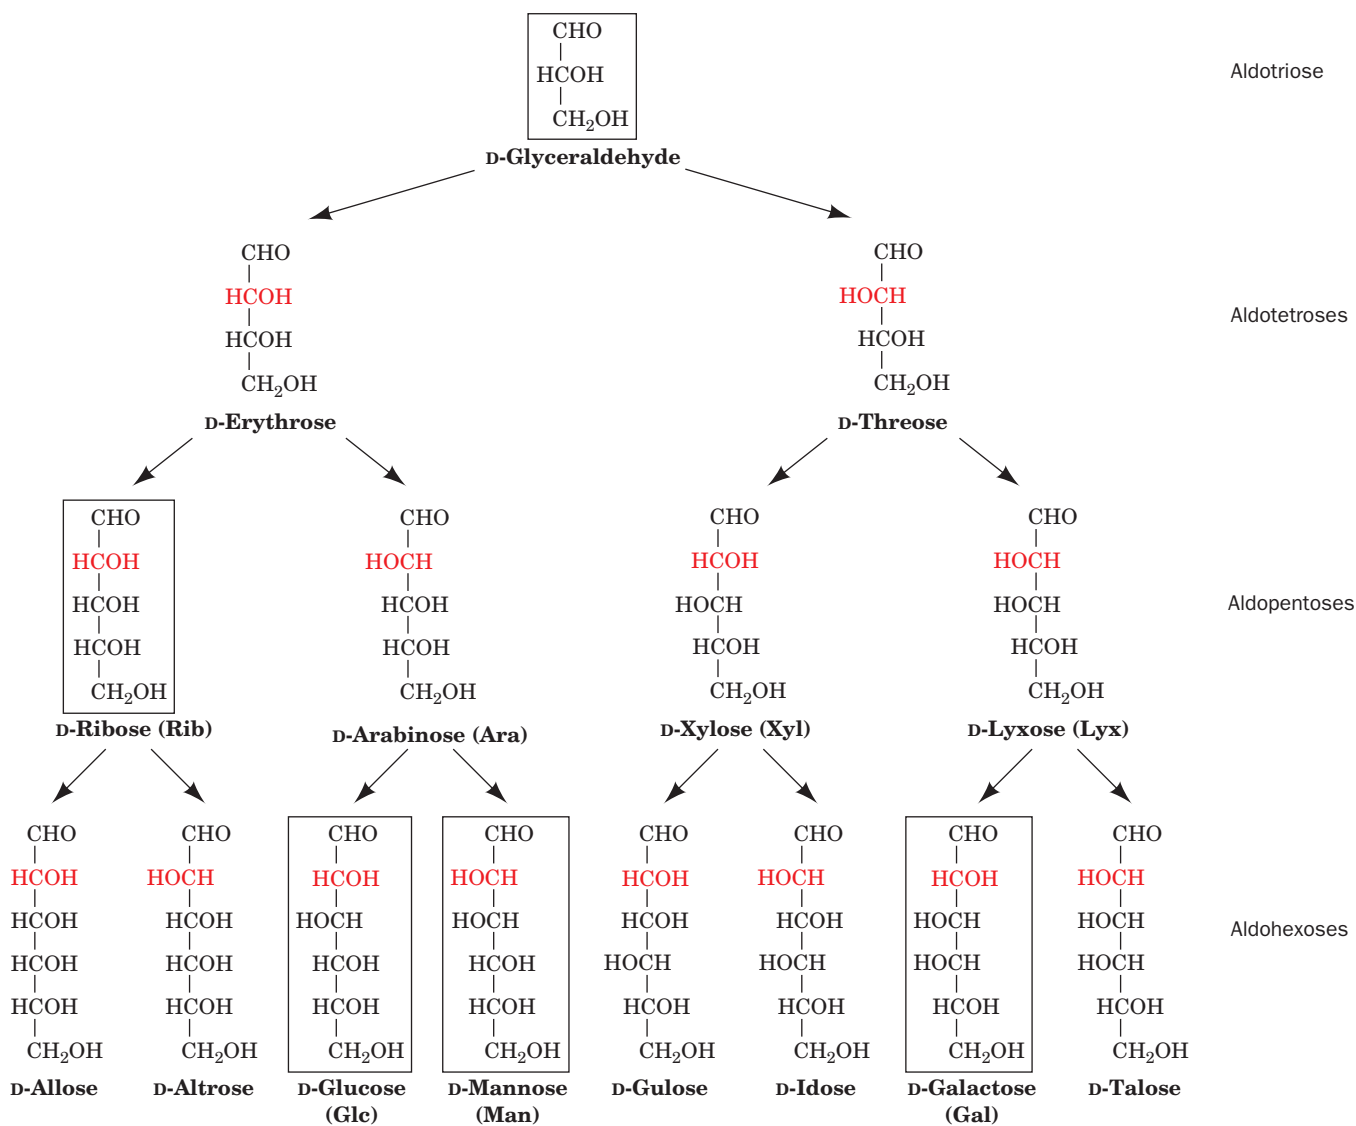

In this section, the structures of the monosaccharides and some of their biologically important derivatives are discussed.

### A. Classification

Monosaccharides are classified according to the chemical nature of their carbonyl group and the number of their C atoms. If the carbonyl group is an aldehyde, as in glucose, the sugar is an **aldose**. If the carbonyl group is a ketone, as in ribulose, the sugar is a **ketose**. The smallest monosaccharides, those with three carbon atoms, are **trioses**. Those with four, five, six, seven, etc., C atoms are, respectively, **tetroses**, **pentoses**, **hexoses**, **heptoses**, etc. These terms may be combined so that, for example, glucose is an **aldohexose**, whereas ribulose is a **ketopentose**.

Examination of D-glucose's molecular formula indicates that all but two of its six C atoms—C1 and C6—are chiral centers, so that D-glucose is one of  $2^4 = 16$  stereoisomers that comprise all possible aldohexoses. In general,  $n$ -carbon aldoses have  $2^{n-2}$  stereoisomers. The stereochemistry and names of the D-aldoses are presented in Fig. 11-1. Emil

Fischer elucidated these configurations for the aldohexoses in 1896. According to the Fischer convention (Section 4-2B), *D* sugars have the same absolute configuration at the asymmetric center farthest removed from their carbonyl group as does *D*-glyceraldehyde. The L sugars, in accordance with this convention, are mirror images of their D counterparts, as is shown below in Fischer projection for glucose.

**Figure 11-1** The stereochemical relationships, shown in Fischer projection, among the D-aldoses with three to six carbon atoms. The arrows indicate stereochemical relationships (not biosynthetic reactions). The configuration about C2 (red)

distinguishes the members of each pair. The L- counterparts of these 15 sugars are their mirror images. The biologically most common aldoses are boxed.

Sugars that differ only by the configuration about one C atom are known as **epimers** of one another. Thus D-glucose and **D-mannose** are epimers with respect to C2, whereas D-glucose and **D-galactose** are epimers with respect to C4 (Fig. 11-1). However, D-mannose and D-galactose are not epimers of each other because they differ in configuration about two of their C atoms.

*D-Glucose is the only aldose that commonly occurs in nature as a monosaccharide.* However, it and several other monosaccharides including D-glyceraldehyde, D-ribose, D-mannose, and D-galactose are important components of larger biological molecules. L Sugars are biologically much less abundant than D sugars.

The position of their carbonyl group gives ketoses one less asymmetric center than their isomeric aldoses (e.g., compare D-fructose and D-glucose). *n*-Carbon ketoses therefore have  $2^{n-3}$  stereoisomers. Those with their ketone

function at C2 are the most common form (Fig. 11-2). Note that some of these ketoses are named by the insertion of *-ul-* before the suffix *-ose* in the name of the corresponding aldose; thus **D-xylulose** is the ketose corresponding to the aldose **D-xylose**. **Dihydroxyacetone**, **D-fructose**, D-ribulose, and D-xylulose are the biologically most prominent ketoses.

## B. Configurations and Conformations

Alcohols react with the carbonyl groups of aldehydes and ketones to form **hemiacetals** and **hemiketals**, respectively (Fig. 11-3). The hydroxyl and either the aldehyde or the ketone functions of monosaccharides can likewise react intramolecularly to form cyclic hemiacetals and hemiketals (Fig. 11-4). The configurations of the substituents to each carbon atom of these sugar rings are conveniently represented by their **Haworth projection formulas**.

A sugar with a six-membered ring is known as a **pyranose** in analogy with **pyran**, the simplest compound containing such a ring. Similarly, sugars with five-membered rings are designated **furanoses** in analogy with **furan**.

The cyclic forms of glucose and fructose with six- and five-membered rings are therefore known as **glucopyranose** and **fructofuranose**, respectively.

### a. Cyclic Sugars Have Two Anomeric Forms

The Greek letters preceding the names in Fig. 11-4 still need to be explained. The cyclization of a monosaccharide renders the former carbonyl carbon asymmetric. The resulting pair of diastereomers are known as **anomers** and the hemiacetal or hemiketal carbon is referred to as the **anomeric carbon**. In the  $\alpha$  anomer, the OH substituent to the anomeric carbon is on the opposite side of the sugar ring from the  $\text{CH}_2\text{OH}$  group at the chiral center that

**Figure 11-2** The stereochemical relationships among the D-ketoses with three to six carbon atoms. The configuration about C3 (red) distinguishes the members of each pair. The biologically most common ketoses are boxed.

**Figure 11-3** The reactions of alcohols with (a) aldehydes to form hemiacetals and (b) ketones to form hemiketals.

**Figure 11-4** Cyclization reactions for hexoses. (a) D-Glucose in its linear form reacting to yield the cyclic hemiacetal  $\beta$ -D-glucopyranose and (b) D-fructose in its linear form reacting to yield the hemiketal  $\beta$ -D-fructofuranose. The cyclic sugars are

shown both as Haworth projections and in stick form embedded in their semitransparent space-filling models with C green, H white, and O red.

designates the D or L configuration (C5 in hexoses). The other anomer is known as the  $\beta$  form (Fig. 11-5).

The two anomers of D-glucose, as any pair of diastereomers, have different physical and chemical properties. For example, the values of the specific optical rotation,  $[\alpha]_D^{20}$ , for  $\alpha$ -D-glucose and  $\beta$ -D-glucose are, respectively,  $+112.2^\circ$  and  $+18.7^\circ$ . When either of these pure substances is dissolved in water, however, the specific optical rotation of the solution slowly changes until it reaches an equilibrium value of  $[\alpha]_D^{20} = +52.7^\circ$ . This phenomenon is known

as **mutarotation**; in glucose, it results from the formation of an equilibrium mixture consisting of 63.6% of the  $\beta$  anomer and 36.4% of the  $\alpha$  anomer (the optical rotations of separate molecules in solution are independent of each other so that the optical rotation of a solution is the weighted average of the optical rotations of its components). The interconversion between these anomers occurs via the linear form of glucose (Fig. 11-5). Yet, since the linear forms of these monosaccharides are normally present in only minute amounts, these carbohydrates are

**Figure 11-5** The anomeric monosaccharides  $\alpha$ -D-glucopyranose and  $\beta$ -D-glucopyranose, drawn as both Haworth projections and ball-and-stick models. These pyranose sugars

interconvert through the linear form of D-glucose and differ only by the configurations about their anomeric carbon atoms, C1.

 See Kinemage Exercise 7-1

**Figure 11-6** Conformations of the cyclohexane ring. (a) In the boat conformation, substituents at the “bow” and “stern” (red) are sterically crowded, whereas those along its sides (green) are eclipsed. (b) In the chair conformation, the substituents that extend parallel to the ring’s threefold rotation axis are designated axial [*a*] and those that extend roughly outward from this symmetry axis are designated equatorial [*e*]. The equatorial substituents about the ring are staggered so that they alternately extend above and below the mean plane of the ring.

accurately described as cyclic polyhydroxy hemiacetals or hemiketals.

### b. Sugars Are Conformationally Variable

Hexoses and pentoses may each assume pyranose or furanose forms. The equilibrium composition of a particular monosaccharide depends somewhat on conditions but mostly on the identity of the monosaccharide. For instance, NMR measurements indicate that whereas glucose almost exclusively assumes its pyranose form in aqueous solutions, fructose is 67% pyranose and 33% furanose, and ribose is 75% pyranose and 25% furanose (although in polysaccharides, glucose, fructose, and ribose residues are exclusively in their respective pyranose, furanose, and furanose forms). Although, in principle, hexoses and larger sugars can form rings of seven or more atoms, such rings are rarely observed because of the greater stabilities of the five- and six-membered rings that these sugars can also form. The internal strain of three- and four-membered sugar rings makes them unstable with respect to linear forms.

The use of Haworth formulas may lead to the erroneous impression that furanose and pyranose rings are planar. This cannot be the case, however, because all of the atoms in these rings are tetrahedrally ( $sp^3$ ) hybridized. The pyranose ring, like the cyclohexane ring, may assume a **boat** or a **chair** conformation (Fig. 11-6). The relative stabilities of these various conformations depend on the stereochemical interactions between the substituents on the ring. The boat con-

**Figure 11-7** The two alternative chair conformations of  $\beta$ -D-glucopyranose. In the conformation on the left, which predominates, the relatively bulky OH and  $\text{CH}_2\text{OH}$  substituents all occupy equatorial positions, whereas in that on the right (drawn in ball-and-stick form in Fig. 11-5, right) they occupy the more crowded axial positions. See Kinemage Exercise 7-1

former crowds the substituents on its “bow” and “stern” and eclipses those along its sides, so that in cyclohexane it is  $\sim 25 \text{ kJ} \cdot \text{mol}^{-1}$  less stable than the chair conformer. The ring substituents on the chair conformer (Fig. 11-6b) fall into two geometrical classes: the rather close-fitting **axial** groups that extend parallel to the ring’s threefold rotational axis and the staggered, and therefore minimally encumbered, **equatorial** groups. Since the axial and equatorial groups on a cyclohexane ring are conformationally interconvertible, a given ring has two alternative chair forms (Fig. 11-7); the one that predominates usually has the lesser crowding among its axial substituents. The conformational situation of a group directly affects its chemical reactivity. For example, equatorial OH groups on pyranoses esterify more readily than do axial OH groups. Note that  $\beta$ -D-glucose is the only D-aldohexose that can simultaneously have all five non-H substituents in the equatorial position (left side of Fig. 11-7). Perhaps this is why glucose is the most abundant naturally occurring monosaccharide. The conformational properties of furanose rings are discussed in Section 29-2Ab in relation to their effects on the conformations of nucleic acids.

### C. Sugar Derivatives

#### a. Polysaccharides Are Held Together by Glycosidic Bonds

The chemistry of monosaccharides is largely that of their hydroxy and carbonyl groups. For example, in an acid-catalyzed reaction, the anomeric hydroxyl of a sugar reversibly condenses with alcohols to form  $\alpha$ - and  $\beta$ -**glycosides** (Greek: *glykys*, sweet) (Fig. 11-8). The bond connecting the anomeric carbon to the acetal oxygen is termed a **glycosidic**

**Figure 11-8** The acid-catalyzed condensation of  $\alpha$ -D-glucose with methanol to form an anomeric pair of methyl-D-glucosides.

**bond.** Polysaccharides are held together by glycosidic bonds between neighboring monosaccharide units. The glycosidic bond is therefore the carbohydrate analog of the peptide bond in proteins. The bond in a nucleoside linking its ribose residue to its base is also a glycosidic bond (Section 5-1A).

The hydrolysis of glycosidic bonds is catalyzed by enzymes known as **glycosidases** that differ in specificity according to the identity and anomeric configuration of the glycoside but are often rather insensitive to the identity of the alcohol residue. Under basic or neutral conditions and in the absence of glycosidases, however, the glycosidic bond is stable, so glycosides do not undergo mutarotation as do monosaccharides. The methylation of the non-anomeric OH groups of monosaccharides requires more drastic conditions than is required for the formation of methyl glycosides, such as treatment with dimethyl sulfate.

### b. Oxidation-Reduction Reactions

Because the cyclic and linear forms of aldoses and ketoses interconvert so readily, these sugars undergo reactions typical of aldehydes and ketones. Mild oxidation of an aldose, either chemically or enzymatically, results in the conversion of its aldehyde group to a carboxylic acid function, thereby yielding an **aldonic acid** such as **gluconic acid**. Aldonic acids are named by appending the suffix *-onic acid* to the root name of the parent aldose.

Saccharides bearing anomeric carbon atoms that have not formed glycosides are termed **reducing sugars** because of the facility with which the aldehyde group reduces mild oxidizing agents. A classic test for the presence of a reducing sugar is the reduction of  $\text{Ag}^+$  in an ammonia solution

**Figure 11-9** D-Glucono- $\delta$ -lactone and D-glucurono- $\delta$ -lactone are, respectively, the lactones of D-gluconic acid and D-glucuronic acid. The  $\delta$  indicates that the O atom closing the lactone ring is also substituent to  $\text{C}_6$ .

(**Tollens' reagent**) to yield a metallic silver mirror lining on the inside of the reaction vessel.

The specific oxidation of the primary alcohol group of aldoses yields **uronic acids**, which are named by appending *-uronic acid* to the root name of the parent aldose. **D-Glucuronic acid**, **D-galacturonic acid**, and **D-mannuronic acid** are important components of many polysaccharides.

**D-Glucuronic acid**                      **D-Galacturonic acid**                      **D-Mannuronic acid**

Uronic acids can assume the pyranose, furanose, and linear forms.

Both aldonic and uronic acids have a strong tendency to internally esterify so as to form five- and six-membered lactones (Fig. 11-9). **Ascorbic acid (vitamin C, Fig. 11-10)** is a  $\gamma$ -lactone that is synthesized by plants and almost all animals except primates and guinea pigs. Its prolonged deficiency in the diet of humans results in the disease known as **scurvy**, which is caused by the impairment of collagen formation (Section 8-2B). Scurvy generally results from a lack of fresh food. This is because, under physiological conditions, ascorbic acid is reversibly oxidized to **dehydroascorbic acid**, which, in turn, is irreversibly hydrolyzed to the vitamin-inactive **diketogulonic acid** (Fig. 11-10).

Aldoses and ketoses may be reduced under mild conditions, for example, by treatment with  $\text{NaBH}_4$  to yield acyclic polyhydroxy alcohols known as **alditols**, which are named by appending the suffix *-itol* to the root name of the parent aldose. **Ribitol** is a component of flavin coenzymes (Section 16-2C), and **glycerol** and the cyclic polyhydroxy alcohol **myo-inositol** are important lipid components

**Figure 11-10** The reversible oxidation of L-ascorbic acid to L-dehydroascorbic acid. This is followed by the physiologically irreversible hydrolysis of its lactone ring to form L-diketogulonic acid.

(Section 12-1). **Xylitol** is a sweetener that is used in “sugarless” gum and candies.

### c. Other Biologically Important Sugar Derivatives

Monosaccharide units in which an OH group is replaced by H are known as **deoxy sugars**. The biologically most important of these is  **$\beta$ -D-2-deoxyribose**, the sugar compo-

nent of DNA's sugar-phosphate backbone (Section 5-1A). **L-Rhamnose** and **L-fucose** are widely occurring polysaccharide components.

In **amino sugars**, one or more OH groups are replaced by an often acetylated amino group. **D-Glucosamine** and **D-galactosamine** are components of numerous biologically important polysaccharides.

***N*-Acetylneuraminic acid (linear form)**

**Figure 11-11** *N*-Acetylneuraminic acid in its linear and pyranose forms. Note that its pyranose ring incorporates the pyruvic acid residue (blue) and part of the mannose moiety.

**$\alpha$ -D-Glucosamine (2-amino-2-deoxy- $\alpha$ -D-glucopyranose)**

**$\alpha$ -D-Galactosamine (2-amino-2-deoxy- $\alpha$ -D-galactopyranose)**

***N*-Acetylmuramic acid (NAM)**

The amino sugar derivative ***N*-acetylmuramic acid**, which consists of ***N*-acetyl-D-glucosamine** in an ether linkage with **D-lactic acid**, is a prominent component of bacterial cell walls (Section 11-3Ba). *N*-Acetylneuraminic acid, which is derived from *N*-acetylmannosamine and pyruvic acid (Fig. 11-11), is an important constituent of glycoproteins (Section 11-3C) and glycolipids (Section 12-1D). *N*-Acetylneuraminic acid and its derivatives are often referred to as **sialic acids**.

## 2 POLYSACCHARIDES

Polysaccharides, which are also known as **glycans**, consist of monosaccharides linked together by glycosidic bonds. They are classified as **homopolysaccharides** or **heteropolysaccharides** if they consist of one type or more than one type of monosaccharide residue. Homopolysaccharides may be further classified according to the identity of

their monomeric unit. For example, **glucans** are polymers of glucose, whereas **galactans** are polymers of galactose. Although monosaccharide sequences of heteropolysaccharides can, in principle, be as varied as those of proteins, they are usually composed of only a few types of monosaccharides that alternate in a repetitive sequence.

*Polysaccharides, in contrast to proteins and nucleic acids, form branched as well as linear polymers.* This is because glycosidic linkages can be made to any of the hydroxyls of a monosaccharide. Fortunately for structural biochemists, many polysaccharides are linear and those that branch tend to do so in only a few well-defined ways.

In this section, we discuss the structures of the simplest polysaccharides, the disaccharides, and then consider the structures and properties of the most abundant classes of polysaccharides. We begin by outlining how polysaccharide structures are elucidated.

### A. Carbohydrate Analysis

The purification of carbohydrates can, by and large, be effected by chromatographic and electrophoretic procedures similar to those used in protein purification (Sections 6-3 and 6-4), although thin layer chromatography (TLC; Section 6-3Dd) is also widely used. Affinity chromatography (Section 6-3C), using immobilized proteins known as **lectins** (Latin: *legere*, to pick or choose), is a particularly powerful technique in this regard. Lectins are sugar-binding proteins that were discovered in plants but are now known to occur in all organisms, where they participate in a wide variety of signaling, cell–cell recognition, and adhesion processes, as well as in targeting newly synthesized proteins to specific cellular locations (Section 12-4Cg). Lectins recognize one or more specific monosaccharides with particular linkages to other sugars in oligosaccharides, usually with exquisite specificity. Their protein–carbohydrate interactions typically include multiple hydrogen bonds, which often include bridging water molecules, and the packing of hydrophobic sugar faces against aromatic side chains (Fig. 11-12). Among the best characterized lectins are jack bean **concanavalin A** (Fig. 8-40), which specifically binds  $\alpha$ -D-glucose and  $\alpha$ -D-mannose residues, and wheat germ **agglutinin** (so named because it causes cells to agglutinate or clump together), which specifically binds  $\beta$ -N-acetylmuramic acid and  $\alpha$ -N-acetylneuraminic acid.

Characterization of an oligosaccharide requires that the identities, anomers, linkages, and order of its component monosaccharides be elucidated. The linkages of the monosaccharides may be determined by **methylation analysis** (also called **permethylation analysis**), a technique pioneered by Norman Haworth in the 1930s. *Methyl ethers not at the anomeric C atom are resistant to acid hydrolysis but glycosidic bonds are not. Consequently, if an oligosaccharide is exhaustively methylated and then hydrolyzed, the free OH groups on the resulting methylated monosaccharides mark the former positions of the glycosidic bonds.* Methylated monosaccharides are often identified by **gas–liquid chromatography (GLC)**; a technique in which the stationary phase is an inert solid, such as diatomaceous earth,

**Figure 11-12** Carbohydrate binding by a lectin in the X-ray structure of human galectin-2 in complex with the disaccharide lactose. This lectin primarily binds  $\beta$ -D-galactose residues. The structure is drawn in stick form with the C and O atoms of lactose's galactose (Gal) and glucose (Glc) residues green and red, and the galectin-2 amino acid side chains violet. Hydrogen bonds between the protein side chains and the sugar residues are represented by dashed yellow lines. [Courtesy of Hakon Leffler, Lund University, Sweden. PDBid 1HLC.]

impregnated with a low-volatility liquid, such as silicone oil, and the mobile phase is an inert gas, such as He, into which the sample has been flash evaporated) combined with mass spectrometry (GLC/MS). HPLC techniques may similarly be used. Other mass spectrometric techniques for analyzing nonvolatile substances are discussed in Section 7-1I. Although all aldoses and ketoses with the same number of C atoms are isomers (Figs. 11-1 and 11-2) and hence have identical molecular masses, they have characteristic fragmentation patterns.

The sequence and anomeric configurations of the monosaccharides in an oligosaccharide can be determined through the use of specific **exoglycosidases**. These enzymes specifically hydrolyze their corresponding monosaccharides from the nonreducing ends of oligosaccharides (the ends lacking a free anomeric carbon atom) in a manner analogous to the actions of exopeptidases on proteins (Section 7-1Ab). For example,  **$\beta$ -galactosidase** excises the terminal  $\beta$  anomers of galactose, whereas  **$\alpha$ -mannosidase** does so with the  $\alpha$  anomers of mannose. Some of these exoglycosidases also exhibit specificity for the **aglycone**, the sugar chains to which the monosaccharide to be excised (the **glycone**) is linked. Through the use of mass spectrometry, the sequence of a polysaccharide may be deduced from the mass decrements generated by exoglycosidases. The use of **endoglycosidases** (hydrolases that cleave glycosidic bonds between nonterminal sugar residues) of varying specificities can also supply useful sequence information. The proton and  $^{13}\text{C}$  NMR spectra of oligosaccharides can provide the complete sequence of an oligosaccharide if sufficient material is available. Moreover, two-dimensional

NMR techniques (Section 8-3Ac) can reveal oligosaccharide structures (e.g., see Section 11-2Eb).

## B. Disaccharides

We begin our studies of polysaccharides by considering disaccharides (Fig. 11-13). **Sucrose**, the most abundant disaccharide, occurs throughout the plant kingdom and is familiar to us as common table sugar. Its structure (Fig. 11-13) was established by methylation analysis as described above and was later confirmed by its X-ray structure. To name a polysaccharide systematically, one must specify its component monosaccharides, their ring types, their anomeric forms, and how they are linked together. Sucrose is therefore *O*- $\alpha$ -D-glucopyranosyl-(1  $\rightarrow$  2)- $\beta$ -D-fructofuranoside, where the symbol (1  $\rightarrow$  2) indicates that the glycosidic bond links C1 of the glucose residue to C2 of the fructose residue. Note that since these two positions are the anomeric carbon atoms of their respective monosaccharides, sucrose is not a reducing sugar (as the suffix *-ide* implies).

The hydrolysis of sucrose to D-glucose and D-fructose is accompanied by a change in optical rotation from *dextro* to *levo*. Consequently, hydrolyzed sucrose is sometimes called **invert sugar** and the enzyme that catalyzes this process,  **$\beta$ -D-fructofuranosidase**, is archaically named **invertase**.

**Lactose** [*O*- $\beta$ -D-galactopyranosyl-(1  $\rightarrow$  4)-D-glucopyranose] or milk sugar (Fig. 11-13) occurs naturally only in milk, where its concentration ranges from 0 to 7% depending on the species. The free anomeric carbon of its glucose residue makes lactose a reducing sugar.

Infants normally express the intestinal enzyme  **$\beta$ -D-galactosidase** or **lactase** that catalyzes the hydrolysis of lactose to its component monosaccharides for absorption into the bloodstream. Many adults, however, including most Africans and almost all Asians, have a low level of this enzyme (as do most adult mammals, since they normally do not encounter milk). Consequently, much of the lactose in any milk they drink moves through their digestive tract to the colon, where its bacterial fermentation produces large quantities of CO<sub>2</sub>, H<sub>2</sub>, and irritating organic acids. This results in an embarrassing and often painful digestive upset termed **lactose intolerance**. Perhaps this is why Chinese cuisine, which is noted for the wide variety of foodstuffs it employs, is devoid of milk products. However, adult members of populations with a tradition of herding cattle, mainly northern Europeans and certain African groups, continue expressing the lactase gene and hence can drink milk without a problem. Modern food technology has come to the aid of milk lovers who develop lactose intolerance: Milk products in which the lactose has been hydrolyzed enzymatically and lactase-containing pills are now widely available.

There are several common glucosyl-glucose disaccharides. These include **maltose** [*O*- $\alpha$ -D-glucopyranosyl-(1  $\rightarrow$  4)-D-glucopyranose], an enzymatic hydrolysis product of starch; **isomaltose**, its  $\alpha$ (1  $\rightarrow$  6) isomer; and **cellobiose**, its  $\beta$ (1  $\rightarrow$  4) isomer, the repeating disaccharide of cellulose. Only a few tri- or higher oligosaccharides occur in significant natural abundance. Not surprisingly, they all occur in plants.

**Figure 11-13** Several common disaccharides.  See Kinemage Exercise 7-2

## C. Structural Polysaccharides: Cellulose and Chitin

Plants have rigid cell walls (Fig. 1-9) that, in order to maintain their shapes, must be able to withstand osmotic pressure differences between the extracellular and intracellular spaces of up to 20 atm. In large plants, such as trees, the cell

**Figure 11-14** Electron micrograph of the cellulose fibers in the cell wall of the alga *Chaetomorpha melagonium*. Note that the cell wall consists of layers of parallel fibers. [Biophoto Associates/Photo Researchers.]

walls also have a load-bearing function. Cellulose, the primary structural component of plant cell walls (Fig. 11-14), accounts for over half of the carbon in the biosphere:  $\sim 10^{15}$  kg of cellulose are estimated to be synthesized and degraded annually. Although cellulose is predominantly of vegetable

**Figure 11-15** The primary structure of cellulose. Here  $n$  may be several thousand.

origin, it also occurs in the stiff outer mantles of marine invertebrates known as **tunicates** (urochordates; Fig. 1-11).

The primary structure of cellulose was determined through methylation analysis. Cellulose is a linear polymer of up to 15,000 D-glucose residues (a glucan) linked by  $\beta(1 \rightarrow 4)$  glycosidic bonds (Fig. 11-15). As is generally true of large polysaccharides, it has no defined size since, in contrast to proteins and nucleic acids, there is no genetically determined template that directs its synthesis.

X-ray studies of cellulose fibers led Anatole Sarko to tentatively propose the model diagrammed in Fig. 11-16. This highly cohesive, hydrogen bonded structure gives cellulose fibers exceptional strength and makes them water insoluble despite their hydrophilicity.

**Figure 11-16** Proposed structural model of cellulose.

Cellulose fibers consist of  $\sim 40$  parallel glucan chains arranged in an extended fashion. Each of the  $\beta(1 \rightarrow 4)$ -linked glucose units in a chain is turned  $180^\circ$  with respect to its preceding residue and is held in this position by intrachain hydrogen bonds (dashed lines). The glucan chains line up laterally to form sheets, and these sheets stack vertically such that they are staggered by half the length of a glucose unit. The entire assembly is stabilized by intermolecular hydrogen bonds between glucose units of neighboring chains. Hydrogen atoms not participating in hydrogen bonds have been omitted for clarity. [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

In plant cell walls, the cellulose fibers are embedded in and cross-linked by a matrix of several polysaccharides that are composed of glucose as well as other monosaccharides. In wood, this cementing matrix also contains a large proportion of **lignin**, a plasticlike phenolic polymer. One has only to watch a tall tree in a high wind to realize the enormous strength of plant cell walls. In engineering terms, they are “composite materials,” as is concrete reinforced by steel rods. Composite materials can withstand large stresses because the matrix evenly distributes the stresses among the reinforcing elements.

Although vertebrates themselves do not possess an enzyme capable of hydrolyzing the  $\beta(1 \rightarrow 4)$  linkages of cellulose, the digestive tracts of herbivores contain symbiotic microorganisms that secrete a series of enzymes, collectively known as **cellulase**, that do so. The same is true of termites. Nevertheless, the degradation of cellulose is a slow process because its tightly packed and hydrogen bonded glucan chains are not easily accessible to cellulase and do not separate readily even after many of their glycosidic bonds have been hydrolyzed. The digestion of fibrous plants such as grass by herbivores is therefore a more complex and time-consuming process than is the digestion of meat by carnivores (cows, e.g., have multichambered stomachs and must chew their cud). Similarly, the decay of dead plants by fungi, bacteria, and other organisms, and the consumption of wooden houses by termites, often takes years.

**Chitin** is the principal structural component of the exoskeletons of invertebrates such as crustaceans, insects, and spiders and is also a major cell wall constituent of most fungi and many algae. It is estimated that  $\sim 10^{14}$  kg of chitin are produced annually, most of it in the oceans, and therefore that it is almost as abundant as is cellulose. Chitin is a homopolymer of  $\beta(1 \rightarrow 4)$ -linked *N*-acetyl-D-glucosamine residue (Fig. 11-17). It differs chemically from cellulose only in that each C2-OH group is replaced by an acetamido function. X-ray analysis indicates that chitin and cellulose have similar structures.

#### D. Storage Polysaccharides: Starch and Glycogen

##### a. Starch Is a Food Reserve in Plants and a Major Nutrient for Animals

Starch is a mixture of glucans that plants synthesize as their principal food reserve. It is deposited in the cytoplasm of plant cells as insoluble granules composed of  **$\alpha$ -amylose** and **amylopectin**.  $\alpha$ -Amylose is a linear polymer of several thousand glucose residues linked by  $\alpha(1 \rightarrow 4)$  bonds (Fig. 11-18a). Note that although  $\alpha$ -amylose is an isomer of cellulose, it has very different structural properties. This is because cellulose's  $\beta$ -glycosidic linkages cause each successive glucose residue to flip  $180^\circ$  with respect to the preceding residue, so that the polymer assumes an easily packed, fully extended conformation (Fig. 11-16). In contrast,  $\alpha$ -amylose's  $\alpha$ -glycosidic bonds cause it to adopt an irregularly aggregating helically coiled conformation (Fig. 11-18b).

Amylopectin consists mainly of  $\alpha(1 \rightarrow 4)$ -linked glucose residues but is a branched molecule with  $\alpha(1 \rightarrow 6)$  branch

**Figure 11-17** The primary structure of chitin. Chitin is a  $\beta(1 \rightarrow 4)$ -linked homopolymer of *N*-acetyl-D-glucosamine.

**Figure 11-18**  $\alpha$ -Amylose. (a) The D-glucose residues of  $\alpha$ -amylose are linked by  $\alpha(1 \rightarrow 4)$  bonds (red). Here  $n$  is several thousand. (b) This regularly repeating polymer forms a left-handed helix with  $\sim 6$  glucose residues per turn. Note the great differences in structure and properties that result from changing  $\alpha$ -amylose's  $\alpha(1 \rightarrow 4)$  linkages to the  $\beta(1 \rightarrow 4)$  linkages of cellulose (Fig. 11-16). [Illustration, Irving Geis. Image from the Irving Geis Collection, Howard Hughes Medical Institute. Reprinted with permission.]

**Figure 11-19 Amylopectin.** (a) Its primary structure near one of its  $\alpha(1 \rightarrow 6)$  branch points (red). (b) Its bushlike structure with glucose residues at branch points indicated in red. The actual distance between branch points averages 24 to 30 glucose residues. Glycogen has a similar structure but is branched every 8 to 14 residues.

points every 24 to 30 glucose residues on average (Fig. 11-19). Amylopectin molecules contain up to  $10^6$  glucose residues, which makes them among the largest molecules occurring in nature. The storage of glucose as starch greatly reduces the large intracellular osmotic pressures that would result from its storage in monomeric form because osmotic pressure is proportional to the number of solute molecules in a given volume.

### b. Starch Digestion Occurs in Stages

The digestion of starch, the main carbohydrate source in the human diet, begins in the mouth. Saliva contains  **$\alpha$ -amylase**, which randomly hydrolyzes all the  $\alpha(1 \rightarrow 4)$  glucosidic bonds of starch except its outermost bonds and those next to branches. By the time thoroughly chewed food reaches the stomach, where the acidity inactivates  $\alpha$ -amylase, the average chain length of starch has been reduced from several thousand to fewer than eight glucose units. Starch digestion continues in the small intestine under the influence of pancreatic  $\alpha$ -amylase, which is similar to the salivary enzyme. This enzyme degrades starch to a mixture of the disaccharide maltose, the trisaccharide **maltotriose**, which contains three  $\alpha(1 \rightarrow 4)$ -linked glucose residues, and oligosaccharides known as **dextrins** that contain the  $\alpha(1 \rightarrow 6)$  branches. These oligosaccharides are hydrolyzed to their component monosaccharides by specific enzymes contained in the brush border membranes of the intestinal mucosa: an  **$\alpha$ -glucosidase**, which removes one glucose residue at a time from oligosaccharides, an  **$\alpha$ -dextrinase** or **debranching enzyme**, which hydrolyzes  $\alpha(1 \rightarrow 6)$  and  $\alpha(1 \rightarrow 4)$  bonds, a **sucrase**, and, at least in infants, a **lactase**. The resulting monosaccharides are absorbed by the intestine and transported to the bloodstream (Section 20-4A).

### c. Glycogen Is “Animal Starch”

Glycogen, the storage polysaccharide of animals, is present in all cells but is most prevalent in skeletal muscle and liver, where it occurs as cytoplasmic granules (Fig. 11-20). The primary structure of glycogen resembles that of amylopectin, but glycogen is more highly branched, with branch points occurring every 8 to 14 glucose residues. Glycogen’s degree of polymerization is nevertheless similar to that of amylopectin. In the cell, glycogen is degraded for metabolic use by **glycogen phosphorylase**, which phosphorytically cleaves glycogen’s  $\alpha(1 \rightarrow 4)$  bonds sequentially inward from its nonreducing ends to yield **glucose-1-phosphate**. Glycogen’s highly branched structure, which has many nonreducing ends, permits the rapid mobilization of glucose in times of metabolic need. The  $\alpha(1 \rightarrow 6)$  branches of glycogen are cleaved by a debranching enzyme. These enzymes play an important role in glucose metabolism and are discussed further in Section 18-1.

### E. Glycosaminoglycans

The extracellular spaces, particularly those of connective tissues such as cartilage, tendon, skin, and blood vessel walls, consist of collagen and elastin fibers (Section 8-2B)

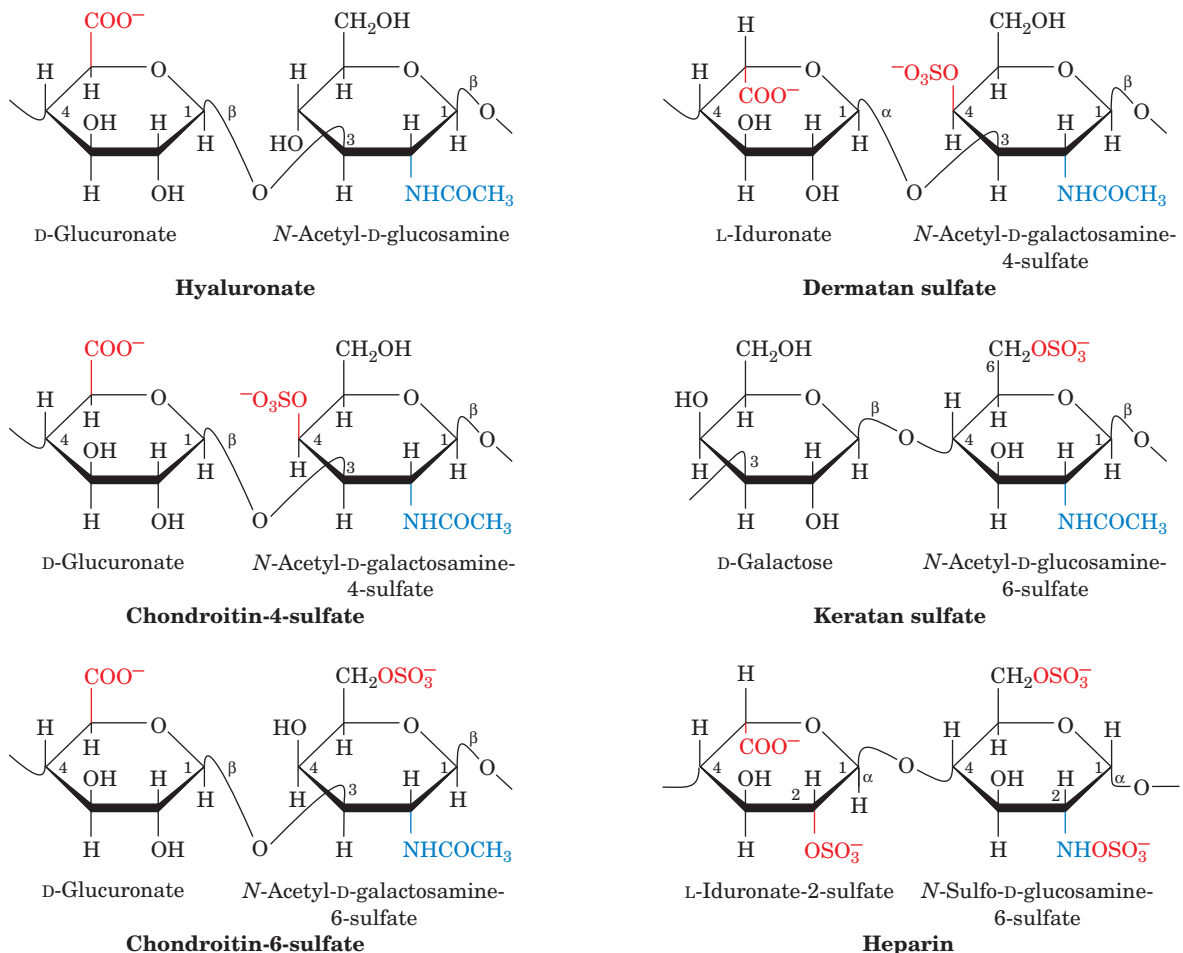

**Figure 11-20** Photomicrograph showing the glycogen granules (pink) in the cytoplasm of a liver cell. The greenish objects are mitochondria and the yellow object is a fat globule. Note that the glycogen granules tend to aggregate. The glycogen content of liver may reach as high as 10% of its net weight. [CNRI/Science Photo Library/Photo Researchers, Inc.]

embedded in a gel-like matrix known as **ground substance**. Ground substance is composed largely of **glycosaminoglycans (GAGs; alternatively, mucopolysaccharides)**, unbranched polysaccharides of alternating uronic acid and hexosamine residues. Solutions of GAGs have a slimy, mucuslike consistency that results from their high viscosity and elasticity. In the following paragraphs, we discuss the structural origin of these important mechanical properties.

#### a. Hyaluronic Acid

**Hyaluronic acid** (also called **hyaluronan**) is an important GAG component of ground substance, synovial fluid (the fluid that lubricates the joints), and the vitreous humor of the eye. It also occurs in the capsules surrounding certain, usually pathogenic, bacteria. Hyaluronic acid molecules are composed of 250 to 25,000  $\beta(1 \rightarrow 4)$ -linked disaccharide units that consist of D-glucuronic acid and N-acetyl-D-glucosamine linked by a  $\beta(1 \rightarrow 3)$  bond (Fig. 11-21). The anionic character of its glucuronic acid residues causes hyaluronic acid to bind cations such as  $K^+$ ,  $Na^+$ , and  $Ca^{2+}$  tightly. X-ray fiber analysis indicates that  $Ca^{2+}$  hyaluronate

**Figure 11-21** The disaccharide repeating units of the common glycosaminoglycans. The anionic groups are drawn in red and the N-acetyl groups are drawn in blue. See Kinemage Exercise 7-3

**Figure 11-22** X-ray fiber structure of  $\text{Ca}^{2+}$  hyaluronate. Three consecutive disaccharide units of the hyaluronate fiber are drawn in stick form with atoms colored according to type with glucuronate C green, *N*-acetyl-D-glucosamine C cyan, H white, N blue, and O red.  $\text{Ca}^{2+}$  ions are represented by blue spheres. The hyaluronate polyanion forms an extended, left-handed, single-stranded helix with a pitch of 28.3 Å and ~3 disaccharide units per turn that is stabilized by intramolecular hydrogen bonds (dashed lines). The positions of the H atoms are inferred and hence the H atoms of the OH groups are not shown. [Based on a fiber X-ray structure by Struther Arnott, Purdue University, PDBid 4HYA.]

forms an extended, left-handed, single-stranded helix with ~3 disaccharide units per turn (Fig. 11-22).

Hyaluronate's structural features suit it to its biological function. Its high molecular mass and numerous mutually repelling anionic groups make hyaluronate an extended, rigid, and highly hydrated molecule which, in solution, occupies a volume ~1000 times that in its dry state. Hyaluronate solutions therefore have a viscosity that is shear dependent (an object under shear stress has equal and opposite forces applied across its opposite faces). At low shear rates, the hyaluronate molecules form tangled masses that greatly impede flow; that is, the solution is quite viscous. As the shear rate increases, the stiff rodlike hyaluronate molecules tend to line up with the flow and thus offer less resistance to it. This viscoelastic behavior makes hyaluronate solutions excellent biological shock absorbers and lubricants.

Hyaluronic acid and other GAGs (see below) are degraded by **hyaluronidase**, which hydrolyzes their  $\beta(1 \rightarrow 4)$  linkages. Hyaluronidase occurs in a variety of animal tissues, in bacteria (where it presumably expedites their invasion of animal tissue), and in snake and insect toxins.

#### b. Other Glycosaminoglycans

Other GAG components of ground substance consist of 50 to 1000 sulfated disaccharide units which occur in proportions that are both tissue and species dependent. The most prevalent structures of these generally heterogeneous substances are (Fig. 11-21)

**1. Chondroitin-4-sulfate** (Greek: *chondros*, cartilage), a major component of cartilage and other connective tissue,

has *N*-acetyl-D-galactosamine-4-sulfate residues in place of hyaluronate's *N*-acetyl-D-glucosamine residues.

**2. Chondroitin-6-sulfate** is instead sulfated at the C6 position of its *N*-acetyl-D-galactosamine residues. The two chondroitin sulfates occur separately or in mixtures depending on the tissue.

**3. Dermatan sulfate** (Greek: *derma*, skin), which is so named because of its prevalence in skin, differs from chondroitin-4-sulfate only by an inversion of configuration about C5 of the  $\beta$ -D-glucuronate residues to form  $\alpha$ -L-iduronate. This results from the enzymatic epimerization of these residues after the formation of chondroitin. The epimerization is usually incomplete, so dermatan sulfate also contains glucuronate residues.

**4. Keratan sulfate** (Greek: *keras*, horn; not to be confused with the protein keratin) consists mainly of alternating  $\beta(1 \rightarrow 4)$ -linked D-galactose and *N*-acetyl-D-glucosamine-6-sulfate residues (and hence lacks uronic acid residues). It is a component of cartilage, bone, cornea, as well as hair, nails, and horn. Keratan sulfate is the most heterogeneous of the major GAGs in that its sulfate content is variable and it contains small amounts of fucose, mannose, *N*-acetylglucosamine, and sialic acid.

**5. Heparin** is a variably sulfated GAG that consists predominantly of alternating  $\alpha(1 \rightarrow 4)$ -linked residues of L-iduronate-2-sulfate and *N*-sulfo-D-glucosamine-6-sulfate. It has an average of 2.5 sulfate residues per disaccharide unit, which makes it the most negatively charged polyelectrolyte in mammalian tissues (Fig. 11-23). Heparin, in contrast to the above GAGs, is not a constituent of connective tissue, but occurs almost exclusively in the intracellular granules of the **mast cells** that line arterial walls, especially in the liver, lungs, and skin. It inhibits the clotting of blood, and its release, through injury, is thought to prevent runaway clot formation (Section 35-1Ea). Heparin is therefore in wide clinical use to inhibit blood clotting, for example, in

**Figure 11-23** NMR structure of heparin. Three consecutive disaccharide units of this helical polymer are shown in stick form. Atoms are colored according to type with glucosamine C green, iduronate C cyan, H white, N blue, O red, and S yellow. The helical repeat unit is two disaccharides with a pitch of 17.5 Å. Note the high density of anionic sulfate groups. [Based on an NMR structure by Barbara Mulloy and Mark Forster, National Institute for Biological Standards and Control, Herts, U.K. PDBid 1HPN.]

postsurgical patients. **Heparan sulfate**, a ubiquitous cell-surface component as well as an extracellular substance in blood vessel walls and brain, resembles heparin but has a far more variable composition with fewer *N*- and *O*-sulfate groups and more *N*-acetyl groups.

### 3 GLYCOPROTEINS

Until about 1960, carbohydrates were thought to be rather dull compounds that were probably some sort of inert filler. Protein chemists therefore considered them to be a nuisance that complicated protein “purification.” In fact, most eukaryotic proteins are **glycoproteins**, that is, they are covalently associated with carbohydrates. Glycoproteins vary in carbohydrate content from <1% to >90% by weight. They occur in all forms of life and have functions that span the entire spectrum of protein activities, including those of enzymes, transport proteins, receptors, hormones, and structural proteins. Their carbohydrate moieties, as we shall see, have several important biological roles, but in many cases their functions remain enigmatic.

The polypeptide chains of glycoproteins, like those of all proteins, are synthesized under genetic control. Their carbohydrate chains, in contrast, are enzymatically generated and covalently linked to the polypeptide without the rigid guidance of nucleic acid templates. The processing enzymes are generally not available in sufficient quantities to ensure the synthesis of uniform products. Glycoproteins therefore have variable carbohydrate compositions, a phenomenon known as **microheterogeneity**, that compounds the difficulties in their purification and characterization.

In this section we consider the structures and properties of glycoproteins. In particular, we shall study the glycoproteins of connective tissues, those of bacterial cell walls, and several soluble glycoproteins. We end by discussing the general principles of glycoprotein structure and function.

#### A. Proteoglycans

Proteins and glycosaminoglycans in ground substance, in **basal laminae** [**basement membranes**; the thin matlike extracellular matrix separating **epithelial cells** (the cells lining body cavities and free surfaces) from underlying cells], and in cell-surface membranes aggregate covalently and non-covalently to form a diverse group of macromolecules known as **proteoglycans**. *Proteoglycans consist of a core protein to which at least one glycosaminoglycan chain, most often keratan sulfate and/or chondroitin sulfate, is covalently linked.* Numerous types of core proteins have been characterized (Table 11-1). Proteoglycans appear to have multiple roles, most notably as organizers of tissue morphology via their interactions with molecules such as collagen; as selective filters that regulate the traffic of molecules according to their size and/or charge; and as regulators of the activities of other proteins, particularly those involved in signaling (see below).

Electron micrographs such as Fig. 11-24a together with reconstitution experiments indicate that proteoglycans can form huge complexes. For example, **aggrecan**, the main proteoglycan component of cartilage, has a bottlebrush-like molecular architecture (Fig. 11-24b), whose **proteoglycan subunit** “bristles” are noncovalently attached to a filamentous hyaluronic acid “backbone” at intervals of 200 to 300 Å. Aggrecan has three domains. Its N-terminal domain forms a globular region of 60 to 70 kD that binds noncovalently

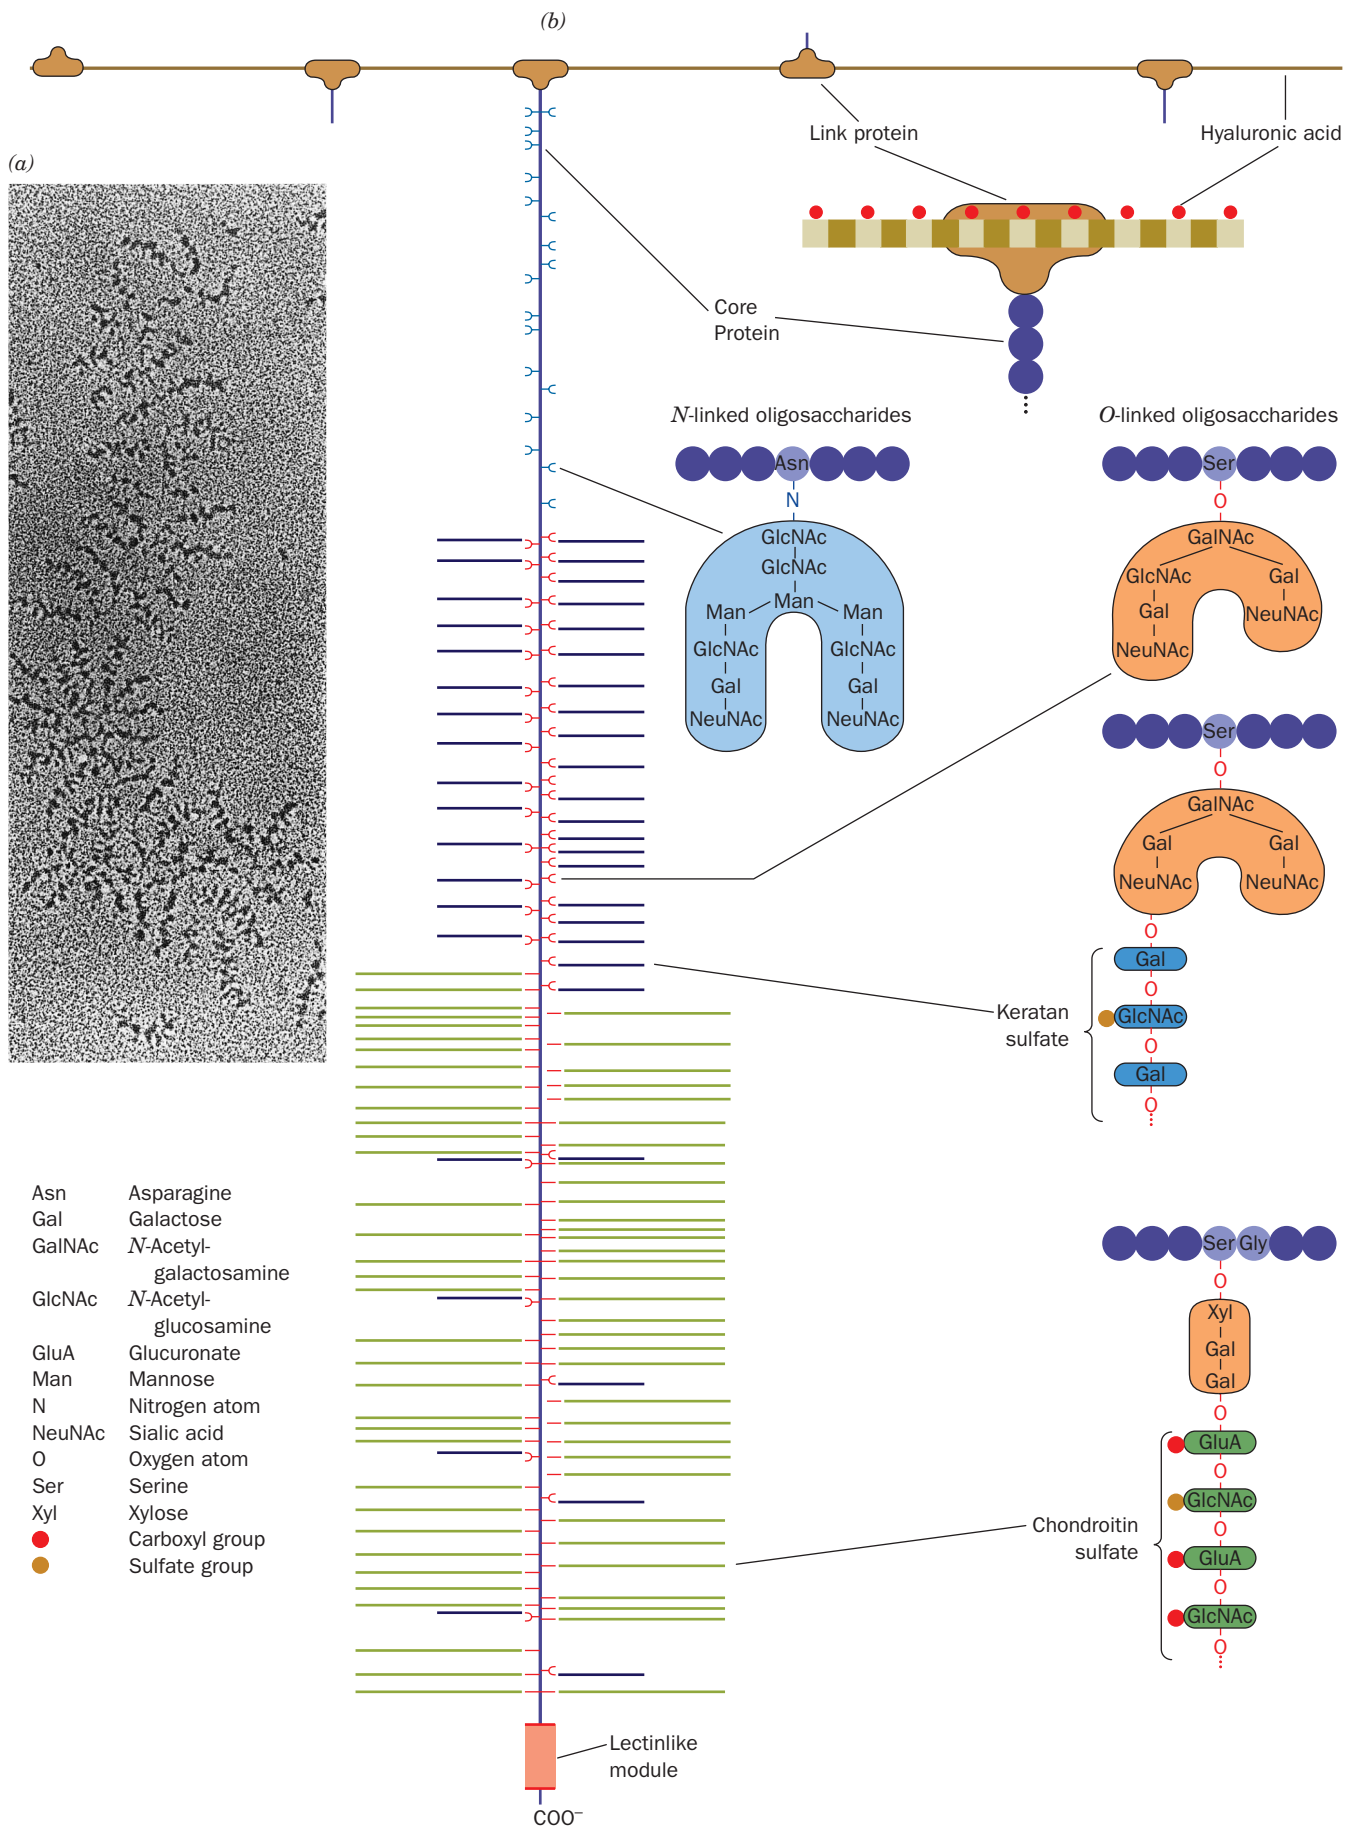

**Table 11-1** Properties of Some Proteoglycans

Proteoglycan	Approximate Core Protein Molecular Mass (kD)	Glycosaminoglycan Type (Number) <sup>a</sup>
<i><b>Proteoglycans interacting with hyaluronic acid</b></i>		
Aggrecan	220	CS (~100), KS (~30)

**Figure 11-24 (Opposite) Proteoglycans.** (a) An electron micrograph showing a central strand of hyaluronic acid, which runs down the field of view, supporting numerous projections, each of which consists of a core protein to which many bushy polysaccharide protrusions are linked. [From Caplan, A.I., *Sci. Am.* **251**(4); 87 (1984). Copyright © 1984 Scientific American, Inc. Used by permission.] (b) The bottlebrush model of the proteoglycan aggrecan. The core proteins, one of which is shown extending down through the middle of the diagram, project from the central hyaluronic acid strand. The core is noncovalently anchored to the hyaluronic acid via its globular N-terminal end in an association that is stabilized by link protein. The core has three saccharide-binding regions: (1) the inner region predominantly binds oligosaccharides via the side chain N atoms of Asn residues; (2) the central region binds oligosaccharides, many of which bear keratan sulfate chains, via the side chain O atoms of Ser and Thr residues; and (3) the outer region mainly binds chondroitin sulfate chains that are linked to the core protein via a galactose–galactose–xylose trisaccharide that is bonded to side chain O atoms of Ser residues in the sequence Ser-Gly. The C-terminal end of the aggrecan core protein consists of a lectinlike sequence.

to hyaluronic acid. This attachment is stabilized by the 40- to 60-kD **link protein**, which is similar in sequence to aggrecan's N-terminal domain. Aggrecan's highly extended central domain is covalently linked to a series of polysaccharides, which comprise nearly 90% of this glycoprotein's mass. They divide the central domain into three regions:

1. An N-terminal region, which overlaps the globular hyaluronic acid-binding domain, binds a relatively few carbohydrate chains. These tend to be oligosaccharides that are covalently bonded to the protein via the amide N atoms of specific Asn residues (Section 11-3Ca).
2. A region rich in oligosaccharides, many of which serve as anchor points for keratan sulfate chains. These oligosaccharides are covalently bonded to side chain O atoms of Ser and Thr residues.
3. A C-terminal region rich in chondroitin sulfate chains, which are covalently linked to the side chain O atoms of Ser residues in Ser-Gly dipeptides via galactose–galactose–xylose trisaccharides.

Aggrecan's C-terminal domain contains a lectinlike module, which binds certain monosaccharide units. Thus, aggrecan probably functions to bind together various constituents of the cell surface and the extracellular matrix (see below).

Altogether, a central strand of hyaluronic acid, which varies in length from 4000 to 40,000 Å, noncovalently binds up to 100 associated aggrecan chains, each of which covalently binds ~30 keratan sulfate chains of up to 250 disaccharide units each and ~100 chondroitin sulfate chains of up to 1000 disaccharide units each. This accounts for the enormous molecular masses of the aggrecans, which range up to 220,000 kD, and for their high degree of **polydispersity** (range of molecular masses). Note, however, that many

proteoglycans do not bind to hyaluronic acid (Table 11-1) and hence function as monomers.

#### a. Cartilage's Mechanical Properties Are Explained by Its Molecular Structure

Cartilage consists largely of a meshwork of collagen fibrils that is filled in by proteoglycans whose chondroitin sulfate and core protein components specifically interact with the collagen. The tensile strength of cartilage and other connective tissues is, as we have seen (Section 8-2Ba), a consequence of their collagen content. Cartilage's characteristic resilience, however, results from its high proteoglycan content. The extended brushlike structure of proteoglycans, together with the polyanionic character of keratan sulfate and chondroitin sulfate, cause this complex to be highly hydrated. The application of pressure on cartilage squeezes water away from these charged regions until charge–charge repulsions prevent further compression. When the pressure is released, the water returns. Indeed, the cartilage in the joints, which lack blood vessels, is nourished by this flow of liquid brought about by body movements. This explains why long periods of inactivity cause joint cartilage to become thin and fragile.

#### b. Proteoglycans Modulate the Effects of Protein Growth Factors

Proteoglycans have been implicated in a great variety of cellular processes. For example, **fibroblast growth factor (FGF)**; growth factors are proteins that function to induce their specific target cells to grow and/or differentiate; Section 19-3Aa) binds to heparin or to the heparan sulfate chains of proteoglycans and is only bound to its cell-surface receptor in complex with these glycosaminoglycans. Since the binding of FGF to heparin or heparan sulfate protects FGF from degradation, the release of this growth factor from the extracellular matrix by the proteolysis of proteoglycan core proteins or by the partial degradation of heparan sulfate probably provides an important source of active FGF–glycosaminoglycan complexes. Several other growth factors interact similarly with proteoglycans. Apparently, the abundant and ubiquitous distribution of proteoglycans limits the action of these growth factors on their target cells to short distances from the cells secreting the growth factors, a phenomenon that probably greatly influences the formation and maintenance of tissue architecture.

### B. Bacterial Cell Walls

Bacteria are surrounded by rigid cell walls (Fig. 1-13) that give them their characteristic shapes (Fig. 1-1) and permit them to live in hypotonic (less than intracellular salt concentration) environments that would otherwise cause them to swell osmotically until their plasma (cell) membranes lysed (burst). Bacterial cell walls are of considerable medical significance because they are responsible for bacterial **virulence** (disease-evoking power). In fact, the symptoms of many bacterial diseases can be elicited in animals merely by the injection of bacterial cell walls. Furthermore, the

**Figure 11-25** Schematic diagram comparing the cell envelopes of (a) gram-positive bacteria and (b) gram-negative bacteria.

characteristic **antigens** (immunological markers; Section 35-2) of bacteria are components of their cell walls and capsules, so that injection of preparations of these substances into an animal often invokes its immunity against these bacteria. Consequently, several vaccines that are based on purified bacterial polysaccharides have recently become available, including those against *Streptococcus pneumoniae*, a major cause of pneumonia, and *Neisseria meningitidis*, a major cause of meningitis.

Bacteria are classified as **gram-positive** or **gram-negative** depending on whether or not they take up gram stain (Section 1-1B). Gram-positive bacteria (Fig. 11-25a) have a thick ( $\sim 250$  Å) cell wall surrounding their plasma membrane, whereas gram-negative bacteria (Fig. 11-25b) have a thin ( $\sim 30$  Å) cell wall covered by a complex outer membrane.

#### a. Bacterial Cell Walls Have a Peptidoglycan Framework

The cell walls of both gram-positive and gram-negative bacteria consist of covalently linked polysaccharide and polypeptide chains that form a framework that completely encases the cell. This substance, whose molecular structure was elucidated in large part by Jack Strominger, is known as a **peptidoglycan** or **murein** (Latin: *murus*, wall). Its polysaccharide component consists of linear chains of alternating  $\beta(1 \rightarrow 4)$ -linked *N*-acetylglucosamine (**NAG**) and *N*-acetylmuramic acid (**NAM**). The NAM's lactic acid residue forms an amide bond with a D-amino acid-containing tetrapeptide to form the peptidoglycan repeating unit (Fig. 11-26). Neighboring parallel peptidoglycan chains are covalently cross-linked through their tetrapeptide side chains. In the gram-positive bacterium *Staphylococcus aureus*, whose tetrapeptide has the sequence L-Ala-D-isoglutamyl-L-Lys-D-Ala, this cross-link consists of a pentaglycine chain that extends from the terminal carboxyl group of one tetrapeptide to the  $\epsilon$ -amino group of the Lys in a neighboring tetrapeptide.

**Atomic force microscopy (AFM;** an imaging technique that reports the variation in the force between a probe that is several nanometers in diameter and a surface of interest as the probe is scanned over the surface; its resolution is as little as several Ångströms) was used by Simon Foster to

image the cell wall of the gram-negative bacterium *Bacillus subtilis* leading to the following model (Fig. 11-27). Several glycan chains are cross-linked much as described above to form a peptidoglycan “rope,” which due to its natural twist, forms an  $\sim 50$ -nm-diameter helical cable of up to  $50$   $\mu\text{m}$  in length that coils around the long axis of the bacterium to form its cell wall. This structure is presumably stabilized by the formation of covalent cross-links between neighboring segments of the coil. The cell walls of gram-negative bacteria appear to be only one layer thick, whereas as those of gram-positive bacteria are postulated to consist of several such layers. How the peptidoglycan imposes cell shape is unknown.

The *D*-amino acids of peptidoglycans render them resistant to proteases. However, **lysozyme**, an enzyme which is present in tears, mucus, and other vertebrate body secretions, as well as in egg whites, catalyzes the hydrolysis of the  $\beta(1 \rightarrow 4)$  glycosidic linkage between NAM and NAG. Consequently, treatment of gram-positive bacteria with lysozyme degrades their cell walls, which results in their lysis (gram-negative bacteria are resistant to lysozyme degradation). Lysozyme was discovered in 1922 by the British bacteriologist Alexander Fleming after he noticed that a bacterial culture had dissolved where mucus from a sneeze had landed. It was Fleming's hope that lysozyme would be a universal antibiotic but, unfortunately, it is clinically ineffective against pathogenic bacteria. The structure and mechanism of lysozyme are examined in detail in Section 15-2.

#### b. Penicillin Kills Bacteria by Inhibiting Cell Wall Biosynthesis

In 1928, Fleming noticed that the chance contamination of a bacterial culture plate with the mold *Penicillium notatum* lysed nearby bacteria (a clear demonstration of Pasteur's maxim that chance favors a prepared mind). This was caused by the presence of **penicillin** (Fig. 11-28), an antibiotic secreted by the mold. Yet the difficulties of isolating and characterizing penicillin, owing to its instability, led to the passage of over 15 years before penicillin was available for routine clinical use. Penicillin specifically binds to and inactivates enzymes that function to cross-link the peptidoglycan strands of bacterial cell walls. Since cell

**Figure 11-26** Chemical structure of peptidoglycan. (a) The repeating unit of peptidoglycan is an NAG–NAM disaccharide whose lactyl side chain forms an amide bond with a tetrapeptide. The tetrapeptide of *S. aureus* is shown. The isoglutamate is so designated because it forms an amide link via its  $\gamma$ -carboxyl group. In some species, its  $\alpha$ -carboxylate group is replaced by an amide group to form D-isoglutamine and/or the L-Lys residue may have a carboxyl group appended to its  $C_\epsilon$  to form **diaminopimelic acid**. (b) The *S. aureus* bacterial cell wall peptidoglycan. In other gram-positive bacteria, the Gly<sub>5</sub> connecting bridges shown here may contain different amino acid residues such as Ala or Ser. In gram-negative bacteria, the peptide chains are directly linked via peptide bonds.

wall expansion also requires the action of enzymes that degrade cell walls, *exposure of growing bacteria to penicillin results in their lysis*; that is, penicillin disrupts the normal balance between cell wall biosynthesis and degradation.

**Figure 11-27** Model of the *B. subtilis* cell wall. The cell wall consists of a right-handed helical cable composed of several peptidoglycan strands that wraps about the bacterium's plasma membrane. The cell is  $\sim 3 \mu\text{m}$  long. [Courtesy of Simon Foster, University of Sheffield, U.K.]

However, since no human enzyme binds penicillin, it is of low human toxicity, a therapeutic necessity.

Penicillin-treated bacteria that are kept in a hypertonic medium remain intact, even though they have no cell wall.

**Penicillin**

**Figure 11-28** Structure of penicillin. Penicillin contains a thiazolidine ring (red) fused to a  $\beta$ -lactam ring (blue). A variable R group is bonded to the  $\beta$ -lactam ring via a peptide linkage. In benzyl penicillin (penicillin G), one of several naturally occurring derivatives that are clinically effective, R is the benzyl group ( $-\text{CH}_2\phi$ ). In **ampicillin**, a semisynthetic derivative, R is the aminobenzyl group [ $-\text{CH}(\text{NH}_2)\phi$ ].

**Figure 11-29** Enzymatic inactivation of penicillin. Penicillinase inactivates penicillin by catalyzing the hydrolysis of its  $\beta$ -lactam ring to form penicillinoic acid.

Such bacteria, which are called **protoplasts** or **spheroplasts**, are spherical and extremely fragile because they are encased by only their plasma membranes. Protoplasts immediately lyse on transfer to a normal medium.

Most bacteria that are resistant to penicillin secrete a  **$\beta$ -lactamase** (also known as **penicillinase**), which inactivates penicillin by hydrolytically cleaving the amide bond of its  $\beta$ -lactam ring (Fig. 11-29). However, the observation that penicillinase activity varies with the nature of penicillin's R group has prompted the semisynthesis of penicillins, such as **ampicillin** (Fig. 11-28), which are clinically effective against penicillin-resistant strains of bacteria. In addition, penicillins are often administered in combination with  $\beta$ -lactamase inhibitors such as **subactam**.

### c. Bacterial Cell Walls Are Studded with Antigenic Groups

The surfaces of gram-positive bacteria are covered by **teichoic acids** (Greek: *teichos*, city walls), which account for up to 50% of the dry weight of their cell walls. Teichoic acids are polymers of glycerol or ribitol linked by phosphodiester bridges (Fig. 11-30). The hydroxyl groups of this sugar-phosphate chain are substituted by D-Ala residues and saccharides such as glucose or NAG. Teichoic acids are anchored to the peptidoglycans via phosphodiester bonds to the C6-OH groups of their NAG residues. They often terminate in **lipopolysaccharides** (lipids that contain polysaccharides; Section 12-1).

The outer membranes of gram-negative bacteria (Fig. 11-25b) are composed of complex lipopolysaccharides, proteins, and phospholipids that are organized in a complicated manner. The **periplasmic space**, an aqueous compartment that lies between the plasma membrane and the peptidoglycan cell wall, contains proteins that transport sugars and other nutrients. The outer membrane functions as a barrier to exclude harmful substances (such as gram stain). This accounts for the observation that gram-negative bacteria are less affected by lysozyme and penicillin, as well as by other antibiotics, than are gram-positive bacteria.

The outer surfaces of gram-negative bacteria are coated with complex and often unusual polysaccharides known as **O-antigens** that uniquely mark each bacterial strain (Fig. 11-31). The observation that mutant strains of pathogenic bacteria lacking O-antigens are nonpathogenic suggests

**Figure 11-30** Structure of teichoic acid. A segment of a teichoic acid molecule with a glycerol phosphate backbone that bears alternating residues of D-Ala and NAG.

**Figure 11-31** Some of the unusual monosaccharides that occur in the O-antigens of gram-negative bacteria. These sugars rarely occur in other organisms.

that O-antigens participate in the recognition of host cells. O-Antigens, as their name implies, are also the means by which a host's immunological defense system recognizes invading bacteria as foreign (Section 35-2A). As part of the ongoing biological warfare between pathogen and host, O-antigens are subject to rapid mutational alteration so as to generate new bacterial strains that the host does not initially recognize (the mutations are in the genes specifying the enzymes that synthesize the O-antigens).

### C. Glycoprotein Structure and Function

#### a. Glycoprotein Carbohydrate Chains Are Highly Diverse

Almost all the secreted and membrane-associated proteins of eukaryotic cells are glycosylated. Indeed, protein glycosylation is more abundant than all other types of post-translational modifications combined. Oligosaccharides form two types of direct attachments to these proteins: **N-linked** and **O-linked**. Sequence analyses of glycoproteins have led to the following generalizations about these attachments.

**1.** In the vast majority of N-glycosidic (N-linked) attachments, an NAG is  $\beta$ -linked to the amide nitrogen of an Asn in the sequence Asn-X-Ser or Asn-X-Thr, where X is any amino acid residue except Pro and only rarely Asp, Glu, Leu, or Trp (Fig. 11-32a). The oligosaccharides in these linkages usually have a distinctive **core** (innermost sequence; Fig. 11-32b) whose peripheral mannose residues are linked to either mannose or NAG residues. These latter residues may, in turn, be linked to yet other sugar residues,

**Figure 11-32** N-Linked oligosaccharides. (a) All N-glycosidic protein attachments occur through a  $\beta$ -N-acetylglucosamino-Asn bond in which the Asn occurs in the sequence Asn-X-Ser/Thr (red) where X is any amino acid. (b) N-Linked oligosaccharides usually have the branched (mannose)<sub>3</sub>(NAG)<sub>2</sub> core shown. (c) Some examples of N-linked oligosaccharides. [After Sharon, N. and Lis, H., *Chem. Eng. News* 59(13), 28 (1981).] See **Kinemage Exercise 7-4**

**Figure 11-33** Some common *O*-glycosidic attachments of oligosaccharides to glycoproteins (red).

so that an enormous diversity of *N*-linked oligosaccharides is possible (e.g., there are  $\sim 10^{12}$  possible hexasaccharides, although only a small fraction of them are actually synthesized). Several *N*-linked oligosaccharides are shown in Fig. 11-32c.

2. The most common *O*-glycosidic (*O*-linked) attachment involves the disaccharide core  $\beta$ -galactosyl-(1 $\rightarrow$ 3)- $\alpha$ -N-acetylgalactosamine  $\alpha$ -linked to the OH group of either Ser or Thr (Fig. 11-33a). Less commonly, glucose, galactose, mannose, and xylose form  $\alpha$ -*O*-glycosides with Ser or Thr (Fig. 11-33b). All other hydroxyl-bearing amino acid side chains occasionally form *O*-glycosidic bonds: those with Tyr (e.g., in the protein **glycogenin**; Section 18-2B), 5-hydroxy-Lys (Hyl; e.g., in collagen; Section 8-2Bb), and 4-hydroxy-Pro (Hyp). However, there seem to be few, if any, additional generalizations that can be made about *O*-glycosidically linked oligosaccharides. They vary in size from a single galactose residue in collagen to chains of up to 1000 disaccharide units in proteoglycans.

*N*-Linked glycans are around 5-fold more common than *O*-linked glycans with only  $\sim 10\%$  of glycoproteins having both types of attachments.

Oligosaccharides tend to attach to proteins at sequences that form  $\beta$  bends. Taken with their hydrophilic character, this observation suggests that *oligosaccharides extend from the surfaces of proteins rather than participate in their internal structures*. Indeed, the relatively few glycoprotein X-ray structures that have yet been reported, for example, those of **immunoglobulin G** (Section 35-2Ba) and the influenza virus **hemagglutinin** (Section 33-4Bb), are consistent with this hypothesis. This accounts for the observation that the protein structures of most glycoproteins are unaffected by the removal of their associated oligosaccharides. Both experimental and theoretical studies indicate that oligosaccharides have

**Figure 11-34** Model of oligosaccharide dynamics in bovine pancreatic ribonuclease B (RNase B). The allowed conformations of the (mannose)<sub>5</sub>(NAG)<sub>2</sub> oligosaccharide (yellow) that is linked to a single site on the protein (purple) are shown in superimposed snapshots. [Courtesy of Raymond Dwek, Oxford University, U.K.]

mobile and rapidly fluctuating conformations (Fig. 11-34; which accounts for the difficulty in crystallizing them). Thus, representations in which oligosaccharides are shown as having fixed three-dimensional structures do not tell the whole story.

### b. Glycoprotein Carbohydrates Have a Variety of Functions

Cells tend to synthesize a large repertoire of a given *N*-linked glycoprotein, in which each variant species (**glycoform**) differs somewhat in the sequences, locations, and numbers of its covalently attached oligosaccharides. For example, one of the simplest glycoproteins, bovine pancreatic **ribonuclease B (RNase B)**, differs from the well-characterized and carbohydrate-free enzyme RNase A (Section 9-1A) only by the attachment of a single *N*-glycosidically linked oligosaccharide chain. The oligosaccharide has the core sequence diagrammed in Fig. 11-35 with considerable microheterogeneity in the position of a sixth mannose residue. The oligosaccharide does not affect the native enzyme's

**Figure 11-35** The microheterogeneous *N*-linked oligosaccharide of RNase B has the (mannose)<sub>5</sub>(NAG)<sub>2</sub> core shown. A sixth mannose residue occurs at various positions on this core.

conformation, substrate specificity, or catalytic properties. However, RNase A folds to its native state more slowly than does RNase B and tends to aggregate. This suggests that the oligosaccharide functions similarly to a molecular chaperone (Section 9-2C), most likely by shielding a hydrophobic patch on the protein surface.

Human **granulocyte-macrophage colony-stimulating factor (GM-CSF)**, a 127-residue protein growth factor that promotes the development, activation, and survival of the white blood cells known as **granulocytes** and **macrophages**, is variably glycosylated at two *N*-linked sites and five *O*-linked sites. Through the generation of mutant varieties of GM-CSF that lack one or both of the *N*-glycosylation sites, it was found that the lifetime of GM-CSF in the bloodstream increases with its level of glycosylation. However, GM-CSF that is produced by *E. coli* and hence is unglycosylated (bacteria rarely glycosylate the proteins they synthesize) has a 20-fold higher specific biological activity than does the naturally occurring glycoprotein.

As the foregoing examples suggest, no generalization can be made about the effects of glycosylation on protein properties; they must be experimentally determined on a case-by-case basis. Nevertheless, it is becoming increasingly evident that glycosylation can affect protein properties in many ways, including protein folding, oligomerization, physical stability, specific bioactivity, rate of clearance from the bloodstream, and protease resistance. Thus, *the species-specific and tissue-specific distribution of glycoforms that each cell synthesizes endows it with a characteristic spectrum of biological properties.*

#### c. O-Linked Glycoproteins Often Have Protective Functions

*O*-Linked polysaccharides tend not to be uniformly distributed along polypeptide chains. Rather, they are clustered into heavily glycosylated (65–85% carbohydrate by weight) segments in which glycosylated Ser and Thr residues comprise 25 to 40% of the sequence. The carbohydrates' hydrophilic and steric interactions cause these heavily glycosylated regions, which are also rich in Pro and other helix-breaking residues, to assume extended conformations. For example, **mucins**, the protein components of **mucus**, are *O*-linked glycoproteins that can be exceedingly large (up to  $\sim 10^7$  D) and whose carbohydrate chains are often sulfated and hence mutually repelling. Mucins, which may be membrane-bound or secreted, therefore consist of stiff chains that are devoid of secondary structure and which occupy time-averaged volumes approximating those of small bacteria. Consequently, mucins, at their physiological concentrations, form intertangled networks that comprise the viscoelastic gels that protect and lubricate the mucous membranes that produced them.

Eukaryotic cells, as we shall see in Section 12-3E, have a thick and fuzzy coating of glycoproteins and **glycolipids** named the **glycocalyx** that prevents the close approach of macromolecules and other cells. How, then, can cells interact? Many cell-surface proteins, such as the receptors for various macromolecules, have relatively short and presum-

ably stiff *O*-glycosylated regions that link these glycoproteins' membrane-bound domains to their functional domains. This arrangement is thought to extend the functional domains in a lollipop-like manner above the cell's densely packed glycocalyx, thereby permitting the functional domain to interact with extracellular macromolecules that cannot penetrate the glycocalyx.

#### d. Oligosaccharide Markers Mediate a Variety of Intercellular Interactions

Glycoproteins are important constituents of plasma membranes (Section 12-3). The location of their carbohydrate moieties can be determined by electron microscopy. The glycoproteins are labeled with lectins that have been conjugated (covalently cross-linked) to **ferritin**, an iron-transporting protein that is readily visible in the electron microscope because of its electron-dense iron hydroxide core. Such experiments, with lectins of different specificities and with a variety of cell types, have demonstrated that *the carbohydrate groups of membrane-bound glycoproteins are, for the most part, located on the external surfaces of cell membranes.* Thus, the viability of cultured cells from multicellular organisms that have any of a large number of glycosylation mutations and the infrequent viability of whole organisms that bear such mutations indicate that oligosaccharides are important for intercellular communications but not for intracellular housekeeping functions.

A further indication that oligosaccharides function as biological markers is the observation that the carbohydrate content of a glycoprotein often governs its metabolic fate. For example, the excision of sialic acid residues from certain radioactively labeled blood plasma glycoproteins by treatment with **sialidase** greatly increases the rate at which these glycoproteins are removed from the circulation. The glycoproteins are taken up and degraded by the liver in a process that depends on the recognition by liver cell receptors of sugar residues such as galactose and mannose, which are exposed by the sialic acid excision. A diverse series of receptors, each specific for a particular type of sugar residue, participates in removing any particular glycoprotein from the blood. A variety of glycoforms for a given glycoprotein therefore probably ensures that it has a range of lifetimes in the blood. *Similar "ticketing" mechanisms probably govern the compartmentation and degradation of glycoproteins within cells.*

The observation that cancerous cells are more susceptible to agglutination by lectins than are normal cells led to the discovery that *there are significant differences between the cell-surface carbohydrate distributions of cancerous and noncancerous cells* (Fig. 11-36). Normal cells stop growing when they touch each other, a phenomenon known as **contact inhibition**. Cancer cells, however, are under no such control and therefore form **malignant tumors** (Section 19-3B).

Carbohydrates are important mediators of cell-cell recognition and have been implicated in related processes such as fertilization, cellular differentiation, the aggregation of cells to form organs, and the infection of cells by

(a)

aggregated into clusters on the cancerous cell. [Courtesy of Garth Nicolson, The Institute for Molecular Medicine, Huntington Beach, California.]

bacteria and viruses. For example, bacteria initiate infections by attaching to host cells (Fig. 11-37) via bacterial proteins known as **adhesins**, which each specifically bind certain host cell molecules (the adhesins' receptors). In gram-negative bacteria such as *E. coli*, adhesins are often minor components of the heteropolymeric rodlike or-

ganelles called pili (Fig. 1-3b). The so-called P pili that mediate the attachment of the *E. coli* strain that causes urinary tract infections in humans do so via an adhesin named **PapG** protein. This protein specifically binds to the  $\alpha$ -D-galactopyranosyl-(1  $\rightarrow$  4)- $\beta$ -D-galactopyranose groups that are present on the surfaces of urinary tract epithelial cells. Electron microscopy studies revealed that the PapG adhesin is located at the end of the P pili's flexible tip, thereby providing this adhesin with considerable steric freedom in binding to its digalactoside receptor.

In the never-ending evolutionary struggle between pathogens and their hosts, mucins have evolved to contain the target oligosaccharides of certain pathogens. These act as decoys that divert these pathogens from their target cells. This, of course, puts selective pressure on the pathogen to evolve a receptor that binds to a different cell-surface oligosaccharide.

#### D. Glycomics

**Glycomics**, the field of study that structurally and functionally characterizes all the carbohydrates in a given cell type, complements genomics (for DNA) and proteomics (for proteins). It is clear that the **glycome** varies with the species, cell type, developmental stage, and even environmental conditions. However, glycomics is far less developed than genomics or proteomics. There are several reasons for this:

1. The branched structures of oligosaccharides greatly increases their complexity and hence the difficulty in determining their sequences relative to those of polynucleotides and polypeptides, which are invariably linear.
2. The microheterogeneity of oligosaccharides, which often has biological significance (Section 11-3Cb), complicates their characterization relative to polynucleotides and polypeptides, which each have unique primary structures.

3. Because the biosynthesis of carbohydrates is not under direct genetic control, there is no method for amplifying them such as the polymerase chain reaction (PCR; Section 5-5F) for nucleic acids and expression systems for proteins (Section 5-5G). Thus, until recently, the only way of obtaining sufficient quantities of a particular polysaccharide was to isolate it from natural sources.

4. Methods for synthesizing specific oligosaccharides have lagged far behind methods for synthesizing polynucleotides and polypeptides (Sections 7-5 and 7-6). This is due to the branching of oligosaccharides, their large number of functional groups that must be differentially protected during elongation reactions, and the chiral nature of glycosidic bonds. However, in recent years, Peter Seeberger has developed automated, solid-phase methods for synthesizing small oligosaccharides, although these methods are, as yet, incapable of synthesizing all desired oligosaccharides, are time-consuming, and still require considerable expertise.

5. The complexity of an organism's glycome greatly exceeds that of its proteome due to the diversity of the gly-

come's constituent carbohydrates and the number of ways they can interact with one another and with proteins.

A recent advance that has greatly accelerated glycomics research is the development of **carbohydrate microarrays** to identify the carbohydrates that specifically bind to a particular protein, RNA, or even whole cells. In this methodology, which is analogous to the use of DNA microarrays (Section 7-6B), up to several thousand different oligosaccharides are covalently or physically immobilized at specific sites on a solid surface such as a glass slide. A fluorescently labeled protein, RNA, or cell type is then incubated with the microarray, which is subsequently rinsed, and the oligosaccharides to which the protein/RNA/cell binds are identified by the fluorescence at their corresponding positions. In addition to their use in basic research, carbohydrate microarrays have been employed in such diverse applications as the identification of pathogens, the diagnosis of human diseases that are characterized by the presence of certain oligosaccharides, and the development of carbohydrate-based drugs and vaccines.

## CHAPTER SUMMARY

Carbohydrates are polyhydroxy aldehydes or ketones of approximate composition  $(C \cdot H_2O)_n$  that are important components of biological systems.

**1 Monosaccharides** The various monosaccharides, such as ribose, fructose, glucose, and mannose, differ in their number of carbon atoms, the positions of their carbonyl groups, and their diastereomeric configurations. These sugars exist almost entirely as cyclic hemiacetals and hemiketals, which, for five- and six-membered rings, are respectively known as furanoses and pyranoses. The two anomeric forms of these cyclic sugars may interconvert by mutarotation. Pyranose sugars have nonplanar rings with boat and chair conformations similar to those of substituted cyclohexanes. Polysaccharides are held together by glycosidic bonds between neighboring monosaccharide units. Glycosidic bonds do not undergo mutarotation. Monosaccharides can be oxidized to aldonic and glycuronic acids or reduced to alditols. An OH group is replaced by H in deoxy sugars and by an amino group in amino sugars.

**2 Polysaccharides** Carbohydrates can be purified by electrophoretic and chromatographic procedures. Affinity chromatography using lectins has been particularly useful in this regard. The sequences and linkages of polysaccharides may be determined by methylation analysis and by the use of specific exoglycosidases. Similar information may be obtained through NMR spectroscopy and/or mass spectrometric techniques. Cellulose, the structural polysaccharide of plant cell walls, is a linear polymer of  $\beta(1 \rightarrow 4)$ -linked D-glucose residues. It forms a fibrous hydrogen bonded structure of exceptional strength that in plant cells is embedded in an amorphous matrix. Starch, the food storage polysaccharide of plants, consists of a mixture of the linear  $\alpha(1 \rightarrow 4)$ -linked glucan  $\alpha$ -amylose and the  $\alpha(1 \rightarrow 6)$ -branched and  $\alpha(1 \rightarrow 4)$ -linked glucan amylopectin. Glycogen, the animal storage polysaccharide, resembles amylopectin but is more highly branched. Digestion of starch and glycogen is initiated by

$\alpha$ -amylase and is completed by specific membrane-bound intestinal enzymes.

**3 Glycoproteins** Proteoglycans of ground substance are mostly high molecular mass aggregates, many of which structurally resemble a bottlebrush. Their proteoglycan subunits consist of a core protein to which glycosaminoglycans, usually chondroitin sulfate and keratan sulfate, are covalently linked. The rigid framework of a bacterial cell wall consists of chains of alternating  $\beta(1 \rightarrow 4)$ -linked NAG and NAM that are cross-linked by short polypeptides to form a helical peptidoglycan cable that wraps around the bacterium. Lysozyme cleaves the glycosidic linkages between NAM and NAG of peptidoglycan. Penicillin specifically inactivates enzymes involved in the cross-linking of peptidoglycans. Both of these substances cause the lysis of susceptible bacteria. Gram-positive bacteria have teichoic acids that are linked covalently to their peptidoglycans. Gram-negative bacteria have outer membranes that bear complex and unusual polysaccharides known as O-antigens. These participate in the recognition of host cells and are important in the immunological recognition of bacteria by the host. Oligosaccharides attach to eukaryotic proteins in only a few ways. In *N*-glycosidic attachments, an NAG is invariably bound to the amide nitrogen of Asn in the sequence Asn-X-Ser(Thr). *O*-Glycosidic attachments are made to Ser or Thr in most proteins and to 5-hydroxylysine in collagen.

Oligosaccharides are located on the surfaces of glycoproteins. Glycoproteins have functions that span the entire range of protein activities, although the roles of their carbohydrate moieties are only poorly understood. For example, ribonuclease B differs from the functionally indistinguishable and carbohydrate-free ribonuclease A only by the attachment of a single oligosaccharide of somewhat variable sequence which increases the protein's rate of folding, whereas the biological properties of granulocyte-macrophage colony-stimulating factor are significantly affected by its multiple oligosaccharide chains. The

viscoelastic and hence protective properties of mucus largely result from the numerous negatively charged oligosaccharide groups of its component mucins. The carbohydrate moieties of glycoproteins in plasma membranes are invariably located on the external surfaces of the membranes. A glycoprotein's carbohydrate moieties may direct its metabolic fate by governing its

uptake by certain cells or cell compartments. Glycoproteins are also important mediators of cell–cell recognition and, in many cases, are the receptors for bacterial attachment, via adhesins, in the initial stages of infection. Glycomics, the carbohydrate analog of genomics and proteomics, seeks to characterize all the carbohydrates in a particular cell type.

## PROBLEMS

1. The trisaccharide drawn below is named **raffinose**. What is its systematic name? Is it a reducing sugar?

**Raffinose**

2. The systematic name of **melezitose** is *O*-α-D-glucopyranosyl-(1 → 3)-*O*-β-D-fructofuranosyl-(2 → 1)-α-D-glucopyranoside. Draw its molecular formula. Is it a reducing sugar?

3. Name the linear form of D-glucose using the (*RS*) chirality nomenclature system. [See Section 4-2C. *Hint*: The branch toward C1 has higher priority than the branch toward C6.]

\*4. Draw the α-furanose form of D-talose and the β-pyranose form of L-sorbose.

5. The NaBH<sub>4</sub> reduction product of D-glucose may be named L-sorbitol or D-glucitol. Explain.

6. How many different disaccharides of D-glucopyranose are possible? How many trisaccharides?

7. A molecule of amylopectin consists of 1000 glucose residues and is branched every 25 residues. How many reducing ends does it have?

8. Most paper is made by removing the lignin from wood pulp and forming the resulting mass of largely unoriented cellulose fibers into a sheet. Untreated paper loses most of its strength when wet with water but maintains its strength when wet with oil. Explain.

\*9. Write a chemical mechanism for the acid-catalyzed mutarotation of glucose.

10. The values of the specific rotation,  $[\alpha]_D^{20}$ , for the α and β anomers of D-galactose are 150.7° and 52.8°, respectively. A mixture that is 20% α-D-galactose and 80% β-D-galactose is dissolved in water at 20° C. What is its initial specific rotation? After several hours, the specific rotation of this mixture reached an equilibrium value of 80.2°. What is its anomeric composition?

11. Name the epimers of D-gulose.

12. Exhaustive methylation of a trisaccharide followed by acid hydrolysis yields equimolar quantities of 2,3,4,6-tetra-*O*-methyl-D-galactose, 2,3,4-tri-*O*-methyl-D-mannose, and 2,4,6-tri-*O*-methyl-D-glucose. Treatment of the trisaccharide with β-galactosidase yields D-galactose and a disaccharide. Treatment of this disaccharide with α-mannosidase yields D-mannose and D-glucose. Draw the structure of the trisaccharide and state its systematic name.

13. The enzyme β-amylase cleaves successive maltose units from the nonreducing end of α(1 → 4) glucans. It will not cleave at glucose residues that have an α(1 → 6) bond. The end products of the exhaustive digestion of amylopectin by β-amylase are known as **limit dextrins**. Draw a schematic diagram of an amylopectin molecule and indicate what part(s) of it constitutes limit dextrins.

14. One demonstration of P.T. Barnum's maxim that there's a sucker born every minute is that new "reducing aids" regularly appear on the market. An eat-all-you-want nostrum, which was touted as a "starch blocker" [and which the Food and Drug Administration (FDA) eventually banned], contained an α-amylase-inhibiting protein extracted from beans. If this substance had really worked as advertised, which it did not, what unpleasant side effects would have resulted from its ingestion with a starch-containing meal? Discuss why this substance, which inhibits α-amylase *in vitro*, would not do so in the intestines after oral ingestion.

\*15. Treatment of a 6.0-g sample of glycogen with Tollens' reagent followed by exhaustive methylation and then hydrolysis yields 3.1 mmol of 2,3-di-*O*-methylglucose and 0.0031 mmol of 1,2,3-tri-*O*-methylgluconic acid as well as other products. (a) What fraction of glucose residues occur at (1 → 6) branch points, and what is the average number of glucose residues per branch? (b) What are the other products of the methylation-hydrolysis treatment and in what amounts are they formed? (c) What is the average molecular mass of the glycogen?

16. The lysis of a culture of *E. coli* yields a solution with mucuslike viscosity. Adding DNase to the solution greatly reduces this viscosity. What is the physical basis of the viscosity?

17. Instilling methyl-α-D-mannoside into the bladder of a mouse prevents the colonization of its urinary tract by *E. coli*. What is the reason for this effect?

# Lipids and Membranes

## CHAPTER 12

### 1 Lipid Classification

- A. Fatty Acids
- B. Triacylglycerols
- C. Glycerophospholipids
- D. Sphingolipids
- E. Cholesterol

### 2 Properties of Lipid Aggregates

- A. Micelles and Bilayers
- B. Liposomes
- C. Bilayer Dynamics

### 3 Biological Membranes

- B. The Secretory Pathway
- C. Vesicle Formation
- D. Vesicle Fusion
- E. Protein Targeting to Mitochondria

### 5 Lipoproteins

- A. Lipoprotein Structure
- B. Lipoprotein Function
- C. Lipoprotein Dysfunction in Atherosclerosis and Alzheimer's Disease

**Membranes** function to organize biological processes by compartmentalizing them. Indeed, the cell, the basic unit of life, is essentially defined by its enveloping plasma membrane. Moreover, in eukaryotes, many subcellular organelles, such as nuclei, mitochondria, chloroplasts, the endoplasmic reticulum, and the Golgi apparatus (Fig. 1-5), are likewise membrane bounded.

*Biological membranes are organized assemblies of lipids and proteins with small amounts of carbohydrate. Yet they are not impermeable barriers to the passage of materials. Rather, they regulate the composition of the intracellular medium by controlling the flow of nutrients, waste products, ions, etc., into and out of the cell.* They do this through membrane-embedded “pumps” and “gates” that transport specific substances against an electrochemical gradient or permit their passage with such a gradient (Chapter 20).

Many fundamental biochemical processes occur on or in a membranous scaffolding. For example, electron transport and oxidative phosphorylation (Chapter 22), processes that oxidize nutrients with the concomitant generation of ATP, are mediated by an organized battery of enzymes that are components of the inner mitochondrial membrane. Likewise, photosynthesis, in which light energy powers the chemical combination of H<sub>2</sub>O and CO<sub>2</sub> to form carbohydrates (Chapter 24), occurs in the inner membranes of chloroplasts. The processing of information, such as sensory stimuli or intercellular communications, is generally a membrane-based phenomenon. Thus nerve impulses are mediated by nerve cell membranes (Section 20-5) and the presence of certain substances such as hormones and nutrients is detected by specific membrane-bound receptors (Chapter 19).

In this chapter, we examine the compositions, structures, and formation of biological membranes and related substances. Specific membrane-based biochemical processes, such as those mentioned above, are dealt with in later chapters.

## 1 LIPID CLASSIFICATION

**Lipids** (Greek: *lipos*, fat) are substances of biological origin that are soluble in organic solvents such as chloroform and methanol but are only sparingly soluble, if at all, in water. Hence, they are easily separated from other biological materials by extraction into organic solvents and may be further fractionated by such techniques as adsorption chromatography, thin layer chromatography, and reverse-phase chromatography (Section 6-3D). Fats, oils, certain vitamins and hormones, and most nonprotein membrane components are lipids. In this section, we discuss the structures and physical properties of the major classes of lipids.

### A. Fatty Acids

**Fatty acids** are carboxylic acids with long-chain hydrocarbon side groups (Fig. 12-1). They are rarely free in nature but, rather, occur in esterified form as the major components of the various lipids described in this chapter. The more common biological fatty acids are listed in Table 12-1. In higher plants and animals, the predominant fatty acid residues are those of the C<sub>16</sub> and C<sub>18</sub> species **palmitic**, **oleic**, **linoleic**, and **stearic acids**. Fatty acids with <14 or >20 carbon atoms are uncommon. *Most fatty acids have an even number of carbon*

**Figure 12-1** Structural formulas of some  $C_{18}$  fatty acids. The double bonds all have the cis configuration.

atoms because they are usually biosynthesized by the concatenation of  $C_2$  units (Section 25-4C). Over half of the fatty acid residues of plant and animal lipids are unsaturated (contain double bonds) and are often polyunsaturated (contain two or more double bonds). Bacterial fatty acids are rarely polyunsaturated but are commonly branched, hydroxylated, or contain cyclopropane rings. Unusual fatty acids also occur as components of the oils and **waxes** (esters of fatty acids and long-chain alcohols) produced by certain plants.

#### a. The Physical Properties of Fatty Acids Vary with Their Degree of Unsaturation

Table 12-1 indicates that the first double bond of an unsaturated fatty acid commonly occurs between its  $C_9$  and  $C_{10}$  atoms counting from the carboxyl C atom (a  $\Delta^9$ - or 9-double bond). In polyunsaturated fatty acids, the double bonds tend to occur at every third carbon atom toward the methyl terminus of the molecule (such as  $-\text{CH}=\text{CH}-\text{CH}_2-\text{CH}=\text{CH}-$ ). Double bonds in polyunsaturated fatty acids are almost never conjugated (as in  $-\text{CH}=\text{CH}-\text{CH}=\text{CH}-$ ). Triple bonds rarely occur in fatty acids or any other compound of biological origin. Two important classes of polyunsaturated fatty acids are denoted  $n-3$  (or  $\omega-3$ ) and  $n-6$  (or  $\omega-6$ ) fatty acids. This nomenclature identifies the last double-bonded carbon atom as counted from the methyl terminal ( $\omega$ ) end of the chain.

Saturated fatty acids are highly flexible molecules that can assume a wide range of conformations because there is relatively free rotation about each of their  $C-C$  bonds. Nevertheless, their fully extended conformation is that of minimum energy because this conformation has the least amount of

**Table 12-1** The Common Biological Fatty Acids

Symbol <sup>a</sup>	Common Name	Systematic Name	Structure	mp (°C)
<b>Saturated fatty acids</b>				
12:0	Lauric acid	Dodecanoic acid	$\text{CH}_3(\text{CH}_2)_{10}\text{COOH}$	44.2
14:0	Myristic acid	Tetradecanoic acid	$\text{CH}_3(\text{CH}_2)_{12}\text{COOH}$	52
16:0	Palmitic acid	Hexadecanoic acid	$\text{CH}_3(\text{CH}_2)_{14}\text{COOH}$	63.1
18:0	Stearic acid	Octadecanoic acid	$\text{CH}_3(\text{CH}_2)_{16}\text{COOH}$	69.6
20:0	Arachidic acid	Eicosanoic acid	$\text{CH}_3(\text{CH}_2)_{18}\text{COOH}$	75.4
22:0	Behenic acid	Docosanoic acid	$\text{CH}_3(\text{CH}_2)_{20}\text{COOH}$	81
24:0	Lignoceric acid	Tetracosanoic acid	$\text{CH}_3(\text{CH}_2)_{22}\text{COOH}$	84.2
<b>Unsaturated fatty acids (all double bonds are cis)</b>				
16:1 $n-7$	Palmitoleic acid	9-Hexadecenoic acid	$\text{CH}_3(\text{CH}_2)_5\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$	-0.5
18:1 $n-9$	Oleic acid	9-Octadecenoic acid	$\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$	13.4
18:2 $n-6$	Linoleic acid	9,12-Octadecadienoic acid	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_2(\text{CH}_2)_6\text{COOH}$	-9
18:3 $n-3$	$\alpha$ -Linolenic acid	9,12,15-Octadecatrienoic acid	$\text{CH}_3\text{CH}_2(\text{CH}=\text{CHCH}_2)_3(\text{CH}_2)_6\text{COOH}$	-17
18:3 $n-6$	$\gamma$ -Linolenic acid	6,9,12-Octadecatrienoic acid	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_3(\text{CH}_2)_3\text{COOH}$	
20:4 $n-4$	Arachidonic acid	5,8,11,14-Eicosatetraenoic acid	$\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_4(\text{CH}_2)_2\text{COOH}$	-49.5
20:5 $n-3$	EPA	5,8,11,14,17-Eicosapentaenoic acid	$\text{CH}_3\text{CH}_2(\text{CH}=\text{CHCH}_2)_5(\text{CH}_2)_2\text{COOH}$	-54
22:6 $n-3$	DHA	4,7,10,13,16,19-Docosahexenoic acid	$\text{CH}_3\text{CH}_2(\text{CH}=\text{CHCH}_2)_6\text{CH}_2\text{COOH}$	
24:1 $n-9$	Nervonic acid	15-Tetracosenoic acid	$\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{CH}(\text{CH}_2)_{13}\text{COOH}$	39

<sup>a</sup>Number of carbon atoms: number of double bonds. For unsaturated fatty acids,  $n$  is the number of carbon atoms,  $n-x$  is the double-bonded carbon atom, and  $x$  is the number of that carbon atom counting from the methyl terminal ( $\omega$ ) end of the chain.

steric interference between neighboring methylene groups. The melting points (mp) of saturated fatty acids, like those of most substances, increase with molecular mass (Table 12-1).

Fatty acid double bonds almost always have the *cis* configuration (Fig. 12-1). This puts a rigid 30° bend in the hydrocarbon chain of unsaturated fatty acids that interferes with their efficient packing to fill space. The consequent reduced van der Waals interactions cause fatty acid melting points to decrease with their degree of unsaturation (Table 12-1). Lipid fluidity likewise increases with the degree of unsaturation of their component fatty acid residues. This phenomenon, as we shall see in Section 12-2Cb, has important consequences for membrane properties.

### B. Triacylglycerols

The fats and oils that occur in plants and animals consist largely of mixtures of **triacylglycerols** (also referred to as **triglycerides** or **neutral fats**). *These nonpolar, water-insoluble substances are fatty acid triesters of glycerol:*

Triacylglycerols function as energy reservoirs in animals and are therefore their most abundant class of lipids even though they are not components of biological membranes.

**Figure 12-2** Scanning electron micrograph of adipocytes. Each contains a fat globule that occupies nearly the entire cell. [Fred E. Hossler/Visuals Unlimited.]

Triacylglycerols differ according to the identity and placement of their three fatty acid residues. The so-called **simple triacylglycerols** contain one type of fatty acid residue and are named accordingly. For example, **tristearoylglycerol** or **tristearin** contains three stearic acid residues, whereas **trioleoylglycerol** or **triolein** has three oleic acid residues. The more common **mixed triacylglycerols** contain two or three different types of fatty acid residues and are named according to their placement on the glycerol moiety.

#### 1-Palmitoleoyl-2-linoleoyl-3-stearoylglycerol

Fats and oils (which differ only in that fats are solid and oils are liquid at room temperature) are complex mixtures of simple and mixed triacylglycerols whose fatty acid compositions vary with the organism that produced them. Plant oils are usually richer in unsaturated fatty acid residues than are animal fats, as the lower melting points of oils imply.

#### a. Triacylglycerols Are Efficient Energy Reserves

Fats are a highly efficient form in which to store metabolic energy. This is because fats are less oxidized than are carbohydrates or proteins and hence yield significantly more energy on oxidation. Furthermore, fats, being nonpolar substances, are stored in anhydrous form, whereas glycogen, for example, binds about twice its weight of water under physiological conditions. Fats therefore provide about six times the metabolic energy of an equal weight of hydrated glycogen.

In animals, **adipocytes** (fat cells; Fig. 12-2) are specialized for the synthesis and storage of triacylglycerols. Whereas

other types of cells have only a few small droplets of fat dispersed in their cytosol, adipocytes may be almost entirely filled with fat globules. **Adipose tissue** is most abundant in a subcutaneous layer and in the abdominal cavity. The fat content of normal humans (21% for men, 26% for women) enables them to survive starvation for 2 to 3 months. In contrast, the body's glycogen supply, which functions as a short-term energy store, can provide for the body's metabolic needs for less than a day. The subcutaneous fat layer also provides thermal insulation, which is particularly important for warm-blooded aquatic animals, such as whales, seals, geese, and penguins, which are routinely exposed to low temperatures.

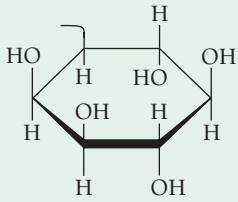

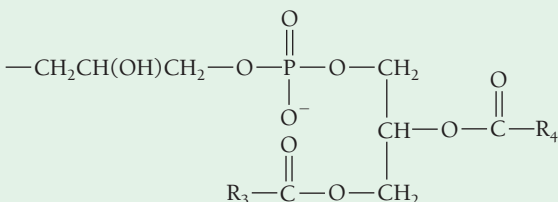

### C. Glycerophospholipids

**Glycerophospholipids** (or **phosphoglycerides**) are the major lipid components of biological membranes. They consist of **sn-glycerol-3-phosphate** (Fig. 12-3a) esterified at its C1 and C2 positions to fatty acids and at its phosphoryl group to a group, X, to form the class of substances diagrammed in Fig. 12-3b. **Glycerophospholipids** are therefore **amphiphilic molecules with nonpolar aliphatic "tails" and polar phosphoryl-X "heads."** The simplest glycerophospholipids, in which X = H, are **phosphatidic acids**; they are present only in small amounts in biological membranes. *In the glycerophospholipids that commonly occur in biological membranes, the head groups are derived from polar alcohols* (Table 12-2). Saturated C<sub>16</sub> and C<sub>18</sub> fatty acids usually

**Figure 12-3 Molecular formula of glycerophospholipids.** (a) The compound shown in Fischer projection (Section 4-2B) can be equivalently referred to as L-glycerol-3-phosphate or D-glycerol-1-phosphate. However, using **stereospecific numbering** (*sn*), which assigns the 1-position to the group occupying the *pro-S* position of a prochiral center (see Section 4-2Ca for a discussion of prochirality), the compound is unambiguously named *sn*-glycerol-3-phosphate. (b) The general formula of the glycerophospholipids. R<sub>1</sub> and R<sub>2</sub> are long-chain hydrocarbon tails of fatty acids and X is derived from a polar alcohol (Table 12-2).

**Table 12-2 The Common Classes of Glycerophospholipids**

Name of X—OH	Formula of —X	Name of Phospholipid
Water	—H	Phosphatidic acid
Ethanolamine	—CH <sub>2</sub> CH <sub>2</sub> NH <sub>3</sub> <sup>+</sup>	Phosphatidylethanolamine
Choline	—CH <sub>2</sub> CH <sub>2</sub> N(CH <sub>3</sub> ) <sub>3</sub> <sup>+</sup>	Phosphatidylcholine (lecithin)
Serine	—CH <sub>2</sub> CH(NH <sub>3</sub> <sup>+</sup> )COO <sup>−</sup>	Phosphatidylserine
<i>myo</i> -Inositol		Phosphatidylinositol
Glycerol	—CH <sub>2</sub> CH(OH)CH <sub>2</sub> OH	Phosphatidylglycerol
Phosphatidylglycerol		Diphosphatidylglycerol (cardiolipin)

**1-Stearoyl-2-oleoyl-3-phosphatidylcholine**

**Figure 12-4** The glycerophospholipid 1-stearoyl-2-oleoyl-3-phosphatidylcholine. (a) Molecular formula in Fischer projection. (b) Energy-minimized space-filling model with C green, H white, N blue, O red, and P orange. Note how the unsaturated oleyl chain (*left*) is bent compared to the saturated stearoyl chain. [Based on coordinates provided by Richard Venable and Richard Pastor, NIH, Bethesda, Maryland.]

occur at the C1 position of glycerophospholipids, and the C2 position is often occupied by an unsaturated C<sub>16</sub> to C<sub>20</sub> fatty acid. Glycerophospholipids are, of course, also named according to the identities of these fatty acid residues (Fig. 12-4). Some glycerophospholipids have common names. For example, phosphatidylcholines are known as **lecithins**; diphosphatidylglycerols, the “double” glycerol phospholipids, are known as **cardiolipins** (because they were first isolated from heart muscle).

#### Plasmalogens

**A plasmalogen**

are glycerophospholipids in which the C1 substituent to the glycerol moiety is bonded to it via an  $\alpha,\beta$ -unsaturated ether linkage in the *cis* configuration rather than through

an ester linkage. **Ethanolamine, choline,** and serine form the most common plasmalogen head groups.

#### D. Sphingolipids

**Sphingolipids**, which are also major membrane components, are derivatives of the C<sub>18</sub> amino alcohols **sphingosine, dihydrosphingosine** (Fig. 12-5), and their C<sub>16</sub>, C<sub>17</sub>, C<sub>19</sub>, and C<sub>20</sub> homologs. Their *N*-acyl fatty acid derivatives, **ceramides**,

**A ceramide**

occur only in small amounts in plant and animal tissues but form the parent compounds of more abundant sphingolipids:

**1. Sphingomyelins**, the most common sphingolipids, are ceramides bearing either a phosphocholine (Fig. 12-6) or a phosphoethanolamine moiety, so that they can also be classified as **sphingophospholipids**. *Although sphingomyelins*

**Sphingosine****Dihydrosphingosine**

**Figure 12-5** Molecular formulas of sphingosine and dihydrosphingosine. The chiral centers at C2 and C3 of sphingosine and dihydrosphingosine have the configurations shown in Fischer projection. The double bond in sphingosine has the trans configuration.

differ chemically from phosphatidylcholine and phosphatidylethanolamine, their conformations and charge distributions are quite similar. The membranous myelin sheath that surrounds and electrically insulates many nerve cell axons (Section 20-5Bc) is particularly rich in sphingomyelin.

**2. Cerebrosides**, the simplest **sphingoglycolipids** (alternatively **glycosphingolipids**), are ceramides with head groups that consist of a single sugar residue. **Galactocerebrosides**, which are most prevalent in the neuronal cell membranes of the brain, have a  $\beta$ -D-galactose head group.

**A galactocerebroside**

**Glucocerebrosides**, which instead have a  $\beta$ -D-glucose residue, occur in the membranes of other tissues. *Cerebrosides, in contrast to phospholipids, lack phosphate groups and hence are most frequently nonionic compounds.* The galactose residues of some galactocerebrosides, however, are sulfated at their C3 positions to form ionic compounds known as **sulfatides**. More complex sphingoglycolipids have unbranched oligosaccharide head groups of up to four sugar residues.

**Figure 12-6** A sphingomyelin. (a) Molecular formula in Fischer projection. (b) Energy-minimized space-filling model with C green, H white, N blue, O red, and P orange. Note its conformational resemblance to glycerophospholipids (Fig. 12-4). [Based on coordinates provided by Richard Venable and Richard Pastor, NIH, Bethesda, Maryland.]

**Figure 12-7** Ganglioside  $G_{M1}$ . (a) Structural formula with its sphingosine residue in Fischer projection. (b) Energy-minimized space-filling model with C green, H white, N blue, O red, and P orange. Gangliosides  $G_{M2}$  and  $G_{M3}$  differ from  $G_{M1}$  only by the

sequential absences of the terminal D-galactose and *N*-acetyl-D-galactosamine residues. Other gangliosides have different oligosaccharide head groups. [Based on coordinates provided by Richard Venable and Richard Pastor, NIH, Bethesda, Maryland.]

**3. Gangliosides** form the most complex group of sphingoglycolipids. They are ceramide oligosaccharides that include among their sugar groups at least one sialic acid residue (*N*-acetylneuraminic acid and its derivatives; Section 11-1Cc). The structures of gangliosides  $G_{M1}$ ,  $G_{M2}$ , and  $G_{M3}$ , three of the hundreds that are known, are shown in Fig. 12-7. Gangliosides are primarily components of cell-surface membranes and constitute a significant fraction (6%) of brain lipids. Other tissues also contain gangliosides but in lesser amounts.

Gangliosides have considerable physiological and medical significance. Their complex carbohydrate head groups, which extend beyond the surfaces of cell membranes, act as specific receptors for certain pituitary glycoprotein hor-

mones that regulate a number of important physiological functions (Section 19-1). Gangliosides are also receptors for bacterial protein toxins such as cholera toxin (Section 19-2Cd). There is considerable evidence that gangliosides are specific determinants of cell-cell recognition, so they probably have an important role in the growth and differentiation of tissues as well as in carcinogenesis (cancer generation). Disorders of ganglioside breakdown are responsible for several hereditary **sphingolipid storage diseases**, such as **Tay-Sachs disease**, which are characterized by an invariably fatal neurological deterioration (Section 25-8Ce).

### E. Cholesterol

**Steroids**, which are mostly of eukaryotic origin, are derivatives of **cyclopentanoperhydrophenanthrene** (Fig. 12-8). The much maligned **cholesterol** (Fig. 12-9), the most abundant steroid in animals, is further classified as a **sterol** because of its C3-OH group and its branched aliphatic side chain of 8 to 10 carbon atoms at C17.

*Cholesterol* is a major component of animal plasma membranes, where it is typically present at 30 to 40 mol %, and occurs in lesser amounts in the membranes of their subcellular organelles. Its polar OH group gives it a weak amphiphilic character, whereas its fused ring system provides it with greater rigidity than other membrane lipids. Cholesterol is therefore an important determinant of membrane

**Cyclopentanoperhydrophenanthrene**

**Figure 12-8** Cyclopentanoperhydrophenanthrene, the parent compound of steroids. It consists of four fused saturated rings. The standard ring labeling system is indicated.

**Figure 12-9 Cholesterol.** (a) Structural formula with the standard numbering system. (b) Energy-minimized space-filling model with C green, H white, O red, and P orange. Cholesterol's rigid ring system makes it far less conformationally flexible than are

membrane lipids: Its cyclohexane rings can adopt either the boat or the chair conformations (Fig. 11-6) but the chair conformation is highly preferred. [Based on coordinates provided by Richard Venable and Richard Pastor, NIH, Bethesda, Maryland.]

properties. It is also abundant in blood plasma lipoproteins (Section 12-5), where ~70% of it is esterified to long-chain fatty acids to form **cholesteryl esters**.

Cholesterol is the metabolic precursor of **steroid hormones**, substances that regulate a great variety of physiological functions including sexual development and carbohydrate metabolism (Section 19-1G). The much-debated role of cholesterol in heart disease is examined in Section 12-5C. Cholesterol metabolism and the biosynthesis of steroid hormones are discussed in Section 25-6.

Plants contain little cholesterol. Rather, the most common sterol components of their membranes are **stigmasterol** and  **$\beta$ -sitosterol**

which differ from cholesterol only in their aliphatic side chains. Yeast and fungi have yet other membrane sterols such as **ergosterol**, which has a C7 to C8 double bond. Prokaryotes, with the exception of mycoplasmas (Section 1-1B), contain little, if any, sterol.

## 2 PROPERTIES OF LIPID AGGREGATES

The first recorded experiments on the physical properties of lipids were made in 1774 by the American statesman and scientist Benjamin Franklin. In investigating the well-known (at least among sailors) action of oil in calming waves, Franklin wrote:

*At length being at Clapham [in London] where there is, on the common, a large pond, which I observed to be one day very*

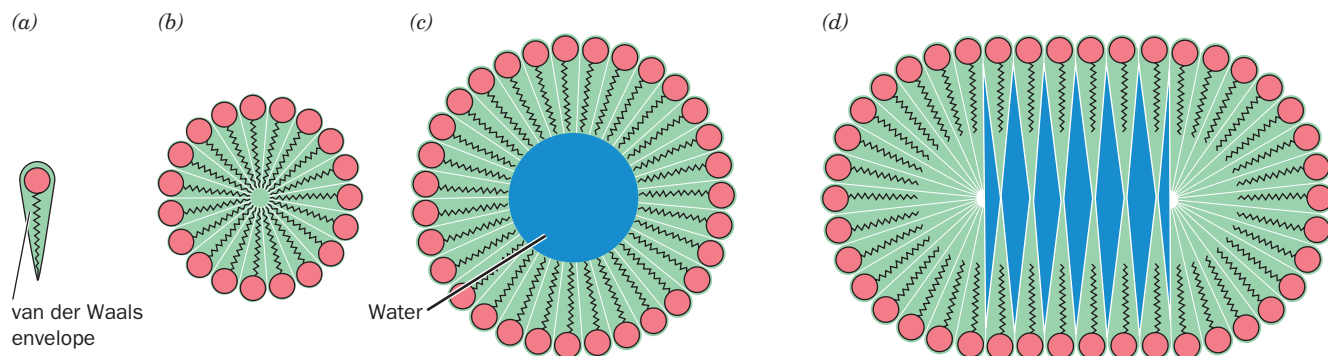

**Figure 12-10** An oil monolayer at the air–water interface. The hydrophobic tails of the lipids avoid association with water by extending into the air.

*rough with the wind, I fetched out a cruet of oil [probably olive oil] and dropt a little of it in the water. I saw it spread itself with surprising swiftness upon the surface. . . . I then went to the windward side, where [the waves] began to form; and there the oil, though not more than a teaspoonful, produced an instant calm over a space several yards square, which spread amazingly, and extended itself gradually till it reached the lee side, making all that quarter of the pond, perhaps half an acre, as smooth as a looking glass.*

This is sufficient information to permit the calculation of the oil layer's thickness (although there is no indication that Franklin made this calculation, we can; see Problem 4). We now know that oil forms a monomolecular layer on the surface of water in which the polar heads of the amphiphilic oil molecules are immersed in the water and their hydrophobic tails extend into the air (Fig. 12-10).

The calming effect of oil on rough water is a consequence of a large reduction in the water's surface tension. An oily surface film has the weak intermolecular cohesion characteristic of hydrocarbons rather than the strong intermolecular attractions of water responsible for its normally large surface tension. Oil, nevertheless, calms only smaller waves; it does not, as Franklin later observed, affect the larger swells.

In this section, we discuss how lipids aggregate to form micelles and bilayers. We shall also be concerned with the physical properties of lipids in bilayers because these aggregates form the structural basis for biological membranes.

**Figure 12-11** Aggregates of single-tailed lipids. The conical van der Waals envelope of single-tailed lipids (a) permits them to pack efficiently in forming a spheroidal micelle (b). The diameters of these micelles and hence their lipid population largely depend on the length of the tails. Spheroidal micelles

## A. Micelles and Bilayers

In aqueous solutions, amphiphilic molecules, such as soaps and detergents, form micelles (globular aggregates whose hydrocarbon groups are out of contact with water; Section 2-1Ba). This molecular arrangement eliminates unfavorable contacts between water and the hydrophobic tails of the amphiphiles and yet permits the solvation of the polar head groups. Micelle formation is a cooperative process: An assembly of just a few amphiphiles cannot shield its tails from contact with water. Consequently, dilute aqueous solutions of amphiphiles do not form micelles until their concentration surpasses a certain **critical micelle concentration (cmc)**. Above the cmc, almost all the added amphiphile aggregates to form micelles. The value of the cmc depends on the identity of the amphiphile and the solution conditions. For amphiphiles with relatively small single tails, such as dodecyl sulfate ion,  $\text{CH}_3(\text{CH}_2)_{11}\text{OSO}_3^-$ , the cmc is  $\sim 1 \text{ mM}$ . Those of biological lipids, most of which have two large hydrophobic tails, are generally  $< 10^{-6} \text{ M}$ .

### a. Single-Tailed Lipids Tend to Form Micelles

The approximate size and shape of a micelle can be predicted from geometrical considerations. Single-tailed amphiphiles, such as soap anions, form spheroidal or ellipsoidal micelles because of their conical shapes (their hydrated head groups are wider than their tails; Fig. 12-11a,b). The number of molecules in such micelles depends on the amphiphile, but for many substances, it is on the order of several hundred. For a given amphiphile, these numbers span a narrow range: Less would expose the hydrophobic core of the micelle to water, whereas more would give the micelle an energetically unfavorable hollow center (Fig. 12-11c). Of course, a large micelle could flatten out to eliminate this hollow center, but the resulting decrease of curvature at the flattened surfaces would also generate empty spaces (Fig. 12-11d).

### b. Glycerophospholipids and Sphingolipids Tend to Form Bilayers

The two hydrocarbon tails of glycerophospholipids and sphingolipids give these amphiphiles a more or less cylindrical

composed of many more lipid molecules than the optimal number would have an unfavorable water-filled center (blue) (c). Such micelles could flatten out to collapse the hollow center, but as such ellipsoidal micelles become elongated they also develop water-filled spaces (d).

**Figure 12-12 Bilayer formation by phospholipids.** The cylindrical van der Waals envelope of phospholipids (a) causes them to form extended disklike micelles (b) that are better described as lipid bilayers.

shape (Fig. 12-12a). The steric requirements of packing such molecules together yields large disklike micelles (Fig. 12-12b) that are really extended bimolecular leaflets. The existence of such **lipid bilayers** was first proposed in 1925 by Evert Gorter and François Grendel, on the basis of their observation that lipids extracted from erythrocytes covered twice the area when spread as a monolayer at the air–water interface (Fig. 12-10) than in the erythrocyte plasma membrane (the erythrocyte’s only membrane). Lipid bilayers typically have thicknesses of  $\sim 60$  Å, as measured by electron microscopy and X-ray diffraction techniques. Since their two head group layers are each expected to be  $\sim 15$  Å thick, their  $\sim 15$ -Å-long hydrocarbon tails must be nearly fully extended. We shall see below that *lipid bilayers form the structural basis of biological membranes*.

(a)

## B. Liposomes

A suspension of phospholipids in water forms multilamellar vesicles that have an onionlike arrangement of lipid bilayers (Fig. 12-13a). On **sonication** (agitation by ultrasonic vibrations), these structures rearrange to form **liposomes**—closed, self-sealing, solvent-filled vesicles that are bounded by only a single bilayer (Fig. 12-13b). They usually have diameters of several hundred Ångstroms and, in a given preparation, are rather uniform in size. Liposomes with diameters of  $\sim 1000$  Å can be made by injecting an ethanolic solution of phospholipid into water or by dissolving phospholipid in a detergent solution and then dialyzing out the detergent. Once formed, liposomes are quite stable and, in fact, may be separated from the solution in which they reside by dialysis, gel filtration chromatography, or centrifugation. Liposomes with differing internal and external environments can therefore be readily prepared. *Biological membranes consist of lipid bilayers with which proteins are associated* (Section 12-3A). Liposomes composed of synthetic lipids and/or lipids extracted from biological sources (e.g., lecithin from egg yolks) have therefore been extensively studied as models for biological membranes.

### a. Lipid Bilayers Are Impermeable to Most Polar Substances

Since biological membranes form cell and organelle boundaries, it is important to determine their ability to partition two aqueous compartments. The permeability of a lipid bilayer to a given substance may be determined by forming liposomes in a solution containing the substance of interest, changing the external aqueous solution, and then measuring the rate at which the substance appears in the new external solution. It has been found in this way that *lipid bilayers are extraordinarily impermeable to ionic and polar substances and that the permeabilities of such substances increase with their solubilities in nonpolar solvents*. This suggests that to penetrate a lipid bilayer, a solute molecule must shed its hydration shell and become solvated by

(b)

liposome. Its wall, as the accompanying diagram indicates, consists of a bilayer. [Courtesy of Walter Stoeckenius, University of California at San Francisco.]

**Figure 12-14** Phospholipid diffusion in a lipid bilayer.

(a) Transverse diffusion (flip-flop) is defined as the transfer of a phospholipid molecule from one bilayer leaflet to the other.  
 (b) Lateral diffusion is defined as the pairwise exchange of neighboring phospholipid molecules in the same bilayer leaflet.

the bilayer's hydrocarbon core. Such a process is highly unfavorable for polar molecules, so that even the  $\sim 30\text{-\AA}$  thickness of a lipid bilayer's hydrocarbon core forms an effective barrier for polar substances. However, measurements using tritiated water indicate that lipid bilayers are appreciably permeable to water. Despite the polarity of water, its small molecular size makes it significantly soluble in the hydrocarbon core of lipid bilayers and therefore able to permeate them.

The stability of liposomes and their impermeability to many substances make them promising vehicles for the delivery of therapeutic agents, such as drugs, enzymes, and genes

(for gene therapy), to particular tissues. Liposomes are absorbed by many cells through fusion with their plasma membranes. If methods can be developed for targeting liposomes to specific cell populations, then the desired substances could be directed toward particular tissues through liposome microencapsulation. Indeed, a number of liposome-delivered anticancer agents and antibiotics are already in use.

### C. Bilayer Dynamics

#### a. Lipid Bilayers Are Two-Dimensional Fluids

The transfer of a lipid molecule across a bilayer (Fig. 12-14a), a process termed **transverse diffusion** or a **flip-flop**, is an extremely rare event. This is because a flip-flop requires the polar head group of the lipid to pass through the hydrocarbon core of the bilayer. The flip-flop rates of phospholipids, as measured by several techniques, are characterized by half-times that are minimally several days.

In contrast to their low flip-flop rates, *lipids are highly mobile in the plane of the bilayer (lateral diffusion, Fig. 12-14b)*. The X-ray diffraction patterns of bilayers at physiological temperatures have a diffuse band, centered at a spacing of  $4.6\text{ \AA}$ , whose width is a measure of the distribution of lateral spacings between the hydrocarbon chains in the bilayer plane. This band, which resembles one in the X-ray diffraction patterns of liquid paraffins, is indicative that *the bilayer is a two-dimensional fluid in which the hydrocarbon chains undergo rapid fluxional (continuously changing) motions involving rotations about their C—C bonds*.

The lateral diffusion rate of lipid molecules can be quantitatively determined from the rate of **fluorescence recovery after photobleaching (FRAP; Fig. 12-15)**. A fluorescent group (**fluorophore**) is specifically attached to a bilayer component, and an intense laser pulse focused on a very small area ( $\sim 3\text{ }\mu\text{m}^2$ ) is used to destroy (bleach) the fluorophore there. The rate at which the bleached area recovers its fluorescence, as monitored by fluorescence microscopy,

**Figure 12-15** The fluorescence recovery after photobleaching (FRAP) technique. (a) An intense laser light pulse bleaches the fluorescent markers (green) from a small region of an immobilized cell that has a fluorescence-labeled membrane component. (b) The fluorescence of the bleached area, as monitored by

fluorescence microscopy, recovers as the bleached molecules laterally diffuse out of it and intact fluorescence-labeled molecules diffuse into it. (c) The fluorescence recovery rate depends on the diffusion rate of the labeled molecule. **See Guided Exploration 11: Membrane structure and the fluid mosaic model**

**Figure 12-16 Model (snapshot) of a lipid bilayer at an instant in time.** The conformations of dipalmitoylphosphatidylcholine molecules in a bilayer surrounded by water were modeled by computer. Atom colors are chain and glycerol C gray except terminal methyl C yellow, ester O red, phosphate P and O green, and choline C and N magenta. Water molecules are represented by translucent blue spheres (those near the bilayer appear dark because they overlap head group atoms). [Courtesy of Richard Pastor and Richard Venable, NIH, Bethesda, Maryland.]  **See Guided Exploration 11: Membrane structure and the fluid mosaic model**

indicates the rate at which unbleached and bleached fluorescence-labeled molecules laterally diffuse into and out of the bleached area, respectively. Such observations indicate, as do magnetic resonance measurements, that lipids in bilayers have lateral mobilities similar to those of the molecules in a light machine oil. Lipids in bilayers can therefore diffuse the  $1\text{-}\mu\text{m}$  length of a bacterial cell in  $\sim 1$  s. Methods for tracking the motions of single molecules in membranes have also been developed that link the molecule of interest to a small latex bead, colloidal gold particle, or fluorescent group, and then observe the movement of the label using high speed video techniques.

Molecular dynamics simulations (Section 9-4a) of lipid bilayers (Fig. 12-16) indicate that their lipid tails are highly

conformationally mobile due to rotations about their C—C bonds. However, the viscosity of these tails sharply increases closer to the lipid head groups because their lateral mobilities are more constrained by interactions with the more rigid head groups. Note that the methyl ends of the tails from opposite leaflets of the bilayer are frequently interdigitated rather than forming entirely separate layers, as Fig. 12-14 might be taken to suggest. This is particularly true in biological membranes because their various lipid molecules have tails of different lengths and/or are kinked due to the presence of double bonds. Molecular dynamics simulations also indicate that a lipid bilayer is flanked by several layers of ordered water molecules. Moreover, as Fig. 12-16 indicates, water molecules commonly penetrate well below the level of the head groups and glycerol residues. Hence, *a lipid bilayer typically consists of an  $\sim 30\text{-}\text{\AA}$ -thick hydrocarbon core bounded on both sides by  $\sim 15\text{-}\text{\AA}$ -thick interface regions containing rapidly fluctuating conglomerations of head groups, water, glycerol, carbonyl, and methylene groups.*

#### b. Bilayer Fluidity Varies with Temperature

As a lipid bilayer cools below a characteristic **transition temperature**, it undergoes a sort of phase change, termed an **order–disorder transition**, in which it becomes a gel-like solid (Fig. 12-17); that is, it loses its fluidity. Below the transition temperature, the diffuse  $4.6\text{-}\text{\AA}$  X-ray diffraction band characteristic of the lateral spacing between hydrocarbon chains in a liquid-crystalline bilayer is replaced by a sharp  $4.2\text{-}\text{\AA}$  band similar to that exhibited by crystalline paraffins. This indicates that the hydrocarbon chains in a bilayer become fully extended and packed in a hexagonal array as in crystalline paraffins.

The transition temperature of a bilayer increases with the chain length and the degree of saturation of its component fatty acid residues for the same reasons that the melting temperatures of fatty acids increase with these quantities. The transition temperatures of most biological membranes are

(a) Above transition temperature

(b) Below transition temperature

**Figure 12-17 Order–disorder transition in a lipid bilayer.**

(a) Above the transition temperature, both the lipid molecules as a whole and their nonpolar tails are highly mobile in the plane of the bilayer. Such a state of matter, which is ordered in some

directions but not in others, is called a liquid crystal. (b) Below the transition temperature, the lipid molecules form a much more orderly array to yield a gel-like solid. [After Robertson, R.N., *The Lively Membranes*, pp. 69–70, Cambridge University Press (1983).]

**Table 12-3** Lipid Compositions of Some Biological Membranes<sup>a</sup>

Lipid	Human		Beef Heart	
	Erythrocyte	Human Myelin	Mitochondria	<i>E. coli</i>

in the range 10 to 40°C. Cholesterol, which by itself does not form a bilayer, decreases membrane fluidity near the membrane surface because cholesterol's rigid steroid ring system interferes with the motions of the fatty acid tails causing them to become more ordered. However, because cholesterol does not extend into the membrane as far as most lipids, it also acts as a spacer that facilitates the increased mobility of the fatty acid tails near their methyl ends. Cholesterol also broadens the temperature range of the order–disorder transition and in high concentrations totally abolishes it. This behavior occurs because cholesterol inhibits the crystallization (cooperative aggregation into ordered arrays) of fatty acid tails by fitting in between them. Thus cholesterol functions as a kind of membrane plasticizer.

The fluidity of biological membranes is one of their important physiological attributes since it permits their embedded proteins to interact (Section 12-3C). The transition temperatures of mammalian membranes are well below body temperatures and hence these membranes all have a

fluidlike character. Bacteria and poikilothermic (cold-blooded) animals such as fish modify (through lipid biosynthesis and degradation) the fatty acid compositions of their membrane lipids with the ambient temperature so as to maintain membrane fluidity. For example, the membrane viscosity of *E. coli* at its growth temperature remains constant as the growth temperature is varied from 15 to 43°C.

### c. Gaseous Anesthetics Alter Neuronal Membrane Structures

Gaseous anesthetics, such as diethyl ether, cyclopropane, **isoflurane** (CF<sub>3</sub>—CHCl—O—CHF<sub>2</sub>), and the noble gas Xe, act by interfering with the transmission of nerve impulses in the central nervous system. Since the body excretes these general anesthetics unchanged, it appears that they do not act by chemical means. Rather, experimental evidence, such as the linear correlation of their anesthetic effectiveness with their lipid solubilities, suggests that these nonpolar substances alter the structures of membranes by

**Table 12-4** Compositions of Some Biological Membranes

Membrane	Protein (%)	Lipid (%)	Carbohydrate (%)	Protein to Lipid Ratio

**Figure 12-18** X-ray structure of the integral membrane protein aquaporin-0 (AQP0) in association with lipids. The protein is represented by its surface diagram, which is colored according to charge (red negative, blue positive, and white uncharged). Tightly bound molecules of dimyristoylphosphatidylcholine are drawn in space-filling form with C green, O red, and P orange. Note how the lipid tails closely conform to the nonpolar surface of the protein, thereby solvating it. The arrangement of the two rows of lipid molecules, with phosphorus–phosphorus distances of  $\sim 35$  Å, matches the dimensions of a lipid bilayer. [Based on an electron crystallographic structure by Stephen Harrison and Thomas Walz, Harvard Medical School. PDBid 2B6O.]

dissolving in their hydrocarbon cores. Nerve impulse transmission, which is a membrane-based phenomenon (Section 20-5), is disrupted by these structural changes to which neuronal membranes seem particularly sensitive.

### 3 BIOLOGICAL MEMBRANES

*Biological membranes are composed of proteins associated with a lipid bilayer matrix.* Their lipid fractions consist of complex mixtures that vary according to the membrane source (Table 12-3) and, to some extent, with the diet and environment of the organism that produced the membrane. *Membrane proteins carry out the dynamic processes associated with membranes, and therefore specific proteins occur only in particular membranes.* Protein-to-lipid ratios in membranes vary considerably with membrane function, as is indicated by Table 12-4, although most membranes are at least one-half protein. The myelin membrane, which functions passively as an insulator around certain nerve fibers (Section 20-5Bc), is a prominent exception to this generalization in that it contains only 18% protein.

In this section, we discuss the properties of membrane proteins and their behavior in biological membranes. Following this, we examine specific aspects of biological membranes, namely, the erythrocyte cytoskeleton, the nature of blood groups, gap junctions, and channel-forming proteins. We consider how membranes are assembled and how their component proteins are directed to them in Section 12-4.

#### A. Membrane Proteins

Membrane proteins are operationally classified according to how tightly they are associated with membranes:

**1. Integral or intrinsic proteins** are tightly bound to membranes by hydrophobic forces (Fig. 12-18) and can only be separated from them by treatment with agents that disrupt membranes. These include organic solvents, detergents (e.g., those in Fig. 12-19), and chaotropic agents (ions that disrupt water structure; Section 8-4E). Integral proteins

**Sodium dodecyl sulfate (SDS)**

X = H, Y =  $\text{COO}^- \text{Na}^+$  **Sodium deoxycholate**

X = OH, Y =  $\text{COO}^- \text{Na}^+$  **Sodium cholate**

X = OH, Y =  $\text{CO}-\text{NH}-(\text{CH}_2)_3-\text{N}^+(\text{CH}_3)_2-(\text{CH}_2)_3-\text{SO}_3^-$  **CHAPS**

$n = 10$  **Dodecyltriethylammonium bromide (DTAB)**

$n = 15$  **Cetyltrimethylammonium bromide (CTAB)**

**Polyoxyethylenelauryl ether**

$n = 4$  **Brij 30**

$n = 25$  **Brij 35**

**Polyoxyethylene-*p*-isooctylphenyl ether**

$n = 5$  **Triton X-20**

$n = 10$  **Triton X-100**

**Figure 12-19** A selection of the detergents used in biochemical manipulations. Note that they may be anionic, cationic, zwitterionic, or uncharged. Ionic detergents are strongly amphiphilic and therefore tend to denature proteins, whereas neutral detergents are unlikely to do so.

tend to aggregate and precipitate in aqueous solutions unless they are solubilized by detergents or water-miscible organic solvents such as butanol or glycerol. Some integral proteins bind lipids so tenaciously that they can be freed from them only under denaturing conditions. Solubilized integral proteins can be purified by many of the protein fractionation methods discussed in Chapter 6.

**2. Peripheral or extrinsic proteins** are dissociated from membranes by relatively mild procedures that leave the membrane intact, such as exposure to high ionic strength salt solutions (e.g., 1M NaCl), metal chelating agents, or pH changes. Peripheral proteins, for example, cytochrome *c*, are stable in aqueous solution and do not bind lipid. They associate with a membrane by binding at its surface to its lipid head groups and/or its integral proteins through electrostatic and hydrogen bonding interactions. Membrane-free peripheral proteins behave as water-soluble globular proteins and can be purified as such (Chapter 6).

In this subsection we concentrate on integral proteins.

### a. Integral Proteins Are Asymmetrically Oriented Amphiphiles

All biological membranes contain integral proteins, which typically comprise ~25% of the proteins encoded by a genome. Their locations on a membrane may be determined through **surface labeling**, a technique employing agents that react with proteins but cannot penetrate membranes. For example, an integral protein on the outer

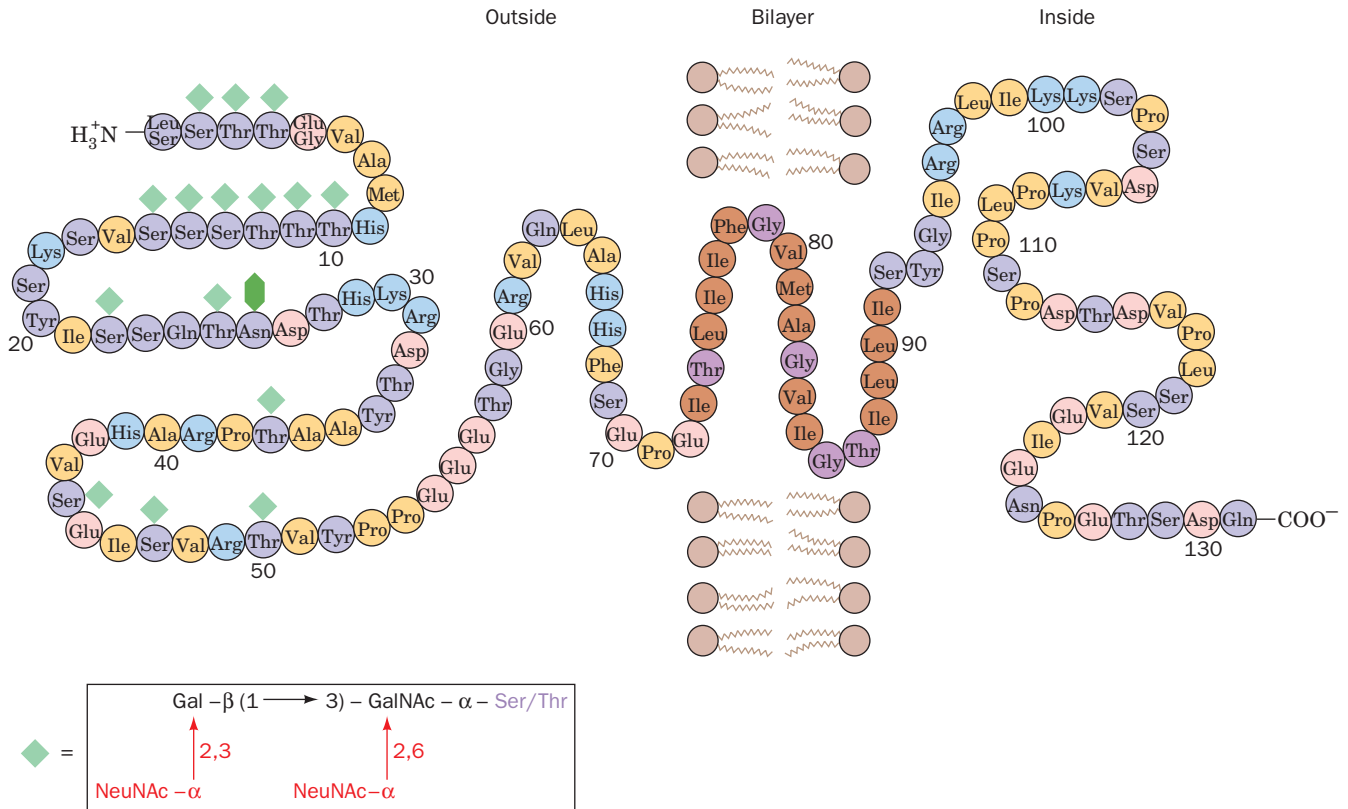

surface of an intact cell membrane binds antibodies elicited against it, but a protein on the membrane's inner surface can do so only if the membrane has been ruptured. Membrane-impermeable protein-specific reagents that are fluorescent or radioactively labeled may be similarly employed. Using such surface-labeling reagents, it has been shown that *some integral proteins are exposed only to a specific surface of a membrane, whereas others, known as transmembrane proteins, span the membrane.* However, no protein is known to be completely buried in a membrane; that is, all have some exposure to the aqueous environment. Such studies have also established that *biological membranes are asymmetric in that a particular membrane protein is invariably located on only one particular face of a membrane or, in the case of a transmembrane protein, oriented in only one direction with respect to the membrane* (Fig. 12-20).

*Integral proteins are amphiphilic; the protein segments immersed in a membrane's nonpolar interior have predominantly hydrophobic surface residues, whereas those portions that extend into the aqueous environment are by and large sheathed with polar residues.* For example, proteolytic digestion and chemical modification studies indicate that the erythrocyte transmembrane protein **glycophorin A** (Fig. 12-21) has three domains: (1) a 72-residue externally located *N*-terminal domain that bears 16 carbohydrate chains; (2) a 19-residue sequence, consisting almost entirely of hydrophobic residues, that spans the erythrocyte cell membrane; and (3) a 40-residue cytoplasmic C-terminal

**Figure 12-20** Diagram of a plasma membrane. Integral proteins (orange) are embedded in a bilayer composed of phospholipids (blue spheres with two wiggly tails) and cholesterol (yellow). The carbohydrate components of glycoproteins (yellow beaded chains) and glycolipids (green beaded chains) occur only

on the external face of the membrane. Most biological membranes have a higher proportion of protein than is drawn here.  See Guided Exploration 11: Membrane structure and the fluid mosaic model

**Figure 12-21** The amino acid sequence and membrane location of human erythrocyte glycophorin A. The protein, which is ~60% carbohydrate by weight, bears 15 *O*-linked oligosaccharides (green diamonds) and one that is *N*-linked (dark green hexagon). The predominant sequence of the *O*-linked oligosaccharides is given below. The protein's transmembrane portion (brown and purple) consists of 19 sequential predominantly hydrophobic residues. Its C-terminal portion, which is located on

the membrane's cytoplasmic face, is rich in anionic (pink) and cationic (blue) amino acid residues. There are two common genetic variants of glycophorin A: glycophorin A<sup>M</sup> has Ser and Gly at positions 1 and 5, respectively, whereas they are Leu and Glu in glycophorin A<sup>N</sup>. [Abbreviations: Gal = galactose, GalNAc = *N*-acetylgalactosamine, NeuNAc = *N*-acetylneuraminic acid (sialic acid)]. [After Marchesi, V.T., *Semin. Hematol.* **16**, 8 (1979).]

domain that has a high proportion of charged and polar residues. The transmembrane domain, as is common in many integral proteins, forms an  $\alpha$  helix, thereby satisfying the hydrogen bonding requirements of its polypeptide backbone. Indeed, the existence of glycophorin A's single transmembrane helix is predicted by computing the free energy change in transferring  $\alpha$  helically folded polypeptide segments from the nonpolar interior of a membrane to water (Fig. 12-22). Similar computations on other integral proteins have also identified their transmembrane helices.

In many integral proteins, the hydrophobic segment(s) anchors the active region of the protein to the membrane. For instance, trypsin cleaves the membrane-bound enzyme

**Figure 12-22** A plot, for glycophorin A, of the calculated free energy change in transferring 20-residue-long  $\alpha$  helical segments from the interior of a membrane to water versus the position of the segment's first residue. Peaks higher than +85 kJ · mol<sup>-1</sup> are indicative of a transmembrane helix. [After Engleman, D.M., Steitz, T.A., and Goldman, A., *Annu. Rev. Biophys. Biophys. Chem.* **15**, 343 (1986).]

**cytochrome *b*<sub>5</sub>** into a polar, enzymatically active ~85-residue N-terminal fragment and an ~50-residue C-terminal fragment that remains embedded in the membrane

**Figure 12-23** Liver cytochrome *b*<sub>5</sub> in association with a membrane. The protein's enzymatically active N-terminal domain (purple), whose X-ray structure has been determined, is anchored in the membrane by a hydrophobic and presumably  $\alpha$  helical C-terminal segment (brown) that begins and ends with hydrophilic segments (purple). The amino acid sequence of the horse enzyme indicates that this hydrophobic anchor consists of a 13-residue segment ending 9 residues from the polypeptide's C-terminus (below). [Ribbon diagram of the N-terminal domain after a drawing by Jane Richardson, Duke University. Amino acid sequence from Ozols, J. and Gerard, C., *J. Biol. Chem.* **253**, 8549 (1977).]

(Fig. 12-23). The asymmetric orientation of integral proteins in the membrane is maintained by their infinitesimal flip-flop rates (even slower than those of lipids), which result from the greater sizes of the membrane protein "head groups" in comparison to those of lipids. The origin of this asymmetry is discussed in Section 12-4.

Relatively few integral proteins have yet been crystallized—and then usually in the presence of detergents, which are but poor substitutes for lipid bilayers. Thus, despite their biological abundance, only ~0.8% of the proteins of known structure are integral proteins (>80% of which are bacterial proteins). A database of these proteins

is maintained at [http://blanco.biomol.uci.edu/Membrane\\_Proteins\\_xtal.html](http://blanco.biomol.uci.edu/Membrane_Proteins_xtal.html). In the remainder of this subsection, we discuss the structures of four integral proteins: bacteriorhodopsin, the bacterial photosynthetic reaction center, porins, and fatty acid amide hydrolase.

### b. Bacteriorhodopsin Contains a Bundle of Seven Hydrophobic Helical Rods

One of the structurally most studied integral proteins is **bacteriorhodopsin (BR)** from the halophilic (salt loving) bacterium *Halobacterium salinarium* that inhabits such salty places as the Dead Sea (it grows best in 4.3M NaCl and is nonviable below 2.0M NaCl; seawater contains 0.6M NaCl). Under low O<sub>2</sub> conditions, its cell membrane develops ~0.5- $\mu$ m-wide patches of **purple membrane** whose only protein component is BR. This 247-residue protein is a light-driven proton pump; it generates a proton concentration gradient across the membrane that powers the synthesis of ATP (by a mechanism discussed in Section 22-3Bh). Bacteriorhodopsin's light-absorbing element, **retinal**, is covalently bound to its Lys 216 (Fig. 12-24). This **chromophore** (light-absorbing group), which is responsible for the membrane's purple color, is also the light-sensitive element in vision.

The purple membrane, which is 75% protein and 25% lipid, has an unusual structure compared to most other membranes (Section 12-3C): Its BR molecules are arranged in a highly ordered two-dimensional array (a two-dimensional crystal). This permitted Richard Henderson and Nigel Unwin, through **electron crystallography** (a technique they devised, resembling X-ray crystallography, in which the electron beam of an electron microscope is used to elicit diffraction from two-dimensional crystals), to determine the structure of BR to near-atomic resolution (3.0 Å). The more recently determined 1.9-Å-resolution X-ray structure of BR, based on single crystals of BR dissolved in lipidic cubic phases (mixtures of lipids and water that form a highly convoluted but continuous bilayer that is interpenetrated by aqueous channels), closely resembles that determined by electron crystallography.

Bacteriorhodopsin forms a homotrimer. Each of its subunits consists mainly of a bundle of seven ~25-residue  $\alpha$  helical rods that each span the lipid bilayer in directions almost perpendicular to the bilayer plane (Fig. 12-25). BR is therefore said to be **polytopic** (multispanning; Greek: *topos*, place). The ~20-Å spaces between the protein molecules in the purple membrane are occupied by this bilayer (Fig. 12-25b). Adjacent  $\alpha$  helices, which are largely

**Figure 12-24** Molecular formula of retinal. Retinal, the prosthetic group of bacteriorhodopsin, forms a Schiff base with Lys 216 of the protein. A similar linkage occurs in **rhodopsin**, the photoreceptor of the eye (Section 19-2B).

**Figure 12-25 Structure of bacteriorhodopsin.** (a) The protein is shown in ribbon form as viewed from within the membrane plane and colored in rainbow order from its N-terminus (*blue*) to its C-terminus (*red*). Its covalently bound retinal is drawn in stick form (*magenta*). [Based on an X-ray structure by Nikolaus Grigorieff and Richard Henderson, MRC Laboratory of Molecular Biology, Cambridge, U.K. PDBid 2BRD.] (b) The X-ray structure of a bacteriorhodopsin trimer with portions of its surrounding trimers as viewed from the extracellular side of the membrane. The protein molecules are shown in ribbon form (*gray*) and their associated lipid tails are shown in ball-and-stick

form in different colors with symmetry-related lipid tails the same color (the lipid head groups are disordered and hence not seen). Only the lipids in the extracellular leaflet are shown; those in the cytoplasmic leaflet have a similar distribution. Note how the seven antiparallel  $\alpha$  helices in each BR monomer are cyclically arranged in two layers of four and three helices with helices adjacent in sequence also adjacent in space (the N to C direction circulates clockwise in this view). [Courtesy of Eva Pebay-Peyroula, Université Joseph Fourier, Grenoble, France. PDBid 1AP9.]  See Kinemage Exercise 8-1

hydrophobic in character, are connected in a head-to-tail fashion by short polypeptide loops. This arrangement places the protein's charged residues near the surfaces of the membrane in contact with the aqueous solvent. The internal charged residues line the center of the helix bundle of each monomer so as to form a hydrophilic channel that facilitates the passage of protons. Other membrane pumps and channels (Chapter 20) have similar structures.

### c. The Photosynthetic Reaction Center Contains Eleven Transmembrane Helices

The primary photochemical process of photosynthesis in purple photosynthetic bacteria is mediated by the so-called **photosynthetic reaction center (PRC)** (Section 24-2B), a transmembrane (TM) protein consisting of at least three nonidentical  $\sim$ 300-residue subunits that collectively bind four **chlorophyll** molecules, four other chromophores, and a nonheme Fe(II) ion. The 1187-residue photosynthetic reaction center of *Rhodospseudomonas (Rps.) viridis*, whose X-ray structure was determined in 1984 by Hartmut Michel, Johann Deisenhofer, and Robert Huber, was the first TM protein to be described in atomic detail (Fig. 12-26). The polytopic protein's TM portion consists of 11  $\alpha$  helices that form a 45-Å-long flattened cylinder with the expected hydrophobic surface. In later chapters

we shall see that the transmembrane portions of most TM proteins consist of bundles of one to  $>20$  helices, most of which are closely perpendicular to the membrane although some may be obliquely oriented and/or not fully traverse the membrane.

### d. Porins Are Channel-Forming Proteins That Contain Transmembrane $\beta$ Barrels

The outer membranes of gram-negative bacteria (Section 11-3B) protect them from hostile environments but must nevertheless be permeable to small polar solutes such as nutrients and waste products. These outer membranes consequently contain embedded channel-forming proteins called **porins**, which are usually trimers of identical 30- to 50-kD subunits that permit the passage of solutes of less than  $\sim$ 600 D. Porins also occur in eukaryotes in the outer membranes of mitochondria and chloroplasts (thereby providing a further indication that these organelles are descended from bacteria; Section 1-2A).

The X-ray structures of several different porins have been elucidated, among them the *Rhodobacter (Rb.) capsulatus* porin, determined by Georg Schulz, and the *E. coli* **OmpF** and **PhoE** porins, determined by Johan Jansonius. The 340- and 330-residue OmpF and PhoE porins share 63% sequence identity but have little sequence similarity with the 301-residue *Rb. capsulatus* porin. Nevertheless, all

**Figure 12-26** X-ray structure of the photosynthetic reaction center of *Rps. viridis*. (a) The H, M, and L subunits, which are respectively shown as pink, blue, and orange ribbons, collectively have 11 transmembrane helices. The four-heme *c*-type cytochrome (green), which does not occur in all species of photosynthetic bacteria, is bound to the external face of the complex. The prosthetic groups are drawn in stick form with C yellow, N blue, and O red with a bound Fe(II) ion represented by a red sphere. The position that the transmembrane protein is

thought to occupy in the lipid bilayer is indicated schematically. (b) A surface diagram, viewed as in Part a, in which hydrophobic residues are tan and polar residues are purple. Note how few polar groups are externally exposed in the portion of the protein that is immersed in the nonpolar region of the lipid bilayer.

[Based on an X-ray structure by Johann Deisenhofer, Robert Huber, and Hartmut Michel, Max-Planck-Institut für Biochemie, Martinsreid, Germany. PDBid 1PRC.]  See Kinemage

#### Exercise 8-2

three porins have closely similar structures. Each monomer of these homotrimeric proteins predominantly consists of a 16-stranded antiparallel  $\beta$  barrel which forms a solvent-accessible pore along the barrel axis that has a length of  $\sim 55$  Å and a minimum diameter of  $\sim 7$  Å (Fig. 12-27; although note that  $\beta$  barrel membrane proteins with 8, 10, 12, 14, 18, 19, 22, and 24 strands are also known). In the OmpF and PhoE porins, the N- and C-termini associate via a salt bridge in the 16th  $\beta$  strand, thereby forming a pseudocyclic structure (Fig. 12-27a). Note that a  $\beta$  barrel fully satisfies the polypeptide backbone's hydrogen bonding potential, as does an  $\alpha$  helix. As expected, the side chains at the protein's membrane-exposed surface are nonpolar, thereby forming an  $\sim 25$ -Å-high hydrophobic band encircling the trimer (Fig. 12-27c). In contrast, the side chains at the solvent-exposed surface of the protein, including those lining the walls of the aqueous channel, are polar. Possible mechanisms for solute selectivity by these porins are discussed in Section 20-2D.

#### e. Fatty Acid Amide Hydrolase Binds to Only One Bilayer Leaflet

Not all integral proteins are TM proteins. For example, the enzyme **fatty acid amide hydrolase (FAAH)** is an integral protein that binds to the cytoplasmic leaflet of the plasma membrane. It is therefore said to be **monotopic** as is cytochrome  $b_5$  (Fig. 12-23). FAAH's X-ray structure, determined by Raymond Stevens and Benjamin Cravatt, reveals that each 537-residue subunit of this homodimer consists of an 11-stranded mixed  $\beta$  sheet surrounded by 28  $\alpha$  helices of various lengths (Fig. 12-28). Its membrane-binding segment consists of a helix-turn-helix motif, whose surface faces outward from the body of the protein to form a hydrophobic plateau. Its component nonpolar residues, many of which are aromatic, are interspersed with several basic residues, which presumably interact electrostatically with the membrane's phospholipid head groups. The structure of this hydrophobic motif resembles that observed in the X-ray structures of two other monotopic integral proteins,

**Figure 12-27** X-ray crystal structure of the *E. coli* OmpF porin. (a) A ribbon diagram of the monomer colored in rainbow order from its N-terminus (blue) to its C-terminus (red). Each strand of this 16-stranded antiparallel  $\beta$  barrel is inclined by  $\sim 45^\circ$  to the barrel axis. Its C-terminal strand is continued by the N-terminal segment (bottom right), thereby forming a pseudo-continuous strand. All porins of known structure have similar structural properties. (b) Ribbon diagram of the trimer embedded in its semitransparent surface and viewed along its threefold axis of symmetry from the cell's exterior showing the pore through each subunit. Each subunit is differently colored. Adjacent  $\beta$  strands in adjoining subunits extend essentially perpendicularly to each other. (c) A space-filling model of the trimer viewed perpendicular to its 3-fold axis. N atoms are blue, O atoms are red, and C atoms are green, except those of Trp and Tyr side chains, which are white. These latter groups delimit an  $\sim 25$ -Å-high hydrophobic band (scale at right) that is immersed in the nonpolar portion of the bacterial outer membrane (with the cell's exterior at the tops of Parts a and c). Compare the hydrophobic band in this figure with that in Fig. 12-26b. [Based on an X-ray structure by Johan Janssonius, University of Basel, Switzerland. PDBid 1OPF.]  See Kinemage Exercise 8-3

**Figure 12-28** X-ray structure of rat liver fatty acid amide hydrolase indicating its proposed disposition in the cytoplasmic leaflet of the plasma membrane. This homodimeric enzyme is viewed along the plane of the membrane with its 2-fold axis of symmetry vertical. It is drawn in ribbon form with each subunit colored in rainbow order from its N-terminus (blue) to its C-terminus (red) except for its putative membrane-binding motif, which is dark green. The enzyme's bound inhibitor, **methyl arachidonyl fluorophosphonate**, is drawn in space-filling form with C green, O red, and P orange. The membrane model was generated by a molecular dynamics simulation of a palmitoyloleoylphosphatidylethanolamine bilayer. [Based on an X-ray structure by Raymond Stevens and Benjamn Cravatt, Scripps Research Institute, La Jolla, California. PDBid 1MT5.]

**prostaglandin H synthase** (Section 25-7B) and **squalene-hopene cyclase** (Section 25-6Ad). Nevertheless, these enzymes have no apparent sequence or structural homology, which suggests that they have independently evolved similar modes of membrane integration.

#### f. Integral Proteins Have Common Structural Features

Hydrophobic forces, as we have seen in Section 8-4, are the dominant interactions stabilizing the three-dimensional structures of water-soluble globular proteins. However, since the membrane-exposed regions of integral proteins are immersed in nonpolar environments, what stabilizes their structures? Analysis of a variety of integral proteins indicates that their membrane-exposed regions have a hydrophobic organization opposite to that of water-soluble proteins: Their membrane-exposed residues are more hydrophobic, on average, than their interior residues, even though these interior residues have average hydrophobicities and packing densities comparable to those of water-soluble proteins. Evidently, *the structures of integral and water-soluble proteins are both stabilized by the exclusion of their interior residues from the surrounding solvent, although in the case of integral proteins, the solvent is the lipid bilayer.* In addition, the low polarity and anhydrous environments of transmembrane proteins are likely to strengthen their hydrogen bonds relative to those of soluble proteins.

In the foregoing TM proteins, those portions of the transmembrane secondary structural elements (helices in BR and the PRC, and  $\beta$  strands in the porins) that contact the bilayer's hydrocarbon core consist mainly of the hydrophobic residues Ala, Ile, Leu, Val, and Phe. The flanking residues, which penetrate the bilayer's interface region, are enriched with Trp, and Tyr. Hence, *TM proteins' hydrophobic transmembrane bands are bordered by rings of Trp and Tyr side chains* (e.g., Fig. 12-27c) *that delineate the water-bilayer interface.* Note that these side chains are oriented such that their polar portions (N and O atoms) extend into the polar regions of the membrane, a phenomenon named **snorkeling**. Lys and Arg side chains near the interface tend to be similarly oriented. In contrast, Phe, Leu, and Ile side chains tend to point toward the membrane core, a phenomenon dubbed **antisnorkeling**.

In each of the foregoing TM proteins, the secondary structural elements that are adjacent in sequence are also adjacent in structure and hence tend to be antiparallel. This relatively simple up-down **topology** results from the constraints associated with the insertion of a folding polypeptide chain into the lipid bilayer (Section 12-4Be).

## B. Lipid-Linked Proteins

*Lipids and proteins associate covalently to form **lipid-linked** proteins, whose lipid portions anchor their attached proteins to membranes and mediate protein-protein interactions.* Proteins form covalent attachments with three classes of lipids: (1) isoprenoid groups such as farnesyl and

geranylgeranyl residues, (2) fatty acyl groups such as myristoyl and palmitoyl residues, and (3) glycoinositol phospholipids (GPIs). In this subsection, we discuss the properties of these lipid-linked proteins.

### a. Prenylated Proteins

A variety of proteins have covalently attached **isoprenoid groups**, mainly the  $C_{15}$  **farnesyl** and  $C_{20}$  **geranylgeranyl** residues (**isoprene**, a  $C_5$  hydrocarbon, is the chemical unit from which many lipids, including cholesterol and other steroids, are constructed; Section 25-6A).

**Isoprene**

**Farnesyl residue**

**Geranylgeranyl residue**

The most common isoprenylation (or just **prenylation**) site in proteins is the C-terminal tetrapeptide CaaX, where C is Cys, "a" is often an aliphatic amino acid residue, and X is any amino acid. However, the identity of X is a major prenylation determinant: Proteins are farnesylated when X is Gln, Met, or Ser and geranylgeranylated when X is Leu. In both cases, the prenyl group is enzymatically linked to the Cys sulfur atom via a thioether linkage. The aaX tripeptide is then proteolytically excised and the newly exposed terminal carboxyl group is esterified with a methyl group (Fig. 12-29).

Two other types of prenylation sites have also been characterized: (1) the C-terminal sequence CXC, in which both Cys residues are geranylgeranylated and the terminal carboxyl group is methyl esterified; and (2) the C-terminal sequence CC in which one or both Cys residues are geranylgeranylated but the carboxyl group is not methylated. Proteins that are so prenylated are almost exclusively members of the **Rab** family of small GTP-binding proteins that participate in intracellular membrane trafficking (Section 12-4Db).

What functions are served by protein prenylation? Many prenylated proteins are associated with intracellular membranes, and mutating their Cys prenylation sites blocks their membrane localization. Evidently, *the hydrophobic prenyl group can act to anchor its attached protein to a membrane.* However, this can only be part of the story since proteins with the same prenyl groups may be localized to different intracellular membranes. Moreover, fusing the CaaX motif from a normally prenylated protein to the C-terminus of a normally unprenylated protein yields a hybrid protein that is correctly prenylated and carboxyl methylated but which remains cytosolic. These

**Figure 12-29 Prenylated proteins.** (a) A farnesylated protein and (b) a geranylgeranylated protein. In both cases, the protein is synthesized with the C-terminal sequence CaaX, where C is Cys, “a” is often an aliphatic amino acid, and X is any amino acid. After the prenyl group is appended to the protein in thioether

linkage with the Cys residue, the aaX tripeptide is hydrolytically cleaved away and the new carboxyl terminus is methyl esterified. When X is Ala, Met, or Ser, the protein is farnesylated and when X is Leu, it is geranylgeranylated.

observations suggest that prenylated proteins may interact with specific membrane-bound receptor proteins and hence that *prenylation also facilitates protein–protein interactions*. This idea is corroborated by the observation that, in certain proteins involved in intracellular signaling [for example, **Ras** (Section 19-3Cf) and the so-called **G proteins** (Section 19-2)], prenylation and carboxyl methylation enhance the intersubunit associations that mediate signal transmission.

### b. Fatty Acylated Proteins

Two fatty acids are known to be covalently linked to eukaryotic proteins:

1. Myristic acid, a biologically rare saturated  $C_{14}$  fatty acid (Table 12-1), which is appended to a protein in amide linkage to the  $\alpha$ -amino group of an N-terminal Gly residue. Myristoylation almost always occurs cotranslationally (as the protein is being synthesized), and this attachment is stable, that is, the myristoyl group has a half-life similar to that of the protein to which it is appended.

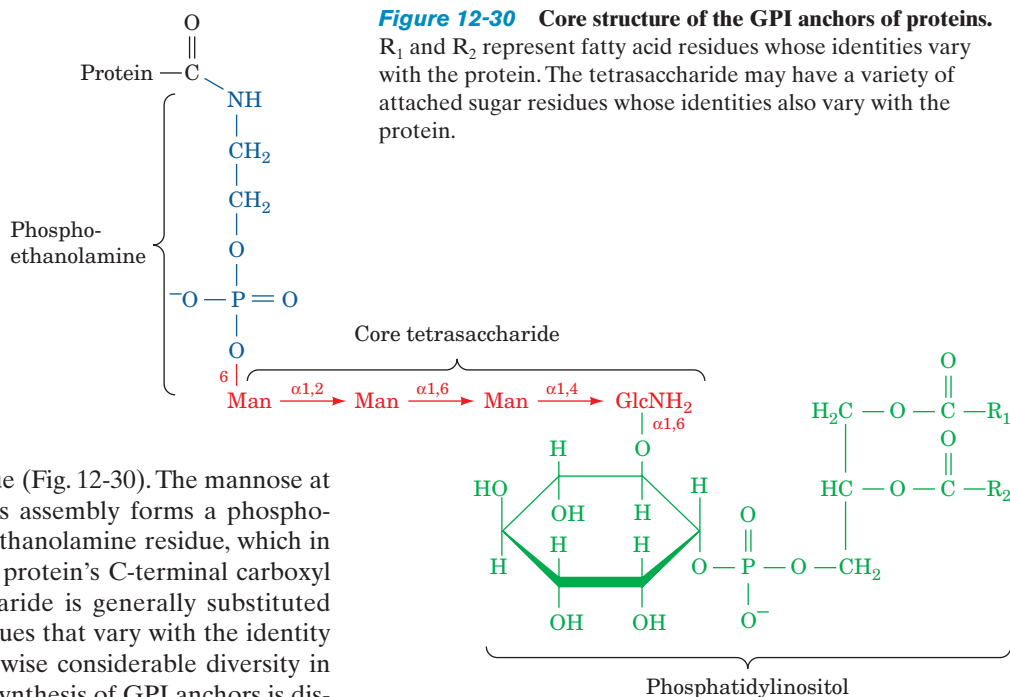

2. Palmitic acid, a biologically common saturated  $C_{16}$  fatty acid, which is joined to a protein in thioester linkage to a specific Cys residue. In some cases, the palmitoylated protein is also prenylated. For example, Ras must be farnesylated and carboxyl methylated as described above before it is palmitoylated at a Cys residue that precedes the protein’s C-terminus by several residues. Palmitoylation occurs post-translationally in the cytosol and is reversible.

*Fatty acyl groups are thought to function as membrane anchors for proteins*, much as do prenyl groups. However, the requirement of many proteins for specific fatty acyl residues suggests that these groups also participate in targeting their attached proteins to specific cellular locations. Indeed, palmitoylated proteins occur almost exclusively on the cytoplasmic face of the plasma membrane, whereas myristoylated proteins are found in a number of subcellular compartments including the cytosol, endoplasmic reticulum, Golgi apparatus, plasma membrane, and nucleus. Many fatty acylated proteins participate in intracellular signaling processes through protein–protein interactions in a manner similar to prenylated proteins. Since the membrane affinities and biological activities of many proteins are enhanced by palmitoylation, the reversibility of palmitoylation appears to be involved in controlling intracellular signaling processes.

### c. GPI-Linked Proteins

*Glycosylphosphatidylinositol (GPI) groups function to anchor a wide variety of proteins to the exterior surface of the eukaryotic plasma membrane.* There is no obvious relationship among the numerous proteins that have GPI anchors, which include enzymes, receptors, immune system proteins, and recognition antigens. Evidently, *GPI groups simply provide an alternative to transmembrane polypeptide domains in binding proteins to the plasma membrane.*

The core structure of GPI anchors consists of phosphatidylinositol (Table 12-2) glycosidically linked to a linear tetrasaccharide composed of three mannose residues

**Figure 12-30** Core structure of the GPI anchors of proteins. R<sub>1</sub> and R<sub>2</sub> represent fatty acid residues whose identities vary with the protein. The tetrasaccharide may have a variety of attached sugar residues whose identities also vary with the protein.

and one glucosaminyl residue (Fig. 12-30). The mannose at the nonreducing end of this assembly forms a phosphoester bond with a phosphoethanolamine residue, which in turn, is amide-linked to the protein's C-terminal carboxyl group. The core tetrasaccharide is generally substituted with a variety of sugar residues that vary with the identity of the protein. There is likewise considerable diversity in the fatty acid residues. The synthesis of GPI anchors is discussed in Section 23-3Bk.

GPI-anchored proteins occur on the exterior surface of the plasma membrane for the same reason as do the carbohydrate residues of glycoproteins (which we discuss in Section 12-4Ca). Proteins destined to be GPI-anchored are synthesized with membrane-spanning C-terminal sequences of 20 to 30 hydrophobic residues (as described in Section 12-4Ba) that are removed during GPI addition. This is corroborated by the observation that GPI-anchored proteins are released from the plasma membrane by treatment with phosphatidylinositol-specific **phospholipases** (Section 19-4B), thereby demonstrating that the mature polypeptides are not embedded in the lipid bilayer.

### C. Fluid Mosaic Model of Membrane Structure

 **See Guided Exploration 11: Membrane structure and the fluid mosaic model** The demonstrated fluidity of artificial lipid bilayers suggests that biological membranes have similar properties. This seminal idea was proposed in 1972 by S. Jonathan Singer and Garth Nicolson in their unifying theory of membrane structure known as the **fluid mosaic model**. The theory postulates that integral proteins resemble “icebergs” floating in a two-dimensional lipid “sea” (Fig. 12-20) and that these proteins freely diffuse laterally in the lipid matrix unless their movements are restricted by associations with other cell components.

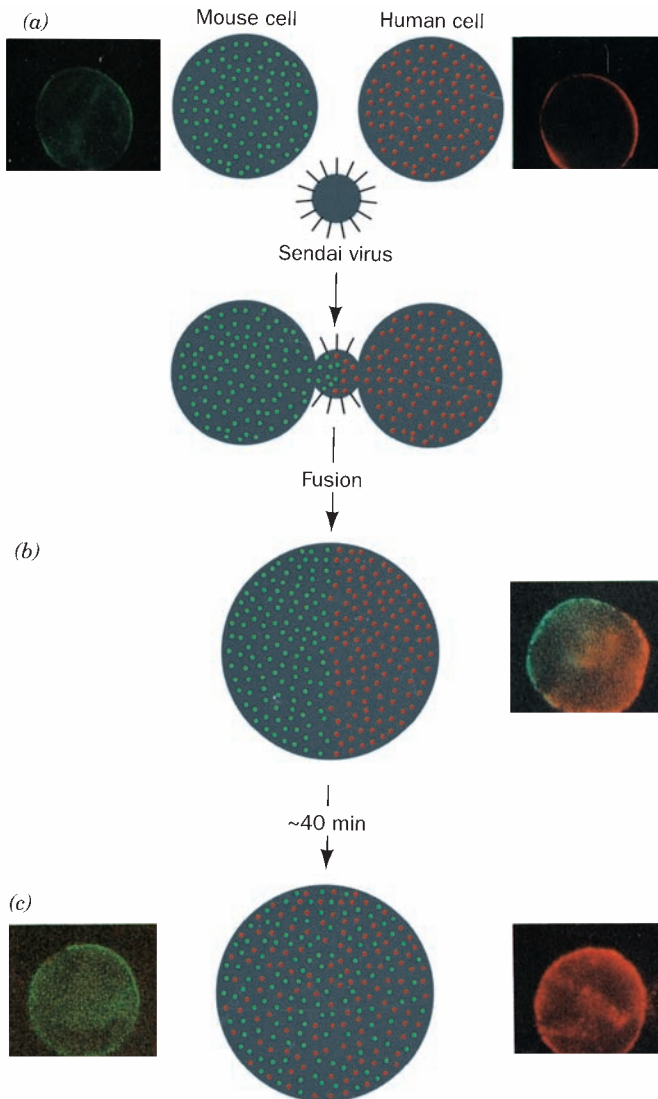

#### a. The Fluid Mosaic Model Has Been Verified Experimentally

The validity of the fluid mosaic model has been established in several ways. Perhaps the most vivid is an experiment by Michael Edidin (Fig. 12-31). Cultured mouse cells were fused with human cells by treatment with **Sendai virus** to yield a hybrid cell known as a **heterokaryon**. The mouse cells were labeled with mouse protein-specific

antibodies to which a green-fluorescing dye had been covalently linked (**immunofluorescence**). The proteins on the human cells were similarly labeled with a red-fluorescing marker. On cell fusion, the mouse and human proteins, as seen under the fluorescence microscope, were segregated on the two halves of the heterokaryon. After 40 min at 37°C, however, these proteins had thoroughly intermingled. The addition of substances that inhibit metabolism or protein synthesis did not slow this process, but lowering the temperature below 15°C did. These observations indicate that the mixing process is independent of both metabolic energy and the insertion into the membrane of newly synthesized proteins. Rather, it is a result of the diffusion of existing proteins throughout the fluid membrane, a process that slows as the temperature is lowered.

Fluorescence photobleaching recovery measurements (Fig. 12-15) indicate that membrane proteins vary in their lateral diffusion rates. Some 30 to 90% of these proteins are freely mobile; they diffuse at rates only an order of magnitude or so slower than those of the much smaller lipids, so that they typically take from 10 to 60 min to diffuse the 20- $\mu\text{m}$  length of a eukaryotic cell. Other proteins diffuse more slowly, and some, because of submembrane attachments, are essentially immobile.

The distribution of proteins in membranes may be visualized through electron microscopy using the **freeze-fracture** and **freeze-etch** techniques. In the freeze-fracture procedure, which was devised by Daniel Branton, a membrane specimen is rapidly frozen to near liquid nitrogen temperatures ( $-196^\circ\text{C}$ ). This immobilizes the sample and thereby minimizes its disturbance by subsequent manipulations. The specimen is then fractured with a cold microtome knife, which often splits the bilayer into monolayers (Fig. 12-32). Since the exposed membrane itself would be

**Figure 12-31** Sendai virus–induced fusion of a mouse cell with a human cell and the subsequent intermingling of their cell-surface components as visualized by immunofluorescence. Human and mouse antigens are labeled with red and green fluorescent markers, respectively. (a) The membrane-encapsulated Sendai virus specifically binds to cell-surface receptors on both types of cells and subsequently fuses to their cell membranes. (b) This results in the formation of a cytoplasmic bridge between the cells that expands so as to form a heterokaryon. (c) After 40 min, the red and green markers are fully intermingled. The photomicrographs were taken through filters that allowed only red or green light to reach the camera; that in Part *b* is a double exposure and those in Part *c* are of the same cell. [Immunofluorescence photomicrographs courtesy of Michael Edidin, Johns Hopkins University.]

destroyed by an electron beam, its metallic replica is made by coating the membrane with a thin layer of carbon, shadowing it (covering it by evaporative deposition under high vacuum) with platinum, and removing the organic matter by treatment with acid. Such a metallic replica can be examined by electron microscopy. In the freeze-etch procedure, the external surface of the membrane adjacent to the

**Figure 12-32** The freeze-fracture technique. A membrane that has been split by freeze-fracture, as is schematically diagrammed, exposes the interior of the lipid bilayer and its embedded proteins.

**Figure 12-33** The freeze-etch procedure. The ice that encases a freeze-fractured membrane (*top*) is partially sublimated away so as to expose the outer membrane surface (*bottom*) for electron microscopy.

cleaved area revealed by freeze fracture may also be visualized by first sublimating (etching) away, at  $-100^{\circ}\text{C}$ , some of the ice in which it is encased (Fig. 12-33).

Freeze-etch electron micrographs of most biological membranes show an inner fracture face that is studded with embedded 50- to 85-Å-diameter globular particles (Fig. 12-34) that appear to be distributed randomly. These particles correspond to membrane proteins, as is demonstrated by their disappearance when the membrane is treated with proteases before its freeze fracture. This is further corroborated by the observation that the myelin membrane, which has a low protein content, as well as liposomes composed of only lipids, have smooth inner fracture faces. Outer membrane surfaces also have a relatively smooth appearance (Fig. 12-34) because integral proteins tend not to protrude very far beyond them. The distributions of individual external proteins may be visualized by staining procedures, such as the use of ferritin-labeled antibodies, to yield electron micrographs similar in appearance to Fig. 11-36.

### b. Membrane Lipids and Proteins Are Unevenly Distributed

The distribution of lipids between the different sides of biological membranes has been established through the use of phospholipid-hydrolyzing enzymes known as **phospholipases**. Phospholipases cannot pass through membranes, so that only phospholipids on the external surfaces of intact cells are susceptible to their action. Such studies indicate that *the lipids in biological membranes, like the proteins, are asymmetrically distributed between the leaflets of a bilayer* (e.g., Fig. 12-35). Carbohydrates, as we have seen (Section 11-3Cd), are located almost exclusively on the external surfaces of plasma membranes.

*Lipids and proteins in plasma membranes may also be laterally organized.* Thus, the plasma membranes of most cells have two or more distinct domains that have different functions. For example, the plasma membranes of **epithelial cells** (the cells lining body cavities and free surfaces) have an **apical domain**, which faces the lumen of the cavity and often has a specialized function (e.g., the absorption of nutrients in intestinal brush border cells; Section 20-4A), and a **basolateral domain**, which covers the remainder of the cell. These two domains, which do not intermix, have different compositions of both lipids and proteins.

A variety of measurements indicate that the hundreds of different lipids and proteins within a given plasma membrane domain are not uniformly mixed but instead often seg-

**Figure 12-34** Freeze-etch electron micrograph of a human erythrocyte plasma membrane. The exposed interior face of the membrane is studded with numerous globular particles that are integral proteins (see Fig. 12-32). The outer surface of the membrane appears smoother than the inner surface because proteins do not project very far beyond the outer membrane surface. [Courtesy of Vincent Marchesi, Yale University.]

regate to form **microdomains** that contain only certain types of lipids and proteins. This may occur for several reasons:

1. Certain integral proteins associate to form aggregates or patches in the membrane (e.g., BR), which in turn may preferentially associate with specific lipids. Alternatively, some integral proteins are localized by attachments to elements of the cytoskeleton (which underlies the plasma membrane; Section 1-2A) or are trapped within the spaces enclosed by the resulting “fences.”

2. Integral proteins may specifically interact with particular lipids. For example, mismatches between the length of an integral protein’s hydrophobic TM band and the average thickness of a lipid bilayer may result in the selective accumulation of certain phospholipids around the protein in an annulus of 10 to 20 layers.

3. Divalent metal ions, notably  $\text{Ca}^{2+}$ , selectively ligate negatively charged head groups such as those of phosphatidylserine, thereby causing these phospholipids to aggregate in the membrane. Such metal ion-induced phase separations are known to regulate the activities of certain membrane-bound enzymes.

**Figure 12-35** Asymmetric distribution of phospholipids in the human erythrocyte membrane. The phospholipid content is expressed as mole percent. [After Rothman, J.E. and Lenard, J., *Science* **194**, 1744 (1977).]

4. Glycosphingolipids (which occur only in the outer leaflet of the plasma membrane) and cholesterol pack together to form mobile **rafts** and ~75-nm-diameter flask-shaped indentations named **caveolae** (Latin for small caves) with which specific proteins preferentially associate. Glycosphingolipids, by themselves, do not form bilayers because their large head groups prevent the requisite close packing of their predominantly saturated hydrophobic tails. Conversely, cholesterol by itself does not form a bilayer due to its small head group. It therefore appears that the glycosphingolipids in these microdomains associate laterally via weak interactions between their carbohydrate head groups with the voids between their tails filled in by cholesterol. The sphingolipid–cholesterol rafts and caveolae are not solubilized at 4°C by uncharged detergents such as Triton X-100 (Fig. 12-19). The low density of the resulting **detergent-resistant membranes (DRMs)** allows their isolation by sucrose density gradient ultracentrifugation (Section 6-5Ba), thereby permitting their associated proteins to be identified. Many of the proteins that participate in transmembrane signaling processes (Chapter 19), including GPI-linked proteins, preferentially associate with DRMs. Caveolae, which appear to be rafts with which one or more homologous proteins named **caveolins** are associated, are likewise enriched with proteins that participate in signaling.

It should be noted that all of these aggregates are highly dynamic structures that rapidly exchange both proteins and lipids with their surrounding membrane as a consequence of the weak and transient interactions between membrane components and their interactions with the underlying cytoskeleton. In fact, single molecule tracking techniques (Section 12-2Ca) have demonstrated that lipid molecules in biological membranes undergo a series of short random motions over short time periods (~10 ms) interspersed by large hops (Fig. 12-36), a process called **hop diffusion**. Evidently, *biological membranes are partitioned rather than continuous two-dimensional fluids.*

**Figure 12-36** Hop diffusion of individual colloidal gold-tagged dioleoylphosphatidylethanolamine molecules in a plasma membrane. The position of each particle was determined at 25- $\mu$ s intervals (a video frame rate of 40,500 frames  $\cdot$  s $^{-1}$ ) over a period of 62 ms (2500 steps). Colored lines connect successive positions of the particle, with differently colored segments representing the various plausible regions in the plasma membrane to which the particle appears to have been transiently confined (in the order purple, blue, green, orange, and red). [Courtesy of Akihiro Kasumi, Nagoya University, Japan.]

## D. The Erythrocyte Membrane

The erythrocyte membrane's relative simplicity, availability, and ease of isolation have made it the most extensively studied and best understood biological membrane. It is therefore a model for the more complex membranes of other cell types. A mature mammalian erythrocyte is devoid of organelles and carries out few metabolic processes; it is essentially a membranous bag of hemoglobin. Erythrocyte membranes can therefore be obtained by osmotic lysis, which causes the cell contents to leak out. The resultant membranous particles are known as erythrocyte **ghosts** because, on return to physiological conditions, they reseal to form colorless particles that retain their original shape. Indeed, by transferring sealed ghosts to another medium, their contents can be made to differ from the external solution.

### a. Erythrocyte Membranes Contain a Variety of Proteins

The erythrocyte membrane has a more or less typical plasma membrane composition of about half protein, somewhat less lipid, and the remainder carbohydrate (Table 12-4). Its proteins may be separated by SDS–polyacrylamide gel electrophoresis (Section 6-4C) after first solubilizing the membrane in a 1% SDS solution. The resulting electrophoretogram for a human erythrocyte membrane exhibits seven major and many minor bands when stained with Coomassie brilliant blue (Fig. 12-37). If the electrophoretogram is instead treated with **periodic acid–Schiff's reagent (PAS)**, which stains carbohydrates, four so-called PAS bands become evident. The polypeptides corresponding to bands 1, 2, 4.1, 4.2, 5, and 6 are readily extracted from the

**Figure 12-37** SDS-PAGE electrophoretogram of human erythrocyte membrane proteins as stained by Coomassie brilliant blue. The bands designated 4.1 and 4.2 are not separated with the 1% SDS concentration used. The minor bands are not labeled for the sake of clarity. The positions of the four sialoglycoproteins that would be revealed by PAS staining are indicated. [Courtesy of Vincent Marchesi, Yale University.]

membrane by changes in ionic strength or pH and hence are peripheral proteins. These proteins are located on the inner side of the membrane, as is indicated by the observation that they are not altered by the incubation of intact erythrocytes or sealed ghosts with proteolytic enzymes or membrane-impermeable protein labeling reagents. These proteins are altered, however, if “leaky” ghosts are so treated.

In contrast, bands 3, 7, and all four PAS bands correspond to integral proteins; they can be released from the membrane only by extraction with detergents or organic solvents. Of these, band 3 and PAS bands 1 and 2 correspond to TM proteins, as indicated by their different labeling patterns when intact cells are treated with membrane-impermeable protein-labeling reagents and when these reagents are introduced inside sealed ghosts. The PAS band 1 is a dimer of glyophorin A, which is formed through an SDS-resistant association between the TM helices of the polypeptide chains (Fig. 12-21); this dimer is the protein’s native form. The PAS band 2 protein is the monomeric form of glyophorin A.

The transport of  $\text{CO}_2$  in blood (Section 10-1C) requires that the erythrocyte membrane be permeable to  $\text{HCO}_3^-$  and  $\text{Cl}^-$  (the maintenance of electroneutrality requires that for every  $\text{HCO}_3^-$  that enters a cell, a  $\text{Cl}^-$  or some other anion must leave the cell; Section 10-1Cb). The rapid transport of these and other anions across the erythrocyte membrane is mediated by a specific **anion channel** of which there are  $\sim 1$  million/cell (comprising  $>30\%$  of the membrane protein). Band 3 protein (929 residues and 5–8% carbohydrate) specifically reacts with anionic protein-labeling reagents that block the anion channel, thereby indicating that the anion channel is composed of band 3 protein. Furthermore, cross-linking studies with bifunctional reagents (Section 8-5Ca) demonstrate that the anion channel is at least a dimer. Hemoglobin and the glycolytic (glucose metabolizing) enzymes **aldolase**, **phosphofruktokinase (PFK)**, and the band 6 protein **glyceraldehyde-3-phosphate dehydrogenase (GAPDH)**; Section 17-2F) all specifically and reversibly bind to band 3 protein on the cytoplasmic side of the membrane. The functional significance of this observation is unknown.

### b. The Erythrocyte’s Cytoskeleton Is Responsible for Its Shape and Flexibility

A normal erythrocyte’s biconcave disklike shape (Fig. 7-19a) assures the rapid diffusion of  $\text{O}_2$  to its hemoglobin molecules by placing them no farther than  $1\ \mu\text{m}$  from the cell surface. However, the rim and the dimple regions of an erythrocyte do not occupy fixed positions on the cell membrane. This can be demonstrated by anchoring an erythrocyte to a microscope slide by a small portion of its surface and inducing the cell to move laterally with a gentle flow of isotonic buffer. A point originally on the rim of the erythrocyte will move across the dimple to the rim on the opposite side of the cell from where it began. Evidently, the membrane rolls across the cell while maintaining its shape, much like the tread of a tractor. This remarkable mechanical property of the erythrocyte membrane results from the presence of a submembranous network of proteins that function as a membrane “skeleton”—the cell’s cytoskeleton. Indeed, this property is partially duplicated by a

mechanical model consisting of a geodesic sphere (a spheroidal cage) that is freely jointed at the intersections of its struts but constrained from collapsing much beyond a flat surface. When placed inside an evacuated plastic bag, this cage also assumes a biconcave disklike shape.

The fluidity and flexibility imparted to an erythrocyte by its cytoskeleton has important physiological consequences. A slurry of solid particles of a size and concentration equal to that of red cells in blood has the flow characteristics approximating that of sand. Consequently, in order for blood to flow at all, much less for its erythrocytes to squeeze through capillary blood vessels smaller in diameter than they are, erythrocyte membranes, together with their cytoskeletons, must be fluidlike and easily deformable.

The protein **spectrin**, so called because it was discovered in erythrocyte ghosts, accounts for  $\sim 75\%$  of the erythrocyte cytoskeleton. It is composed of two similar polypeptide chains, band 1 ( $\alpha$  subunit; 2418 residues) and band 2 ( $\beta$  subunit; 2137 residues), which sequence analysis indicates each consist of repeating 106-residue segments that are predicted to fold into triple-stranded  $\alpha$  helical coiled coils (Fig. 12-38a,b). Electron microscopy indicates that these large polypeptides are loosely intertwined to form a flexible wormlike  $\alpha\beta$  dimer that is  $\sim 1000\ \text{\AA}$  long (Fig. 12-38c). Two such heterodimers further associate in a

### Figure 12-38 (Opposite) The human erythrocyte cytoskeleton.

(a) Structure of an  $\alpha\beta$  dimer of spectrin. Both of these antiparallel polypeptides contain multiple 106-residue repeats, which are thought to form flexibly connected triple helical bundles. Two of these heterodimers join, head to head, to form an  $(\alpha\beta)_2$  heterotetramer. [After Speicher, D.W. and Marchesi, V., *Nature* **311**, 177 (1984).] (b) X-ray structure of two consecutive repeats of chicken brain  $\alpha$ -spectrin. Each of these 106-residue repeats consists of a down-up-down triple helical bundle in which the C-terminal helix of first repeat (R16; red) is continuous, via a 5-residue helical linker (green), with the N-terminal helix of the second repeat (R17; blue). The helices within each triple helical bundle wrap around each other in a gentle left-handed supercoil that is hydrophobically stabilized by the presence of nonpolar residues at the *a* and *d* positions of heptad repeats on all three of its component  $\alpha$  helices (Fig. 8-26). Despite the expected rigidity of  $\alpha$  helices, there is considerable evidence that spectrin is a flexible wormlike molecule. [Courtesy of Alfonso Mondragón, Northwestern University, PDBid 1CUN.] (c) Electron micrograph of an erythrocyte cytoskeleton that has been stretched to an area 9 to 10 times greater than that of the native membrane. Stretching makes it possible to obtain clear images of the cytoskeleton, which in its native state is so densely packed and irregularly flexed that it is difficult to pick out individual molecules and to ascertain how they are interconnected. Note the predominantly hexagonal network composed of spectrin tetramers cross-linked by junctions containing actin and band 4.1 protein. [Courtesy of Daniel Branton, Harvard University.] (d) Model of the erythrocyte cytoskeleton. The so-called junctional complex, which is magnified in this drawing, contains actin, **tropomyosin** (which, in muscle, also associates with actin; Section 35-3Ac), and band 4.1 protein, as well as **adducin**, **dematin**, and **tropomodulin** (not shown). [After Goodman, S.R., Krebs, K.E., Whitfield, C.F., Riederer, B.M., and Zagen, I.S., *CRC Crit. Rev. Biochem.* 23, 196 (1988).]

**Figure 12-39** X-ray structure of human ankyrin repeats 13 to 24. The polypeptide is shown in ribbon form colored in rainbow order from its N-terminus (blue, repeat 13) to its C-terminus (red, repeat 24). [Based on an X-ray structure by Peter Michaely, University of Texas Southwestern Medical Center, Dallas, Texas. PDBid 1N11.]

head-to-head manner to form an  $(\alpha\beta)_2$  heterotetramer. These tetramers, of which there are  $\sim 100,000/\text{cell}$ , are cross-linked at both ends by attachments to bands 4.1 and 5 to form a dense and irregular protein meshwork that underlies the erythrocyte plasma membrane (Fig. 12-38*c,d*). Band 5, a globular protein that forms filamentous oligomers, has been identified as **actin**, a common cytoskeletal element in other cells (Section 1-2Ae) and a major component of muscle (Section 35-3Ac). Spectrin also associates with band 2.1, an 1880-residue monomer known as **ankyrin**, which, in turn, binds to band 3, the anion channel protein. This attachment anchors the cytoskeleton to the membrane. Indeed, on solubilization of spectrin and actin by low ionic strength solutions, the erythrocyte ghosts' biconcave shape is lost and their integral proteins, which normally occupy fixed positions in the membrane plane, become laterally mobile.

Ankyrin's N-terminal 798-residue segment consists almost entirely of 24 tandem  $\sim 33$ -residue repeats known as **ankyrin repeats** (Fig. 12-39), which also occur in a variety of other proteins. Each ankyrin repeat consists of two short (8- or 9-residue) antiparallel  $\alpha$  helices followed by a long loop. These structures are arranged in a right-handed superhelical stack. The entire assembly forms an elongated concave surface that is postulated to bind various integral proteins as well as spectrin. Immunochemical studies have revealed spectrinlike, ankyrinlike, and band 4.1-like proteins in the cytoskeletons of a variety of tissues.

### c. Hereditary Spherocytosis and Elliptocytosis Arise from Defects in the Erythrocyte Cytoskeleton

Individuals with **hereditary spherocytosis** have spherical erythrocytes that are relatively fragile and inflexible. These individuals suffer from hemolytic anemia because the spleen, a labyrinthine organ with narrow passages that normally filters out aged erythrocytes (which lose flexibility toward the end of their  $\sim 120$ -day lifetime), prematurely removes spherocytotic erythrocytes. The hemolytic anemia may be alleviated by the spleen's surgical removal. However, the primary defects in spherocytotic cells are reduced

synthesis of spectrin, the production of an abnormal spectrin that binds band 4.1 protein with reduced affinity, or the absence of band 4.1 protein.

**Hereditary elliptocytosis** (having elongated or elliptical red cells; also known as **hereditary ovalocytosis**), a condition that is common in certain areas of Southeast Asia and Melanesia, confers resistance to malaria in heterozygotes (but apparently is lethal in homozygotes). This condition arises from defects in the erythrocyte anion channel. A common such defect consists of a 9-residue deletion that inactivates this TM protein. The consequent reduced capacity of red cells to import phosphate or sulfate ions may inhibit the intraerythrocytic growth of rapidly developing malarial parasites.

The camel, the renowned “ship of the desert,” provides a striking example of adaptation involving the erythrocyte membrane. This remarkable animal is still active after a loss of water constituting 30% of its body weight and, when thus dehydrated, can drink sufficient water in a few minutes to become fully rehydrated. The rapid uptake of such a large amount of water by the blood, which must deliver it to the cells, would lyse the erythrocytes of most animals. Yet camel erythrocytes, which have the shape of flattened ellipsoids rather than biconcave disks, are resistant to osmotic lysis. Camel spectrin binds to its membrane with particular tenacity, but on spectrin removal, which requires a strong denaturing agent such as guanidinium chloride, camel erythrocytes assume a spherical shape.

### E. Blood Groups

The outer surfaces of erythrocytes and other eukaryotic cells are covered with complex carbohydrates that are components of plasma membrane glycoproteins and glycolipids. They form a thick, fuzzy cell coating, the **glycocalyx** (Fig. 12-40), which contains numerous identity markers that function in various recognition processes. Human erythrocytes have 30 genetically distinct blood group systems comprised of  $>600$  known **blood group determinants**, although many of these determinants are rare or occur only in certain ethnic groups. Of these systems, only two—the **ABO blood group system** (discovered in 1900 by Karl

**Figure 12-40** The erythrocyte glycocalyx as revealed by electron microscopy using special staining techniques. It is up to 1400 Å thick and composed of closely packed, 12- to 25-Å-diameter oligosaccharide filaments linked to plasma membrane-associated proteins and lipids. [Courtesy of Harrison Latta, UCLA.]

Landsteiner) and the **rhesus (Rh) blood group system**—have major clinical importance. The various blood groups are identified by means of suitable antibodies or by specific plant lectins.

#### a. ABO Blood Group Substances Are Carbohydrates

The ABO system consists of three blood group substances, the **A, B, and H antigens**, which are components of erythrocyte surface sphingoglycolipids. [Antigens are characteristic constellations of chemical groups on macromolecules that elicit the production of specific antibodies when introduced into an animal (Section 35-2Aa). Each antibody molecule can specifically bind to at least two of its corresponding antigen molecules, thereby cross-linking them.] Individuals with type A cells have A antigens on their cell surfaces and carry anti-B antibodies in their serum; those with type B cells, which bear B antigens, carry anti-A antibodies; those with type AB cells, which bear both A and B antigens, carry neither anti-A nor anti-B antibodies; and type O individuals, whose cells bear neither antigen, carry both anti-A and anti-B antibodies. Consequently, the transfusion of type A blood into a type B individual, for example, causes an anti-A antibody–A antigen reaction, which agglutinates (clumps together) the transfused erythrocytes, resulting in an often fatal blockage of blood vessels. The H antigen is discussed below. Anti-A and anti-B antibodies, which are not present at birth, appear to arise through an immune response to A-like and B-like antigens in food and/or to the colonization of the infant gut by bacteria that produce such antigens [the immune system normally suppresses the production of antibodies directed against the body's own antigens (Section 35-2Ac) so, for example, a type A individual does not produce anti-A antibodies].

The ABO blood group substances are not confined to erythrocytes but also occur in the plasma membranes of many tissues as glycolipids of considerable diversity. In fact, in the ~80% of the population known as secretors, these antigens are secreted as *O*-linked components of glycoproteins into various body fluids, including saliva, milk, seminal fluid, gastric juice, and urine. These diverse molecules, which are 85% carbohydrate by weight and have molecular masses ranging up to thousands of kilodaltons, consist of multiple oligosaccharides attached to a polypeptide chain.

The A, B, and H antigens differ only in the sugar residues at their nonreducing ends (Table 12-5). The H antigen occurs in type O individuals; it is also the precursor oligosaccharide of A and B antigens. Type A individuals have a 303-residue glycosyltransferase that specifically adds an *N*-acetylgalactosamine residue to the terminal position of the H antigen, whereas in type B individuals, this enzyme, which differs by four amino acid residues from that of type A individuals, instead adds a galactose residue. In type O individuals, the enzyme is inactive because its synthesis terminates after its 115th residue.

Do the different blood groups confer any biological advantages or disadvantages? Epidemiological studies indicate

**Table 12-5 Structures of the A, B, and H Antigenic Determinants in Erythrocytes**

Type	Antigen
H	Galβ(1 → 4)GlcNAc... ↑ 1,2 L-Fucα
A	GalNAcα(1 → 3)Galβ(1 → 4)GlcNAc... ↑ 1,2 L-Fucα
B	Galα(1 → 3)Galβ(1 → 4)GlcNAc... ↑ 1,2 L-Fucα

Abbreviations: Gal = galactose, GalNAc = *N*-acetylgalactosamine, GlcNAc = *N*-acetylglucosamine, L-Fuc = L-fucose.

that type A and B individuals are less susceptible to cholera infections than are type O individuals, with the relatively rare type AB individuals being highly resistant to this deadly disease. Apparently, type A and B oligosaccharides block a receptor for the bacterium causing cholera, *Vibrio cholera* (Section 19-2Cd). In addition, type O individuals, particularly nonsecretors, have a higher incidence of peptic (stomach) ulcers. However, type A individuals have a higher incidence of stomach cancer, heart disease, and pernicious anemia (Section 25-2Ee).

#### F. Gap Junctions

Most cells in multicellular organisms are in metabolic and electrical as well as physical contact with neighboring cells. This contact is brought about by tubular particles, named **gap junctions**, that join discrete regions of neighboring plasma membranes much like hollow rivets (Fig. 12-41). Indeed, these intercellular channels are so widespread that many whole organs are continuous from within. Thus gap junctions are important intercellular communication channels. For example, the synchronized contraction of heart muscle is brought about by flows of ions through gap junctions (heart muscle is not innervated as is skeletal muscle). Likewise, gap junctions serve as conduits for some of the substances that mediate embryonic development; blocking gap junctions with antibodies that bind to them causes developmental abnormalities in species as diverse as hydras, frogs, and mice. Gap junctions also function to nourish cells that are distant from the blood supply, such as bone and lens cells. Thus, it is not surprising that, in humans, defects in gap junctions are associated with certain neurodegenerative diseases, cataracts, deafness, several skin diseases, and developmental anomalies.

Gap junctions consist of a single sort of protein subunit known as a **connexin**. A single gap junction consists of two apposed hexagonal rings of connexins, called **connexons**, one from each of the adjoining plasma membranes

**Figure 12-41 Model of a gap junction.** Gap junctions between adjacent cells consist of two apposed plasma membrane–embedded hexagonal studs that bridge the gap between the cells.

Gap junctions hold cells a fixed distance apart—the gap. Small molecules and ions, but not macromolecules, can pass between cells via the gap junction’s central channel.

(Fig. 12-41). Cells are normally connected by clusters of hundreds to thousands of connexons. A given animal expresses numerous genetically distinct connexins, with humans, for example, expressing 21 different connexins ranging in molecular mass from 25 to 50 kD. Many types of cells simultaneously express several different species of connexins, and in cells that do so, there is considerable evidence that at least some connexons may be formed from two or more species of connexins. Moreover, the gap junctions joining two cells may consist of two different types of connexons. These various types of gap junctions presumably differ in their selectivities for the substances they transmit.

Mammalian gap junction channels are minimally 16 to 20 Å in diameter, which Werner Loewenstein established by microinjecting single cells with fluorescent molecules of various sizes and observing with a fluorescence microscope whether the fluorescent probe passed into neighboring cells. The molecules and ions that can pass freely between neighboring cells are limited in molecular mass to a maximum of ~1000 D; macromolecules such as proteins and nucleic acids cannot leave a cell via this route.

The diameter of a gap junction channel varies with  $\text{Ca}^{2+}$  concentration: The channels are fully open when the  $\text{Ca}^{2+}$  level is  $<10^{-7} M$  and narrow as the  $\text{Ca}^{2+}$  concentration increases until, above  $5 \times 10^{-5} M$ , they close. This shutter system is thought to protect communities of interconnected cells from the otherwise catastrophic damage that would result from the death of even one of their members. Cells generally maintain very low cytosolic  $\text{Ca}^{2+}$  concentrations ( $<10^{-7} M$ ) by actively pumping  $\text{Ca}^{2+}$  out of the cell as well as into their mitochondria and endoplasmic reticulum (Section 20-3B;  $\text{Ca}^{2+}$  is an important intracellular messenger whose cytosolic concentration is precisely regulated).  $\text{Ca}^{2+}$  floods back into leaky or metabolically depressed

cells, thereby inducing closure of their gap junctions and sealing them off from their neighbors.

#### a. Connexins Contain Transmembrane Four-Helix Bundles

The X-ray structure of the gap junction formed by the 226-residue human **connexin 26 (Cx26)**, determined by Tomitake Tsukihara, reveals a 12-mer with  $D_6$  symmetry, a height of 155 Å, and a maximal diameter of 92 Å that encloses a central channel (Fig. 12-42a). The extracellular portion of each connexon extends 23 Å from the extracellular surface and interdigitates with the opposite connexon by 6 Å to span an intercellular gap of 40 Å. Each Cx26 subunit forms an up–down–up–down four-helix bundle in which both the N- and C-termini occupy the cytosol. The central channel has a diameter of ~40 Å at its cytosolic entrance that funnels down to 14 Å near the extracellular surface of the membrane and then widens to 25 Å in the extracellular space (Fig. 12-42b). The positively charged funnel entrance would attract negatively charged molecules. However, the region of maximal channel constriction is negatively charged, which should also affect the channel’s charge selectivity.

#### G. Channel-Forming Proteins

A number of bacterial toxins are synthesized as water-soluble monomers that, on interacting with their target membrane via a specific receptor protein, spontaneously insert into the membrane as a TM pore. This process, which for many such **channel-forming toxins (CFTs)** requires their oligomerization, causes the leakage of small ions and molecules from the target cell, thereby killing it through loss of osmotic balance. The formation of only one CFT-based pore is often sufficient to kill a cell.

**Figure 12-42** X-ray structure of the connexin 26 gap junction. (a) View perpendicular to the protein's 6-fold axis (parallel to the planes of the membranes) in which the protein is drawn in ribbon form embedded in its semitransparent molecular surface. Each connexin of the upper connexon has a different color, whereas one connexin in the lower connexon is colored in rainbow order from its N-terminus (blue) to its C-terminus (red) with the remaining connexins purple. The extent of the

(b) transmembrane region was deduced from the distribution of hydrophobic and aromatic residues (Section 12-3Af). (b) Cutaway drawing through the surface diagram of the gap junction channel. The channel surface is colored according to its electrostatic potential with red positive, blue negative, and white neutral. [Part a based on an X-ray structure by, and Part b courtesy of Tomitake Tsukihara, University of Osaka, Japan. PDBid 2ZW3.]

One of the best characterized CFTs is  **$\alpha$ -hemolysin**, which the human pathogen *Staphylococcus aureus* secretes as a water-soluble 293-residue monomer and which spontaneously inserts into the membranes of erythrocytes and several other types of cells in the form of heptameric pores. Even though the  $\alpha$ -hemolysin monomer is water-soluble and lacks clearly hydrophobic segments, the heptamer acts as a typical TM protein in that it is not released from the membrane by treatment with high salt, low pH, or chaotropic agents but, instead, requires treatment with detergents for this to occur.

The X-ray structure of detergent-solubilized  $\alpha$ -hemolysin, determined by Eric Gouaux, reveals a striking mushroom-shaped heptameric complex that is 100 Å in height and 100 Å in diameter (Fig. 12-43a,b). A 14- to 46-Å-diameter solvent-filled channel, which runs along the protein's 7-fold axis, forms a TM pore. The stem of the mushroom, the protein's TM segment, consists of a 52-Å-high and 26-Å-diameter, porinlike, 14-stranded, antiparallel  $\beta$  barrel composed of seven 2-stranded antiparallel  $\beta$  sheets, one from each subunit (Fig. 12-43b). The remainder of each subunit

consists of a  $\beta$  sandwich domain and a rim domain, which together form a 70-Å-long ellipsoid (Fig. 12-43c). Seven of these ellipsoids are distributed in a ring, thereby forming the mushroom's cap and rim. The rim domain projects toward and probably interacts with the membrane's phospholipid head groups via the basic and aromatic residues that extend from the crevice between the top of the stem and rim.

A variety of experimental evidence indicates that the spontaneous formation of the heptameric TM pore occurs via several discrete steps: (1) the binding of the aqueous monomer to the membrane surface, probably through the interaction of the protein's polypeptide loops with the surface groups of the lipid bilayer; (2) the formation of the heptamer on the surface of the membrane; and (3) the insertion of the 14-stranded  $\beta$  barrel through the membrane to form the TM pore. The structural details of this process are as yet unknown, although it seems clear that there is little change in the monomers' secondary structure on their assembly to form the heptameric TM pore. The reason why monomers do not form heptamers in aqueous solution is

**Figure 12-43** X-ray structure of  $\alpha$ -hemolysin. Views (a) along and (b) perpendicular to the heptameric transmembrane pore's 7-fold axis. Each subunit is drawn with a different color. (c) The monomer unit with its three domains drawn in different colors. [Courtesy of Eric Gouaux, Columbia University. PDBid 7AHL.]

probably due to differences between the strengths of the intrasubunit interactions in the monomer in aqueous solution and the intersubunit interactions in the heptamer in the membrane.

Not all CFTs form pores using  $\beta$  barrels. Rather, a variety of CFTs, notably several *E. coli* proteins known as **colicins**, form pores that are lined with  $\alpha$  helices. Most such pores consist of monomers.

#### 4 MEMBRANE ASSEMBLY AND PROTEIN TARGETING

*As cells grow and divide, they synthesize new membranes. How are such asymmetric membranes generated? One way in which this might occur is through self-assembly. Indeed, when the detergent used to disperse a biological membrane is removed, liposomes form in which functional integral proteins are embedded. In most cases, however, these model membranes are symmetrical, both in their lipid distribution between the inner and outer leaflets of the bilayer and in the orientations of their embedded proteins. An alternative hypothesis of membrane assembly is that it occurs on the scaffolding of preexisting membranes; that is, membranes are generated by the expansion of old ones rather than by the creation of new ones. In this section we shall see that this is, in fact, how biological membranes are generated. In doing so, we shall consider how proteins*

(c)

are inserted into and passed through membranes as well as how portions of membranes in the form of vesicles pinch off from one membrane and fuse with another, thereby transporting proteins and lipids between these membranes. These highly complex processes are indicative of the intricacies of biological processes in general.

Trinitrobenzenesulfonic acid (TNBS)

Phosphatidylethanolamine (PE)

Figure 12-44 Reaction of TNBS with PE.

### A. Lipid Distributions in Membranes

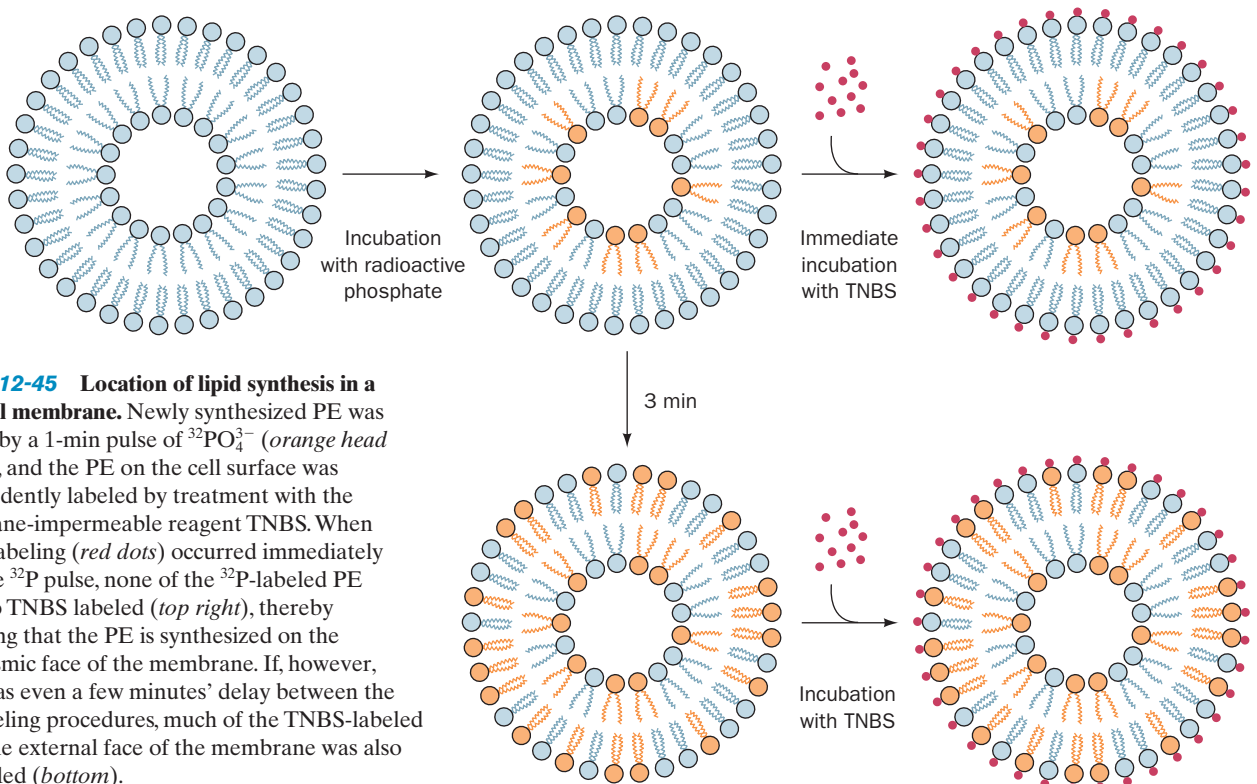

The enzymes involved in the biosynthesis of membrane lipids are mostly integral proteins (Section 25-8). Their substrates and products are themselves membrane components, so that membrane lipids are fabricated on site. Eugene Kennedy and James Rothman demonstrated this to be the case in bacteria through the use of selective labeling. They gave growing bacteria a 1-min pulse of  $^{32}\text{PO}_4^{3-}$  so as to label radioactively the phosphoryl groups of only the newly synthesized phospholipids. **Trinitrobenzenesulfonic acid (TNBS)**, a membrane-impermeable reagent that combines with phosphatidylethanolamine (**PE**; Fig. 12-44), was then immediately added to the cell suspension. Analysis of the resulting doubly labeled membrane showed that none of the TNBS-labeled PE was radioactively labeled. This observation indicates that *newly made PE is synthesized on the cytoplasmic face of the membrane* (Fig. 12-45, top right).

#### a. Membrane Proteins Catalyze

##### Phospholipid Flip-Flops

If an interval of only 3 min is allowed to elapse between the  $^{32}\text{PO}_4^{3-}$  pulse and the TNBS addition, about half of the  $^{32}\text{P}$ -labeled PE is also TNBS labeled (Fig. 12-45, bottom). This observation indicates that the flip-flop rate of PE in the bacterial membrane is  $\sim 100,000$ -fold greater than it is in bilayers consisting of only phospholipids (where, it will be recalled, the flip-flop rates have half-times of many days).

How do phospholipids synthesized on one side of the membrane reach its other side so quickly? Phospholipid flip-flops appear to be facilitated in two ways:

**Figure 12-45** Location of lipid synthesis in a bacterial membrane. Newly synthesized PE was labeled by a 1-min pulse of  $^{32}\text{PO}_4^{3-}$  (orange head groups), and the PE on the cell surface was independently labeled by treatment with the membrane-impermeable reagent TNBS. When TNBS labeling (red dots) occurred immediately after the  $^{32}\text{P}$  pulse, none of the  $^{32}\text{P}$ -labeled PE was also TNBS labeled (top right), thereby indicating that the PE is synthesized on the cytoplasmic face of the membrane. If, however, there was even a few minutes' delay between the two labeling procedures, much of the TNBS-labeled PE in the external face of the membrane was also  $^{32}\text{P}$  labeled (bottom).

1. Membranes contain proteins known as **flippases** that catalyze the flip-flops of specific phospholipids. These proteins tend to equilibrate the distribution of their corresponding phospholipids across a bilayer; that is, the net transport of a phospholipid is from the side of the bilayer with the higher concentration of the phospholipid to the opposite side. Such a process, as we shall see in Section 20-2, is a form of **facilitated diffusion**.

2. Membranes contain proteins known as **phospholipid translocases** that transport specific phospholipids across a bilayer in a process that is driven by ATP hydrolysis. These proteins can transport certain phospholipids from the side of a bilayer that has the lower concentration of the phospholipids being translocated to the opposite side, thereby establishing a nonequilibrium distribution of the phospholipids. Such a process, as we shall see in Section 20-2, is a form of **active transport**.

The observed distribution of phospholipids across membranes (e.g., Fig. 12-35) therefore appears to arise from the membrane orientations of the enzymes that synthesize phospholipids combined with the countervailing tendencies of ATP-dependent phospholipid translocases to generate asymmetric phospholipid distributions and those of flippases to randomize these distributions.

#### b. A Membrane's Characteristic Lipid Composition Can Arise in Several Ways

In eukaryotic cells, lipids are synthesized on the cytoplasmic face of the endoplasmic reticulum, from where they are transported to other membranes. Perhaps the most important mechanism of lipid transport is the budding off of membranous vesicles from the ER and their subsequent fusion with other membranes (Sections 12-4C and 12-4D). However, this mechanism does not explain the different lipid compositions of the various membranes in a cell. Lipids may also be transported between membranes by the **phospholipid exchange proteins** present in many cells. These proteins spontaneously transfer specific phospholipids, one molecule at a time, between two membranes separated by an aqueous medium. A membrane's characteristic lipid composition may also arise through on-site remodeling and/or selective degradation of its component lipids through the action of specific enzymes (Section 25-8A).

### B. The Secretory Pathway

Membrane proteins, as are all proteins, are ribosomally synthesized under the direction of messenger RNA templates such that each polypeptide grows from its N-terminus to its C-terminus by the stepwise addition of amino acid residues (Section 5-4B). Cytologists have long noted two classes of eukaryotic ribosomes, those free in the cytosol and those bound to the endoplasmic reticulum (**ER**) so as to form the **rough endoplasmic reticulum (RER)**, so called because of the knobby appearance its bound ribosomes give it; Fig. 1-5). Both classes of ribosomes are nevertheless structurally identical; they differ only in the nature of the polypeptide they are synthesizing. *Free*

*ribosomes synthesize mostly soluble and mitochondrial proteins, whereas membrane-bound ribosomes manufacture TM proteins and proteins destined for secretion, operation within the ER, or incorporation into lysosomes* (membranous organelles containing a battery of hydrolytic enzymes that function to degrade and recycle cell components; Section 1-2Ad). These latter proteins initially appear in the RER.

#### a. The Secretory Pathway Accounts for the Targeting of Many Secreted and Membrane Proteins

How are RER-destined proteins differentiated from other proteins? And how do these large, relatively polar molecules pass through the RER membrane? These processes occur via the **secretory pathway**, which was first described by Günter Blobel, César Milstein, and David Sabatini around 1975. Since ~25% of the different species of proteins synthesized by all types of cells are integral proteins and many others are secreted, ~40% of the various types of proteins that a cell synthesizes must be processed via the secretory pathway or some other protein targeting pathway (e.g., that which directs proteins to the mitochondrion; Section 12-4E). In this subsection, we first present an overview of the secretory pathway and then discuss its various aspects in detail. The secretory pathway is outlined in Fig. 12-46:

1. *All secreted, ER-resident, and lysosomal proteins, as well as many TM proteins, are synthesized with leading (N-terminal) 13- to 36-residue **signal peptides**.* These signal peptides consist of a 6- to 15-residue hydrophobic core flanked by several relatively hydrophilic residues that usually include one or more basic residues near the N-terminus (Fig. 12-47). Signal peptides otherwise have little sequence similarity. However, a variety of evidence indicates they form  $\alpha$  helices in nonpolar environments.

2. When the signal peptide first protrudes beyond the ribosomal surface (when the polypeptide is at least ~40 residues long), the **signal recognition particle (SRP)**, a 325-kD complex of six different polypeptides and a 300-nucleotide RNA molecule, binds to both the signal peptide and the ribosome accompanied by replacement of the SRP's bound GDP by GTP. The SRP's resulting conformational change causes the ribosome to arrest further polypeptide growth, thereby preventing the RER-destined protein from being released into the cytosol as well as averting premature protein folding that would preclude the protein from entering the ER (see below).

3. The SRP-ribosome complex diffuses to the RER surface, where it is bound by the **SRP receptor (SR)** in complex with the **translocon**, a protein pore in the ER membrane through which the growing polypeptide will be extruded. In forming the SR-translocon complex, the SR's bound GDP is replaced by GTP.

4. The SRP and SR stimulate each other to hydrolyze their bound GTP to GDP (which is energetically equivalent to ATP hydrolysis), resulting in conformational changes that cause them to dissociate from each other and

**Figure 12-46** The ribosomal synthesis, membrane insertion, and initial glycosylation of an integral protein via the secretory pathway. (1) Protein synthesis is initiated at the N-terminus of the polypeptide, which consists of a 13- to 36-residue signal sequence. (2) A signal recognition particle (SRP) binds to the ribosome and the signal sequence emerging from it, thereby arresting polypeptide synthesis. (3) The SRP is bound by the transmembrane SRP receptor (SR) in complex with the translocon, thereby bringing together the ribosome and the translocon. (4) The SRP and SR hydrolyze their bound GTPs, causing them to dissociate from the ribosome–translocon complex. The ribosome then resumes the synthesis of the polypeptide, which passes through the translocon into the

of the ER. (5) Shortly after the entrance of the signal sequence into the lumen of the endoplasmic reticulum, it is proteolytically excised. (6) As the growing polypeptide chain passes into the lumen, it commences folding into its native conformation, a process that is facilitated by its interaction with the chaperone protein BiP (not shown). Simultaneously, enzymes initiate the polypeptide’s specific glycosylation. Once the protein has folded, it cannot be pulled out of the membrane. At points determined by its sequence, the polypeptide becomes anchored in the membrane (proteins destined for secretion pass completely into the ER lumen). (7) Once polypeptide synthesis is completed, the ribosome dissociates into its two subunits. See the Animated Figures

from the ribosome–translocon complex. This permits the bound ribosome to resume polypeptide synthesis such that the growing polypeptide’s N-terminus passes through the

translocon into the lumen of the ER. Most ribosomal processes, as we shall see in Section 32-3, are driven by GTP hydrolysis.

signal peptides are preceded by basic residues (blue). [After Watson, M.E.E., *Nucleic Acids Res.* **12**, 5147–5156 (1984).]

5. Shortly after the signal peptide enters the ER lumen, it is specifically cleaved from the growing polypeptide by a membrane-bound **signal peptidase** (polypeptide chains with their signal peptide still attached are known as **preproteins**; signal peptides are alternatively called **presequences**).

6. The nascent (growing) polypeptide starts to fold to its native conformation, a process that is facilitated by its interaction with an ER-resident chaperone protein Hsp70 (Section 9-2C). Enzymes in the ER lumen then initiate **post-translational modification** of the polypeptide, such as the specific attachments of “core” carbohydrates to form glycoproteins (Section 23-3B); the formation of disulfide bonds as facilitated by protein disulfide isomerase (Section 9-2A), an ER-resident protein; and the attachment of GPI anchors (Section 23-3Bk).

7. When polypeptide synthesis is completed, the protein is released from both the ribosome and the translocon, and the ribosome dissociates from the RER. Secretory, ER-resident, and lysosomal proteins pass completely through the RER membrane into the lumen. TM proteins, in contrast, contain one or more hydrophobic ~22-residue TM sequences that remain embedded in the membrane.

The secretory pathway also occurs in prokaryotes for the insertion of certain proteins into the cell membrane (whose exterior is equivalent to the ER lumen). Indeed, all forms of life yet tested have homologous SRPs and SRs. However, in bacteria, the binding of the SRP to the ribosome does not arrest translation.

### b. The Cryo-Electron Microscopy Structure of the SRP in Complex with a Translating Ribosome Reveals How the SRP Binds Signal Peptide and Arrests Translation

Mammalian SRPs consist of six polypeptides known as **SRP9**, **SRP14**, **SRP19**, **SRP54**, **SRP68**, and **SRP72** (where the numbers are their molecular masses in kilodaltons) and an ~300-nucleotide (nt) 7S RNA [Fig. 12-48; RNAs are often classified according to their sedimentation rate in Svedberg units (S), which increases with their molecular mass (Section 6-5Aa)]. Many prokaryotic SRPs are much simpler; that in *E. coli* consists of a single polypeptide named **Ffh** that is homologous to SRP54 (Ffh for *Fifty-four* homolog) and a 4.5S RNA (114 nt) that, in part, is predicted to have a secondary structure similar to that portion of the 7S RNA to which SRP54 binds. Indeed, replacing SRP54 with Ffh or vice versa yields functional SRPs, at least *in vitro*, thereby suggesting that the Ffh–4.5S RNA complex is a structurally minimized version of the eukaryotic SRP.

The 12-Å resolution cryo-electron microscopy (cryo-EM)-based structure of canine SRP in complex with a wheat germ ribosome containing a nascent (growing) polypeptide chain was determined by Joachim Frank and Roland Beckmann. The structure reveals that the so-called S domain of the ~270-Å-long SRP binds at the base of the large (60S) ribosomal subunit next to the exit of the tunnel through which newly synthesized polypeptide emerges, whereas the Alu domain bends around the large subunit to contact the ribosome at the interface between its large and small (40S) subunits (Fig. 12-49).

**Figure 12-48** Sequence and secondary structure of canine 7S RNA. Its various double helical segments (denoted H1 through H8) and loops (denoted L1 and L1.2), are drawn in red and yellow with Watson–Crick base pairs represented by connecting lines and non-Watson–Crick base pairs indicated by dots. The positions at which the various SRP proteins bind to the 7S RNA are indicated in cyan, blue, and gray. [Courtesy of Roland Beckmann, Humboldt University of Berlin, Germany.]

The ribosome–SRP structure was modeled by fitting the much higher resolution X-ray structures of the yeast ribosome (Section 32-3Af) and various SRP fragments to the cryo-EM–derived electron density (Figs. 12-49d and 12-50). The model indicates that the 7S RNA consists mainly of a long double helical rod that is bent at two positions named hinge 1 and hinge 2 (RNA, as does DNA, can form a base-paired double helix, although its conformation is distinctly different from that of B-DNA; Section 29-1Bc). The signal sequence exiting the ribosome, which was modeled as an  $\alpha$  helix, binds to SRP54, which contacts the ribosome near the mouth of its peptide exit tunnel.

SRP54 consists of three domains: the N-terminal N domain; the central G domain, which contains the SRP’s GTPase function and together with the N domain mediates the SRP’s interaction with the SRP receptor; and the C-terminal M domain, which is rich in methionine (25 of its 209 residues in humans). The N domain forms a bundle of four antiparallel  $\alpha$  helices that closely associates with the G domain, which consists of an open  $\beta$  sheet (Section 8-3Bi) that structurally resembles those of other GTPases. The M domain contains a deep groove that binds the helical signal sequence. The groove is lined almost entirely with hydrophobic residues including many of SRP54’s Met residues (the Met side chain has physical properties similar to that of an *n*-butyl group). Its flexible unbranched Met side chain “bristles” presumably provide the groove with the plasticity to bind a variety of different signal sequences so long as they are hydrophobic and form an  $\alpha$  helix.

Ribosomes, as we shall see in Section 32-3Dk, employ protein **elongation factors** to deliver aminoacyl-tRNAs and to motivate the sequence of reactions that appends an amino acid residue to the growing polypeptide chain. The eukaryotic SRP’s Alu domain, which is required for translational arrest, contacts the ribosome’s intersubunit region at the same positions to which the ribosomal elongation factors bind. This suggests that the Alu domain arrests translation by binding to the ribosome with sufficient affinity to block the binding of the ribosome’s required elongation factors. This is corroborated by the observation that

**Figure 12-49** Cryo-EM structure of a translating wheat germ ribosome in complex with canine SRP at 12 Å resolution.

(a) Surface diagram showing the small (40S) ribosomal subunit in yellow, the large (60S) ribosomal subunit in blue, the SRP in red, and the tRNA occupying the ribosomal P-site (to which the growing polypeptide chain is covalently linked; Fig. 5-28) in green. C1 to C6 indicate the six positions at which the SRP

contacts the ribosome and h1 and h2 indicate the 7S RNA's hinge positions. St and SB stand for stalk and stalk base. (b) As in Part a but rotated 70° about the vertical axis. [Courtesy of Roland Beckmann, Humboldt University of Berlin, Germany.]

bacterial SRP's, which do not arrest translation on binding to a ribosome, lack Alu domains.

### c. Secretory Pathway Initiation Is Driven by GTP Hydrolysis

In eukaryotes, the SRP receptor is a heterodimer of subunits named **SR $\alpha$**  and **SR $\beta$** . SR $\beta$  is a 271-residue integral protein that has an N-terminal TM segment, whereas SR $\alpha$  is a 638-residue peripheral protein that is apparently membrane-bound through the association of its N-terminal segment with SR $\beta$ . Both SR $\alpha$  and SR $\beta$  are GTPases.

In *E. coli*, the SR consists of a single 497-residue subunit named **FtsY**, whose C-terminal portion is homologous to that of SR $\alpha$ , although their N-terminal portions have no

sequence similarity. Curiously, the X-ray structure of the C-terminal portion of FtsY closely resembles that of the N and G domains of SRP54, with which it shares ~34% identity.

The targeting of the SRP-ribosome complex to the ER membrane is mediated by the GTPase functions of SRP54, SR $\alpha$ , and SR $\beta$ . In numerous biological systems, mainly those mediating translation (Section 32-3), vesicle transport (Sections 12-4C and 12-4D), and signal transduction (Section 19-2), GTPases function as molecular switches that endow the system with unidirectionality and specificity. These so-called **G proteins** have at least two stable conformations: GDP-bound and GTP-bound. Interconversion between these states only occurs in a unidirectional cycle due to the irreversibility of GTP hydrolysis. In most cases, a G protein must interact with other proteins in order to change conformational states. Thus, GTP hydrolysis often requires stimulation by a specific **GTPase activating protein (GAP)**, and the exchange of bound GDP for GTP may require the assistance of a specific **guanine nucleotide exchange factor (GEF)**; (Section 19-2Ca). The need for these particular factors confers specificity on the system.

The GEF for the SRP is the complex of the newly emerged signal sequence with the M domain of SRP54, which induces the adjoining G domain to exchange its bound GDP for GTP (Fig. 12-46, Stage 2). The formation of the resulting SRP · GTP complex results in a conformational change that locks the SRP to the ribosome, which, in turn, induces translational arrest. The GEF for the SR appears to be an empty translocon, which thereby associates with the resulting SR · GTP complex to which the SRP · GTP-ribosome complex then binds (Fig. 12-46, Stage 3). Evidently, the SRP and SR, both in their GTP forms, act as “molecular matchmakers” to bring together an empty translocon with a ribosome synthesizing a signal sequence-bearing polypeptide. The SRP and the SR then reciprocally stimulate each other's GTPase functions (act as mutual GAPs; neither protein alone has significant GTPase activity) followed by their dissociation, yielding free SRP · GDP and SR · GDP complexes ready to participate in a new

**Figure 12-50** Molecular model of the SRP. The transparent cryo-EM-based electron density is shown in white and the ribbon diagrams of the X-ray structures of SRP proteins and RNA fragments that have been docked into it are colored as is indicated in Fig. 12-48. The signal sequence, modeled as an  $\alpha$  helix, is green. Note that no atomic resolution structure of the SRP68/72 heterodimer is available. [Courtesy of Roland Beckmann, Humboldt University of Berlin, Germany. PDBid 2G05.]

**Figure 12-51** Cryo-EM structure of the eukaryotic SR-SRP-ribosome complex at 8 Å resolution. The complex is oriented and colored as in Fig. 12-49*b* with the SR colored green. [Courtesy of Roland Beckmann, Humboldt University of Berlin, Germany.]

round of the secretory pathway (Fig. 12-46, Stage 4). The release of the SRP and SR permits the now translocon-associated ribosome to recommence translation, thereby extruding the polypeptide it is synthesizing into or through the ER membrane as described below.

In the structure of the SRP-ribosome complex (Fig. 12-49), the S domain of the SRP blocks the binding of the translocon at the mouth of the peptide exit tunnel. However, the cryo-EM-based structure of the SR-SRP-ribosome complex (but lacking SRβ's TM segment), determined by Irmgard Sinning and Beckmann, reveals that the SR contacts both the large ribosomal subunit and the S domain of the SRP (Fig. 12-51) in a way that pushes the SRP S domain in the SRP-ribosome complex away from the peptide exit site. This allows the translocon access to its ribosomal binding site and presumably positions it such that the M domain-bound signal sequence can readily be transferred to it. The position of the eukaryotic SRP's Alu domain on the ribosome is unaffected by the binding of the SR.

#### d. The Translocon Forms a Transmembrane Pore

How are preproteins transported across or inserted into the RER membrane? In 1975, Blobel postulated that these processes are mediated by a TM channel. However, it was not until 1991 that he was able to show that these channels actually exist through electrophysiological measurements indicating that the RER membrane contains ion-conducting channels. These increase in number when the ribosome-bearing side of the RER is treated with **puromycin** (an antibiotic that causes the ribosome to prematurely release the growing polypeptide; Section 32-3Df), thereby suggesting that the channels are usually plugged by the presence of the polypeptides. By linking fluorescent dyes whose fluorescence is sensitive to the polarity of their environment to a nascent polypeptide, Arthur Johnson demonstrated

that these channels, now called translocons, enclose aqueous pores that completely span the ER membrane.

The various ER transmembrane proteins that comprise the translocon were identified through the use of photoactivatable groups that were attached to signal sequences and mature regions of preproteins. On exposure to light of the proper wavelength, the photoactivatable groups react with nearby proteins to form covalent cross-links, thereby permitting the identification of these proteins. The central component of the translocon, named **Sec61** (Sec for *secretion*) in eukaryotes and the **SecY** complex in prokaryotes, is a heterotrimeric protein. Its α and γ subunits, but not its β subunit, are essential for channel function and are conserved across all kingdoms of life (these subunits are respectively named Sec61α, Sec61β, and Sec61γ in eukaryotes and SecY, SecE, and SecG in bacteria).

The X-ray structure of the SecY complex from the archaeon *Methanococcus jannaschii*, determined by Stephen Harrison and Tom Rapoport, reveals that its α, β, and γ subunits, respectively, have 10, 1, and 1 TM α helices (Fig. 12-52*a,b*). The α subunit's TM helices are wrapped around an hourglass-shaped channel whose minimum diameter is ~3 Å (Fig. 12-52*c*). The channel is blocked at its extracellular end by a short, relatively hydrophilic helix (blue unnumbered helix in Fig. 12-52*a,b* and yellow helix in Fig. 12-52*c*). A variety of evidence indicates that this helix functions as a plug to prevent small molecules and ions from leaking across the membrane in the absence of a translocating polypeptide and that an incoming signal peptide pushes this helix aside. The γ subunit extends diagonally across the back of the α subunit so as to buttress it. The β subunit makes relatively tenuous contacts with the α subunit, which likely explains why the β subunit is dispensable for translocon function.

A cryo-EM-based structure of a mammalian ribosome-Sec61 complex (Fig. 12-53*a*), determined by Rapoport and Christopher Akey at 11 Å resolution, reveals that a single Sec61 channel is positioned over the ribosome's peptide exit tunnel with Sec61's 6/7 and 8/9 loops extending into the peptide exit tunnel (Fig. 12-53*b*). Indeed, mutating the positively charged residues of the 6/7 and 8/9 loops, which presumably bind to negatively charged ribosomal RNA, abolishes ribosome binding.

How wide is the SecY complex's **protein-conducting channel (PCC)** when it is translocating a polypeptide? At minimum, it would have to be ~7 Å across (the diameter of an extended anhydrous polypeptide), although if a TM sequence assumed its helical conformation while still in the PCC, the PCC would have to be at least ~12 Å wide. Such widening could be accomplished by movements of the helices from which the pore ring side chains emanate. The maximum dimensions of the PCC, as estimated from a consideration of the SecY structure (Fig. 12-52), are 15 × 20 Å. Such movements are supported by molecular dynamics calculations (Section 9-4a). Despite the large pore size of an active translocon, the ER membrane's permeability barrier is largely maintained. Evidently, the pore ring fits around the translocating polypeptide chain like a gasket, thereby preventing the passage of small molecules and ions during polypeptide translocation.

**Figure 12-52** X-ray structure of the *M. jannaschii* SecY complex. (a) X-ray structure of the complex, with shading indicating the positions of membrane phospholipid head groups (violet) and hydrocarbon tails (pink). The  $\alpha$  subunit of SecY (436 residues) is colored in rainbow order and its helices are numbered from its N-terminus (dark blue) to its C-terminus (red), the  $\beta$  subunit (74 residues) is magenta, and the  $\gamma$  subunit (53 residues) is purple. (b) View of SecY from the cytosol. The

translocon's putative lateral gate is on the left between helices 2 and 7. (c) Cross-section of the protein-conducting channel as viewed from the bottom of Part b. The helix that plugs the channel is yellow and the six hydrophobic side chains that form the narrowest part of the channel, the so-called pore ring, are green. The ribosome's small (S) and large (L) subunits are yellow and blue, a tRNA occupying the ribosome's exit site (Section 32-3Bd) is red, and the Sec61-TRAP complex is magenta. LD is TRAP's luminal domain. (b) A thin slab showing the interface between the ribosome and Sec61. The modeled structures of the ribosome

and Sec61, shown as ribbons, are embedded in their transparent surface diagrams, which are colored as in Part a. Note how loops 6/7 and 8/9 of Sec61 are inserted into the ribosome's peptide exit tunnel (T), where they interact with RNA helices H7 and H50. L26e is a protein subunit. [Courtesy of Tom Rapoport, Harvard Medical School; and Christopher Akey, Boston University School of Medicine. PDBid 3DKN.]

**Figure 12-54** The stages of polypeptide translocation of a secretory protein. The red line represents the hydrophobic portion of the signal sequence. The process begins with the insertion of the nascent peptide as a loop into the PCC (*left*). The signal sequence then binds as an  $\sim 2$ -turn helix between the SecY/Sec61  $\alpha$  subunit's helices 2 and 7, which helps displace the plug helix (*middle*). Finally, the signal sequence is excised by the signal protease (*not shown*) and the nascent peptide enters the ER through the PCC (*right*). [Courtesy of Tom Rapoport, Harvard Medical School.]

The translocation of a secretory protein begins with its insertion as a loop into the PCC (Fig. 12-54, *left*). This was established by using a mutant protein whose signal sequence is not excised by the signal protease and showing, through proteolysis experiments, that the protein's N- and C-termini both remained on the ER membrane's cytoplasmic side. Subsequently, as was shown by photo-cross-linking experiments, the signal sequence forms an  $\sim 2$ -turn helix that inserts between TM helices 2 and 7 of Sec61 $\alpha$  (Fig. 12-54, *middle*). The separation of helices 2 and 7 (the lateral gate; Fig. 12-52*b*) helps displace the plug helix, which following signal sequence excision, allows the nascent polypeptide pass through the PCC into the ER (Fig. 12-54, *right*).

Additional components of the mammalian translocon are named **translocating chain-associated membrane protein (TRAM)**,  $\sim 375$  residues; predicted to have 8 TM helices with both its N- and C-termini in the cytosol) and **translocon-associated membrane protein (TRAP)**; an  $\sim 800$ -residue heterotetramer with its  $\alpha$ ,  $\beta$ , and  $\delta$  subunits each having one TM helix and its  $\gamma$  subunit having four TM helices). Through the use of Sec61-containing liposomes that either did or did not also contain TRAM, Rapoport demonstrated that TRAM is required for the translocation and membrane integration of most but not all preproteins into the liposome. Whether or not a given preprotein requires TRAM for translocation depends on its signal sequence, although no particular characteristic of this sequence appears to be critical for TRAM dependence. TRAP, which is seen in Fig. 12-53*a*, functions similarly to increase the translocational efficiency of proteins with certain signal sequences.

#### e. The Translocon Laterally Inserts Transmembrane Helices Into the ER Membrane

In addition to forming a conduit for soluble proteins to enter the ER, *the translocon must insert an integral protein's TM segments into the ER membrane*. The translocon, in concert with the ribosome, recognizes these TM segments and installs them into the lipid bilayer via a lateral gate between helices 2 and 7 in the SecY/Sec61  $\alpha$  subunit (Fig. 12-55).

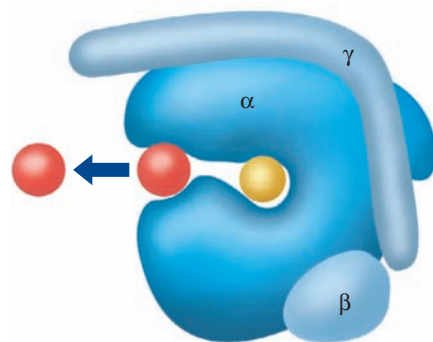

**Monotopic** (alternatively, **single-pass**) TM proteins fall into one of three classes:

**1. Type I proteins** have cleavable N-terminal signal sequences. They are inserted into the membrane much like secretory proteins (Fig. 12-54) but have an  $\sim 22$ -residue hydrophobic **stop-transfer anchor sequence** that the translocon laterally inserts into the membrane as a helix. Hence a type I protein has its N-terminus in the ER.

**2. Type II proteins** lack a cleavable N-terminal signal sequence. However, they have an  $\sim 22$ -residue hydrophobic **signal-anchor sequence**, not necessarily near the protein's N-terminus, that is recognized by the SRP. The SRP then passes the nascent polypeptide to the translocon, which laterally inserts the signal-anchor sequence into the membrane oriented such that the protein's N-terminus is in the cytoplasm. This requires the polypeptide to loop around inside the translocon before being inserted into the membrane (Fig. 12-56, *lower portion*). The C-terminal segment of a type II protein is presumably extruded into the gap between the ribosome and the translocon (Fig. 12-53*a*) before being passed through the translocon.

**3. Type III proteins**, like type II proteins, lack a cleavable N-terminal signal sequence and have a signal-anchor sequence that is not necessarily near the protein's N-terminus. However, the orientation of these signal-anchor sequences in the membrane is opposite to that of type II proteins. Hence the way that type III proteins are inserted into the membrane resembles that of type I proteins (Fig. 12-56, *upper portion*). They differ, however, in that the transfer of a type III protein's N-terminal segment across the membrane cannot be initiated until after its signal-anchor sequence has been synthesized.

For polytopic (alternatively, **multipass** or **type IV**) TM proteins, looping must occur each time an additional helix is to be installed in the membrane. Evidently, the PCC of the

**Figure 12-55** Model for the insertion of a TM helix into a membrane. The translocon (*blue*) is viewed as in Fig. 12-52*b*. A polypeptide chain (*yellow*) is shown bound in the translocon's pore during its translocation through the membrane, and a TM helix (*red*) is shown passing through the translocon's lateral gate and being released into the membrane (*arrow*). [Based on a drawing by Dobberstein, B. and Sinning, I., *Science* **303**, 320 (2004).]

**Figure 12-56** The generation of types II and III proteins.

Here, the red line represents a signal-anchor sequence. The N-terminus of a type III protein must pass through the translocon before its succeeding TM helix is laterally installed in the membrane (*top*). However, for a type II protein, whose N-terminus is retained in the cytoplasm (*bottom*), the subsequently synthesized polypeptide (represented by the loop between the ribosome and the translocon) must pass through the PCC. For polytopic TM proteins, these two processes alternate. [Based on a drawing by Tom Rapoport, Harvard Medical School.]

active translocon has sufficient room for successive TM segments to reverse their direction prior to being inserted into the ER membrane. Helices may be inserted into the membrane either singly or in pairs, depending on their hydrophobicity and their ability to form stable helix–helix interactions.

What controls the orientations of the helices in a TM protein, that is, its **topogenesis**? Most TM proteins, as Gunnar von Heijne pointed out, adopt an orientation such that their cytoplasmically exposed ends, those that are not translocated across the membrane, are more positively charged (have more Arg and Lys residues) than their lumenally exposed ends—the **positive-inside rule**. This appears mainly due to the charge distribution within the translocon, which is oriented with its more positive face on the cytoplasmic side of the membrane (in accordance with the positive-inside rule). In fact, mutating certain charged residues of Sec61 $\alpha$  so as to reverse their charge (e.g., changing an Arg to Glu), inverts the orientation of the TM helices it installs in the membrane. Another important influence on the orientation of a TM helix is its hydrophobicity gradient: The more hydrophobic end of a TM helix is preferentially translocated across the membrane.

Despite the foregoing, one might reasonably expect that the membrane orientation of the N-terminal TM helix of a polytopic TM protein dictates the orientations of the succeeding TM helices (many, if not all, of which have yet to be synthesized at the time the N-terminal helix is inserted into the membrane). However, the deletion or insertion of a TM helix from/into a polypeptide does not necessarily change the membrane orientations of the succeeding TM helices: When two successive TM helices have the same preferred orientation, one of them may be forced out of the membrane. Moreover, the topological organization of TM proteins is influenced by the membrane lipid composition.

This suggests that the translocon's lateral gate frequently opens and closes so as to allow its transiting peptide to sample the outside lipid environment and only inserts a peptide segment into the lipid bilayer if it is thermodynamically favorable to do so; that is, helix insertion may be considered as a partitioning between the aqueous environment in the translocon and that of the membrane.

Polytopic TM proteins can fold to their native conformations only after all their TM helices have been inserted into the membrane. This process is guided by packing interactions between helices as well as specific interactions with membrane lipids. Thus, although a TM protein's sequence determines its topology, it does so for a specific membrane lipid environment. Evidently, the lipid composition of a membrane and the topologies of its embedded TM proteins have coevolved.

#### f. Protein Folding in the ER Is Monitored by Molecular Chaperones

The ER, as does the cytosol, contains a battery of molecular chaperones that assist in protein folding and act as agents of quality control. The best characterized of these is the Hsp70 homolog (Section 9-2C) **BiP** (for *binding protein*). BiP associates with many secretory and TM proteins although, if folding proceeds normally, these interactions are weak and short-lived. However, proteins that are improperly folded, incorrectly glycosylated, or improperly assembled form stable complexes with BiP that are often exported, via a poorly understood process involving the translocon called **retrotranslocation**, to the cytosol where they are proteolytically degraded (Section 32-6). The entire process is named **ERAD** (for *ER-associated degradation*). Two other notable ER-resident chaperones are **calreticulin** and **calnexin**, homologous proteins that participate in facilitating and monitoring the folding and assembly of glycoproteins (Section 23-3Bf). The ER also contains protein disulfide isomerases (PDIs; Section 9-2A) and peptidyl prolyl cis–trans isomerases (PPIs; Section 9-2B).

Abnormalities of protein folding and assembly are important mechanisms of disease (e.g., Section 9-5). For instance, **cystic fibrosis** is the most common life-threatening recessive genetic disease in the Caucasian population (affecting one in ~2000 individuals). It occurs in homozygotes for a defective **cystic fibrosis transmembrane regulator (CFTR) protein**, a 1480-residue glycoprotein with 12 TM helices that functions as a Cl<sup>-</sup> transporter in the plasma membrane of epithelial cells. Individuals with cystic fibrosis produce highly viscous mucus that, in its most damaging effects, blocks the small airways in the lungs. This leads to persistent infections, which cause severe progressive lung degeneration that is usually fatal by around age 30. Although cystic fibrosis is caused by any of more than 1000 known mutations in the CFTR gene, 70% of the cases arise from the deletion of Phe 508 ( $\Delta$ F508), which is located in a cytoplasmic domain of the CFTR protein (which is initially inserted into the ER membrane). Although this mutant domain in  $\Delta$ F508 folds to nearly its native conformation ( $\Delta$ F508 retains almost full biological activity), it does so much more slowly than in the wild-type protein. This results in its retrotranslocation

and degradation by an, in this case, overly zealous proteolytic surveillance system (Section 32-6B).

### g. Some Proteins Are Post-Translationally Transported through Membranes

The secretory proteins we discussed pass through the membrane as they are being synthesized by the ribosome, that is, their membrane translocation occurs cotranslationally. However, some secretory proteins are translocated only after they have been fully synthesized in the cytoplasm, that is, post-translationally. Nevertheless, both co- and post-translational translocation is mediated by the translocon. Yet, the translocon is a passive pore, that is, it does not provide the free energy that drives translocation. In cotranslational translocation, it is the ribosomally mediated extension of the polypeptide that pushes it through the translocon.

In eukaryotes, post-translationally translocated secretory proteins have signal sequences that are only moderately hydrophobic; they are not recognized by the SRP but still bind to Sec61. These proteins are bound by cytoplasmic chaperones, which keep them in a loosely folded or unfolded state that permits them to pass through the translocon. Their translocation is driven by a so-called **Brownian ratchet** mechanism that is mediated by the partnering of Sec61 with the tetrameric TM complex **Sec62/Sec63** and the luminal Hsp70-like chaperone BiP (Fig. 12-57). The polypeptide in the translocon randomly slides back and forth via Brownian motion. However, in the ER, the so-called J-domain (a homolog of the *E. coli* cochaperone DnaJ; Section 9-2C) on the luminal surface of Sec63 induces BiP to hydrolyze its bound ATP to ADP. The resulting BiP-ADP complex then binds the polypeptide emerging from the translocon, which prevents it from sliding back toward the cytoplasm. When the peptide again slides forward, another BiP-ADP complex binds to it, etc., until the entire polypeptide has entered the ER. BiP eventually exchanges

**Figure 12-57** Scheme for post-translational translocation in eukaryotes. As the translocating polypeptide enters the ER through Sec61, the BiP-ATP complex binds to Sec63, whose J-domain induces BiP to hydrolyze its bound ATP to ADP. The resulting BiP-ADP complex binds to the emerging peptide so as to prevent its backsliding. As additional peptide segments emerge from Sec61, the process repeats until the entire protein has entered the ER. BiP eventually exchanges its bound ADP for ATP causing it to release the peptide, which then folds to its native conformation. [Courtesy of Tom Rapoport, Harvard Medical School.]

its ADP for ATP, which causes it to release the polypeptide, which then folds to its native conformation.

In bacteria, the motor that drives post-translational translocation is **SecA**, which binds to the cytoplasmic face of the SecY complex and pushes the polypeptide through the translocon via repeated cycles of ATP hydrolysis. SecA is aided in doing so by the cytosolic chaperone **SecB**, which prevents the polypeptide from folding in the cytoplasm.

### C. Vesicle Formation

Shortly after their polypeptide synthesis is completed, the partially processed transmembrane, secretory, and lysosomal proteins appear in the Golgi apparatus (Fig. 1-5), a 0.5- to 1.0- $\mu\text{m}$ -diameter organelle consisting of a stack of 3 to 6 or more (depending on the species) flattened and functionally distinct membranous sacs known as **cisternae**, where further post-translational processing, mainly glycosylation, occurs (Section 23-3Bg). The Golgi stack (Fig. 12-58) has two distinct faces, each comprised of a network of interconnected membranous tubules: the **cis Golgi network (CGN)**, which is opposite the ER and is the port through which proteins enter the Golgi apparatus; and the **trans Golgi network (TGN)**, through which processed proteins exit to their final destinations. The intervening Golgi stack contains at least three different types of sacs, the **cis**, **medial**, and **trans cisternae**, each of which contains different sets of glycoprotein processing enzymes.

Proteins transit from one end of the Golgi stack to the other while being modified in a stepwise manner, a process that is described in Section 23-3Bg. These proteins are transported via two mechanisms:

1. They are conveyed between successive Golgi compartments in the cis to trans direction as cargo within membranous vesicles that bud off of one compartment and fuse with a successive compartment, a process known as forward or **anterograde transport**.

2. They are carried as passengers in Golgi compartments that transit the Golgi stack, that is, the cis cisternae eventually become trans cisternae, a process called **cisternal progression** or **maturation**. This process is mediated through the backward or **retrograde transport** of Golgi-resident proteins from one compartment to the preceding one via membranous vesicles.

The cisternal progression mechanism has been clearly shown to occur but the significance of the anterograde transport mechanism is as yet unclear. In any case, on reaching the trans Golgi network, the now mature proteins are sorted and sent to their final cellular destinations.

#### a. Membrane, Secretory, and Lysosomal Proteins Are Transported in Coated Vesicles

The vehicles in which proteins are transported between the RER, the Golgi apparatus, and their final destinations, as well as between the different compartments of the Golgi apparatus, are known as **coated vesicles** (Fig. 12-59). This is because these 60- to 150-nm-diameter

**Figure 12-58 Post-translational processing of proteins.** Proteins destined for secretion, insertion into the plasma membrane, or transport to lysosomes are synthesized by RER-associated ribosomes (*blue dots; top*). As they are synthesized, the proteins (*red dots*) are either translocated into the lumen of the ER or inserted into its membrane. After initial processing in the ER, the proteins are encapsulated in vesicles that bud off from the ER membrane and subsequently fuse with the cis Golgi network. The proteins are progressively processed in the cis, medial, and trans cisternae of the Golgi. Finally, in the trans Golgi network (*bottom*), the completed glycoproteins are sorted for delivery to their final destinations, the plasma membrane, **secretory vesicles**, or lysosomes, to which they are transported by yet other vesicles.

**Figure 12-59 Electron micrographs of coated vesicles.** (a) Clathrin-coated vesicles. Note their polyhedral character. membranous sacs are initially encased on their outer (cytosolic) faces by specific proteins that act as flexible scaffolding in promoting vesicle formation. A vesicle buds off from its membrane of origin and later fuses to its target membrane. *This process preserves the orientation of the transmembrane protein* (Fig. 12-60), so that the lumens of

**Figure 12-60** The fusion of a vesicle with the plasma membrane preserves the orientation of the integral proteins embedded in the vesicle bilayer. The inside of the vesicle and the exterior of the cell are topologically equivalent because the same side of the protein is always immersed in the cytosol. Note that any soluble proteins contained within the vesicle would be secreted. In fact, proteins destined for secretion are packaged in membranous secretory vesicles that subsequently fuse with the plasma membrane as shown.

the ER and the Golgi cisternae are topologically equivalent to the outside of the cell. This explains why the carbohydrate moieties of TM glycoproteins and the GPI anchors of GPI-linked proteins occur only on the external surfaces of plasma membranes.

The three best characterized types of coated vesicles are distinguished by their protein coats:

**1. Clathrin** (Fig. 12-59a), a protein that forms a polyhedral framework around vesicles that transport TM, GPI-linked, and secreted proteins from the Golgi to the plasma membrane. The clathrin cages, which were first characterized by Barbara Pearse, can be dissociated to flexible three-legged proteins known as **triskelions** (Fig. 12-61) that consist of three so-called heavy chains (**HC**, 1675 residues) that each bind one of two homologous light chains, **LCa** or **LCb** (~240 residues), at random.

**2. COPI** protein (Fig. 12-59b; COP for *coat protein*), which forms what appears to be a fuzzy rather than a polyhedral coating about vesicles that carry out both the anterograde and retrograde transport of proteins between successive Golgi compartments. In addition, COPI-coated vesicles return escaped ER-resident proteins from the Golgi to the ER (see below). COPI consists of seven different subunits ( $\alpha$ , 160 kD;  $\beta$ , 110 kD;  $\beta'$ , 102 kD;  $\gamma$ , 98 kD;  $\delta$ , 61 kD;  $\epsilon$ , 31 kD; and  $\zeta$ , 20 kD). The soluble complex comprising the COPI protomer is named **coatomer**.

**3. COPII** protein (Fig. 12-59c), which transports proteins from the ER to the Golgi. The COPII vesicle components are then recycled by COPI-coated vesicles for participation in another round of vesicle formation (the COPI vesicle components entering the ER are presumably recycled by COPII-coated vesicles). The COPII coat consists of the GTPase **Sar1**, the heterodimer **Sec23/24** in which Sec23 is a Sar1-specific GAP and Sec24 functions in cargo selection,

**Figure 12-61** Electron micrograph of triskelions. The variable orientations of their legs are indicative of their flexibility. [Courtesy of Daniel Branton, Harvard University.]

and the heterodimer **Sec13/31**, which forms polyhedral cages (see below).

All of the above coated vesicles also carry receptors, which bind the proteins being transported, as well as **fusion proteins**, which mediate the fusion of these vesicles with their target membranes. We discuss these processes below and in Section 12-4D.

### b. Clathrin Cages Are Formed by Overlapping Heavy Chains

Clathrin-coated vesicles (CCVs) are structurally and functionally better characterized than those coated with COPI or COPII. Clathrin forms polyhedral cages in which, as a cryo-EM study by Harrison, Tomas Kirchhausen, and Thomas Walz has shown most clearly (Fig. 12-62a), each vertex is the center (hub) of a triskelion, and its edges,

which are  $\sim 225$  Å long, are each formed by the interdigitated legs of four triskelions—two antiparallel proximal segments and two distal segments (Fig. 12-62b). Such polyhedra (Fig. 12-62c), which have 12 pentagonal faces and a variable number of hexagonal faces (for geometric reasons explained in Section 33-2A), are the most parsimonious way of enclosing spheroidal objects in polyhedral cages. The volume enclosed by a clathrin polyhedron, of course, increases with its number of hexagonal faces (a “minicoat” is too small to contain a transport vesicle).

The triskelion’s  $\sim 475$ -Å-long legs are each formed by the 1675-residue heavy chains (HCs), which trimerize via their C-terminal domains (Fig. 12-62b). In addition to projecting outward from its hub (vertex), each leg curls toward the center of the particle such that three ankles meet and interact  $\sim 75$  Å below a hub that is two vertices away from each of their hubs.

(a)

**Figure 12-62 Anatomy of clathrin-coated vesicles.** (a) A cryo-EM-based image of a light chain-free clathrin cage from bovine brain at 7.9 Å resolution. The particle shown, a so-called hexagonal barrel, which has  $D_6$  symmetry, consists of 36 triskelions. Three of its interdigitated but symmetry-unrelated triskelions are drawn in red, yellow, and green. (b) A cryo-EM-based image of a triskelion labeled with the names of its various segments. The N-terminus of each heavy chain occupies the terminal domain and its C-terminus is located in the vertex joining the three heavy chains to form the triskelion. (c) Diagrams of the three polyhedral structures that are formed when triskelions assemble into clathrin cages *in vitro*. The minicoat

(b)

(c)

has tetrahedral ( $T$ ) symmetry, the hexagonal barrel has  $D_6$  symmetry, and the soccer ball has icosahedral ( $I$ ) symmetry (symmetry is discussed in Section 8-5B). These polyhedra consist of 28, 36, and 60 triskelions, respectively. The arrangement of one triskelion within the hexagonal barrel is indicated in blue. *In vivo*, clathrin forms membrane-enclosing polyhedral cages with a large range of different sizes (number of hexagons). The hexagonal barrel seen in Part a is only  $\sim 700$  Å in diameter, whereas clathrin-coated membranous vesicles are typically  $\sim 1200$  Å in diameter or larger. [Courtesy of Stephen Harrison, Tomas Kirchhausen, and Thomas Walz, Harvard Medical School.]

**Figure 12-63** Structure of the clathrin heavy chain. (a) The X-ray structure of the N-terminal domain and part of the linker of rat HC. The N-terminal domain forms a seven-bladed  $\beta$  propeller (yellow) that is seen here in side view, and the linker (red) forms an  $\alpha$  solenoid. (b) The  $\beta$  propeller as viewed from the top along its pseudo-7-fold axis. [Parts *a* and *b* courtesy of Tomas Kirchhausen, Harvard Medical School. PDBid 1BPO.] (c) The X-ray structure of bovine clathrin HC residues 1210 to 1516 as viewed with its N-terminus on the left. The helices are alternately colored yellow and green with the exception of the three N-terminal helices, which are colored gray to indicate that they are poorly resolved. The orange, green, and blue bars denote the regions of CHCR5, CHCR6, and CHCR7, respectively. [Courtesy of Peter Hwang, University of California at San Francisco. PDBid 1B89.] (d) A backbone model of a triskelion (residues 1–1597) generated by docking the foregoing X-ray structures together with homology models of the remaining CHCRs into the cryo-EM-determined electron density of a heavy chain (Fig. 12-62a). [Courtesy of Stephen Harrison, Tomas Kirchhausen, and Thomas Walz, Harvard Medical School. PDBid 1XI4.]

Although the X-ray structure of an entire HC has not been determined, those of its N-terminal portion and a part of its proximal segment have been elucidated:

1. The N-terminal segment (residues 1–494; Fig. 12-63*a,b*), whose structure was determined by Harrison and Kirchhausen, consists of two domains: (i) an N-terminal seven-bladed  **$\beta$  propeller** in which each structurally similar propeller blade is formed by a four-stranded antiparallel  $\beta$  sheet (Fig. 12-63*b*; the terminal domain) named the **WD40** sequence motif because it often contains the dipeptide WD and is  $\sim 40$  residues long; and (ii) a C-terminal linker that consists of 10  $\alpha$  helices of variable lengths (2–4 turns) connected by short loops and arranged in an irregular right-handed helix (a helix of helices, that is, a **superhelix**) named an  **$\alpha$  solenoid** (alternatively, an  **$\alpha$ -zigzag**).

2. The proximal segment (residues 1210–1516; Fig. 12-63*c*), whose structure was determined by Peter Hwang and Robert Fletterick, consists of 24 linked  $\alpha$  helices that are arranged similarly but more regularly than the above  $\alpha$  solenoid to form a rod-shaped right-handed superhelix. The rigidity of this motif is attributed to its continuous hydrophobic core together with the efficient interdigitation of its side chains where its crossing antiparallel  $\alpha$  helices come into contact (Section 8-3B).

Sequence and structural alignments indicate that HC residues 537 to 1566 consist of seven homologous  $\sim 145$ -residue **clathrin heavy chain repeats (CHCRs)** that are arranged in tandem and which each contain 10 helices (the proximal segment consists of all of CHRC6 together with the C- and N-terminal portions of CHRC5 and CHRC7; Fig. 12-63*c*). This has permitted the generation of a backbone model of a triskelion by docking the foregoing X-ray structures and homology models of the CHCRs whose structures have not been experimentally determined in the cryo-EM-determined electron density (Fig. 12-63*d*; homology modeling is discussed in Section 9-3B). Each HC leg consists of an extended superhelix of linked  $\alpha$  helices. Nevertheless, triskelion legs exhibit considerable flexibility (Fig. 12-61), a functional necessity for the formation of different sized vesicles as well as for the budding of a vesicle from a membrane surface, which is accompanied by a change in its curvature. The HC appears to flex mainly along its knee and ankle segments (Fig. 12-62*b*).

The proximal segment bears extensive hydrophobic surface patches that follow the grooves between adjacent helices. Apparently, the lengthwise association of two proximal segments in a clathrin cage (Fig. 12-62*a*) is stabilized by the burial of these hydrophobic patches through the complementary packing of the helices of one proximal leg in the grooves on another.

Light chains (LCs) are not required for clathrin cage assembly. Indeed, LCs inhibit heavy chain polymerization *in vitro*, which suggests that they have a regulatory role in preventing inappropriate clathrin cage assembly in the

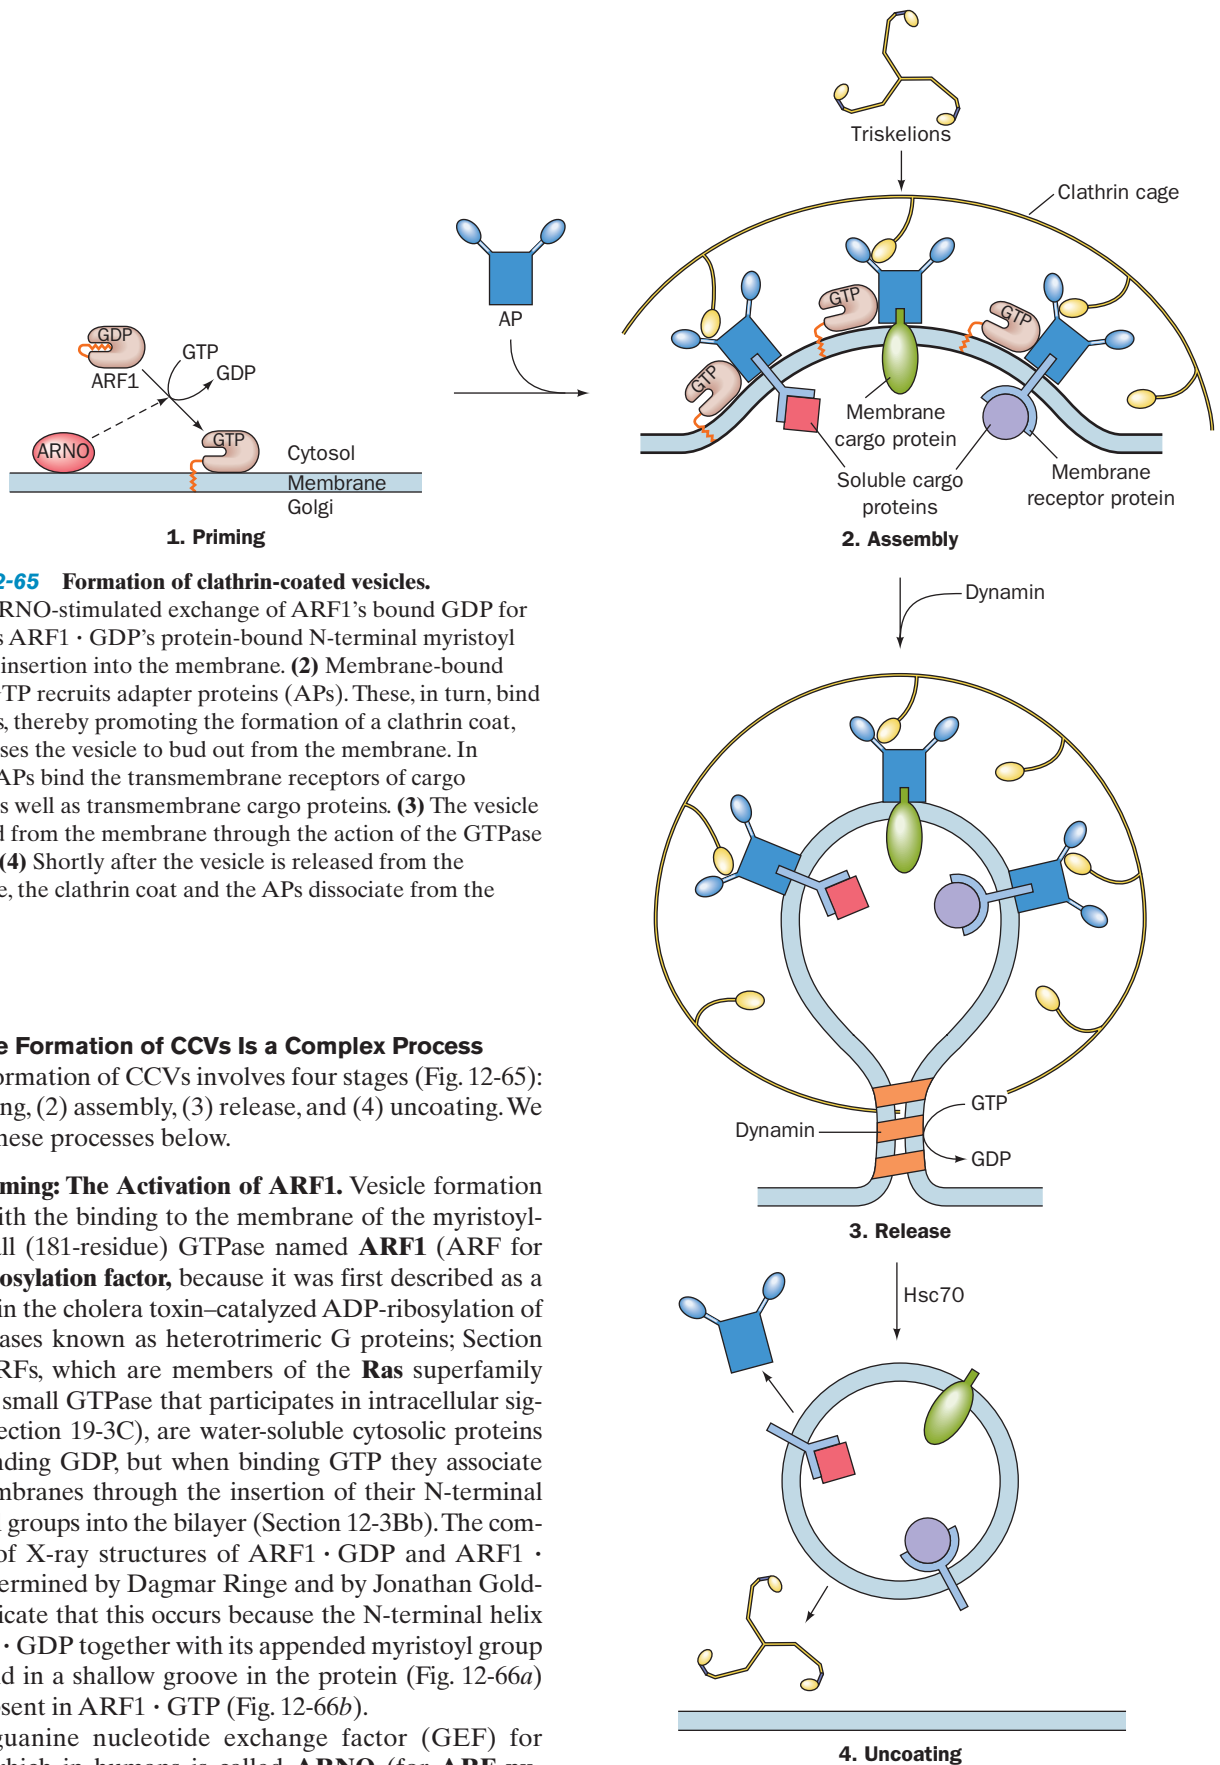

**Figure 12-64** Arrangement of light chains on a clathrin cage. The differences between the cryo-EM-determined electron densities of a hexagonal barrel with and without light chains are shown in yellow with the light chain-free electron density shown in blue. [Courtesy of Stephen Harrison, Tomas Kirchhausen, and Thomas Walz, Harvard Medical School.]

cytosol. Comparison of the cryo-EM structures of intact and LC-free hexagonal barrels reveals that the central portion of an LC consists of a 71-residue helix that binds to a surface formed by the interhelical loops along the HC proximal segment with the C-terminus of the LC closest to the triskelion hub (Fig. 12-64). The segments of the 60% identical LCa and LCb that differ in sequence are largely confined to their N- and C-terminal regions, which do not participate in HC binding and hence are likely to contain sites for the attachment of cytosolic factors that regulate vesicle uncoating.

### c. Clathrin-Coated Vesicles Also Participate in Endocytosis

CCVs, as we have seen, transport TM and secretory proteins from the trans Golgi network (TGN) to the plasma membrane (Fig. 12-58). In addition, through a process known as **endocytosis** (discussed in Section 12-5Bc), they act to engulf specific proteins from the extracellular medium by the invagination of a portion of the plasma membrane and to transport them to intracellular destinations.

**Figure 12-65** Formation of clathrin-coated vesicles.

(1) The ARNO-stimulated exchange of ARF1's bound GDP for GTP frees ARF1 · GDP's protein-bound N-terminal myristoyl group for insertion into the membrane. (2) Membrane-bound ARF1 · GTP recruits adapter proteins (APs). These, in turn, bind triskelions, thereby promoting the formation of a clathrin coat, which causes the vesicle to bud out from the membrane. In addition, APs bind the transmembrane receptors of cargo proteins as well as transmembrane cargo proteins. (3) The vesicle is released from the membrane through the action of the GTPase dynamin. (4) Shortly after the vesicle is released from the membrane, the clathrin coat and the APs dissociate from the vesicle.

#### d. The Formation of CCVs Is a Complex Process

The formation of CCVs involves four stages (Fig. 12-65): (1) priming, (2) assembly, (3) release, and (4) uncoating. We outline these processes below.

**1. Priming: The Activation of ARF1.** Vesicle formation begins with the binding to the membrane of the myristoylated small (181-residue) GTPase named **ARF1** (ARF for **ADP-ribosylation factor**, because it was first described as a cofactor in the cholera toxin-catalyzed ADP-ribosylation of the GTPases known as heterotrimeric G proteins; Section 19-2). ARFs, which are members of the **Ras** superfamily (Ras is a small GTPase that participates in intracellular signaling; Section 19-3C), are water-soluble cytosolic proteins when binding GDP, but when binding GTP they associate with membranes through the insertion of their N-terminal myristoyl groups into the bilayer (Section 12-3Bb). The comparison of X-ray structures of ARF1 · GDP and ARF1 · GTP, determined by Dagmar Ringe and by Jonathan Goldberg, indicate that this occurs because the N-terminal helix of ARF1 · GDP together with its appended myristoyl group are bound in a shallow groove in the protein (Fig. 12-66a) that is absent in ARF1 · GTP (Fig. 12-66b).

The guanine nucleotide exchange factor (GEF) for ARF1, which in humans is called **ARNO** (for **ARF nucleotide-binding site opener**; 399 residues), contains an

(a)

**Figure 12-66** X-ray structures of (a) ARF1 · GDP and (b) ARF1 · GMPPNP. (GMPPNP is a nonhydrolyzable GTP analog in which the O atom linking GTP's β- and γ-phosphorus atoms is replaced by an NH group.) The bound nucleotides are drawn in stick form in white with their phosphorus atoms magenta and their bound Mg<sup>2+</sup> ions shown as lavender spheres. In ARF1 · GDP, the protein's N-terminal helix (red) together with its covalently linked myristoyl group (not present in the X-ray structures) are bound in a shallow hydrophobic groove on the surface of the protein formed in part by the residues of loop λ3.

(b)

However, the replacement of GDP by GMPPNP (and presumably GTP) induces a conformational change in residues 37 to 53 (yellow) that displaces strand β2 by two residues along strand β3, a shift of 7 Å. The resulting movement of loop λ3 eliminates the binding site for the N-terminus, thereby making the myristoyl group available for membrane insertion (residues 1–17 of the GMPPNP complex are disordered). [Courtesy of Jonathan Goldberg, Memorial Sloan-Kettering Cancer Center, New York. The X-ray structure of ARF1 · GDP was determined by Dagmar Ringe, Brandeis University. PDBid 1HUR.]

~200-residue domain similar to the highly conserved yeast protein **Sec7**. When ARNO or its isolated Sec7 domain is incubated with myristoylated ARF1 · GDP, it fails to catalyze nucleotide exchange unless lipid micelles are also present, thereby suggesting that ARNO is activated only when localized to a membrane surface. Indeed, ARNO contains a **pleckstrin homology (PH) domain**, an ~100-residue module occurring in numerous proteins (Section 19-3Ce) that binds the minor membrane phospholipid **phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub>)**,

**Phosphatidylinositol-4,5-bisphosphate (PIP<sub>2</sub>)**

which is also a precursor of compounds that participate in intracellular signaling (Section 19-4A).

**2. Assembly: Adaptor Proteins Link Cargo Proteins to the Clathrin Coat.** Membrane-bound ARF1 · GTP acts to recruit **adaptor proteins (APs)** to the membrane surface. APs bind clathrin HC together with TM proteins that are either receptors that selectively bind soluble cargo proteins inside the budding vesicle or are cargo proteins themselves. APs comprise the central cores of CCVs and, in fact, are the scaffolding on which clathrin cages form. The APs bind clathrin via its N-terminal β propeller domain (Fig. 12-63a), which forms the knobs that project inward from clathrin cages (Fig. 12-62a). The grooves between the propeller blades on the top face of the β propeller (Fig. 12-63b) probably form the AP binding sites.

**AP1** is the most common AP contained in the coated vesicles originating from the TGN, whereas the homologous **AP2** predominates in endocytotic vesicles. Both APs are heterotetramers: AP1 consists of the subunits γ, β1 (~110 kD each), μ1 (~50 kD), and σ1 (~17 kD), whereas the corresponding subunits of the better characterized AP2 are named α, β2, μ2, and σ2 (Fig. 12-67). Electron microscopy and X-ray studies indicate that the large subunits each consist of a trunk and an appendage domain joined by

**Figure 12-67 Schematic diagram of the AP2 heterotetramer.** AP1 has a similar structure. [After Pearse, B.M., Smith, C.J., and Owen, D.J., *Curr. Opin. Struct. Biol.* **10**, 223 (2000).]

a flexible and proteolytically sensitive hinge region (Fig. 12-67). The AP2 hinge region of  $\beta 2$  binds to the clathrin  $\beta$  propeller, whereas the cytoplasmic domains of target proteins bind most commonly to  $\mu 2$  via YXX $\phi$  sequences (where  $\phi$  is a bulky hydrophobic residue), but in some cases to its  $\alpha$  and  $\sigma 2$  subunits via [D/E]XXXL[L/I] sequences, which are known as **dileucine motifs**. This explains why the proteolytic excision of AP2's appendage domain prevents the assembly of clathrin coats, although the remaining AP2 trunk can still bind to membranes that contain proteins bearing a YXX $\phi$  internalization signal. In addition, both AP1 and AP2 bind PIP<sub>2</sub> and mutating their PIP<sub>2</sub>-binding sites prevents them from localizing to their target membranes.

Mammals have two additional heterotetrameric APs, **AP3** and **AP4**, both of which function in the TGN. Moreover, database searches for AP homologs have identified a family of monomeric clathrin adapters named **GGAs** (for Golgi-localized  $\gamma$ -ear-containing ARF-binding proteins), whose C-terminal domain is homologous to the appendage or "ear" domain of AP1's  $\gamma$  subunit (and AP2's  $\alpha$  subunit; Fig. 12-67). These various adapter proteins participate in the transport of their target proteins between different pairs of membranes so that CCVs are multifunctional entities.

### 3. Release: Vesicle Scission Is Mediated by Dynamin.

The budding of a CCV from its parent membrane appears to be mechanically driven by the formation of the clathrin cage. However, the actual scission of the coated bud from its parent membrane to form a coated vesicle requires the participation of **dynamin**, an ~870-residue GTPase. Dynamin contains a PIP<sub>2</sub>-binding PH domain, which recruits dynamin to the membrane. On binding GTP, dynamin forms a helical oligomer that wraps about the base of the budding vesicle so as to squeeze this region down to a thin tube (Fig. 12-68). The oligomerization together with the presence of PIP<sub>2</sub> stimulates dynamin to hydrolyze its bound GTP (dynamin also contains a GAP domain), causing the helical oligomer to lengthen its pitch. However, the

**Figure 12-68 Electron micrograph of a budding coated vesicle.** The vesicle was incubated with the nonhydrolyzable GTP analog **GTP $\gamma$ S** (in which a terminal O atom on the  $\gamma$ -phosphorus of GTP is replaced by S) and then treated with gold-tagged anti-dynamin antibodies (*black dots*). Note that the dynamin surrounds a long narrow tube at the base of the budding vesicle that has not pinched off from the membrane. [Courtesy of Pietro De Camilli, Yale University School of Medicine.]

way in which this process releases the vesicle from the membrane is not well understood.

### 4. Uncoating: The Recycling of Clathrin and Adapter Proteins.

Shortly after the formation of a CCV, the clathrin is released as triskelions, thereby recycling them for participation in the formation of additional coated vesicles. This process is mediated by the ATPase **Hsc70** (Hsc for *heat shock cognate*), an ~650-residue homolog of the chaperone Hsp70 (Section 9-2C) present in all eukaryotic cells, which on ATP hydrolysis forms a complex with clathrin. Hsc70 is recruited to the appropriate sites on the clathrin lattice by the ~910-residue cochaperone **auxilin**, which binds to specific sites on the clathrin heavy chains. Auxilin contains a J-domain that induces Hsc70 to hydrolyze its bound ATP to ADP, thereby causing Hsc70 to bind to and dismantle the clathrin lattice. The cryo-EM structure of the clathrin "hexagonal barrel" in complex with Hsc70 and a J-domain-containing fragment of auxilin at 28 Å resolution, determined by Alasdair Steven, indicates that Hsc70 is located within diffuse rings inside the clathrin cage's pentagonal and hexagonal rings (Fig. 12-69). This suggests that triskelions are pried out of the clathrin lattice by the concerted action of up to six Hsc70 molecules. This may occur by a simple clockwise rotation of a triskelion as viewed in Fig. 12-62a. On the subsequent exchange of its bound ADP for ATP, the Hsc70 releases its bound triskelions.

Following clathrin release from newly formed vesicles, the APs are also released. This process may be initiated by the hydrolysis of ARF1's bound GTP to GDP, which would release ARF1 from the membrane and, presumably, from binding an AP. In any case, the coating and uncoating of vesicles by clathrin must be closely regulated processes since both occur simultaneously.

**Figure 12-69** Cryo-EM-based image of a clathrin hexagonal barrel in complex with Hsc70 and a J-domain-containing fragment of auxilin at 28 Å resolution. The clathrin cage is gold and electron density attributable to the Hsc70 is blue. The white arrow indicates the position at which the Hsc70 most closely approaches the clathrin lattice. [Courtesy of Alasdair Steven, NIH, Bethesda, Maryland.]

A variety of regulatory and accessory proteins of largely unknown function have also been implicated in CCV formation. Moreover, many of the proteins described above are each present in several isoforms. Hence it is clear that our understanding of this process is far from complete.

**e. The Assembly of COPI- and COPII-Coated Vesicles Resembles That of Clathrin-Coated Vesicles**

COPI- and COPII-coated vesicles are both assembled in processes, elucidated in large part by Randy Schekman, that resemble CCV assembly:

**1. Priming:** COPI-coated vesicles are primed identically to CCVs: ARF1 is recruited to the membrane by the ARNO-promoted exchange of its bound GDP for GTP (Fig. 12-65, Step 1). COPII-coated vesicle assembly is similarly primed but by different proteins: **Sar1** (for secretion-associated and Ras-related protein-1) is the small ARF family GTPase that carries out this process, and the exchange of its GDP for GTP is mediated by the transmembrane GEF **Sec12**.

**2. Assembly:** ARF1 · GTP stoichiometrically recruits intact coatamers to form COPI-coated vesicles. Most of the seven COPI coatamer subunits have homologs in the clathrin system and function accordingly: The  $\beta$ -,  $\gamma$ -,  $\delta$ -, and  $\zeta$ -COPs correspond to the  $\beta$ 2,  $\alpha$ ,  $\mu$ 2, and  $\sigma$ 2 subunits of AP2, respectively (Fig. 12-67), and the  $\alpha$ - and  $\epsilon$ -COPs correspond to the clathrin heavy and light chains. In COPII coat formation, Sar1 · GTP recruits the TM complex **Sec23/24**, which in turn recruits cargo proteins and **Sec13/31**, which forms the budding vesicle's polyhedral outer shell (see below).

**3. Release:** Both COPI- and COPII-coated vesicles spontaneously bud off from their parent membranes; these processes appear to have no requirement for an analog of dynamin as does CCV release.

**4. Uncoating:** As is the case for CCVs, COPI- and COPII-coated vesicles uncoat shortly after being released from their parent membranes. These processes appear to be initiated by the hydrolysis of the GTPs bound to ARF1 and Sar1, which thereby weaken the attachment of COPI and COPII to their respective vesicles. The GTPase activating protein (GAP) for COPI vesicles, a 415-residue protein named **ARF GAP**, appears to be a component of the COPI coat. In COPII vesicles, Sec23 is the GAP for Sar1.

**f. The Components of COPII and Clathrin Cages Are Structurally Similar but Functionally Different**

Cryo-EM studies of the COPII component Sec13/31 by Bridget Carragher and William Balch reveal that, *in vitro*, this heterodimer forms a 600-Å-diameter cuboctahedral cage (Fig. 12-70). A cuboctahedron has *O* symmetry (the symmetry of a cube; Section 8-5B) and has 24 edges of equal length; 12 vertices, each of which is formed by the

**Figure 12-70** Cryo-EM structure of the human Sec13/31 COPII cage at 30 Å resolution. The views are along the cuboctahedral cage's 2-fold axis (left), its 3-fold axis (middle), and its 4-fold axis (right). The surfaces of the cage elements are

colored according to their distance from the center of the cage with blue nearest and yellow farthest. The scale bar is 500 Å long. [Courtesy of Bridget Carragher and William Balch, The Scripps Research Institute, La Jolla, California.]

interaction of four edges (in contrast to clathrin cages whose vertices are each formed by the intersection of three edges; Fig. 12-62c); and 14 faces, of which 8 are equilateral triangles and 6 are squares. *In vivo*, COPII vesicles are often larger than 600 Å in diameter. However, several larger polyhedra are known whose vertices are each formed by the intersection of four equal-length edges.

Although the full-length Sec13/31 complex has not been crystallized, its limited proteolysis led to two X-ray structures determined by Jonathan Goldberg:

1. That of the 297-residue Sec13 in complex with residues 1 to 411 of the 1297-residue Sec31 (Fig. 12-71a). Sec13 forms six blades of a  $\beta$  propeller and the Sec31 fragment forms a seven-bladed  $\beta$  propeller with its C-terminal segment contributing a seventh blade to the Sec13  $\beta$  propeller. Each blade of these propellers consists of a WD40 repeat as do the blades of the clathrin  $\beta$  propeller.

2. That of the Sec13/31 edge element (Fig. 12-71b), which is a 2-fold symmetric heterotetramer that contains the full length Sec13 in complex with residues 370–763 of Sec31. As in the previous structure, Sec13 forms six blades of a  $\beta$  propeller with a seventh blade contributed by the here N-terminal segment of the Sec31 fragment. The remainder of the Sec31 fragment consists of an  $\alpha$  solenoid with its N-terminal end folded back over itself and its C-terminal end overlapping the C-terminal end of another Sec31 fragment to form an interlocked dimer. Thus, the central portion of the complex consists of a double layer of  $\alpha$  solenoids.

Since the same segment of Sec31 passes through Sec13 in both complexes and their Sec13 subunits are superimposable, this strongly suggests that the Sec13/31 complex contains the assembly unit shown in Fig. 12-71c. This assembly unit has been docked into the cryo-EM-determined struc-

**Figure 12-71** X-ray structures of portions of the Sec13/31 complex from yeast. (a) The Sec13/31 vertex element, which consists of Sec13 (orange) in complex with residues 1 to 411 of Sec31 (green). The complex forms two seven-bladed  $\beta$  propellers with one blade of the mainly Sec13  $\beta$  propeller contributed by the C-terminal portion of the Sec31 fragment. (b) The Sec13/31 edge element, which is a heterotetramer composed of two molecules each of Sec13 (red and orange) and residues 370 to

763 of Sec31 (light and dark green). The complex is viewed along its 2-fold axis and oriented as in Part a. Here Sec13 forms  $\beta$  propellers as in Part a and the Sec31 fragment forms a 215-Å-long double layered  $\alpha$  solenoid. (c) Molecular model of the Sec13/31 assembly unit drawn as a surface diagram that is colored and oriented as in Parts a and b. [Courtesy of Jonathan Goldberg, Memorial Sloan-Kettering Cancer Center, New York, New York. PDBids 2PM6 and 2PM9.]

**Figure 12-72** Molecular model of the COPII cage viewed approximately along its 3-fold axis. Its 48 Sec13/31 subunits are drawn in worm form colored as in Fig. 12-71. Four Sec31  $\beta$  propellers associate to form each vertex of the cuboctahedral cage with the remaining portions of the heterotetrameric Sec13/31 assembly units forming its edges. The inner diameter of the cage is  $\sim 520$  Å. [Courtesy of Jonathan Goldberg, Memorial Sloan-Kettering Cancer Center, New York, New York.]

ture of the Sec13/31 cage (Fig. 12-70) to yield the model for the COPII cage drawn in Fig. 12-72.

It is instructive to consider the similarities and differences between COPII and clathrin cages. Both consist of seven-bladed  $\beta$  propellers and  $\alpha$  solenoids. In COPII cages, all such motifs participate in forming its edges with four Sec31  $\beta$  propellers associating to form each of its vertices. In contrast, clathrin cages are constructed entirely from their  $\alpha$  solenoidal segments with three such segments associating to form each of its vertices and with their  $\beta$  propeller motifs located in the interior of the cage, where they interact with adapter proteins. Moreover, the  $\sim 40$ -Å-diameter edges of COPII cages each consist of a double layer of  $\alpha$  solenoids, whereas the  $\sim 120$ -Å-diameter edges of clathrin cages each consist of the interdigitated  $\alpha$  solenoidal segments from four triskelions. Evidently, evolution has molded the similar components of these cages to different functions. Sequence analysis of COPI coat proteins have identified  $\alpha$  solenoid and  $\beta$  propeller motifs, which suggests that the clathrin-, COPI-, and COPII-coated vesicles arose from the same proto-coatamer.

The C-terminal segment of Sec31, which is not present in the forgoing X-ray structures, contains an apparently unstructured Pro-rich segment (residues 770–1110 are 20% Pro) that has been implicated in binding the Sar1–Sec23/24 complex (which initiates vesicle budding by binding to the cytoplasmic regions of cargo TM proteins). Based on the X-ray structure of the Sar1–Sec23/24 complex and the fact that a cuboctahedral Sec13/31 cage

has 48 binding sites for this complex, it would appear that the Sar1–Sec23/24 complex forms a 50-Å-thick layer beneath the surface of the COPII cage. Indeed, cryo-EM studies on COPII vesicles assembled from purified Sec13/31 and Sec23/24 complexes reveal that the Sec23/24 complexes form a cage that is concentric to and inside the Sec13/31 cage.

#### g. Proteins Are Directed to the Lysosome by Carbohydrate Recognition Markers

How are proteins in the ER selected for transport to the Golgi apparatus and from there to their respective membranous destinations? A clue as to the nature of this process is provided by the human hereditary defect known as **I-cell disease** (alternatively, **mulcolipidosis II**), which in homozygotes is characterized by severe progressive psychomotor retardation, skeletal deformities, and death by age 10. The lysosomes in the connective tissue of I-cell disease victims contain large inclusions (after which the disease is named) of glycosaminoglycans and glycolipids as a result of the absence of several lysosomal hydrolases. These enzymes are synthesized on the RER with their correct amino acid sequences but, rather than being dispatched to the lysosomes, are secreted into the extracellular medium. This misdirection results from the absence of a mannose-6-phosphate recognition marker on the carbohydrate moieties of these hydrolases because an enzyme required for mannose phosphorylation fails to recognize the lysosomal proteins. The mannose-6-phosphate residues are normally bound by a receptor in the coated vesicles that transport lysosomal hydrolases from the Golgi apparatus to the lysosomes (Section 23-3Bj). Other glycoproteins are directed to their intracellular destinations by similar carbohydrate markers.

#### h. ER-Resident Proteins Have the C-Terminal Sequence KDEL

Most soluble ER-resident proteins in mammals have the C-terminal sequences KDEL (HDEL in yeast), KKXX, or KXKXXX (where X represents any amino acid residue), whose alteration results in the secretion of the resulting protein. By what means are these proteins selectively retained in the ER? Since many ER-resident proteins freely diffuse within the ER, it seems unlikely that they are immobilized by membrane-bound receptors within the ER. Rather, it has been shown that ER-resident proteins, as do secretory and lysosomal proteins, readily leave the ER via COPII-coated vesicles but that ER-resident proteins are promptly retrieved from the Golgi and returned to the ER in COPI-coated vesicles. Indeed, coatamer binds the Lys residues in the C-terminal KKXX motif of transmembrane proteins, which presumably permits it to gather these proteins into COPI-coated vesicles. Furthermore, genetically appending KDEL to the lysosomal protease **cathepsin D** causes it to accumulate in the ER, but it nevertheless acquires an *N*-acetylglucosaminyl-1-phosphate group, a modification that is made in an early Golgi compartment. Presumably, a membrane-bound receptor in a post-ER compartment binds the KDEL signal and the

resulting complex is returned to the ER in a COPI-coated vesicle. **KDEL receptors** have, in fact, been identified in yeast and humans. However, the observation that former KDEL proteins whose KDEL sequences have been deleted are, nevertheless, secreted relatively slowly suggests that there are mechanisms for retaining these proteins in the ER by actively withholding them from the bulk flow of proteins through the secretory pathway.

#### D. Vesicle Fusion

Vesicles that travel only short distances ( $<1 \mu\text{m}$ ) between their parent and target membranes (e.g., between neighboring Golgi cisternae) do so via simple diffusion, a process that typically takes from one to several minutes. However, vesicles that have longer distances to commute (e.g., from the TGN to the plasma membrane) are actively transported along cytoskeletal microtubules (Section 1-2A) by the motor proteins **dynein** and **kinesin**, which unidirectionally crawl along microtubule “tracks” in an ATP-driven process (Section 35-3H).

##### a. Vesicle Fusion Is Most Easily Studied in Yeast and in Synapses

On arriving at its target membrane, a vesicle fuses with it, thereby releasing its contents on the opposite side of the target membrane (Fig. 12-60). How do vesicles fuse and why do they fuse only with their target membranes and not other membranes? Progress in answering these questions has been made mainly by using two experimental approaches, the genetic dissection of this process in yeast and its biochemical analysis in **synapses**, the junctions between neurons (nerve cells) and between neurons and muscles (Fig. 12-73).

When a nerve impulse in the presynaptic cell reaches a synapse, it triggers the fusion of **neurotransmitter-containing synaptic vesicles** with the **presynaptic membrane** (a specialized section of the neuron’s plasma membrane), thereby releasing the neurotransmitter (a small molecule) into the  $\sim 200\text{-\AA}$ -wide **synaptic cleft** (the process whereby membranous vesicles fuse with the plasma membrane to release their contents outside the cell is called **exocytosis**). The neurotransmitter rapidly diffuses across the synaptic cleft to the postsynaptic membrane, where it binds to specific receptors that then trigger the continuation of the nerve impulse in the postsynaptic cell (Section 20-5C). The homogenization of nerve tissue causes its presynaptic endings to pinch off and reseal to form **synaptosomes**, which can be readily isolated by density gradient ultracentrifugation for subsequent study.

##### b. Vesicle Fusion Requires the Coordinated Actions of Many Proteins

*Biological membranes do not spontaneously fuse.* Indeed, being negatively charged, they strongly repel one another at short distances. These repulsive forces must be overcome if biological membranes are to fuse. As we shall see below, we are just beginning to understand how this complicated process occurs.

**Figure 12-73** Transmission of nerve impulses across a synaptic cleft. (a) Electron micrograph of a frog neuromuscular junction in which the synaptic vesicles are undergoing exocytosis (arrows) with the presynaptic membrane (top). [Courtesy of John Heuser, Washington University School of Medicine, St. Louis, Missouri.] (b) The neurotransmitter, which is thereby discharged into the synaptic cleft, rapidly (in  $<0.1 \text{ ms}$ ) diffuses to the postsynaptic membrane, where it binds to transmembrane receptors, triggering a new nerve impulse.

Studies of the mechanism of vesicle fusion were pioneered by Rothman, who demonstrated that the fusion process is blocked by low concentrations of the cysteine-alkylating agent ***N*-ethylmaleimide (NEM)**,

indicating the presence of an **NEM-sensitive fusion (NSF) protein**. NSF is a cytosolic ATPase that does not bind to membranes unless a **soluble NSF attachment protein (SNAP)** is also present. SNAPs bind to membranes in the absence of NSF, demonstrating that SNAPs bind before NSF. SNAPs bind to alkali-extracted membranes, which indicates that **SNAP receptors (SNAREs)** are integral or lipid-linked proteins.

Three classes of proteins appear to participate in all vesicle fusion reactions:

**1. Rab proteins**, which are small (20–29 kD) GTPases of the Ras superfamily that play a central role in directing vesicle transport. Cells express numerous Rab isoforms, 11 in yeast and 63 in humans, each localized to a specific membrane compartment. Rab proteins have two tandem Cys residues at their C-termini, both of which are geranylgeranylated (Section 12-3Ba). A soluble protein named **GDP dissociation inhibitor (GDI)** binds to Rab · GDP so as to mask its geranylgeranyl groups and thus maintain it in the cytoplasm. However, when Rab · GDP interacts with a cognate **Rab-GEF** on the surface of its target vesicle, the geranylgeranyl groups on the resulting Rab · GTP are unmasked and insert into the vesicle membrane—much like the anchoring of ARF1 · GTP to the Golgi membrane (Fig. 12-65). Rab · GTP then binds to rodlike proteins emanating from the vesicle's target membrane known as **tethering factors** to form a relatively loose association between the two membranes. After vesicle fusion, Rab hydrolyzes its bound GTP to GDP in a process induced by a specific **Rab-GAP** and the resulting Rab · GDP is extracted from the membrane by GDI, thereby recycling the system. Rab proteins are also implicated in initiating the actual membrane fusion step (see below) as well as in the vesicle interactions with the cytoskeleton that function in transporting vesicles to their proper destinations.

**2. SNAREs**, which form cognate combinations of membrane-associated proteins known as **R-SNAREs** and **Q-SNAREs** (because they contain conserved Arg and Gln residues in their cytoplasmic domains; they were originally named **v-SNAREs** and **t-SNAREs**, respectively, because they are mainly associated with the vesicle and target membranes). The best characterized SNAREs are those functioning at neuronal synapses: **Synaptobrevin** (alternatively, **VAMP** for vesicle associated membrane protein) is an R-SNARE, whereas **syntaxin** and **SNAP-25** (for synaptosome associated protein of 25 kD) are Q-SNAREs. *R-SNAREs and Q-SNAREs associate to firmly anchor the vesicle to its previously loosely tethered target membrane*, a process called “docking.” The docked complexes, which are described below, are eventually disassembled by NSF in association with a SNAP protein. (Note that SNAP-25 is not a SNAP protein; by curious coincidence, the two independently characterized proteins were assigned the same acronym before it was realized that they are functionally associated.)

**3. The SM proteins** (so called because they are named **Sec1** in yeast and **Munc18** in mammals), which in synapses bind to syntaxin so as to prevent synaptobrevin and SNAP-

25 from binding to it. Mutational studies indicate that these 65- to 70-kD hydrophilic proteins are essential for vesicle fusion.

### c. SNAREs Form a Stable Four-Helix Bundle

The R-SNARE synaptobrevin and the Q-SNAREs syntaxin and SNAP-25 form a highly stable complex; boiling SDS solution is required to dissociate it. Synaptobrevin and syntaxin each have a C-terminal TM helix, and SNAP-25 is anchored to the membrane via palmitoyl groups that are linked to Cys residues in its central region. The X-ray structure of the associating portions of this complex (Fig. 12-74a), determined by Reinhard Jahn and Axel Brünger, reveals it to be a bundle of four parallel ~65-residue  $\alpha$  helices with two of the helices formed by the N- and C-terminal segments of SNAP-25. Since synaptobrevin is anchored in the vesicle membrane and syntaxin and SNAP-25 are anchored in the target membrane, this so-called core complex firmly ties together the two membranes (Fig. 12-74b).

**Figure 12-74** X-ray structure of the syntaxin–synaptobrevin–SNAP-25 core complex. (a) Ribbon diagram showing the syntaxin helix (Sx) in red, the synaptobrevin helix (Sb) in blue, and the N- and C-terminal helices of SNAP-25 (Sn1 and Sn2) in green. (b) Model of the synaptic fusion complex linking two membranes (gray). The helices of the core complex are colored as in Part a. The transmembrane C-terminal extensions of syntaxin and synaptobrevin are modeled as helices (light green). The loop connecting the N- and C-terminal helices of SNAP-25 is speculatively represented as an unstructured loop (brown). Recall that this loop is anchored to the membrane via Cys-linked palmitoyl groups (not shown). The cleavage sites for the various clostridial neurotoxins are indicated by the arrows. [Courtesy of Axel Brünger, Yale University. PDBid 1SFC.]

The four helices of the core complex wrap around each other with a gentle left-handed twist. For the most part, the sequence of each helix has the expected 7-residue repeat,  $(a-b-c-d-e-f-g)_m$ , with residues *a* and *d* hydrophobic (Section 8-2A; note that this property is characteristic of 4- and 3-helix bundles as well as of coiled coils). However, the central layer of side chains along the length of the 4-helix bundle consists of an Arg residue from synaptobrevin that is hydrogen bonded to three Gln side chains, one from syntaxin and one from each of the SNAP-25 helices. These highly conserved polar residues are sealed off from the aqueous environment such that their interactions are enhanced by the low dielectric constant of their environment. It therefore appears that these interactions serve to bring the four helices into proper register.

Since cells contain large numbers of different R-SNAREs and Q-SNAREs (25 in yeast and 36 in humans), it would seem likely that their interactions are at least partially responsible for the specificity that vesicles exhibit in fusing with their target membranes. Indeed, Rothman has shown this to be the case by determining, *in vitro*, the rate of fusion of liposomes bearing different SNAREs. In testing all the R-SNAREs in the yeast genome against Q-SNAREs known to be localized to the yeast Golgi, vacuole, and plasma membranes, he found that liposome fusion only occurs when the combinations of R- and Q-SNAREs correspond to those mediating membrane flow *in vivo*. Nevertheless, it seems likely that the *in vivo* specificity of vesicle fusion is augmented by other mechanisms such as the localization of cognate R- and Q-SNAREs to particular regions in the cell and by the actions of regulatory proteins including, as is indicated above and discussed below, Rab proteins.

#### d. Tetanus and Botulinus Toxins Specifically Cleave SNAREs

The frequently fatal infectious diseases **tetanus** (which arises from wound contamination) and **botulism** (a type of food poisoning) are caused by certain anaerobic bacteria of the genus *Clostridium*. These bacteria produce extremely potent protein neurotoxins that inhibit the release of neurotransmitters into synapses. In fact, botulinus toxins are the most powerful known toxins; they are  $\sim 10$  millionfold more toxic than cyanide ( $10^{-10} \text{ g} \cdot \text{kg}^{-1}$  will kill a mouse).

There are seven serologically distinct types of botulinus neurotoxins, designated **BoNT/A** through **BoNT/G**, and one type of tetanus neurotoxin, **TeTx**. Each of these homologous proteins is synthesized as a single  $\sim 150$ -kD polypeptide chain that is cleaved by host proteases to yield an  $\sim 50$ -kD L chain that remains disulfide-linked to the  $\sim 100$ -kD H chain (Fig. 12-75). The H chains bind to specific types of neurons (via gangliosides and protein receptors), where they facilitate the uptake of the L chain by endocytosis. The L chains are proteases, and each cleaves its target SNARE at a specific site (Fig. 12-74b). This prevents the formation of the core complex and thereby halts the exocytosis of synaptic vesicles. The H chain of TeTx specifically binds to inhibitory neurons (which function to moderate excitatory nerve impulses) and is thereby responsible for the spastic paralysis characteristic of tetanus. The H chains of the BoNTs instead bind to motor neurons (which

**Figure 12-75 Model of clostridial neurotoxins and their activation by host proteases.** The disulfide bond linking the L and H segments is cleaved after the neurotoxin is taken up by its target neuron.

innervate muscles) and thus cause the flaccid paralysis characteristic of botulism.

The administration of carefully controlled quantities of botulinus toxin (trade name Botox) is medically useful in relieving the symptoms of certain types of chronic muscle spasms. Moreover, this toxin is used cosmetically: Its injection into the skin relaxes the small muscles causing wrinkles and hence these wrinkles disappear for  $\sim 3$  months.

#### e. Bilayer Fusion Is Mechanically Induced

The association of Q-SNAREs on a vesicle with an R-SNARE on its target membrane brings the two bilayers into close proximity, yielding a so-called **trans-SNARE complex**. But what induces the fusion of the juxtaposed bilayers? The answer, which is diagrammed in Fig. 12-76, is that the mechanical forces arising from the formation of a ring of several (estimated to be 5–10) trans-SNARE complexes pulls together apposing bilayers. This expels the contacting lipids between them so as to join their outer leaflets, a process known as **hemifusion**. Indeed, the pressure (force/area) within the ring of trans-SNARE complexes is estimated to be 100 to 1000 atm. In the resulting transient structure, no aqueous contact between the two membrane systems has yet been established. However, as the fusion process proceeds (the trans-SNAREs continue zipping up), the two inner leaflets of the now partially joined membranes come together to form a new bilayer, whose component lipids are subsequently similarly expelled to yield a **fusion pore**. The fusion pore then rapidly expands, thereby fully joining the two membranes as well as their contents. Thus, vesicle fusion is driven by the protein folding forming the trans-SNARE complexes.

As we discussed above, liposomes containing the corresponding Q- and R-SNAREs spontaneously fuse. However, this *in vitro* process takes 30 to 40 minutes whereas, for example, the *in vivo* fusion of a synaptic vesicle with the presynaptic membrane takes  $< 0.3$  ms (Section 20-5C). This suggests that other proteins such as Rab proteins and/or their **effectors** (proteins with which they interact) participate in mediating the bilayer fusion process.

#### f. The Structure of the nSec1–Syntaxin Complex Suggests a Function for Rab Protein

The neuronal SM protein, which is named **nSec1**, binds to syntaxin with high affinity to form a complex that is mutually exclusive with the formation of the syntaxin–

**Figure 12-76 Model for SNARE-mediated vesicle fusion.**

Here the R-SNARE and the Q-SNAREs are schematically

represented by red and blue worms. [After a drawing by Chen, Y.A. and Scheller, R.H., *Nature Rev. Mol. Cell Biol.* **2**, 98 (2001).]

synaptobrevin–SNAP-25 complex. The X-ray structure of nSec1 in complex with the cytoplasmic domain of syntaxin (Fig. 12-77), determined by William Weis, reveals that this portion of the 288-residue syntaxin forms an N-terminal

up–down–up–down four-helix bundle. Syntaxin’s C-terminal helix (but lacking its TM portion) adopts a bent and somewhat irregular conformation, which differs from that in the core complex displayed in Fig. 12-74. In contrast, the

**Figure 12-77 X-ray structure of the complex between nSec1 and syntaxin.** (a) Ribbon diagram of syntaxin with its N-terminal 3-helix bundle (Habc) red and the cytoplasmic portion, its C-terminal helix (H3; the segment that forms a component of the core complex), purple. (b) Ribbon diagram of nSec1 with its

three domains differently colored. (c) The nSec1–syntaxin complex colored as in Parts a and b and viewed such that the nSec1 is rotated by 90° about the vertical axis relative to Part b. [Courtesy of William Weis, Stanford University School of Medicine. PDBid 1DN1.]

remaining N-terminal 3-helix bundle is closely superimposable on the NMR structure of this segment alone. The 594-residue nSec1 is an arch-shaped molecule that binds syntaxin, and in particular its C-terminal helix, in the cleft of the arch (Fig. 12-77c).

The formation of the syntaxin–synaptobrevin–SNAP-25 complex that mediates vesicle fusion requires that the nSec1–syntaxin complex dissociate and that syntaxin’s N-terminal 3-helix bundle release the C-terminal helix. Mutational studies indicate that a Rab protein and/or its effectors mediate this process. It has therefore been proposed that the binding of Rab and/or its effectors to the nSec1–syntaxin complex causes nSec1 to change conformation, which in turn induces syntaxin’s N-terminal 3-helix bundle to release the C-terminal helix, thereby permitting the SNARE complex to form. Thus Rab controls the availability of syntaxin.

### g. NSF Mediates Core Complex Disassembly

The SNARE complex in the fused membranes, the so-called **cis-SNARE complex**, must eventually be dissociated in order for its component proteins to participate in a new round of vesicle fusion. This process is mediated by NSF, an ATP-dependent cytosolic protein that binds to SNAREs (SNAP receptors) through the intermediacy of adaptor proteins called SNAPs (soluble NSF attachment proteins). Although it was initially proposed that the NSF-mediated disassembly of the cis-SNARE complex somehow directly drove membrane fusion, it is now clear that NSF functions to recycle SNAREs after their participation in membrane fusion, that is, *NSF functions as an ATP-driven molecular chaperone*. However, since trans-SNARE complexes form spontaneously, *membrane fusion is indirectly driven by NSF-mediated ATP hydrolysis*.

NSF is a hexamer of identical 752-residue subunits. Sequence analysis and limited proteolysis studies indicate that each subunit consists of three domains:

1. An N-terminal so-called N domain (residues 1–205), which mediates NSF’s interactions with SNAPs and SNAREs.
2. A D1 domain (206–487), which binds ATP and catalyzes its hydrolysis in a process that drives the disassembly of the cis-SNARE complex.
3. A C-terminal D2 domain (488–752), which is homologous to D1. D2 binds ATP with a much higher affinity than does D1 but hydrolyzes it very slowly, if at all. D2 · ATP mediates the hexamerization of NSF, which is required for NSF activity.

The X-ray structure of the D2 domain of NSF was independently determined by Weis and by Jahn and Brünger. Its wedge-shaped subunits associate to form a 116-Å-diameter and 40-Å-high disk-shaped hexamer that has an ~18-Å-diameter central pore (Fig. 12-78). The ATP is bound near the interface between two subunits, where it presumably helps stabilize their association.

**Figure 12-78** X-ray structure of the NSF D2 hexamer as viewed from its N-terminal end along its 6-fold axis. Each subunit is differently colored. The bound ATPs are drawn in ball-and-stick form. [Courtesy of Axel Brünger, Yale University. PDBid 1NSF.]

Electron micrographs by Jahn and John Heuser of intact NSF in the presence of ATP have the appearance of an ~120-Å-diameter hexagonal ring with a 30- to 50-Å central opening when seen in top view (Fig. 12-79a) and of a 120-Å by 150-Å rectangle when seen in side view (Fig. 12-79b). The length of the rectangle is about twice the height of the D2 disk, which suggests that D1 forms a D2-like hexagonal disk that stacks on D2. In the presence of ADP, NSF has an identical appearance, which suggests that D1 rapidly hydrolyzes its bound ATP to form ADP. However, in the presence of the nonhydrolyzable ATP analog ATP $\gamma$ S (in which a terminal O atom on the  $\gamma$ -phosphorus atom of ATP is replaced by S), NSF displays six globular feet that are tightly packed around the somewhat smaller hexagonal ring (Fig. 12-79c). Since the hexagonal rings but not the globules are seen when D1–D2 constructs are imaged in the presence of ATP $\gamma$ S, the globules must be the N domains. Evidently, the N domains are held tightly around the central disk of stacked D1 and D2 hexamers when D1 binds ADP but are released when D1 binds ATP.

The mechanism whereby NSF disassembles the cis-SNARE complex is largely unknown. The rod-shaped SNARE core complex (Fig. 12-74a), which is 20 to 25 Å in diameter, is too wide to fit inside the 18-Å-diameter central pore of the D2 hexamer (and presumably the similarly shaped D1 hexamer) without significant structural changes. It is therefore unlikely that the core complex binds inside NSF’s central cavity in a manner similar to the way that the GroEL–GroES chaperonin system binds its substrate proteins (Section 9-2Ca). Moreover, electron micrographs indicate that the complex of SNAP and the

**Figure 12-79** Quick-freeze/deep-etch electron micrographs of NSF hexamers. (a) Top and (b) side views in the presence of ATP. (c) Top view in the presence of ATP $\gamma$ S. [Courtesy of John Heuser, Washington University School of Medicine, St. Louis, Missouri.]

three SNARE proteins binds to one end of NSF in the presence of ATP $\gamma$ S (but not at all in the presence of ADP). Since NSF oligomers containing mixtures of active and inactive D1 domains are unable to disassemble SNARE complexes, it appears that the NSF subunits function in a cooperative manner.

### E. Protein Targeting to Mitochondria

Although mitochondria contain functioning genetic and protein synthesizing systems, their genomes encode only a handful of inner membrane proteins (13 in humans; 8 in yeast). The vast majority of mitochondrial proteins (~99%), which comprise 10 to 20% of intracellular proteins, are encoded by nuclear genes and are synthesized by cytosolic ribosomes. They must therefore traverse one or both mitochondrial membranes (Section 1-2Ac) to reach their final destinations. In this subsection, we discuss how proteins are imported into mitochondria and are directed to their correct destinations [outer membrane, inner membrane, intermembrane space, or **matrix** (the space enclosed by the inner membrane)]. Our rapidly developing knowledge of this process was elucidated in large part through investigations in yeast and in the pink bread mold *Neurospora crassa* by Walter Neupert, Nikolaus Pfanner, Trevor Lithgow, and Gottfried Schatz. However, there is considerable evidence that this process is well conserved among all eukaryotes. The transport systems we describe

here and in Section 12-4B resemble those that mediate the import of proteins into chloroplasts (in which proteins must cross up to three membranes; Section 1-2Ag) and peroxisomes (Section 1-2Ad).

#### a. Proteins Must Be Unfolded for Import Into Mitochondria

Most nuclear-encoded mitochondrial proteins are fully synthesized by cytosolic ribosomes before they are imported into mitochondria; that is, they are post-translationally imported. One might expect, therefore, that mitochondrial proteins, many of which are integral proteins, would at least partially fold and/or nonspecifically aggregate in the cytosol before encountering the mitochondrial import system. Yet a variety of evidence indicates that *only unfolded proteins can pass through mitochondrial membranes*. For example, **dihydrofolate reductase (DHFR)**, a normally cytosolic enzyme, is imported into yeast mitochondria when it is preceded by the targeting sequence (see below) of a cytosolically synthesized mitochondrial protein. However, the importation of this chimeric protein is arrested by the presence of **methotrexate**, an analog of DHFR's normal substrate **dihydrofolate** (Section 28-3Be), which binds to DHFR with such high affinity that it stabilizes the protein's native conformation.

*The import competence of mitochondrially destined proteins is maintained in the cytosol by a variety of ATP-dependent molecular chaperones.* These include members of the Hsp70 family (Section 9-2C) and, in mammals, a protein named **mitochondrial import stimulation factor (MSF)**. Consequently, the genetically engineered shut-down of Hsp70 production in yeast causes the cells to cytosolically accumulate proteins that would otherwise be imported into the mitochondria. Moreover, the rate of the Hsp70-facilitated mitochondrial import of a protein is enhanced by its prior denaturation by urea. Evidently, Hsp70 functions in this process as an ATP-driven "protein unfoldase."

#### b. Translocation of Proteins Across the Outer Mitochondrial Membrane

*Most cytosolically synthesized matrix proteins have cleavable N-terminal signal sequences that do not interact with the SRP.* These presequences consist of 10 to 80 residues that form amphipathic helices with one face positively charged. However, many mitochondrial proteins, including most metabolite carrier proteins of the inner membrane (see below), have poorly characterized internal targeting sequences.

The protein subunits that participate in importing proteins across the outer mitochondrial membrane are called **TOM proteins** (for translocase of the outer mitochondrial membrane) and are named Tomxx, where xx is the molecular mass of the subunit in kilodaltons. Likewise, many of the proteins involved in translocating proteins across the inner mitochondrial membrane are called **TIM proteins** (for translocase of the inner mitochondrial membrane) and are named Timxx.

**Figure 12-80 Schematic diagram of the mitochondrial protein import machinery in yeast.** See the text for a description. The subunit compositions of these complexes in mitochondria from

other organisms are similar. [After Bolender, N., Sickmann, A., Wagner, R., Meisinger, C., and Pfanner, N., *EMBO Rep.* **9**, 42–49 (2008).]

The **TOM complex**, the machinery that imports all mitochondrial proteins through the outer mitochondrial membrane, does so as follows (Fig. 12-80, top left—green):

1. The signal sequences of unfolded preproteins associate with the cytoplasmic domains of mitochondrial receptor proteins: N-terminal signal sequences interact mainly with **Tom20** in complex with **Tom22**, whereas internal signal sequences interact mainly with **Tom70**. The NMR structure of a portion of Tom20's cytosolic domain in complex with an 11-residue segment of a presequence peptide (Fig. 12-81), determined by Toshiya Endo and Daisuke Kohda, reveals that the Tom20 domain consists mainly of five helices. Its two N-terminal helices form a nonpolar surface groove in which the helical presequence binds, mainly via hydrophobic interactions rather than ionic interactions. Evidently, Tom20 recognizes the presequence's amphipathic helix but not its positive charges. These positive charges, which are required for mitochondrial import, interact with Tom22.

2. Tom20 and Tom70 deliver preproteins to the **general import pore (GIP)**, so called because all nuclear-encoded mitochondrial proteins must pass through it. The GIP is formed by **Tom40**, a polytopic TM protein, which CD measurements indicate consists mainly of  $\beta$  sheets and hence has a TM  $\beta$  barrel structure that presumably resembles that of bacterial porins (Fig. 12-27). Electrophysiological measurements demonstrate that Tom40 contains a cation-selective hydrophilic channel through which precursor proteins are transported. Tom40 is closely associated with three small single pass TM subunits, **Tom5**, **Tom6**, and **Tom7**, to form

the **TOM core complex**. The deletion of any one of these small subunits has only minor effects but the deletion of all three is lethal. They appear to stabilize the TOM complex but their individual functions are largely unknown. Electron micrographs of the *Neurospora* TOM core complex (Fig. 12-82) reveal an  $\sim 70$ -Å-high ( $\sim 20$  Å larger than the thickness of the lipid bilayer) and  $\sim 120$ -Å-wide particle containing two  $\sim 21$ -Å-diameter pores that presumably are the protein-conducting channels. This agrees with permeability experiments using cations of various sizes, which indicate that the Tom40 pore is  $\sim 22$  Å in diameter.

3. The forces driving the translocation of polypeptides through the TOM complex remain largely enigmatic. A proposed mechanism, the **acid chain hypothesis**, is that the positively charged presequence is sequentially transferred between acidic (negatively charged) patches to which it binds with successively higher affinities. Such patches are present on the cytoplasmic faces of Tom20, Tom22, and Tom5, as well as on the intermembrane faces of Tom40 and Tom22.

At this stage, the import pathway for mitochondrial proteins splits several ways. We discuss these various pathways below.

### c. Translocation of Proteins Into the Matrix

Polypeptides with N-terminal signal sequences, which include the precursors of all matrix-destined proteins, most inner membrane proteins, and many proteins that occupy the intermembrane space (**IMS**), are translocated across the inner mitochondrial membrane by the **TIM23 complex**

**Figure 12-81** NMR structure of the cytoplasmic domain of rat **Tom20** in complex with the C-terminal 11-residue segment (GPRLSRLLSYA) of the 22-residue presequence of the rat mitochondrial enzyme aldehyde dehydrogenase. The diagram is a superposition of the 20 final structures in the NMR analysis (Section 8-3A) in which the residues used to make the superposition are blue (Tom20) and red (presequence) and the remaining residues are gray (Tom20) and orange (presequence). [Courtesy of Toshiya Endo, Nagoya University, Nagoya, Japan, and Daisuke Kohda, Biomolecular Engineering Research Institute, Osaka, Japan. PDBid 1OM2.]

(Fig. 12-80, *bottom left*—yellow). This complex contains a protein channel formed by **Tim23**, which is closely associated with **Tim17**. The peripheral protein **Tim50** binds the polypeptide emerging from the Tom40 channel and passes it to **Tim23**. Electron microscopy studies indicate that the TOM and TIM23 complexes are in apposition at sites where the inner and outer mitochondrial membranes approach each other most closely. Indeed, **Tim21** transiently associates with Tom22 across this contact site by displacing the emerging signal sequence.

In the presence of methotrexate, the above DHFR chimera becomes stuck in the membrane with the spacer that linked the enzyme to its N-terminal presequence simultaneously spanning the TOM and TIM23 complexes. The N-terminal end of the spacer is presumably trapped in the matrix through its association with **mtHsp70** (see below). Consequently, if the spacer is so short that it cannot span both membranes (less than ~40 residues), no stable translocation intermediate is formed. Thus, it appears that presequences make their way between the TOM and TIM23 complexes without the aid of chaperones.

**Figure 12-82** Electron microscopy-based image of the TOM core complex particles from *Neurospora*. The particles, which are shown in top view (*left*) and side view (*right*), contain two openings that presumably represent the mitochondrial outer membrane's protein-conducting channels. [Courtesy of Stephan Nussberger and Walter Neupert, Universität München, Germany.]

The translocation of a protein across the inner mitochondrial membrane requires energy in the form of both ATP and an electrostatic potential across the inner mitochondrial membrane. This so-called **membrane potential** (Section 20-1),  $\Delta\Psi$ , which is metabolically generated (Section 22-3Ba), apparently functions to electrophoretically transport the positively charged N-terminal signal sequence into the matrix (the matrix is negatively charged with respect to the cytosol).

The ATP is utilized by matrix Hsp70 (mtHsp70; alternatively, **mHsp70**), the central component of the **presequence translocase-associated motor (PAM; Fig. 12-80, bottom left—orange)**. This molecular chaperone binds to **Tim44** on the inner face of the inner mitochondrial membrane, where it is thought to mechanically pull the protein through the Tim23 pore via a Brownian ratchet mechanism (Section 12-4Bg). **Pam 18** (alternatively, **Tim14**), which associates with Tim44, has a J-domain that presumably recruits mtHsp70 and induces it to hydrolyze its bound ATP to ADP, thus activating it to bind the incoming polypeptide. **Pam16** (alternatively **Tim16**), which binds Tim14, is thought to act as a negative regulator of Tim14 by physically blocking its access to mtHsp70. **Pam17** is required for the assembly of the Pam18–Pam16 module. The matrix protein **Mge1** stimulates mtHsp70 to exchange its bound ADP for ATP, thus permitting it to participate in another cycle of the Brownian ratchet.

Once a preprotein, or at least its N-terminal segment, has entered the matrix, its N-terminal signal sequence is excised by **matrix processing peptidase (MPP)**, an essential protein. The imported protein then folds/assembles to its native state, a process that is facilitated by a battery of ATP-dependent chaperone proteins including mtHsp70 (only about 10% of which is associated with Tim44) and Hsp60/Hsp10 (homologs of the GroEL/ES system; Section 9-2C).

Some of the polypeptides that are translocated by the TIM23 complex have a stop-transfer anchor sequence. The TIM23 complex laterally inserts the resulting TM helix into the inner mitochondrial membrane (Fig. 12-80, *bottom, far left*) such that its N-terminal portion occupies the matrix, where MPP excises its N-terminal signal sequence.

#### d. Insertion of Metabolite Carrier Proteins Into the Inner Mitochondrial Membrane

The mitochondrial inner membrane is impermeable to nearly all polar substances and hence contains numerous (35 in yeast) **metabolite carrier proteins** to permit the acquisition of reactants and the delivery of products. The most abundant members of this family are the **ATP–ADP translocator** (which exchanges the ATP synthesized in the matrix for the ADP product of cytosolic ATP hydrolysis; Section 20-4C) and the **phosphate carrier** (which returns the phosphate product of cytosolic ATP hydrolysis to the matrix; Section 22-1Ba). All metabolite carrier proteins have six TM helices with both their N- and C-termini in the IMS.

Most members of the metabolite carrier family lack N-terminal signal sequences and are therefore translocated through the TOM complex via interactions with its Tom70 receptor. Curiously, however, the Tom20–Tom22 complex is the receptor for most other outer membrane proteins that have internal signal sequences. Metabolite carrier proteins are escorted across the IMS by a hexameric complex of the homologous proteins **Tim9** and **Tim10**, (Tim9)<sub>3</sub>(Tim10)<sub>3</sub>, which is thought to shield the hydrophobic domains of the metabolite carrier proteins (Fig. 12-80, *middle—blue*). Metabolite carrier proteins in a preparation of mitochondria depleted of Tim9 and Tim10 are not inserted into the GIP, as indicated by their failure to reach a protease-resistant state. This suggests that it is the binding of the Tim9–Tim10 complex to an unfolded metabolite carrier protein that drives its translocation across the outer mitochondrial membrane.

The Tim9–Tim10 complex delivers the metabolite carrier protein to the peripheral protein **Tim12** (a homolog of Tim9 and Tim10), which is associated with the integral proteins **Tim22** (which is homologous to Tim 23), **Tim54**, and **Tim18** to form the **TIM22 complex** (Fig. 12-80, *bottom middle—gold*). *Tim22 then mediates the lateral insertion of the metabolite carrier protein into the inner mitochondrial membrane, where it assembles to form homodimers.* This process occurs via an unknown but membrane potential-dependent mechanism. The functions of Tim54 and Tim18 are unknown.

#### e. Soluble Proteins Occupying the Intermembrane Space Are Imported via Three Mechanisms

Despite the fact that its width is around that of a membrane bilayer, the IMS contains a large collection of essential proteins. The precursors of some of these proteins are imported, as described above, such that they become anchored to the IMS by a single TM helix that has its N-terminal end in the matrix (Fig. 12-80, *bottom, far left*). Such a protein is then cleaved by an inner membrane protease on the C-terminal side of its TM helix, thereby releasing it into the IMS, where it folds to its native conformation. Since the mature protein lacks a signal sequence, it is no longer subject to importation into the matrix and hence remains in the IMS. **Coproporphyrinogen oxidase**, which participates in heme biosynthesis (Section 26-4Ae), is such a protein.

Many small proteins that lack N-terminal signal sequences are imported, via the TOM complex, into the IMS.

There they assume their native fold, thus trapping them in the IMS—the so-called **folding-trap mechanism**. Such proteins have conserved patterns of Cys and/or His residues that enable them to bind metal ion-containing cofactors in the IMS or to form disulfide bonds, both of which stabilize their native structures. [Note that the latter proteins are among the few intracellular proteins that have disulfide bonds (Section 8-4D). Evidently, the IMS has an oxidative environment.] For example, **apocytochrome c** (cytochrome *c* without its covalently attached heme group; Fig. 9-39) folds when the IMS-resident enzyme **cytochrome c heme lyase (CCHL)** catalyzes the attachment of its heme group, whereas Tim9, Tim10, and Tim12 each contain twin CX<sub>3</sub>C motifs that form disulfide bonds.

A third class of IMS-resident proteins remain in the IMS through their association with the inner membrane, that is, they are peripheral proteins. CCHL is a member of this class of proteins.

#### f. Many Polytopic Inner Membrane Proteins Are First Imported to the Matrix

Many cytosolically synthesized polytopic proteins destined for insertion into the mitochondrion's inner membrane are first imported into the matrix as described above and then inserted into the inner membrane, an indirect routing that reflects the mitochondrion's bacterial origin [the primordial mitochondrion, being a gram-negative bacterium, synthesized all of its proteins in its cytoplasm (the primordial matrix) so that membrane-bound or intermembrane proteins had to be exported to these destinations]. These proteins, for the most part, are synthesized with bipartite N-terminal targeting sequences whose inner (more C-terminal) segments, once exposed by the removal of the above-described N-terminal presequence, direct the proteins to the inner membrane. The insertion of several such proteins into the inner mitochondrial membrane is mediated by the TM protein **Oxa1**, which also occupies the inner mitochondrial membrane (Fig. 12-80, *bottom right, pink*). Oxa1, which binds mitochondrial ribosomes on its matrix side, also inserts mitochondrially synthesized proteins into the inner mitochondrial membrane. As might be expected, Oxa1 is related to a protein that inserts proteins into the inner membrane of gram-negative bacteria.

#### g. Insertion of $\beta$ Barrel Proteins Into the Outer Mitochondrial Membrane

The outer membranes of mitochondria and chloroplasts contain proteins, such as porins (Section 12-3Ad) and Tom40, that have TM  $\beta$  barrels. These are the only places in eukaryotic cells that TM  $\beta$  barrels occur, which also reflects the bacterial origins of these organelles (Sections 1-2Ac and 1-2Ag).

$\beta$  barrel proteins are imported into the IMS by the TOM complex. There they are bound by the Tim9–Tim10 complex, which escorts them to the **SAM complex** (for sorting and assembly machinery; alternatively **TOB complex** for topogenesis of mitochondrial outer membrane  $\beta$  barrel), which in turn inserts them into the outer mitochondrial membrane (Fig. 12-80, *top right—purple*). The SAM complex

**Table 12-6** Characteristics of the Major Classes of Lipoproteins in Human Plasma

is formed by the TM  $\beta$  barrel-containing protein **Sam50** (alternatively, **Tob55** or **Tom55**) in association with **Sam37** (**Mas37/Tom37**), **Sam35** (**Tob35/Tom38**), and **Mdm10** (mitochondrial distribution and morphology 10).  $\beta$  barrel proteins are inserted into the outer membrane from its inner side, which presumably is also an evolutionary consequence of the mitochondrion's bacterial origin. Nevertheless, the TOM and SAM complexes are functionally coupled as indicated by the observation that when  $\beta$  barrel proteins are imported into mitochondria lacking Sam50, they accumulate in the TOM complex rather than in the IMS. Sam50 is homologous to the bacterial outer membrane protein **Omp85**, which participates in inserting  $\beta$  barrel proteins into the bacterial outer membrane.

## 5 LIPOPROTEINS

Lipids and proteins associate noncovalently to form **lipoproteins**, which function in the blood plasma as transport vehicles for triacylglycerols and cholesterol. In this section, we discuss the structure, function, and dysfunction of lipoproteins, and how eukaryotic cells take up lipoproteins and other specific proteins from their external medium through receptor-mediated endocytosis.

### A. Lipoprotein Structure

Lipids, such as phospholipids, triacylglycerols, and cholesterol, are but sparingly soluble in aqueous solution. Hence, they are transported by the circulation as components of lipoproteins, globular micellelike particles that consist of a nonpolar core of triacylglycerols and cholesteryl esters surrounded by an amphiphilic coating of protein, phospholipid, and cholesterol. Lipoproteins have been classified into five broad categories on the basis of their functional and physical properties (Table 12-6):

**1. Chylomicrons**, which transport exogenous (externally supplied; in this case, dietary) triacylglycerols and cholesterol from the intestines to the tissues.

**2–4. Very low density lipoproteins (VLDL), intermediate density lipoproteins (IDL), and low density lipoproteins (LDL)**, a group of related particles that transport endogenous (internally produced) triacylglycerols and cholesterol from the liver to the tissues (the liver synthesizes triacylglycerols from excess carbohydrates; Section 25-4).

**5. High density lipoproteins (HDL)**, which transport endogenous cholesterol from the tissues to the liver.

Lipoprotein particles undergo continuous metabolic processing, so that they have variable properties and compositions (Table 12-6). Each contains just enough protein, phospholipid, and cholesterol to form an  $\sim 20\text{-\AA}$ -thick monolayer of these substances on the particle surface (Fig. 12-83). Lipoprotein densities increase with decreasing particle diameter because the density of their outer coating is greater than that of their inner core.

**Figure 12-83** LDL, the major cholesterol carrier of the bloodstream. This spheroidal particle consists of some 1500 cholesteryl ester molecules surrounded by an amphiphilic coat of 800 phospholipid molecules, 500 cholesterol molecules, and a single 4536-residue molecule of apolipoprotein B-100.

**Table 12-7** Properties of the Major Species of Human Apolipoproteins

Apolipoprotein	Number of Residues	Molecular Mass <sup>a</sup> (kD)	Function
A-I	243	29	Activates LCAT <sup>b</sup>
A-II	77	17	Inhibits LCAT, activates hepatic lipase
B-48	2152	241	Cholesterol clearance
B-100	4536	513	Cholesterol clearance
C-I	56	6.6	Activates LCAT?
C-II	79	8.9	Activates LPL <sup>c</sup>
C-III	79	8.8	Inhibits LPL, activates LCAT?
D	169	19	Unknown
E	299	34	Cholesterol clearance

<sup>a</sup>All apolipoproteins are monomers but apoA-II, which is a disulfide-linked dimer.

<sup>b</sup>LCAT = lecithin-cholesterol acyltransferase.

<sup>c</sup>LPL = lipoprotein lipase.

### a. Apolipoproteins Have Amphipathic Helices That Coat Lipoprotein Surfaces

The protein components of lipoproteins are known as **apolipoproteins** or just **apoproteins**. At least nine apolipoproteins are distributed in significant amounts in the different human lipoproteins (Tables 12-6 and 12-7). Most of them are water-soluble and associate rather weakly with lipoproteins. Hence, they readily transfer between lipoprotein particles via the aqueous phase. CD measurements indicate that *apolipoproteins have a high helix content, which increases when they are incorporated in lipoproteins*. Apparently, the helices are stabilized by a lipid environment, presumably because helices fully satisfy the polypeptide backbone's hydrogen bonding potential in a lipoprotein's water-free interior.

### b. The X-ray Structure of ApoA-I Mimics That in HDL

**Apolipoprotein A-I (apoA-I)** is HDL's major apoprotein. Sequence analysis indicates that apoA-I consists mainly of repeated amphipathic  $\alpha$  helices of 11 or 22 residues that provide the protein's lipid-binding regions. *These putative  $\alpha$  helices, as well as similar helices that occur in most other apolipoproteins, have their hydrophobic and hydrophilic residues on opposite sides of the helical cylinders* (Fig. 12-84). Furthermore, the polar helix face has a zwitterionic character in that its negatively charged residues project from the center of this face, whereas its positively charged residues are located at its edges. Indeed, a synthetic 22-residue polypeptide of high helix-forming propensity, which was designed by E. Thomas Kaiser to have this polarity distribution but to otherwise have minimal similarity to the repeating apoA-I sequences, behaves much like apoA-I in binding to egg lecithin liposomes. Evidently, the structural role of apoA-I, and probably most other apolipoproteins, is fulfilled by its helical segments rather than by any organized tertiary structure. This suggests that *lipoprotein  $\alpha$  helices float on phospholipid surfaces, much like logs on water*. The phospholipids are presumably arrayed with their charged groups bound to

oppositely charged residues on the polar face of the helix and with the first few methylene groups of their fatty acid residues in hydrophobic association with the nonpolar face of the helix.

A variety of criteria indicate that apoA-I undergoes significant secondary structural changes on binding lipid. However, apo  $\Delta(1-43)$ A-I, a truncation mutant that lacks residues 1 to 43 of the 243-residue human apoA-I, has a

**Figure 12-84** A helical wheel projection of the amphipathic  $\alpha$  helix constituting residues 148 to 164 of apolipoprotein A-I. (In a helical wheel representation, the side chain positions are projected down the helix axis onto a plane.) Note the segregation of nonpolar, acidic, and basic residues to different sides of the helix. Other apolipoprotein helices have similar polarity distributions. [After Kaiser, E.T., in Oxender, D.L. and Fox, C.F. (Eds.), *Protein Engineering*, p. 194, Liss (1987).]

(a)

(a) View along the 2-fold axis relating the cyan and yellow subunits and the green and magenta subunits. (b) View from the top of Part a along the 2-fold axis relating the cyan and magenta subunits and the green and yellow subunits. The third pairings, cyan with green and magenta with yellow,

(b)

which interact along most of their lengths, probably maintain their identities in HDL particles, whereas the other pairings, whose interactions are less extensive, are unlikely to do so. [Based on an X-ray structure by David Borhani, Southern Research Institute, Birmingham, Alabama, and Christie Brouillette, University of Alabama Medical Center, Birmingham. PDBid 1AV1.]

conformation that closely resembles that of lipid-bound apoA-I, whether or not lipid is present. Lipid-free apo  $\Delta(1-43)$ A-I is therefore likely to provide a valid structural model for lipid-bound apoA-I.

The X-ray structure of apo  $\Delta(1-43)$ A-I (Fig. 12-85) was determined by David Borhani and Christie Brouillette. It revealed that, over most of its length, each polypeptide chain forms a pseudocontinuous amphipathic  $\alpha$  helix that is punctuated by kinks at Pro residues that are spaced mainly at intervals of 22 residues to form 10 helical segments arranged in the shape of a twisted horseshoe. Two such monomers (e.g., the cyan and magenta monomers in Fig. 12-85) associate in an antiparallel fashion along most of their lengths to form a dimer that has the shape of a twisted elliptical ring. Two such dimers, in turn, associate via their hydrophobic surfaces to form an elliptical tetramer with  $D_2$  symmetry that has outer dimensions of  $135 \times 90 \text{ \AA}$  and an inner hole of  $95 \times 50 \text{ \AA}$ . The surface of this tetrameric ring, which consists of up-down-up-down 4-helix bundles over about three-fourths of its circumference, is hydrophilic with a uniform electrostatic potential, whereas the interior of each 4-helix bundle contains mainly Val and Leu side chains. Since, in this conformation, these hydrophobic residues are unavailable for binding to lipid, it is postulated that they associate in the lipid-free crystal so as to shelter the lipid-binding face of apo  $\Delta(1-43)$ A-I dimers from contact with water (which fills the spaces in the crystal).

The sizes and shapes of the apo  $\Delta(1-43)$ A-I dimer and tetramer seem ideal for wrapping around the 50- to 120- $\text{\AA}$ -diameter HDL particles. Since HDL particles often contain two or four apoA-I monomers, it is proposed that when pairs of apoA-I monomers bind to HDL, they do so as the above-described antiparallel dimer. Its exposed nonpolar

side chains could then hydrophobically interact with the HDL particle's buried nonpolar groups. Two such dimers could associate on the surface of an HDL particle to form a tetramer, although, most probably, in a different manner than is seen in the structure of apo  $\Delta(1-43)$ A-I.

## B. Lipoprotein Function

The various lipoproteins have different physiological functions, as we discuss below.

### a. Chylomicrons Are Delipidated in the Capillaries of Peripheral Tissues

Chylomicrons, which are assembled by the intestinal mucosa, function to keep exogenous triacylglycerols and cholesterol suspended in aqueous solution. These lipoproteins are released into the intestinal lymph (known as **chyle**), which is transported through the lymphatic vessels before draining into the large body veins via the thoracic duct. After a fatty meal, the otherwise clear chyle takes on a milky appearance.

Chylomicrons adhere to binding sites on the inner surface (endothelium) of the capillaries in skeletal muscle and adipose tissue. There, within minutes after entering the bloodstream, the chylomicron's component triacylglycerols are hydrolyzed through the action of **lipoprotein lipase (LPL)**, an extracellular enzyme that is activated by **apoC-II**. The tissues then take up the liberated monoacylglycerol and fatty acid hydrolysis products. The chylomicrons shrink as their triacylglycerols are progressively hydrolyzed until they are reduced to cholesterol-enriched **chylomicron remnants**. The chylomicron remnants reenter the circulation by dissociating from the capillary endothelium and are subsequently taken up by the liver, as is

**Figure 12-86** Model for plasma triacylglycerol and cholesterol transport in humans. [After Brown, M.S. and Goldstein, J.L., in Brunwald, E., Isselbacher, K.J., Petersdorf, R.G., Wilson, J.D.,

Martin, J.B., and Fauci, A.S. (Eds.), *Harrison's Principles of Internal Medicine* (11th ed.), p. 1652, McGraw-Hill (1987).]

 See the Animated Figures

explained below. *Chylomicrons therefore function to deliver dietary triacylglycerols to muscle and adipose tissue and dietary cholesterol to the liver* (Fig. 12-86, left).

#### b. VLDL Are Degraded Much Like Chylomicrons

VLDL, which are synthesized in the liver as lipid transport vehicles, are also degraded by lipoprotein lipase (Fig. 12-86, right). The VLDL remnants appear in the circulation, first as IDL and then as LDL. In the transformation of VLDL to LDL, all their proteins but **apoB-100** are removed and much of their cholesterol is esterified by the HDL-associated enzyme **lecithin-cholesterol acyltransferase (LCAT)**, as is discussed below. This enzyme transfers a fatty acid residue from atom C2 of lecithin to cholesterol with the concomitant formation of **lysolecithin** (Fig. 12-87).

ApoB-100, a 4536-residue monomeric glycoprotein (and thus one of the largest monomeric proteins known), has a hydrophobicity approaching that of integral proteins and contains relatively few amphipathic helices. Hence, in contrast

to the other, less hydrophobic plasma apolipoproteins, apoB-100 is neither water-soluble nor transferred between lipoprotein particles. Each LDL particle contains but one molecule of apoB-100, which immunoelectron microscopy indicates has an extended form that covers at least half of the particle surface (Fig. 12-83). Chylomicrons, however, contain **apoB-48**, a 2152-residue protein that is identical in sequence to the N-terminal 48% of apoB-100. Indeed, both proteins are encoded by the same gene. The remarkable mechanism by which this gene expresses different length proteins in liver and intestines is discussed in Section 31-4A.

#### c. Cells Take Up Cholesterol through Receptor-Mediated Endocytosis of LDL

Cholesterol, as we have seen, is an essential component of animal cell membranes. The cholesterol may be externally supplied or, if this source is insufficient, internally synthesized (Section 25-6A). Michael Brown and Joseph Goldstein have demonstrated that *cells obtain exogenous cholesterol*

**Figure 12-87** Reaction catalyzed by lecithin-cholesterol acyltransferase (LCAT). The transferred acyl group is most often a linoleic acid residue.

mainly through the endocytosis (engulfment) of LDL in complex with **LDL receptor (LDLR)**, a cell-surface transmembrane glycoprotein that specifically binds apoB-100. LDLR also binds chylomicron remnants via their apoE components.

LDLR is an 839-residue glycoprotein that has a 767-residue N-terminal ligand-binding **ectodomain** (extracellular domain; Greek: *ectos*, outside), a 22-residue TM segment that presumably forms an  $\alpha$  helix, and a 50-residue C-terminal cytoplasmic domain. The X-ray structure of

LDLR's ectodomain, determined by Brown, Goldstein, and Deisenhofer at pH 5.3 (for reasons explained below), confirms the results of sequence studies indicating that this protein consists of, from N- to C-terminus, seven tandemly repeated  $\sim 40$ -residue Cys-rich modules, two  $\sim 40$ -residue EGF-like domains (EGF is the acronym for **epidermal growth factor**, a hormonally active polypeptide that stimulates cell proliferation; Section 19-3), a six-bladed  $\beta$  propeller domain, and an EGF-like domain (Fig. 12-88). The Cys-rich modules, designated R2 to R7 (R1 is disordered and hence unseen), are arranged in an  $\sim 140$ -Å-long arc that loops around to the EGF-like domains

**Figure 12-88** X-ray structure of the extracellular domain of the human LDL receptor at 3.7 Å resolution. The protein is drawn in ribbon form with each of its observed modules given a different color. Its eight bound Ca<sup>2+</sup> ions are represented by cyan spheres, and two N-linked carbohydrates (a tetrasaccharide and a pentasaccharide) are shown in stick form with C green, N blue, and O red. Disulfide linkages are drawn in yellow. The Cys-rich modules are labeled R2 through R7 and the EGF-like domains are labeled EGF-A through EGF-C. The absence of the R1 module and the fragmented appearance of the R2 and R3 modules are due to the disorder of the missing segments. [After an X-ray structure by Michael Brown, Joseph Goldstein, and Johann Deisenhofer, University of Texas Southwest Medical Center, Dallas, Texas. PDBid 1N7D.]

**Figure 12-89** Freeze-etch electron micrograph of coated pits on the inner surface of a cultured fibroblast's plasma membrane. Compare this figure with that of clathrin-coated vesicles (Fig. 12-59a). [Courtesy of John Heuser, Washington University School of Medicine, St. Louis, Missouri.]

and the  $\beta$  propeller. Each Cys-rich module binds a  $\text{Ca}^{2+}$  ion and consists of two loops connected by three disulfide bonds. Note that they are devoid of regular secondary structure (helices and sheets). The EGF-like domains likewise each bind a  $\text{Ca}^{2+}$  ion (except for EGF-C), have three disulfide bonds, and lack regular secondary structure. Modules R4 and R5, which are critical for ligand binding, bind to one face of the  $\beta$  propeller via extensive and conserved side chain interactions. The Cys-rich modules each have a somewhat different conformation, which suggests that they are pliable. Moreover, modules R2, R3,

R6, and R7, and presumably R1, which are also implicated in LDL binding, appear to be unconstrained by interactions with the rest of the protein. This presumably explains why LDLR can bind lipoproteins of varying sizes and compositions.

LDLRs cluster into **coated pits**, which serve to gather the cell-surface receptors that are destined for endocytosis while excluding other cell-surface proteins. The coated pits, which have a clathrin backing (Fig. 12-89), invaginate into the plasma membrane to form clathrin-coated vesicles (Fig. 12-90; Section 12-4C) that subsequently fuse with lysosomes. *Such receptor-mediated endocytosis* (Fig. 12-91) is a general mechanism whereby cells take up large molecules, each through a corresponding specific receptor. Indeed, the liver takes up chylomicron remnants in this manner through the mediation of a separate **remnant receptor** that specifically binds apoE.

At neutral pH, LDLR binds LDL via its Cys-rich modules, most importantly R4 and R5. However, in the acidic environment of the endosome, LDLR releases its bound LDL (Fig. 12-91). The X-ray structure of LDLR at pH 5.3 (Fig. 12-88), the pH of the endosome, suggests that this occurs via LDL's displacement from modules R4 and R5 by LDLR's  $\beta$  barrel domain. This model is bolstered by the observation that, at pH 5.3, the interface between modules R4 and R5 and the  $\beta$  barrel domain contains several conserved His-containing salt bridges that presumably form only when these His residues are protonated. Moreover, an LDLR construct in which the EGF-like domains and the  $\beta$  propeller domain have been deleted readily binds LDL but does not release it at acidic pH. Thus it is likely that at neutral pH, LDLR assumes an open and flexible conformation in which the R4 and R5 modules do not associate with the  $\beta$  barrel domain but, instead, are available to bind LDL.

(a)

(b)

to pinch off from the cell membrane to form a coated vesicle enclosing the bound LDL. [From Anderson, R.G.W., Brown, M.S., and Goldstein, J.L., *Cell* **10**, 356 (1977). Copyright © 1977 by Cell Press.]

**Figure 12-91** Sequence of events in the receptor-mediated endocytosis of LDL. LDL specifically binds to LDL receptors (LDLRs) on clathrin-coated pits (1). These bud into the cell (2) to form coated vesicles (3), whose clathrin coats depolymerize as triskelions, resulting in the formation of uncoated vesicles (4). These vesicles then fuse with vesicles called **endosomes** (5), which have an internal pH of  $\sim 5.0$ . The acidity induces LDL to dissociate from LDLR. LDL accumulates in the vesicular portion of the endosome, whereas LDLR concentrates in the

membrane of an attached tubular structure, which then separates from the endosome (6) and subsequently recycles LDLR to the plasma membrane (7). The vesicular portion of the endosome (8) fuses with a lysosome (9), yielding a **secondary lysosome** (10), wherein the apoB-100 component of LDL is degraded to its component amino acids and the cholesteryl esters are hydrolyzed to yield cholesterol and fatty acids. An LDLR molecule cycles in and out of the cell every 10 to 20 minutes during its  $\sim 20$ -hour lifetime.

In the lysosome, as demonstrated by radioactive labeling studies, LDL's apoB-100 is rapidly degraded to its component amino acids (Fig. 12-91). The cholesteryl esters are hydrolyzed by a lysosomal lipase to yield cholesterol, which is subsequently incorporated into the cell membranes. Any excess intracellular cholesterol is reesterified for storage within the cell through the action of **acyl-CoA:cholesterol acyltransferase (ACAT)**.

The overaccumulation of cellular cholesteryl esters is prevented by two feedback mechanisms:

**1.** High intracellular levels of cholesterol suppress the synthesis of LDLR, thus decreasing the rate of LDL accumulation by endocytosis (although LDLR cycles in and out

of the cell every 10 to 20 min, it is slowly degraded by the cell such that its half-life is  $\sim 20$  h).

**2.** Excess intracellular cholesterol inhibits the biosynthesis of cholesterol (Section 25-6Bb).

**d. ApoE's Receptor Binding Domain Contains a Four-Helix Bundle**

ApoE is a 299-residue monomeric protein that consists of two independently folded domains: an N-terminal domain that binds strongly to LDLR but only weakly to lipid and a C-terminal domain that binds to the lipoprotein surface but lacks affinity for LDLR. Proteolysis of apoE yields fragments corresponding to apoE's N-terminal domain

**Figure 12-92** Ribbon diagram of the receptor-binding domain of human apolipoprotein E. The polypeptide chain is colored in rainbow order from its N-terminus (blue) to its C-terminus (red). Residues 61, 112, and 158 are colored orange, magenta, and gray, respectively. [Based on an X-ray structure by David Agard, University of California at San Francisco. PDBid 1LPE.]

(residues 1–191) and C-terminal domain (residues 216–299). Sequence analysis suggests that the C-terminal domain is largely composed of helices. The X-ray structure of the N-terminal domain (Fig. 12-92), determined by David Agard, reveals that it consists mainly of five  $\alpha$  helices, four of which form an elongated (65 Å) up–down–up–down four-helix bundle. The helices of the four-helix bundle, as expected, are strongly amphipathic, with their hydrophobic residues sequestered inside the protein, out of contact with solvent, whereas their hydrophilic residues are solvent-exposed. The structure appears to be further stabilized by numerous salt bridges on the protein’s highly charged surface.

The C-terminal helix of the apoE N-terminal fragment contains nine closely spaced basic residues that are not involved in salt bridges, thereby producing a large positively charged patch on the protein surface. ApoE variants in which one of these basic residues is replaced by a neutral or acidic residue all display reduced affinity for LDLR, thereby suggesting that the patch forms apoE’s binding site for LDLR. Hence this C-terminal helix has been dubbed apoE’s receptor-binding helix.

LDLR binds apoB-100 and apoE with comparable affinities. ApoB-100 (but not apoB-48) contains a conserved segment that is similar to apoE’s receptor-binding

helix, although the two proteins otherwise have no apparent sequence similarity. In VLDL, the receptor-binding domain of apoB-100 is unavailable for receptor binding but is exposed on transformation of the VLDL to LDL.

#### e. HDL Transports Cholesterol from the Tissues to the Liver

HDL has essentially the opposite function of LDL: *It removes cholesterol from the tissues.* HDL is assembled in the plasma from components obtained largely through the degradation of other lipoproteins. *Circulating HDL acquires its cholesterol by extracting it from cell-surface membranes and converts it to cholesteryl esters through the action of LCAT, an enzyme that is activated by apoA-I.* HDL therefore functions as a cholesterol scavenger.

*The liver is the only organ capable of disposing of significant quantities of cholesterol* (by its conversion to bile acids; Section 25-6C). This occurs through the mediation of both LDLR and a specific HDL receptor named **SR-BI** (for scavenger receptor class B type I). About half of the VLDL, after its degradation to IDL and LDL, is taken up by the liver via LDLR-mediated endocytosis (Fig. 12-86, right). However, hepatocytes (liver cells) take up cholesteryl esters from HDL by an entirely different mechanism: Rather than being engulfed and degraded, the SR-BI-bound HDL selectively transfers its component cholesteryl esters to the cell. The lipid-depleted HDL then dissociates from the cell and reenters the circulation.

### C. Lipoprotein Dysfunction in Atherosclerosis and Alzheimer’s Disease

**Atherosclerosis**, the most common form of **arteriosclerosis** (hardening of the arteries), is characterized by the presence of **atheromas** (Greek: *athera*, mush), arterial thickenings that, on sectioning, exude a pasty yellow deposit of almost pure cholesteryl esters (Fig. 12-93).

*Atherosclerosis is a progressive disease that begins as intracellular lipid deposits in the smooth muscle cells of the inner arterial wall. These lesions eventually become fibrous, calcified plaques that narrow and even block the arteries.* The resultant roughening of the arterial wall promotes the formation of blood clots, which may also occlude the artery. A blood flow stoppage, known as an **infarction**, causes the death of the deprived tissues. Although atheromas can occur in many different arteries, they are most common in the coronary arteries, the arteries supplying the heart. This results in **myocardial infarctions** or “heart attacks,” the most common cause of death in Western industrialized countries.

#### a. Deficient LDL Receptors Result in Atherosclerosis

*The development of atherosclerosis is strongly correlated with the level of plasma cholesterol.* This is particularly evident in individuals with **familial hypercholesterolemia (FH)**. Homozygotes with this inherited disorder have such high levels of the cholesterol-rich LDL (which is often referred to as “bad cholesterol”) in their plasma that their plasma cholesterol levels are three- to fivefold greater than the average level of  $\sim 175 \text{ mg} \cdot 100 \text{ mL}^{-1}$ . This situation results in the

**Figure 12-93** An atherosclerotic plaque in a coronary artery. The vessel wall is dramatically thickened as a result of lipid accumulation and activation of inflammatory processes. [© Eye of Science/Photo Researchers.]

deposition of cholesterol in their skin and tendons as yellow nodules known as **xanthomas**. However, far greater damage is caused by the rapid formation of atheromas that, in homozygotes, cause death from myocardial infarction as early as the age of 5. Heterozygotes, which comprise ~1 person in 500, are less severely afflicted; they develop symptoms of coronary artery disease after the age of 30.

Cells taken from FH homozygotes completely lack functional LDLR, whereas those taken from heterozygotes have about half of the normal complement. Homozygotes and, to a lesser extent, heterozygotes are therefore unable to utilize the cholesterol in LDL. Rather, their cells must synthesize most of the cholesterol for their needs. The high level of plasma LDL in these individuals results from two related causes:

1. Its decreased rate of degradation because of the lack of LDLR.
2. Its increased rate of synthesis from IDL due to the failure of LDLR to take up IDL.

Over 1000 mutations of LDLR that cause FH have been discovered. These mutants have been grouped into five classes depending on the nature of the defect in LDLR functioning they cause (Fig. 12-91): (1) failure to produce detectable amounts of protein; (2) partial or complete failure to be transported to the plasma membrane; (3) impaired ligand binding; (4) failure to localize to clathrin-coated pits and in internalization; and (5) defects in ligand release and recycling. Class 4 mutants are caused by changes in LDLR's so-called **sorting sequence**, NPXR, in its cytoplasmic domain, which binds to AP2 in clathrin-coated pits.

The long-term ingestion of a high-fat/high-cholesterol diet has an effect similar to although less severe than FH. A high intracellular level of cholesterol suppresses the synthesis of LDLR (Section 25-6Bb), thereby reducing the amount of LDL that a cell takes up from the circulation. Excessive dietary cholesterol, delivered to the tissues via chylomicrons, therefore contributes to high plasma LDL levels.

### b. Scavenger Receptors Take Up Oxidized LDL

Atherosclerotic plaques in individuals with FH contain **macrophages** (a type of white blood cell that ingests and, if possible, destroys a variety of foreign and endogenous substances) that contain so much cholesterol that they are known as **foam cells**. How do macrophages take up cholesterol? Macrophages from both normal individuals and those with FH have few LDLRs and therefore take up little native LDL. However, they avidly take up, by endocytosis, LDL that has been chemically modified by the acetylation of its Lys residues (which eliminates this side chain's positive charge, thereby increasing LDL's negative charge). The macrophage cell-surface receptors that bind acetylated LDL are known as **scavenger receptors** because they also bind certain other polyanionic molecules.

Scavenger receptors avidly take up oxidized LDL. The unsaturated fatty acids of LDL are highly susceptible to chemical oxidation but, in the blood, are protected from oxidation by antioxidants. However, these antioxidants are thought to become depleted when LDL is trapped for an extended time within the artery walls (where it is thought to gain access by an injury to the arterial lining through which plasma leaks into the arterial wall). As a consequence, oxygen radicals convert LDL's unsaturated fatty acids to aldehydes and oxides that react with its Lys residues, thereby mimicking acetylation. The ingested LDL is degraded as described above and its cholesterol converted to cholesteryl esters, which accumulate as insoluble residues.

The physiological significance of this scenario has been demonstrated by the observations that antibodies against aldehyde-conjugated Lys residues stain atherosclerotic plaques, that LDL from atherosclerotic plaques binds to scavenger receptors and produces foam cells *in vitro*, and that antioxidants inhibit atherosclerosis in rabbits that have an animal counterpart of FH. It should be noted that tobacco smoke oxidizes LDL, which may explain why smoking leads to an increased incidence of atherosclerosis. High plasma levels of LDL, of course, also accelerate LDL uptake.

If this model of atheroma formation is correct, then the optimal level of plasma LDL is the lowest concentration that can adequately supply cholesterol to the cells. Such a level, which is thought to be ~25 mg of cholesterol · 100 mL<sup>-1</sup>, occurs in various mammalian species that are not naturally susceptible to atherosclerosis as well as in newborn humans. Yet the plasma LDL level in adult Western men averages ~7-fold higher than this supposed optimal level. The reasons for such a high plasma cholesterol level are poorly understood (but see below), although it is clear that it is affected by diet and by environmental stress. Medical strategies for reducing the level of plasma cholesterol are considered in Section 25-6Bd.

### c. Atherosclerosis Is a Multifactorial Disease

Epidemiological studies indicate that high plasma levels of HDL (which is often referred to as "good cholesterol") are strongly correlated with a low incidence of cardiovascular disease. Women have HDL levels higher than men and also less heart disease. Many of the factors that decrease the incidence of heart disease also tend to increase HDL

levels. These include strenuous exercise, weight loss, certain drugs such as alcohol, and female sex hormones known as **estrogens** (Section 19-1Gb). Conversely, cigarette smoking is inversely related to HDL concentration. Curiously, in communities that have a very low incidence of coronary artery disease, both the mean HDL and LDL concentrations are low. The reasons for these various effects are unknown.

There is also a strong inverse correlation in humans between the risk for atherosclerosis and the plasma level of apoA-I, HDL's major protein component, which is required for its assembly. To investigate whether apoA-I has a direct antiatherogenic effect, mice of a strain that develops diet-induced **fatty streak lesions** in their large blood vessels were genetically modified to express high plasma levels of human apoA-I (fatty streak lesions are the precursors of atherosclerotic plaques, which these mice have too short a lifetime to develop). These transgenic mice are significantly protected from developing fatty streak lesions. Yet transgenic mice that overexpress mouse **apoA-II**, another major HDL protein, develop more and larger fatty streak lesions than their nontransgenic counterparts. Since the plasma HDL-cholesterol levels in the latter transgenic mice are significantly elevated, it appears that both the composition and the level of plasma HDL are important atherosclerotic mediators. Similarly, transgenic mice that express high levels of human apoE or human LDLR resist the elevation in plasma LDL levels that would otherwise be brought on by a cholesterol-rich diet, whereas mice in which the gene encoding apoE has been knocked out rapidly develop atherosclerotic lesions.

**Cholesteryl ester transfer protein (CETP)** is a plasma protein that exchanges neutral lipids (e.g., cholesteryl esters and triacylglycerols) among lipoproteins and hence functions analogously to phospholipid exchange proteins (Section 12-4Ab). Since VLDL and LDL are triacylglycerol-rich whereas HDL are cholesteryl ester-rich (Table 12-6), CETP mediates the net transport of cholesteryl esters from HDL to VLDL and LDL (and of triacylglycerols in the opposite direction). Consequently, animals that express CETP have higher cholesterol levels in their VLDL and LDL and lower cholesterol levels in their HDL than animals that do not express CETP. Mice of a strain that normally have little or no CETP activity were made transgenic for CETP and fed an atherogenic (high-fat, high-cholesterol) diet. These transgenic mice developed atherosclerotic lesions far more rapidly than their similarly fed nontransgenic counterparts. Since the two types of mice had similar total plasma cholesterol levels, these results suggest that *the progression of atherosclerotic lesions is more a function of how cholesterol is partitioned between lipoproteins than it is of the total plasma cholesterol level.*

Increased risk of atherosclerosis in humans is also associated with elevated plasma levels of lipoprotein **Lp(a)**, a variant of LDL in which apoB-100 is tightly associated with the 4259-residue plasma protein **apo(a)**. Rodents and most other nonprimate mammals lack the gene for apo(a). However, mice transgenic for human apo(a) rapidly develop fatty streak lesions when given a high-fat diet (approximating human diets in industrialized Western countries).

Apo(a) mainly consists of repeated segments that are homologous to **plasminogen**, a plasma protein that, when activated, functions to proteolytically dismantle blood clots (Section 35-1Fa). The normal function of apo(a) in humans is unknown, although it has been hypothesized that it participates in healing blood vessel wounds.

#### d. Tangier Disease Eliminates HDL Synthesis

Most cells do not consume cholesterol by converting it to steroid hormones or bile acids, for example, but all cells require cholesterol to maintain membrane fluidity. Cholesterol in excess of this requirement can be esterified by the action of ACAT and stored as cholesteryl esters in intracellular deposits. Cholesterol can also be eliminated from cells by a mechanism illuminated through studies of individuals with **Tangier disease**. In this recessive inherited disorder, almost no HDL is produced, because cells have a defective transport protein, known as **ATP-cassette binding protein A1 (ABCA1)**. In normal individuals, ABCA1 functions as a flippase (Section 12-4Aa) that transfers cholesterol, cholesteryl esters, and other lipids from the inner to the outer leaflet of the plasma membrane, from where they are captured by apoA-I to form HDL. Cells lacking ABCA1 cannot dispose of their excess cholesterol and therefore accumulate cholesteryl esters in their cytoplasm. Macrophages thus engorged with lipids contribute to the development of atherosclerosis and consequently individuals with Tangier disease exhibit symptoms similar to those with FH.

#### e. ApoE4 Is Implicated in Both Cardiovascular Disease and Alzheimer's Disease

There are three common allelic variants of apoE in humans: **apoE2** (occurring in 15% of the population), which has Cys at positions 112 and 158; **apoE3** (78% occurrence), in which these residues are Cys and Arg, respectively (Fig. 12-92 shows the structure of apoE3 with residues 112 and 158 magenta and white); and **apoE4** (7% occurrence), in which these residues are both Arg. These differences have medical significance: ApoE3 has a preference for binding to HDL, whereas apoE4 has a preference for binding to VLDL, which is probably why apoE4 is associated with elevated plasma concentrations of LDL and thus an increased risk of cardiovascular disease. Evidently, changes in apoE's N-terminal domain can affect the function of its C-terminal lipoprotein-binding domain.

ApoE4, as we have seen in Section 9-5B, is also associated with a greatly (16-fold) increased incidence of Alzheimer's disease (AD). This observation is perhaps less surprising when it is realized that apoE is expressed by certain nerve cells and is present in the cerebrospinal fluid, where it functions in mediating cholesterol transport, much as it does in blood plasma (cholesterol is abundant in nerve cell plasma membranes, which mediate neurotransmission; Section 20-5B).

Brain tissue from AD victims reveals numerous extracellular amyloid plaques, which consist of fibrillar deposits of amyloid  $\beta$  ( $A\beta$ ) peptide that arises through proteolysis of the normally occurring amyloid precursor protein (Section 9-5B). Amyloid plaques appear to be AD's pathogenic

agent. Immunochemical staining indicates that apoE is associated with amyloid plaques. *In vitro* experiments demonstrate that both apoE3 and apoE4 form SDS-stable complexes with A $\beta$  peptide that, after long incubation times, aggregate and precipitate from solution as a matrix of fibrils that closely resemble those in amyloid plaques. ApoE4 forms this complex more readily than apoE3 and yields a denser, more extensive matrix.

Comparison of the X-ray structures of apoE4 and apoE3 reveals that there are only minor differences in their backbone conformations, which are restricted to the immediate vicinity of their site of difference (residue 112: Cys in ApoE3 and Arg in ApoE4). The only two side chains in apoE4 that undergo changes in conformation relative to those in apoE3 are Glu 109, which swings around in apoE4 to form a salt bridge with Arg 112, and Arg 61 (orange in Fig. 12-92), which contacts Cys 112 in apoE3 but swings away to accommodate the new salt bridge in apoE4. Thus, both Glu 109 and Arg 61 are candidates for mediating the functional differences between apoE3 and apoE4. However, the mutagenic substitution of Ala for Glu 109 in apoE3 does not significantly alter its preference for binding to HDL over VLDL. In contrast, the substitution of Thr for Arg 61 in apoE4 gives this protein an apoE3-like preference for HDL over VLDL. Evidently, the position of Arg 61 is critical in determining the HDL/VLDL preference of apoE. This hypothesis is supported by the observation that residue 61 is invariably Thr in the 10 apoEs of known sequences from other species. None of these species exhibits the complete pathology of AD, although it remains to be

demonstrated that Arg 61 actually contributes to the differential binding of apoE3 and apoE4 to A $\beta$  peptide.

#### f. ApoE2 Has a Low Affinity for LDL Receptor

*ApoE2 binds to LDLR with only 0.1% of the affinity of apoE3 or apoE4.* Thus the presence of apoE2 is the underlying cause of **familial type III hyperlipoproteinemia**, which is characterized by elevated plasma cholesterol and triglyceride levels and hence accelerated coronary artery disease.

The defective binding of apoE2 to LDLR is caused by the substitution of Cys for Arg 158, a position (gray in Fig. 12-92) that lies outside the previously identified receptor-binding region, residues 136 to 150 (located in the bottom half of the C-terminal helix in Fig. 12-92). In apoE3, Asp 154 forms a salt bridge with Arg 158 (which is situated one turn farther along the  $\alpha$  helix). In apoE2, since Arg 158 is replaced with Cys, this salt bridge cannot form. Rather, as the X-ray structure of apoE2 reveals, Asp 154 forms a salt bridge with Arg 150 (which is situated one turn earlier on the  $\alpha$  helix), thereby altering the side chain conformation of this LDLR-binding residue. In fact, the disruption of this abnormal salt bridge by the mutagenic replacement of Asp 154 in ApoE2 with Ala restores LDLR binding affinity to a nearly normal level.

Individuals with type III hyperlipoproteinemia are particularly responsive to a low-fat, low-calorie diet and to a reduction in body weight. It is therefore postulated that the altered lipid composition of lipoproteins under such a regimen causes significant amounts of apoE2 to assume a receptor-active conformation, leading to normal or near-normal rates of lipoprotein clearance from the circulation.

## CHAPTER SUMMARY

**1 Lipid Classification** Fatty acids are long-chain carboxylic acids that may have one or more double bonds that are usually *cis*. Their anions are amphiphilic molecules that form micelles in water. Fatty acids rarely occur free in nature but rather are components of lipids. The most abundant class of lipids, the triacylglycerols or neutral fats, are nonpolar molecules that constitute the major nutritional store of animals. The lipids that occur in membranes are the phospholipids, the sphingolipids, and, in eukaryotes, cholesterol or similar sterols. Sphingolipids such as cerebrosides and gangliosides have complex carbohydrate head groups that act as specific recognition markers in various biological processes.
